HISTORICAL SKETCHES

NUMBER 12

HISTORICAL SKETCHES—A NEW FEATURE

UNFORTUNATELY, few chemists seem to have more than a passing interest in the history of chemistry. In contrast to the situation in the humanities, where the average student is expected to steep himself in the classics, the average chemistry graduate has little knowledge of the history of his chosen discipline. We take this situation for granted today, yet this has not always been the case.

The German poet and dramatist, Johann Wolfgang von Goethe, himself an amateur scientist, declared "Die Geschichte der Wissenschaft ist die Wissenschaft selbst" (This history of science is science itself). Many of the founders of chemistry were well acquainted with its history. The first history of chemistry in the English language was written in 1830–1831 by the Scottish chemist, Thomas Thomson, an active practicing scientist, and August Kekulé spent much time reading the classics of chemistry before making any original discoveries of his own.

Such a lack of historical perspective can result in a distorted view of chemistry. Science is more than its usual dictionary definition as "organised or classified knowledge". In addition to its cognitive, factual aspects, science is a process—the search for knowledge carried out by struggling and committed practitioners, both successful and unsuccessful, working in the context of their scientific, social, and political milieu, i.e. an exciting human activity. In the words of Professor John C. Bailar, Jr., "One cannot really understand or appreciate the present position of science unless he knows something of the slow and tortuous steps through which it developed. The scientist's ability to help it move forward will be greatly enhanced by an understanding of the thinking of the chemists who built the theories which we use today".[1]

Yet a knowledge and appreciation of history is not limited to its cultural and inspirational value. It can also be directly applicable to contemporary research efforts. As a case in point, when Lord Rayleigh encountered discrepancies between the density of atmospheric nitrogen and that of nitrogen prepared from compounds, he sought suggestions from the readers of the journal *Nature*.[2] William Ramsay[3] suggested that Rayleigh read Henry Cavendish's paper[4] of 1785 on nitrogen, which more than a century earlier had predicted the presence of an unknown gas in the atmosphere. Together Ramsay and Rayleigh went on to discover the first of the inert gases, argon, in 1894 and thereby to uncover the existence of a completely unsuspected periodic group of elements.

"**Historical Sketches**" is a new feature that will consist of occasional articles concerned with historical aspects of inorganic and organometallic chemistry, including biographies, developments of concepts and theories, and the role of inorganic and organometallic chemistry in human affairs.

Persons wishing to contribute an article to "**Historical Sketches**" should contact: Professor George B. Kauffman, Department of Chemistry, California State University at Fresno, Fresno, CA 82740, U.S.A.

ANNOUNCEMENT

Executive Editor, North America

The publisher, Robert Maxwell, and the Editors, are delighted to announce that Professor Malcolm Chisholm has agreed to become Executive Editor with responsibility for the United States and Canada. Contributions for *POLYHEDRON* from North American authors should be sent to:

<div align="center">

Professor Malcolm Chisholm
Department of Chemistry
Indiana University
Bloomington
IN 47405
U.S.A.

</div>

We trust that this new arrangement will reduce delays in mailing of manuscripts and proofs and so assist in more rapid publishing.

AUTHOR INDEX

THE ORIGIN AND DISSEMINATION OF THE TERM "LIGAND" IN CHEMISTRY†

WILLIAM H. BROCK

Language has always been a central feature of chemical development. As Lavoisier noted in the *Méthode de Nomenclature Chimique* (1787):

> There are . . . three things to distinguish in all physical science: the series of facts which form the science; the ideas which recall the facts; and the words which express them. The word must suggest the idea; the idea must depict the fact: these are three marks of the same stamp.[1]

Savory has discussed the fortunate way in which scientists can invent words merely by defining them so that others may know how and when to use them, the only criterion being that of intelligibility.[2] However, it need not necessarily follow that a neologism will be automatically adopted by the scientific community, even if it does satisfy Lavoisier's criterion that it should suggest the idea of a definite chemical phenomenon. Force of habit alone will insure that a system of revolutionary character will not be accepted. The reformation of a nomenclature has to proceed step by step. For example, Auguste Laurent was responsible for a large chemical vocabulary, little of which was subsequently adopted; similarly, Charles Mansfield's strange language in his *Theory of Salts* was completely ignored.[3] Are there, therefore, perhaps criteria for the adoption and acceptance of scientific words? What makes a successful neologism?

An examination of the origins, dissemination, and eventual adoption of the term *ligand*, which is used by chemists to refer to atoms or groups attached to a central atom in the formation of coordination compounds or organometallic compounds,[4] throws some light on these questions. It will be suggested that it is essential that a successful conceptual term should possess an international form, i.e. that it is derived from Latin or Greek (with Roman transliteration).[5] Furthermore, in the twentieth century it has become necessary for a new term to be used in influential papers (i.e. ones which attract

multiple citation), and for the term to be endorsed by *Chemical Abstracts* and leading journals. Since the Second World War this process has been assisted by the nomenclature commissions of the International Union of Pure and Applied Chemistry (IUPAC). In principle, a term can be introduced in an English, German, French, Scandinavian, or any other language, but the acceptance of a new chemical term may be seriously delayed until it is adopted in English-language publications.

While engaged in pioneering experimental work on the hydrides of boron during his First World War sojourn at the Kaiser-Wilhelm-Institut für Chemie in Berlin, Alfred Stock (1876–1946) directed his attention to the analogous hydrides of silicon. Their highly reactive and volatile character, it was thought, might have military applications. At a meeting of the Kaiser–Wilhelm-Institut on 27 November 1916 Stock discussed the similarities between carbon and silicon chemistry first noticed by Wöhler.[6] For Stock, these analogies were made more evident and interesting by the deeper knowledge of atomic structure that was then becoming available to chemists:

> The surprisingly rapid development of our knowledge of the nature of atoms promises that in the not too distant future, it will be possible to develop an atomic-structural chemistry in which fundamental chemical properties of atoms, such as their affinities and valencies, will be explicable from their atomic structure.[7]

In the published version of the paper in 1917, the phrase "affinities and valencies" was accompanied by a footnote:

> To prevent misunderstandings the meaning of several words used here must be explained. Affinity is the expression for the firmness with which one element binds other elements or radicals (generally: "Ligands" (*ligare*[Latin], to bind); the introduction of a word hitherto lacking simplifies the manner of expression for this immediately clear concept).— Valence (*Valenz*) means the unit of force which can bind a univalent ligand; positive valencies bind nega-

tive ligands, negative valencies bind positive ligands.—Atomicity (*Wertigkeit*) is the number of valencies which an atom manifests; the highest atomicity is the highest number of valencies observed for an element.[8]

Thus Stock first coined "ligand" (Latin gerundive *ligandum*, "that should be bound") to fill the gap caused by the absence of a general term for the immediately clear concept of elements and radicals bound to another element.

Having made this clarification in the context of silicon chemistry—not, it should be stressed, in the context of Werner's coordination theory or in a discussion of inorganic complexes, Stock made no further use of the term ligand in the paper. Nor did he use it frequently in later experimental papers.[9] Although Stock's paper of 1917 was reviewed for the British Chemical Society in 1919,[10] the reviewer, E. C. C. Baly, drew no attention to the footnote; perhaps rightly, he was far more interested in Stock's preparation of, and proposed nomenclature for, the silanes.

Indeed, the word ligand seems to have been totally ignored by English-language chemists until the 1940s. It does not occur, for example, in either the first (1917) or second (1924) editions of the *German-English Dictionary for Chemists* by the American chemist and abstractor, Austin M. Patterson.[11] Furthermore, its adoption by coordination chemists in the 1950s evidently suggested to some of them that it was a term of recent vintage. In a monograph on chelating agents published in 1964, the Australian chemist D. P. Mellor dated "its introduction about 20 years ago," i.e. to about 1944.[12] As we shall see, Mellor was partly right. Similarly, although it does not purport to refer to the first recorded use of words, the *Oxford English Dictionary* cites a paper by Leslie E. Orgel published in 1952 as containing the word ligand.[13] Recent textbook writers are either content to define ligands as molecules coordinated to a central metal atom[14] or to use the term without any explanation.

How then did the word ligand come to be introduced into the English language? And how did it become a term particularly associated with Werner's chemistry of coordination compounds?

The classical textbooks of coordination chemistry by Werner, Urbain and Sénéchal, and Weinland[15] had no term corresponding to ligand (although Werner occasionally used "Addend"), probably because Werner's distinction between primary and secondary valencies made it difficult to consider all coordinated atoms or groups as equivalent. The widespread dissatisfaction with Werner's *Hauptvalenz* and *Nebenvalenz* acted as a strong deterrent to his entire theory for a number of years. A clear distinction between the two types of valence was not always possible, and a number of chemists considered the notion of primary and secondary valence bonds vague and unfounded.[16] Stock's proposal was not followed in the second edition of Weinland's book (1924) or in the fifth and final edition of Werner's *Neuere Anschauungen* edited by Paul Pfeiffer (1923).

However, during the 1920s the distinction between primary and secondary valencies disappeared—in Germany, through the elaboration of Walther Kossel's theory of electronic shells[17] by A. Magnus,[18] and in America and England through the atomic theories of G. N. Lewis[19] and N. V. Sidgwick.[20] In Germany a commission of the Deutsche Chemische Gesellschaft composed of R. Lorenz, R. J. Meyer, S. Meyer, P. Pfeiffer, A. Rosenheim and A. Stock was appointed to deal with the nomenclature of inorganic chemistry which had become confusing and troublesome. Its published rules[21] recommended that use of a Roman numeral (the Stock number[22]) to designate the "valence" (oxidation state) of an element. The complete German proposal, which was not published in German but is known from a French translation,[23] probably contained the term ligand to designate atoms, groups or molecules attached to a central atom—although it is absent in the preliminary version.[24] The proposal was submitted by Stock at the Hauptversammlung des Vereins deutscher Chemiker at Nürnberg in 1925, and one can deduce from the appearance of ligand in German literature since 1927 that the term was included in his report. The fourth edition of Ephraim's distinguished textbook, *Anorganische Chemie* (1929), adopted the word when introducing the elements of Periodic Group IV and referred to Stock explicitly as its originator.[25] According to Ephraim, echoing Stock, "Organic chemistry owes its diversity principally to the equal binding forces of the carbon atom towards the most dissimilar ligands". By 1930, therefore, the word ligand had become widely used in German publications,[26] including the monographs on stereochemistry by Stefan Goldschmidt and Freudenberg,[27] and was even adopted by the Japanese coordination chemist, Ryūtarō Tsuchida, when writing in English on spectrochemical series in a Japanese journal.[28] Due to the demonstration by Werner's former student and colleague, Paul Pfeiffer (1875–1951), that there was a close relationship between Werner's coordination theory and the structure of crystals as revealed by the then new experimental technique of X-ray diffraction,[29] one might have expected that geochemists and crystallographers would have used ligand at an early date. However, to take one example, the crystallographer, V. M. Goldschmidt, used instead the phrase "nächste Nachbarn" (nearest neighbours).[30]

Meanwhile, however, the international chemical community had moved along a different path. After the First World War the Union Internationale de Chimie Pure et Appliquée (UIC) was established, without Germany as a member, and with French as its official language. In 1921 the UIC appointed a Commission (with the Dutch chemist, W. P. Jorissen, as chairman) to deal with the nomenclature of inorganic chemistry.[31] At a meeting in 1926 the Commission discussed Werner's proposal[32] to use the endings -a, -o, -i, -e, -an, -on, -in, -en, to designate eight different valencies. Although this proposal had already been adopted officially by the previous international union (Association Internationale des Sociétés Chimiques) at a congress in 1913, it was rejected because grammatical and phonetic difficulties made it unacceptable in several languages, including English. Instead the Commission adopted the use of Stock numbers.[33] Following a further conference at Washington in 1926, a definite proposal was drawn up by Marcel Delépine and published by Jorissen in a Dutch journal.[34] The proposal contained detailed rules for naming coordination compounds by the use of Stock numbers; the term ligand was, however, not used.

After 1930, when Germany had been re-admitted to the UIC, a collaboration between the International and German Commissions on nomenclature was initiated, and a French translation (by Delépine) of the German proposal was published by R. J. Meyer.[35] In this there occurs the expression "ordre des constituants liés à

l'atome central"[36] as a rendering of the original "Reihenfolge der Liganden". Clearly, ligand was not acceptable as a French term.

At a further meeting in 1936, the International Commission, which now comprised H. Remy from Hamburg as the German representative, Jorissen, Delépine and Fichter (the English member, Clarence Smith, was absent), drafted a proposal which was finalised at a meeting in Berlin in 1938 and adopted at the Tenth Congress of the UIC at Rome in the same year. (Here A. Damiens and H. Bassett had replaced Delépine and Smith.) The German version was published in 1940 by Remy, who mentioned that Stock had been active in the German chemists' deliberations.[37] However, in translating this German report, Bassett, of the University of Reading, who perhaps showed a lack of linguistic instinct, rendered ligands as "attached atoms or groups",[38] just as the French had done in 1937. Although Bassett was not a coordination chemist, it is astonishing that he did not adopt ligand, the derivation of which from Latin ligare seems obvious.[39] No doubt he was affected by the outbreak of the Second World War, and the absence of the word in English textbooks,[40] Patterson's German–English Dictionary for Chemists,[41] and Chemical Abstracts.[42] Since Bassett's translation was used in the American version[43] with only minor amendments of spelling and footnotes, not surprisingly the word was omitted in Janet Scott's review of inorganic nomenclature published in 1943.[44] Similarly, the French version of the 1938 Rules avoided the term by rendering ligands as "radicaux".[45] The reluctance of English chemists to employ ligand is underlined by the use of the word groups in the English translation of Walter Hückel's important text, *Anorganische Strukturchemie*.[46]

On the other hand, there seems to have been less reluctance to take ligand into other languages either directly from German usage or from the German version of the 1938 Rules. For example, around 1935 K. A. Jensen introduced ligand into Danish, having learned the term from Pfeiffer's chapter on coordination chemistry in Freudenberg's *Stereochemie*.[47] After first using it in a paper on platinum complexes,[48] which he published in German, Jensen subsequently used it in Danish papers.[49] On Jensen's suggestion, Jannik Bjerrum (who became Jensen's colleague at the University of Copenhagen in 1936) adopted the word in 1941 in the context of discussions of stepwise equilibria, e.g. a "step system consisting of a central group M and n ligands A" and "ligand effect".[50] Although the two chemists used ligand freely in Danish and German conversations on coordination chemistry, Bjerrum was initially in doubt whether he could use ligand in English. However, Jensen assured him that because Stock's term was of Latin origin it could be used in any language. In this way, together with Tsuchida, Bjerrum became the first to use ligand in an English publication. His use of the term was also immediately accepted by some Swedish chemists[51] who were working in the same field.

Although in Brazil the German chemist Heinrich Rheinboldt, who was a Professor of Chemistry in São Paulo, introduced *ligante* into Portugese as a translation of ligand,[52] there seems to be no other language into which ligand has been taken from the German. The German version of the 1938 Rules was not translated into Russian. The word *addend*, which was in use in Russian chemistry around 1950, was obviously derived from Werner's *Neuere Anschauungen*. A little later the expression "addends or ligands" was used, for example in a book on coordination chemistry by Golovnya and Fedorov.[53] The Russian term "teoriya polya ligandov" has been used for "ligand field theory" since at least 1962.[54] Similarly, ligand did not appear in the huge Czech and Polish 6-language dictionaries published in the 1950s.[55] The former cites the German version of the 1938 Rules but uses the term "koordinované molekuly" for ligands. However, after 1960 ligand is used in Czech, Polish and Croatian. Clearly, its introduction into Slavic languages was due to the impact of the huge quantity of papers on coordination chemistry which were published in English during the early post-war years.

How then did *ligand* suddenly become so widespread in English? A decisive factor was undoubtedly the first post-war meeting in London in 1947 of the revived International Union, which was retitled the International Union of Pure and Applied Chemistry (IUPAC). Once again, nomenclature discussions were reopened by a Commission on the Nomenclature of Inorganic Chemistry, using the 1938 Rules as a starting point.[56] Although Bassett (who had replaced Jorissen as chairman) was not very happy with the proposal to adopt the continental nomenclature for coordination compounds, Niels Bjerrum[57] and K. A. Jensen, seconded by Bassett's secretary, R. V. G. Ewens, argued vigorously that the primary work of the Commission had to be an expansion of, and a more precise formulation of, the 1938 Rules. It followed that ligand should be used instead of expressions such as "attached groups and molecules". On the basis of this discussion Bassett and Ewens published a review paper[58] in 1949 in which ligand was used and which also contained the proposal (due to Ewens) to use the charge of the entire ion (later known as the Ewens–Bassett number) in cases where the central atom had no well-defined oxidation state.

Following further meetings of the Commission, a considerably extended set of rules for the nomenclature of inorganic chemistry was prepared and presented as "Tentative Rules" at a conference in Stockholm[59] in 1953. The contents of the new Rules were therefore known four years before they were finally adopted by the Council of the IUPAC at the conference in Paris in 1957 and published as "Nomenclature of Inorganic Chemistry 1957".[60]

The adoption of ligand into English by the IUPAC commission became immediately known to many chemists from the review paper by Ewens and Bassett[61] and by verbal information. However, the word ligand was already familiar to some English chemists—to those who worked with equilibria in solution from Bjerrum's thesis[62] and to those who worked with the preparation of coordination compounds of platinum and other transition metals from the German literature.[63] The effect of the IUPAC decision was primarily to reassure chemists that ligand would be an acceptable word in an English text. This is clearly demonstrated by the following fact: Bjerrum's English thesis exerted a great influence on coordination chemists working with the determination of stability constants. As has already been mentioned, the thesis induced Swedish chemists to use ligand, but chemists using English as their mother tongue accepted it only around 1949.[64]

The explosive dissemination of ligand during the 1950s can be explained as the result of a sort of branched chain reaction, the traces of which it is impossible to map out. It is reasonable to assume that the initiators were those

to whom the term was already familiar and who used ligand in their lectures and discussions. The foci for the dissemination of ligand in English were apparently University College, London, The Butterwick Research Laboratories, Welwyn, and the laboratory for inorganic chemistry at the University of Oxford. By communication between supervisor and student and between authors, referees and editors, the term became employed in a great number of English and American papers, in what Nyholm described as "The Renaissance of Inorganic Chemistry",[65] and from these it spread into other languages. The first two coordination chemistry conferences, at Welwyn in September 1950[66] and Copenhagen in August 1953,[67] undoubtedly did much to make the term familiar. In a lecture for the American Chemical Society in 1951 Fernelius stated "The coordinated ions or molecules have been referred to as ligands or ligates, addenda, and adducts", but his preference is evident from the text that follows where he employs ligand (together with "coordinated group").[68] Thus the term ligand was in widespread use even before the Stockholm conference in 1953.

At this time, too, ligand became frequently used in the context of "ligand field theory"—an expression first appearing in print in 1954 in the published version of the paper delivered by L. E. Orgel and L. E. Sutton at the Copenhagen meeting.[69] At the Solvay meeting in Brussels in May 1956, J. Bjerrum, C. K. Jørgensen, R. S. Nyholm and L. E. Orgel discussed the advantages of using "ligand field theory", and under what conditions.[70]

After Jannik Bjerrum had been appointed a full Professor in Copenhagen in 1948, he had a great number of American and Danish chemists working very intensely on· coordination chemistry, and several important publications in English[71] combined to make the term ligand known, and his American students brought it to the U.S.A. R. S. Nyholm, who attended the Welwyn Conference as an ICI Fellow, probably brought the term ligand to Australia on his return there the same year. At a meeting on coordination chemistry in Sydney[72] in 1953, Nyholm read a paper entitled "Nature of the Metal-Ligand Bond in Complex Compounds", leading his countryman, D. P. Mellor, to comment that "The use of the anything but euphonious term 'ligand' to designate the atom, group of atoms, or molecule attached to the central metal atom has now become so widespread that it is not likely to be abandoned."

CONCLUSIONS

As Crosland has noted in connection with organic nomenclature, "The establishment of any system of nomenclature presupposes the authority of an individual or group to impose such a system."[73] Partly because the phenomenon of isomerism forced attention on the problems of indexing compounds very early, organic chemists seem to have found international co-operation comparatively straightforward. (The Geneva Rules of 1892 were revised at Liège in 1930.) Conversely, as Fernelius has noted, since inorganic chemistry lacked "the barrier to mutual understanding" which the large numbers of compounds raised for organic chemistry, the inorganic nomenclature commission set up in 1919 "had to pioneer for such co-operative effort",[74] its communications and authority being hampered by the aftermath of the First World War and the disruption caused by the Second World War, when agreement might otherwise have been reached.[75]

By expressing in a non-committal way that something is "bound" to a central atom, ligand could be used in abstract papers without implying adherence to misleading metaphorical images. Its strength lay in its ready extension into combinations such as "ligand field", "ligand effect", or transformations such as "ligancy". Moreover, as we have seen, the term's Latin origin meant that it could be used in most Indo-European languages with no, or only minor, changes (see Appendix). Hence its adoption in influential post-war papers and its acceptance by the IUPAC Nomenclature Commission in 1947 were probably momentous for its acceptance by languages other than German.

MacKay and R. Ann MacKay, Modern Inorganic Chemistry. London (1968); L. E. Orgel, An Introduction to Transition Metal Chemistry. Ligand Field Theory. New York (1960).

[15]A. Werner, Neuere Anschauungen auf dem Gebiete der anorganischen Chemie. Braunschweig (1905) (Werner often uses the verb "addieren" and the noun "Addition", and occasionally the term "Addenden", e.g. p. 45); G. Urbain and A. Sénéchal, Introduction à la Chimie des Complexes. Paris (1913); R. Weinland, Einführung in die Chemie der Komplex-Verbindungen (Werner Koordinationslehre) in elementarer Darstellung. Stuttgart (1919), 2nd Edn. Stuttgart (1924). Note also the absence in P. Pfeiffer, Organische Molekülverbindungen, 2nd Edn. Stuttgart (1927); G. Urbain, La Coordination des Atomes dans la Molécule et la Symbolique Chimique. Paris (1933).

[16]Werner was never satisfied with his artificial valence dichotomy, which he always regarded as tentative (vorläufig) and purely formal, and he sometimes wrote formulae without distinguishing the two types of valence. In an address before the British Association for the Advancement of Science at Leicester, he stated:

> If . . . the distinction between principal and auxiliary bonds and principal and auxiliary valencies is kept up, it is because it seems necessary, in view of the present transitional state of the doctrine of valency, to construct sharply defined partial conceptions which can afterwards serve as the foundation stones of a more comprehensive conception of valency ("Valency", Chemical News 1907, 96, 128–131).

See G. Schwarzenbach, Die Entwicklung der Valenzlehre und Alfred Werner, Experientia 1966, 22, 633–646 and Alfred Werner and his accomplishments. In Fasciculus Extraordinarius Alfred Werner 1866–1919, pp. 38–63. Basel (1967).

[20]N. V. Sidgwick, Co-ordination compounds and the Bohr atom. J. Chem. Soc. 1923, 123, 725–730. For an annotated version of this article see G. B. Kauffman, Classics in Coordination Chemistry, Part 3: Twentieth-Century Papers (1904–1935), pp. 132–142. New York (1968). See also Sidgwick's The Electronic Theory of Valency. London (1927). Sidgwick's systematic application of Lewis' "dative bond" to coordination compounds made chemists realize its widespread importance. Sidgwick never used ligand either at this time or later (but see note 66 below), referring instead to "groups" and "co-ordinate links", the term "link" meaning "bond" and having no linguistic connection with ligand through the Latin. We thank Dr. L. E. Sutton for confirming that Sidgwick did not use ligand. See Sutton's notice of Sidgwick in C. C. Gillispie (Ed.), Dictionary of Scientific Biography, Vol. 12, pp. 418–420. New York (1975).

[36]Helv. Chim. Acta, 1937, 20, 171. "Reihenfolge der Liganden" is added in parenthesis after "ordre des constituants liés à l'atome central".

[37]I.U.C. Kommission für die Reform der Nomenclature der anorganischen Chemie: Richtsätze für die Benennung anorganischer Verbindungen. Ber. dtsch. Chem. Ges. 1940, 73A,

53–70. Remy also published an historical account of the 1938 Rules in 1942. See his "Die Richtsätze für die Benennung anorganischer Verbindungen. *Die Chemie* 1942, **55**, 267.

[38]W. P. Jorissen, H. Bassett, A. Damiens, F. Fichter and H. Remy, Rules for naming inorganic compounds: report of the committee for the reform of inorganic chemical nomenclature, 1940. *J. Chem. Soc.* 1940, 1404–1415. Because of the publication date, these are often called the 1940 Rules.

[39]Other, later, derivations were ligancy (see Linus Pauling, *The Nature of the Chemical Bond*, 3rd Edn, p. 2. Cornell University Press (1960) and R. S. Cahn, Sir Christopher K. Ingold and V. Prelog, Specification of molecular *chirality*. *Angew. Chem. Intern. Ed.* 1966, **5**, 386); and *ligate* (Cahn, Ingolb and Prelog, p. 386).

[40]In H. J. Eméleus and J. S. Anderson, *Modern Aspects of Inorganic Chemistry*, which was first published in 1938 and which in its several later unrevised impressions exerted a tremendous influence on post-World War II British chemistry students, the term ligand was not used until the 1960 edition. This refers (p. 115) to "so-called ligands". We owe this information to Professor J. Chatt, who adds: It seems that the name ligand was not familiar to main group chemists even then". Ligand was also notably absent in the work of American coordination chemists, e.g. John C. Bailar, Jr., The stereochemistry of complex inorganic compounds. *Chem. Rev.* 1936, **19**, 67–87, and Symposium on complex inorganic compounds: introduction to the symposium, *Ibid.* 1937, **21**, 1–2; M. J. Copley, L. S. Foster and J. C. Bailar, Jr., The stabilization of valences by coordination. *ibid.* 1942, **30**, 227–238; N. F. Hall, The acid-base properties of complex ions. *ibid.* 1936, **19**, 89–99; H. Diehl, The chelate rings. *ibid.* 1937, **21**, 39–111. Diehl writes only of "unidentate" and "bidentate groups" (dentate from Latin *dens* = tooth).

Finally, despite the fact that directions for the preparation of coordination compounds occur fairly frequently in the first five volumes of the journal of procedures, *Inorganic Syntheses* (Vol. 1, Ed., H. S. Booth, 1939; Vol. 2, Ed., W. C. Fernelius, 1946; Vol. 3, Ed., L. F. Audrieth, 1950; Vol. 4, Ed., J. C. Bailar, Jr., 1953; Vol. 5, Ed., T. Moeller, 1957), the term ligand does not appear until Vol. 6, 1960 (see pp. 67, 74, 176, 198).

[41]See note 11.

[42]That the term was still not used in the Fifth Decennial Index (1947–56) is perhaps more an indication that abstracts are better for locating compounds than concepts. The word finally appeared in the Sixth Collective Index (1957–61). See, however, note 62 below.

[43]*J. Am. Chem. Soc.* 1941, **63**, 889–897.

[44]J. D. Scott, Notes on the nomenclature of inorganic compounds, *Inorganic Syntheses* 1946, **2**, 257–267 ("Attached groups", p. 262). Her earlier, lengthier report, The need for reform in inorganic chemical nomenclature. *Chem. Rev.* 1943, **32**, 73–97 also avoids the term ("coordinating groups", p. 88), though she hailed the 1940 Report as a "giant stride towards improved and internationally standized nomenclature". Both reports arose from an interest in nomenclature at Ohio State University where *Chemical Abstracts* were produced and where Fernelius was editing *Inorganic Syntheses*, Vol. 2 (letter W. Conrad Fernelius, 9 February 1981). See W. C. Fernelius *et al.*, *Chem. Eng. News* 1948, **26**, 520–523.

[55]E. Votoček, *Chemický Slovník*. Prague (1952); Z. Sobecka, W. Choinski and P. Majorek, *Dictionary of Chemistry and Chemical Technology*. Oxford (1966). However, in an English–Polish Chemical Dictionary, edited by D. Kryt (Warsaw, 1964), the Polish word for ligand is given as "ligand, addent".

[56]At the meeting in 1947 the only member present from the old commission was Bassett. Some new members had been appointed by national delegations, but only A. Silverman and A. Ölander continued as members. The young British chemist, R. V. G. Ewens (who was killed in a railway accident in 1948), served as secretary. Niels Bjerrum and K. A. Jensen, who were present only as observers, were elected titular members at the following meeting (Amsterdam, 1949), together with J. Bénard, E. H. Buchner and G. H. Cheesman. At subsequent meetings between 1951 and 1955, W. Feitknecht, L. Malatesta and H. Remy became members of the commission which was finally responsible for the 1957 Rules.

[62]Bjerrum's thesis was abstracted for *Chemical Abstracts* 1941, **35**, 6527–6534, by J. P. McReynolds at Ohio State University, where it attracted much interest (letter from W. Conrad Fernelius, 9 February 1981). The term ligand is used repeatedly in the abstract.

[63]E.g. R. S. Nyholm, Studies in coordination chemistry, Parts I–IV, *J. Chem. Soc.* 1950, 843–859.

[64]E.g. from the Inorganic Chemistry Laboratory at Oxford, H. Irving and R. J. P. Williams, On the order of stability of metal complexes. *Nature* 1948, **162**, 746, which is the first use of ligand in a British paper known to us. According to Prof. R. J. P. Williams, Prof. Irving adopted the term from Bjerrum's thesis.

[65]R. S. Nyholm, *The Renaissance of Inorganic Chemistry*, an inaugural lecture, University College, London (1956). Reprinted in Aaron J. Ihde and W. F. Kieffer (Eds.), *Selected Readings in the History of Chemistry*, pp. 181–184, Easton, Pa. (1965), from *J. Chem. Educ.* 1957, **34**, 166–169.

[66]Imperial Chemical Industries, *A Discussion on Coordination Chemistry*. Butterwick Research Laboratories Report No. BRL/146, The Frythe, Welwyn, Herts., 1951 (typescript prepared by J. Chatt and R. G. Wilkins). Ligand was used in six of the eleven lectures as well as in discussion. The participants included N. V. Sidgwick, H. Irving, G. Schwarzenbach, A. F. Wells, R. S. Nyholm, J. Chatt, R. G. Wilkins, K. A. Jensen, L. E. Orgel and L. E. Sutton. Sidgwick's remarks in discussion, in which *ligand* is used, were probably the subject of editing. See note 20.

[67]*Proceedings of the Symposium on Co-ordination Chemistry*,

Copenhagen, 1953. Danish Chemical Society, 1954. The word ligand was used in 17 of the 34 papers presented at this meeting: Danish: J. Bjerrum (pp. 35 and 51), J. Koefoed (p. 41), and K. A. Jensen (p. 119); German: O. Schmitz-Du Mont (p. 55), W. Klemm (p. 97), and K. Gleu (p. 126); Swedish: Sture Fronaeus (p. 63), I. Leden (p. 79), and D. Dyrssen (p. 133); Dutch: van Panthaleon van Eck (p. 67); Austrian: Nelly Konopik (p. 108); English: L. E. Orgel and L. E. Sutton (p. 21), P. George (p. 56), R. J. P. Williams (p. 68), N. N. Greenwood (p. 101), and J. Chatt (p. 115); American: A. W. Adamson (p. 49).

[68]W. Conrad Fernelius, Nomenclature of coordination compounds and its relation to general inorganic nomenclature. *Chemical Nomenclature*, p. 9. Advances in Chemistry Series, American Chemical Society (1953). The term "aducts" was Werner's. Despite Fernelius's support for *ligand* in his review it was not adopted in the influential college text, T. Moeller, *Inorganic Chemistry*. New York and London (1952). Pauling did not use the terms ligand or ligancy in print before 1945. J. C. Bailar, Jr. used terms like "donor molecule" (e.g. *J. Am. Chem. Soc.* 1953, **75**, 4574–4575) and "coordinating agent" (e.g. *ibid.* 1952, **74**, 3131–3134, 3535–3538), adopting ligand only in 1954 (*ibid.* 1954, **76**, 4051–4052).

[69]L. E. Orgel and L. E. Sutton, Factors determining the stability of complexes. *Proceedings* (note 67), pp. 17–24. As the report of the "Discussion" (p. 24) makes clear, the paper was revised for publication by Sutton, and papers published by Orgel during 1955 continued to use the term "crystal field". (See Spectra of transition-metal complexes. *J. Chem. Phys.* (June 1955), **23**, 1004–1014 which was submitted 11 October 1954; and Electronic structures of transition-metal complexes. *ibid.* (Oct. 1955), **23**, 819–823 which was submitted 28 December 1954). In an important paper entitled Ligand field theory, J. S. Griffith and L. E. Orgel stated: "We regard them both [i.e. crystal field and molecular orbital theory] as expressing certain aspects of a more complete theory which we call ligand field theory. *Quart. Rev.* 1957, **11**, 381–393.

[70]*Quelque Problèmes de Chimie Minérale*, 10. Conseil de Chimie Solvay, Bruxelles, 1956, p. 233, Nyholm's recommendation citing Orgel and Sutton's Copenhagen paper (note 67). Approval of the term came from Orgel himself (p. 314), J. Bjerrum (p. 339) and C. K. Jørgensen (p. 348). According to C. K. Jørgensen, Comparative ligand field studies. *Acta Chem. Scand* 1957, **11**, 53–72 submitted August 1956, "Orgel, Nyholm, J. Bjerrum and the present author proposed at the Xth Solvay Conference, Bruxelles, May 1956, to use the word 'ligand field theory' to denote the crystal field theory extended with the molecular orbital theory for partly intermixing with the orbitals of the ligands, when applied especially to the action of the first coordination sphere on the partly filled *d*-shell in a transition group complex" (p. 53, note). Hence it was at the Solvay meeting that the use of the term was defined.

APPENDIX

The adoption of ligand in other languages

The 1957 Nomenclature Rules and/or the revised 1970 Rules were translated into several languages: Czech,[76] Danish,[77] Dutch,[78] French,[79] German,[80] Hungarian,[81] Italian,[82] Japanese,[83] Norwegian,[84] Portugese,[85] Romanian,[86] Spanish,[87] Swedish,[83] and Russian.[89] The respective national committes had, therefore, to make a decision which word they would use for ligand in their languages. In most cases ligand was used with only small changes (often only of the plural form). In Japanese the word "hai-i shi" (coordinating entity or body) was retained for ligand. Yuji Shibata (1882–1980), who had studied under Werner at Zürich in 1911–1912, introduced the term "hai-i ki" (coordinating radical) in 1929. This was altered to "hai-i shi" by Shibata's student, Tsuchida, in 1938.[90] Examples are:

ligand (ligands)	English, French
ligand (liganden)	Dutch, German
ligand (ligander)	Danish, Norwegian, Swedish
ligand (ligandy)	Czech, Polish, Russian
ligando (ligandos)	Portuguese, Spanish
ligandum (ligandumok)	Hungarian
ligante (ligantes)	Spanish, Brazilian Portuguese
legante (leganti)	Italian
ligand (liganzi)	Romanian

Most languages (including Japanese) have also adopted Stock numbers, the only exceptions being Czech and Slovak,[91] where a very old system devised by J. S. Presl in 1828 has been retained.[92] In this system various valences are expressed by suffixes (manganity, manganisty, manganovy, etc.).

EFFECT OF ADDED SALTS ON THE RATES OF DISSOCIATION AND RACEMIZATION OF TRIS(1,10-PHENANTHROLINE)IRON(II) ION IN AQUEOUS METHANOL SOLUTIONS

SATOSHI TACHIYASHIKI*

and

HIDEO YAMATERA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya, 464, Japan

Abstract—The kinetics of dissociation and racemization of $[Fe(phen)_3]^{2+}$ have been studied in aqueous methanol solutions containing perchlorate, chloride, and thiocyanate ions. The racemization rate was decreased by ClO_4^- and increased by SCN^-, while the dissociation rate was decreased by ClO_4^- and increased slightly by Cl^- and remarkably by SCN^-. The effect of anions on the reaction rates became remarkable with the increase in methanol content of the solutions. The results were reasonably explained in terms of ion association. The dissociation rate of the complex ion in the ion-pair increased in the order, $ClO_4^- < Cl^- < SCN^-$, of associated anions, suggesting the ion-pair interchange mechanism for the dissociation. The ion-association constants were determined to be 11 ± 4, 18 ± 4, and 25 ± 15 ($I = 0.1$, 25°C) for ClO_4^-, Cl^-, and SCN^-, respectively, in 0.64 mole-fraction (0.8 volume-fraction) aqueous methanol.

INTRODUCTION

The kinetics of dissociation of $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ have been studied extensively, and the effect of added salts on the reaction rates has been discussed in terms of ion-pair formation in aqueous[1] and non-aqueous[2,3] solutions. Blandamer *et al.*[4] studied the kinetics of the reactions of $[Fe(bpy)_3]^{2+}$ with cyanide and hydroxide ions in binary aqueous solvent mixtures. On the standpoint of associative mechanism they have concluded that the chemical potential changes of anions with the change in solvent composition were dominant in determining reactivities in their reaction with $[Fe(bpy)_3]^{2+}$.

We previously studied the effect of various inorganic anions on the rates of dissociation and racemization of $[Fe(phen)_3]^{2+}$ in aqueous solutions.[1] We analyzed the experimental results considering the ion-pair formation of the complex ion with an anion, and found the following trends. (1) The dissociation rate constant of the complex existing in the ion-pair increases with the increase in proton affinity (basicity) of the anion: $I^- < Br^- < Cl^- < NO_2^- < OCN^- < N_3^- < F^- < OH^- \simeq CN^-$. (2) The intramolecular racemization rate constant, given by apparent racemization rate constant minus dissociation rate constant, increases with the increase in polarizability (softness) of the anion: $OH^- \simeq CN^- \simeq F^- \simeq Cl^- < Br^- \simeq NO_2^- < OCN^- < I^- < N_3^-$. We thought it desirable to extend the study to include the systems containing perchlorate, which is one of the hardest, least basic anions, and thiocyanate, which is a very soft anion. However, the effects of these anions were difficult to measure in aqueous solution because of the low solubility of $[Fe(phen)_3]^{2+}$ in the presence of these anions;

only the effect of the thiocyanate ions on the racemization rate were measured in supersaturated solutions.

In the present study, the effects of perchlorate and thiocyanate ions on the dissociation and racemization of $[Fe(phen)_3]^{2+}$ were investigated in aqueous methanol solutions. It was also our object to study the solvent effect on the rates of dissociation and to see whether or not the reactions in aqueous methanol solutions can be explained by the same mechanism as in aqueous solutions.

EXPERIMENTAL

The dissociation and racemization rates were obtained respectively from the changes in absorbance (510 nm) and optical rotation (546 nm) of the solution containing 5×10^{-5} mol dm^{-3} $[Fe(phen)_3]$ $(ClO_4)_2$ in a thermostated (± 0.1°C) quartz cell. In measuring the dissociation rate of the complex, 3.1×10^{-4} mol dm^{-3} nickel(II) perchlorate was added to the sample solution except for the cases where the concentration of the nickel(II) salt or perchloric acid is explicitly described; nickel(II) and hydrogen ions are effective as scavengers of liberated phenanthroline molecules.[1] The absorbances at 510 nm of the complex-salt solutions containing nickel(II) or hydrogen ions became negligible after a sufficient time, indicating that the complex ions completely dissociated to give solvated iron(II) ions. All the reactions were followed for four half-lives, and were found to be first order in the metal complex concentration in the time range studied. The dissociation and racemization rates obtained were reproducible within ± 2 and $\pm 5\%$, respectively. Methanol, a guaranteed reagent of Wako Pure Chemical Indistries, Ltd., was purified by fractional distillation. Mixed solvents were prepared by mixing appropriate volumes of the methanol and water; 0.6 and 0.8 volume fractions of methanol corresponds to 0.40 and 0.64 mole fractions (m.f.), respectively. The racemization and dissociation experiments were carried out mainly in 0.40 and 0.64 m.f. aqueous methanol solutions, respectively. Solutions of higher methanol concentrations are not suited for investigating the effect of SCN^- ions on the rates because the reactions

---

proceed too fast. Other reagents and techniques were the same as those described in our previous paper.[1]

RESULTS AND DISCUSSION

As shown in Table 1, both the dissociation and intramolecular racemization rates increased in the presence of SCN^-, and they are decreased by ClO_4^- in 0.40 m.f. aqueous methanol solutions. The results extend the previous findings in aqueous solutions that the intramolecular racemization rate increased with the increase in the polarizability of the anion, while the dissociation rate increased with increasing basicity of the anion.[1] The same order of the effect of the added anions was also observed in 0.64 m.f. aqueous methanol and in pure methanol (Tables 2 and 3). The retarding effect of ClO_4^- on the racemization rate were also reported in several solvent systems by Van Meter and Neumann.[5]

For the analysis of the experimental results, the following reaction processes were assumed:

$$[Fe(phen)_3]^{2+} + X^- \underset{}{\overset{K_{(x)}^{IP}}{\rightleftharpoons}} [Fe(phen)_3]^{2+} \cdot X^- \qquad (1)$$

$$[Fe(phen)_3]^{2+} \overset{k_d}{\rightarrow} [Fe(phen)_2]^{2+} + phen$$

$$\overset{fast}{\rightarrow} Fe^{2+} + 3phen \qquad (2)$$

$$[Fe(phen)_3]^{2+} \cdot X^- \overset{k_{d(X)}^{IP}}{\rightarrow} [Fe(phen)_2]^{2+} \cdot X^- + phen$$

$$\overset{fast}{\rightarrow} Fe^{2+} + 3phen + X^-. \qquad (3)$$
Then the thermodynamic ion-association constant for reaction (1), $K_{(X)}^{IP}$, and the dissociation rate constant, k_d^{obsd}, are given by:

$$K_{(X)}^{IP} = \frac{[Fe(phen)_3^{2+} \cdot X^-]}{[Fe(phen)_3^{2+}][X^-]} \frac{1}{f_2}. \qquad (4)$$

$$k_d^{obsd} = \frac{k_d + k_{d(X)}^{IP} K_{(X)}^{IP} f_2 [X^-]}{1 + K_{(X)}^{IP} f_2 [X^-]} \qquad (5)$$

where k_d and $k_{d(X)}^{IP}$ are the rate constants for reactions (2) and (3), respectively. The activity coefficient, f_z, of an ion with a charge of $\pm z$ was estimated by using the extended Debye–Hückel equation:

$$\log f_z = -\frac{Az^2\sqrt{I}}{1 + Ba\sqrt{I}} + bI \qquad (6)$$

where $A = 0.2174$ $(e^2/\epsilon kT)\sqrt{(8\pi N\ e^2/1000\epsilon kT)}$ and $B = \sqrt{(8\pi N\ e^2/1000\epsilon kT)}$ with usual meanings of the notations.[6] The values of $a = (7-10)\times 10^{-8}$ cm and $b = 0.1z^2$ were assumed in the calculation, together with $\epsilon = 78.5$ for water and $\epsilon = 44.0$ for 0.64 m.f. aqueous methanol.

We first examine the effect of ion association on the concentration of free anion([X⁻]) and the ionic strength (I). The concentration of the complex salt was much lower than those of the added salt, and therefore it suffice to consider the effect of ion association only between added ions:

$$M^{n+} + X^- \rightleftharpoons M^{n+} \cdot X^- \qquad (7)$$
where M^{n+} ($n = 1$ or 2) and X^- represent the cation and anion of the added salt. The association constant, K, is given by:

$$K = \frac{[M^{n+}\cdot X^-]}{[M^{n+}][X^-]}\frac{f_{n-1}}{f_n f_1} = \frac{x}{(c-x)(nc-x)}\frac{f_{n-1}}{f_n f_1} \qquad (8)$$

where c is the total concentration of the added salt, and x the concentration of the ion-pair at equilibrium. With the knowledge of the values of K and f_z, the net concentration of the free anion, $nc - x$, can be obtained from eqn (8). In the absence of the experimental ion-association constants for such systems, K values for dipositive and mononegative ions and for monopositive and mononegative ions were calculated theoretically[7] using various values $((3-6)\times 10^{-8}$ cm$)$ of the closest distance of approach between ions. The approximate f_z values were obtained from eqn (6) by assuming the value of a to be $(3-6)\times 10^{-8}$ cm, and with the first approximation of $I = n(n+1)c/2$. Then, the value of x was calculated from eqn (8). The f_z were recalculated with $I = n(n+1)c/2 - nx$ to give a better x value as the second step of approximation. Further repetition of the procedure reproduced the x value within the limits of experimental error. The net concentration of the free anion and the ionic strength of the medium were calculated by the use of the x value thus obtained.

With the [X⁻] and I values obtained, the $K_{(X)}^{IP}$ and $k_{d(X)}^{IP}$ values were determined to give the best fit between the observed kinetic data and the calculated curve according to eqn (5). In obtaining the $K_{(X)}^{IP}$ and $k_{d(X)}^{IP}$ values for X = Cl⁻ and SCN⁻, we disregarded the effect of

perchlorate ions, contained in a low concentration $(7.2\times 10^{-4}\ \text{mol dm}^{-3})$ as counter ions of the complex cations and the added nickel(II) ions. The $K_{(X)}^{IP}$ values were transformed to the concentration ion-association constant, $K_{C(X)}^{IP}$, at $I = 0.1$ by means of eqn (6).

The rate constant for the dissociation of the complex ion in the ion-pair (eqn (3)) increased in the order, ClO₄⁻ < Cl⁻ < SCN⁻, of the associated anion in 0.64 m.f. aqueous methanol (Table 4). The sequence is consistent with those obtained in aqueous solutions;[1] i.e. the rate constant for the ion-pair increased with the increase in the pKa of the conjugate acid of the anion. This suggests that the mechanism of dissociation in this case is the same as that in aqueous solutions (ion-pair interchange mechanism[1]).

The dissociation rate constants of the complex in the presence of SCN⁻ and of Cl⁻ increased with the increase in methanol content, as can be seen from a comparison of the results given in Tables 1–3. Similar results were obtained for the dissociation of [Fe(bpy)₃]²⁺ by Seiden et al.[2] The increase in rate with the increase in methanol content is caused by the increase in the reactivity of the ion-pair as well as the increase in the association constant (see Table 4). The larger reactivity of the ion-pair in the solution of higher methanol content can be well understood by considering the influence of the dielectric constant of the medium. The free-energy difference between the polar ion-pair and the less polar activated complex is larger in a medium with a higher dielectric constant.[8] Thus, the activation energy becomes smaller with the decrease in the dielectric constant of a medium, or with the increase in methanol content. In this connection, it is interesting to note the fact that [Fe(phen)₃]Cl₂ and [Fe(pbm)₃](SCN)₂ are converted to [Fe(phen)₂Cl₂][9] and [Fe(pbm)₂(SCN)₂][10] in dichloromethane and chloroform, respectively, at rates much faster than the dissociation rates of the tris-complexes in aqueous solutions.

The dissociation rate of the free complex cation in 0.64 m.f. aqueous methanol was found to be considerably smaller than that in dimethyl sulfoxide (Table 4) reported by Farrington et al.,[3] in spite of the fact that the dielectric constants of the two solvents are almost the same. Similar but more pronounced tendencies were observed, when the complex cation was ion-paired with ClO₄⁻ and with Cl⁻. This shows that the coordinating ability, in addition to the dielectric constant, of solvent molecules makes a significant contribution to the dissociation rate of the complex ion.

As shown in Table 4, the ion-association constants increased in the order of ClO₄⁻ < Cl⁻ < SCN⁻ in 0.64 m.f. aqueous methanol; a consistent order was previously found in aqueous solution.[1] The $K_{C(X)}^{IP}$ values for Cl⁻ and SCN⁻ were greater in 0.64 m.f. aqueous methanol than in water. This trend is consistent with the theoretical prediction (Table 4). Table 4 also lists the $K_{C(X)}^{IP}$ values reported for ClO₄⁻ and Cl⁻ in dimethyl sulfoxide;[3] the values are much greater than those obtained in 0.64 m.f. aqueous methanol in the present study. However, the literature values cannot directly be compared with the present results, since the former were derived without allowance for the ion association of the added salt and for the change in ionic strength.

The effect of added salts on the rate of dissociation of [Fe(phen)₃]²⁺ in aqueous methanol solutions can reasonably be understood in terms of ion association of the complex with anions.

NMR STUDY OF INTRAMOLECULAR PROCESSES IN EDTA METAL COMPLEXES

MARIA CARLA GENNARO*, PIERO MIRTI and CLAUDIO CASALINO
Istituto di Chimica Analitica, Università di Torino, via Giuria 5, I 10125, Torino, Italy

Abstract—The kinetics of the intramolecular acetate scramblings occurring in thirteen ethylenediaminetetraacetate (EDTA) complexes has been studied by analyzing the modification observed in the NMR spectra of their D_2O solutions, when temperature is changed. The experimental results indicate that the Δ, Λ conversion is a fast process on the NMR time scale for each of the complexes considered, whereas the nitrogen inversion occurs at an observable rate in the case of the Cd(II), In(III), Sc(III), Y(III) and Lu(III) chelates and is too rapid in the other complexes. Computer analysis of the experimental NMR spectra has been performed in order to obtain enthalpy, entropy and free energy of activation concerning the N inversion of the cited chelates. Twist and bond breaking mechanisms are discussed with reference to both scrambling processes.

INTRODUCTION

Proton magnetic resonance has proved to be a powerful technique in studying the intramolecular processes occurring in organic molecules.[1] Among the various fields of application of this technique, a particular interest can be found in the study of the labilities of the coordination bonds in metal complexes, because of the wide use of such compounds in many branches of modern chemistry. Particularly, polyaminepolycarboxylic acids are widely used as chelating agents, and among them, ethylenediaminetetraacetic acid (EDTA) is by far the most employed. The study of the intramolecular rearrangements occurring in EDTA complexes may therefore be considered worth being done. However, such an investigation should require a detailed knowledge of the structure of the solution forms of the metal chelates; unfortunately, literature data do not agree when dealing with the number of the coordination sites actually utilized by the ligand.[2–9] In this paper the generally accepted octahedral hexacoordinate structure will be referred to; the possible presence of differently coordinated species in solution would not affect the sense of the considerations given, because a rapid averaging among the various forms is very likely to occur in the working experimental conditions.

An hexacoordinate complex in solution can be present in two different configurations, which are normally referred to as Δ or Λ, respectively.[10] The two configurations show the same NMR spectrum, which is mainly characterized by the presence in the molecule of eight methylene protons in the four acetate groups. These protons can experience different magnetic environments owing to their different steric arrangement in the complex. Particularly, an acetate group can be referred to as in plane or out of plane, depending on its position in relation to the plane formed by the metal ion and the two nitrogen atoms. If the complex has a symmetrical structure, as in the case of EDTA chelates, the two out of plane positions are equivalent and so are the two in plane ones. Besides, each methylene proton in an acetate group can occupy an axial or equatorial position, in relation to the fact that the hydrogen to carbon bond is parallel or not to the symmetry axis passing through the centre of

the corresponding five-membered ring. In conclusion, the NMR spectrum of the methylene protons of a Δ or Λ configuration of an EDTA complex will show, in the absence of any intramolecular exchange, resonances corresponding to four magnetically non-equivalent protons, which can be named as out-of-plane axial and equatorial, and in-plane axial and equatorial, and will be referred to in this paper as H_a^0, H_e^0, H_a^i and H_e^i, respectively. Particularly, these protons give rise to two AB quartets in the NMR spectrum, because of the geminal coupling between the hydrogen nuclei belonging to the same acetate group.

A sufficient lability of the coordination bonds can cause, if not prevented by an excessive rigidity of the ligand backbone, an interchange between the Δ and Λ configurations (Δ, Λ conversion), or provoke the lone pair inversion of the nitrogen atoms (nitrogen inversion). The two processes are not necessarily interdependent, and give rise to different patterns in the NMR resonances of the methylene protons. In fact, both cause the two AB quartets to coalesce into only one AB pattern, but the spectral parameters are different in the two cases, because of the different exchange mechanism. Particularly, the Δ, Λ conversion makes the H_e^0 and H_a^0 protons average their magnetic environments with the H_a^i and H_e^i nuclei, respectively, whereas the nitrogen inversion causes an exchange of the type $H_e^0 \leftrightarrows H_e^i$ and $H_a^0 \leftrightarrows H_a^i$[11] (Fig. 1). When the processes occur simultaneously, a single methylene proton is bound to experience and average all the magnetic environments related to the axial and equatorial protons, in-plane and out-of-plane, and the NMR spectrum shows the collapse of the AB quartet into a single peak.

The possibility of observing the described modifications in the NMR spectrum of an EDTA chelate, depends on the fact that the considered intramolecular scramblings occur at a rate of the order of the extent of the NMR spectrum itself; therefore, only in this case is it possible to study the kinetics of these exchange processes.

The situations which may be encountered when dealing with an octahedral complex are summarized in Table 1. It must be noted that in the given scheme the possibility of a breaking of the metal-to-nitrogen bonds without previous rupture of the metal-to-oxygen bonds

---

Fig. 1. General scheme of the intramolecular acetate scrambling processes in an octahedral symmetric complex.

Table 1. Summary of situations arising in the NMR spectrum of an octahedral symmetric complex, depending on the labilities, on the NMR time scale, of the metal to ligand bonds

Bonds' lability on the NMR time scale		Acetate scrambling occurring by		Number of methylenic protons with different magnetic environments	shape of the NMR spectrum
M − O	M − N	Δ,Λ conversion	nitrogen inversion		
not labile	not labile	no	no	4 (H_e^o , H_a^o , H_e^i , H_a^i)	two AB patterns
labile	not labile	no	no	4 (H_e^o , H_a^o , H_e^i , H_a^i)	two AB patterns
		yes	no	2 ($H_e^o \rightleftharpoons H_a^i$, $H_a^o \rightleftharpoons H_e^i$)	one AB pattern
labile	labile	no	yes	2 ($H_e^o \rightleftharpoons H_e^i$, $H_a^o \rightleftharpoons H_a^i$)	one AB pattern
		yes	yes	1 ($H_e^o \rightleftharpoons H_a^o \rightleftharpoons H_e^i \rightleftharpoons H_a^i$)	one single peak

has not been taken into account, because it is inconsistent with the considered structure of the complexes. On the same grounds, it follows that the nitrogen inversion (which requires the rupture of the M–N link to occur) can only take place in conditions in which also the Δ, Λ conversion occurs, unless this is hindered by steric factors. Because the EDTA backbone is flexible enough to allow the configurational exchange, it follows that the resonances of the methylene protons in the NMR spectrum of an EDTA chelate can be expected to change with the labilities of the coordination bonds by giving the coalescence of the two AB quartets into one AB pattern and then into a single peak.

EXPERIMENTAL

Weighed amounts of dried ethylenediaminetetraacetic acid and metal nitrates (C. Erba, Merck, K and K reagents) were dissolved in deuterium oxide in order to prepare solutions with concentrations of the metal complex ranging from 0.05 to 0.10 M Potassium deuteroxide was used to adjust the pD of the solutions to a value ensuring the complete formation of the complex in the investigated range of temperature, excluding any hydroxo- or protonated form.[12]

NMR spectra were recorded by means of a Varian T-60 spectrometer, equipped with a T-6057 lock-decoupler and a T-6080 temperature controller. The calibration of the probe temperature meter was obtained by measuring the chemical shift of the hydroxyl protons of both methanol and ethylene glycol.[13] The homogeneity of the magnetic field was checked before each run with the magnetic field locked on the HOD line.

Intramolecular rate constants (k) were obtained by complete line shape analysis of the experimental spectra; a slightly modified version of the DNMR program[14] was used, which performed calculation and plots of theoretical spectra by the input data of chemical shifts, coupling constants and transverse relaxation times of the exchanging sites; these were obtained from the spectra recorded in absence of the studied exchange process. The most reliable value of k was chosen for each spectrum by searching for the best fitting with the theoretical ones, computed by progressive adjustments of the imposed rate constant.

RESULTS AND DISCUSSION

Mg(II), Ca(II), Sr(II), Ba(II), Zn(II), Cd(II), Pb(II), Sc(III), Y(III), La(III), Lu(III), Al(III) and In(III) complexes of EDTA have been studied. In all cases the NMR spectra recorded at the lowest working temperature (the solutions' freezing points) revealed that the configurational exchange between the Δ and Λ forms was fast on the NMR time scale. Particularly, all spectra, except those recorded on Cd-, In-, Sc-, Y- and Lu-EDTA solutions, consisted of a single peak in all the investigated range of temperature (273–373 K), denoting the magnetic equivalence of all the methylene protons. This allows us to state that in these cases also the nitrogen inversion is a fast process on the NMR time scale. As a consequence, it was not possible to give a quantitative treatment of the kinetics of the intramolecular processes occurring in the corresponding complexes.

Things were different when examining the spectra recorded on Cd-, In-, Sc-, Y- and Lu-EDTA solutions. In these cases the resonances of the methylene protons consist of an AB pattern at the lowest working temperature; this means that two sets of protons interchanging their magnetic environments are present in the complexes in these conditions and supports the hypothesis of a rapid configurational exchange, but a slow nitrogen inversion on the NMR time scale. The failure to obtain the splitting of the AB quartet into two patterns prevented the possibility of studying the Δ, Λ conversion, but the N inversion was successfully investigated by analyzing the progressive collapse of the AB quartet with the increase of temperature. At such purpose the AB pattern was dealt with as the "frozen" spectrum with respect to the studied process and provided the spectral parameters required as input data in the computer program. It must be noted that only in the case of the indium complex was the complete collapse of the quartet into a single line observed, whereas this was not achieved for the other chelates up to their solutions' boiling point. However, the spectral modifications observed were sufficient to allow a reliable treatment of the exchange process also in these

cases. Furthermore, as regards the Cd-EDTA spectra, satellite peaks were observed, arising from the coupling of the proton with the ^{111}Cd and ^{113}Cd nuclei; these peaks were not taken into account in the computer analysis of the spectra owing to their relatively low intensity.

Figures 2 and 3 show the NMR spectra recorded at different temperatures on In- and Sc-EDTA solutions, together with their best fitting computed ones; for simplicity reasons, only the most characteristic inner peaks of the AB quartets are reported. The spectra of Cd-, Y- and Lu-EDTA complexes showed a behaviour rather similar to that of ScEDTA.

The intramolecular rate constants (k) obtained by the computer analysis of the spectra were plotted as ln k vs
the reciprocal of the absolute temperature (T) (Fig. 4) and allowed to obtain frequency factors and activation energies of the studied processes, and therefore enthalpies, entropies and free energies of activation (see Table 2). By doing that, a transmission coefficient has to be taken into account, which gives the probability of the exchange process to occur actually after having reached the activated state; in the present case, its value has been set equal to 1/2 because of the identity of the energy levels of the exchanging sites and the consequent equal probability of reforming the nitrogen coordination having or not undergone the lone pair inversion.

The search for a likely pathway of intramolecular rearrangements in metal complexes is a much discussed problem and has been the object of several studies.[15-31] These include both dissociative and twist mechanisms, requiring or not the rupture of the coordination bonds, respectively. In the particular case of the processes studied in the present work, it must be noted that the twist mechanism, which may be suitable to account for the rapid Δ, Λ conversion of the investigated complexes, cannot explain a nitrogen inversion. In fact, this process can only occur if the metal to nitrogen bond is broken. However, the negative values obtained for the entropies of activation are more easily associated with twist rather than dissociative pathways[27] and are consistent with the increased state of order intrinsic in the trigonal prism representing the activated state of the twist process.[29] All that could be accounted for if a "twist with rupture" sequence is accepted, as proposed by Eaton et al.,[27] who supposed the possibility of a bond breaking in the intermediate state of the twist pathway.

Examination of literature data allows a comparison between the results of the present work with several others concerning EDTA complexes, even though these are mostly limited to qualitative deductions drawn from the presence or not of multiplet patterns in the NMR spectra. So Kula et al.[19] have shown the labilities of the metal-to-oxygen bonds in alkaline earth, Zn, Pb, Hg and

Table 2. Summary of activation parameters

metal ion	activation enthalpy (Kcal/mol) at 298 K	activation entropy (e. u.) at 298 K	free energy of activation (Kcal/mol) at 298 K
Sc(III)	4.1 ± 0.2	− 38.5 ± 0.7	15.6 ± 0.4
In(III)	3.1 ± 0.2	− 40.4 ± 0.8	15.1 ± 0.5
Y(III)	2.4 ± 0.3	− 44.4 ± 0.8	15.7 ± 0.5
Lu(III)	2.1 ± 0.4	− 45 ± 1	15.5 ± 0.8
Cd(II)	2.0 ± 0.4	− 45 ± 1	15.4 ± 0.7

Al complexes and Day and Reilley[10] have given evidence of the lifetimes of both oxygen and nitrogen coordination in the Pb, Cd and Co(III) complexes. Chan et al.[32] have studied the Mo(VI) binuclear complex, Ryhl[33] the lanthanum and lutetium complexes and Baisden and coworkers[34] the alkaline earth, Bi, Y, La, Lu and In chelates. Everhart and Evilia,[31] at last, have investigated the Ni and Co(II) systems. The results given in these papers are in agreement with those of this work, when referring to comparable situations. Particularly, Baisden and coworkers have put forward the hypothesis of a correlation between the z^2/r ratio (where z is the charge and r the radius of the cation) and lifetime of the intramolecular bonds, and proposed the value $z^2/r = 9$ as the limit beyond which an AB quartet is to be expected in the NMR spectrum of an EDTA chelate. This is in agreement with the whole of the data available on EDTA chelates, with the exceptions of the Cd (slow nitrogen inversion with $z^2/r = 4$) and Al complexes (fast interconversion despite its $z^2/r = 18$).

Another attempt to interpret the results obtained can be made by admitting that the lifetime of a coordination bond is mainly due to steric effects rather than to changes in the bond character itself;[5] this leads to considering the size of the metal ion as an important factor in determining the lability of the metal-to-ligand links.

The results concerning ten out of the thirteen complexes investigated are consistent with the hypothesis of setting a radius of 1 Å as the value over which the metal-to-nitrogen bond is labile enough to give a fast N inversion on the NMR time scale. The disagreement is given, in this case, by the fast N inversion observed for the complexes formed with the small Mg, Zn and Al ions.

Abstract—Ab initio calculations including the effects of solvation on the hydrogen bonding interactions between F^- and phosphorous acid, HPO_3H_2, have been performed, resulting in a value of 61 kJ mol^{-1} for the hydrogen bond energy of $[HPO_3H_2F]^-$. Attempts to show that this species exists in aqueous solution have been made using ^{17}O, ^{19}F and ^{31}P NMR spectroscopy and pH and conductance studies, but these indicate that the principal reaction is an acid-base neutralization. Crystals of $KF.HPO_3H_2$ grow from aqueous solution but these are not the same as those from methanol solution which are known to be strongly hydrogen bonded.

INTRODUCTION

The bifluoride ion still ranks as the species which possesses the strongest hydrogen bond[1] but several other examples of strong or short bonds involving the fluoride ion are known.[2] In $KF.(CH_2CO_2H)_2$ and $KF.(CH_2CO_2D)_2$ the F^- acts as the acceptor to two hydrogen bonds formed with the carboxylic acid groups of different succinic acid molecules and $r(O\cdot\cdot F)$ is 244 pm.[3]

In crystals of $Te(OH)_6.2KF$ the fluoride ions each form three OHF hydrogen bonds and $r(O\cdot\cdot F)$ is 258.[4] A similar situation is present in $Te(OH)_6.NaF$.[5] The shortest OHF bonds are those in crystals of $(KHPO_3.HF)_2$ whose structure is based on cyclic dimers of the anion. The value of $r(O\cdot\cdot F)$ is 238 pm with the proton lying nearer the fluoride so that the hydrogen bond is essentially between a hydrogen phosphite group and HF, (I).[6] The OHO bonds holding the dimers together are also quite short, $r(O\cdot\cdot O) = 256$ pm.
Somewhat surprisingly there has been no further investigation of $(KHPO_3.H.HF)_2$ since its discovery[7] and structural detetermination.[6,8] In view of the rarity of the OHF hydrogen bonds we have calculated the hydrogen bond energy of this bond and studied mixed solutions of KF and HPO_3H_2 with a view to observing (I) in an aqueous environment, following our discovery that crystals of the same empirical composition $KF.HPO_3H_2$ will grow from a saturated aqueous solution of KF and HPO_3H_2. The original method for producing the adduct used methanol as the solvent or alternatively an aqueous solution of HF and $KHPO_3H$.[8]

THEORETICAL PROCEDURE

Ab initio LCAO–MO–SCF calculations were performed on HPO_3H_2, HPO_3H^-, $HPO_3H_2F_2^{2-}$, HPO_3^{2-}, $HPO_3H_2F^-$ and HPO_3HF^{2-} using a version of the program GAUSSIAN 76.[9] This program has been modified to perform level-shifting of the Hartree–Fock Hamiltonian[10] directly in the atomic orbital basis to guarantee the convergence of the iterative SCF calculations.[11] Geometry optimizations (bond lengths to within ±1 pm, bond angles to within ±0.1°) were performed with the split-valence 4–31G and 44–31G basis sets,[12] using standard univariate quadratic interpolation procedures.

(a) *Phosphite ion*, HPO_3^{2-}

Starting with a tetrahedral geometry about phosphorus the following optimized parameters were obtained: $r(PH) = 150.8$ pm, $r(PO) = 159.8$ pm, HPO = 102.9°.

(b) *Hydrogen phosphite ion*, HPO_3H^-

To the optimized HPO_3^{2-} arrangement a proton was added with $r(OH) = 90.0$ pm and POH = 109.5°, and the structure was reoptimized to produce the values of (II). The dihedral angle HOPH was assumed to be zero.

(II)
(c) *Phosphorous acid*, HPO_3H_2

The addition of another proton to (II) followed by reoptimization produced only marginal changes: $r(OH) = 96.2$ pm; POH = 119.6°.

---

*Author to whom correspondence should be addressed.

(d) *Hydrogen phosphite fluoride*, [HPO₃HF]²⁻

Adding a fluoride ion to (II) with $r(HF) = 120.0$ pm, the structure of the ion was optimized at the hydrogen bond centre to give $r(OH) = 105.1$ pm, $r(HF) = 137.4$ pm OHF = 180° (assumed) and POH = 121.6°, assuming the hydrogen bond to be linear.

(e) *Phosphorous acid fluoride*, [HPO₃H₂F]⁻

Starting from the optimized structure of (c), structure (III) was calculated by optimizing the parameters shown under the assumptions of a linear hydrogen bond and zero HOPH dihedral angles.
(III)

(f) *Phosphorous acid difluoride*, [HPO₃H₂F₂]²⁻

Starting with the optimized structure of (III) a second fluoride was added to the remaining acidic hydrogen such that $r(OH)$, $r(HF)$ and POH are equal to those in (III).

The hydrogen bond energy of [HPO₃H₂F]⁻ was then computed using the extended [6s4p/4s2p/2s1p] concentrated Gaussian basis set of Dunning[13] with an s-orbital scaling factor of √(2) and a p-orbital exponent of 0.7 for the protons. The effect of the addition of a set of single 3d Gaussian polarization functions $(\alpha_d = 0.43)$[14] on phosphorus was studied. This basis set has been shown to be sufficiently complete to yield hydrogen bond energies which are stable against further basis extensions and against "ghost orbital" corrections.[15] Single determinant SCF wavefunctions are generally adequate for the calculations of the energies of strong hydrogen bonds between closed shell molecules since the molecular extra correlation energy and the zero-point vibrational corrections are both small (*ca.* 5%).[16] Finally, the effect of solvation on the hydrogen bonding interaction was studied using the non-specific solvation method.[17] The results of the calculations are presented in Table 1.

EXPERIMENTAL

Instruments

Perkin Elmer 457 IR spectrometer (KBr discs, nujol mulls); Beckman pH electrode; Bruker HFX90 NMR spectrometer (¹⁹F, 84.66 MHz, referenced to CFCl₃; ³¹P, 36.43 MHz, referenced to 85% H₃PO₄) and Bruker WM250 NMR spectrometer (¹⁷O, 39.909 MHz, referenced to H₂O). *Materials*: KF, KHF₂, KHPO₃H and HPO₃H₂ were analytical grade, HF was a 40% solution in water.

Preparation of KF.HPO₃H₂

HPO₃H₂ (5 g, 0.06 mol) and KF (3.5 g, 0.06 mol) were dissolved in water (10 cm³). Evaporation under vacuum at room temperature produced crystals of the adduct KF.HPO₃H₂ m.p. 170°. Found: P, 22.0; H, 2.1; F, 13.6; K, 27.4%. Calculated for H₃FKO₃P: P, 22.1; H, 2.1; F, 13.5; K, 27.8%. The same compound was also grown from a solution of KHPO₃H in aqueous HF. The crystals are stable in air and can be recrystallized from water. Their solubility is ⩾4000 gkg⁻¹, the actual solubility being difficult to determine exactly because of the high viscosity of such solutions; the solubility of HPO₃H₂ in water at 0°C is 3090 gkg⁻¹.[18] When saturated solutions of KF and HPO₃H₂ were mixed a temperature rise of 12°C was recorded.

Crystals grown from an aqueous solution containing a 1:2 mole ratio of HPO₃H₂:KF were identified as KHF₂ by their IR spectrum and analysis. Found: P, <1; H, 1.4; F, 48.0; K, 49.2%. Calculated for F₂HK: H, 1.3; F, 48.7; K, 50.1%. Crystals grown from an aqueous solution of HPO₃H₂ and KHF₂ were also identified as KHF₂.

DISCUSSION

The original discoverers of (KHPO₃H.HF)₂ prepared it by anhydrous methods such as grinding together KF and phosphorous acid and extracting the syrup which formed with hot methanol.[6,8] Crystals of adduct were also obtained by complete dehydration of an aqueous solution of KHPO₃H in 40% HF followed by methanol extraction.[7]

Crystals of composition KF.HPO₃H₂ grow from a saturated solution of KF and HPO₃H₂. The melting point of these is 170°, compared to the 96° reported for (KHPO₃H.HF)₂. Alternative hydrogen bonded structures for the higher melting crystals can still involve OHF bonds, such as (IV), which is a polymeric rather than a dimeric form of (I), or (V), which has the HF molecules participating in two strong hydrogen bonds.

(IV)

(V)
A structure similar to (V) has been discovered in the adduct of KF and malonic acid, KF.CH₂(CO₂H)₂.[19] Yet a third possibility is a polymeric anion involving F⁻ ions forming two hydrogen bonds to acidic groups as is found in KF.(CH₂CO₂H)₂.[20] In this last example the pK₁ of succinic acid at 4.16[21] is sufficiently less than that of HF (3.45) to prevent proton transfer to form HF as occurs with malonic acid (2.83) and HPO₃H₂ (2.00).

So far crystals of the new KF.HPO₃H₂ have not been produced which can be investigated by X-ray diffraction methods. It is even possible for them to be a mixed salt. The crystal structure of (KHPO₃H.HF)₂, however, shows short hydrogen bonds[6] and we now report on the calculated energies of such bonds between HPO₃H₂ and F⁻, this being the first time that the hydrogen bonding of an acid of a second row element has been computed.

Structure optimization of the hydrogen bonded com-

plex between F⁻ and HPO₃H₂ gave the parameters of (III) and showed the hydrogen bonding proton to reside near the fluorine nucleus at about the bond distance of hydrogen fluoride. In this respect the system is like the arrangement in the crystal dimers, (I). Using the double-zeta basis set the energy of the hydrogen bond of [HPO₃H₂F]⁻ is calculated to be 66 kJ mol⁻¹ relative to the lower energy isolated pair HPO₃H⁻ + HF.

Defined with respect to the components used in our synthesis of the complex, i.e. HPO₃H₂ + F⁻, the interaction energy is 308 kJ mol⁻¹. Again this is in accord with the exothermicity observed when solutions of HPO₃H₂ and KF are mixed.

Taking phosphorus 3d orbitals into account in our calculations changed these energies to 48 kJ mol⁻¹ (with respect to HPO₃H⁻ + HF) and 328 kJ mol⁻¹ (HPO₃H₂ + F⁻). Taking solvation effects of methanol into account altered these values to 61 and 124 kJ mol⁻¹ respectively. The former is thus the hydrogen bond energy of the complex, according to the agreed definition for systems of this kind.[22] Solvation effects in water are found to be virtually identical. This value is rather smaller than might have been predicted from the shortness of the hydrogen bond, r(O··F) = 238 pm (observed), 234 pm (calculated).

As a result of a referee's comments about the ion [HPO₃H₂F₂]²⁻ and its relative stability with respect to other species, including HF₂⁻, we have computed the relative energies of all possible combinations of HPO₃H₂ + 2F⁻ in both the free and solvated states. These are shown in Fig. 5. The double OHF hydrogen bond of [HPO₃H₂F₂]²⁻ is stable with respect to HPO₃H₂ + 2F⁻ by 244 kJ mol⁻¹ (122 kJ mol⁻¹ per hydrogen bond) in the free state, but unstable by 24 kJ mol⁻¹ (12 kJ mol⁻¹ per bond) in the solvated state. These are the *defined* hydrogen bond energies.[22] It does not mean that the hydrogen bonds in this complex ion are stronger than that of [HPO₂H₂F]⁻, in the free state; it is merely a consequence of changing the base from which the hydrogen bond energy is defined.

Figure 5 also shows that in the free state HF₂⁻ is the favoured hydrogen bonded species, but in solution [HPO₃H₂F]⁻ should be the preferred species.

How do the hydrogen bond energies of phosphorous acid—fluoride bonds compare with other strong hydrogen bonds' energies? The calculated hydrogen bond energy of HF₂⁻ (free state) is 214 kJ mol⁻¹ and r(F··F) = 226 pm.[1] The calculated energy of each of the hydrogen bonds between a single fluoride ion and two formic acid molecules, [HCO₂H··F··HO₂CH]⁻, is 179 kJ mol⁻¹ and the measured distance r(O··F) is 244 pm.[20] Other O··H··F strong hydrogen bond energies are 149 kJ mol⁻¹ for [H₃BO₃F]⁻,[23] 149 kJ mol⁻¹ for [RCONH₂F]⁻,[24] 127 kJ mol⁻¹ for [RCO₂HF]⁻,[20] and 101 kJ mol⁻¹ for [H₂O.F]⁻.[25] Other evidence and especially IR data supports these as being strong hydrogen bonds. Thus the value of 48 kJ mol⁻¹ for [HPO₃H₂F]⁻ (gas phase) appears rather too low. The calculated values for [HPO₃H₂F₂]⁻, on the other hand, appear to be of comparable strength, and are probably more representative of the energy of the PO··H··F⁻ bond in these ions.

The calculated Mulliken populations lend no support to the hypothesis of pπ–dπ back-donation on to the phosphorus atom; most of the negative charge is localized within the hydrogen bond itself.

Calculations have also been carried out on the species [HPO₃HF]²⁻, which show it to be unstable with respect

to HPO_3H^- and F^- by $184\,kJ\,mol^{-1}$ ($95\,kJ\,mol^{-1}$ if $3d$ orbitals are included) but is stable with respect to HPO_3^{2-} and HF by $204\,kJ\,mol^{-1}$ ($202\,kJ\,mol^{-1}$ if $3d$ orbitals are included). Again by the agreed definition of strong hydrogen bonds this doubly charged ion is thus unstable by $95\,kJ\,mol^{-1}$. However the $[HPO_3HF]^{2-}$ complex may be postulated as a hydrogen bonded intermediate in the reaction sequence:

$$HPO_3^{2-} + HF \rightarrow [HPO_3HF]^{2-} \rightarrow HPO_3H^- + F^-.$$

In solution the $[HPO_3HF]^{2-}$ complex is calculated to be stable with respect to both $HPO_3H^- + F^-$ (by $201\,kJ\,mol^{-1}$) and $HPO_3^{2-} + HF$ (by $138\,kJ\,mol^{-1}$).

The addition of KF to a solution of HPO_3H_2 should result in an acid-base neutralization reaction which is conventionally expressed as (1)

$$HPO_3H_2 + KF \rightarrow HF + KHPO_3H \qquad (1)$$
but is better expressed as (2), bearing in mind the nature of the species involved in solution. That a strongly

$$H_3O^+ + F^- \rightarrow [H_2\overset{+}{O}H\overset{-}{F}] \qquad (2)$$
hydrogen bonded complex $[H_2\overset{+}{O}-H-\overset{-}{F}]$, is present as the chief species in hydrofluoric acid has recently been determined by Giguère.[26]

The resulting solution from the reaction of KF and HPO_3H_2 can however be seen as involving an equilibrium between the two possible acceptors and the donor HF (3).

$$[H_2O\cdot\cdot HF] + HPO_3H^- \rightleftharpoons H_2O + [HPO_3H\cdot\cdot HF]^-. \qquad (3)$$
Only in concentrated solutions will $[HPO_3H_2F]^-$ be favoured but it may be possible to detect the presence of this ion under normal conditions, thus showing its relative hydrogen bond strength.

Excess fluoride over that required to neutralize HPO_3H_2 will not lead to the neutralization of HPO_3H^-. Instead the excess F^- would also compete as an acceptor for HF (4) in an equilibrium that lies very much to the

$$H_2O\cdot\cdot HF + F^- \rightleftharpoons H_2O + HF_2^- \qquad (4)$$
bifluoride side.

Evidence for the ion $[HPO_3H_2F]^-$ existing in aqueous solution was sought with the aid of ^{17}O, ^{19}F, and ^{31}P NMR spectroscopy. No unambiguous confirmation of its presence under these conditions was found. The spectra did nevertheless reveal some information.

The ^{17}O chemical shift of the phosphite oxygens is shown in Fig. 1 which reveals a sharp discontinuity at $112.5\,ppm$ corresponding to the end-point of (1). The value of $\delta(^{17}O, HPO_3H^-)$ is the same as that reported by Christ *et al.*[27] For HPO_3H_2 and HPO_2H^- the half-height line-width was $205\,Hz$, much less than the $600\,Hz$ reported,[27] and the doublet structure easily observed as $J_{OP} = 91.6\,Hz$, which is of the same order as the $98\,Hz$ of $J_{OP}[HPO(OMe)_2]$ and similar compounds.[28]

In this system the change in $\delta(^{17}O, HPO_3H_2)$ can be explained as simply due to the neutralization of the strongest acid proton by the base F^-. There is no in-
Fig. 1. $\delta(^{17}O, HPO_3H_2)$ vs mole ratio of added KF; $[HPO_3H_2 = 1.0\,m]$.

dication of any very strong hydrogen bonding between the conjugate base HPO_3H^- and HF or F^- even when the latter is in an excess beyond that necessary for the formation of HF_2^-.

The ^{19}F NMR signal from these solutions varies during the addition of KF to HPO_3H_2 solution in the manner shown in Fig. 2. The changes in $\delta(^{19}F)$ can be explained in terms of (1) and (4). In solutions of composition up to half neutralization there is an upfield shift from $\delta(F^-) = 118\,ppm$ towards $\delta(HF\,aq) = -196\,ppm$ as expected. No indication exists as to whether the HF is hydrogen bonding to HPO_3H^- or H_2O.

At half neutralization the signal begins to move downfield and almost linearly; back extrapolation to the
Fig. 2. $\delta(^{19}F, KF\,aq)$ vs mole ratio of added HPO_3H_2; $[HPO_3H_2 = 1.0\,M]$.

vertical axis gives a $\delta(^{19}F)$ of -165 ppm, exactly the value quoted for aqueous HF_2^-.[29] Thus above a ratio of $0.5:1$ of $KF:HPO_3H_2$ the predominant fluoride environment would appear to be HF_2^-, which exchanges with F^- as the ratio of $F^-:HF_2^-$ increases, thus causing the further downfield shift.

In methanol solution $KF.HPO_3H_2$ has moderate solubility and $\delta(^{19}F) = -184.8$ ppm, which is about that of HF and in the region expected for a strong hydrogen bond as in (I). Extra KF can be dissolved in such solutions up to a maximum ratio of $1.75\ KF:1\ HPO_3H_2$ (at 0.1 M concentration), and the signal moves downfield to -174.8 ppm. This is not likely to be due to the formation of HF_2^-, which is insoluble in this solvent but rather to the hydrogen bonded complex $[HPO_3H_2F_2]^{2-}$ with both protons of the acid engaged in such bonds.

The effect on $\delta(^{31}P, HPO_3H_2)$ of adding KF to its solution is shown in Fig. 3. There is also a sharp discontinuity at equimolar concentrations. Excess fluoride has little effect on $\delta(^{31}P, HPO_3H^-)$ showing that no strong hydrogen bonding is occurring between them.

The addition of KF to HPO_3H_2 however results in a broadening of the ^{31}P signal which reaches a maximum of 20 Hz $(W_{1/2})$ at half neutralization, and then disappears at the equimolar concentrations of the end point. This broadening would seem to support the formation of $HPO_3H_2F^-$.

The effect of hydrogen bonding on J_{PH} of hypophosphorous acid has been noted.[30] The principal influences on J_{PH} was the immediate acid proton environment of the molecule: thus $J_{PH}(H_2PO_2H_2^+) > J_{PH}(H_2PO_2H) > J_{PH}(H_2PO_2^-)$. The effect on $J_{PH}(HPO_3H_2)$ of added F^- is to change it from 674 Hz to 668 Hz (0.25 $KF:HPO_3H_2$), to 659 Hz (0.5:1), to 651 Hz (0.75:1) to 643 Hz (1:1), to 630 Hz (2:1), to 621 Hz (3:1) to 612 Hz (4:1). The value for $K^+HPO_3H^-$ in solution is 563 Hz. These values suggest that the acid protons of phosphorous acid are not being effectively removed by F^- to give HPO_3H^-, even when the base F^- is in excess. A close association of the

conjugate base with the HF in the formation of $[HPO_3H.HF]^-$ would explain the J_{PH} values observed. Equilibrium (3) may not be entirely upset in favour of (4) under these conditions.

Conductance and pH changes as a solution of 0.1 M HPO_3H_2 is titrated with 0.7 M KF are shown in Fig. 4. The results are consistent with (2) followed by (4). In the original study of $KF.HPO_3H_2$, crystals were first obtained by dehydrating $KHPO_3H$ solution in aqueous HF and these were then extracted with methanol to obtain the desired product. We were interested to see if the original crystals from aqueous solution contained KHF_2, as might be expected. When a solution of KF in glacial acetic acid is evaporated to dryness the resulting crystals are a mixture of the various strongly hydrogen bonded salts KHF_2, $KH(CH_3CO_2)_2$ and $KF.CH_3CO_2H$.[17] KHF_2 is particularly easily characterized by a strong sharp peak at *ca* 1200 cm^{-1}.

The i.r. spectrum of our crystals consists of very broad bands as expected for a strongly hydrogen bonded complex. The region 3500–1500 cm^{-1} shows a continuum with three broad maxima at *ca* 2750, 2250 and 1700 cm^{-1}. Below this there are sharper bands at 1255s, 1195 (sh), 1155s, 1078s, 1050s, 1015s, 910m, 835mw, 540s, 480s, and 445w cm^{-1} (KBr disc). The shoulder at 1195 cm^{-1} could arise from KHF_2 but in any event this cannot be a major component of these crystals.

In conclusion it can be said that an aqueous solution of HPO_3H_2 and KF behaves as if it were HPO_3H^- and HF, and that there is some evidence for an association between them in terms of a hydrogen bond. Addition of excess KF produces HF_2^-. *Ab initio* calculations suggest that the hydrogen bond in $[HPO_3H_2F]^-$ is not as strong as other hydrogen bonds formed between the fluoride ion and molecules containing first row atoms, yet the structure of (I) shows short, and therefore strong, hydrogen
Fig. 3. $\delta(^{31}P, HPO_3H_2)$ vs mole ratio of added KF; $[HPO_3H_2 = 1.0\ M]$.
Fig. 4. pH and conductance (mmhos) plots for HPO_3H_2 (0.1 M) titrated with KF (0.7 M).
Fig. 5. Relative energy diagram for all combinations of $HPO_3H_2 + 2F^-$, not to scale. ($[6s4p1d/4s2p/2s1p]$ basis set.)

bonds. Crystals of composition $KF.HPO_3H_2$ grown from aqueous solutions are not the same as those from methanol i.e. (I), and they may even be a mixed phosphite bifluoride salt reflecting the species that are present in solution.

RESONANCE INDUCED PROPERTIES IN MONOTHIOCARBAMATES DERIVED FROM AROMATIC AMINES: COMPARISON OF THE COORDINATION CHEMISTRY OF INDOLE AND INDOLINE MONOTHIOCARBAMATES[1]

ROBERT D. BEREMAN,* DONALD M. BAIRD, JON BORDNER and JAY R. DORFMAN
Department of Chemistry, North Carolina State University, Raleigh, NC 27650, U.S.A.

Abstract—The syntheses of two new monothiocarbamate ligands and selected transition element complexes of each are reported. The complexes of indoline-N-carbothioate (*intc*) prepared are: $NiL_2 \cdot 1.5H_2O$, ZnL_2, $NiL_2 \cdot 2py$, $ZnL_2 \cdot 2py$. The complexes of indole-N-carbothioate (*iltc*) are: NiL'_2, ZnL'_2, CuI'. IR spectral results support a bidentate ligand behavior for both new monothiocarbamates except in $ZnL_2 \cdot 2py$. Comparison of the IR spectral features of *bis*(indolylcarbamoyl)-disulfide with that of coordinated indole-N-carbothioate allowed an assignment of the C–S and C–O vibrational frequencies. Evidence for differences in major resonance contributions to the electronic structures of each new ligand are presented. The crystal structure of the *bis*(indolylcarbamoyl)disulphide is also presented and a comparison is made to pyrrole-N-carbothioate, another aromatic amine monothiocarbamate. The disulphide crystallizes in the centrosymmetric monoclinic space group $P2_1/c$ with $a = 15.645(4)$Å, $b = 5.228(1)$Å, $c = 19.271(7)$Å, $\beta = 97.20(2)°$, $V = 1564(1)$Å^3, d(obsd)(calcd) = (1.50)(1.52) for a molecular weight = 356.1 and $Z = 4$. Diffraction data were collected with a Syntex P1 diffractometer with Cu$K\alpha$ radiation. Least squares refinement resulted in $R_f = 7.0\%$ for all 1213 non zero reflections have (I) $> 3\sigma$(I).

INTRODUCTION

In contrast to the large amount of work which has centered on the coordination chemistry of dithiocarbamate (dtc) complexes in recent years,[2] much less attention has been drawn to possibly more interesting monothiocarbamate ligands (mtc).[3] A comparison of potential resonance contributions to the ground state electronic structures of dithiocarbamates (Scheme I) with that of monothiocarbamates (Scheme II) suggests that a wider variety of chemistry might be expected to result from these latter systems. These *seem* to be supported from the limited structural results available for monothiocarbamate complexes.[4] It is also apparent that the sulphur atom in dialkyl-monothiocarbamates has considerable "mercaptide" character and polymeric complexes often result.[4c,5,6] To date, the primary

concern in monothiocarbamate chemistry has been to determine if differences between similar monothio- and dithiocarbamates exist. In an effort to alter the reactivity *within* the monothiocarbamate class, we have attempted to affect the bonding properties of the –COS moiety by altering the peripheral ligand structure. We have shown that the coordination chemistry of dithiocarbamate and dithiolate ligands can be dramatically altered by choosing R groups which favour one of the various possible resonance structures.[7,8] In particular, we have employed aromatic amines in dithiocarbamate complexes which virtually eliminate resonance form IB (Scheme I) and new coordination complexes and structures resulted.[7] In addition, we have recently shown that pyrrole-N-carbothioate(ptc) does yield coordination compounds of different stoichiometry ($Ni_2(ptc)_4 \cdot THF$)[9] or electronic structure ($Ni(ptc)_2py_2$)[4f] than dialkylmonothiocarbamates.

iltc

intc

iltc–iltc
To establish more firmly the chemistry observed to date, we have prepared the aromatic amine monothiocarbamate derived from indole and the nonaromatic analogue derived from indoline. These ligands, *iltc* and *intc*, respectively, and representative transition element complexes have been prepared. Particular attention has been given to the assignment of the IR vibrational features due to the ligands and the interpretation of differences observed. In order to facilitate this IR study, the disulphide (*iltc–iltc*) derived from the indole ligand was prepared. The crystal and molecular structure of this molecule is also reported and a comparison of the significant bond distances is made with those reported[4j] in Ni(ptc)$_2$py$_2$ in order to further establish the nature of the resonance contributions in these new monothiocarbamates.

EXPERIMENTAL

Syntheses

Potassium indole-N-carbothioate (Kiltc). Indole (0.05 mole) was dissolved in 100 ml of dry THF (distilled from Na/benzophenone) under Ar. Potassium metal (0.05 mole) was added to the stirred solution and H$_2$ evolution began immediately. This reaction was allowed to continue for 24 hr during which a fine white precipitate formed. The reaction mixture was cooled to 0° and COS was bubbled into the solution until the solid dissolved (5 min.). This was followed by passing Ar into the solution to remove excess COS. Dry, chilled pentane was then added until a slightly turbid solution was produced. Refrigeration of this mixture for several hours produced a white, extremely air sensitive powder. The product was collected by filtration and used without further purification (yield ~ 80%).

Potassium indoline-N-carbothiolate (Kintc). Kintc was prepared as with *Kiltc* above. However, once formed, *Kintc* is air and moisture stable and can be handled in the atmosphere (yield ~ 95%).

Ni(*intc*)$_2$·1.5 H$_2$O. Kintc (1.0 g) was dissolved in 50 ml of 95% ethanol to which was added a solution of 0.71 g of NiBr$_2$·6H$_2$O in 50 ml of 95% ethanol. A green precipitate formed immediately and the reaction mixture was stirred for 1 hr. The product was collected by filtration, washed with ethanol and ether, and dried under vacuum (yield ~ 70%). IR data indicated that H$_2$O was present in the product. Found: C, 48.87; H, 4.36; S, 14.49; N, 6.34; Calc. for C$_{36}$H$_{30}$N$_4$O$_7$S$_4$Ni$_2$: C, 48.88; H, 4.56; S, 14.50; N, 6.33%.

Zn(*intc*)$_2$. This white compound was prepared in an identical manner to Ni(*intc*)$_2$·1.5 H$_2$O using ZnBr$_2$ (yield ~ 85%). Found: C, 51.00; H, 3.90; S, 15.60; N, 6.60. Calc. for C$_{18}$H$_{12}$N$_2$O$_2$S$_2$Zn: H, 3.82; S, 15.20, N, 6.64%.

Ni(*intc*)$_2$·2py. This compound was prepared by the recrystallization of Ni(*intc*)$_2$·1.5 H$_2$O from pyridine. Found: C, 58.57; H, 4.63; S, 11.09. Calc. for C$_{28}$H$_{22}$N$_4$O$_2$S$_2$Ni: C, 58.65; H, 4.57; S, 11.19%.

Zn(*intc*)$_2$·2py. This compound was prepared by recrystallization of Zn(*intc*)$_2$ from pyridine. Spectroscopic analysis for pyridine confirmed the stoichiometry.

Cu(*iltc*). Two equivalents of *Kiltc* in anhydrous THF were added to a solution of one equivalent of CuBr$_2$ in anhydrous THF. The intense colour characteristic of Cu(II) disappeared rapidly and an orange precipitate formed (yield ~ 70%). Found: C, 45.30; H, 3.25. Calc. for C$_9$H$_6$NOSCu: C, 45.58; H, 3.40%.

Ni(*iltc*)$_2$. K(*iltc*)$_2$ (1.0 g) in 50 ml of anhydrous THF was added very slowly to 0.50 g of NiBr$_2$ in 50 ml of anhydrous THF. A yellow solution and a white precipitate formed. The solid KBr was removed by filtration, the volume of the solution was reduced and anhydrous hexane was added. Refrigeration of this solution resulted in the formation of an air sensitive yellow powder. The product was collected by filtration and dried under vacuum for several hours. An IR spectrum showed that no THF was present in the dry product (yield ~ 80%).

Zn(*iltc*)$_2$. This white product was prepared employing the same procedure as that for Ni(*iltc*)$_2$ (yield ~ 70%).

Bis(indolylcarbamoyl)disulphide (iltc–iltc). The solution obtained after the isolation of Cu(*iltc*) above, when cooled yielded the disulphide of indole-N-carbothioate. Found: C, 61.23; H, 3.50: S, 18.32. Calc. for C$_{18}$H$_{12}$N$_2$O$_2$S$_2$: C, 61.34; H, 3.43; S, 18.20%.

Analyses. Elemental analyses were carried out at Atlantic Microlabs, Atlanta, Georgia.

Spectroscopic methods. IR spectra were recorded on a Perkin–Elmer 512 spectrophotometer using mull prepared in an inert atmosphere. Electronic spectra were recorded either on a Cary 14 or Hitachi 110 spectrophotometer.

CRYSTAL DATA COLLECTION AND STRUCTURE DETERMINATION

A nearly cubic crystal (0.14 mm × 0.16 mm × 0.20 mm) of *bis*(indolylcarbamoyl)disulphide was obtained from a slow evaporation of a saturated THF solution.

The crystal survey, unit cell dimension determination and data collection were accomplished on a Syntex P1̄ diffractometer using copper radiation ($\lambda = 1.5418$ Å) at room temperature employing procedures common to these laboratories.[10] Details of the crystal survey and data collection parameters are summarized in Table 1.

The diffractometer output and all subsequent crystallographic calculations were processed using subprograms of the CRYM crystallographic computer system.[11] Data processing procedures were as before.[10]

The refined coordinates were plotted using the ORTEP computer program of Johnson[12] (Fig. 1). Thermal parameters are available as part of the supplementary materials. Tables 2 and 3 contain final significant bond distances and angles. All other data pertaining to the structure have been deposited.†

RESULTS AND DISCUSSION

Potassium indole-N-carbothioate is a white, extremely air and moisture sensitive solid. All manipulations involving this ligand were done under inert atmosphere conditions. We were primarily interested in neutral complexes of divalent metals and Ni(II) and Zn(II) complexes were studied in detail. However, Cr(III) and Fe(III) complexes were also prepared as well as [Mo(II)]$_2$ compounds and these will be reported later.

---

†*Supplementary material available.* A listing of observed and calculated structure factor amplitudes (8 pages), atom coordinates (2 pages), and nonhydrogen anisotropic temperature factors (1 page) have been deposited with the Editor from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Base.

Indoline, unlike indole is not an aromatic amine and we expected that *intc* would behave as a normal dialkyl monothiocarbamate. If *intc* does indeed behave as a normal monothiocarbamate, then any difference between the properties of *intc* and the aromatic analogue *iltc* could be attributed to a decrease in the importance of the resonance form which concentrates charge on the amine nitrogen. (Clearly, both of these ligand systems have very similar steric properties, and the ligand "bite" should be nearly the same for each.) *Intc* was synthesized using the same procedure used to produce *iltc*. However, *Kintc* is air and moisture stable. Once isolated it can be stored under ambient conditions for long periods. The transition metal complexes of *intc* could be formed in aqueous ethanolic solution in open vessels. The Ni(II) and Zn(II) complexes were synthesized as well as *bis*-pyridine adducts of the Ni(II) and Zn(II) compounds. The reaction between *intc* and $Mo_2(Ac)_4$ was studied but will be reported later.

We were interested in two aspects of these ligands. First, what were the resonance properties of *intc* and *iltc* relative to those of dialkyl monothiocarbamates? Second, if the aromatic amine ligand does have peculiar resonance properties, how would the reactivity patterns of the ligand be affected?

With respect to the first point, an IR analyses of a series of metal complexes of these ligands could provide the information on the resonance properties. A great deal of work has centred on the positions of the ν(C⚊O) and ν(C⚊N) as well as ν(C—S) frequencies in the IR spectra of dialkyl monothiocarbamate complexes. It has been generally felt that dialkyl monothiocarbamates favoured resonance form IIB with some contribution from form IIA (Scheme II). Thus, IR spectra of R_2mtc should have resonances corresponding to a partial carbon-to-nitrogen double bond as well as a partial carbon-to-oxygen bond. The carbon-to-sulphur bond vibration, on the other hand, should be found in a region corresponding to a single bond. Early reports by Krankovits *et al.*[13] and

McCormick *et al.*[14] assigned a broad, strong band between $1500\,cm^{-1}$ and $1600\,cm^{-1}$ to ν(C⚊O) and ν(C⚊N). The position of this band will be indicative of the electronic properties of the various monothiocarbamates and therefore a study of the position of this band in the aromatic monothiocarbamate complexes should prove useful.

ν(C⚊S) bands have been reported in most cases to occur in the $650-700\,cm^{-1}$ region. This corresponds to the single carbon to sulphur bond region. Fay, on the other hand, reported ν(C–S) in the $950-1000\,cm^{-1}$ region for dithiocarbamates.[15]

The ν(C⚊O) band in the potassium salt *iltc* appears at $1525\,cm^{-1}$. The same band for Me_2mtc is reported at $1519\,cm^{-1}$ while Et_2mtc is at $1520\,cm^{-1}$.[15] The higher frequency found in the new ligand reported here is taken as indicative of increased multiple band character in the carbon to oxygen bond. The equivalent band in the Ni(II) complex appears at $1560\,cm^{-1}$. The question of bonding mode in these complexes arises here since previously values of ν(C⚊O) above $1550\,cm^{-1}$ have been assumed to indicate monodentate coordination through sulfur only. However, since the frequency ν(C⚊S) and ν(C⚊N), ν(C⚊O) in the ligand itself is higher than previously found, it is likely that the ligand is bonded in a bidentate fashion.[16]

A very strong broad band at around $1250-1300\,cm^{-1}$ appeared in all the complexes *iltc*. We suggest that this band is ν(C–N) since it is well within the region normally associated with carbon-to-nitrogen single bond vibrations $(1250-1350\,cm^{-1})$.[17] We suggest this assignment with some confidence, based on three observations. First, the ν(C⚊O) bands in all the *iltc* complexes are fairly sharp as opposed to the often very broad bands exhibited in this region in the dialkyl compound. The broadness of the band in R_2mtc complexes is apparently due to the presence of both the ν(C⚊O) and ν(C⚊N) bands in a highly coupled vibrational state.[18,19] The sharpness of this band in the spectra of our complexes suggests that ν(C⚊O) and ν(C⚊N) vibrations are not highly coupled in *iltc* complexes. Therefore, we might expect to find ν(C⚊N) at some other frequency. Secondly, a band corresponding to ν(C–N) single bond vibration was detected as a strong band at $1250-1300\,cm^{-1}$ in the aromatic dithiocarbamates.[20] The results of an X-ray diffraction study on $Fe(pdtc)_3$ showed a C–N bond distance which approximated a single bond distance of $[1.364(\text{Å})]$.[21]

Finally, we felt that if we could move the ν(C⚊O) band out of the $1500-1600\,cm^{-1}$ region which the strong band at $1250\,cm^{-1}$ remained we could conclude that the ν(C–N) band was not coincident with (C–O). Toward this end bis(indolylcarbamoyl)disulphide was synthesized. Since ν(C⚊O) had been assigned at $1680\,cm^{-1}$ in previous carbamoyldisulphides we felt that *iltc–iltc* would behave similarly.[22,23] The IR spectrum of this molecule does exhibit a band at $1680\,cm^{-1}$, which no bands appear between $1500\,cm^{-1}$ and $1600\,cm^{-1}$. The strong band at $1250\,cm^{-1}$ remains, however. Thus, based on these three pieces of evidence, it seems clear that we could assign this band to the carbon to nitrogen single bond vibration.

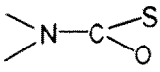
The IR band corresponding to the ν(C⚊S) vibration proved difficult to assign. ν(C⚊S) band positions in dithiocarbamates have been reported to occur in the $960-1000\,cm^{-1}$ region. These bonds have been shown crystallographically to possess considerable double bond

character.[24,25] If the resonance properties of the aromatic monothiocarbamate were predominated by a form which imparted some multiple bond character to the C–S bond, we would expect to find a band in the 950–1000 cm^{-1} region. Indeed this was the case. However, most previous reports concerning the IR-spectra of monothiocarbamates assigned a medium intensity band in the 650–700 cm^{-1} region to ν(C–S). A band of this sort also appeared in the spectra of our complexes. It was not until the results of a three dimensional X-ray diffraction study on Ni(ptc)$_2$·2py were obtained that we could make the assignment.[4j] This compound has by far the shortest C–S bond distance reported for a monothiocarbamate. Therefore we assign the band in the 950–1000 cm^{-1} region to ν(C⟶S).

It seems clear then that the aromatic nature of the indole ring does predominate the resonance properties of the monothiocarbamates derived from this amine. Since forms IIA and IIA′, but not IIB (Scheme II) completely describe the electronic structure of these ligands, we might expect the structural properties of *iltc* to mimic those of thiobenzoate rather than other monothiocarbamates.

An IR analysis was also carried out on *Kintc* and the complexes of this ligand. These spectra had two important features. First, the ν(C⟶O), ν(C⟶N) band in the 1500–1600 cm^{-1} region is very strong and very broad. This band in the spectra of *intc* complexes appears to be identical with the analogous band in the spectra of the dialkyl monothiocarbamate complexes. Second, no band assignable to ν(C⟶S) could be found in the 950–1000 cm^{-1} region. However, as is true for dialkyl species, a weak to medium band assignable to ν(C–S) is observed in the 650–700 cm^{-1} region. The broadness of the 1500–1600 cm^{-1} band is apparently due to the presence of both the ν(C⟶O) and ν(C⟶N) bands, as has been proposed by previous workers for dialkyl monothiocarbamate complexes.[13,14] As suggested above, the difference in the ν(C⟶N) resonance frequency is due to a shift in resonance properties brought on by the aromatic nature of indole as compared to indoline. IR spectra of the *intc* complexes indicate a predominance of IIB in Scheme II. The low ν(C–S) frequency along with the rather high ν(C⟶N) frequency are indicative of a C–S bond of essentially single bond character and a C–N bond with considerable multiple bond character. Comparison of the ν(C⟶O) frequency of *Kintc* (1520 cm^{-1}) with that of *Kiltc* (1535 cm^{-1}) show much less multiple bond character in the C–O bond of the non-aromatic *intc* system.

Since resonance form IIB (Scheme II) is much more important in the description of the properties of *intc*, we

would expect the sulphur atom to have considerable "mercaptide" character. This mercaptide character has been implicated as the predominant feature in the structural properties of the dialkyl monothiocarbamates.[4b] The complexes formed in our studies with *intc* are, in every case, identical to the analogous compounds formed with dialkyl monothiocarbamates as ligands (R = Me, Et, Pr, pip, pyr).[4b,18] Ni(*intc*)$_2$ is a green, insoluble solid. This insolubility precluded any molecular weight measurements. However, this same property indicates some degree of polymerization. The electronic spectrum of this compound indicates octahedral coordination for the Ni(II) atom. This fact also indicates some type of polymerization, undoubtedly involving sulphur atoms bridging adjacent Ni atoms, since elemental analysis shows no solvent molecules which might complete the octahedral coordination. In each of these properties Ni(*intc*)$_2$ mimics Ni(R$_2$mtc)$_2$ (R = Me, Et, etc.).[14] On the other hand, Ni(*iltc*)$_2$ is a red, soluble compound which appears to have a structure identical to Ni$_2$(ptc)$_4$·3THF.[9]


Zn(*intc*)$_2$ is also polymeric in nature as are the dialkyl complexes of Zn.[18] ν(C⟶O) for Zn(*intc*)$_2$ is located at 1530 cm^{-1} while the same band in Zn(pipmtc)$_2$ appears at 1525 cm^{-1}. It is known that reaction of Zn(pipmtc)$_2$ with amine bases such as pyridine or piperidine result in tetrahedral *bis*-amine adducts in which the monothiocarbamate is not coordinated. The X-ray structure of Zn(pipmtc)$_2$·2pip[4f] has been reported. The ν(C⟶O) band in this compound appears at a much higher frequency since the oxygen of the ligand is not bound to Zn. Zn(intc)$_2$ also reacts with pyridine to form Zn(intc)$_2$·2py. ν(C⟶O) is shifted to a frequency of 1590 cm^{-1} and therefore likely has a structure identical to that of the piperidine derivative.

Molecular structure of iltc–iltc

The crystal structure of *bis*(indolylcarbamoyl)disulphide was obtained to investigate the structural characteristics associated with resonance contributions of coordinated aromatic monothiocarbamates to non-delocalized systems. Table 4 summarizes the important bond lengths for this disulphide and also lists those same values found in Ni(ptc)$_2$·2py for comparison.[4j] These data are remarkable in that clearly, little C–N double bond character exists in the coordinated *ptc*. The elongated C–O bond and shortened C–S bond in the coordinated *ptc* are as expected from the IR analyses.

Table 4.

	Ni(ptc)$_2$·2py		iltc-iltc	
N–C	1.409 (12)	1.392 (14)	1.397 (10)	1.391 (11)
C–O	1.254 (12)	1.231 (11)	1.183 (10)	1.204 (10)
C–S	1.675 (10)	1.713 (10)	1.826 (8)	1.801 (9)

Abstract—The use of an indirect potentiometric method with the glass electrode in a $N_3^-/HN_3/UO_2^{2+}$ solution leads to ligand number $\bar{n}$, at several azide concentrations, at 2.0 M ionic strength (NaClO₄), aqueous medium and $25.0 \pm 0.1°C$. The analysis of data under conditions where hydrolysis is avoided leads to the six overall stepwise constants: $\beta_1 = 1.39 \times 10^2 \, M^{-1}$; $\beta_2 = 8.26 \times 10^3 \, M^{-2}$; $\beta_3 = 4.9 \times 10^5 \, M^{-3}$; $\beta_4 = 7.1 \times 10^5 \, M^{-4}$; $\beta_5 = 2.3 \times 10^6 \, M^{-5}$; $\beta_6 = 1.2 \times 10^7 \, M^{-6}$.

INTRODUCTION

The reaction of uranyl cations with azide ion gives rise to strongly yellow coloured complexes as has been deduced by Feinstein[1] from spectrophotometric data, and who suggested analytical applications. Equilibrium studies have followed concerning the formation of the monoazide species with the resulting evidence of the existence of three species.[2–5] No mention of azide complexes was found in a review.[6]

Although those studies were not complete, the analytical potentialities alone of the reaction suggest a more detailed study of the complex formation equilibria. These are presented in this paper from measurements in aqueous solutions of ionic strength 2.0 M held with NaClO₄ and at 25°C. This has been conveniently performed by an indirect potentiometric method, by analogy to the one succesfully applied to a similar cobalt II/azide system.[7]

EXPERIMENTAL

Reagents and solutions

All reagents were chemically pure or of analytical grade (Merck, Fisher, K and Lab., Eastman, Carlo Erba). Sodium perchlorate and sodium azide were recrystallized twice from ethanol. Standardization of sodium perchlorate was performed gravimetrically by drying an aliquot of 5 M stock solution (for ionic strength adjustments) to constant weight at 110°C. Recrystallized sodium azide was washed with ethanol, dried in a desiccator over calcium chloride for several hours, followed by one hour in an oven at 110°C. This treatment produces a non-hygroscopic salt which can be used as a primary standard.[7] Uranyl perchlorate was prepared from uranyl acetate by treatment with a controlled excess of diluted perchloric acid and concentrated in a water bath. The uranyl content of the stock solution (1 M, with 0.1 M free perchloric acid), was gravimetrically determined as U_3O_8.[8] The excess of free strong acid (0.1 M) was calculated by pH measurements of 0.1 M uranyl solution at ionic strength 2.0 M held with NaClO₄ (see below).

Apparatus and procedures

A digital potentiometer, Orion 801A, was used in all pH measurements with a glass electrode combined with a calomel

reference electrode filled with saturated sodium chloride solution. All measurements were carried out at $25.0 \pm 0.1°C$. The conditional pH data measured at 2.0 M ionic strength (referring to hydrogen ion concentration instead of activity) require the use of a 2.00 standard pH solution, which is a 0.0100 M perchloric acid solution in 1.99 M NaClO₄. A 5 ml, Methrom piston burette Model EA. 734-5 was used for the reagents.

To 20.00 ml of a working azide solution of ionic strength 2.0 M a volume (0.5–1.5 ml) of 2.000 M perchloric acid was added, to obtain an azide/hydrazoic acid buffer of conditional pH_1. Then one small volume of standard uranyl 1 M solution was added (up to 1.5 ml) and a pH_2 was measured in a few seconds, due to "normal" complex equilibria, readily attained. After that a slow hydrolytic process takes places and a lower pH_3, is measured after its stabilization within ten minutes. The treatments of data with mass balances and all corrections due to dilution by reagent additions, was performed with a program for the Hewlet Packard HP-97 calculator, as described.[7] The pH_1 plus pH_2 data lead to conventional $\bar{n}$ data vs free ligand concentration. The pH_3 data lead to false conventional $\bar{n}$ data in average ligand numbers referred to hydrolyzed complexes if the adequate correction in the program is not introduced (see Results and Discussion). Program for HP-97 (Hewlet Packard Calculator) were used in the integration of $\bar{n}$ vs log (N_3^-) data and in other steps of the whole calculation process.'

RESULTS AND DISCUSSION

(1) *General pattern of the uranyl azide reaction*

The procedure adopted to obtain the equilibrium constants, is a competitive method based on measurement of the change of the conditional pH (referring to hydrogen ion concentration instead of its activity) of an azide/hydrazoic acid buffer, by the presence of uranyl cation. The mass balance applied to the system based on its pH change leads to final values of the ligand and average ligand number ($\bar{n}$) as has been fully discussed.[7]

It should be pointed out that the merit of this approach is to use a conditional pK of the weak acid (HN_3) of each particular working solution, instead of an average value, in order to compensate for some factors which could be a source of error, such as drifts in junction potential or reference electrode potential.

Figure 1 presents a series of selected $\bar{n}$ vs (N_3^-) data

Fig. 1. Experimental data vs ligand concentration for uranyl/azide system, at 25.0°C and ionic strength 2.0 M.

Fig. 2. Tentative $\bar{n}$ data calculation on basis of monohydrolysis of uranyl cation, UO_2OH^+, vs free ligand concention.

referring to uranyl concentrations from 10^{-3} M to 10^{-1} M. The pH changed from 3.3 to 5.1 from the lower to the maximum azide concentration and an average pK of 4.46 ± 0.06 was calculated for hydrazoic acid from the set of the working solutions. No evidence of polynuclear species was found as $\bar{n}$ does not seem too dependent on the uranyl concentration. However, special care was taken in order to avoid hydrolysis of uranyl cation or its complexes, which has been found possible at higher pH and lower azide concentration. The data of Fig. 1 are confidently free from hydrolysis phenomenon (see also Experimental).

The $\bar{n}$ data arrived at for higher ligand concentrations are surprisingly high, evidencing a system with six sucessive complexes. This is not usually found in such a system, possibly because of difficulties inherent in the use of the indirect method, instead of the direct potentiometric one, which is widely accepted as being the most reliable. The uranyl cation is bulky enough to coordinate six monocoordinative ligands especially if the affinity is high enough to exchange some of the several coordinated water molecules and if the ligand is not abnormally large. In fact, recent measurements[9] confirm the existence of more than four thiocyanate ligands in uranyl complexes.

Another series of measurements was taken in conditions which favours hydrolysis, which is a slow process. The first initial equilibrium position is reached a few seconds after uranyl addition. Then a second equilibrium position is achieved after some minutes of pH drift toward lower values. Under such conditions a huge positive error in $\bar{n}$ data results because a false mass balance is considered in the normal calculation program[7] which does not distinguish between the causes of the pH lowering, whether due to complexation of the ligand, or due to hydrogen ions released by hydrolysis. The hydrolysis of uranyl cation was considered in the classical work of Ahrland[10] and that of Sutton.[11] A number of hydrolysis products are formed between the monohydrolysis, species $U_2O(OH)^+$ (actually $U_2O_5^{2+}$), and the fully hydrolysed $UO_2(OH)_2$.

Figure 2 shows an attempt to calculate $\bar{n}$ values from the hydrolyzed solutions based on a quantative formation of complexes with $UO_2(OH)^+$. This was done by including in the mass balances a release of (H^+) from hydrolysis, equivalent to the uranyl concentration. The results in Fig. 2 are highly dispersive and do not fit entirely the model of monohydrolysis. This could be acceptable for ligand concentrations lower than 0.5 M but not for higher ones, because a decreasing $\bar{n}$ is obtained which reveals a high hydrogen ion correction due to hydrolysis. It was inferred that at azide ion concentration higher than 0.50 M and hydrazoic acid
0.1 M the hydrolysis is progressively smaller and can be neglected at 1.0 M azide.

(2) *Calculation of the equilibrium constants*

This system is complicated by the presence of several stepwise complexes. Direct treatment of the $\bar{n}$ function data to obtain formation constants is well known to be inadequate in such cases. The Froneaus function F_0 is a commendable means if it can be obtained by integration from $\bar{n}$ vs $\log(L)$ data as fully discussed formerly.[12,13]

The integration should start from a lower value of $\bar{n}$ than 0.5 and its corresponding ligand concentration. In order to provide short increments in (N_3^-) and $\bar{n}$, conveniently distributed, we have normalized the available data by an appropriate procedure in short ranges by enlarged plot adjustment. In some ranges the $\bar{n}$ and (N_3^-) data were fitted to power, logaritmic or linear curves with the help of a calculator. The normalized data are presented in Table 1 as well as F_0 which is a well known polynomial.[12,13]

$$F_0 = 1 + \sum_1^n \beta_n(L)^n \qquad (1)$$

being β_n the overall formation constant of the species $VO_2(L)_n$ of ligand (L). All those normalized data are in Table 1.

The equilibrium constants were determined through a combination of strategies by using the classical graphic method[13] with some refinements, as will be described below.

The F_1 subsidiary function[13]

$$F_1 = \frac{F_0 - 1}{(L)} = \beta_1 + \beta_2(L) + \cdots \beta_j(L)^{(j-1)} \qquad (2)$$

was plotted vs (N_3^-) and presented a virtually linear relationship at low ligand concentration. A linear regression with the first five point of F_0 vs $((N_3^-)$, by a least squares fit, provided β_1 on intersection and β_2 as a slope. These preliminary data are 139 M^{-1} for β_1 and 9300 M^{-2} for β_2. The F_2 and F_3 subsidiary functions were then calculated[13] and the plot F_3 vs (N_3^-) was found to be a non-linear curve easily extrapolable to obtain β_3, as usual.

The F_4 function was calculated and provided data reliable only for azide concentrations higher than 0.2 M. This has been found to provide a steep non-linear curve when plotted vs (N_3^-), which is

$$F_4 = \beta_4 + \beta_5(N_3^-) + \beta_6(N_3^-)^2. \qquad (2)$$

The usual extrapolation procedure does not provide a reliable result for this β_4, not only because the curve is steep, but because the extrapolation is performed from high ligand concentration. This is a problem very common in systems with more than four ligands. In order to obtain more reliable data a matrix solution for the three unknown β_4, β_5 and β_6 constants was done based on a weighting factor previously proposed[14] for the F_0 data

$$W'_i = \frac{F_0 \max}{F_i} \qquad (3)$$

On this basis the F_0 data from 0.2 M to 1.0 M [azide] were used to build a system of three equations with six unknowns. As β_2, β_2 and β_3 were known, then a system of three unknowns was obtained, as shown in Table 2.

A refining of the constants started with the use of another auxiliary function, F'_i, where the formation constant terms with higher than two ligands were subtracted out from the F_0 data

$$F'_i =$$
$$\frac{F_0 - (1 + 4.88 \times 10^5 (N_3)^3 + 7.59 \times 10^5 (N_3)^4 + 2.70 \times 10^6 (N_3)^5)}{(N_3^-)}$$
$$\qquad (4a)$$

$$F'_i = \beta_i + \beta_2(L). \qquad (4b)$$

These F'_i data are now much closer to a linear equation than F_1 vs (N_3^-) data. Thus more reliable β_1 and β_2 data were now obtained from linear regression of F'_i vs (N_3^-). Figure 3 shows this typical plot.

The β_3 values were reestructured from these F_3 data in Table 1.

With these new β_1, β_2 and β_3 data a 6×6 system of linear equations was converted in a 3×3 one as shown in Table 2.

The solution of this matrix lead to new values of β_4, β_5, β_6, which were considered final.

An attempt to solve the entire system by a 6×6 matrix did not provide a real value for β_5: It shows that the solution of this system in parts is sometimes more reliable because there is a lack of F_0 data at higher ligand concentration, where the $\bar{n}$ data becomes less and less accurate. The final values are:

$$\beta_1 = \frac{[UO_2(N_3)]^+}{[UO_2^{2+}](N_3^-)} = 1.39 \times 10^{-2} \qquad K_1 = 139$$

Table 2. Conversion of a 6×6 matrix to 3×3 by introducing $\beta_1 = 1.39 \times 10^2\,M^{-1}$, $\beta_1 = 8.26 \times 10^3\,M^{-2}$; $\beta_3 = 5.1 \times 10^5\,M^{-3}$; of the 3×3 matrix: $\beta_4 = 6.1 \times 10^5\,M^{-4}$; $\beta_5 = 3.1 \times 10^6\,M^{-5}$; $\beta_6 = 1.2 \times 10^7\,M^{-6}$

$4.9615 \times 10^7 = 820.89$	$\beta_1 + 189.67$	$\beta_2 + 45.239$	$\beta_3 + 11.172$	$\beta_4 + 2.8605$	$\beta_5 + 0.75912 \quad \beta_6$
$4.9618 \times 10^7 = 78.892$	$\beta_1 + 35.499$	$\beta_2 + 16.443$	$\beta_3 + 7.8749$	$\beta_4 + 3.9136$	$\beta_5 + 2.0218 \quad \beta_6$
$6.6158 \times 10^7 = 6.7783$	$\beta_1 + 5.3251$	$\beta_2 + 5.3251$	$\beta_3 + 4.7751$	$\beta_4 + 4.3143$	$\beta_5 + 3.9267 \quad \beta_6$
$2.5660 \times 10^7 = 11.172$	$\beta_4 + 2.8605$	$\beta_5 + 0.75912$	β_6		
$4.1253 \times 10^7 = 7.8749$	$\beta_4 + 3.9136$	$\beta_5 + 2.0218$	β_6		
$6.3503 \times 10^7 = 4.7741$	$\beta_4 + 4.3143$	$\beta_5 + 3.9267$	β_6		
Fig. 3. Plot of F_1^1 data vs (N_3^-) in order to obtain a more reliable β_1 and β_2 (eqn 4).

Fig. 5. The average free energy change per ligand in the uranyl/azide system.

The uncertainty of the constants is not easily estimated. However the calculated F_0 data by eqn (1) differ by $\pm 0.14\%$ from the integrated value. This gives good support for the calculation procedure. The calculated $\bar{n}$ is consistent with the experimental $\bar{n}$ within $\pm 2.8\%$ which is a final test for both experimental data aquisition and calculation procedure. The β_1 and β_2 constants can be expresed in three significant figures and the others β_n by two.

Figure 4 shows the tendency of ligand attachment to uranyl cations. A marked decrease is observed at the entrance of the fourth ligand which could well be related to a change in configuration of the coordination centre.

Figure 5 shows that the average free energy changes non-linearly with the ligand and also presents a break at the third ligand. The literature does not refer to the attachment of six ligands to one uranyl cation. However in a review[16] the existence of several uranyl complexes with three bicoordinative ligands such as carbonate and oxalate was mentioned. The distribution of the ligands was in a hexagonal bipyramid (symmetry D_{6h}) with the two oxo ions placed in the vertical axis.[16,17] The same structure as for these octacoordinated complexes can be similarly attributed to the present system, where up to six small linear ligands can be attached to uranyl cations.

Fig. 4. The tendency toward stepwise attachment of azide ligands to uranyl cation.

$$\beta_2 = \frac{[UO_2(N_3)_2]}{(UO_2^{2+})(N_3^-)^2} = 8.26 \times 10^3\,M^{-2}\,K_2 = \frac{\beta_2}{\beta_1} = 59.4$$

$$\beta_3 = \frac{[UO_2(N_3)_3]^-}{[UO_2^{2+}](N_3^-)^3} = 5.1 \times 10^5\,M^{-3} \quad K_3 = \frac{\beta_3}{\beta_2} = 61$$

$$\beta_4 = \frac{[UO_2(N_3)_4]^{2-}}{[UO_2^{2+}](N_2^-)^4} = 6.1 \times 10^5\,M^{-4} \quad K_4 = \frac{\beta_4}{\beta_3} = 1.2$$

$$\beta_5 = \frac{[UO_2(N_3)_5]^{3-}}{[UO_2^{2+}](N_3^-)^5} = 3.1 \times 10^6\,M^{-5} \quad K_5 = \frac{\beta_5}{\beta_4} = 5.0$$

$$\beta_6 = \frac{[UO_2(N_3)_6]^{4-}}{(UO_2^{2+})(N_3^-)^6} = 1.2 \times 10^7\,M^{-6} \quad K_6 = \frac{\beta_6}{\beta_5} = 3.8.$$

THE STUDY OF ENANTIOSELECTIVITY IN COPPER COMPLEXES WITH SOME 1,3-DICARBONYL LIGANDS BY CIRCULAR DICHROISM SPECTROSCOPY

A. A. KURGANOV,* L. YA. ZHUCHKOVA and V. A. DAVANKOV
Nesmeyanov Institute of Organo-Element Compounds, U.S.S.R. Academy of Sciences, 117813 Moscow, U.S.S.R.

Abstract—The circular dichroism spectra of copper(II) complexes with hydroxymethylene camphor, hydroxymethylene menthone, and trifluoroacetyl camphor as well as of mixed-ligand complexes with acetylacetone have been studied in different solvents at different temperatures. The changes observed in the spectra are attributed to a strong coordination of the solvent molecules in axial positions of square-planar complexes. It has been shown that the contributions of two ligands to the net spectrum of circular dichroism are additive and that the absorption spectra of the complexes do not depend on the optical configuration of the ligands. The conclusion has been drawn that no noticeable inter-ligand interactions exist in the complexes and no enantioselective effects are exhibited.

INTRODUCTION

Enantioselective effects in labile coordination compounds attract attention of many researchers due to an important role which they play in a number of biological systems[1] and in connection with the development of the method of ligand-exchange chromatographic resolution of racemic compounds.[2,3] The most part of investigations in this field involves amino acid ligands[1,2] whereas information on ligands of other types is much more limited. In previous papers we have considered the reasons for enantioselectivity in copper(II) complexes with N - alkyl - α - amino acids[4] and 1,2-diamines.[5] In this report we present the results of studying enantioselectivity in copper(II) complexes with 3-hydroxymethylene camphor (HMC), 3-trifluoroacetyl camphor (TFC), and 2-hydroxymethyl menthone (HMM).

1R – HMC   1R – TFC   1R – HMM
Complexes of transition metals with 1,3-dicarbonyl ligands were the object of numerous studies and are covered in several reviews.[6,7] These papers, however, give only minimum attention to chiroptical properties of Cu(II) complexes with HMC, TFC and HMM which, in our opinion, deserve thorough investigation.

RESULTS AND DISCUSSION

1. CD spectra of complexes

As is seen from Fig. 1, the spectra of circular dichroism (CD) of copper complexes with HMC, TFC, and HMM are characterized by 1–2 bands in the region of d–d transitions of Cu(II) atom and by a number of bands in a shorter wavelength region. Such a shape of the CD

spectrum, as is now well known, is related to the formation of a pseudoaromatic chelate ring in the complexes of 1,3-diketones and is caused by considerable delocalization of π-electron system of ligands.

We considered it interesting to study the effect of solvent and temperature on the shape of the CD spectrum. In aprotic non-polar solvents (hexane, toluene) the bands at ~560 and ~700 nm have a maximum intensity. The intensity decreases in solvents capable of coordination in axial positions of square-planar complexes (methanol, acetone, dioxane, acetonitrile). In the UV region the solvent effects weakly the shape of the CD spectra of Cu(HMC)$_2$ and Cu(TFC)$_2$ whereas in the case of Cu(HMM)$_2$ this effect is strongly pronounced and the transition from acetonitrile to hexane results in an almost complete disappearance of the band at ~340 nm and in a sign change of the band at ~400 nm. It should be, however, noted that correlation with the type of the solvent for Cu(HMM)$_2$ is less pronounced than for Cu(HMC)$_2$ and Cu(TFC)$_2$. Temperature practically does not affect the shape of the CD spectra: the most sensitive to a temperature change proves to be the band at ~400 nm whose intensity (in the case of Cu(HMC)$_2$) decreases by about 20% with a temperature rise from 25 to 55° (in methanol). The intensity of other bands changes by only 5–10%.

The fact that there is no correlation between the dependence of the CD spectra on the type of the solvent and temperature in a readily coordinating solvent may be explained if the equilibrium between a square-planar complex and its adduct with the solvent is almost completely shifted towards adduct and does not depend on temperature. This conclusion is supported by data in the literature,[8,9] showing that the formation constant of such adducts with a composition 1:1† is ~10^2 for Cu(HMC)$_2$ and Cu(HMM)$_2$ and ~10^3 l/mol for Cu(TFC)$_2$. Since the solvent concentration is high, these values correspond to almost quantitative formation of the adduct in solution.

Thus, the changes observed in CD spectra of Cu(HMC)$_2$ and Cu(TFC)$_2$, when passing from non-coordinating solvents to coordinating ones, are probably due to the formation of adducts with the solvents and refer, mainly, to the region of d–d transitions. As regards

†The data obtained mainly, for different nitrogen-containing axial ligands.
Fig. 1(a).
Fig. 1(b).
Fig. 1(c).

Fig. 1. CD spectra of the complexes Cu[(1S)-HMC]₂ (A), Cu[(1S)-TFC]₂ (B), Cu[(1R)-HMM]₂ (C) in different solvents: 1, hexane; 2, methanol; 3, dioxane; 4, acetone; 5, toluene; 6, acetonitrile.

Cu(HMM)₂ whose ligands are conformationally more labile than the ligands of camphor derivatives, the formation of adducts, is most likely accompanied by conformational changes and the effect of the solvent manifests itself in the whole region of wave lengths from 200 to 700 nm.

2. Enantioselectivity in complexes Cu(HMC)₂, Cu(TFC)₂ and Cu(HMM)₂

Enantioselectivity in complexes of the ML₂ type arises when there is a mutual effect between two ligands entering into the complex. This mutual effect appears in different forms. Thus, for instance, in the case of complexes of N - alkyl - α - amino acids[10] it manifests itself in the different ability of the complexes containing two ligands of identical or opposite configuration, to the addition of a solvent molecule in the axial position of Cu²⁺. In the CD spectra the mutual effect of the ligands appears as a deviation from additivity of the contributions of both ligands into the net CD spectrum.

To detect the deviations from the additivity of contributions, we have studied CD spectra of mixed complexes in which HMC, HMM, or TFC was one of the ligands and the acetylacetone (AA) molecule was the second ligand. Acetylacetone is one of the smallest ligands of the 1,3-dicarbonyl type and one may expect that no noticeable steric interactions with the second ligand will take place. Only in the case of Cu(HMC)₂ small deviations in the region ~ 620 nm were detected
Fig. 2. CD spectra of mixed complexes Cu{[(1S)-HMC](AA)}, 1,3-initial complexes, 2-mixed complex. Chloroform as a solvent.

(Fig. 2). The formation constant of mixed complex is also close to 4 which means that distribution of the ligands in the system Cu(HMC)₂-Cu(AA)₂-Cu(HMC)(AA) is almost statistical in nature.

The absorption spectra of Cu[(1R)-(HMC)]₂, Cu[(1S)-(HMC)]₂ and Cu[(1R,1S)-(HMC)]₂ as well as of Cu[(1R)-TFC]₂, Cu[(1S)-TFC]₂ and Cu[(1R,1S)-(TFC)]₂ are completely identical; the differences between them are within the limits of accuracy of the measurements.

All the results obtained indicate that in complexes
Fig. 3. CD spectra of mixed complexes HMC and TFC in methanol (A) and hexane (B). (1) Cu[(1R)–HMC]₂, (2) Cu[(1S)–HMC]₂, (3) Cu[(1S)–TFC]₂, (4) Cu{[(1R)–HMC][(1S)–TFC]}, (5) Cu{[(1S)–HMC][(1S)–TFC]}.

Cu(HMC)₂, Cu(TFC)₂ and Cu(HMM)₂ there are no noticeable inter-ligand interactions which could have caused great enantioselective effects. Axial positions of these complexes are easily accessible for the solvent molecules and the strength of the adducts formed does not depend on the optical configuration of the ligands comprising the complex. This situation is similar to that observed for the complexes of unsubstituted α-amino α acids and contrasts with the properties of the complexes of N - alkyl - α - amino acids.[4]

No enantioselectivity was observed in studying the majority of the systems containing complexes Cu(HMC)₂–Cu(TFC)₂ (Fig. 3) or Cu(HMC)₂–Cu(HMM)₂ (Fig. 4). In these cases a complete additivity of contributions of two ligands was observed, as a rule, which enter into the complex composition and the CD spectrum of the mixed complex is almost an average of the CD

spectra of the initial compounds. The noticeable deviations are observed only in the system Cu(1S)–(HMC)₂–Cu(1S)–(TFC)₂ in hexane (Fig. 4b). The constant of formation of the mixed complex (log k = 1.1) points that the mixed structure is more preferred than the initial ones. At the same time the CD spectrum of the corresponding diastereoisomeric structure Cu(1R)–HMC(1S)–(TFC) is intermediate between the CD spectra of the initial complexes and therefore, we cannot find the constnat of its formation. Thus, no quantitative information can be obtained about the possible difference in stability of these mixed-ligand diastereoisomeric structures.

EXPERIMENTAL

(1) Preparation of (1R); (1S) and (1R,1S)-hydroxy-methylene camphor, (1S)-trifluoroacetyl camphor and

Table 1. Elemental analyses of synthesized complexes found (calculated)

Complex	C	H	Cu	F
1. Cu[(1R)–HMC]$_2$	62.5 (62.6)	7.0 (7.1)	15.5 (15.1)	—
2. Cu[(1S)–HMC]$_2$	62.4 (62.6)	6.9 (7.1)	15.3 (15.1)	—
3. Cu[(1R,1S)–HMC]$_2$	62.1 (62.6)	6.9 (7.1)	14.5 (15.1)	—
4. Cu[(1R)–TFC]$_2$	51.5 (51.7)	4.9 (5.0)	11.2 (11.3)	20.2 (20.4)
5. Cu[(1S)–TFC]$_2$	51.2 (51.7)	4.8 (5.0)	11.5 (11.3)	20.0 (20.4)
6. Cu[(1R,1S)–TFC]$_2$	51.4 (51.7)	5.2 (5.0)	11.7 (11.3)	20.7 (20.4)
7. Cu[(1R)–HMM]$_2$	62.0 (62.0)	8.2 (7.9)	15.2 (14.9)	—
8. Cu[(AA)]$_2$	46.0 (45.5)	5.5 (5.3)	24.4 (24.3)	—

(1R)-hydroxymethylene menthone was performed as described in Refs. 10–12. The products obtained were purified by either steam distillation (hydroxymethylene camphor) or vacuum distillation.

(2) Copper complexes with the synthesized ligands were prepared as described in Ref. 13 and purified by recrystallization from dioxane (for HMC) or by sublimation *in vacuo* (for HMM and TFC). The data of the elemental analyses are given in Table 1.

Acetylacetonate complex of copper was synthesized as described in Ref. 14 and purified by recrystallization from a mixture of methanol with chloroform. The data of the elemental analyses are given in Table 1.

(3) CD spectra of the complexes were recorded on the automatic spectropolarimeter "J-20 JASCO" (Japan) at a concentration of 5×10^{-3} mol/l (in the visible region) or 5×10^{-4} mol/l (in the UV region). The absorption spectra were recorded on the automatic spectrophotometer (GDR) at the same concentrations.

(4) Mixed complexes were prepared in solution by mixing the solutions of two different individual complexes. The constants of the formation of mixed complexes and their spectra were calculated by following the procedure described in Ref. 4.

Abstract—The He(I) photoelectron spectra of acetylacetone (HAA) and its metallo complexes, $M(II)(AA)_2$ (M(II) = Mn, Co, Ni, Cu and Zn), have been measured. These spectra show characteristic metal-dependence, from which the assignment is made. The order of the orbital energy level, $d \gtrsim \pi_3 > n_- > n_+$, holds for all the complexes reported here. The splitting of these orbitals is found to depend on the central metal ion specifically.

INTRODUCTION

Considerable efforts have been made to understand the electronic structure of metal complexes. Although the UV-VIS absorption spectroscopy has been the most useful experimental method for this purpose, it is available only for the energy differences between a ground and an excited state, and therefore, the energies of the occupied orbitals (i.e. ionization potential, IP) cannot be obtained. In the case decades, photoelectron (PE) spectroscopy has been proved to be useful to study the electronic structure of various organic compounds. However, PE study concerning the metallo complexes is quite limited due to the difficulty of the measurement of the IP in the vapour phase. In this manuscript, we succeeded in obtaining the PE spectra of a series of divalent metallo complexes with acetylacetone. Despite numerous reports on the electronic structure of the transition metallo complexes, $M(III)(AA)_3$, little attention has been paid to those of the divalent ones, $M(II)(AA)_2$. In order to gain an insight into the electronic structure of the divalent metallo acetylacetonates, especially partly filled d-shell, of which theoretical investigation is still lacking, we discuss here the electronic structure on the basis of UV PE spectra of acetylacetone and its divalent metal complexes such as Mn, Co, Ni, Cu and $Zn(AA)_2$.

EXPERIMENTAL

Acetylacetone and its metallo derivatives were all commercially available. These complexes for PES measurements were purified by a vacuum sublimation.

Photoelectron spectra, with He(I) resonance line at 21.21 eV, were recorded on a Perkin-Elmer PS 18 spectrometer using a heated inlet probe. The spectra were calibrated by the simultaneous admission of Xe and Ar gases mixture into the heated target chamber containing the sample vapour. The sample was heated gradually until the desired temperature was reached: the setting temperature was 91°C for $Zn(AA)_2$, 115°C for $Co(AA)_2$, 142°C for $Cu(AA)_2$, 174°C for $Ni(AA)_2$ and 200°C for $Mn(AA)_2$. The instrumental resolution was 20–30 mV for Ar $^2P_{1/2,3/2}$ peaks.

RESULTS AND DISCUSSION

He(I) PE spectra of the acetylacetonate complexes of divalent metals are illustrated in Figs. 1 and 2. The IPs for these complexes are listed in Table 1 together with some literature data.[1] As Figs. 1 and 2 show, the PE bands between 7 and 12 eV for the compounds are well resolved, while the bands at the higher ionization energy (IE) region which arise from ionization of C–H and C–C σ-bonding electrons, are overlapped and have no fine structure. Thus, we are concerned with the bands between 7 and 12 eV.

The PE spectrum of HAA shows two well resolved bands at 9.0 and 9.6 eV, which have been assigned[1,2] to the ionization due to the π_3 electron of the enol ring and the n_- electron of the oxygen lone pair, respectively. The third band has been assigned to the ionization from the symmetric combination (n_+) of the two oxygen lone pair orbitals by use of trifluoroacetylacetone.[1]

Figure 1 reveals that $Zn(AA)_2$ provides two intense bands at 8.34(A) and 9.29(B) eV. The low IE bands[1] of $Be(AA)_2$ has been assigned to π_3 and n_- electron ionization, respectively. The C and C' bands in Fig. 1 are well resolved and the gap of these two bands is 0.83 eV, which is in strong contrast to the overlapping of the corresponding bands of $Be(AA)_2$ (0.27 eV gap). These bands are attributable to the ionization of n_+ orbitals. The splitting of the n_+ orbital can be accounted for by a simple molecular orbital interaction model. In the gas phase, the divalent metal compounds is expected to exist as a monomer.[3] The electron diffraction studies[4,5] have shown that the structure of Ni and $Cu(AA)_2$ are almost square planar. Planar symmetry $(D_{2h}$ point group) allows the n_+ orbitals to show B_{2u} and A_g transformation. The interaction of the metal $ns(a_g)$ and $np(b_{2u})$ valence AOs provides two n_+ orbitals having energy gap, which depends on the extent of mixing of these two AOs. On the basis of PE spectra of $Zn(AA)_2$ and $Be(AA)_2$, this orbital mixing of $Zn(AA)_2$ is more enhanced than that of $Be(AA)_2$.

As Fig. 2 shows, $Ni(AA)_2$ gives well-resolved bands at low IE region. The d-electron ionizations appear as the

*Author to whom correspondence should be addressed.
Fig. 1. He(I) photoelectron spectrum of $Zn(AA)_2$.

first three bands, which has been confirmed by use of mono and dithio analogues of $Ni(AA)_2$.[6] In contrast to this, d ionization peaks were not separately observed for Mn, Co and $Cu(AA)_2$, because these bands are masked under the broad envelope of the bands between 8 and 9 eV. It is to be noted in Fig. 2 that $Cu(AA)_2$ shows the first band (d) as a shoulder of the second broad and intense band (A) at 8.18 eV, and $Co(AA)_2$ also exhibits a shoulder peak at 7.93 eV. The corresponding bands were not observed in the spectrum of $Zn(AA)_2$ (Fig. 1). This finding makes us assign these shoulder bands to metal d orbitals. It is emphasized that the band ascribed to the ionization of the metal d orbital has lower intensity than that of oxygen and carbon p orbitals due to its small cross section.[7,8] In Fig. 2, the bands denoted as d have relatively small intensity, indicative of the validity of the above assignment. Under D_{2h} symmetry, the crystal field theory provides us with the order in the d orbital energy $d_{xy} > d_{xz} \sim d_{yz} > d_{z2} > d_{x2-y2}$. On the basis, the first band of $Ni(AA)_2$ has been assigned to the ionization from nearly degenerate $d_{xz,yz}$ orbitals,[6] since the upper d_{xy} orbital is empty. In the case of nearly quadratic

chromophere of $Cu(AA)_2$[4] with d^9 configuration, the first band at 7.66 eV is analogously considered as the electron-ejection from the singly occupied d_{xy} orbital. According to the above energy order of d orbitals in the case of quadratic chromophere and on the basis of the observed PE spectra of $Cu(AA)_2$ and $Ni(AA)_2$, it is worth noting that the d-orbital level of $Ni(AA)_2$ is higher than that of $Cu(AA)_2$. This trend about d orbital energy has also been found in the case of diethyldithiocarbamate[9] and difluorodithiophosphate[10] complexes of Ni and Cu. In the AA complexes of Cu and Ni, the Ni–O bond distance is shorter than the Cu–O distance.[4,5] This fact leads to the expectation that Ni ion interacts with the ligand more strongly than Cu ion, eventually indicative of the destabilization of the d orbitals of the Ni complex. The experimental observation on the relative d-orbital levels for Ni and $Cu(AA)_2$ should be theoretically reproduced. For our SCF UHF calculation, we used two Slater-type functions of different effective nuclear charges for $3d$ atomic orbitals.[11] The MO energies show that d levels of Ni complex lie higher by *ca.* 0.5 eV than those of the Cu complex.

Table 1. Vertical ionization potentials (peak maxima) from the photoelectron spectra of acetylacetone (HAA) and $M(II)(AA)_2$

Compound	Bands												eV
	d			A		B			C				
HAA[a]				9.00		9.60							
Mn(AA)$_2$	-[b]			-[b]		9.20			9.98	10.32	11.29		
Co(AA)$_2$	7.93			8.11	8.36	8.62	8.78		9.70	10.35	10.80	11.58	
Ni(AA)$_2$	7.62	8.05	8.21	8.59	8.78	9.02	9.39		10:24		11.02	11.59	
Cu(AA)$_2$	7.66			8.18	8.43	9.02			9.70	10.18	11.42	11.85	
Zn(AA)$_2$				8.34		9.29			10.38	10.72	11.55		

a) Ref.1   b) The overlapping bands between 7 and 8 eV are too complicated to separate each band, corresponding to the ionization of d and π_3 orbitals.
Fig. 2. He(I) photoelectron spectra of Mn(II)(AA)$_2$, Co(II)(AA)$_2$, Ni(II)(AA)$_2$ and Cu(II)(AA)$_2$.

Fig. 3. Correlation diagram of ionization energy in the PE spectra of M(II)(AA)$_2$. All the ionization energies except for Be(AA)$_2$[1] were obtained in the present experiment. The shaded portion shows a region with possible ionization energies obtained from the broad PE band.

The higher IE bands

As shown in Figs. 1 and 2, the PE bands (A) in the next higher IE region of Co, Ni and Cu(AA)$_2$ reveal the similarity close to the band A of Zn(AA)$_2$, characteristic of π_3 ionization. The unresolved broad band between 7.5 and 8.3 eV, however, appears in the spectrum of Mn(AA)$_2$. This band results from d and π_3 ionization which lie close in energy to those of Ni, Co and Cu(AA)$_2$. Figure 3 shows the energy level diagram of photoionized states constructed from the present results of PE measurements. It is emphasized in Fig. 3 that the π_3 level of Ni(AA)$_2$ is lower than those of other complexes. A simple analysis of the valence orbital interaction explains as follows: the stabilization of the π_3 orbital energy for Ni(AA)$_2$ results from an increase of the mixing among metal $3d(b_{3g})$, $4p(b_{1u})$, and $\pi_3(B_{3g}$ and $B_{1u})$ orbitals due to the relatively shorter Ni-O bond length in the square planar structure (D_{2h}).

The B-labeled bands at 8.5 eV are significantly associated with ionization from oxygen lone pair combination (n). The splitting (B and B') shows the metal-dependence, which is ascribed to the extent of the mixing between $n_-(B_{3u}$ and $B_{1g})$, metal $3d(b_{1g})$ and $4p(b_{3u})$ orbitals. Figure 3 also shows that the n_+ band splitting (C and C') of Co(AA)$_2$ is greater than that for other metal complexes. This implies an unusual structure of Co(AA)$_2$ in the vapour phase. It has been found[12] that unlike Ni(AA)$_2$, Co(AA)$_2$ encounters a tetrahedral form in the highly diluted solution. Hence, the greater splitting is associated with the structure such as tetrahedral form. PE spectra are, thus, available for the structural analysis, which should be developed together with the analysis of the electronic structure of metallo complexes.

The C-labeled peaks around 10 eV are assigned to ionizations of the n_+ electrons, which correspond to the peaks at 10.38 and 10.72 eV in the spectrum of Zn(AA)$_2$. The positions of these bands are not sensitive to the metal ions, while the splitting of bands C show the metal-dependence. By analogy with the splitting of n_-, this is explained in terms of the interaction between n_+, $4s$ and $4p$ orbitals. The former interaction is less sensitive to the structural deviation from the planarity of the complex than the latter, because of the spherical symmetry of the $4s$ orbital.

The weak bands about 11 eV in Fig. 2 are associated with the ionization from π_2 orbital, an anti-symmetric combination of the localized C-O π-bonding orbitals. As the electronegativity of the metal ion increases from Mn to Cu, these bands appear to shift to higher IE region except for the Co complex (Fig. 3). This unusual feature for Co(AA)$_2$ is also due to the structural deformation from the square planar to tetrahedral form.

METAL COMPLEXES OF PYRIMIDINE-DERIVED LIGANDS—III†

TRIS-COMPLEXES OF Co(II), Ni(II) AND Cu(II) FLUOROBORATES, PERCHLORATES AND IODIDES WITH 3,5-DIMETHYL-1-(4',6'-DIMETHYL-2'-PYRIMIDYL) PYRAZOLE, A POTENTIAL ANTI-TUMOUR AGENT

(Received 5 July 1982)

Abstract—Tris-complexes of Co(II), Ni(II), Cu(II) fluoroborates, perchlorates and iodides with the title ligand conform to the composition $M(DPymPz)_3X_2$, nH_2O [M = Co(II), Ni(II), Cu(II); X = ClO_4, BF_4 and I, n = 0, 2]. Physico-chemical characterisations of the complex species have been made from electronic and vibrational spectra, magnetic susceptibility measurements in the solid state and conductivity measurements in solution. Electronic spectral features together with the corresponding ligand field parameters suggest an overall octahedral environment for all the metallic complexes. For $[CuN_6]$ environment a D_3 symmetry is thought to be highly probable. Ir data point out the pyrazolyl nitrogen (tertiary) and one of the pyrimidyl nitrogens as bonding sites in forming these complexes while the anion (X) retains its identity (as in free form) in the said species.

INTRODUCTION

The significant role played by the pyrimidine derivatives (the ring system being an integral part of several nucleic acids, vitamins etc.) in many biological systems, has currently stimulated research into the coordination modes of pyrimidine-based ligands in order to gain detailed knowledge of the role of metal ions in such systems. Moreover, certain pyrimidino–pyrazoles are recently being studied in the fight against cancer.[1] As a part of our programme[2,3] to investigate the interaction of a variety of biologically active pyrimidine-derived ligands with metal ions, the present communication intends to report the coordination aspect of a pyrimidyl-pyrazole viz. the title ligand (hereinafter abbreviated as DPymPz) with isolation and physico-chemical characterisation of a few tris-complexes with $[MN_6]$ environment.

EXPERIMENTAL

Preparation of the ligand. The ligand was prepared by a condensation reaction of one mole 2 - hydrazino - 4,6 - dimethyl pyrimidine[4a,4b] (prepared in our laboratory) with 1.1 moles of freshly distilled acetylacetone following the method of Giuliano *et al.*[4c] The product yielded white flakes on recrystallisation from water. It melted with decomposition at 65°C (lit. m.p. 65°C) (Found: C, 65.07; H, 6.69; N, 27.98. Calc. for $C_{11}H_{14}N_4$: C, 65.34; H, 6.69; N, 27.98%). The ligand has been further characterised by its PMR spectral data recorded in DMSO-d_6 (not reported in the literature). The 80 MHz PMR spectrum of DPymPz shows two sharp one proton singlets at $\delta 7,18$ and $\delta 6.12$ which correspond to C-5' proton of the pyrimidine ring and C-4 proton of the pyrazole ring respectively; one 6-proton singlet at $\delta 2.47$ may be ascribed to the methyl groups at the C-6' and C-4' of the pyrimidine ring.[5] On the other hand two 3-proton singlets appearing at $\delta 2.45$ and $\delta 2.21$ in all probability correspond to two methyl groups at the C-3 and C-5 positions of the pyrazole ring;[5] the difference of these δ values is attributed to the greater shielding experienced by the C-5 methyl group of the pyrazole ring as these protons lie in approximate to the shielding region of the pyrimidine ring which is disposed in a perpendicular fashion with the pyrazole ring.

Preparation of the metal complexes. All the tris-complexes excluding the iodide one of Cu(II) were prepared by addition of hot ethanolic solution of the ligand (0.015 mole) to a solution of the hydrated metal(II) salt (0.005 mole) in the same solvent. The resultant solution, so formed, was heated at water-bath temperature for 5–10 min and then left at room temperature in a desiccator over concentrated H_2SO_4. The desired compound, in each case, separated within 24 hr. The compound was filtered, washed with ethanol and dried over silica gel. The compound of the composition $Cu(DPymPz)_3I_2$, $2H_2O$ was prepared by digesting the corresponding perchlorate complex (Table 1) with a saturated aqueous solution of KI at water-bath temperature for 15 min. The compound was filtered, washed repeatedly with ice-cold water and then with ethanol and collected as before.

Elemental analysis. Metal contents (*viz.* cobalt, nickel and copper) in the respective metal complexes were determined gravimetrically as anhydrous $CoSO_4$, nickel dimethyl glyoxime and $[Cu(en)_2HgI_4]$ (en = ethylene diamine) respectively. Nitrogen and carbon were estimated by micro-analytical laboratory of the Department. Chlorine and iodide were estimated gravimetrically as silver halides.

Physico-chemical measurements like molar conductance and magnetic susceptibility, electronic (both reflectance and solution) and vibrational spectral measurements were done as described earlier.[3]

RESULTS AND DISCUSSION

The analytical data for the complexes along with their colours, effective magnetic moment values and molar conductances are given in Table 1. The complexes are

L = DPymPz

soluble in water and common non-donor organic solvents. The aqueous solutions of complex species suffer appreciable change in colour with time indicating extensive solvolysis.

All the tris-complexes are magnetically normal high-spin 6-coordinate complexes (Table 1). The magnetic moments of the cobalt(II) complexes are above the spin only value of 3.89 B.M. for high spin octahedral complexes due to high orbital contribution.[6] Molar conductance data (in ohm^{-1} cm^2 mole^{-1}) in acetonitrile solution of the complexes indicate their ionic nature (1:2) at least in the said solvent.[7]

Co(II) *complexes.* The diffuse reflectance spectra of the Co(II) complexes are characterised by two main bands appearing around ~9.8 kK and ~20.7 kK which may be ascribed to $\nu_1[4T_{1g}(F) \rightarrow {}^4T_{2g}]$ and $\nu_3[{}^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)]$ transitions respectively in an idealised octahedral environment.[8] The position of ν_3 band in the d.r.s. of the corresponding iodide complex could not be located in the expected position; alternatively, a broad band appeared at 22.42 kK which is believed to be mixed up with intense charge transfer absorption. The relevant ligand field parameters[9] viz. Dq (1096 and 1120 cm^{-1}), B (804 and 808 cm^{-1}) and β (0.82 and 0.83) for the fluoroborate and perchlorate complexes confirm the proposed pseudo-octahedral configuration. Electronic spectra (Table 2) of these complexes in methanol are characterised by a main band around 20.00 kK which indicate that there is no remarkable change in stereochemistry on dissolution in the said solvent.

Ni(II) *complexes.* The complexes have mostly identical spectral bands both in solid and in solution. Each is characterised by two main bands around ~10.4 and ~17.0 kK which may be attributed to $\nu_1[{}^3A_{2g} \rightarrow {}^3T_{2g}(F)]$ and $\nu_2[{}^3A_{2g} \rightarrow {}^3T_{1g}(F)]$ transitions respectively in an O_h symmetry. The calculated[10,11] ligand field parameters viz. Dq (1030 and 1040 cm^{-1}), B (972 and 1048 cm^{-1}) and β (0.93–1.01) closely correspond to those having (NiN$_6$) environment.[12] The ν_2/ν_1 ratio of 1.63–1.65 (Table 2) characterises all the Ni(II) complexes as essentially pseudo-octahedral species suggesting strong T_{1g} term interactions.[13] In the present study absence of ν_3 band $[{}^3A_{2g} \rightarrow {}^3T_{1g}(P)]$ may be either due to intense internal $\pi-\pi^*$ transitions of the ligand or due to intense CT absorption, arising from metal to ligand via the π antibonding level of the heterocyclic ligand.[14] The strong band at 25.97 kK with high molar extinction coefficient ($\epsilon \sim 1.52$ cm^{-1} mole^{-1}) in the spectrum of Ni(DPymPz)$_3$I$_2$, 2H$_2$O in methanol may be of charge-transfer origin.

Cu(II) *complexes.* The tris-pyrimidyl–pyrazole Cu(II) ions as perchlorate, fluoroborate and iodide salts furnish interesting spectral features having well-defined absorption bands near 10.12 kK which persist more or less in the same region both in the solid state and in nitromethane solution; additional bands around 6.00 kK (d.r.s.) and near 14.28 kK (in solution of nitromethane) are also discernible. The spectral data remind us of the well known Cu(bipy)$_3^{2+}$ and Cu(o-phen)$_3^{2+}$ [15] and our earlier reported Cu(DPyPz)$_3^{2+}$ [15a] [where DPyPz represents a molecule of 3,5 - dimethyl - 1 - (2' - pyridyl)pyrazole, having structural resemblance to our present ligand]. The point symmetry in these tris-Cu(II) species may, therefore, be regarded as essentially D$_3$ in which the $^2T_{2g}$ level (in O_h) is split into $^2E + {}^2A_1$ while the ^2E_g level is unaffected. The two transitions corresponding to $^2A_1 \leftarrow {}^2E$ and $^2E \leftarrow {}^2E$ are expected in order of increasing energy.[16] The main spectral bands in the present Cu(II) complexes are con-

sistent with this expectation. Although in absence of polarised data it is a conjecture, but it seems reasonable to consider Cu(DPymPz)$_3^{2+}$ as being essentially a trigonally distorted octahedral complex both in the solid state and in solution.

IR spectra

The i.r. spectrum of the uncomplexed ligand furnishes recognisable bands in the region 1600–1400 and at 1000 and 750 cm^{-1} which may be assigned to the $\nu_{C\dots C} + \nu_{C\dots N}$ and out-of-plane deformation vibrations respectively of both (1,2)-diazole (pyrazole) and (1,3)-diazine (pyrimidine) systems. On complexation these bands are found to experience shifts in the higher energy side ($\Delta\nu \sim 15$–30 cm^{-1}) indicating, thereby, the expected participation of both pyrazolyl and pyrimidyl ring nitrogens (one of the pyrimidyl nitrogens at a time as verified through construction of molecular model); contemplation of forming a stable 5-membered ring with the metal ion is thus supported. In the far i.r. spectra of a few compounds, the appearance of bands at 300–315 cm^{-1}(w) and around 245 cm^{-1}(ms) attributable to M–N (pyrazole ring)[17a,17b] and M–N (pyrimidine ring)[18] respectively further support the proposition.

Mode of linkage of the counterion (X)

Perchlorate complexes. The appearance of broad strong band at *ca.* 1110–1070 cm^{-1} (ν_1) along with another strong one at 625 cm^{-1} (ν_4) indicate the presence of ionic perchlorate species (T_d) in the compounds.[19]

Fluoroborate complexes. The strong broad bands at *ca.* 1120–1040 cm^{-1} (ν_3) indicate the presence of ionic fluoroborate species in the compounds.[20,21]

Therefore, the ligand (DPymPz) exhibits a neutral bidentate (N–N) function through the tertiary nitrogen atom of the pyrazole and one of the pyrimidine ring nitrogen atoms in complexation with a metal ion giving tris-complexes of [MN$_6$] environment with a relatively heavy counterion.

Further studies with the title ligand using different metal ions [like Fe(II), Pd(II), Pt(II)] are in progress and will be published in due course.

ALKOXY, AMIDO AND THIOLATO COMPLEXES OF TRIS (3, 5-DIMETHYLPYRAZOLYL)BORATO(NITROSYL) MOLYBDENUM FLUORIDE, CHLORIDE AND BROMIDE

A. STEPHEN DRANE and JON A. McCLEVERTY*†

Department of Chemistry, The University, Sheffield S3 7HF, England

Abstract—The complexes Mo{HB(Me₂pyz)₃}(NO)XY {HB(Me₂pyz)₃ ≡ HB(3, 5-Me₂C₃HN₂)₃; X=Y=F, Cl or Br; X=F, Y=OEt, NHMe or SBuⁿ; X=Cl, Y=NHR (R=Me Et, Buⁿ, Ph, p-MeC₆H₄), NMe₂ and SR (R=Buⁿ, C₆H₁₁, CH₂Ph, Ph); X=Br, Y=NHMe, NMe₂ and SBuⁿ} have been prepared and characterised spectroscopically. Their properties are generally similar to those of their iodo-analogues.

In a series of papers we have described the reactions of Mo{HB(Me₂pyz)₃}(NO)I₂, (1; X=Y=I) [HB(Me₂pyz)₃ =HB(3, 5-Me₂C₃HN₂)₃≡tris(3, 5-dimethyl-pyrazolyl)borate] with alcohols,[1,2] amines[3,4] and thiols,[5] affording alkoxy, amido and thiolato complexes of the type (1; X = I, Y=OR, NHR or SR). Our use of the diiodide precursor (1, X=Y=I) was dictated partly by its ease of preparation from (1, X=Y=CO),[1,6] and partly because the iodide ligand is bulky and therefore likely to be a good leaving group in potential substitution reactions. However, we felt that the preparation of the other halide derivatives should be attempted in order to explore the effects of the changes in electronegativity and ligand size in the properties of this unusual series of complexes.

SYNTHETIC STUDIES

In earlier attempts to prepare chloro- and bromo-complexes of the type (1; X=Y=CO) with chlorine and bromine we noted that partial halogenation of the pyrazolyl rings, especially at C-4, occurred very readily.[1] This caused great difficulties, and we were frequently unable to reproduce our results. Thus alternative routes to (1; X=Y=Cl and Br) were sought.

We have employed two methods for making the chloride and bromide precursors. Trofimenko had shown[7] that (1; X=Y=CO) reacted with NOCl to give (1; X=Y=Cl), and we found this the easiest and quickest way to prepare the chloride. The product so obtained was not usually very pure, but was entirely satisfactory for further reactions. The bromide was obtained similarly, using NOBr, and was isolated as a pure orange powder. The other method of synthesis involved reaction of (1; X=Y=OR; R usually Et) with HCl or HBr. The chloride was obtained as a yellow solid and this method is the best way of isolating the pure material. While the conversion of bis-alkoxide to dichloride is 70%, however, the overall yield from (1; X=Y=CO) is only 30%, requiring conversion of the dicarbonyl to (1; X=I; Y=OEt) and of this to (1, X=Y=OEt). The bromide obtained from HBr addition to (1; X=Y=OR) was not obtained sufficiently pure to justify exploration of this route, traces of water frequently interfering with the purification of the compound.

The difluoride, (1; X=Y=F) has not been previously described but was made by reaction of (1; X=Y=OEt) with aqueous HF. It was isolated as a virtually insoluble pale green solid (it is very slightly soluble in CHCl₃) which was substantially less stable towards air and moisture than its chloro-, bromo- and iodo-analogues.

The alkoxides (1; X=Cl, Br or I, Y=OR) have been previously described,[1] and are prepared by refluxing the appropriate dihalide in an alcohol. However, the fluoro ethoxide, (1, X=F, Y=OEt), despite the insolubility of the parent difluoride, is formed rapidly in ethanol without heating. The mono-amido species (1, X=F, Y=NHMe), (1; X=Cl, Y=NHMe, NHPh and NHC₆H₄Me-p) and (1; X=Br, Y=NHMe) were prepared in the same way as their iodo analogues,[3] namely by reaction of the dihalide with two mole equivalents of the amine in solution at room temperature. Similarly, the thiolato species (1, X=F, Y=SBuⁿ), 1, X=Cl, Y=SBuⁿ, SC₆H₁₁, SCH₂Ph and SPh) and (1, X=Br, Y=SBuⁿ) were obtained by refluxing the dihalide in hydrocarbon solvents containing the appropriate thiol.[5]

Of some interest was our ability to synthesise relatively stable dimethylamido complexes, (1; X=Cl or Br, Y=NMe₂). These compounds were obtained in the same way as their mono-alkylamido analogues, and are significantly more stable towards air, moisture and other hydroxylic solvents than the corresponding iodo complex (1; X=I, Y=NMe₂).[3] Indeed, the iodo species has been used as a convenient precursor for making alkoxides and monoalkylamides under mild conditions. We presume the lower chemical reactivity of the related chloro- and bromo-complexes is related to the relief of steric strain following the replacement of the iodide group by the less bulky Cl and Br.

Spectral studies

The IR spectra of the new complexes (Table 2) exhibit bands typical of the HB(Me₂pyz)₃ ligand, and a strong absorption due to ν(NO). The dichloride and dibromide exhibit ν(NO) at values very similar to those of the diiodide, whereas the frequency in the difluoride was lower. On electronegativity grounds alone, we would have expected an *increase* in ν(NO) in the difluoride if any change occurred. It is possible, however, that (1; X=Y=F) is di- or poly-meric, with Mo–F–Mo bridges, which would be consistent with its insolubility. The coordination sphere of the metal would then increase from 6 to 7 by virtue of F atom bridging, leading to more electron donation to Mo, and hence a lowering of ν(NO) relative to the other dihalides. There is very little evidence for a

halide or N- or S- ligand substituent effect on $\nu(NO)$ of the other monohalide complexes. In general $\nu(NO)$ in the amido and thiolato species averages 1664 and 1683 cm^{-1}, which is consistent with our observations elsewhere.[5]

The ^{1}H NMR spectra (Table 2) of the new complexes are generally unremarkable, and are consistent with the formulation of the new species. A group of signals in the region δ 2.7-1.9 is associated with the methyl groups of the pyrazolyl ring. The shape of these signals varies from compound to compound but in one complex (1; X=Y=Cl) it appears as a singlet. We have no explanation for this effect, but it is very useful for characterisation purposes. The group of signals occurring in the region δ 6.1-5.3 is due to the protons attached to C-4. In those complexes of the type (1; X=Y), the signals appear as a doublet of relative intensity 2:1. In the species where X ≠ Y, we would expect three singlets, since there is no plane of symmetry in the complexes, and this is usually observed. In two cases viz. (1; X=Cl, Y=SBu^n or SC$_6$H$_{11}$) only two resonances, of relative intensity 1:2, are observed and we assume this is due to accidental degeneracy; this effect has been noted before. In these complexes, as in all others reported previously, protons attached to the C

atom α to the donor atom at Mo resonate at lower fields than expected, and we reiterate that this is probably due to the strong electron-withdrawing properties of the metal. The NH signals in the mono-alkyl and aryl-amides also resonate at low fields (δ 12.7-12.3) for the same reason. The signals due to the dimethylamido group in (1; X=Cl or Br, Y=NMe$_2$) appear as two singlets, because of the asymmetry of the complexes, and the lack of facile inversion at the amido N atom in these complexes.

Conclusion

The properties of the new complexes are generally very similar to those of their iodo-analogues. We have noted in a qualitative way that the apparent rates at which the monosubstituted fluoro-, chloro- and bromo-complexes were generally faster than those of the related iodo-complexes. While we believe that the mechanism of formation of the species (1; X=I, Y=OR, Y=OR, NHR or SR) from (1; X=Y=I)[8] involves prior one-electron transfer, we are not yet in a position to determine whether this occurs with the other dihalides. This possibility is being studied.

EXPERIMENTAL

The complex Mo{HB(Me$_2$pyz)$_3$}(NO)(CO)$_2$ was prepared as described elsewhere.[1,6] All reactions were carried out under nitrogen and in N$_2$-degassed solvents. All yields are quoted relative to the molybdenum-containing precursor. IR and ^{1}H NMR spectral data were obtained using PE 297 and PE 180 spectrophotometers, and PE R34 instruments, respectively. Molecular weights were determined osmometrically in chloroform.

Mo{HB(Me$_2$pyz)$_3$}(NO)Cl$_2$ (1; X=Y=Cl)—*Method* 1. Nitrosyl chloride was generated *in situ*, and was bubbled through a dichloromethane solution of Mo{HB(Me$_2$pyz)$_3$}(NO)(CO)$_2$. The yellow-brown solution which formed was then evaporated to dryness *in vacuo*, and ethanol added in the cold. The slurry which formed was filtered, the *complex* being collected as a yellow powder. This could be recrystallised from toluene to give orange-red crystals (containing variable amounts of toluene of crystallisation) which, after repeated washing with n-pentane, changed to a yellow powder.

Method 2. Mo{HB(Me$_2$pyz)$_3$}(NO)(OEt)$_2$ was prepared as previously described, and dissolved in toluene. HCl gas was then bubbled through the stirred solution for 30 min during which time the colour of the solution became orange-red and some orange solid precipitated. The mixture was then refluxed for 30–45 min, filtered and allowed to cool slowly to room temperature. During this time, orange crystals separated which were collected by filtration, thoroughly washed with n-pentane, to afford the *complex* as a yellow powder (yield quantitative).

Mo{HB(Me$_2$pyz)$_3$}(NO)Br$_2$ (1; X=Y=Br). Nitrosyl bromide was generated in the same way as NOCl.[7] The red-brown gas was purified by passing through CaCl$_2$ and KCl, and was bubbled through a solution of Mo{HB(Me$_2$pyz)$_3$}(NO)(CO)$_2$ in dichloromethane. An orange solution quickly formed, and this was reduced in volume *in vacuo*. Ethanol was then added in the cold, causing precipitation of an orange powder. This was collected by filtration, recrystallised from toluene affording orange-red crystals of the toluene-solvated species. On repeated washing with n-pentane, the *complex* was obtained as an orange powder.

Mo{HB(Me$_2$pyz)$_3$}(NO)F$_2$, (1; X=Y=F). Mo{HB(Me$_2$pyz)$_3$}(NO)(OEt)$_2$ (0.3 g) was dissolved in dichloromethane (25 cm^3) and conc. HF (40% in water, 0.2 cm^3, PTFE beaker) was added. The mixture was stirred for 1 hr, and the solvent then removed *in vacuo* leaving the *complex* as a pale green powder (0.26 g, 90%).

Mo{HB(Me$_2$pyz)$_3$}(NO)F(OEt); (1; X=Y, Y=OEt). Mo{HB(Me$_2$pyz)$_3$}(NO)F$_2$ was suspended in ethanol and stirred at room temperature for 1 hr. The solvent was reduced in volume *in vacuo*, and the purple *complex* filtered off and dried *in vacuo*.

Mo{HB(Me$_2$pyz)$_3$}(NO)F(NHMe); (1; X=F, Y=NHMe). Mo{HB(Me$_2$pyz)$_3$}(NO)F$_2$ was suspended in methylamine and stirred at −10°C for 2 hr. The amine was then allowed to evaporate at room temperature, leaving the *complex* as a pale orange powder.

Mo{HB(Me$_2$pyz)$_3$}(NO)F(SBu^n); (1; X=F, Y=SBu^n). Mo{HB(Me$_2$pyz)$_3$}(NO)F$_2$ was suspended in n-heptane, and n-butanethiol (slight excess) added. The mixture was refluxed overnight and cooled, the brown *complex* being collected by filtration and dried *in vacuo*.

Mo{HB(Me$_2$pyz)$_3$}(NO)NHMe; (1; X=Cl, Y=NHMe). Mo{HB(Me$_2$pyz)$_3$}(NO)Cl$_2$ (0.3 g), dissolved in dichloromethane (30 cm^3), was treated with methylamine (33% ethanolic solution, 0.2 cm^3). The mixture was stirred at room temperature for 30 min during which time the solution became orange. The volume of solvent was reduced *in vacuo* to ca. 5 cm^3 and, after addition of diethylether, the precipitated [NH$_3$Me]Cl filtered off. The filtrate was reduced *in vacuo* to ca. 5 cm^3 whereupon the *complex* formed orange crystals (0.25 g, 83%).

The corresponding *ethyl-* and *n-butyl-amides* were obtained similarly as orange crystals (85 and 76% yields, respectively).

Mo{HB(Me$_2$pyz)$_3$}(NO)Cl(NMe$_2$) (1; X=Cl, Y=NMe$_2$). To Mo{HB(Me$_2$pyz)$_3$}(NO)Cl$_2$ (0.3 g) dissolved in dichloromethane (20 cm^3) was added dimethylamine (0.1 cm^3). The colour of the solution immediately became orange and the mixture was stirred for 30 min. The volume of the solution was reduced *in vacuo* to ca. 5 cm^3, treated with diethylether which caused precipitation of [NH$_2$Me$_2$]Cl which was filtered off. The filtrate was slowly

evaporated, effecting crystallisation of the orange *complex* (0.19 g, 61%).

Mo{HB(Me$_2$pyz)$_3$}(NO)Cl(NHPh); (1; X=Cl, Y=NHPh). A mixture of Mo{HB(Me$_2$pyz)$_3$}(NO)Cl$_2$ (0.3 g) and freshly redistilled aniline (0.1 ml) in dichloromethane (30 cm^3) was stirred overnight at room temperature. The solution had became yellow-brown, and the solvent was removed *in vacuo*. The residue was extracted with diethylether, the extract being filtered and allowed to cool at −5° until the *complex* had precipitated as a brown powder (0.26 g, 78%).

The related *p-toluidide*, Mo{HB(Me$_2$pyz)$_3$}(NO)Cl-(NHC$_6$H$_4$Me), (1; X=Cl, Y=p-MeC$_6$H$_4$NH), was prepared similarly using *p*-toluidine (0.1 g) and was isolated as a brown powder (0.27 g, 79%).

Mo{HB(Me$_2$pyz)$_3$}(NO)Cl(SBu^n); (1; X=Cl, Y=SBu^n). A mixture of Mo{HB(Me$_2$pyz)$_3$}(NO)Cl$_2$ (0.3 g) and n-butanethiol (0.2 cm^3) in n-heptane (20 cm^3) was refluxed overnight. The yellow-black solution which had formed was reduced *in vacuo* to ca. 10 cm^3 and the *complex* allowed to form as black crystals which were collected by filtration (0.23 g, 74%).

The related complexes Mo{HB(Me$_2$pyz)$_3$}(NO)Cl(SR) R=C$_6$H$_{11}$, CH$_2$Ph *and* Ph) were prepared similarly, using C$_6$H$_{11}$SH (0.2 cm^3), PhCH$_2$SH (0.1 g) and PhSH (0.2 cm^3) and were isolated as black (R=Ph) or dark green (R=C$_6$H$_{11}$, CH$_2$Ph) crystals. The yields were 0.26 g (75%), 0.25 g (72%) and 0.27 g (80%) respectively, and the toluene-α-thiolate could be recrystallised from dichloromethane/*n*-hexane mixtures; giving black microcrystals.

Mo{HB(Me$_2$pyz)$_3$}(NO)Br(NHMe); (1; X=Br, Y=NHMe). To Mo{HB(Me$_2$pyz)$_3$}(NO)-Br$_2$ (0.3 g) dissolved in dichloromethane (20 cm^3) was added methylamine (33% solution in ethanol, 0.2 cm^3). The solution immediately became orange, and was stirred at room temperature for 30 min. The volume of the solvent was then reduced to ca. 5 cm^3, and diethylether was added causing precipitation of [NH$_3$Me]Br which was filtered off. The volume of the filtrate was slowly reduced *in vacuo* until crystallisation began, and the *complex* formed as orange crystals at −5° (0.20 g, 73%).

Mo{HB(Me$_2$pyz)$_3$}(NO)Br(NMe$_2$); (1; X=Br, Y=NMe$_2$). A mixture of Mo{HB(Me$_2$pyz)$_3$}(NO)Br$_2$ (0.3 g) and dimethylamine (0.2 cm^5) in dichloromethane (20 cm^3) was stirred for 10 min, during which time an orange solution rapidly formed. The volume of the solvent was reduced *in vacuo* to ca. 5 cm^3, and diethylether added causing precipitation of [NH$_2$Me$_2$]Br, which was filtered off. The filtrate was partially evaporated *in vacuo* and allowed to stand at −5° until the *complex* had formed as orange crystals (0.16 g, 57%).

Mo{HB(Me$_2$pyz)$_3$}(NO)Br(SBu^n); (1; X=Br, Y=SBu^n). A mixture of Mo{HB(Me$_2$pyz)$_3$}(NO)Br$_2$ (0.25 g) and n-butanethiol (0.2 cm^3) in n-heptane (20 cm^3) was refluxed overnight during which time a yellow-black solution had formed. The solvent was evaporated *in vacuo* to ca. 10 cm^3, and the complex precipitated as an olive-green powder (0.22 g, 71%).

NEW CHEMICAL REACTIVITY IN AROMATIC DITHIOCARBAMATE AND MONOTHIOCARBAMATE LIGANDS: SYNTHESES OF Mo₂L₄·2THF (L = PYRROLE OR INDOLE MONOTHIOCARBAMATE OR PYRROLE DITHIOCARBAMATE) AND Mo₂L₄ (L = INDOLINE MONOTHIOCARBAMATE)[1]

ROBERT D. BEREMAN,* DONALD M. BAIRD and CHARLES G. MORELAND
The Department of Chemistry, North Carolina State University, Raleigh, NC 27650, U.S.A.

Abstract—The reactions between $Mo_2(C_2H_3O_2)_4$ and several new dithio- and monothiocarbamates have been studied. The first example of a dimolybdenum compound of a dithiocarbamate with the "molybdenum acetate" structure is reported (Mo_2L_4·2THF; L = pyrrole dithiocarbamate). In addition, the synthesis of $Mo_2L'_4$·2THF (L' = pyrrole monothiocarbamate, indole monothiocarbamate, indole dithiocarbamate) and $Mo_2L''_4$ (L" = indoline monothiocarbamate) are reported. A discussion of the unique stabalization of the dithiocarbamate bridge by "aromatic" dithio- and monothiocarbamates is presented.

INTRODUCTION

The chemistry of compounds containing metal–metal bonds constitutes one of the major topics of inorganic chemistry currently attracting vigorous and diverse research efforts.[2] This realm of metal–metal bonds was largely unknown prior to 1970 and is an exciting area of study. A large array of ligands have been coordinated to the dimolybdenum unit (Mo_2^{4+}) including halides, amines and carboxylates.[3–5] Perhaps the most well studied of these systems are the carboxylates which have the structural features indicated below as shown by an X-ray diffraction study performed by Cotton.[6]
One of the most glaring absences in this array of ligands is the lack of dithiocarbamate (dtc) and mono-thiocarbamate (mtc) complexes of the dimolybdenum unit. The paucity of dithiocarbamate compounds is because of the unusual metal insertion into the C–S bond

of the dithiocarbamate, resulting in a thiocarbene linkage and a Mo=Mo double bond (Scheme 1).[7]

We choose to view this reaction as a "nucleophilic" attack of one of the Mo–Mo bonds on the CS_2 carbon (Scheme 2). If indeed this model were valid, we felt that
Scheme II

we could exploit the unique resonance properties of new aromatic mono- and dithiocarbamates recently prepared in these laboratories to synthesize the first examples of mono- or dithiocarbamate dimolybdenum complexes that adopted the dimolybdenum acetate structure. That is, we have recently show that "aromatic" dithiocarbamates such as those derived from pyrrole have only a minor contribution from the resonance form IIIB often used to describe dithiocarbamates[8] and it is this resonance form which would favor the "nucleophilic" attack for one of the Mo–Mo bonds on the CS_2 carbon.

EXPERIMENTAL

Syntheses of ligands

Potassium salts of pyrrole-N-carbodithioate (pdc), pyrrole-N-carbothioate (ptc),[9] indole-N-carbodithioate (ildc),[9] indole-N-

Mo₂(Ac)₄ + 4(Et₂dtc)Na ⟶
Scheme I

*Author to whom correspondence should be addressed.

carbothioate (iltc),[1] and indoline-N-carbothioate (intc)[1] were prepared as reported previously.

Mo₂(pdc)₄·2THF

Excess (1.7 eq.) of potassium pyrrole-N-carbodithioate dissolved in 50 ml dry THF was added slowly to a mixture of 1 g Mo₂ (OAc)₄ (OAc = acetate) in dry THF. The yellow color of the Mo₂(OAc)₄ was immediately replaced by a deep purple color. After all the Kpdc was added, the solution was filtered to remove any insoluble materials. The volume of the solution was reduced to about 50 ml, and 10 ml hexane was added. Refrigeration for several days produced purple crystals of Mo₂(pdc)₄·2THF. This compound was recrystallized by dissolution in THF and addition of an equal volume of hexane. Several elemental analyses were attempted; however, in each case some THF was lost so that analyses usually indicated somewhere between one and two THF molecules per Mo₂ unit. NMR spectra of freshly prepared samples integrated in such a way as to indicate two THF molecules per four pyrrole groups. NMR(d_6-DMSO) δ 2.0 (4H, m), 3.82 (4H, m), 6.57 (4H, m), 8.03 (4H, m). Found: C, 35.67; H, 3.31; S, 28.75; Calc. for $C_{28}H_{32}N_4O_2S_8Mo_2$: C, 37.14; H, 3.56; S, 28.35. This corresponds to the loss of approx. 20% of the THF.

Mo₂(iltc)₄·2THF

This compound was prepared by the same method as that above used for Mo₂(ptc)₄·2THF. This compound is dark purple and can be recrystallized from THF and hexane. Elemental analyses corresponded to approx. Mo₂(ildc)₄·1.6 THF. NMR again however integrated to give 2THF/4 indole groups.

Mo₂(ptc)₄·2THF and Mo₂(ptc)₄

A solution of 1.5 g Kptc in 50 ml THF was added slowly through a Schlenk frit to a mixture of 0.97 g Mo₂(OAc)₄ in 100 ml dry THF. During this period an orange solution formed and KOAc precipitated from solution. After an additional 1 hr of stirring the solution was filtered. The volume of solution was reduced by half by vacuum evaporation and an equal volume of hexane was added. Refrigeration for several days afforded an orange powder which was shown to be Mo₂(ptc)₄·2THF by NMR. However, when recrystallized from CH₂Cl₂, the THF molecules were lost. Found: C, 34.35; H, 2.39; S, 18.33; Calc. for $C_{20}H_{16}N_4O_4S_4Mo_2$: C, 34.50; H, 2.32; S, 18.41.

Mo₂(iltc)₄·2THF

A solution of 2 g Kiltc in 100 ml dry THF was added through a Schlenk frit to mixture of 0.98 g Mo₂(Ac)₄ in 50 ml dry THF. During this period an orange solution and a colorless precipitate formed (KAc). The solution was filtered to remove KAc. The volume of the solution was reduced to half and an equal volume of hexane was added. Refrigeration produced an orange powder which was collected by filtration.

Mo₂(Intc)₄

Since Kintc shows only very limited solubility in dry THF, this reaction was attempted in very dry ethanol. 1 g Kintc was added directly to 0.5 g Mo₂(Ac)₄ in 100 ml ethanol. After stirring for 2 hr an orange-red precipitate formed. This precipitate was collected on a Schlenk frit and dried under vacuum. This compound is *extremely* air sensitive. Exposure to air for even the briefest period transforms the compound to a brown and then black powder.

Spectral data collection

IR spectra were determined as before.[1] Optical data were obtained on either a Cary 14 or a Hitachi 110 spectrophotometer.

NMR

The ¹H and ¹³C NMR spectra were obtained on a Bruker WM-250 spectrometer operating in the pulsed-FT mode. The ¹H NMR spectra were run at 250 MHz and the ¹³C NMR spectra at 62.5 MHz.

RESULTS AND DISCUSSION

The reaction of the aromatic dithiocarbamates, pyrrole-N-carbodithioate and indole-N-carbodithioate, with Mo₂(OAc)₄ in dry THF, leads to dark purple compounds which we formulate as Mo₂L₄·2THF based on spectral analyses. IR and electronic spectra and ¹H and ¹³C spectral results suggest that a slow decomposition occurs wherein THF is lost with the *possible* concomitant formation of a thiocarbene linkage. All aromatic dithio- and monothio- ligands behaved in an identical fashion. Therefore, only data for Mo₂(pdc)₄·2THF and Mo₂(ptc)₄·2THF are presented.

IR studies

A report by Steele and Stephenson[10] of the attempted synthesis of a diethyldithiocarbamate complex of dimolybdenum suggested that in the presence of air the green reaction product immediately formed the violet Mo₂O₃(Et₂dtc)₄ compound. These Mo(V) dimers have been studied extensively by Newton[11] and the ν(Mo=O) vibration frequencies for Mo₂O₃(R₂dtc)₄ occur close to 938 cm⁻¹ as a strong band in the IR spectra. Since the molybdenum pyrroledithiocarbamate compound was also violet, the IR spectrum was recorded in order to rule out the presence of the Mo₂O₃ core. The spectrum of this compound exhibited bands at 1250 cm⁻¹, ν(C⎯⎯N), as well as bands at 1100 and 850 cm⁻¹ that are characteristic of the presence of pdc. However, no bands appeared between 900 and 1000 cm⁻¹ that were strong enough to be assigned to ν(Mo=O). The only band in this region was a medium intensity band at 980 cm⁻¹ which also appears in the IR spectra of all pdc complexes as well as in the spectrum of the ligand itself.[8,9] Therefore, this band is assumed to arise from the ligand, not from a Mo–O bond.

The IR spectrum of the analogous monothiocarbamate complex was also recorded. No Mo=O bands occured in this spectrum either. The ν(C⎯⎯O) frequency was located near 1580 cm⁻¹ in Mo₂(ptc)₄ which is fairly high; however, we feel that the oxygen is indeed coordinated to Mo in this orange compound.[1]

ELECTRONIC SPECTRA

The electronic spectra of both the dithiocarbamate and monothiocarbamate were recorded in CH₂Cl₂ solution between 900 and 350 nm. The lowest energy band was found at 510 nm for the dithiocarbamate and at 405 nm for the monothiocarbamate. This band is believed to correspond to the $\delta \rightarrow \delta^*$ transition, if indeed, the molybdenum acetate structure is preserved in these compounds. While the $\delta \rightarrow \delta^*$ band occurs between 500 and 700 nm ($\epsilon = 200$–3000) for most Mo₂⁴⁺ species,[12] it occurs at a much higher energy (340 nm) for tetrakiscarboxylates.[13] However, San Filippo and Sniadoch[14] have found that values for the $\delta \rightarrow \delta^*$ transition in aryl-carboxylates appear as a broad intense band centered between 350 and 480 nm. If our argument which eliminates resonance form IIIB (Scheme 3) were correct, we could then describe the aromatic mono- and dithio-carbamate as a COS or CS₂ group attached to an aromatic ring similar to monothio- or dithiobenzoate. As a result we can suggest that the position of the band in the spectra of our complexes agrees nicely with position and

III A   III B
Scheme III

shape of the same band in arylcarboxylates of dimolybdenum. In other words, the spectra can be interpreted as indicating the presence of a Mo–Mo quadruple bond in these compounds. The spectra of both the monothio- and dithio-derivatives are very similar. Thus we believe, on the basis of this and the NMR data (see below), that the structures of the compounds are similar. Finally, the shift of the $\delta \rightarrow \delta^*$ band in the monothiocarbamate to higher energy is as expected for replacing a sulfur donor with an oxygen donor.

^1H NMR

The proton NMR spectrum of both the pdc complex and the ptc complex of Mo_2^{4+} exhibit resonance lines characteristic of the pyrrole ring; a pair of multiplets suggestive of an A A'B B' system. The pyrrole resonances are centered about δ 8.03 and δ 6.56 for the dithiocarbamate complex and δ 7.57 and δ 6.56 for the monothiocarbamate. Both spectra also exhibit resonances characteristic of THF. Integration of the spectra give pyrrole/THF as 2:1 as would be expected for a molybdenum acetate structure with two axially coordinated THF molecules. It is very important to note that THF molecules would not be expected to be associated with the thiocarbene complexes as the reported examples do not have solvent molecules associated.[15,16] On the other hand, Mo_2^{4+} does not have a strong affinity to bond donor molecules on the axial position except when the ligand is a dithio ligand.[17,18]

In order to be sure that the THF was coordinated, additional THF was added to the NMR sample of the monothiocarbamate complex. Exchange between coordinated and uncoordinated THF molecules is apparently slow on the NMR time scale since two sets of resonances were observed. Resonances at δ 3.72 and δ 1.86 associated with uncoordinated THF and resonances at δ 3.12 and δ 1.24 associated with coordinated THF were observed. The assignments were made based on the integration for ptc/THF using the upfield resonances, while the positions of the downfield resonances correlate closely with the reported value for uncoordinated THF (δ 1.79 and δ 3.60).[19]

^{13}C NMR

A recent study by van der Linden et al. reported the position of the CS_2 carbon in the ^{13}C spectra of 71 dithiocarbamates.[20] The carbon of the CS_2 group was found between 185 and 220 p.p.m. for every example. We felt that the ^{13}C spectrum of the dithiocarbamate complex here could help distinguish whether the molybdenum acetate structure of the thiocarbene structure was present in this compound. The spectrum of a dithiocarbamate with the acetate structure should exhibit only a single resonance line in the CS_2 region, while a dithiocarbamate with the thiocarbene structure should exhibit a pair of resonances in this region corresponding to the thiocarbene carbon and the normal dithiocarbamate carbon respectively. Unfortunately, the intensity of this resonance is very weak since there are no hydrogens

attached to the carbon. The lack of hydrogens coupled with limited solubility of the complex in available NMR solvents made detection of the desired signal very difficult. However, a spectrum of the complex (dissolved in d_8-THF) obtained by scanning 32000 times at 63.5 MHz did display resonance lines in the CS_2 carbon region. Unfortunately, there were three lines which were barely detectable and might correspond to the CS_2 carbon. The time frame of the experiment was sufficiently long that it appeared that a decomposition was occurring during the experiment. The most intense resonance line was at 209.8 p.p.m. and is suggested to result from $Mo_2(pdc)_4 \cdot 2THF$ which has the molybdenum acetate structure. This suggested assignment is made based on the proximity of this line to the CS_2 resonance in Kpdc which was found at 217 p.p.m.

In summary, it appears that the products of the reaction between $Mo_2(Ac)_4$ and Kpdc or Kptc have the molybdenum acetate structure, based on ^1H NMR and electronic spectra, at least for the length of time it takes to perform those measurements. However, the ^{13}C spectra as well as the loss of THF during mailing time for elemental analysis point to slow decomposition to thiocarbene or a dithiocarbamate-thiocarbene equilibrium.

ESR STUDY ON PHOTOREACTION OF FORMATO COMPLEX OF EUROPIUM(III) IN HCOOH–HCOONa BUFFER SOLUTION

NAGAO AZUMA* and AKIRA MATSUMOTO

Laboratory of Chemistry, Faculty of General Education, Ehime University, Matsuyama 790, Japan

and

JIRO SHIOKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita 565, Japan

Abstract—Matrix isolation ESR study showed that the ligated $HCOO^-$ ion was decomposed into H^+ and $\cdot COO^-$ radical anion through CTTM process at $\lambda = 254$ nm, by contrast, $\cdot CH_3$ radical and CO_2 were produced from CH_3COO^- ligand. In order to explain the photo- and related reactions in the liquid solution, a proposal is made for a cyclic scheme conjugated with the photo-decomposition of the complex. The cycle consists of three steps; photo-reduction of H^+ by Eu^{2+}, radical alternation from $\cdot H$ to $\cdot COO^-$, and oxidation of $\cdot COO^-$ by Eu^{3+}.

INTRODUCTION

Photochemistry of aqueous solutions of Eu^{3+} was studied extensively by Stein *et al.*[1] They observed the evolution of molecular hydrogen from the solutions containing H-atom scavengers, which was due to the following reactions:

$$Eu^{3+} - H_2O \xrightarrow{h\nu} \cdot OH + H^+ + Eu^{2+}, \qquad (1)$$

$$H^+ + Eu^{2+} \xrightarrow{h\nu} \cdot H + Eu^{3+} \qquad (2)$$

and

$$\cdot H + HR \longrightarrow \cdot R + H_2. \qquad (3)$$
The reduction of Eu^{3+} by $\cdot R$ radical was proposed by them and was supported by means of pulse radiolysis of Eu^{3+} aqueous solution in the presence of formic acid, $HR = HCOOH$.[2] Previously we have studied the photo-reaction of $Eu(CH_3COO)_3$ in $CH_3COOH–CH_3COONa$ buffer solutions in which the organic species were used as H-atom scavenger and as ligand.[3] The acetato complexes were subjected to CTTM breakdown at $\lambda = 254$ nm, giving both CO_2 and $\cdot CH_3$ radical.

On the other hand, the two types of the breakdown are possible for $M^{n+}–HCOO^-$ complexes, that is,

$$U^{6+}–HCOO^- \xrightarrow{h\nu} \cdot COO^- + H^+ + U^{5+} \qquad (4)^4$$

and

$$Ce^{4+}–HCOO^- \xrightarrow{h\nu} \cdot H + CO_2 + Ce^{3+}. \qquad (5)^5$$
In order to clarify the primary step of the photoreaction of europium(III) formate system, an ESR study has been carried out for UV-irradiated $Eu(HCOO)_3$ in frozen HCOOH–HCOONa buffer solutions by means of the matrix isolation method. Based on the ESR study and result from room-temperature experiment,[6] a model of the reaction scheme will be proposed for the liquid solution of this system.

EXPERIMENTAL

$Eu(HCOO)_3$ was prepared by the method in literature.[7] The compositions of the samples were as follows:

Sample A; 0.01N-$Eu(HCOO)_3$ + 0.1N–HCOOH,
B; 0.01N-$Eu(HCOO)_3$ + 0.05N–HCOOH
+ 0.05N–HCOONa,
C; 0.01N-$Eu(HCOO)_3$ + 0.1N–HCOONa.

Samples F (0.1N–HCOOH) and S (0.1N–HCOONa) were employed in order to be compared with the above samples.

The samples filled in quartz tubes for ESR measurement were deaerated and irradiated at 77 K with $\lambda = 254$ nm from a 120W low-pressure mercury lamp. The first derivative ESR spectra were recorded on an X-band spectrometer at 77 K and elevated temperatures.

RESULTS AND DISCUSSION

The ESR spectra recorded at 77 K are presented in Fig. 1. Each sample showed a singlet and two kinds of doublet absorptions. The singlet can be assigned to carboxyl radical anion, $\cdot COO^-$, or its conjugate acid, $\cdot COOH$, with an anisotropic g-factor; $g_x = 2.003$, $g_y = 1.997$, and $g_z = 2.001$ which are very close to the values published.[8] One of the doublets is due to atomic hydrogen with a splitting of 50.4 mT (not being shown in Fig. 1). The anisotropic ESR parameters of the other are approximated as axial symmetry; $g_\parallel = 1.997$, $g_\perp = 2.003$, $A_\parallel = 14.5$, $A_\perp = 12.7$, and $A_{iso} = 13.3$ mT. This doublet is assigned to formyl radical, $\cdot CHO$, by comparing these parameters with those for that radical in CO matrix.[9]

Unresolved structure on the low-field portion of the central singlet appeared more evidently with increasing acidity of the sample. On warming to 100 K, the H-resonances were not observed any longer. The signals from $\cdot CHO$ survived till 150–170 K. In this temperature region, the line shapes of the central singlets were deformed strongly and, ultimately, anisotropic doublet

Fig. 1. ESR spectra of samples F, A, B, C and S recorded at 77 K with increasing field from left to right. The samples were UV-irradiated at 77 K for 150–180 min. The arrows show signal from Mn^{2+} in MgO ($a = 8.65$ mT).

spectra emerged at 200–230 K. These doublets were too weak to be characterized completely and disappeared at almost the same temperature region as just above. Although we cannot conclude at present whether these doublets are identical with the unresolved structures observed at 77 K, radical(s) of X–ĊH–Y type, such as HO–ĊH–O⁻(H),[10] ⁻OOC–O–ĊH–O⁻(H),[11] and O = CH–O–ĊH–O⁻(H), may be responsible in view of the presumptive ESR parameters. These radicals are regarded as the spin adducts of ·H, ·COO⁻ and ·CHO with HCOO⁻ or HCOOH.

Ratios for the peak-to-peak height of the CHO-signals to those of the COO⁻(H)-ones vs the irradiation time examined at 77 K are shown in Fig. 2, where the arrow indicates the time for the first detection of the H-resonance from each sample. All the ratios increase rapidly until the H-atoms are trapped in the matrices and, thereafter, do so gradually with increasing irradiation time. The value of the ratio and its slope are dependent on the acidity, and so is the ratio, R_0, extrapolated to zero time.

At the outset let us consider samples F and S. Taking
Fig. 2. The ratio of peak-to-peak height of the low-field component of the CHO-signal to that of the COO⁻(H)-signal vs the irradiation time examined at 77 K. The meaning of the arrows is presented in the text.

into account the direct proportion between the peak-height and radical-concentration ratios, the acidity dependent R_0 suggests a greater v_F/v_C ratio for F than for S. Here v_F and v_C are the rates for the CHO- and COO⁻(H)-formations, respectively. The positive slope would be expected if the rate for the decay of ·COO⁻(H) were faster than that of ·CHO or if there were some process, such as

$$\cdot COO^-(H) + X \rightarrow \cdot CHO + Y. \tag{6}$$

Formic acid in frozen 4M–HClO₄ aqueous solution containing Ce^{4+} was decomposed into ·H, ·CHO and ·COOH upon irradiation with $\lambda = 300$–360 nm.[5] These processes must take place also in the present case. It should be noted that $HCOOH + h\nu \rightarrow \cdot CHO + \cdot OH$ was more difficult than $HCOOH + h\nu \rightarrow \cdot H + \cdot COOH$ in view of the bond dissociation energies.[12] The mobile radicals, ·H and ·OH, are scavenged by the solutes and the radicals. Some of the scavenging modes give ·COO⁻(H) and ·CHO as follows;

$$\cdot H + HCOO^-(H) \rightarrow \cdot COO^-(H) + H_2, \tag{7a}$$

$$\cdot OH + HCOO^-(H) \rightarrow \cdot COO^-(H) + H_2O, \tag{7b}$$

and

$$\cdot H + HCOO^-(H) \rightarrow \cdot CHO + OH^-(H_2O). \tag{8}$$

The long induction period for the H-atom trapping supports the presence of the scavenging processes. On the other hand, both ·COO⁻(H) and ·CHO radicals exhibit UV-absorption around 254 nm with $\epsilon_{250} \simeq 1800$[13] and $\epsilon_{250} = 800$,[14] respectively. The UV-photo-decomposition of formyl radical has been noted by Adrian *et al.*[9]

$$\cdot CHO \xrightarrow{h\nu} \cdot H + CO. \tag{9}$$
The following decays of ·COO⁻(H) in matrix are proposed;

$$\cdot COOH \xrightarrow{h\nu} \cdot H + CO_2 \tag{10}$$

and

$$\cdot COO^- + H^+ \xrightarrow{h\nu} \cdot H + CO_2. \tag{11}$$
The value $\Delta H = 1$ kcal[15] for (10) and the photobleaching of ·COO⁻ in a matrix with $\lambda \leq 425$ nm[16] likely support this proposal. A certain fraction of these H-atoms gives ·CHO via (8), which is equivalent to the process (6).

The concentration ratio [·CHO]/[·COO⁻(H)] for sample C is significantly lower than that for the parent sample, i.e. sample S, as can be seen from Fig. 2. This decrease can be attributed to the increase in [·COO⁻] in view of the same [HCOO⁻] in both the samples. Therefore, the primary step of the photoreaction of the complexes is likely as follows;

$$Eu^{3+}-HCOO^- \xrightarrow{h\nu} \cdot COO^- + H^+ + Eu^{2+}. \tag{12}$$

The quantum yield for (2) has been measured at 77 K.[17] Some of Eu^{2+} ions with $\epsilon_{250} \simeq 2000$[1a] will reduce H^+ ions also in the present case.

It may be expected from the stability constants[18] that about 95 and 1% of Eu^{3+} ions are complexed in samples C and A, respectively. An apparent ϵ_{250} of the formato complexes in C was estimated as to 50–150. Then, the complexes in C absorb the light effectively but those in A do little. In the early stage of the irradiation, the behaviour of A will consequently be similar to that of sample F. After the exclusive decrease in [HCOOH], sample A finds itself in the situation

$$\epsilon(HCOOH) \cdot [HCOOH] \simeq$$
$$\epsilon(Eu^{3+}-HCOO^-) \cdot [Eu^{3+}-HCOO^-],$$

so the complexes in A become the light absorber in the later stage of the irradiation. Here the ϵ's denote the absorption coefficients of the indicated species. Thus, the downward deviation of the peak-height ratio of A from that of F in the later stage can be explained also based on the reaction (12).

On the other hand, we have proposed the following reaction for acetate system;[3]

$$Eu^{3+}-CH_3COO^- \xrightarrow{h\nu} \cdot CH_3 + CO_2 + Eu^{2+}. \quad (13)$$

In order to conclude whether $\cdot COO^-(H)$ radicals are present in the acetate system or not, the similar examination has been carried out by using ^{13}C-enriched samples. There has not appeared the $^{13}\cdot COO^-(H)$ radical featured by an anisotropic ^{13}C-doublet splitting of about 15 mT.[8b,16,19] Therefore, Eu^{2+} and H-atom reduced from H^+ by Eu^{2+} do not or scarcely reduce CO_2 into $\cdot COO^-$ and $\cdot COOH$, respectively, in the frozen acetate system and, accordingly, also in the frozen formate system. The process (12) is thus supported.

The results of the room-temperature experiment for samples F and A are summarized as follows.[6] (i) There appeared Eu^{2+} ions in A upon irradiation. (ii) The yields of CO_2, CO, and H_2 from HCOOH were respectively: F; 0.47, 0.21, 0.32, and A; 0.95, 0.04, 0.74. (iii) The material balance for F was approximately matched by assuming the yield 0.32 of HCHO which was detected qualitatively, (iv) and so was the balance for A by employing the decomposition ratio, $HCOOH : HCOO^- = 0.76 : 0.24$. (v) There was detected no acid other than formic acid in both F and A after the irradiation. In order to realize these results, the qualitative model for the reaction scheme is proposed in Schemes 1 and 2.

The Scheme 1 for the decomposition of the aqueous formic acid solution consists of three sub-cycles, I–III.

The cycles I and II hold the hydrogen atom in common and the steps in them have been discussed in the preceding sections. Owing to the mobility of $\cdot COO^-(H)$, $\cdot CHO$, and $HCOO^-(H)$ in the liquid phase, our photosteps to evolve CO_2 and CO probably include certain dark-reactions.[20,21] Smithies and Hart[21] have shown the following propagation steps in the chain reaction for γ-irradiated aqueous formic acid solution:

$$\cdot COOH + HCOOH \longrightarrow CO_2 + \cdot CHO + H_2O \quad (14)$$

and

$$\cdot CHO + HCOOH \longrightarrow HCHO + \cdot COOH. \quad (15)$$

These steps also connect the two sub-cycles and form cycle III. The evolution of CO_2, CO, H_2 and HCHO can be qualitatively realized by means of this scheme.

Scheme 2 shows how the europium redox couple prevents the cycle III in sample A. Because of $pK_a = 1.4 - 3.8$[22] for $\cdot COOH$ vs $pH = 2.6$ for A, $\cdot COO^-$ is exclusively used for simplicity in the same scheme. The
Scheme 2. Catalized decomposition of HCOOH.

rate for the following step (16) is so greater than that for the step (14) that $\cdot CHO$ is scarcely produced via cycle III:

$$\cdot COO^-(H) + Eu^{3+} \longrightarrow CO_2 (+H^+) + Eu^{2+}. \quad (16)$$

The ESR result indicates the faster rate for the production of the $\cdot COO^-(H)$ radical than for the formation of the $\cdot CHO$ radical. Therefore, the rates for the steps (7's)

Scheme 1. Decomposition of HCOOH. $^*\cdot COOH \rightleftharpoons \cdot COO^- + H^+$ should be noted. $^{**}\cdot OH$ radical will be reduced to H_2O via (7b), although the ESR evidence for this reaction could not be given.

are faster than that for (8), and the CO gas is hence scarcely evolved no longer. The ratio for the presumptive yield of HCHO to the observed yield of CO in sample A is much smaller than that in F, which may suggest the oxidation of the ·CHO radical:

$$\cdot CHO + Eu^{3+} \longrightarrow CO + H^+ + Eu^{2+}. \tag{17}$$
The material balance shown in (iv) indicates that $HCOO^-$ is decomposed faster than HCOOH, at least, by 30 times in consideration of their initial concentrations. This minimum ratio estimated roughly for the rate constants is about 1/10 of the $k_{H+HCOO^-}/k_{H+HCOOH}$ ratio estimated in solutions containing ferricyanide.[23] Here k's are the rate constants for the indicated H-abstraction reactions. This result is also consistent with the proposed scheme which includes the radical alternation step from ·H to ·COO⁻(H) via H-abstraction. The easily detectable amount of Eu^{2+} in the irradiated solution indicates the greater rate for the step (16) than for the step (2).

ANNOUNCEMENT

10th International Symposium on the Reactivity of Solids, Dijon, 27 August–1 September 1984

The organizing Committee of the 10th International Symposium on the Reactivity of Solids has the pleasure to inform you that the Symposium will be held at the University of Dijon, France, from 27 August to 1 September 1984.

The closing dates for contributions are 1 March 1983 for titles (50 words), 30 November 1983 for abstracts (2 pages), and 31 May 1984 for registration.

Further details and registration forms may be obtained from the Executive Secretary of the Organizing Committee.

SYNTHESIS AND CHARACTERIZATION OF COBALT(II), NICKEL(II) AND COPPER(II) PERCHLORATE COMPLEXES WITH BIS [(DIPHENYLPHOSPHINYL)METHYL] PHENYLPHOSPHINE OXIDE, BIS [(DIPHENYLPHOSPHINYL)METHYL]ETHYL PHOSPHINATE, AND BIS [(DIPHENYLPHOSPHINYL)METHYL] PHOSPHINIC ACID

P. BRONZAN-PLANINIĆ and H. MEIDER*
Department of Physical Chemistry, Rudjer Bošković Institute, Zagreb, Yugoslavia

Abstract—The synthesis and characterization of cobalt(II), nickel(II) and copper(II) perchlorate complexes containing *bis* [(diphenylphosphinyl)methyl] phenylphosphine oxide (RPPh), *bis* [(diphenylphosphinyl)methyl] ethyl phosphinate (RPOEt), and *bis* [(diphenylphosphinyl)methyl] phosphinic acid (RPOH) have been studied. The substituent at the central phosphorus atom of the ligand is responsible for the types of complexes formed. The new complexes $[M(RPPh)_2](ClO_4)_2.nH_2O$, $[M(RPPh)_3](ClO_4)_2.4H_2O$, $[M(RPOEt)_2](ClO_4)_2.2H_2O$, and $[M(RPOH)_3]$ $(ClO_4)_2.nH_2O$ are characterized as high spin and most of them have an octahedral or distorted octahedral geometry [M = Co(II), Ni(II), or Cu(II); n = 2−5]. The coordination of two P = O groups from one ligand to the metal has been proposed for most of the complexes formed. The coordination of all three P = O groups has been assumed for complexes $[M(RPPh)_2](ClO_4)_2.nH_2O$ and $[M(RPOEt)_2](ClO_4)_2.2H_2O$.

INTRODUCTION

Many diphosphine oxides have been extensively studied as ligands in the formation of complexes with transition metals.[1–4] However, trisphosphine oxides and related compounds have received little attention. In fact, only a few data have been reported on the formation of complexes with the tridentate organophosphorus compound *bis*-methylimido-triphosphoric-acid-*pentakis*-dimethylamide (TRIPA). In this ligand, three phosphoryl groups are bridged by nitrogen atoms. The coordination of all P = O groups to the metal has been proposed.[5]

Organophosphorus compounds with three phosphoryl groups bridged by methylene groups, although already known for ten years,[6,7] have not been used in complex formation studies. These ligands were probably considered to be unsuitable for the preparation of complexes regarding the fact that the three P = O groups, bridged only by methylene groups, could sterically hinder the formation of stable chelate rings with metal ions.

Therefore, we have decided to study the formation of metal complexes with a group of ligands corresponding to the general formula $[(C_6H_5)_2P(O)CH_2]_2P(O)R$. We have chosen ligands which differ only by the substituent (R) at the central phosphorus atom. The substituent is either a phenyl, an ethoxy, or a hydroxy group. Depending on the nature of the substituent R, the ligands: *bis*[(diphenylphosphinyl)methyl] phenylphosphine oxide (RPPh), *bis*[(diphenyl-phosphinyl)methyl]ethyl phosphinate (RPOEt), and *bis*[(diphenyl-phosphinyl)methyl]-phosphinic acid (RPOH) are characterized as a phosphine oxide (R = C₆H₅), a phosphinate (R = OC₂H₅), and a phosphinic acid (R = OH), respectively.

The aim of this investigation was to establish the coordination properties of these ligands and define the influence of the substituent at the central phosphorus atom (R) on their capability for complex formation. It was also important to establish the conditions under which the ligands act as bidentate or tridentate complexing agents. Another question is the ability of the ligands to form binuclear complexes. The ligands RPPh, RPOEt, and RPOH have a structure similar to that of triketonates which are known for their ability to form binuclear copper(II), nickel(II) and cobalt(II) complexes.[8] Therefore, the formation of binuclear complexes by these organophosphorus compounds cannot be excluded.

Our previous investigations of the formation of zirconium(IV) and hafnium(IV) complexes with RPPh, RPOEt, and RPOH in solution and in the solid state[9] showed that the coordination of all phosphoryl groups might be proposed. However, the formation of polymeric species could not be excluded and, therefore, the coordination of all three P = O groups to the same metal ion in the above complexes is still an open question.

This paper describes the preparation and properties of cobalt (II), nickel(II), and copper(II) perchlorate complexes with the ligands RPPh, RPOEt, and RPOH. The results obtained show clearly the influence of the substituent (R) on the ability of the ligands to form complexes. Physico-chemical measurements indicate that the coordination of all three P = O groups to one metal ion is possible only in a few complexes formed.

RESULTS AND DISCUSSION

Complex formation

Perchlorate complexes isolated had different composition depending on the ligand-to-metal ratios in the reaction mixtures. The reaction of cobalt(II), nickel(II), and copper(II) perchlorates with solutions of the ligands yielded crystalline complexes listed in Table 1.

Complexes formed with RPPh. Two types of metal(II) perchlorate complexes were formed with this ligand. Compounds corresponding to the formula $[M(RPPh)_2]$ $(ClO_4)_2.nH_2O$ (M = Co(II), Ni(II) or Cu(II); *n* varies from

a) Calculated values are given in parentheses.

2 to 5) were isolated by dissolving metal(II) salts and ligands in absolute ethanol in the ratio of 1:2. Complexes having the composition [M(RPPh)$_3$](ClO$_4$)$_2$.4H$_2$O were obtained by mixing metal(II) perchlorates in ethanol solutions with a large excess of the ligand (ligand/metal ⩾ 3).

Complexes formed with RPOEt. Regardless of the reaction ratio used, only one type of metal complex was formed with this ligand. Unstable complexes containing coordinated ethanol were precipitated. After all the amount of ethanol had been released, complexes corresponding to the formula [M(RPOEt)$_2$] (ClO$_4$)$_2$.2H$_2$O(M = Co(II), Ni(II) or Cu(II)) were formed.

Complexes formed with RPOH. Nickel(II) and cobalt(II) complexes formed with RPOH contained quantities of the reagents in a stoichiometric ratio of 1:3. The isolated cobalt(II) and nickel(II) complexes corresponded to the formulae [Co(RPOH)$_3$](ClO$_4$)$_2$.3H$_2$O and [Ni(RPOH)$_3$](ClO$_4$)$_2$.2H$_2$O, respectively. No copper(II) complexes could be isolated.

Infrared spectral studies

The most significant absorption bands in the spectra of the ligands and their complexes are those of P = O stretching vibrations. The spectra of the ligands exhibit three strong bands in the range from 1250 to 1150 cm^{-1} which correspond to the P = O stretching vibration. In the spectra of the complexes these bands are shifted by 20–80 cm^{-1} towards lower wave numbers, thus indicating that the ligands are coordinated to the metals through oxygen atoms (Table 2 and Fig. 1).

The spectra of the complexes with RPPh exhibit only one absorption band corresponding to the P = O stretching vibration, with a maximum at 1170 cm^{-1}. The shape of this band is different for complexes with different ligand-to-metal ratios. The band appearing in the spectra of [M(RPPh)$_2$](ClO$_4$)$_2$.nH$_2$O (M = Co(II), Ni(II) or Cu(II), n = 2–5) is narrow, while the band in the spectra of [M(RPPh)$_3$](ClO$_4$)$_2$.4H$_2$O is rather broad.

The RPOEt spectrum exhibits a maximum at 1245 cm^{-1} which can be assigned to the P = O vibration of the central phosphoryl group.[10] As the spectra of the complexes do not show this maximum, this indicates that the central P = O group from the ligand is coordinated. Bands assigned to P–OC$_2$H$_5$ vibrations appear in both the RPOEt spectrum and the spectra of the complexes at 1035 and 965 cm^{-1}. However, the bands in the latter spectra are of much lower intensity.

The RPOH spectrum is characterized by three broad bands at 2600 cm^{-1}, 2200 cm^{-1}, and 1620 cm^{-1}, which can be assigned to P(O)OH vibrations perturbed by strong hydrogen bonding. These bands are absent in the spectra
Fig. 1. IR spectra of (a) [Co(RPPh)$_3$] (ClO$_4$)$_2$.4H$_2$O; (b) [Co(RPOEt)$_2$](ClO$_4$)$_2$.2H$_2$O; (c) [Co(RPOH)$_3$](ClO$_4$)$_2$.3H$_2$O in the region of 1700–625 cm^{-1}.

of the complexes [M(RPOH)$_3$](ClO$_4$)$_2$.nH$_2$O. OH vibrations of the monomer[10,11] coordinated to the metal, which appear at 3500–3600 cm^{-1}, are overlapped by the absorption of OH vibrations of water molecules present in the complexes. A sharp band appears at 980 cm^{-1}. The intensity of the band decreases from cobalt(II) through nickel(II) to copper(II) complexes. This absorption band probably corresponds to the P–O(H) vibration[10] appearing in the spectrum of the ligand at 955 cm^{-1}.

Absorption bands appearing in the spectra of the ligands in the range 785–815 cm^{-1} are assigned to the P–C–P linkage vibrations;[12] in some of the spectra of the complexes these bands are shifted towards lower wave numbers.

As can be seen from the spectral data, the perchlorate ion does not seem to be coordinated to the metal ion. The perchlorate ion retains its Td symmetry as shown by its unsplit bands at 1090 cm^{-1} (ν_3), 935 cm^{-1} (ν_1) and 625 cm^{-1} (ν_4).

All the spectra exhibit two bands with maxima at ~ 3400 cm^{-1} and ~ 1630 cm^{-1}. The first maximum is assigned to O–H stretching and the second one to H–O–H bending modes from lattice or coordinated water molecules. In the region 785–805 cm^{-1}, in which absorption bands corresponding to coordinated water molecules are expected[13], the P–C–P vibrational bands are always present and they can overlap the wagging and rocking mode of the coordinated water. Band assignments for the ligands and complexes are listed in Table 2.

Conductivity measurements

Conductivity measurements of metal perchlorate complexes were carried out at room temperature from 10^{-3}M nitrobenzene solutions. All complexes which were isolated had molar conductance values close to those expected for 2 : 1 electrolytes[14] (Table 2).

Magnetic properties

All perchlorate complexes prepared are high-spin paramagnetic substances. The effective magnetic moments (μ_{eff}) for the cobalt(II) complexes isolated were estimated to be between 4.74 and 5.15 B.M. The magnetic moments of the [Co(RPPh)$_3$](ClO$_4$)$_2$.4H$_2$O and [Co(RPOH)$_3$](ClO$_4$)$_2$.3H$_2$O complexes were estimated to be 5.10 and 5.15 B.M., respectively. These values are due to the regular octahedral surrounding. The magnetic moments of the [Co(RPPh)$_2$](ClO$_4$)$_2$.3H$_2$O and [Co(RPOEt)$_2$](ClO$_4$)$_2$.2H$_2$O complexes were evaluated to be 4.86 and 4.74 B.M., respectively. These values indicate a loss in orbital degeneracy of the ground state, caused by any lower symmetry component. Hence, a departure from the regular octahedral surrounding of the cobalt(II) ion may be assumed in these complexes. The effective magnetic moments of nickel(II) perchlorate complexes range from 3.18 to 3.30 B.M. and are indicative of spin-free octahedral complexes with a significant orbital contribution. The copper(II) perchlorate complexes have effective magnetic moments in the range from 1.92 to 2.07 B.M. These values are characteristic of one unpaired d^9 electron and are more or less independent of the stereochemistry of the complexes. Table 2, shows the effective magnetic moments obtained for the complexes studied.

Electronic spectral data

For most of the perchlorate complexes studied there were recorded both, solid-state and solution electronic

spectra (Table 3). The solution spectra were sufficiently similar to the solid-state mull spectra to preclude any significant solvent interaction. All the complexes are very poorly coloured, and the visible absorption bands are of low intensity. The intensity, position and shape of the bands are typical of octahedral cobalt(II) and nickel(II) complexes.[15]

Whilst cobalt and nickel are expected to form more or less regular six coordinate complexes copper rarely does. The complexes [Cu(RPPh)$_2$](ClO$_4$)$_2$.2H$_2$O and [Cu(RPOEt)$_2$](ClO$_4$)$_2$.2H$_2$O are characterized by a broad, asymmetric band in the near IR region with maxima at 11700 and 11400 cm^{-1}, respectively. The bands can be compared with the spectra of known tetragonal distored copper(II) complexes. This distorsion is characteristic of Cu(II) compounds, and it appears as a consequence of the Jahn–Teller effect.[16] The complex [Cu(RPPh)$_3$](ClO$_4$)$_2$.4H$_2$O is white in colour and gives a single peak with maximum shifted to 10400 cm^{-1}. According to the low intensity of this band the possibility that this complex might be trigonal or tetrahedral has to be excluded.[16]

Spectral data of the nickel(II) complexes were used to calculate ligand field parameters, D$_q$ and B (Table 3). In the spectra of these complexes only two bands (ν_2 and ν_3) were assigned, and therefore the method given by Underhill and Billing was used.[17] Values of the parameters obtained for the ligands RPPh, RPOEt and RPOH are of the same order of magnitude as values of parameters for similar ligands having a weak ligand field.[18]

EXPERIMENTAL

Materials

Analytical-grade solvents and cobalt(II) perchlorate (Fluka) were used throughout the preparation. Nickel(II) perchlorate and copper(II) perchlorate were prepared by fuming their nitrates with perchloric acid.[19,20] Bis[(diphenylphosphinyl)methyl]-phenylphosphine oxide (RPPh), bis[(diphenylphosphinyl)methyl]ethyl phosphinate (RPOEt), and bis[(diphenylphosphinyl)methyl] phosphinic acid (RPOH) were prepared using the method of Kabachnik et al.[6]

For conductivity measurements, nitrobenzene was purified using the method of Taylor and Kraus.[21]

Physical measurements

IR spectra were recorded on KBr pellets and nujol mulls in the region 4000–625 cm^{-1} using a Perkin–Elmer Model 257 spectrophotometer. Electronic spectra were recorded by means of a Carry Model 17 spectrophotometer. Magnetic susceptibilities were determined at 295 K using the Gouy method with CuSO$_4$.5H$_2$O as calibrant.

Electrolytic-conductance measurements were performed at 295 K on a Tacussel conductivity bridge, type Cd7.

Elemental analyses were performed in the Microanalytical Laboratory of the Rudjer Bošković Institute.

The amount of water was determined using the Karl–Fischer method.

Preparation of complexes

General method of preparation. Metal(II) perchlorates as well as ligands were dissolved in hot absolute ethanol. Adequate amounts of these solutions were mixed together. After a few days (1–5) the crystalline precipitates were filtered off and washed with absolute ethanol and diethylether. The complexes isolated were dried at room temperature.

[M(RPPh)$_3$](ClO$_4$)$_2$.nH$_2$O. 0.75 mmol of the metal(II) perchlorate (0.274 g Co(ClO$_4$)$_2$.6H$_2$O or Ni(ClO$_4$)$_2$.6H$_2$O; 0.224 g Cu(ClO$_4$)$_2$.2H$_2$O) dissolved in 3 ml of hot absolute ethanol was mixed with 1.5 mmol (0.831 g) of RPPh dissolved in 7 ml of ethanol. After 5 days the crystalline precipitates were filtered off

* = nujol mull.

and washed. Yields of 89.9%, 83.1% and 78.8% were obtained for Co(II), Ni(II), and Cu(II) complexes, respectively.

$[M(RPPh)_3](ClO_4)_2 \cdot 4H_2O$. 0.5 mmol of metal(II) perchlorate (0.183 g Co(ClO$_4$)$_2$.6H$_2$O or Ni(ClO$_4$)$_2$.6H$_2$O; 0.149 g Cu(ClO$_4$)$_2$.2H$_2$O) dissolved in 2 ml of hot absolute ethanol was added dropwise to a solution of 1.5 mmol of RPPh (0.831 g in 7 ml of absolute ethanol). An immediate precipitate was formed. After the mixture was allowed to stand for a short time, the crystalline precipitates were filtered off and washed. Yields of 44.7%, 40.3% and 46.3% were obtained for Co(II), Ni(II), and Cu(II) complexes, respectively.

$[M(RPOEt)_2](ClO_4)_2.2H_2O$. 0.75 mmol of the metal(II) perchlorate (0.274 g Co(ClO$_4$)$_2$.6H$_2$O or Ni(ClO$_4$)$_2$.6H$_2$O; 0.224 g Cu(ClO$_4$)$_2$.2H$_2$O) dissolved in 3 ml of hot absolute ethanol was added to a warm solution of 1.5 mmol (0.784 g) of RPOEt in 10 ml of absolute ethanol. The crystalline precipitates were filtered off, washed, and allowed to stand for a few weeks to stabilize

(replacement of ethanol by water molecules). Yields of 84.7%, 78.1% and 86.5% were obtained for Co(II), Ni(II), and Cu(II) complexes, respectively.

$[Co(RPOH)_3](ClO_4)_2.3H_2O$ and $[Ni(RPOH)_3]$ $(ClO_4)_2.2H_2O$. 0.5 mmol (0.183 g) of metal(II) perchlorate dissolved in 2 ml of hot absolute ethanol was added to a solution of 1.5 mmol (0.741 g) of RPOH dissolved in 30 ml of hot absolute ethanol. After 5 days the crystalline precipitates were filtered off and washed. Yields of 36.5 and 63.2% were obtained for Co(II) and Ni(II) complexes, respectively.

Abstract—The title compounds have been prepared from reactions of $Co_2(CO)_6$(μ-HOR₂CC₂R') or $Co_2(CO)_6$(μ-HOR₂CC₂R₂OH) complexes with Fe(CO)₅ in acetone. In the latter set of reactions the homobimetallic butatriene compounds, $Fe_2(CO)_6$-(μ-R₂C=C=CR₂), are also obtained. The striking feature of these reactions is the ability of Fe(CO)₅ to dehydroxylate the organic moiety and to replace a Co(CO)₃ unit forming mixed iron–cobalt derivatives. A direct interaction between the iron and the carbon atom, originally bearing the lost –OH group, is evident from the bulk of the spectroscopic data; thus the organic chain acts as an overall 5 electron donor, according to the E.A.N. formalism. The heterobimetallic compounds have been characterized by elemental analysis, mass spectrometry, IR spectroscopy and NMR studies. For the phosphine derivative FeCo(CO)₅(PPh₃)(H₂CC₂CH₂OH) a crudely refined X-ray analysis has been performed.

INTRODUCTION

Mixed metal compounds containing metal–metal bonds are receiving increasing attention since it has been suggested that the presence of different metallic centres on the same molecule can be important in the activation of organic substrates in stoichiometric and catalytic reactions.[1] Furthermore, they might represent a source for the preparation of highly dispersed metals on inorganic supports.[2] The development of new syntheses designed to produce stable heterometallic compounds is therefore worthwhile.

Actually, in the case of the synthesis of heterobimetallic complexes, all the possible combinations of metallic fragments bearing carbonyl and/or cyclopentadienyl ligands have been explored. Consequentely, a plethora of 34 electron heterobimetallic compounds has been obtained, mainly by Vahrenkamp[3] in the case of neutral complexes and by Ruff[4] in the case of ionic ones. Considering only first row Group VIII metals the following heterobimetallic complexes have been characterized: FeCo(CO)₆(η-C₅H₅),[5] FeNi(CO)₃(η-C₅H₅)₂,[6] CoNi(CO)₅-(η-C₅H₅)[5] and [FeCo(CO)₈⁻].[4]

So far, however, there have been few reports which have dealt with their reactivity toward unsaturated hydrocarbons. In principle an acetylenic moiety should be able to replace two CO groups in each of these complexes leading to the tetrahedral M₂C₂ structural framework, schematically represented below, already found in the corresponding

homobimetallic compounds: $Fe_2(CO)_6$(μ-C₂Bu₂') (which formally has an Fe–Fe double bond)[7], $Co_2(CO)_6$(μ-C₂R₂)[8] and Ni₂(η-C₅H₅)₂(μ-C₂R₂).[9]
The heterobimetallic acetylenic complex [(CO₃Co–Ni(η-C₅H₅)](μ-C₂R₂) has been recently isolated from both the reaction of Ni(η-C₅H₅)₂(μ-C₂R₂) with $Co_2(CO)_8$ and the reaction of $Co_2(CO)_6$(μ-C₂R₂) with [Ni(CO)(η-C₅H₅)]₂.[10,11] Its solid state structure confirmed the expected pseudo-tetrahedral M₂C₂ framework.[10] On the contrary in 1963 Bassett,[12] in an attempt to prepare an acetylenic iron–nickel complex, observed only disproportionation:

2 FeNi(CO)₃(η-C₅H₅)₂ + RC≡CR→[Fe(CO)₂(η-C₅H₅)]₂ Ni₂(η-C₅H₅)₂(μ-C₂R₂).
A quite different synthetic route was employed by Yasufuku et al.[13] who carried out the reaction of an ethynyltriphenylphosphonium salt with (η-C₅H₅)₂Ni and Fe₂(CO)₉ obtaining the complex [(CO)₃Fe–Ni(η-C₅H₅)]-(μ-Ph₃PC₂H), formulated as an internal salt, in which the functionalized alkyne formally acts as a 5e-donor.

During our previous studies of the reactions of alkynes

with cobalt and iron carbonyls,[14] we found that the homobimetallic complex, $Co_2(CO)_6(EtC_2CHOHMe)$ (Ia) (formed *in situ* by oxygen incorporation from water present in the solvent) reacted further with excess $Fe(CO)_5$ to give the heterobimetallic compound $FeCo(CO)_6(MeHCC_2Et)$ (IIa). This reaction offers further evidence of the dehydroxylation ability of iron carbonyls toward unsaturated alcohols. With the aim of testing the validity of this method in synthesizing novel mixed iron-cobalt derivatives, we have carried out the reactions of $Fe(CO)_5$ with $Co_2(CO)_6(\mu$-acetylene) complexes, bearing one or two hydroxyl group α to the triple bond. In this way several $FeCo(CO)_6(\mu$-alkynyl) complexes have been obtained and spectroscopic analysis has unambiguously established their structure.

EXPERIMENTAL

Reactants and physical measurements

All reactions were carried out under nitrogen. $Co_2(CO)_8$ and $Fe(CO)_5$ were purchased from Fluorochem Ltd., 2-butyn-1-ol, 2-butyn-1, 4-diol and 2, 5-dimethyl-3-hexyn-2, 5-diol were from Farchan Division. $Co_2(CO)_6(MeC_2CH_2OH)$ (Ib), $Co_2(CO)_6(HOCH_2C_2CH_2OH)$ (Ic) and $Co_2(CO)_6$-$(HOMe_2CC_2CMe_2OH)$ (Id) complexes were synthesized using $Co_2(CO)_8$ and the corresponding alkyne according to previously reported procedures.[16] The purity of these compounds was checked by IR and MS spectroscopy, ^{13}CO (94.3%) was obtained from Monsanto Res. Corp. The heterobimetallic complexes were analyzed by use of a F & M 185 C, H, N analyzer and a Perkin–Elmer 303 Atomic Absorption Spectrophotometer. The IR spectra were recorded on a Perkin–Elmer 580 B instrument using 0.5 mm NaCl cells. The mass spectra were measured on a Hitachi Perkin–Elmer RMU-6H spectrometer. ^1H and ^{13}C NMR spectra were recorded on a Jeol C60-HL and a Jeol-PS-100-FT instruments respectively. Chemical shifts were reported downfield positive with respect to SiMe₄. $Cr(acac)_3 (\simeq 10^{-3} M)$ was added as a shiftless relaxation agent for the ^{13}C NMR measurements. The temperature was monitored by a Jeol-JNM-BT-P-5-H-100E temperature control unit. The physical properties, analytical data, IR spectra for the complexes are listed in Table 1; ^1H and ^{13}C NMR data in Table 2.

Preparation of $FeCo(CO)_6(H_2CC_2CH_3)$ (IIb)

In a typical run 1.0 g (2.7 mmol) of $Co_2(CO)_6(HOH_2CC_2CH_3)$ (Ib) and 2.0 ml (14.4 mmol) of $Fe(CO)_5$ were refluxed in 200 cm³ of acetone for 10 hr. After cooling and filtration the excess of $Fe(CO)_5$ and the solvent were removed *in vacuo* and the residue dissolved in dichloromethane and chromatographed on tlc preparative plates (Kieselgel P. F. Merck, eluant light petroleum and 10% diethyl ether). Besides unreacted Ia ($\simeq 20\%$) and a small amount of $Fe_3(CO)_{12}$, $FeCo(CO)_6(H_2CC_2CH_3)$ (IIb), ($\simeq 40\%$) was eluted. Mass spectrum m/e 336 [M⁺], followed by loss of six carbonyl groups.

Preparation of $FeCo(CO)_6(H_2CC_2CH_2OH)$ (IIc)

Ic and $Fe(CO)_5$ in the above ratio were refluxed in acetone for 10 hr. The same separation procedure afforded unreacted Ic ($\simeq 25\%$), small amount of $Fe_3(CO)_{12}$, $Fe_2(CO)_6(H_2CC_2CH_2)$ (IIIc) ($\simeq 5\%$) and $FeCo(CO)_6(H_2CC_2CH_2OH)$ (IIc), ($\simeq 25\%$). Mass spectrum m/e 352 [M⁺] followed by loss of six carbonyl groups and concomitant loss of H_2O.

Preparation of $FeCo(CO)_6(HMeCC_2CMe_2OH)$ (IId)

Id and $Fe(CO)_5$ reacted in the same conditions to afford unreacted Id ($\simeq 15\%$), small amount of $Fe_3(CO)_{12}$, $Fe_2(CO)_6(Me_2CC_2CMe_2)$ (IIId) ($\simeq 35\%$) and $FeCo(CO)_6(Me_2CC_2CMe_2OH)$ (IId) ($\simeq 25\%$). Mass spectrum m/e 408 [M⁺] followed by loss of six carbonyl groups and concomitant loss of H_2O.

Isotopic enrichment of IIc *and* IId

0.2 g of complex (IIc or IId) were dissolved in 100 cm³ of

cyclohexane and stirred for 4 days at $+40°C$ in the presence of <1 Atmosphere of ^{13}CO. Further purification on a SiO_2 column using light petroleum with 20% $CHCl_3$ as eluant was carried out before running the spectra.

Preparation of $FeCo(CO)_5(PPh_3)(H_2CC_2CH_2OH)$ (IVc)

1.0 g (2.8 mmol) of IIc was dissolved in 100 cm³ of acetone and added with 0.73 g (2.8 mmol) of PPh_3. The mixture was refluxed for 20 hr. After cooling and filtration, the solvent was removed under vacuum and the residue dissolved in CH_2Cl_2 and chromatographed on tlc (eluant light petroleum and 20% $CHCl_3$). Unreacted IIc ($\simeq 25\%$) and $FeCo(CO)_5(PPh_3)(H_2CC_2CH_2OH)$ (IVc) ($\simeq 40\%$) have been eluted.

Crystallographic data collection of IVc

Red-orange crystals of IVc were grown by slow cooling of a saturated solution of IVc in n-heptane, chloroform 2:1 mixture under N_2 atmosphere. A very thin crystal was used for the X-ray analysis. Crystal data are as follows: $C_{27}H_{20}FeCoO_6P$, M = 586.21, $a = 10.505(8)$, $b = 12.787(12)$, $c = 10.477(9)$ Å, $\alpha = 111.13(6)$, $\beta = 105.25(6)$, $\gamma = 84.60(7)°$, $U = 1266$ Å³, $Z = 2$, $D_c = 1.54$ g/cm³, space group $P\bar{1}$.

The intensities of 1949 reflections with θ in the range 3–22° were measured on a Siemens AED diffractometer (using the Nb-filtered Mo-K α radiation), but only 519, having $I \ge 2$ $\sigma(I)$ were considered observed and used in the analysis. The structure was solved by Patterson and Fourier methods, but the limited number of the observed reflections and the poor quality of them prevented a satisfactory refinement of the structure.

RESULTS AND DISCUSSION

Although all the reactions were performed in identical conditions, higher yields of the heterobimetallic complexes (II) were obtained from the alkyneol reactants (Ia, Ib) than from the alkynediols (Ic, Id). This is due to successive dehydroxylation and ligand transfer to Fe, which lead to the well known butatriene derivatives (IIIc, IIId) as shown in the following scheme:

$Co_2(CO)_6(HOR_2C-C\equiv C-R')$ [Ia, Ib]

$+ Fe(CO)_5$ $\Big\downarrow$ $-OH$

$FeCo(CO)_6(R_2C-C\equiv C-R')$ [IIa, IIb]

$Co_2(CO)_6(HOR_2C-C\equiv C-CR_2OH)$ [Ic, Id]

$+ Fe(CO)_5$ $\Big\downarrow$ $-OH$

$FeCo(CO)_6(R_2C-C\equiv C-CR_2OH)$ [IIc, IId]

$+ Fe(CO)_5$ $\Big\downarrow$ $-OH$

$Fe_2(CO)_6(R_2C=C=C=CR_2)$ [IIIc, IIId]
The heterobimetallic compounds are quite stable in the solid state under N_2 atmosphere, but they smoothly decompose in solution. They all have similar IR spectra (see Table 1), the slight shifts observed for the CO stretching frequencies can be related to the different electronic properties of the sustituents (H, Me, Et, OH). In the complexes IIc and IId the presence of the –OH group is confirmed by weak absorptions near 3600 cm⁻¹, which can be observed in concentrated CCl_4 solution.

Also their MS characteristics are very similar and strongly resemble those of the $Co_2(CO)_6(\mu$-alkyne)

Fig. 1. Structures of the homometallic complexes (I) and (III) and proposed structure of the heterobimetallic complex (II).

FeCo(CO)$_6$(MeCC$_2$CMe$_2$OH) (**IId**) shows four methyl resonances (see Table 2); as the temperature is increased the two lowfield signals broaden and merge into a new resonance at +45°C ($\Delta G^{\ddagger}$ = 74.4 kJ/mol) and on this basis we assign the two lowfield peaks to the –CMe$_2$OH group. This dynamic process has to be related to a partially hindered rotation around the ≡C–CMe$_2$OH bond. Similar arguments were used to assign the resonances in the other compounds prepared here. The ^{13}C NMR spectra of the title compounds are quite similar: of the two quaternary acetylenic carbon resonances one is found in the spectral region typical of the Co$_2$(CO)$_6$(μ-alkyne) complexes[18] and one in a lower field region (117.6–123.7 ppm) of the spectrum, which is assigned to the acetylenic carbon bonded to the carbon σ interacting with the iron atom. This low field shift is indicative of a change from sp to sp^2 hybridisation and suggests a delocalized bonding framework for the $\mu_2 - \eta^3$ system. In Fig. 1 are shown the structures of Co$_2$(CO)$_6$(μ-alkyne)[8] (**I**) and Fe$_2$(CO)$_6$(μ-butatriene)[19] (**III**) co-plexes together with the proposed structure of the title compounds (**II**). Complexes I, II and III are isoelectronic: two, three and four carbon atoms are engaged in the bonding scheme with the bimetallic fragment and the organic chain acts as a four-, five- and six-electron donor.

Although the chemical and spectroscopic evidence strongly support the proposed structure (**II**), several attempts were made to confirm it by X-ray analyses. However all were unsuccessful. In order to overcome crystallization problems the FeCo(CO)$_5$(PPh)-(R$_2$CC$_2$CR') derivatives were synthesized. The best result was achieved for R=H, R'=CH$_2$OH (**IVc**), though also in this case the quality of the crystals was poor and the crystals were twinned. An accurate structure determination was thus impossible, but the most significant features of the molecular structure could be extracted. The proposed structure, shown in Fig. 2, is in agreement with that proposed on the basis of the spectroscopic data (**II**). The organic ligand is σ-bonded to the Fe atom through the terminal C(6) carbon and η^2-interacts with both the metal atoms (Fe–Co distance: 2.55 Å) via the C(7)–C(8) bond. The triphenylphosphine group has substituted one carbonyl in an apical position on the cobalt atom. Similar regiospecific substitution of the phosphine for CO group in Co$_2$(CO)$_5$(PR$_3$)(μ-alkyne)

compounds.[1] It is interesting to note the relatively high abundance of the fragment corresponding to the [FeCoC$_3$H$_3$]$^+$ ion. Analogous [Co$_2$C$_3$H$_n$]$^+$ fragments have not been observed in the MS spectra of the Co$_2$(CO)$_6$(μ-C$_2$R$_2$) complexes. This supports the view that the heterobimetallic moiety is bonded to three carbon atoms of the organic chain. The high stability of the Fe–Co bond is suggested from the presence of 50–80% [FeCo]$^+$ ions in all the spectra. For **IIc** and **IId** the presence of the -OH group is further corroborated by the observation of a fragment ion which constitutes loss of H$_2$O from [M$^+$].

The assignment of the ^{1}H NMR signals of FeCo(CO)$_6$(H$_2$CC$_2$CH$_3$) (**IIb**) is straightforward: the methylene group appears as two broad singlets of relative intensity 1 at δ 3.98 and 3.93 respectively, the methyl group as a singlet of intensity 3 at δ 2.69. This pattern remains unchanged as the temperature is increased up to +80°C; above this temperature decomposition of sample is observed. The room temperature ^{1}H NMR spectrum of

Fig. 2. Proposed molecular shape of the compound FeCo(CO)$_5$(PPh$_3$) (H$_2$CC$_2$CH$_2$OH) (IVc).

derivatives has been reported on the basis of IR[20] and ^{13}C NMR[18] data. The poor accuracy of the structural parameters hampers a detailed discussion of the molecular structure. The J_{CH} values in the ^{13}C NMR spectrum of $FeCo(CO)_6(H_2CC_2CH_2OH)$ (IIc) also supports this picture. In the proton-coupled spectrum two triplets are observed at δ 62.8 and 69.2. The first shows J_{CH} = 142 Hz consistent with an sp^3 carbon bearing an electron withdrawing substituent ($HO-CH_2$), while the second shows J_{CH} = 161 Hz, suggesting a partial rehybridation towards an sp^2 character ($Fe-CH_2$). Similar features are observed for the corresponding monophosphine derivative (IVc) (see Table 2).

In conclusion, we feel that the structure of the title compounds (II) can be envisaged as the result of building up two halves obtained by dividing along the organic chain and the metal–metal bond the two homometallic compounds (I) and (III).

Dynamic behaviour

All the ^{13}C NMR spectra of the title complexes show two sets of CO absorptions at room temperature: the sharp Fe–CO resonances lie in the range 211.5–209.0 ppm, the very broad Co–CO resonances in the 207.6–201.0 ppm region. This assignment is consistent with previous observations of mixed iron-cobalt clusters, showing that the COs bonded to Fe resonate at lower field than the Co bonded ones.[21] In the VT ^{13}C NMR studies of [13]CO enriched samples of IIc and IId, lowering of temperature to −80°C results in a progressive sharpening of the Co–CO resonances. It then follows that the broadening observed in room temperature spectra is only due to the moderately rapid quadrupolar relaxation induced by the Co nuclei (I = 7/2). On the other hand, in the same temperature range the Fe–CO resonance splits into three peaks of relative intensity ratio 1 : 1 : 1, whose weighted average chemical shifts are in good accord with the room temperature value (IIc, −50°C, FeCO: 212.4, 210.3, 205.6; IId, −60°C, FeCO: 211.9, 209.4, 206.7).

At room temperature the carbonyls are locally exchanging at each "M(CO)₃" unit, but only the scrambling at Fe(CO)₃ can be frozen in the low temperature limiting spectrum. On the contrary the room temperature ^{13}C NMR spectrum of IVc shows three CO absorptions, one sharp at δ = 211.5 and two very broad at δ = 207.6 and 205.5 of relative intensity ratio 3 : 1 : 1. It follows that the presence of the bulky triphenylphosphine group

quenches, even at room temperature, the localized exchanged process at the Co(CO)₂ unit. Owing to the broadening of these two resonances, no J_{CP} could be extracted.

SYNTHESIS OF TWO DIBENZO-3, 2, 3-TETRAMINES AND THEIR Ni(II), Zn(II) and Cd(II) COMPLEXES. THE X-RAY STRUCTURE OF DIIODO-[2, 3:10, 11-DIBENZO-1, 5, 8, 12-TETRAAZADODECANE]CADMIUM(II)

CHRISTOPHER W. G. ANSELL,* MARY McPARTLIN, PETER A. TASKER
and ANTOINETTE THAMBYTHURAI

School of Chemistry, The Polytechnic of North London, Holloway Road, London N7 8DB, England

Abstract—Convenient syntheses of the tetramines 2, 3:10, 11-dibenzo-1, 5, 8, 12-tetraazadodecane, (L1), and 3, 4:9, 10-dibenzo-1, 5, 8, 12-tetraazadodecane, (L2), are described. Both ligands form complexes with Ni(II), Zn(II) and Cd(II). The X-ray structure of [Cd(L1)I$_2$], confirms a five coordinate geometry for the Cd atom, where the two iodines are bonded to the metal and (L1) acts as a tridentate ligand. The complex crystallises in the monoclinic space group P2$_1$/c with $a = 19.741(4)$ Å, $b = 8.726(3)$ Å, $c = 12.221(4)$ Å, and $\beta = 104.55(3)°$. The structure was refined to R = 0.062 for 1051 reflections.

INTRODUCTION

Recently[1], macrocyclic species of the type (1) below have been extensively studied in this laboratory with a view to establishing the electrochemical properties of their divalent metal complexes and the coordinative selectivity of the ligand system towards a range of metal ions.

(1)

$R = -(CH_2)_2-, -(CH_2)_3-, -(CH_2)_4-$
As an extension to this work, we here report convenient synthetic routes to the known[2] tetramine 2, 3:10, 11-dibenzo-1, 5, 8, 12-tetraazadodecane, (L1), and to the related ligand 3, 4:9, 10-dibenzo-1, 5, 8, 12-tetraazadodecane, (L2). Both species may be regarded as open chain analogues of the systems (1). The preliminary results of complexation reactions of the ligands are also presented, together with the X-ray structure of [Cd(L1)I$_2$].

RESULTS AND DISCUSSION

Scheme 1 outlines the synthetic route to the tetramines (L1) and (L2). Refluxing methyl anthranilate and ethylenediamine together for 3 days yields the diamide (2) as white plates after recrystallisation. Reduction with LiAlH$_4$ in diethyl ether gives (L1) in 75% yield. Mixing 2:1 quantities of anthranilonitrile with oxalyl chloride in diethyl ether gives an immediate white precipitate of (3) in 93% yield. Reduction of all four func-

tional groups by LiAlH$_4$ to give (L2) is accomplished readily and in 85% yield. Both (L1) and (L2) are pale yellow oils which, as has been observed in their aliphatic analogues[3], from solid hydrated species in moist air. Both readily form crystalline salts of stoichiometry L.2HX and L.4HX, where X = Cl$^-$ or ClO$_4^-$. In confirmation of the reported[2] instability of L1.4HX in aqueous media, it was found that both L1.2HX and L2.2HX could be readily isolated from aqueous solutions of the tetra-acid salt.

(L1) and (L2) both from complexes with Ni(II), Zn(II) and Cd(II), (see Table 1). Reaction of a 1:1 mixture of Ni(ClO$_4$)$_2$.6H$_2$O and either (L1) or (L2) in methanol gives a blue-green solution which, upon treatment with excess NH$_4$NCS deposits mauve precipitates of [Ni(L1 or L2)NCS$_2$]. νNCS occurs as a single sharp band at 2100 cm^{-1} in their infrared spectra, which is consistent[4] with N-bonded thiocyanate in a single environment. This observation, taken with the magnetic moments of 3.22 and 3.23 BM for the Ni(II) complexes of (L1) and (L2) respectively, the similarity of the ligands and the analy-

tically confirmed stiochiometries points to a *trans*-octa-hedral geometry for the nickel atom in both complexes, with the tetramine occupying the equatorial donor sites.

Reaction of ZnI₂ and CdI₂ in methanol with (L1) and (L2) gave good yields of the corresponding metal complexes [M(L1 or L2)I₂]. Crystals of the complex [Cd(L1)I₂] could be obtained from methanol and the X-ray structure of this species was undertaken. Figure 1 is a diagram of the complex, showing the numbering scheme. Hydrogen atoms have been omitted for clarity. The five coordinate geometry of the cadmium atom is immediately apparent. (L1) acts as a tridentate ligand via the anilino–nitrogen donor N(2a) and both aliphatic nitrogens N(1a) and N(1b). The two bonded iodines occupy the remaining sites. Severe disorder was apparent for the phenyl ring incorporating the uncomplexed –NH₂ group, but the essentials of the stereochemistry around the metal ion are nonetheless established. The geometry of the donors around the cadmium is best described as a distorted square based pyramid, with N(1a), N(2a), N(1b) and I(1) defining the base and I(2) in the apical position. The constituent atoms of the base are coplanar to within 0.24 Å, and the Cd atom is located 0.68 Å above their least squares plane towards the iodine I(2). The bond lengths between the Cd atom and the nitrogen donors are all close to 2.4 Å and are similar to those reported[5] in other five coordinate cadmium diiodide species containing tridentate polyamines. The bond lengths between Cd and I(1), and Cd and I(2) (2.795(3) Å and 2.791(3) Å) are in the range previously reported[6] for Cd–I bonds. More details of the environment of the metal ion are given in the caption to Fig. 1.

EXPERIMENTAL

2, 3 : 10, 11-*Dibenzo*-1, 5, 8, 12-*tetraazadodecane*-4, 9-*dione*, (2)

Ethylenediamine (7 cm³, 105 mmol) and methyl anthranilate (50 cm³, 387 mmol) were refluxed together for three days. The mixture solidified on cooling and was washed with portions of ethanol. The white residue was recrystallised from a 1 : 1 mixture of methanol and chloroform (500 cm³) to give the title diamide (2) (8.0 g, 25%) as white plates, m.p. 246–8°. Mass spectrum: 298 (M+) expected: 298. Principal IR bands (KBr disc) 3480(s), 3375(s), 3300(s, b), 1630(s, b), 1582(s).

2, 3 : 10, 11-*dibenzo*-1, 5, 8, 12-*tetraazadodecane*, (L1)

Lithium aluminium hydride (2.9 g, 77 mmol) was added to dry ether contained in a 2 dm³ 3-necked flask fitted with a sealed mechanical stirrer and a Soxhlet extractor and condenser. (2) (3.7 g, 12.4 mmol) was placed in a thimble in the Soxhlet extractor. The ether was refluxed gently in a heating mantle, and after 16 hr. all the solid had been introduced to the flask. The mixture was treated sequentially with water (3 cm³), 15% sodium hydroxide solution (3 cm³), and water (8.5 cm³). The mixture was filtered and the residue washed with ether. The combined filtrates were dried over magnesium sulphate and evaporated to give the product as a pale yellow oil (2.5 g, 75%). NMR(CDCl₃):2.68 σ (methylene, singlet) 3.0–3.7 σ (NH, broad, complex) 3.28 σ (NH, singlet) 3.71 δ (benzyl methylene, singlet) 6.4–7.3 δ (aromatics, complex). Addition of D₂O causes collapse of the signals at 3.28 and 3.0–3.7 δ. Mass spectrum: 270(M+); expected:270.

2, 2'-(oxalyldiimino)bis(o-benzonitrile), (3)

Anthranilonitrile (12.5 g, 0.1 mol) was dissolved in dry ether (150 cm³). Oxalyl chloride (6.2 g, 0.05 mol) was added slowly
Fig. 1. The molecular structure of [Cd(L1)I₂]. Principal bond lengths and angles are: Cd–I(1) 2.795(3), Cd–I(2) 2.791(3), Cd–N(2a) 2.398(21), Cd–N(1a) 2.366(21), Cd–N(1b) 2.384(23)Å. I(2)–Cd–I(1) 106.5(1), N(2a)–Cd–I(1) 94.8(6), N(2a)–Cd–I(2) 112.6(6), N(1a)–Cd–I(1) 158.1(6), N(1a)–Cd–I(2) 95.2(6), N(1a)–Cd–N(2a) 79.1(8), N(1b)–Cd–I(1) 95.1(6). N(1b)–Cd–I(2) 108.3(6), N(1b)–Cd–N(2a) 132.9(8), N(1b)–Cd–N(1a) 74.8(8).

dropwise with vigorous stirring. The white precipitate of (3) was filtered, washed copiously with methanol and ether and dried *in vacuo*. Yield 14.3 g, 93%. The nmr spectrum of this compound could not be obtained due to its extreme insolubility. Principal IR bands(Nujol): 3320(s), 2250(s), 1700(s), 1620(m), 1600(m). Mass spectrum: 266(M+). Expected 266.

3, 4:9, 10-*dibenzo*-1, 5, 8, 12-*tetraazadodecane* (L2)

To a suspension of LiAlH₄ (5.2 g) in dry ether (500 cm³) in a 1 dm³ flask fitted with a reflux condenser was added in portions over twenty minutes (3) (10.0 g, 0.035 mol). The reaction mixture became yellow/green. After 12 hr under reflux the colour had faded, and the mixture was treated carefully and sequentially with water (5 cm³), 15% sodium hydroxide solution (5 cm³) and water (15 cm³). The basic hydroxides left after filtration were extracted three times with dichloromethane (200 cm³) and the combined extracts and filtrate evaporated after drying over MgSO₄ to give (L2) (8.9 g, 85%) as a pale yellow oil. Principal IR(Nujol): 3350(m), 3250(m), 1620(s), 1600(s). NMR: (CDCl₃): 3.43 δ (methylene, singlet) 3.84 δ (methylene, singlet) 2.0–3.0 δ (broad, NH) 6.4–7.3 δ (aromatics, complex). Addition of D₂O

†Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

causes collapse of the signal 2.0–3.0 δ. Mass spectrum: 270(M+) expected: 270.

Salts of the tetramines

To a solution of the ligand (L1 or L2) in 1:1 dichloromethane: methanol was added an excess of either conc; HCl or HClO₄. The tetraacid salts precipitated on standing. The corresponding diacid salt could be obtained by treatment of an aqueous solution of the tetraacid salt with NEt₃ until precipitation was complete. The yields for both procedures are quantitative.

[Ni(*L1 or L2*) (*NCS*)₂]

Nickel(II) perchlorate hexahydrate (1.11 g, 3 mmol) was added to a hot solution of (L1) or (L2) (0.81 g, 3 mmol) in methanol and the blue–green solution stirred for 5 min. Ammonium thiocyanate (1.0 g, excess) was then added to precipitate the di(thiocyanato) complexes as mauve microcrystalline powders, yield 1.09 g, 82%.

[*M(L1 or L2)I₂*]*M* = Zn, Cd

0.15 Millimolar quantities of Metal(II) iodide and tetramine were mixed in warm methanol (30 cm³). On standing and cooling, analytically pure samples of the complexes were deposited. For the complexes of (L1), crystals of X-ray quality could be grown from methanol. The yields in the syntheses were greater than 65% in each case.

X-ray crystal structure

Crystal data: [C₁₆H₂₂N₄CdI₂]. M = 636.2, monoclinic, space group P2₁/c, a = 19.741(4) Å, b = 8.726(3) Å, c = 12.221(4) Å, β = 104.55(3)°, U = 2037.7 Å³, Z = 4. F(000) = 1200, μ(mo–Kα) = 38.23 cm⁻¹. Cc = 2.07 gcm⁻³. R = 0.062, Rw = 0.065 for 1051 unique intensity data, F > 6(σ)F.

The X-ray data were collected as previously described.[7] The cadmium and both iodine atoms were located from a Patterson map and all remaining non-hydrogen atoms from subsequent difference maps. Anisotropic thermal parameters were assigned to the cadmium and both iodines. Hydrogen atoms were not located directly but constrained to lie 0.95 Å from the parent carbon atom. A severe disorder was apparent for the phenyl ring containing the uncoordinated amino group. This disorder could not be satisfactorily resolved. N(2b) and C(7b) were fixed at the positions found in the difference map and the disordered phenyl ring refined as a regular hexagon of C–C bond distance 1.395 Å. Hydrogen atoms were not included on the disordered ring, N(2b) or C(7b). Neutral atom scattering factors were taken from reference 8. All crystallographic calculations were performed using SHELX.[9] Final atomic coordinates, bond lengths and angles together with tables of Fo/Fc have been deposited as supplementary material with the editor, from whom copies are available on request.†

ELECTROCHEMICAL REDUCTION OF DIALKYLAMIDE AND BIS-TRIMETHYLSILYLAMIDO COMPLEXES OF CHROMIUM(III) AND YTTERBIUM IN NON-AQUEOUS SOLVENTS

D. C. BRADLEY* and MUSHTAQ AHMED

Department of Chemistry, Queen Mary College, Mile End Road, London E1 4NS, England

Abstract—The electrochemical reductions of (a) $Cr[N(SiMe_3)_2]_3$, $Cr(NPr_2^i)_3$, $Cr(NO)[N(SiMe_3)_2]_3$, $Cr(NO)(NPr_2^i)_3$ and $Cr(NO)(OBu^t)_2(NPr_2^i)$ in acetonitrile, and (b) $Yb[N(SiMe_3)_2]_3$ in dimethylsulphoxide, have been studied using cyclic voltammetry (platinum bead electrode) and controlled potential coulometry (mercury pool electrode). The results are interpreted in terms of quasi-reversible or irreversible one-electron reduction and possible side-reactions. A number of similar complexes of titanium, vanadium, manganese, iron and cobalt were investigated but electrochemical studies were precluded due to reactions with solvent and/or supporting electrolyte.

INTRODUCTION

The synthesis of the metal dialkylamides $M(NR_2)_x$ and *bis*-trimethylsilyamides ($R = Me_3Si$) and their characterization by spectroscopic and X-ray crystallographic studies have revealed considerable details concerning their structure and chemical reactivity[1,2]. In particular it has been shown that by using particularly bulky ligands, the transition metals, lanthanides and actinides may be constrained to abnormally low coordination numbers and some unusual chemical reactivity. To gain further insight into the chemical behaviour of some of these compounds, we have explored their electrochemical behaviour in non-aqueous solvents. It was hoped that these studies would reveal reversible electrochemical processes from which useful data on the relative stability of different oxidation states could be deduced. It was further hoped that the results might point the way to novel methods of synthesis of new complexes which are not amenable to isolation using conventional procedures.

Since derivatives of titanium(IV and III), chromium(III and II) and cobalt(II and I) were known exhibiting two consecutive valence states, some of their compounds were selected for study. In addition it was considered worthwhile to investigate the *tris*-silylamides of iron and ytterbium.

RESULTS AND DISCUSSION

Although extensive studies were carried out in various non-aqueous solvents on a large number of compounds, meaningful results were obtained only on some chromium compounds in acetonitrile and ytterbium *tris*-silylamide in dimethylsulphoxide. Attempts were made to establish the electrochemical behaviour of these metal dialkylamides by studying Cyclic Voltammetry at a platinum bead electrode and by Controlled Potential Electrolysis at a mercury pool electrode.

(a) Cyclic voltammetry

The experiments were carried out at various voltage scan rates on dilute solutions of the metal dialkylamide

(0.2–1.0 millimolar) in acetonitrile with tetraethylammonium tetrafluoroborate (0.1 M) as supporting electrolyte. In Fig. 1 are shown the cyclic voltammograms of $Cr[N(SiMe_3)_2]_3$ and $Cr(NPr_2^i)_3$ with the behaviour of the supporting electrolyte alone for comparison. The chromium compounds each showed a main reduction wave which was quasi-reversible or irreversible. At very slow scan rates a small peak at $+0.10$ V appeared after the anodic peak of the main reduction wave and this suggested that a product of the quasi-reversible or irreversible electron transfer processes was being oxidized. Bearing in mind the chemical reactivity of these metal complexes it was considered necessary to demonstrate their stability under these electrochemical conditions. Thus the peak current for $Cr[N(SiMe_3)_2]_3$ was found to be unchanged over a five day period giving confidence to the reliability of the results. Some comparative data on peak potentials (Ep) at the same voltage scan rate are listed in Table 1 for $Cr[N(SiMe_3)_2]_3$, $Cr(NO)[N(SiMe_3)_2]_3$, $Cr(NPr_2^i)_3$, $Cr(NO)(NPr_2^i)_3$ and $Cr(NO)(OBu^t)_2(NPr_2^i)$. Unfortunately the lack of true reversibility limits the scope for discussion of these data, but it is clear that the di-isopropylamido-complexes have slightly lower reduction potentials than the *bis*-trimethylsilylamido-complexes whilst the addition of nitric oxide appears to make only a small change in the peak potentials.

Data obtained for each compound over a 40-fold range in voltage scan rate (0.0125–0.5 V/sec) are presented in Tables 2–6 and give some indication of the electrochemical behaviour of each complex. Thus it appears that the peak current (ip_c) was approximately proportional to the square root of the voltage scan rate. The "best-behaved" compounds were $Cr(NPr_2^i)_3$, and $Cr(NO)(NPr_2^i)_3$ which showed peak potentials almost invariant with voltage scan rate in contrast with the behaviour of the chromium silylamide complexes.

The ytterbium *tris*-silylamide $Yb[N(SiMe_3)_2]_3$ gave reproducible and reliable cyclic voltammograms in dimethylsulphoxide solution (Fig. 2) using sodium perchlorate as supporting electrolyte. One main reduction peak was obtained and the peak potentials were almost independent of voltage scan rate (Table 7). The stability of the ytterbium complex in dimethylsulphoxide solution was

  voltage scan rate of 0.1 volts/sec., vs. $Ag/AgClO_4$. Potentials ± 0.004 v.

confirmed by finding that the peak current remained constant over a 5-day period.

(b) *Controlled potential electrolysis*

Using a mercury-pool electrode, constant potential coulometry was carried out at -1.00 V (vs $Ag/AgClO_4$ electrode) on solutions of $Cr[N(SiMe_3)_2]_3$, $Cr(NPr^i_2)_3$, and $Cr(NO)(OBu^t)_2(NPr^i_2)$ in acetonitrile. The results (Table 8) showed that only $Cr(NPr^i_2)_3$ gave quantitative reduction whilst the electrolysis of the other compounds was accompanied by other reactions. Moreover it was noted in the electrolysis of $Cr(NPr^i_2)_3$ under controlled potential that the current rapidly declined to zero and the colour of the solution was discharged. Similarly the controlled potential electrolysis of $Yb[N(SiMe_3)_2]_3$ in dimethylsulphoxide at -1.20 V (vs $Ag/AgClO_4$ electrode) gave quantitative reduction (Table 8) with the current rapidly declining to zero with rapid discharge of the colour of the solution.

The above results suggest that one-electron reductions

have occurred but that only in $Cr(NPr^i_2)_3$, $Yb[N(SiMe_3)_2]_3$ and probably $Cr(NO)(NPr^i_2)_3$ is there quasi-reversibility.

Before discussing this interesting electrochemical behaviour of these low coordination complexes of chromium it is useful to review some of their chemistry. Both $Cr[N(SiMe_3)_2]_3$ and $Cr(NPr^i_2)_3$ were shown to be monomeric 3-coordinated paramagnetic Cr(III) complexes with interesting X-ray structures[3-5] and electronic configurations as deduced from spectroscopic studies.[6-8] They do not form addition compounds with neutral ligands such as THF but react more or less readily with water, oxygen, nitric oxide, carbon dioxide and carbon–disulphide. The *tris*-di-isopropylamide is extremely sensitive to dioxygen and it is difficult to prepare a dilute solution free from the blue coloured initial product of oxygenation which gives an intense characteristic ESR signal.[9] The reaction with nitric oxide gave the considerably more stable diamagnetic mono-nitrosyls $Cr(NO)(NR_2)_3$ (R = $SiMe_3$ or Pr^i) in which the chromium is tetrahedrally coordinated.[10] The linear CrNO systems and diamag-

[c] Electrolysis at -1.20 volts $(Ag/AgClO_4)$ in Me_2SO at 25°C using 0.4M $NaClO_4$ supporting electrolyte.

netism suggested that the low-spin electronic structure corresponded to a pseudo-Cr(II) $3d^4$ complex due to the NO acting as a 3-electron donor. By contrast the truly bivalent complex $Cr[N(SiMe_3)_2]_2(THF)_2$ was isolated as an extraordinarily oxygen-sensitive paramagnetic square planar (trans) compound with the high spin $3d^4$ configuration.[11]

It seemed reasonable to expect that the electrochemical reduction of $Cr(NR_2)_3$ ($R = SiMe_3$ or Pr^i) might give rise to a reversible 1-electron transfer involving the formation of an unstable 3-coordinate Cr(II) anion $[Cr(NR_2)_3]^-$.

$$Cr(NR_2)_3 + e \rightleftharpoons [Cr(NR_2)_3]^-. \qquad (1)$$

Since the solvent CH_3CN is potentially a donor ligand the unstable anion might then react by forming either a neutral high spin square planar complex $Cr(NR_2)_2(CH_3CN)_2$ or a diamagnetic tetrahedral anion $[Cr(NR_2)_3(CH_3CN)]^-$.

$$[Cr(NR_2)_3]^- + 2CH_3CN \rightleftharpoons Cr(NR_2)_2(CH_3CN)_2 + NR_2^- \qquad (2)$$

$$[Cr(NR_2)_3]^- + CH_3CN \rightleftharpoons [Cr(NR_2)_3(CH_3CN)]^-. \qquad (3)$$
In the first case, the dialkylamide anion NR_2^- released (eq. 2) might react with the solvent leading to irreversible reactions. Metal dialkylamides are known to react with acetonitrile.[12] Additional experiments confirmed that lithium dialkylamides did react with solutions of the supporting electrolyte in acetonitrile. In the anodic phase of the cyclic voltammetry the dialkylamide anion could be oxidized to the radical which could also lead to irreversible reactions.

$$NR_2^- - e \rightarrow NR_2 \qquad (4)$$

$$2NR_2 \rightarrow R_2NNR_2 \qquad (5)$$

$$2NR_2 \rightarrow R_2NH + \text{imine}. \qquad (6)$$

The feasibility of the alternative reaction of $[Cr(NR_2)_3]^-$ with one molecule of CH_3CN (eqn 3) should depend on the ability of one acetonitrile ligand and three dialkylamido groups to promote sufficient splitting of the d-orbital energy levels to produce a stable tetrahedral diamagnetic Cr(II) species.

Dealing first with the electrochemistry of $Cr[N(SiMe_3)_2]_3$ the data in Tables 2 and 8 suggest that the electron-transfer reduction is not wholly reversible but it is not clear what chemical reactions are subsequently involved. The formation of $Cr[N(SiMe_3)_2]_2(CH_3CN)_2$ (eqn 2) analogous to the THF complex would be accompanied by the release of $[N(SiMe_3)_2]^-$ which in the form of its lithium derivative reacts rapidly with the supporting electrolyte in acetonitrile. In assessing the possibility of forming a stable diamagnetic tetrahedral species $Cr[N(SiMe_3)_2]_3(CH_3CN)$ it must be noted that the $3d^5$ complex $Fe[N(SiMe_3)_2]_3$ is high-spin.[8,13] Unfortunately we found that $Fe[N(SiMe_3)_2]_3$ reacted immediately with acetonitrile with decomposition and we could not determine whether it would form a low-spin complex with one molecule of CH_3CN of addition. Although the strong π-acceptor NO^+ does cause spin pairing by coordination with $Cr[N(SiMe_3)_2]_3^-$, it seems that CH_3CN (which is not a good π-acceptor is not capable of producing a stable diamagnetic adduct and thus eqn (2) appears to be favoured relative to (3) for the silylamide complex.

The data in Tables 4 and 8 show that the electrochemical reduction of $Cr(NPr_2^i)_3$ is quasi-reversible and its cyclic voltammogram (C) in Fig. 1 looks much more reversible than that of $Cr[N(SiMe_3)_2]_3$ (B). It also appears that $Cr(NP_2^i)_3$ has a less negative reduction potential than the silylamide. Therefore the reduced species from the di-isopropylamide is more readily formed and is more stable than the corresponding disilylamide complex. Thus if $[Cr(NPr_2^i)_3(CH_3CN)]^-$ (eqn 3) is relatively stable, a more reversible system is expected to occur. It is relevant to note here that in $Cr(NO)(NPr_2^i)_3$ the NO stretching frequency (1643 cm^{-1}) is lower than that in $Cr(NO)[N(SiMe_3)_2]_3$ $(1698 \text{ cm}^{-1})^{[10]}$, which implies greater delocalisation of the two pairs of d-electrons into the π^* antibonding (NO^+) orbitals in the di-isopropylamide complex and presumably greater stability. Therefore it is reasonable to suggest that although CH_3CN is not a strong π-acceptor it would in fact form a more stable adduct with $[Cr(NPr_2^i)_3]^-$ than with $Cr[N(SiMe_3)_2]_3^-$.

Turning now to the electrochemical behaviour of the nitrosyl complexes $Cr(NO)[N(SiMe_3)_2]_3$, $Cr(NO)(NPr_2^i)_3$ and $Cr(NO)(OBu^t)_2(NPr_2^i)$, the data in Tables 3, 5 and 6 show that the peak potential of the silylamido complex varied most with the voltage scan rate whereas the potentials for the tris-di-isopropylamido complex were practically independent of the scan rate. Somewhat surprisingly the data for $Cr(NO)(NR_2)_3 (R = SiMe_3$ and $Pr^i)$ are very close to the values for the parent 3-coordinated species $Cr(NR_2)_3$. Assuming that a one-electron reduction gives the anionic species $[Cr(NO)(NR_2)_3]^-$ the additional electron must be accommodated in a higher energy $3d$-orbital unless there is an electronic rearrangement.

$$Cr(NO)(NR_2)_3 + e \rightleftharpoons [Cr(NO)(NR_2)_3]^-. \qquad (7)$$
The NO could change into a 2-electron donor or it might dissociate or be replaced by acetonitrile (viz. eqns 8 and 9) depending on whether $R = SiMe_3$ or Pr^t.

$$2CH_3CN + [Cr(NO)(NR_2)_3]^- \rightarrow Cr(NR_2)_2(CH_3CN)_2 + NR_2^- + NO \qquad (8)$$

$$CH_3CN + [Cr(NO)(NR_2)_3]^- \rightleftharpoons [Cr(NR_2)_3(CH_3CN)]^- + NO. \qquad (9)$$
Thus the dissociation (eqn 8) might be expected for the silylamide but the di-isopropylamide derivative may retain its nitric oxide as a 2-electron donor in preference to acetonitrile (eqn 9). The electrochemical behaviour of the mixed ligand complex $Cr(NO)(OBu^t)_2(NPr^i)$ is interesting in view of the value of its ν_{NO} 1684 cm^{-1} which is nearer to that of $Cr(NO)[N(SiMe_3)_2]_3$ than to $Cr(NO)(NPr_2^i)_3$.[10] In fact its cyclic voltammetric (Table 6) behaviour was indeed more akin to that of the tris-silylamido complex and its coulometric behaviour (Table 8) showed that the electron transfer reduction process was accompanied by other reactions.

Finally we note that the electrochemical behaviour of $Yb[N(SiMe_3)_2]_3$ in DMSO showed a quasi-reversible 1-electron reduction. A cyclic voltammogram is shown in Fig. 2 and the data in Table 7 show that the peak potentials are almost independent of voltage scan rate. The coulometric data in Table 8 also show that a simple reduction takes place implying considerable stability for the Yb(II) species formed. This is not surprising since the anion $Yb[N(SiMe_3)_2]_3^-$ (eqn 1) would be isoelectronic with the stable neutral lutecium complex $Lu[N(SiMe_3)_2]_3$.[14,15] In

fact the solvent would probably coordinate to give {Yb[N(SiMe₃)₂]₃(DMSO)}⁻ since it has been shown that the lanthanide *tris*-silylamides form stable complexes with phosphine oxides Ln[N(SiMe₃)₂]₃(R₃PO).[16,17]

EXPERIMENTAL

All of the compounds studied, especially the 3-coordinated complexes, are air-sensitive and it was found to be essential to take extremely rigorous precautions in manipulating the dilute solutions used in the electrochemical measurements.

Preparations

The compounds were prepared by using essentially the original methods reported[1,2] and purity was checked by an appropriate physical measurement (i.e. m.p., IR-, NMR- or mass-spectra) and elemental analyses. The following compounds were prepared: $Ti(NEt_2)_4$, $TiCl[N(SiMe_3)_2]_3$, $Ti[N(SiMe_3)_2]_3$, $V[N(SiMe_3)_2]_3$, $Cr[N(SiMe_3)_2]_3$, $Cr(NPr_2^i)_3$, $Cr(NO)[N(SiMe_3)_2]_3$, $Cr(NO)(NPr_2^i)_3$, $Cr(NO)(OBu^t)_2(NPr_2^i)$, $Mn[N(SiMe_3)_2]_2$, $Fe[N(SiMe_3)_2]_3$, $Co[N(SiMe_3)_2]_2$, and $Yb[N(SiMe_3)_2]_3$.

Careful preliminary work was carried out to determine whether stable solutions in a suitable non-aqueous solvent could be made in the presence of an excess of a supporting electrolyte. Unfortunately some of the above compounds proved to be too reactive towards either the solvent or the electrolyte. Solvents tried were acetonitrile, dimethyl-sulphoxide, dimethylformamide, methylene chloride and propylene carbonate and the electrolytes were tetraalkyl-ammonium salts of chloride, iodide, perchlorate, tetrafluoroborate and tetraphenylborate.

ELECTROCHEMICAL STUDIES

Acetonitrile was very rigorously purified by the method of Walter and Ramaley[18] and finally collected by fractional distillation. Dimethylsulphoxide was purified as described by Mann[19] and stored over molecular sieve (type 5A).

For Cyclic Voltammetry a standard three-electrode, IR-compensated system was used (Fig. 3) with an Electrochemical Instrument. Calibration was made using aqueous $[Fe(oxalate)_3]^{3-}$ solution and also *bis*-cyclopentadienyliron(II) in acetonitrile with 0.2 M NaClO₄ as supporting electrolyte.

Platinum wire was used for both the auxiliary and the working electrodes. The reference electrode was $Ag/AgClO_4(0.02 M)\{(NEt_4)BF_4, (0.2 M)\}$ in acetonitrile[20] and was separated from the test solution by a salt-bridge containing the same solution of supporting electrolyte in acetonitrile as used in the test solution. The platinum bead working electrode was cleaned in nitric acid (1 M), washed with water and rinsed with the acetonitrile/supporting electrolyte solution. The current–voltage data were displayed on a Tektronix D13 storage-oscilloscope and/or an X–Y recorder. Measurements were performed using positive feedback circuitry to minimize the IR drop in potential.

All measurements were made at $25.0 \pm 0.2°C$ under an atmosphere of purified argon.

Coulometric measurements were made on 50 ml solutions using a mercury-pool electrode (dia. 4.6 cm) at a constant potential on the plateau of the reduction wave. The very small contribution from the background current due to the supporting electrolyte was subtracted.
Fig. 3. Cyclic voltammograms in dimethylsulphoxide (25°). Yb[N(SiMe₃)₂]₃ (0.4 mM), NaClO₄ (0.4 M) voltage scan rate 0.05 V sec.⁻¹.

PHOTOREDUCTION OF CHLOROHEMIN IN
PURE PYRIDINE

CARLO BARTOCCI,* ANDREA MALDOTTI, ORAZIO TRAVERSO,
CARLO A. BIGNOZZI and VITTORIO CARASSITI

Centro di Studio sulla Fotochimica e Reattività degli Stati Eccitati dei Composti di Coordinazione del C.N.R.,
Istituto Chimico dell'Università di Ferrara, Via L. Borsari, 46, Ferrara, Italy

Abstract—Chlorohemin (Fe(III)PPCl) undergoes photoreduction when irradiated in pure pyridine solution with 400–450 nm light. A thermal reduction is observed to occur simultaneously with the photochemical one, but after a one hour irradiation about 75% of the reduction product is formed in a photochemical way. Both five- and six-coordinated species are observed to be present in solution; however, only the Fe(III)PPpy$^+$ five coordinated complex is photoreducible. A mechanism is proposed whereby the primary photochemical act is an axial pyridine → iron electron transfer process yielding Fe(II)PP and py$^+$ species. The Fe(II)PP moiety gives rise to the formation of the spectrophotometrically detectable Fe(II)PP(py)$_2$ complex. ESR spin trapping results are consistent with the formation of 2-pyridyl radicals from py$^+$ cation by fast transfer of a proton to a pyridine molecule.

INTRODUCTION

The study of porphyrin iron complexes under conditions approaching the physiological state appears very useful for a thorough understanding of the vital functions these compounds play in biological systems. Thus, redox processes involving the central iron as well as the porphyrin ring are a matter of particular interest due to the role that the cytochromes, heme-containing proteins, play in the transfer of electrons in the respiratory chain.

The use of photochemical methods appears quite well suited to the study of electron transfer processes in complex molecular systems such as iron porphyrins, since irradiation, at suitably selected wavelengths, allows one to avoid the difficulties arising from simultaneous reactions that often occur when more usual chemical methods are used. Recently, Bartocci *et al.*[1] reported a study on the photochemical reduction of Fe(III) protoporphyrin IX chloride (chlorohemin) in pyridine-containing aqueous alcoholic solutions. In that paper it was observed that, under irradiation, Fe(III) was reduced to Fe(II) and that a bis-pyridine Fe(II) protoporphyrin complex was formed. However, the use of aqueous mixed solvents presented some problems in establishing the photoreduction mechanism since, under those conditions, complex coordination equilibria impeded a clear identification of the photoreactive species.[2] For this reason, although an alcoholate → iron electron transfer was indicated as the most likely means of photoreduction, other mechanisms involving pyridine or OH$^-$ could not be ruled out.

In a recent paper[3] on the photoreduction of ferrideuteroporphyrin in benzene, water, or micelle solutions containing primary or secondary alcohols, Bizet *et al.* indicated that an alcoholate → Fe(III) intramolecular electron transfer was responsible for the primary photoreduction.

However, the results reported in this paper cannot be correlated with those obtained by Bartocci *et al.*[1] due to the different natures of both the solvents and the substrate used. Therefore, in order to provide a clearer

understanding of the possible mechanism in the photoreduction of hemin, the photochemical behavior of chlorohemin in pure pyridine is reported here. The use of pure pyridine produces two advantages with respect to mixed aqueous solvents: (i) it allows one to study the photochemical behavior of chlorochemin under conditions which approach the aprotic environment of the heme-containing protein sheath. (ii) a better understanding of the nature of the axial ligands can be obtained.

EXPERIMENTAL

Materials

Commercial chlorohemin (Fluka) was recrystallized following the reported[4] glacial acetic acid method.

Spectroscopic grade pyridine (Merck) was dried with calcium hydride, twice distilled and used within 24 hr after the purification. Phenyl-*tert*-butylnitrone (PBN) (Aldrich) was used without further purification. All the other chemicals were reagent grade commercial products.

Apparatus and methods

UV–VIS spectra were recorded in the 350–700-nm range with a Varian Cary 219 Spectrophotometer. X-band electron spin resonance spectra were recorded with a Bruker 220 SE spectrometer and calibrated using α,α'-diphenylpicrylhydrazyl (DPPH). Irradiations were carried out with a 150 W xenon lamp, equipped with a glass filter which cut off light with wavelengths shorter than 400 nm. The irradiation light was focussed on the reaction vessel through quartz lenses. In order to identify radical intermediates, solutions contained in 2-mm tubes were irradiated in the presence of PBN as spin trap[5] in the ESR cavity.

All other experiments were carried out using spectrophotometric cells as reaction vessels. The solutions were degassed before irradiation to less than 10^{-5} Torr by means of at least three vacuum line freeze/thaw pump cycles. Before running the experiments in oxygenated solutions, oxygen was allowed to flow into the previously degassed solutions until a pressure of 1 atmosphere was reached.

RESULTS

Irradiation of 1 × 10^{-4} M deaerated pyridine solutions of Fe(III)PPCl by light with λ > 400 nm resulted in the spectral variations shown in Fig. 1. The new bands at 480, 524 and 556 nm are typical of Fe(II)PP(py)$_2$ (bis-pyridine hemochrome) formed in the photoreduction

---

Fig. 1. Spectral variations observed upon $\lambda > 400$ nm irradiation of a 1×10^{-4} M deaerated solution of Fe(III)PPCl in
pure pyridine at 25°C, O, initial spectrum; irradiation periods, 10 min.

process.[1] The net isosbestic points observed at 535, 544 and 578 nm indicate that the photoreaction did not involve the porphyrin ring.[1]

In Fig. 2 the spectral variations observed when an identical solution was kept in the dark during the above photochemical run are reported. It can be observed that spectral variations are qualitatively the same as those observed under irradiation (Fig. 1). This suggests that both thermal and photochemical reduction of Fe(III)PPCl occur simultaneously to yield Fe(II)PP(py)$_2$. Polarographic measurements[6] showed that the Fe(II) concentration immediately after the dissolution of the chlorohemin in pyridine was quite negligible. This permits the calculation of the Fe(II)PP(py)$_2$ fraction formed by the thermal reaction. Using absorbance variations reported in Figs. 1 and 2, it was seen that 24% of the reduction product was thermally formed after 1 hr.

No appreciable photoreduction was observed to occur under the following conditions:

(1) By irradiation with light of $\lambda > 450$ nm.

(2) In an oxygen atmosphere (see Experimental). When oxygen was allowed to bubble into the previously irradiated solutions, spectral variations were observed indicating that the expected re-oxidation of the Fe(II) complex was occurring very slowly.

(3) In the presence of an excess of chloride (i.e. the pyridinium salt). In this case there is a wide difference between the absorption spectra of chlorohemin in pyri-

dine solutions with or without an excess of chloride (Fig. 3).

At 100 K, 2×10^{-3} M pyridine solutions of chlorohemin exhibit a typical[7] high-spin ESR spectrum with $g_\perp = 6$ and $g_\parallel = 2$ (Fig. 4). The addition of excess Cl$^-$ or oxygenation did not modify the ESR spectrum.

ESR experiments were carried out at room temperature during the irradiation of carefully deaerated pyridine solutions of chlorohemin containing 5×10^{-2} M phenyl-*tert*-butylnitrone (PBN) as a spin trap. An intense spectrum increasing with irradiation time was revealed (Fig. 4), suggesting the involvement of radical intermediates in the photoreduction process. It consists of 1:1:1 doublets with $a_N = 14.5$ G and $a_H = 2.2$ G. An identical solution kept in the dark did not exhibit any ESR signals. Since the use of a nitroso spin trap yields direct information on radical species structure,[8] it is often utilized. However, when irradiated with $\lambda > 400$ nm light the pyridine solutions of nitroso compounds usually used as spin traps (e.g. 2,4,6-tri-*tert*-butylnitrosobenzene, TBN), exhibit ESR signals which clearly indicate the photoinstability of these compounds.

DISCUSSION

The apparent thermal reduction of Fe(III)PPCl in pure pyridine is a very striking phenomenon. In fact, some noticeable reduction of this compound in pyridine was observed several years ago,[9] although the presence of
Fig. 2. Spectral variations observed when a 1×10^{-4} M pyridine solution of Fe(III)PPCl was kept 1 hr in the dark. O; initial spectrum.

Fe(II) under these conditions was afterwards ruled out by other authors.[10,11] To date, the nature of this self-reduction is not clear. One cannot rule out the possibility that, even after a careful purification of all chemicals used, some impurities remain in solution, and are responsible for the observed reduction.

Comparison of the spectral variations reported in Figs. 1 and 2 indicates that formation of the reduced species Fe(II)PP(py)$_2$ is strongly accelerated under irradiation and that more than 75% of the reduction products are formed by photochemical means.

When chlorohemin is dissolved in pure pyridine, axial complexes are formed.[10,12] Several structures consisting of bis-pyridine and chloro-pyridine six-coordinated as well as chloro and pyridine five-coordinated complexes could be proposed. Our ESR results, however, indicate that only high-spin species are present, ruling out the presence of appreciable amounts of Fe(III)PP(py)$_2$ which is known[13] to exhibit an ESR spectrum typical of low spin or, at most, mixed high-spin/low-spin species. Thus the only possible Fe(III) protoporphyrin complexes present in pyridine solutions of chlorohemin are Fe(III)PPCl, Fe(III)PPpy$^+$ and Fe(III)PPpyCl. The presence of iron porphyrin complexes containing undissociated chloride ligand in pure pyridine is not unexpected. In fact, the replacement of Cl$^-$ by pyridine is not likely due to the low coordinating ability of pyridine on Fe(III) porphirin axial positions as well as its low

solvating power with respect to Cl$^-$ ions. On the other hand, the clear change in the absorption spectrum observed when an excess of pyridinium chloride is present (Fig. 3) suggests that appreciable amounts of pyridine-containing complexes are in equilibrium with chloro-containing complexes. Therefore, the situation in a pyridine solution of chlorohemin can be accurately described by Scheme 1.
Scheme 1.

$$py^+ \rightarrow products \quad (6)$$
Scheme 2.

In the presence of excess Cl⁻, the equilibria reported in Scheme 1 predominantly favour species I and/or III. The absence of appreciable photoreduction in these conditions clearly indicates that $Fe(III)PPpy^+$ is the only photoreducible species. On these grounds three mechanisms can be proposed for the photoreduction process.

(1) Intermolecular electron transfer from the pyridine solvent to the excited $Fe(III)PPpy^+$ complex.

(2) Intramolecular electron transfer from coordinated pyridine to central Fe(III).

(3) Intramolecular electron transfer from the porphyrin ring to central Fe(III).

Due to the short lifetime of the excited species,[14] bimolecular processes involving excited states are known to be quite unusual and hence mechanism 1 can be ruled out. Mechanism 3 implies that a porphyrin→Fe(III) charge transfer transition is responsible for the photoreduction. However, unless pyridine leads to a drastic change in the excited state energy of the complex it is very likely that a fast deactivation to low-energy $d–d$ states occurs before any photoreduction can occur. Therefore, an electron transfer from the coordinated pyridine to central Fe(III) (Mechanism 2) appears to be the most probable process. On this bases, Scheme 2 summarizes the photoreduction mechanism.

Due to the probable dissociative character of the pyridine→Fe(III) charge transfer excited state, the excitation (eqn 1) is followed by an instantaneous charge separation (eqn 2). The diffusion away of Fe(II)PP and py^+ moieties (eqn 4) occurs in competition with the solvent-cage back electron transfer (eqn 3). The coordination of two pyridine molecules in the axial positions of Fe(II)PP (eqn 5) gives the spectrophotometrically-detected $Fe(II)PP(py)_2$ complex.

The ESR trapping results (Fig. 5) show that radical species are formed as photoredox products. The signal observed, consisting of a triplet of doublets, and the

hyperfine splitting values are consistent with the 2-pyridyl radical[15] trapped by PBN:
This suggests that the pyridine radical cation formed in the primary photoreduction (eqn 4) gives rise to very fast proton transfer to a pyridine molecule yielding a 2-pyridyl radical (eqn 7).

$$(7)$$
There seems to be a discrepancy between the observed photoinactivity of the Fe(III)PPpyCl complex and the primary photoreduction which occurs through an electron transfer from coordinated pyridine to Fe(III). However, this discrepancy can be justified by taking the electron donor character of the chlorine ligand into consideration. In fact, coordination of Cl⁻ in the axial position *trans* to pyridine increases the central metal electron density, making inner-sphere Fe(III) reduction more difficult in the pyridine chloro complex than in the pyridine complex. As a consequence, the pyridine→Fe(III) CT absorption band is expected to be shifted towards wavelengths lower than those of the irradiating light.

The re-oxidation of $Fe(II)PP(py)_2$, observed when previously-irradiated hemin solutions are kept in an oxygen atmosphere, is very slow in accordance with the known[16] stability of this complex towards oxidation by

5 G
Fig. 5. ESR spectrum obtained at 298 K after 1 hr irradiation with $\lambda > 400$ nm light of Fe(III)PCl in pyridine solution containing 5×10^{-2} M PBN.

oxygen. For this reason, when irradiation is carried out in an oxygen atmosphere the absence of any appreciable photoreduction can be ascribed to fast re-oxidation of intermediate Fe(II)PP before pyridine axial coordination (eqn 5), rather than to oxidation of the final product.

The irradiation wavelength range (see results) within which the photoredox process has been observed, suggests that a charge transfer pyridine → Fe(III) absorption band should be present in this spectral region, although the very intense π–π^* band centered at 400 nm (Soret Band) hides it completely.

These results point to the strong possibility that a mechanism involving an electron transfer from pyridine to Fe(III) is involved in hemin photoreduction in pyridine-containing mixed solvents, although other mechanisms, e.g. alcoholate → Fe(III) electron transfer, may be more likely in these cases.

NOTES

Metal template synthesis of chromium(III) complexes

Abstract—Chromium(III) complexes of Schiff bases resulting from the condensation of one mole of diacetyl with two moles of ethylene-diamine or 1,3 diaminopropane has been isolated by metal template reaction. The isolated complexes have been assigned *cis* configurations.

A large number of metal template reactions, particularly for the synthesis of macrocyclic complexes, have been reported. But all these reactions have been carried out in the presence of divalent metal ions like Cu(II), Ni(II), Co(II), Zn(II) and Mn(II).[1-3] A trivalent metal ion due to its higher nuclear charge should be equally efficient in polarising the $\ce{>C=O}$ bond and hence should be efficient for metal template reactions. Unfortunately there are not many reports on the metal template reactions of trivalent metal ions.[4] Hence we attempted the metal template reactions of chromium(III) for the condensation of diacetyl and ethylenediamine or 1,3-diaminopropane and we were able to isolate complexes of the ligands A and B in appreciable yield.

A   **B**
EXPERIMENTAL

Elemental analysis. Carbon and hydrogen was analysed by the courtesy of the microanalyst of the University of Madras. Nitrogen content was evaluated using micro-Kjeldahl technique and chromium was analysed as chromate after oxidising an aqueous solution of the complex with alkaline peroxide.

Conductivity measurements. Conductivity measurements were performed using a Mullard conductivity bridge. Molar conductance were determined at 25°C in acetonitrile solution (10^{-3} M).

Spectral measurements. The electronic spectrum of the aqueous solution of the complexes were measured using a Pye–Unicam SP 1800 spectrophotometer. IR spectra of the complexes were obtained with a Perkin–Elmer 337 model grating spectrophotometer and KBr mull sampling technique.

Preparation of [Cr A(H$_2$O)$_2$](ClO$_4$)$_3$. Chromium(III) acetate hexahydrate (3.4 g) in 50 ml of acetonitrile was refluxed with diacetyl (0.86 g) for 15 min. Then ethylenediamine (1.2 g) was added to the reaction mixture and again refluxed for another 4 hr. Volume of the solution was reduced to 25 ml by rotary evaporation. To this solution NaClO$_4$ (3.4 g) was added, filtered and cooled. The red orange crystals which formed were removed by filtration, washed with cold methanol and ether. Found: C, 17.41; H, 3.81; N, 9.92; Cr, 9.12. Calc. for Cr(C$_8$H$_{22}$N$_4$O$_2$)(ClO$_4$)$_3$: C, 17.25; H, 3.95; N, 10.06; Cr, 9.34%.

Preparation of [Cr B(H$_2$O)$_2$](ClO$_4$)$_3$. This complex was prepared in a similar way as the above one by taking 1,3 diaminopropane in the place of ethylenediamine (1.2 g) was added. Found: C, 20.32; H, 4.49; N, 9.44; Cr, 8.81. Calc. for Cr(C$_{10}$H$_{26}$N$_4$O$_2$)(ClO$_4$)$_3$: C, 20.53; H, 4.45; N, 9.58; Cr, 8.89%.

Preparation of [Cr A(H$_2$O)(NCS)](NCS)$_2$. The diaquo complex

[Cr A(H$_2$O)$_2$](ClO$_4$)$_3$ (1.1 g) was refluxed with KSCN (0.58 g) in 30 ml of acetonitrile for 30 min. The precipitated KClO$_4$ was filtered off. On cooling the solution the desired product was obtained. Found: C, 31.72; H, 4.89; N, 23.52; Cr, 12.48. Calc. for Cr(C$_8$H$_{20}$N$_4$O)(NCS)$_3$: C, 31.88; H, 4.83; N, 23.67; Cr, 12.56%.

Preparation of [Cr B(H$_2$O)(NCS)](NCS)$_2$. It was prepared in a similar way as the above complex by treating the diaquo complex [Cr B(H$_2$O)$_2$](ClO$_4$)$_3$ with KSCN. Found: C, 35.12; H, 5.48; N, 22.03; Cr, 11.62. Calc. for Cr(C$_{10}$H$_{24}$N$_4$O)(NCS)$_3$: C, 35.29; H, 5.42; N, 22.17; Cr, 11.76%.

RESULTS AND DISCUSSION

The elemental analyses show that 2 molecules of diamine have condensed with 1 molecule of diacetyl. Even when the reaction was carried out with the molar ratio of diamine and diketone as 1:1, the same products were obtained, showing that the Schiff's base formed does not react further with another molecule of diketone to form a macrocycle. The charge characteristics of the complexes have been determined by conductivity measurements. Molar conductance of the complexes [Cr A(H$_2$O)$_2$](ClO$_4$)$_3$, [Cr B(H$_2$O$_2$)$_2$](ClO$_4$)$_3$, [Cr A(H$_2$O)(NCS)](NCS)$_2$ and [Cr B(H$_2$O) (NCS)](NCS)$_2$ were found to be 399, 372, 224 and 219 Ω^{-1} cm^2 respectively. It is evident therefore, that in the absence of added thiocyanate, the compounds crystallize as diaquo complexes and in the presence of added thiocyanate as aquothiocyanato complexes.

The electronic spectral data for the complexes are shown in Table 1. All the complexes show two absorption bands in the visible region due to the $^4A_{2g}(F) \rightarrow {}^4T_{2g}(F)$ and $^4A_{2g}(F) \rightarrow {}^4T_{1g}(F)$ transitions. The thiocyanato derivatives show the high energy charge-transfer bands in addition to the d–d transitions. If the complexes were to have *trans* configuration, one would expect splitting of the d–d bands,[5] but in the present case no splitting has been observed. The spectra are typical of *cis* configuration.

The IR spectra of all the complexes show bands in the region of 1630–1600 cm^{-1} (C=N stretch) and no band which could be assigned to carbonyl stretching frequency is observed. All the complexes show strong bands in the region of 3300–3200 cm^{-1} (N—H stretch). The wagging mode of coordinated water shows up in the region 820–790 cm^{-1}. The thiocyanato complexes show an additional band at 2060 cm^{-1} whereas the diaquo complexes have additional bands in the region of 1150–1100 cm^{-1} for perchlorate. Absorptions in the CH$_2$ rocking region (940–860 cm^{-1}) have been used by previous workers for assigning configuration of cobalt and chromium complexes.[6] The complexes isolated show three medium intensity bands in this region, which is typical of the *cis*-configuration. *Trans*-complexes are known to show 4–5 bands in this region.

The fact that ring closure to give a macrocycle does not take place, is again indicative of a *cis*-configuration for the isolated complexes. In a folded *cis*-configuration the macrocycle with four imine linkages will be highly strained. In a planar *trans*-configuration ring closure would have been much easier. The template synthesis of macrocyclic complexes of chromium(III) would also have been possible if the precursor complexes were in a *trans*-configuration.

Hexahalogenotin(IV) complexes in aqueous mixed hydrogen halide solutions in the glassy state

(Received 27 July 1982)

Abstract—The configurations of hexahalogenotin(IV) complex ions in glassy aqueous mixed hydrogen halide solutions were determined by Mössbauer and Raman spectroscopies. *Trans*-(SnF$_4$Cl$_2$)$^{2-}$, (SnCl$_5$Br)$^{2-}$ and *trans*-(SnF$_4$Br$_2$)$^{2-}$ ions are the main tin complex ions in the aqueous Sn(IV)–HF–HCl, Sn(IV)–HCl–HBr and Sn(IV)–HF–HBr solutions in the glassy state, respectively.

INTRODUCTION

It is well known that Sn(IV) ions in aqueous solution containing excess HX (X = F, Cl and Br) exist as hexahalogenotin(IV) complex ions (SnX$_6^{2-}$).[1-3] In considering the differences of the complex formation abilities and sizes of halide ions (F$^-$, Cl$^-$ and Br$^-$), it seemed interesting to investigate what configurations among various mixed-halide tin(IV) complex ions are stabilized in a binary mixture of aqueous HX solutions at low temperatures.

As Mössbauer and Raman spectroscopies are both powerful tools for elucidating a local configuration around a complex ion in the solid, we used both methods in this study to characterize the mixed-halide tin(IV) complex ions in binary hydrogen halide solutions in the glassy state. It is shown that employment of both spectroscopic methods enabled us to determine the configurations of mixed-halide tin(IV) complex ions more easily than the case where only one method would have been employed.

EXPERIMENTAL

Aqueous sample solutions were prepared from anhydrous SnF$_4$, SnCl$_4$ and SnBr$_4$ by dissolving them in aqueous HX solutions and subsequent diluting and mixing resultant aqueous solutions: 3SnF$_4$ · 100HF · 300H$_2$O, 6SnCl$_4$ · 100HCl · 600H$_2$O, 6SnBr$_4$·100HBr·600H$_2$O, and three solutions of the composition 3SnX$_4$·3SnY$_4$·50HX·50HY·600H$_2$O (X and Y denote different halide ions: F$^-$Cl$^-$ and Br$^-$). Glass formation was attained by quenching each solution in liquid nitrogen.

The Mössbauer spectra of the glassy solutions (0.6 cm^3, corresponding to the absorber thickness of 6 mgSn/cm^2) were measured at 77 K against a Ca ^{119m}SnO$_3$ source with a constant acceleration type spectrometer. All isomer shift data are reported with respect to BaSnO$_3$ resonance at room temperature. The Raman spectra were taken with a JASCO R-800 spectrometer using 500–600 mW of the 514.5 nm line of a CR-8 argon-ion laser as an exciting source. The details of the Mössbauer and Raman measurements were essentially the same as those previously reported.[3,4]

RESULTS AND DISCUSSION

The Mössbauer spectra for all the glassy solutions are shown in Fig. 1 together with the obtained Mössbauer parameters (isomer shift: δ and line width: Γ) for each spectrum. The Mössbauer parameters obtained for the monohalide solutions are in good agreement with the reported values[5,6] for the [SnX$_6$]$^{2-}$ complex ions, confirming that Sn(IV) ions exist as [SnX$_6$]$^{2-}$ in these mono-halide solutions in the glassy state. From the results for the mono-halide solutions, it is expected that Sn(IV) ions in the mixed-halide solutions also have the six coordination as the total concentration of halide ions is the same as that in the mono-halide solutions.

As compared with the mono-halide complexes, line broadening was observed in all mixed-halide solutions. There are two possible causes for the observed line broadening: one is due to the result of unresolved quadrupole splitting and the other the existence of several different mixed-halide tin complexes in the mixed-halide solutions. However, the line broadening is almost the same magnitude as that for the mixed-halide complexes of the type [(C$_2$H$_5$)$_4$N]$_2$·[SnX$_4$Y$_2$],[7] indicating that one or two com-

Hexahalogenotin(IV) complexes in aqueous mixed hydrogen halide solutions in the glassy state

(Received 27 July 1982)

Abstract—The configurations of hexahalogenotin(IV) complex ions in glassy aqueous mixed hydrogen halide solutions were determined by Mössbauer and Raman spectroscopies. *Trans*-(SnF$_4$Cl$_2$)$^{2-}$, (SnCl$_5$Br)$^{2-}$ and *trans*-(SnF$_4$Br$_2$)$^{2-}$ ions are the main tin complex ions in the aqueous Sn(IV)–HF–HCl, Sn(IV)–HCl–HBr and Sn(IV)–HF–HBr solutions in the glassy state, respectively.

INTRODUCTION

It is well known that Sn(IV) ions in aqueous solution containing excess HX (X = F, Cl and Br) exist as hexahalogenotin(IV) complex ions (SnX$_6$$^{2-}$).[1–3] In considering the differences of the complex formation abilities and sizes of halide ions (F$^-$, Cl$^-$ and Br$^-$), it seemed interesting to investigate what configurations among various mixed-halide tin(IV) complex ions are stabilized in a binary mixture of aqueous HX solutions at low temperatures.

As Mössbauer and Raman spectroscopies are both powerful tools for elucidating a local configuration around a complex ion in the solid, we used both methods in this study to characterize the mixed-halide tin(IV) complex ions in binary hydrogen halide solutions in the glassy state. It is shown that employment of both spectroscopic methods enabled us to determine the configurations of mixed-halide tin(IV) complex ions more easily than the case where only one method would have been employed.

EXPERIMENTAL

Aqueous sample solutions were prepared from anhydrous SnF$_4$, SnCl$_4$ and SnBr$_4$ by dissolving them in aqueous HX solutions and subsequent diluting and mixing resultant aqueous solutions: 3SnF$_4$ · 100HF · 300H$_2$O, 6SnCl$_4$ · 100HCl · 600H$_2$O, 6SnBr$_4$·100HBr·600H$_2$O, and three solutions of the composition 3SnX$_4$·3SnY$_4$·50HX·50HY·600H$_2$O (X and Y denote different halide ions: F$^-$Cl$^-$ and Br$^-$). Glass formation was attained by quenching each solution in liquid nitrogen.

The Mössbauer spectra of the glassy solutions (0.6 cm^3, corresponding to the absorber thickness of 6 mgSn/cm^2) were measured at 77 K against a Ca ^{119m}SnO$_3$ source with a constant acceleration type spectrometer. All isomer shift data are reported with respect to BaSnO$_3$ resonance at room temperature. The Raman spectra were taken with a JASCO R-800 spectrometer using 500–600 mW of the 514.5 nm line of a CR-8 argon-ion laser as an exciting source. The details of the Mössbauer and Raman measurements were essentially the same as those previously reported.[3,4]

RESULTS AND DISCUSSION

The Mössbauer spectra for all the glassy solutions are shown in Fig. 1 together with the obtained Mössbauer parameters (isomer shift: δ and line width: Γ) for each spectrum. The Mössbauer parameters obtained for the monohalide solutions are in good agreement with the reported values[5,6] for the [SnX$_6$]$^{2-}$ complex ions, confirming that Sn(IV) ions exist as [SnX$_6$]$^{2-}$ in these mono-halide solutions in the glassy state. From the results for the mono-halide solutions, it is expected that Sn(IV) ions in the mixed-halide solutions also have the six coordination as the total concentration of halide ions is the same as that in the mono-halide solutions.

As compared with the mono-halide complexes, line broadening was observed in all mixed-halide solutions. There are two possible causes for the observed line broadening: one is due to the result of unresolved quadrupole splitting and the other the existence of several different mixed-halide tin complexes in the mixed-halide solutions. However, the line broadening is almost the same magnitude as that for the mixed-halide complexes of the type [(C$_2$H$_5$)$_4$N]$_2$·[SnX$_4$Y$_2$],[7] indicating that one or two com-

Fig. 1. Mössbauer spectra of the Sn(IV)–HX or Sn(IV)–HX–HY solutions in the glassy state. The unit for both isomer shift (δ) and line width (Γ) is in mm/s.

plexes predominate in the mixed-halide solutions in the glassy state. We conclude, therefore, that the line broadening in the mixed-halide solution is mainly the result of unresolved quadrupole splitting.

It is difficult to determine what type of the $[SnX_pY_q]^{2-}$ ion $(p+q=6)$ is stabilized in the glassy mixed-halide solution only from the Mössbauer parameters. In these solutions, the equilibrium reactions among various tin(IV) complex ions must be displaced to one side in the glassy state, resulting in the trapping of most stable tin complex ions.

It is well established[6,7] that there is a linear relation between isomer shift and the average electronegativity of the halides in the coordination sphere of the tin atom for the complexes of the types $(SnX_6)^{2-}$ and $(SnX_4Y_2)^{2-}$ ions. Our results for the $(SnF_6)^{2-}$, $(SnCl_6)^{2-}$ and $(SnBr_6)^{2-}$ ions, shown in Fig. 2, also fall on a straight line with a slope of -0.40, which is very close to the value of -0.41 for the complexes of the $(SnX_6)^{2-}$ ions $(X = F, Cl, Br$ and $I)$ reported by Clausen and Good.[7] Assuming that the isomer shifts of these mixed-halide solutions are also on the same straight line, we can get the possible halide configurations for the stabilized tin complex ions: $[SnF_3Cl_3]^{2-}$ and $[SnF_4Cl_2]^{2-}$ ions for the Sn(IV)–HF–HCl solution, $[SnF_3Br_3]^{2-}$ and $[SnF_4Br_2]^{2-}$ ions for the Sn(IV)–HF–HBr solution, and $[SnCl_3Br_3]^{2-}$, $[SnCl_4Br_2]^{2-}$ and $[SnCl_5Br]^{2-}$ ions for the Sn(IV)–HCl–HBr solution. We cannot at the moment preclude the possibility that two or more tin complex ions are equally stabilized at low temperatures. However, as noted before, the line width broadening validates to a first approximation the assumption that a single tin complex species predominates in the mixed-halide solutions in the glassy state.

From Raman spectra shown in Fig. 3, we can immediately confirm that $[SnX_6]^{2-}$ ion is the predominant tin complex ions in the mono-halide solutions. In the glassy Sn(IV)–HCl–HBr solution, the Sn–Cl stretching Raman band is observed at 310 cm^{-1}, only a few wavenumbers away from the value (314 cm^{-1}) for the $[SnCl_6]^{2-}$ ions, while the Sn–Br stretching band at 204 cm^{-1} is distant from the value (186 cm^{-1}) for the $[SnBr_6]^{2-}$ ions. This suggests that the number of chloride ions coordinating to a Sn(IV) ion is close to six. Therefore, we conclude that $[SnCl_5Br]^{2-}$ ions are the predominant species in the glassy Sn(IV)–HCl–HBr solution. This conclusion is supported by the observation that there are four polarized Raman bands because the MX$_5$Y configuration (M is a central atom) is expected to give four polarized Raman bands.[8] The δ value ($+0.57$ mm/s) is a
Fig. 2. Relation between isomer shift and the average electronegativity. $[SnF_3Br_3]^{2-}$ is represented by F_3Br_3 in the figure. The straight line is based on the data of the SnX_6^{2-} ions ($\square$). The open circle ($\bigcirc$) indicates the most probable configuration stabilized in each mixed halide solution.

little smaller than that ($+0.67$ mm/s) for the $[SnCl_4Br_2]^{2-}$ ions[7] is also consistent with our conclusion. The half-band width for the Sn–Cl stretching Raman band is almost the same as that for the $[SnCl_6]^{2-}$ ions, indicating that a single tin complex ion, i.e. $[SnCl_5Br]^{2-}$, predominates in the glassy solution.

The Raman spectra for the glassy Sn(IV)–HF–HCl and Sn(IV)–HF–HBr solutions are shown in Fig. 4. In these solutions, there are only two (one is a Sn–F stretching and the other a Sn–Cl or Sn–Br stretching Raman band) polarized Raman bands ascribable to the tin complex ions. Accordingly among the possible configurations expected from the Mössbauer data, we consider that trans-$[SnF_4Cl_2]^{2-}$ and trans-$[SnF_4Br_2]^{2-}$ ions are the dominant tin complex ions in these solutions, respectively. In the case of the latter solution, the Sn–Br stretching band at 225 cm^{-1} is a little diffuse toward a lower frequency region, suggesting that there exist a small amount of other complex ions such as $[SnF_3Br_3]^{2-}$ ions.

Complexes of bivalent cations with a hydroxamic acid from maize extracts

Cyclic hydroxamic acids may constitute up to 2% of the dry weight of Gramineae such as wheat, maize and rye.[1] The chelating properties of hydroxamic acids[2] suggest that those present in Gramineae may play a role in the plant mineral nitrition.[3] We report here the stability constants of complexes between bivalent cations and 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one

(DIMBOA), the main hydroxamic acid isolated from maize extracts.[4]

EXPERIMENTAL

Stability constants of the complexes were determined by potentiometric titration of a 3.4 mM solution of the cation (as chloride) in 0.66 mM $HClO_4$ with a 10 mM solution of the anion of DIMBOA (pH 8.5), under constant ionic strength (0.1 M with $NaClO_4$). Titrations were carried out at $3 \pm 0.5°$. Under these conditions the decomposition of DIMBOA[5] was negligible (half-life = 32.7 hr) compared with the time needed for titration (20 min). The pK_a of DIMBOA at this temperature and ionic strength was 6.96. The data obtained was analyzed by the method of Bjerrum.[6] Distribution diagrams were calculated with a modified version of the program COMICS.[7]

RESULTS AND DISCUSSION

The formation curves (Fig. 1) allow the estimation of the logarithms of the stability constants of the 1 : 1 complexes of Cu (5.4), Ni (4.5), Zn (4.2), Mn (3.4) and Ca (3.0) and of the 2 : 1 complexes of Ni (3.6) and Zn (3.5). The low stability of the Mg complex and the insolubility of the Fe complex precluded the estimation of their stability constants. A precipitate appeared during the titration of the Cu when an $\bar{n}$ value of 0.5 was reached.
Fig. 1. Formation curves for complexes between DIMBOA and bivalent cations. pA = − log [DIMBOA].

The formation constant of the 1 : 1 complex between DIMBOA and Cu has been determined by the method of Irving–Rosotti at 10, 20 and 30°.[8] Extrapolation of these data to 3° gives a value of log $K_1 = 5.7$, comparable to that reported in this paper. The formation constants of the 1 : 1 complexes follow the Irving–Williams order, i.e. Mn(Ni(Cu)Zn, as shown for other ligands.[9] The complexes of DIMBOA were less stable than those of hydroxamic acids of the type Ar–NOH–CO–Ar,[10] probably a reflection of the greater pK_a values of these latter acids.

The distribution of species in a solution containing DIMBOA, citric acid and malic acid, and Cu(II), Zn(II), Ca(II), Mn(II) and Fe(III) cations was calculated at pH 5.5, the pH of the plant extract. Citric and malic acids are two of the most abundant complexing agents found in maize exudates. The concentrations used in the calculations were those determined in whole plants.[4,11,12] Formation constants were obtained from the literature.[3,13] Under these conditions, 57% of the DIMBOA remained uncomplexed, while the complexes CaL, FeL₂ + FeL₃, CuL, ZnL + ZnL₂ and MnL with L = DIMBOA anion were 35, 7, 0.1, 0.5 and 0.3% of the total DIMBOA, respectively. In all cases, these complexes accounted for a substantial proportion of the total cation (Table 1). More of each cation was complexed by DIMBOA than by citric and malic acids together. Thus, it is possible that DIMBOA and other related hydroxamic acids in Gramineae may participate in the plant mineral nutrition as chelating agents. To further establish the participation of hydroxamic acids in mineral nutrition it would be necessary to determine their concentration as well as that of organic acids, cations and hydrogen ions in the different plant compartments at the tissular and cellular levels.

Isolation of dithiocarbamate anions as salts of biscyclopentadienyl titanium(IV) chelates

Abstract—A series of $[Cp_2TiL]^+[RR'NCS_2]^-$ complexes, where L is the conjugate base of acetylacetone, benzoylacetone or 8-hydroxyquinoline and $R = CH_3$, $R' = C_6H_5CH_2$; $R = C_2H_5$, $R' = C_6H_4CH_3$; $R = H$, $R' = C_5H_9$; $RR' = C_6H_{12}$, have been synthesised in aqueous medium by the reaction of $[Cp_2TiL]^+Cl^-$ with $RR'NCS_2^-Na^+$. Conductivity measurements in nitrobenzene solution indicate that these complexes are electrolytes. Both the IR and NMR studies demonstrate that the ligand L is chelating in all these complexes. Consequently, tetrahedral coordination about the titanium atom is proposed. In addition to these studies, elemental analyses and magnetic susceptibility have been carried out for these complexes.

INTRODUCTION

During the course of our recent investigations,[1-3] we elucidated that coordination of four oxygen or two oxygen and two nitrogen atoms by strong covalent bonds to the $RR'M^{2+}(IV)$ moiety ($R = R' = C_5H_5$; $R = C_5H_5$, $R' = C_4H_4N$; $R = C_5H_5$, $R' = C_9H_7$ and $M = Ti$ or Zr) would lead to weakening of the metal-ring bonds. In this communication we report an extension of these studies to the dithiocarbamate derivatives of biscyclopentadienyl titanium(IV) chelates, with the aim that behaviour of free dithiocarbamate anion would provide additional information on the nature of bonding. A number of complexes of the type $[Cp_2TiL]^+[RR'NCS_2]^-$, where L is the conjugate base of acetylacetone, benzoylacetone or 8-hydroxyquinoline and $R = CH_3$, $R' = C_6H_5CH_2$; $R = C_2H_5$, $R' = C_6H_4CH_3$; $R = H$, $R' = C_5H_9$; $RR' = C_6H_{12}$ have been synthesised. These compounds possess a low solvation energy, as evident from the ease of their preparation.

EXPERIMENTAL

Reagents and general techniques

All the chemicals and reagents used were of analytical grade. Biscyclopentadienyl titanium(IV) dichloride was obtained from Fluka AG Switzerland and used as such without further purification. Nitrobenzene for conductance measurements was purified by the method described by Fay *et al.*[4] Sodium dithiocarbamates were prepared by the method of Gilman and Blatt.[5]

Microanalyses of carbon and hydrogen contents were carried out in our Departmental Microanalytical laboratory. Titanium, nitrogen and sulphur were estimated by the standard methods as described by Vogel.[6]

Conductance measurements were made in nitrobenzene at $30.00 \pm 0.05°C$ using an Elico Conductivity Bridge Model CM82. Solid state IR spectra were recorded in "KBr pellets" in the region $4000-200 \text{ cm}^{-1}$ with a Perkin–Elmer 621 grating spectrophotometer. Magnetic measurements were carried out by Gouy's method using mercury tetrathiocyanatocobaltate(II) as calibrant. Proton NMR spectra were recorded in $CDCl_3$ on a Perkin–Elmer R-32 spectrophotometer at a sweep width of 900 Hz. The magnetic field was calibrated with a standard sample of $CHCl_3$ and TMS (1% by volume).

Preparation of complexes

An aqueous solution of $[Cp_2TiL]^+Cl^-$ where L is the conjugate base of acetylacetone, benzoylacetone or 8-hydroxyquinoline was obtained by stirring an aqueous solution of Cp_2TiCl_2 with slight excess of acetylacetone, benzoylacetone or 8-hydroxyquinoline for 2 hr. Any resulting precipitate was removed by filtration. The filtrate was then added slowly with shaking, to a concentrated hot aqueous solution of appropriate sodium dithiocarbamate. The precipitate so obtained was digested on water bath at 60–70° for 1 hr. It was then filtered, washed with hot water, diethyl ether (40–60°) and finally dried under vacuum. In order to remove any acetylacetone impurity, the precipitates were dissolved in dichloromethane and reprecipitated by adding petroleum ether (60–80°).

RESULTS AND DISCUSSION

Table 1 lists the analytical data and physical characteristics of the complexes. The complexes are quite stable in the solid state and in solution. They are moderately soluble in dichloromethane, chloroform, carbon tetrachloride and nitrobenzene. All the complexes are thermally stable but decompose slowly at higher temperatures without melting. Conductivity measurements reveal that the chelates are 1:1 electrolytes in nitrobenzene. Magnetic susceptibility values at room temperature indicate that all these complexes are diamagnetic in nature.

The assignments of IR bands have been made on the basis of published work. The IR spectra of the compounds show usual peaks for C_5H_5 group,[7] *viz.*, the C–H stretching frequency at $\sim 3000 \text{ cm}^{-1}$, the perpendicular hydrogen wagging mode at $\sim 860 \text{ cm}^{-1}$, the parallel hydrogen wagging vibration at $\sim 1030 \text{ cm}^{-1}$. The band owing to C–C stretching mode and ring breathing mode of π-bond occur at ~ 1430 and $\sim 1170 \text{ cm}^{-1}$ respectively. Apart from this, an additional band near 440 cm^{-1} can be assigned to $Ti-C_5H_5$ vibrations.[8]

$[Cp_2Tiox]^+[RR'NCS_2]^-$ d	60	Yellowish	203	63.08 (62.90)	5.52 (5.64)	9.76 (9.67)	12.84 (12.90)	5.71 (5.64)

a where R = CH_3, R' = $C_6H_5CH_2$; b where R = C_2H_5, R' = $C_6H_4CH_3$; c where R = H, R' = C_5H_9 and d where RR' = C_6H_{12}

The bands occurring around $1560 \, cm^{-1}$, $1520 \, cm^{-1}$ and $475 \, cm^{-1}$ in the $[Cp_2Tiacac]^+[RR'NCS_2]^-$ and $[Cp_2Tibzac]^-[RR'NCS_2]^-$ complexes may be assigned to $\nu(C \cdots O)$, $\nu(C \cdots C)$ and $\nu(Ti-O)$ vibrations.[9] Further, the phenyl group of benzoylacetonato group is indicated by additional peaks at $\sim 1640 \, cm^{-1}$ (C–C stretching), $\sim 1340 \, cm^{-1}$ (C–H stretching), $\sim 760 \, cm^{-1}$ (C–H out of plane bending) and $\sim 700 \, cm^{-1}$ (methylene rocking vibration).[10]

The IR spectra of $[Cp_2Tiox]^+[RR'NCS_2]^-$ complexes show an intense absorption at $\sim 1340 \, cm^{-1}$ due to the vibration of the $C \cdots N$ bond in the 8-hydroxyquinolinato group. The free 8-hydroxyquinoline shows this absorption in the $1450–1500 \, cm^{-1}$ range. This indicates considerably less double bond character of the (C–N) bond in the 8-hydroxyquinolinate group. It may be assumed that the lone pair on nitrogen is involved in the formation of a coordinate bond with the titanium(IV) ion, thus reducing double bond formation of the $C \cdots N$ bond as compared to free 8-hydroxyquinoline and indicating that the 8-hydroxyquinolinato group is chelating in all the 8-hydroxyquinoline complexes.[41] Apart from this, the bands occurring around 750, 1100, 530 and $505 \, cm^{-1}$ may be assigned to in plane ring deformation, C–O stretching, $\nu(M-O)$ and $\nu(C-O)$ in plane bending frequencies.[12,13]

The ^1H NMR spectra of these complexes have been recorded in deuterated chloroform. The resonance signal due to cyclopentadienyl groups were observed as a singlet near δ 6.60 ppm. The existence of a single sharp C_5H_5 resonance is attributed to rapid rotation of the ring about the metal ring axis.

The γ-protons (–CH=) resonance of the acetylacetonato and benzoylacetonato group in the chelates occur at a lower field (δ 6.1–6.0 ppm). This is probably due to at least, in part to the net positive charge on the complex ion. The δ values of methyl protons (δ 2.5 ppm) in acetylacetonato and benzoylacetonato moiety in the complexes is also lower than the values reported for other acetylacetonato and benzoylacetonato complexes. It may also be due to the cationic charge on the complex ion.[14] The

^1H NMR spectra of 8-hydroxyquinolinato chelates show that the protons at C_2 absorb at a lower field (δ 9.05, q, J = 4.0 Hz, 1.8 Hz) than observed for free 8-hydroxyquinoline (δ 8.78). This supports the conclusion that 8-hydroxyquinolinato ligand is chelating.

The resonance signals of different alkyl, cyclopentyl and hexamethylene groups in the dithiocarbamate moiety occur at almost the same frequency as for the free dithiocarbamate ligand. The intensities of all the resonance lines were determined by planimetric integration. The integrated proton ratios correspond to the formula assigned for these complexes.

Both the IR and ^1H NMR studies carried out for the present complexes indicate that ligand L is chelating and Cp_2Ti^{2+} moiety possess a wedge like sandwich structure with essentially tetrahedral coordination about the metal atom similar to that of dichlorides.[15] Typical vibrational frequencies assigned to the dithiocarbamate moiety in all the chelates fully support the view that dithiocarbamate anion is free anion.

The possibility of ligand L bonding by simple hardsphere coulombic interactions to Cp_2Ti^{2+} moiety is ruled out because in such cases a bischelate complex in contrast with the present observations, with four oxygen or two oxygen and two nitrogen atoms in the xy plane and parallel cyclopentadienyl rings could be isolated. Such a structure would maximise the coordination number of the metal ion and simultaneously maximise the total metal ring overlap. Since, the π-clouds are used in the formation of metal-ring bonds and would exert a less steric effect on the equatorial ligands, this configuration cannot be described as unstable on the basis of steric grounds.

Abstract. Glycine coordinated to cupric ions reacts in basic solution with a stoichiometric quantity of aldehydes to give β-hydroxyaminoacids. When the reaction contains a mixture of aldehydes, one of them being acetaldehyde, threonine is produced in the solution together with a variable amount of the bulkier substituted serine. An intermediate complex may be isolated which affords a larger proportion of substituted serines with predominance of the *threo* isomers. Acetaldehyde and benzaldehyde give a 66% yield of *threo* β-phenylserine.

Introduction. Condensation of aldehydes on amino acids complexed to metal ions[1] leads to various products. Such reactions provide a route for the synthesis of β-hydroxyaminoacids[2], but even under mild reaction conditions, serine for example undergoes a complex degradation pattern[3]. Schiff base formation has been used to protect amino groups, but yields are only fair[4]. This prompts us to report that mixed aldehyde condensation reactions can give specific β-hydroxyaminoacids in good yields.

Results. When 20 mmoles of acetaldehyde or acetone are added together with 20 mmoles of an aliphatic or aromatic aldehyde to 10 mmoles of *cis bis*-glycinato copper (II) monohydrate (I), a variety of condensation products is observed. Concentrated solutions precipitate blue to green complexes at room temperature after a few hours. The solids and the mother liquors treated as previously described[5] give different aminoacids in total recovery yields of 60 to 84% after recrystallisation from water/EtOH. The final products, analysed by ^{1}H NMR, are listed in the table. The yields are not statistically distributed and reflect stereoelectronic effects.

Acetaldehyde is the most reactive aldehyde and threonine in the *threo* to *erythro* ratio of 6/4 can be produced (run 8) in 96% yield. When acetaldehyde is mixed with other aldehydes, as in runs 9, 15, 17 and 18, threonine is the major product isolated from the mother liquors. However, these same reactions also give solid precipitates which rarely contain unreacted glycine, and yield less threonine than the other possible β-hydroxyamino acid. Comparing runs 10 and 11, the proportion of threonine increases when the stoichiometric ratio acetaldehyde/(I) is greater than 2. Strongly basic conditions or long reaction periods often result in the partial decomposition of the amino acids. The runs with acetone typically develop a gray color and brown to black copper precipitate. Operating under a nitrogen atmosphere (run 2) only slightly increases the recovery of amino acids.

Of special interest is the high *threo* to *erythro* ratio of substituted serines (IV) obtained from the solid intermediate complexes (III), as evidenced in runs, 9, 12, 13 and 15 to 18. We improved the results of run 13 with a larger scale reaction and obtained a 66% yield of the pure *threo* isomer (see experimental part). This clearly makes a mixed aldehyde method as attractive as the Schiff base one. Indeed, we only obtained a 21.5% yield of phenylserine as a mixture of isomers from a modification of the previously used procedure on N-pyruvilideneglycinatoaquo copper[6].

Discussion. Erlenmeyer synthesized phenylserine in 1893 by condensing two moles of benzaldehyde on one mole of glycine, with no other metal than sodium. Aliphatic aldehydes, however, require cupric ions to promote the reactions, the only reported exception to our knowledge being isobutyraldehyde[7]. The small yields of *threo* and *erythro* phenylserines obtained (run 14) and reported[8] when benzaldehyde is used alone could reflect condensation on uncomplexed glycine (copper hydroxide precipitates quantitatively from (I) at pH 12). Phenolic aldehydes do not react to give the desired products. Salicylaldehyde for example prefers to chelate the cupric ions in a Schiff base type complex. 4-methyl-benzaldehyde, on the other hand, mixed with equimolar acetaldehyde produces tolylserine[9] in 39% yield.

a
The reaction contains:1: NaOH = 1.5 $\underline{M}$, 2: 10 ml H$_2$O, 3: NaOH = 0.75 M, 4: NaOH = 0.50 M, 5: 15 ml H$_2$O, 6: 100 ml H$_2$O, 7: 1.5 g Na$_2$CO$_3$, 8: N$_2$ atmosphere, 9: NaOH = 0.33 $\underline{M}$, 10: NaOH = 0.05 $\underline{M}$.

b
The compound used is: a: acetaldehyde, b: benzaldehyde, c: acetone.

c
Abreviations for amino acids are: gly = glycine, dimeser = 3, 3'-dimethyl-serine, thr = threonine, φser = 3-phenylserine, isobutser = 3-isobutylserine, t-butser = 3-t-butylserine, n-butser = 3n-butylserine.

Another feature of the mixed aldehyde method is that excess aldehydes are not needed. We also note that a stoichiometric quantity of 4 moles acetaldehyde for one mole (I), run in D_2O and NaOD, gives a 94% yield of threonine after 5 hours, with no indication of deuterium incorporation at the α-carbon. Acetaldehyde reacts rapidly at the coordinated nitrogen to form a N-hydroxyethyl derivative (II), as evidenced by the rapid colour change from blue to violet. Subsequently or simultaneously, the seond aldehyde reacts with the α-carbanion formed under basic conditions and cyclises to give the *bis*-oxazolidine copper (II) complex (III)[10].
It has been suggested that steric interactions in intermediate complexes are responsible for the enantioselectivity in related aldol condensations[11] and reactions on similar amino acid[12] and peptide[13] Schiff base complexes. A recent report states stereoselectivity may be ascribed to steric inter-cycle interactions[8] in analogy with conclusions drawn from reactions on octahedral cobalt (III) complexes[14]. This is unlikely to hold true for labile square-planar copper (II) complexes. The exclusive formation of *threo* phenylserine from (III) and of the *threo* isomer of threonine by electrodecomposition[5] arises from intra-cycle steric interactions between substituents on the oxazolidine ring. Analysis of the solids in runs 15 to 18 shows threonine is present in *threo/ertho* ratios of 75/25 and the other substituted serines in corresponding ratios near 90/10, except for *t*-butylserine with a 40/60 ratio[15]. When the bulky substituents R and R'in (III) occupy pseudo equatorial positions in the oxazolidine ring then the *threo* isomer results. An *erythro* product requires R' in a pseudo axial position. A *threo/erythro* ratio near unity is observed for all amino acids isolated from the mother liquors, reflecting epimerisation at the α-carbon in basic solutions. Oxazolidines are known to be formed with very high stereoretention[16].

Conclusion. In previous work formaldehyde coupled with acetaldehyde gave inconclusive results[17]. Our findings show mixed aldehyde condensation without formaldehyde give β-hydroxyaminoacids readily and provide insight into the mechanism of this reaction.

Experimental. *Cis-bis* glycinato-copper (II) monohydrate was prepared by mixing aqueous solutions of two moles of glycine with one mole of copper sulphate and adjusting the pH to 7. The precipitate was recyrstallized once from water. The aldehydes used were of commercial origin. n-Butyraldehyde, isobutyraldehyde and pivalaldehyde were of technical grade.

The condensation reactions were carried out with magnetic stirring in tightly closed Erlenmeyer flasks, to avoid loss of acetaldehyde by evaporation. Because the reactions are exothermic, a Stirr-Kool model SK-12 from Thermoelectrics was used to maintain the temperature below 28° in the initial stages. In several runs, the solid precipitates were separated from the mother liquors by filtration. Both fractions were decomposed with concentrated ammonia and the aminoacids were recovered from a Dowex 50W-8X resin by elution with 1 M NH₄OH, followed by evaporation to dryness *in vacuo*. The products were recrystallized by slowly adding ethanol to concentrated aqueous solutions. The weight of the fractions was determined and the mole % of amino-acids determined by integration of the corresponding NMR peaks in D_2O solution. In some cases, the *threo* to *erythro* isomers gave distinct absorptions. Paper chromatography was used for semi-quantitative separation of *threo* and *erythro* isomers with a solvent composed of 40 ml n-butanol, 5 ml acetone, 30 ml H_2O and 5 ml concentrated NH₄OH, followed by revelation with ninhydrin.

Threo phenylserine in 66% yields was obtained by condensing 5.7 ml acetaldehyde and 10.2 ml benzaldehyde on 11 g of (I) in 10 ml H_2O + 20 ml NaOH 1 M in a 50 ml closed Schlenk Tube. An 85 hours reaction period gave a blue complex (III) which was washed with cold ethanol (yield 16.5 g). This compound was insoluble in water (with or without acetic acid) and could not be electrolysed. It was decomposed with concentrated ammonia and gave 11.96 g of phenylserine.

Abstract – The INDO method was applied to estimate the interaction energy attributable to clathration in Hofmann's benzene clathrate using a model. Host–guest and guest–guest interactions were clarified and a stabilization energy fairly consistent with that obtained by differential scanning calorimetry was calculated.

INTRODUCTION

In previous work,[1] the enthalpy changes associated with guest liberation of the Hofmann's clathrates $Ni(NH_3)_2Ni(CN)_4 \cdot 2G$ (G= C_6H_6, C_4H_4S, C_4H_5N, and C_6H_5OH) were determined by differential scanning calorimetry(DSC). The enthalpy changes for the pyrrole and phenol clathrates were greater than those for the benzene and thiophene clathrates by ca.10 kJ mol^{-1} respectively. The difference seemed too great to be explained in terms of dipole–dipole interaction among the guests and it was mainly ascribed to the π hydrogen bond between the CN group of the host lattice and the hydrogen atom (–NH or –OH) of the guest molecule. The presence of such bonding in the aniline clathrate and its contribution to the stability were pointed out earlier in connection with its study by infrared spectroscopy.[2] In that paper, the presence of a hydrogen bond between ammine ligand and aromatic guest was also suggested. It stimulated the author to evaluate the host–guest interaction by the molecular orbital method and relate it to the enthalpy change. Methods ranging from the extended Hückel MO to *ab initio* SCF MO have been used to investigate the π hydrogen bond for various systems.[3] To the author's knowledge, such an estimate of the stabilization energy by MO calculations has not been made for Hofmann's clathrate. However, a single crystal of Hofmann's pyrrole or phenol clathrate has not yet been obtained[4] and only data from powder X-ray diffractometry are available. Therefore the author first carried out MO calculations for the benzene clathrate, whose crystal structure was analyzed first by Rayner and Powell.[5]

METHOD

Since the d orbital cannot be treated in the version of the CNDO/2 and INDO programs used here,[6] the calculations were performed on the model illustrated in Figures 1 and 2. In the model, both the octahedral and the square planar nickel atoms were ignored and HCN was used instead of the CN group. The carbon and nitrogen atoms of HCN were located at the same positions as those in the original crystal structure.[5] The interatomic distance and bond angle of NH_3 were assumed to be identical with those of the equilibrium structure in the gas phase. The intermolecular energy was calculated as the difference between the total energy of the

coupled molecule and the sum of the total energy of the separate molecules. Although the calculations were performed using both CNDO/2 and INDO, the author describes here only the result by the latter method, noting that no significant difference was found between the results using both methods.

<div align="center">RESULTS AND DISCUSSION</div>

The results of the MO calculations proved that NH_3-C_6H_6, CN-C_6H_6 and C_6H_6-C_6H_6 interactions contribute to the stabilization arising from clathration.

The interaction between NH_3 and C_6H_6 was calculated by rotating NH_3 about its C_3 axis : the rotation of the ammine ligand with little hindrance was known from proton magnetic resonance spectra.[7] The dependence of the intermolecular energy(ΔE) on the rotation angle(Θ) of NH_3 is shown in Figure 3. From least-squares fitting using the program of SALS,[8] equation(1) was obtained.

$$\Delta E = -0.001410 - 0.000788 \sin(3(\Theta + 18.40)) \tag{1}$$

It indicates that the mean value of the energy for interaction between NH_3 and C_6H_6 is 0.001410 a.u.. There being four NH_3 molecules around a C_6H_6 molecule, the mean value of the total interaction energy is 0.005640 a.u., which was ascertained by performing the MO calculation on the combination of a C_6H_6 molecule and four NH_3 molecules. In this case, the intermolecular energy is due to the π hydrogen bond forming between NH_3 as the proton donor and C_6H_6 as the π electron donor. The variation of the energy with the rotaion angle corresponded to that of the charge transfer from C_6H_6 to NH_3.

As to the interaction between CN and C_6H_6, the bond order matrix indicated that the interaction between 1s orbitals of the hydrogen atoms of C_6H_6 and 2p orbitals of the carbon

Fig. 3. Dependence of the intermolecular energy (ΔE) on the rotation angle (θ) of NH_3. The numbering of atoms is consistent with that in Figure 1.

atom of HCN contributed to the stabilization. The effect was greater for HCN almost perpendicular to the ring of C_6H_6 (HCN(1) in Table 1) than for HCN almost parallel to the ring of C_6H_6 (HCN(2) in Table 1. See Figure 2.). In this case, it may as well be distinguished from the π hydrogen bond because the hydrogen atoms of C_6H_6 are unlike those of NH_3, which are partially positively charged. When C_6H_6 rotated about the C_2 axis perpendicular to the nickel cyanide network, the minimum point of the interaction energy was found in the vicinity of the angle actually found in the crystal structure.[5] Therefore the orientation of C_6H_6 seemed to be determined by the interaction between the guest molecule and the CN group of the host lattice.

The guest-guest interaction energy was calculated between a C_6H_6 molecule and others lying vertical to it, while no appreciable interaction was found between a guest and others lying parallel to it(See Figure 2). The bond order matrix showed that the interaction between 2p orbitals of the carbon atoms of a C_6H_6 molecule and 1s orbitals of the hydrogen atoms of another C_6H_6 molecule contributed to the stabilization just as in the case of C_6H_6 and HCN.

The results of the INDO calculations are listed in Table 1. The stabilization energy from clathration amounted to ca.30 kJ mol^{-1}, consistent with the result obtained by DSC.[1]

It is impossible to perform a similar calculation on Hofmann's phenol clathrate because single crystal structure data have not yet been obtained. However, the interaction energy for the π hydrogen bond between the hydrogen atom of the OH group and the CN group of the host lattice was calculated, assuming (a) that C_6H_5OH was situated in the middle of the adjacent nickel cyanide networks whose separation was known from X-ray powder data and (b) that the orientation of the guest molecule was identical with that of the benzene clathrate. The intermolecular energy was ca.21 kJ mol^{-1}. It is greater by ca.20 kJ mol^{-1} than that of the benzene clathrate. The value is thought to correspond to the difference between the enthalpy changes of the respective clathrates.[1]

The model for Hofmann's clathrate adopted here poses considerable problems in some respects. For example, the electron density of each atom in the model is not identical with that in the original clathrate. The structure of NH_3 assumed here must be a little different from that in the actual clathrate. The interaction between the guest molecule and the hydrogen atom of HCN was not negligible in the MO calculation. However, the result obtained here seems to be reasonable and may well hold also for the actual clathrate.

The characterization and thermal stability of a cluster $HRu_3(CO)_{10}(O–Si{\diagdown}^{\diagup})$ grafted on silica surface

Abstract—$Ru_3(CO)_{12}$, supported on silica in the absence of oxygen, reacts with silanol groups of the surface to produce a grafted cluster $HRu_3(CO)_{10}(OSi{\diagdown}^{\diagup})$, which has been characterized by IR and Raman spectroscopy; the molecular formula of this cluster is in agreement with the stoichiometric balance of CO evolved during its formation from $Ru_3(CO)_{12}$. The grafted cluster is an intermediate step to produce by thermal decomposition small metallic ruthenium particles of 14 Å together with some Ru(II) carbonyl species encapsulated in the silica surface.

Recent interest has been devoted to the chemical behaviour and the catalytic activity of mononuclear or cluster carbonyl complexes supported on inorganic oxides.[1]

Some attention has been paid to the chemistry of $Ru_3(CO)_{12}$ on silica[2–4] since it was reported that $Ru_3(CO)_{12}$ on silica is active in various catalytic reactions, such as α-olefin hydrogenation or isomeration[5,6] or CO reduction to hydrocarbons.[7]

However, in the previous works,[2–4] which were mainly supported by surface IR studies, it was difficult to understand the real surface chemistry, because the experiments were not carried out in the absence of surface adsorbed water and of dioxygen, since the samples were always prepared in the air. On the contrary under our standard experimental conditions,[8] we could investigate the adsorption of $Ru_3(CO)_{12}$ on silica surfaces, treated under high vacuum at 500°C for 16–20 hr, and follow the transformation of the supported cluster under different experimental conditions, including progressive heating in high vacuum.

In this way, we have found that the first "species" obtained by thermal decomposition of $Ru_3(CO)_{12}$ physisorbed on partially dehydrated silica is a grafted molecular cluster $HRu_3(CO)_{10}(OSi{\diagdown}^{\diagup})$ resulting from the oxidative addition of a surface silanol group into the metal–metal bond of the original cluster. Such grafted cluster thermally decomposes only above *ca.* 373 K to produce, upon aggregation, ruthenium metal particles covered with CO and some oxidized Ru(II) carbonyl surface species.

When $Ru_3(CO)_{12}$, dissolved in pentane solution, is adsorbed under vacuum onto a silica disc which was previously treated at 773 K under vacuum (10^{-5} torr) for 16 hr, the resulting IR spectrum exhibits bands at 2063 (s), 2032 (m), 2018 (m, sh) which are identical in frequency and intensity to those of $Ru_3(CO)_{12}$. By treatment under vacuum at *ca.* 353 K for a few hours a progressive modification of the spectrum is observed with new carbonyl bands appearing at 2111 (w), 2077 (m), 2066 (m), 2033 (s, br) and 1995 (sh) cm^{-1}.

The new IR spectrum is quite similar in intensity and frequencies to that of the well characterized osmium cluster $(H)Os_3(CO)_{10}(OSi{\diagdown}^{\diagup})$ grafted on a silica Surface[8]; in addition similar IR spectra are reported for molecular clusters of the type $(H)Ru_3(CO)_{10}X$ ($X = SC_2H_5$)[9] (Table 1).

The Raman spectrum of the supported cluster after decarbonylation at 318 K has been recorded using low power (< 30 mW) of the 647.1 nm laser line and sample spinning cell techniques in order to avoid any decomposition. In the low frequency region this spectrum exhibits several bands of the starting $Ru_3(CO)_{12}$ cluster[10] and two additional new bands at 201 and 162 cm^{-1} which can be tentatively assigned to metal–metal

stretching vibrations of a grafted cluster. The stoichiometry of the surface reaction:

$$Ru_3(CO)_{12} + HOSi{\diagdown}^{\diagup} \rightarrow (H)Ru_3(CO)_{10}(OSi{\diagdown}^{\diagup}) + 2CO$$
is confirmed by the following experiment. A pentane solution of $Ru_3(CO)_{12}$ (30 mg; 0.05 m.mole) was adsorbed onto a silica sample (about 1 g) previously treated at 773 K under vacuum for 16 hr. After removal of the solvent under vacuum at room temperature, thermal decomposition of the supported cluster at increasing temperature, resulted in the evolution of 1.7 ± 0.2 moles of CO/mole of cluster in the temperature range of 343–393 K. No significant evolution of H_2 nor CO_2 was observed in this temperature range which is in agreement with the proposed structure
$$HRu_3(CO)_{10}(OSi{\diagdown}^{\diagup}).$$

The thermal stability of the grafted ruthenium cluster has been followed by analysis of the gas phase during thermal decomposition by infrared spectroscopy and electron microscopy Upon heating the grafted cluster $(H)Ru_3(CO)_{10}(OSi{\diagdown}^{\diagup})$ above 393 K, a progressive evolution of about 10 moles of CO per mole of cluster was observed when the temperature was increased up to 523 K. Meanwhile a certain amount of H_2 was evolved, which may be ascribed to a partial oxidation of zerovalent ruthenium by surface OH groups with formation of surface oxidised Ru(II) $(CO)_n$ species.[2] After thermal decarbonylation of $HRu_3(CO)_{10}(O–Si{\diagdown}^{\diagup})$ above 393 K or at 393 K for 16 h under high vacuum (10^{-5} mm Hg), the IR spectrum presented a broad peak centered at 2037 cm^{-1}, typical of CO coordinated to metallic ruthenium, and some peaks of smaller intensity at 2122, 2081 and 1957 cm^{-1} probably corresponding to Ru(II) $(CO)_n$ ($n = 2, 3$) species formed in low concentration.

As it is well known for CO coordinated to metallic ruthenium[11] a progressive decarbonylation occurs with increasing temperature, corresponding to a shift of $\nu(CO)$ frequency from 2037 cm^{-1} at $\theta \approx 1$ to 1985 cm^{-1} at $\theta \approx 0.1$. Such decarbonylation is reversible as determined by the frequency and intensity of the $\nu(CO)$ band obtained after recarbonylation at 25°C. The presence of small particles of ruthenium metal was confirmed by electron microscopy. Such particles exhibit a very narrow distribution of particle size around 14 Å. Similar sizes have been obtained in another laboratory.[17]

The assignment of the other IR bands to a mixture of Ru(II) carbonyl species is substantiated by the easy formation of surface species characterised by similar IR absorptions, by thermal encapsulation of $Ru(II)CO_3Cl_2$ into silica (Table 1). These oxi-

^{a}hexane; ^{b}nujol mull; ^{c}on silica heated in vacuum at 500°C; ^{d}CH$_2$Br$_2$; ^{e}CH$_2$Cl$_2$; ^{f}CH$_2$Cl$_3$; ^{g}from Ru$_3$(CO)$_{12}$ on silica heated in vacuum at 500°C; ^{h}from [Ru(CO)$_3$Cl$_2$]$_2$ on silica heated in vacuum at 500°C.
dised species are in thermal equilibrium of decarbonylation (and carbonylation) (Table 1):

$$[Ru(CO)_3(OSi{\small\diagdown})_2]_n \underset{CO}{\rightleftharpoons} [Ru(CO)_2(OSi{\small\diagdown})_2]_n + n\ CO.$$
Similar species are obtained by treatment of $Ru_3(CO)_{12}$ adsorbed on silica or the grafted cluster $(H)Ru_3(CO)_{10}(OSi{\small\diagdown})$ with oxygen, confirming that an oxidation of the ruthenium atoms occurs. Finally a molecular species with similar IR absorption bands at 2062 (s), 1995 (s) cm^{-1} is obtained by treatment of $[Ru(CO)_3Cl_2]_2$ with TlOSiPh$_3$ (Table 1).

The various steps leading to surface grafting and then to the formation of metallic particles and Ru(II) carbonyl species (see Scheme) require well defined and narrow conditions, so that all these species may coexist if the experiments are not carried out under the appropriate conditions, which explains some of the previous results.[5] It is worth mentioning that $Ru_3(CO)_{12}$ reacts much like $Os_3(CO)_{12}$ with the silanol groups of silica, whereas $Fe_3(CO)_{12}$ exhibits a different behaviour.[12]

However in contrast with the corresponding osmium species, the ruthenium grafted cluster is not stable at room temperature in the presence of oxygen or adsorbed water.

It is probably for this reason that this particular surface species was not detected by previous workers,[2,3] whilst the corresponding surface osmium species $(H)Os_3(CO)_{10}X$ $(X = OSi{\small\diagdown}, OAl{\small\diagdown}, OZn, OTi{\small\diagdown})$, were observed even if the original samples were prepared in the air.[13]

In addition, in contrast to osmium, the ruthenium grafted cluster decomposes above *ca* 393 K to metal particles covered with CO and to oxidised Ru(II) surface carbonyl species, whilst with osmium the metallic state is reached under more drastic conditions.[8]

REACTIONS OF METAL COMPLEXES WITH CARBOHYDRATES. 3.[1,2]

THE CRYSTAL STRUCTURE OF (ETHYLENEDIAMINE)(2-[(2-AMINOETHYL)AMINO]-

2-DEOXY-L-SORBOSE)NICKEL(II) DICHLORIDE HEMI METHANOL –

[Ni(en)(L-sor-en)]Cl$_2 \cdot \frac{1}{2}$CH$_3$OH

We have previously reported the synthesis and characterization of new nickel(II) complexes containing N-glycoside which were derived from the reaction of tris(ethylenediamine)nickel(II) dichloride dihydrate with D-glucose, D-mannose, or D-fructose, including the X-ray structure determination of the complex derived from D-fructose (Figure 1).[1]

The bindings of carbohydrates to metal ions are interesting matters as coordination phenomena,[3] and as bioinorganic systems. As a part of study to elucidate interactions between metals and carbohydrates, we present both the synthesis and the crystal structure of a nickel complex containing an N-glycoside (L-sor-en) formed by the reaction between ethylenediamine and L-sorbose, where L-sor-en is 2-[(2-aminoethyl)amino]-2-deoxy-L-sorbose (Figure 2). L-sorbose, which is C5 epimer of D-fructose, is considerably important as an intermediate in the chemical synthesis of L-ascorbic acid.

Figure 1. A perspective drawing of [Ni(en)(D-fru-en)]$^{2+}$.
Figure 2. Reaction scheme.

The complex was synthesized as follows. L-Sorbose (17.6 mmol) was added to the solution containing [Ni(en)$_3$]Cl$_2$ 2H$_2$O (8.8 mmol) in 80 mL of methanol. As a catalyst NH$_4$Cl (8.8 mmol) was added.[4] The violet solution was refluxed for 1h., then it became blue. It was evapolated to 40 mL and loaded on a Sephadex LH-20 gel permeation column, and eluted with methanol. The reaction materials seperated into violet, blue, yellow, and orange bands. The blue fractions were collected and concentrated to about 15 mL, then it was kept at 5°C. Blue crystals were obtained and were recrystallized from a minimum amount of hot methanol.

Elemental analysis indicates that this complex has one ethylenediamine ligand (en), and one N-glycoside ligand (L-sor-en). Calculated for [Ni(en)(L-sor-en)]Cl$_2 \cdot \frac{1}{2}$CH$_3$OH (C$_{10.5}$H$_{28}$N$_4$O$_{5.5}$Cl$_2$Ni): C, 29.46; H, 6.61; N, 13.09; Cl, 16.56 Found: C, 29.19; H, 6.86; N, 13.36; Cl, 16.50. The near infrared and visible spectrum of methanolic solution shows three bands with comparatively low intensities, which are characteristic of octahedral Ni(II) complex (Figure 4). The magnetic moment at room temperature is 3.16μ_B, which falls within the range of reported octahedral nickel(II) complexes. The structure of this complex was determined by as X-ray crystallographic study. This compound crystallizes in the monoclinic space group C2 with a = 17.862 (2) Å, b = 8.212 (1) Å,

c = 12.644 (2) Å, β = 90.89°, and z = 4. After absorption correction, the structure was solved by heavy atom methods, and structure parameters including almost all hydrogen atoms were refined by least-square methods to R = 0.032 (Rw = 0.042)[5] for 2680 independent reflections with Fo>3σ(Fo). All calculations were performed with universal program system UNICS III.[6]

A perspective drawing of the complex cation showing thermal motion is given in Figure 3. It reveals that nickel is octahedrally coordinated with a bidentate ethylenediamine ligand and a tetradentate N-glycoside ligand of L-sor-en. The pyranose ring is in the usual α-$^2C_5$ chair form.[7] The conformation of bidentate ligand en is δ. The absolute configuration of the secondary nitrogen atom is S. The nickel-nitrogen bond distances fall within the expected range (Table 1). Each of the interior angles of five-membered chelate rings subtended at nickel atom is smaller than ninety degrees. They are normal for five-membered chelate rings.

Figure 3.   A perspective drawing of [Ni(en)(L-sor-en)]$^{2+}$.

The CD spectra of [Ni(en)(L-sor-en)]$^{2+}$ and [Ni(en)(D-fru-en)]$^{2+}$ in methanol are shown in Figure 4. They have opposite sign of CD curves in the first absorption region.

Table 1.   Selected bond length and angles.

bond length (Å)		angles (degree)	
Ni-O(1)	2.137(3)	O(1)-Ni-N(1)	76.1(1)
Ni-O(3)	2.118(2)	O(3)-Ni-N(1)	78.2(1)
Ni-N(1)	2.109(3)	O(3)-Ni-N(2)	162.8(1)
Ni-N(2)	2.068(3)	N(1)-Ni-N(2)	84.6(1)
Ni-N(3)	2.059(3)	N(3)-Ni-N(4)	83.9(1)
Ni-N(4)	2.078(3)		

It is generally accepted that the contribution of vicinal effect to optical activity, which is the effect of asymmetric groups on the ligand, is small. The structure of [Ni(en)(L-sor-en)]$^{2+}$ ion is similar to that of [Ni(en)(D-fru-en)]$^{2+}$ ion except for the absolute configurations around the C(5) atom and the gauche conformation of bidentate ethylenediamine chelate, which usually makes a rapid interconversion between δ and λ in solution. Therefore, it is a very interesting fact that the CD spectra of both complexes are quite different from each other as stated above.

The result of two crystal structures suggest the usual coordination patterns of the N-glycoside ligands derived from ketoses.

Figure 4.   Absorption and CD spectra of [Ni(en)(L-sor-en)]$^{2+}$ and [Ni(en)(D-fru-en)]$^{2+}$.

THERMAL INTRAMOLECULAR ELECTRON TRANSFER REACTIONS OF [N,N'-ETHYLENE-
BIS(SALICYLIDENEAMINATO)](2,4-PENTANEDIONATO)COBALT(III) COMPLEXES
IN THE SOLID STATE

Setsuko KINOSHITA*, Kikuo MIYOKAWA, Hisanobu WAKITA, and Isao MASUDA

Department of Chemistry, Faculty of Science, Fukuoka University,
Nanakuma, Jonan-ku, Fukuoka 814-01, Japan

ABSTRACT——The title complexes with the formula Co(salen)L where L is a series
of 2,4-pentanedionates underwent thermally induced one-electron transfer
reactions from L to Co(III). The reaction left behind a stoichiometric amount
of the crystalline Co^{II}(salen) complex which took up oxygen in a molar ratio
of $Co:O_2$ = 2:1. The kinetic analyses showed that the electron transfer
reaction rate was apparently dominated by activation entropy rather than by
activation enthalpy.

Thermally induced intramolecular electron transfer reactions occurring in solid
transition metal complexes are of significance in connection with the catalytic behavior
of metal complexes. However, there have so far been only a few investigations on such
redox reactions.[1,2] Present paper communicates that upon heating, the solid Co^{III}(salen)L[3]
undergo one-electron transfer reaction from the L to the Co(III) ion and leave behind a
stoichiometric amount of Co^{II}(salen) in the crystalline form which is active toward oxygen
uptake in the solid phase.

TG and DTA curves recorded in a flowing nitrogen atmosphere showed that Co(salen)L
were endothermally decomposed in the 440-490K temperature range. The weight-loss in the
TG curves corresponded to the following decomposition scheme: Co^{III}(salen)L $\longrightarrow Co^{II}$(salen).
The analytical data and μ_{eff} = 2.51 μ_B(300K) of the solid pyrolysis product also supported
the above scheme. Moreover, the IR spectra and X-ray powder diffraction patterns of the
pyrolysis products were in fair agreement with those of the authentic Co^{II}(salen) complex
prepared by the literature method.[4] The pyrolysis gas chromatographic measurements[1]
carried out under the conditions: Column packing, DEGA; pyrolysis temperature, 490K,
confirmed that the gaseous products evolved by the pyrolysis included 1/2 mol of the
corresponding free HL per mole of the pyrolyzed Co(salen)L complex. For Co(salen)(acac),
gaseous products were found to include, besides HL, non-stoichiometric amount of acetone,
methanol, and ethanol.

Under non-isothermal conditions,[5] the reactions were found to proceed following the
contracting-disc equation: $1-(1-\alpha)^{1/2}$ = kt, where α is the molar fraction of the Co(II)
complex produced from the Co(III) complex; k, the rate constant; and t, the reaction time.
The kinetic results are given in Table 1. As Table 1 shows, the rate constants at
460K increase in the following order of the mixed ligand L: acetylacetonato < propionyl-
acetonato < n-butyrylacetonato < n-caproylacetonato. Therefore, from the increase in the
rate constants the activation enthalpy $\Delta H^{\ddagger}$ may generally be expected to decrease in the
above order. However, contrary to this expectation the $\Delta H^{\ddagger}$ values actually increase in

Table 1. Kinetic data of the thermal electron transfer reactions of $Co^{III}(salen)L$

L	$\Delta H^{\ddagger}(460K)/kJ\ mol^{-1}$	$\log(A/s^{-1})$	$\Delta S^{\ddagger}(460K)/JK^{-1}mol^{-1}$	$k(460K)/s^{-1}$
acetylacetonato	193±3	18.7±0.5	101±9	$(2.00\pm0.72)\times10^{-4}$
propionylacetonato	227±6	23.4±0.6	190±11	$(1.38\pm0.27)\times10^{-3}$
n-butyrylacetonato	252±9	26.6±0.9	252±17	$(3.09\pm0.92)\times10^{-3}$
n-caproylacetonato	298±11	32.2±1.4	359±26	$(7.75\pm2.45)\times10^{-3}$

$\Delta H^{\ddagger}$, Activation enthalpy; A, pre-exponential factor; k, rate constant. The values of
activation entropy $\Delta S^{\ddagger}$, were calculated from the relation, $\Delta S^{\ddagger}= R(\ln\frac{Ah}{kT} - 1)$, where R is
gas constant, k Boltzman constant, h Plank constant, and T absolute temperature.
The kinetic analysis was carried out on the basis of the fact that all reactions followed
the contracting-disc equation.

this order. This fact led us to take the entropy term into consideration. The $\Delta S^{\ddagger}$ values,
activation entropy, calculated by assuming κ(transmission coefficient) = 1 are shown in
Table 1. It is seen from Table 1 that the $\Delta S^{\ddagger}$ value for L = n-caproylacetonato complex is
$ca.$ 3.5 times larger than that for L = acetylacetonato complex. Thus, it is clear that
the activation entropy plays an important role in the present solid state reactions. The
positive and rather large $\Delta S^{\ddagger}$ values are considered to suggest that the reaction rate is
determined by the dissociation process of L^6, which occurs with the concomitant electron
transfer process.

It is noticed that the pyrolysis of the complexes gave rise to the $Co^{II}(salen)$ complex
in a crystalline form. On standing this $Co^{II}(salen)$ complex in dry air or oxygen atmos-
phere at room temperature, it took up oxygen in a few hours and turned the color from
brown to black. The O_2-adduct liberated oxygen endothermally at $ca.$ 340K with a weight-
loss 4.8%, corresponding to the composition of the O_2-adduct, $[Co(salen)]_2O_2$. The O_2-
adduct showed μ_{eff} = 1.06 μ_B at 300K.

Preparation and Chelation Properties of the Polystyrene Resins Containing Pendant Multidentate Ligands

TOSHISHIGE M. SUZUKI* and TOSHIRO YOKOYAMA

Government Industrial Research Institute, Tohoku

Haranomachi, Sendai, Japan 983

Chelating polymer resins have been widely applied to metal ion collector in the fields of environmental chemistry and chemical industry.[1] Since the stability of a metal complex increases with the number of chelate rings, it is desirable to immobilize multidentate ligand into polymer matrix. Blasius prepared chelating resins by the reaction of alkylpolyamines with chloromethylated styrene-divinylbenzene copolymer.[2] But the intra- and interstrand bridging reactions are inevitable by the N-alkylation of the primary and the secondary amino groups of polyamine. These bridging reactions bring about the decrease in ligand content introduced in the polymer and steric restrictions for the chelate formation. Improved methods have been reported to avoid such bridging reactions,[3,4] but they require relatively long reaction steps.

In this communication we report a simple method to introduce multidentate ligands based on diethylenetriamine into polystyrene beads without causing the undesirable bridging reactions. The preparative scheme is given in Fig. 1.
Fig. 1   Reaction   scheme

Preparation of the chelating resins.   Reaction of bis(salicylidene-iminate)diethylenetriamine (93.3 g) with resin **1**[5] (26.0 g) in refluxed dioxane (400 cm^3) for 48 h gave yellow resin **2**. Yield: 50.4 g. Hydrolysis of **2** (49.1 g) with 6M HCl (600 cm^3) at 60 °C for 12 h yielded **3** in hydrochloride form. The resin in the free amine form was obtained by treatment with 2 M aqueous ammonia. Yield: 30.5 g. A mixture of sodium monochloroacetate (117.5 g in 200 cm^3 of water) and **3** (30.0 g) was heated at 70 °C for 12 h. Aqueous sodium carbonate solution was added to maintain the reaction solution basic (pH 9–10). The resin was washed with 2M HCl, water and acetone and vacuum dried. Yield: 49.9 g. Resin **5** was obtained by stirring resin **3** (5 g) with carbon disulfide (15.2 g) and sodium ethoxide (13.4 g) in ethanol (100 cm^3) at 50 °C for 12 h. Yield: 7.9 g. The analytical data of the resins are summerized in Table 1 along with the concentration of ligating groups and the reaction conversion.

Table 1. Analytical data and concentration of ligating groups of the resins

Resin	Analytical data (%)		Concentration of ligating group [a] (mmole/g-resin)	Conversion (%)[b]
	Cl	N		
1	20.5	–	5.78	–
2	1.09	8.81	2.10	94
3	0	12.70	3.02	72
4	0	7.74	1.84	87
5	0	7.58	1.80	78

a) Calculated from actual chlorine content (1), and nitrogen content (2, 3, 4 and 5).[6] Concentration of ligating group $= \dfrac{\% \; N}{14 \; n}$ X 10, where n=number of nitrogen atom.

b) Based on the ratio of the actual ligand content to the theoretical value calculated from total displacement of chlorine by ligand.[6]

Characterization and evaluation of the resins. The Schiff base bound resin 2 is presumed to have a structure as depicted in Fig. 1 in which direct N-alkylation has occurred. It is noted that bis(salicylideneiminate)ethylene-diamine did not react with 1, indicating that O-alkylation of the hydroxide groups in the ligand did not take place. Hence 2 does not contain bridging structures in the ligand moiety. Resin 2 gave IR band at around 1630 cm^{-1} due to (C=N) stretching vibration of the pendant ligand. Acid hydrolysis of 2 gave 3, where ν(C=N) band disappeared. Strong band of ν(C=O) was observed at around 1730 cm^{-1} for the resin 4 indicating that the desired reaction had took place.
Fig. 2 Chelation capacity vs. pH curves for the resin 4

All the chelating resins form complexes with various transition metal ions, i.e. Cu^{2+}, Ni^{2+}, Co^{2+} and Zn^{2+} and most of the reactions are accompanied by an obvious change in color of the polymer beads. The chelation capacities (maximum uptake of metal ion by 1 g of dry resin) of the present resins are in the range 1.2 to 3.0 mmole/g-resin at the optimum pH region. Resin 4 can retain metal ions at wide pH range (Fig. 2) and the chelation capacities are much higher than those of commercially available resins containing iminodiacetic acid. This is because the ligand moiety of 4 consists of two sets of iminodiacetic acid and can react with metal ions in 1 : 1 or 1 : 2 (ligand : metal ion) ratio.

SYNTHESIS AND SPECTRAL STUDIES ON PLATINUM COMPLEXES WITH MONO- AND BIDENTATE N-DONOR ORGANIC LIGANDS†

P. UMAPATHY* and RASHIDA A. HARNESSWALA

National Chemical Laboratory, Poona 411008, India

Abstract—Platinum(II) complexes of types $PtLX_2$, PtL_2X_2, $PtLX'$ and the Pt(IV) complexes PtLXY (where L = mono- or bidentate organic ligand containing nitrogen donor atoms; X = Cl or Br; X' = oxalate or malonate and Y = Br) have been synthesized and characterized from their elemental analysis, IR and X-ray photoelectron spectral data. The Pt $4f_{7/2}$ binding energies indicate that 1,8-naphthalene-diamine ligand is a better donor of electron density to the metal than other ligands studied here. The Cl $2p_{3/2}$ binding energies in the square planar Pt(II) complexes are observed in the range 198.8 ± 0.8 eV. The ν (Pt–Cl) vibrations (ca 335 and 320 cm^{-1}) corresponding to two cis-Cl ligands were observed in the IR spectra.

The extent of the interaction between cis-dichloro-bis-(theophylline)platinum(II) with calf thymus DNA has been studied. The UV difference spectra resulting from aquated Pt^{II}(theoph)$_2$-DNA interaction exhibit bands at 282 and 292 nm attributable to the change in the electron distribution of the base moieties induced by binding with platinum and due to the loss of base stacking. Melting profiles for the DNA samples treated with Pt-complex showed decrease in the melting temperature. Binding of the guanine residues of the DNA, involving probably (N7)–O(6) positions to the metal is implied.

INTRODUCTION

The encouraging and rapid progress in clinical development of anti-tumour platinum drugs has been the main impetus behind studies of the mechanism of action. Currently[1] the most convincing mechanism for the cytotoxic action of these agents on cells in culture is that reactions with DNA impair its function as a template for further DNA replication. The anti-cancer action of cis-dichlorodiammine platinum(II) cis-PtCl$_2$(NH$_3$)$_2$ (cis-platin), which is currently used in many hospitals in the treatment of ovarian, testicular and other forms of cancer, is thought to involve coordination to a guanosine residue in DNA. Little is presently known about the specific covalent attachment sites of cis-PtCl$_2$(NH$_3$)$_2$ and platinum uracil blues on DNA. However, various studies have implicated N-7 and possibly O–6 of guanine.[2–5] Although high overall response rates for cis-platin in the treatment, particularly ovarian and testicular forms of cancer, were reported[6,7] when the drug was used in combination with vinblastine and bleomycin or doxorubicin, efforts increasingly are being made to synthesize new platinum compounds with decreased toxicity and greater therapeutic properties. We have, in continuation of our work[8] on Pt(II) and Pd(II) chelates, synthesised several new Pt(II) complexes of the type, $PtLX_2$, PtL_2X_2, $PtLX'$ and Pt(IV) complexes PtLXY where L = mono- or bidentate ligand, such as, 8-aminoquinoline, 1,8-naphthalenediamine or a derivative of 1,10-phenanthroline, theophylline, 5-nitro-2-aminopyridine, etc. X = Cl or Br; X' = oxalate or malonate; Y = Br.

Some of these compounds were screened for their activity at Imperial Cancer Research Fund Laboratories, London, and the preliminary in vitro tests indicate appreciable antitumour activity, especially for the compounds dichloro(8-aminoquinoline)Pt(II) and oxalato(8-aminoquinoline)-Pt(II). Furthermore, we have also studied in solution the reaction of dichloro-bis-(theophylline)Pt(II) with calf thymus DNA by recording the UV difference spectra at various pH's and temperatures. Solubility problems precluded the study of other Pt-complexes.

EXPERIMENTAL

K$_2$PtCl$_4$ and K$_2$PtBr$_4$ were prepared by the reported methods.[9,10] The ligands, 5-notro- and 5,7 - dibromo - 1,10 - phenanthroline, 5 - nitro - 2 - aminopyridine, 1 - isonicotinyl - 2D - glucosylhydrazine, theophylline, 7 - methyltheophylline, 6 - amino - 5 - nitroso - 1,3 - dimethyl uracil were synthesized by the known procedures.[11–15] Their purity was checked by elemental analysis, m.ps and spectral data. Calf thymus DNA (Type I), thymine hydrochloride, 8 - amino - quinoline and 1,8-naphthalenediamine were purchased. (Sigma Chemical Co., Fluka AG, Buchs SG, Switzerland and Aldrich Chemical Company, Inc., U.S.A.) All other chemicals used were of reagent grade. Solvents were purified and dried prior to use. IR spectra were recorded on a Perkin–Elmer model 599B infrared spectrophotometer.

X-ray photoelectron spectra were recorded using a VG Scientific ESCA–3MK–2 electron spectrometer. Powered samples were mounted on a nickel sample holder. Magnesium K$_\alpha$ radiation (1253 · 6) was used as a source. Nitrogen 1s, Pt 4f, Cl 2p, Br 3p binding energies were referred to C 1s line of impurity carbon at 283 eV. An attempt was also made to reference the spectra to the Au $4f_{7/2}$ line at 83 eV by vacuum deposition of gold onto the sample. The final values of the binding energies for each sample were determined from measurements in triplicate on several sample preparations and their accuracy is within ±0.20 eV. Visual examination of the samples after measurement revealed no evidence of radiation damage.

DNA stock solutions were prepared by dissolving DNA in 0.01 M phosphate buffers pHs 6.8, 8.04 and 9.95 containing 0.01 M NaCl by gentle stirring in a refrigerator. The concentration of DNA was estimated by absorbance measurement at 260 nm using the coefficient ϵ (P) = 6650.[16] The platinum complexes were dissolved before use in 0.01 M phosphate buffer, pH 6.8 containing 0.01 M NaCl. The aquated cis-Pt(theoph)$_2^{2+}$ was prepared by stirring solutions of stoichiometric amounts of AgNO$_3$ and cis-Pt(theoph)$_2$Cl$_2$ overnight at room temperature in dark. The AgCl that precipitated was removed by filtration and the clear filtrate was diluted with buffer to the final stock concentration [1.0×10^{-14}M aq cis(theoph)$_2$Pt^{++}]. The pH adjust-

ment of all solutions to 6.8 was made by the addition of standard NaOH solution. All the pH measurements were made on a digital pH meter, model PHN63 (Radiometer, Copenhagen).

Reactions were carried out at different concentrations of DNA, concentration of aq. cis-(theoph)₂Pt⁺⁺, temperature and pH. The difference spectra were obtained using four 1 cm path length cells. The sample compartment contained two cells, one containing the reaction solution (cis-(theophy)₂Pt⁺⁺/DNA) and the other containing the buffer solution, whereas the reference compartment contained individual cells of DNA and the aquated cis-(theoph)₂Pt⁺⁺ solutions respectively at the same conditions (0.01 M phosphate buffer, pH, temperature and initial concentration). The difference spectra reported at 30°C were obtained on a 0.500 expanded absorbance scale on a Pye Unicam Model SP8-100 spectrophotometer. The melting temperature, Tm, is defined as the temperature at half denaturation.[17] Melting profiles were recorded manually (rate of heating 5°/min. initially and 1°/min. in the steep part of the curve at 260 nm.

Pt(II) complexes of the type Pt(II)LX₂, Pt(II)L₂X₂ were synthesized by following the general procedure given below:

Clear (filtered if necessary) solutions of K₂PtCl₄ or K₂PtBr₄ in water (10 ml) and the appropriate organic ligand in excess of hot water (80 ml) in 1:1 or 1:2 mole ratios were mixed together and heated on a water-bath for about 8–12 hr. (In case of 5 - nitro - and 5,7 - dibromo - 1,10 - phenthroline solvent DMF was used and the mixture was refluxed; in the preparation of 1-isonicotinyl - 2D - glucosyl hydrazine complex, the reaction mixture was stirred at room temperature for 24 hr.) The solid products that separated out were collected on a filtered under suction, washed with hot water repeatedly (5 ml portions) and dried under vacuum. Yield ~ 80%.

(9) *Dichlorobis(theophylline)platinum(II)*, Pt(theoph)₂Cl₂: decomp. ~340°C. Found: C, 27.54; H, 3.4; N, 16.36; Cl, 11.78; Pt, 30.93. Calc. for C₁₄H₁₆N₈O₄Cl₂Pt: C, 26.84; H, 2.57; N, 17.89; Cl, 11.31; Pt, 31.11%.

(10) *Dichlorobis(2-aminopyridine)platinum(II)*, Pt(2-NH₂py)₂Cl₂: decomp. 280°C (285°C).[20] Found: C, 26.28; H, 3.2; Pt, 43.05. Calc. for C₁₀H₁₂N₄Cl₂Pt: C, 26.42; H, 2.64; Pt, 42.96%.

(11) *Dichlorobis(5 - nitro - 2 - aminopyridine)platinum(II)*: Pt(5 - NO₂ - 2 - NH₂ - py)₂Cl₂: decomp. >300°C. Found: C, 21.11; H, 2.5; N, 14.83; Pt, 36.18. Calc. for C₁₀H₁₀N₆O₄Cl₂Pt: C, 22.05; H, 1.84; N, 15.44; Pt, 35.86%.

(12) *Dichloro bis(6 - amino - 5 - nitroso - 1,3 - dimethyl uracil)-*: platinum(II), Pt(6 - NH₂ - 5 - NO, 1,3-CH₃ Urac)₂Cl₂: decomp. ~216°C Found: C, 22.63; H, 2.92; N, 16.82; Cl, 11.0; Pt, 30.38. Calc. for C₁₂H₁₆N₈O₆Cl₂Pt: C, 22.72; H, 2.53; N, 17.67; Cl, 11.18; Pt, 30.76%.

(13) *Dichloro bis(thymine)platinum(II)*, Pt(thy)₂Cl₂: decomp. 280°C. Found: C, 22.20; H, 2.6; N, 9.48; Cl, 12.84; Pt, 38.03. Calc. for C₁₀H₁₂N₄Cl₂Pt. C, 23.17; H, 2.33; N, 10.81; Cl, 13.68; Pt, 37.65%.

(14) *Tetrachloro(8 - aminoquinoline)platinum(IV)*; Pt(8–NH₂Q)Cl₄: Chlorine was bubbled into a well stirred suspension of Pt(8–NH₂Q)Cl₂ (0.41 g; 0.001 mole) in dry chloroform (~120 ml) for 20–25 min. After an additional 20 min. of stirring, the yellow product was filtered out, washed twice with CHCl₃ (5 ml portions) and vacuum dried. Yield of the greenish yellow product 0.32 g (66%). decomp 300°C. Found: C, 21.36; H, 1.87; N, 6.24; Pt, 39.71. Calc. for C₉H₈N₂Cl₄Pt: C, 22.51; H, 1.68; N, 5.83; Pt, 40.64%.

(15) *Dibromodichloro(8 - aminoquinoline)platinum(IV)*: Pt(8–NH₂Q)Cl₂Br₂: To a suspension of Pt(8–NH₂Q)Cl₂ (0.41 g; 0.001 mole) in chloroform (~ 50 ml) bromine (2 g) in chloform (50 ml) was added dropwise with stirring at room temperature. The stirring was continued for 4 hr. The greenish brown solid obtained was collected on a filter, washed with chloroform (20–25 ml) and dried in vacuum. Yield, 0.4 g (71%), decomp. ~260°C. Found: C, 19.94; H, 2.02; N, 4.76; Pt, 33.6. Calc. for C₉H₈N₂Cl₂Br₂Pt: C, 19.09; H, 1.41; N, 4.92; Pt, 34.23%.

(16) *Oxalato(8 - aminoquinoline)platinum(II)*, Pt(8–NH₂Q) (Oxal): Clear (filtered if necessary) solutions of potassium *bis*-oxalatoplatinate(II) dihydrate[21] in water (10 ml) (0.39 g; 0.001 mole) and 8-aminoquinoline in hot water (25 ml) (0.14 g; 0.001 mole) were mixed together and heated on a water bath for 4 hr. The deeply coloured violetish-black solid that separated was collected on a filter, washed with hot water and dried under vacuum. Yield 0.3 g (69%); decomp ~290°C. Found: C, 30.52; H, 2.49; N, 5.96; Pt, 44.78. Calc. for C₁₁H₈N₂O₄Pt: C, 30.82; H, 1.89; N, 6.56; Pt, 45.66%.

(17) *Malonato(8-aminoquinoline)platinum(II)*, Pt(8-NH₂.Q) (Malon): was prepared by following the above procedure starting with potassium *bis*-malonatoplatinate(II) dihydrate and 8-aminoquinoline: Yield ~65%. decomp. ~310°C. Found: C, 31.64; H, 2.66; N, 6.72; Pt, 43.78. Calc. for C₁₂H₁₀N₂O₄Pt: C, 32.64; H, 2.28; N, 6.35; Pt, 44.21%.

RESULTS AND DISCUSSION

The interaction of platinum complex, dichloro-*bis*-(theophylline)platinum(II) with calf thymus DNA in buffer solutions was followed by UV difference spectral and melting techniques. The UV difference spectrum for the DNA solution mixed with cis-Pt-(theoph)₂Cl₂ did not change indicating no reaction with DNA bases. However when the aquated Pt-complex was mixed with DNA, the spectrum exhibited large hyperchromism with a wavelength shift of the peak absorption from 259 to 282–290 nm (Figs. 1 and 2). It was postulated[22,23] that reactions of compounds such as cis-PtCl₂(NH₃)₂ with the DNA bases and even DNA itself *in vivo* go through an aquation product, supposedly [Pt(NH₃)₂(H₂O)₂]²⁺. Rosenberg *et al.*[24-27] recently have shown that aqueous solutions of the aquation product are very complex and, in addition to such species as the above contain substantial amounts of hydroxide-bridged species containing two, three and four platinum atoms. The aquated cis-Pt(theoph)₂Cl₂ solution may contain presumably cis-[(theoph)₂Pt(H₂O)₂]²⁺, cis-[(theoph)₂Pt(H₂O)(OH)]⁺ species along with hydroxide bridged species containing two or three platinum atoms. The extent of the reaction depends on pH, time, temperature and the mole ratio of Pt/DNA system. The time required to reach the end of the reaction under optimum conditions (pH 8–9, time 24 hr; mole ratio 1:2) is of the order of 24–30 hr at 30°C.
Fig. 1. UV difference spectra resulting from aquated cis-(theoph)$_2$ Pt^{II}-DNA interaction pH, 6.8; T 30 and 60°C
[DNA] 0.5 mg/ml of buffer, [Pt^{II}] $= 1 \times 10^{-4}$ M.

It seems well established[4,28] now that the interaction between Pt compounds and DNA takes place through the complex aquated charged species of platinum and that a high concentration of chloride ions (> 0.01 M) inhibits the reaction to an appreciable extent. The aquo complexes bind more readily to cellular targets such as DNA since water is relatively a good leaving group. Furthermore, the formation of charge aquo complexes equally may raise the affinity of the complexes to phosphates.[29] The UV difference spectrum in the reactions with aquated species of the Pt-complex with DNA at pH 6.8 and at pH 8.04 exhibit λ_{max} at 282 nm and at 292 nm respectively while λ_{min} was observed in both at 250 nm. ΔA at 282 nm and at 292 nm increased with increasing concentration of DNA as well as Pt-concentration. Similar changes were noticed when DNA was treated with another Pt-complex namely potassium bis-malonatoplatinum(II)dihydrate. The reaction with DNA was however, rapid compared with [(theoph)$_2$Pt(OH)(H$_2$O)]$^+$.

Melting profiles of DNA samples treated with platinum complexes were examined and the results show increase in melting temperatures, Tm. (Tm for (theoph)$_2$Pt(II), 65° and for K$_2$PtC$_3$H$_2$O$_4$, 61°C). Binding of the Pt-complex to DNA distorts the secondary structure of neighbouring base pairs in DNA and helps to destroy the secondary structure of DNA on heating.[17] The results suggest that the increment of ΔA at 282 nm may be attributed to the loss of base stacking. The increment of ΔA at 292 nm may be due to the change in electron distribution of base moieties induced by binding with platinum.

The interaction of the aquated species cis-[(theo)$_2$Pt(OH)-(H$_2$O)]$^+$ conceivably liberates a hydroxide from the coordination sphere on complexation which would yield a net increase in pH. It was in fact, observed that at pH ~ 9.00 the shift of the 259 nm band (of DNA) was quite large. It is also possible that the aquated species binds to guanine residue at N-7 position with the resulting liberation of proton at N-1 position as
Fig. 2. UV difference spectra resulting from aq cis-(theoph)$_2$ Pt^{II}-DNA interaction pH 9·95 T 30°C; 68 hr.

has been postulated[30] in the cis-(NH$_3$)$_2$Pt(II)-inosine reaction. Scobell and O'Connor[31] observed in their studies of aquated cis-(NH$_3$)$_2$Pt(II) with nucleic acid constituents that deprotonation of the guanosine does not occur and that in the complexation reaction monodentate coordination occurs with displacement of water. The interaction of the aquated species [(cis-(theoph)$_2$Pt(H$_2$O)$_2$]$^{2+}$ with DNA may be predominant at pH 6.8. Millard et al.[32] have suggested that in the cis-(NH$_3$)$_2$Pt^{II} interaction with DNA, guanosine acts as a chelate, binding through the N-7 and O-6 positions. The binding mode of cis-(NH$_3$)$_2$Pt(II) to DNA as an interbase crosslink which corresponds to the intrastrand crosslink has also been suggested.[33–35] The large shift of the 259 nm band of DNA to 292 nm at pH ~9.00 observed in the UV difference spectrum of aquated cis-(theop)$_2$Pt(II)-DNA interaction, is indicative of chelation possible involving N-7-O-6 positions of the guanine residues, rather than Pt-intrastrand crosslinking. In the UV difference spectra resulting from aquated cis-

(NH$_3$)$_2$Pt(II)-guanosine interaction the peak was observed[30] at ~290 nm.

The XPS data for the platinum complexes investigated are given in Table 1. The Pt 4f$_{7/2}$ binding energies of compounds Nos. 1–5 imply a marked decrease of electron density on the metal relative to 1,8-naphthalenediamine complex. All the complexes are formally square planar Pt(II) compounds presumably containing cis-PtCl$_2$ fragment. Variations in relaxation effect should be minimized in this series and the differences in metal binding energies should primarily be due to differences in the electron donating ability of the coordinated ligands.[36] The data indicate that 1,8-naphthalenediamine is a better complexing agent, i.e. better donors of electron density compared to 5,6 - dibro - 1,10 - phenanthroline or 7-methyl theophylline. The substantial shift in the binding energy of N(1s) clearly confirms a net electron transfer from nitrogen to platinum in these complexes. The N(1s) photoelectron spectra of these complexes consist of doublets or broad bands indicative of unresolved peaks.
Fig. 2(a). Concentrations same as Fig. 2 after 140 hr.

The directly coordinated nitrogen has presumably the greater positive charge.

The change in the Pt $4f_{7/2}$ binding energies shows both the effect of oxidation state and of ligand character. The higher the formal oxidation state of platinum the higher the binding energy. All the platinum(II) complexes of the general formula $Pt^{II}X_2L_2$ or PtX_2L investigated here have $4f_{7/2}$ binding energies ranging from 74.4 to 73.4 eV, which is in agreement with the range reported by Riggs[37] for Pt(II) complexes.

The $Cl(2p_{3/2,1/2})$ binding energies for all the complexes studied studied are in the range 198.8 ± 0.8 eV. In general, within the closely related series of complexes, the chlorine binding energy gives a good indication of the effect of changes in overall electron density on the Pt–Cl bond. The Cl(2p) binding energies of these complexes of the type PtL_2Cl_2 or $PtLCl_2$ are lower than that of $K_2(PtCl_4)$ indicating partial ionic character of the Pt–Cl bond. In complexes, where L = a bidentate ligand, the square planar geometry presumably implies cis-Cl configuration. The IR spectral date confirm this. The other complexes may also have cis-chlorines in view of the observed narrow range of Cl(2p) binding energies. X-ray crystallographic data show quite clearly that there is a considerable increase in metal-halogen bond length in going from trans- to cis-isomer in square planar Pt(II) and Pd(II) complexes of the type $(PR_3)_2MX_2$. For X = Cl, n.q.r. data[38] suggest that the bond lengthening is accompanied by a considerable electron drift to chlorine. Clark and Adams[39] observed that in a given cis-trans pair, the binding energy of the metal is the same but that of the halogen is considerably lower in the cis-isomer. The ^{35}Cl resonance signals in the three trans-L_2PtCl_2 complexes are found at higher frequencies than in the corresponding cis-complex and this difference is related to the charges on the ligands. The tentative conclusion is that the trans- influence in the ^{35}Cl quadrupole resonance of the complexes of the type L_2MCl_2 [M = Pt(II) or Pd(II), Ni(II)] manifests itself in a general lowering of the frequencies on going from trans- to the cis-complex and the difference Δ being related to the position of the ligand L in the trans-series. There is evidence,[40] however, that relative to $PtCl_4^{2-}$, the binding energy of the cis-chlorines is raised (decrease in negative charge) and that of the trans-chlorine is lowered. This is in agreement with the other ground state phenomena which relate to the trans- effect; increase in Pt–Cl bond length is accompanied by electron drift to chlorine.
Fig. 2(b). Concentrations same as Fig. 2 after 4 hr, T 55°C.

The infrared spectra of Pt(II) complexes with organic ligands, 8-aminoquinoline, 5-nitro- or 5,7-dibromo-1,10-phenanthroline, 1-isonicotinyl-2D-glucosyl hydrazine, theophylline and its methyl derivative, etc. show absorptions in the region 600–200 cm^{-1}, assignable to Pt-halogen stretching vibrations which are absent in the spectra of the corresponding ligands. The spectrum of the complex Pt(8-NH$_2$Q)Cl$_2$ shows two medium intense absorption at ca. 335 and at ca. 320 cm^{-1} ascribable to ν(Pt-Cl) vibrations corresponding to two Cl ligands in cis-arrangement. The ν(Pt-Cl) absorptions in the spectra of the complexes, Pt(5-NO$_2$-1,10 phen)Cl$_2$, Pt(5,7-Br$_2$-1,10-phen)Cl$_2$ and Pt(ISNGH)Cl$_2$ are observed at 340 and 335 cm^{-1}; 345 and 335, 330 and 300 cm^{-1} respectively. In the IR spectra of Pt(II) complexes with nitrogen donor ligands (mono- or bidentate) bands observed at ca. 330 and 320 cm^{-1} have been assigned to asymmetric and symmetric ν(Pt-Cl) vibrations corresponding to two Cl ligands in cis-arrangement.[18,20] The medium intense band observed at ca. 270 cm^{-1} with a shoulder at ca. 275 cm^{-1} in the spectrum of Pt(8-aminoQ)Br$_2$ may arise due to (Pt-Br)-vibrations. In view of the bidentate nature of the ligand and the square planar geometry presumed for these complexes, these bands may tentatively be assig-

ned to cis-ν(Pt-Br) vibrations. ν(Pt-Br) vibrations in Pt(II) complexes with N-methyl imidazole[41] and in Pt(II) complex anions[42] were reported to occur at ca. 220 cm^{-1} and at ca. 205 cm^{-1} respectively.

In the spectra of Pt(IV) complexes, Pt(8-NH$_2$Q)Cl$_4$ and Pt(8-NH$_2$Q)Cl$_2$Br$_2$ (isolated by the reactions of Pt(8-NH$_2$Q)Cl$_2$ with halogens), absorption bands at 350(sh), 345 and 320 cm^{-1} were observed. It is, however, difficult to locate precisely the trans- ν(Pt-Cl) vibrations since this region is obscured by the strong absorptions caused by the equatorial chlorides. However, the absorption observed at ca. 255 cm^{-1} in (Pt(8-NH$_2$Q)Cl$_2$Br$_2$ may arise due to trans-ν(Pt-Br) vibrations. In Pt(II) complexes with 1,10-phenanthroline and its derivatives, axial bromides are reported[19] to absorb at 251–253 cm^{-1}. All platinum complexes containing the bidentate ligand, 8-aminoquinoline show ν(N-H) at ca. 3120 cm^{-1} in their IR spectra indicating a coordinated NH$_2$[18,43].

The Pt(II) complex with methyl theophylline shows bands at 350(s), 345(s) assignable to asymmetric and symmetric cis-ν(Pt-Cl) vibrations. The Pt(II) complex with theophylline shows medium to strong intense band at 330 cm^{-1} with a shoulder at 325 cm^{-1}. The shoulder could be due to symmetric Pt-Cl vibration and indicates

the *cis*-complex. The IR spectrum of Pt(II)-theophylline complex shows strong bands at 1500–1700 cm^{-1} and 1200–1250 cm^{-1} attributed to theophylline coordination.[44] Theophylline anion is bound to metal through N-7 in most of the reported metal–ion theophylline complexes,[45,46] and various other ligands are attached to the central metal. In fact the anion does not seem to act as a chelate in many complexes whose structures have been determined.[47] Recently a new mode of theophylline anion metal bonding—a trimeric complex with trimethyl platinum(IV) which contains Pt-N(7)-N(9)-Pt bridges and a weak direct (C-6) O-Pt bond has been however, reported by Hall *et al.*[48] In methyl theophylline (caffeine) anion formation through loss of a proton on nitrogen (N-7) is not possible and N-9 lone pair is the only nitrogen site available for bonding. The crystal and molecular structure of aquadichloro caffeine copper(II), [CuCl$_2$(C$_8$H$_{10}$N$_4$O$_2$)H$_2$O], has been determined.[49] The caffeine ligand acts as a unidentate and N-9 is involved in bonding with copper.

CRYSTAL AND MOLECULAR STRUCTURE OF
[N N'-(3,3'-DIPROPYLAMINE)-
BIS(SALICYLIDENEAMINATO)MONOACETATE]COBALT(III)
COMPLEX

NAOHIDE MATSUMOTO*, MASAHIKO IMAIZUMI and AKIRA OHYOSHI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami 2-39-1, Kumamoto
860, Japan

Abstract—The crystal and molecular structure of [N,N'-(3,3'-dipropylamine)*bis*(salicyclideneaminato)-monoacetate]cobalt(III) complex has been determined by a three-dimensional X-ray diffraction study. In the complex, the cobalt ion has an octahedral coordination environment with *cis*-geometry for the two salicyclideneaminato moieties. An oxygen atom of the acetate ion is coordinated to cobalt ion and another oxygen atom is hydrogen-bonded to the secondary amine nitrogen atom.

INTRODUCTION

It is well known that the complex [N,N'-(3,3'-dipropyl-amine)*bis*(salicyclideneaminato)]cobalt(II) (1) reacts reversibly with molecular oxygen to form the 1:1 O_2 adduct complex.[1] Recently, a single-crystal X-ray diffraction study has confirmed that the coordination geometries of the precursor complex (1) and its 1:1 O_2 adduct complex (2) are a trigonal bipyramid and an octahedron, respectively, with *trans*-geometry for the two salicyclideneaminato moieties as shown in Fig. 1.[2] This result implies that the conformational rearrangement of the ligand has occurred during the formation of the O_2 adduct.

In this study, the crystal structure of the title compound containing the same ligand, has been determined by the single-crystal X-ray diffraction technique. Since the electronic structure of the 1:1 O_2 adduct was assumed to be $Co^{III}-O_2^-$ based on the ESR spectral investigation,[3] it is of interest to compare the coordination geometry of the present complex with that of the 1:1 O_2 adduct. In addition, this structural result can be expected to propose a clearer idea for the conformational rearrangement during the formation of the O_2 adduct (2) from the precursor complex (1).

---

*Copies are available, on request, from the Editor at Queen Mary College.

RESULTS AND DISCUSSION

The structure of the title compound with the atom numbering scheme is shown in Fig. 2. As shown in Fig. 2, the cobalt atom assumes an octahedral coordination array with *cis*-geometry for the two salicyclideneaminato moieties and the dihedral angle between the two benzene rings is 82.8°. The average Co–O(phenolic) bond length of 1.888(7) Å is shorter than the Co–O(3)(acetate) bond length of 1.924(7) Å. The average Co–N(imine) bond length of 1.933(8) Å is shorter than the Co–N(secondary amine) bond length of 1.983(9) Å. An oxygen atom of the acetate is coordinated to the cobalt atom. It is noteworthy that another oxygen atom is hydrogen-bonded to the secondary amine nitrogen atom and the distance (O(4) $\cdots$ N(4)) is 2.825 Å.

The saturated six-membered chelate ring defined by Co, N(1), C(8), C(9), C(10) and N(2) takes a boat conformation and the other six-membered chelate ring defined by Co, N(2), C(11), C(12), C(13) and N(3) takes a chair conformation.

The coordination geometry of the present complex is apparently different from both the trigonal bipyramid of the precursor (1) and the octahedron with *trans*-geometry of the O_2 adduct (2). The coordination geometry containing this type of ligand system seems to be affected by both the sixth ligand, i.e. O_2 and CH_3COO^-, and the hydrogen bond. In the present complex, a

1   **2**

Fig. 2. Perspective drawing of the molecule. The thermal ellipsoids are drawn at 20% probability level and hydrogen atoms are omitted for clarity.

hydrogen bond between an oxygen atom of the acetate and the secondary amine nitrogen atom might be one of the important factors in the adoption of a *cis*-geometry. The observed *cis*-geometry of the Schiff base ligand is similar to those of the binuclear μ-peroxo-cobalt(III) complex [4] and the 1:1:1 peroxyquinolato-cobalt(III) complex obtained from 2,4,6-tri-t-butylphenol, molecular oxygen and the cobalt(II) complex.[5] However, the conformation of the two saturated six-membered chelate rings assumes chair-envelope and skew-chair forms for the former and the latter complexes, respectively. These structural results indicate that the ligand system is flexible.

EXPERIMENTAL

The title complex was prepared according to the literature.[1] Brown rhombic crystals suitable for the X-ray diffraction work were obtained from the ethylether solution. A crystal was examined with a Rigaku Denki AFC-5 four-circle automated diffractometer. The unit cell dimensions and their estimated standard deviations were obtained from a least-squares fit to setting angles of 15 reflections using Mo Kα graphite monochromatized radiation at room temperature. The crystal data are as follows: $CoO_4N_3C_{22}H_{26}$, F.W. = 455.4; Found; C, 57.79; H, 5.84: N, 9.18. Calc. C, 58.02; H, 5.75; N, 9.23%. Monoclinic, space group = $P2_1/n$, a = 16.846(4), b = 9.417(2), c = 14.032(4) Å, β = 111.29(1)°, V = 2074.1(9) Å^3, D_m = 1.44 (by flotation method in aqueous KI solution), D_x = 1.458 g · cm^{-3}, Z = 4, μ(Mo Kα) = 10.3 cm^{-1}.

Intensity data were collected by the $\theta - 2\theta$ scan technique with a scan rate 8° min^{-1}. For the weak reflections the peak scan was repeated up to four times depending on their intensities. The intensities of three standard reflections were monitored every 100 reflections and showed a good stability. A total of 3628 reflections with 2.5° < 2θ < 48° were collected and of which 2381 independent reflections with $|F_o| > \sigma(|F_o|)$ were used for the structure determination. The intensity data were corrected for Lorentz and polarization effects, but not for absorption.

The structure was solved by the conventional heavy-atom

method, and refined by block-diagonal least-squares, in which the function minimized was $\Sigma w(|Fo| - k|Fc|)^2$, where k is scale factor and $w = 1$ is adopted. The atomic scattering factors were taken from the International Tables for X-ray Crystallography Vol. IV.[6] Anomalous dispersion corrections for Co were also taken from the literature.[6] All the calculations were carried out on a FACOM M-200 computer at the Computer Center of Kyushu University by the use of a local version of the UNICS II system.[7,8]

Final refinement including hydrogen atoms which were experimentally determined yielded the final values of 8.69 and 9.60% for $R_1 = \Sigma||Fo| - |Fc||/\Sigma|Fo|$ and $R_2 = [\Sigma w(|Fo| - |Fc|)^2/\Sigma w|Fo|^2]^{1/2}$, respectively. The final shifts in the atomic parameters of the nonhydrogen atoms were less than 0.25σ. A final difference Fourier synthesis showed no peaks higher than 0.7 eÅ^{-3}.

Final positional and thermal parameters with their estimated standard deviations and a list of observed and calculated struc-

ture factors have been deposited as supplementary data.* Bond lengths and angles are given in Table 1(a, b), respectively.

Abstract—Interaction of the tetra-nuclear phosphinecarbonyl complex of zero-valent palladium, $Pd_4(CO)_5(PEt_3)_4$ (I), with a four-fold excess of 8-(α-bromomercuryethyl)quinoline gives a new neutral heteronuclear cluster $Pd_4Hg_2Br_2(CO)_4(PEt_3)_4$ (IV). The structure of (IV) was determined by an X-ray analysis. The molecule of (IV) contains a "butterfly" $Pd_4(\mu_2\text{-}CO)_4(PEt_3)_4$ moiety, whose triangular "wings" are capped by Hg atoms bonded also to bromo-ligands. The metal Hg_2Pd_4 polyhedron consists of two heteroatomic Pd_3Hg tetrahedra with a common Pd–Pd edge. The IR- and ^{31}P-NMR spectra of (IV) were also studied.

INTRODUCTION

As has been found recently, the mononuclear carbonyl derivatives of zero-valent palladium tend to form polyhedral cluster complexes under mild conditions.[1,2] A high reactivity of the compounds thus obtained, their diversity and interconversions of clusters with differently sized and shaped Pd_n polyhedra, observed in organic media, give rise to a growing interest to this area of coordination chemistry.[3–7] To date structural studies have been made of a number of cluster complexes of Pd with carbonyl ligands, including tetra-nuclear derivatives wherein the Pd_4 moiety has a configuration of a planar tetragon,[3] "butterfly",[4] distorted[5] and symmetrical[6] tetrahedron. The recently synthesized complex $Pd_4(CO)_5(PR_3)_4$ (I, R = Et, Bu^n), probably having a "butterfly" structure, by analogy with the earlier studied cluster $Pd_4(CO)_5(PMe_2Ph)_4$ (II),[4] may serve as a starting compound in the synthesis of more complex homo- and heternuclear Pd clusters. The transformation of (I) into the symmetrical tetrahedral complex $Pd_4(CO)_6(PR_3)_4$ (III), found in solution, and the ability of (I) to further condensation with coordination of phosphine to give decanuclear Pd clusters[6] suggested rich synthetic potentialities of reactions involving (I). Until recently, however, the only chemical interactions of homo- and heteronuclear Pd clusters studied have been limited by their interconversions under variation of ligand concentration,[6,7] whereas the action of "modifying" reagents on complexes of the $Pd_n(CO)_x(PR_3)_y$ type has resulted in the complete decomposition of the polynuclear structure.

In the present study we have found a method of modifying (I) by treatment with the organomercury compound, 8-(α-bromomercuryethyl)quinoline,* and determined the structure of the resulting heteronuclear cluster. A peculiarity of this reaction, in contrast to the earlier cases studied,[6,7] consists in retaining a metalloligand framework existing in the starting complex and in its "enlargement" by two HgBr fragments to form a heteroatomic Hg_2Pd_4 metallopolyhedron, wherein the Hg atom increases its coordination from a linear one in the starting compound to tetrahedral in the reaction product.

EXPERIMENTAL

All the operations involved in the synthesis, isolation and investigation of $Pd_4Hg_2Br_2(CO)_4(PEt_3)_4$ (IV) were carried out under CO. The IR spectrum was measured with an IR-10 instrument in KBr pellets. The ^{31}P-NMR spectrum was studied at $-70°C$ in toluene with a Bruker–HX–90 spectrometer. Chemical shifts were measured relative to H_3PO_4 (85% concentration).

Synthesis of (IV)

To a suspension of 8-(bromomercuryethyl)quinoline[8] (1.22 g) in benzene (28 ml) was added $Pd_4(CO)_5(PEt_3)_4$ (0.73 g), obtained as described elsewhere,[2] and the mixture was stirred under CO at 20°C for 30 min. CO was evolved and a black precipitate (Pd, Hg) formed. The reaction mixture was left for 15 hr at 5°C, then the solution was filtered off from the precipitate, and pentane (200 ml) was added to the orange filtrate. The orange–red crystalline precipitate of (IV) was filtered off, washed with pentane and dried in vacuo. 0.26 g (23.5%) of (IV) was obtained; dec. temp. 86°C. Found: C, 21.81; H, 3.91; Br, 10.45; Hg, 25.79; Pd, 26.90. Calcd. for $C_{28}H_{66}O_4P_4Br_2Hg_2Pd_4$, C, 21.41; H, 3.85; Br, 10.18; Hg, 25.55; Pd, 27.09%. IR (ν, cm^{-1}): CO 1855 (s), 1897 (m); C–H 2880 (s), 2908 (s), 2930 (s). ^{31}P–{^1H}–NMR, δ (ppm): 8.7 triplet, 2P; 20.9 triplet, 2P; ^3J (^{31}P, ^{31}P) 23.1 Hz.

For an X-ray structural analysis the ruby-coloured crystals of (IV) were obtained in a similar manner with the only difference that the filtrate, after separation of the black metal precipitate, was diluted with pentane (100 ml).

X-Ray structural study of (IV)

The crystals of (IV) are monoclinic, $a = 20.205(5)$, $b = 16.815(6)$, $c = 13.183(4)$ Å, $\beta = 97.17(2)°$, space group C2/c, Z = 4. Unit cell parameters and intensities of 4273 independent reflections (of which 3933 with $I > 2\sigma$ were used in calculations) were measured at $-120°C$ with an automatic four-circle Syntex P2$_1$ diffractometer (λMoK$_\alpha$, graphite monochromator, $\theta/2\theta$ scan, $2\theta \leqslant 50°$). Absorption corrections were made according to the method described in Ref. [9]. The structure was solved by direct methods using the MULTAN program and refined by full-matrix least-squares in an anisotropic approximation. Finally $R = 0.050$, $R_w = 0.066$ for 3426 reflections with $I > 5\sigma(I)$ and sin $\theta/\lambda > 0.10$. Atomic coordinates of the independent part of the molecule of (IV), which occupies a special position on the two-fold axis, and their anisotropic thermal parameters have been deposited as supplementary material with the Editor, from whom copies are available.‡ All the calculations were performed with an Eclipse S/200 computer by the modified EXTL programs.§

†Reactions of phosphine-carbonyl Pd clusters with other organomercury compounds will be described elsewhere.

‡Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

§Program modification was carried out in our laboratory by A. I. Yanovsky and R. G. Gerr.

RESULTS AND DISCUSSION

Initially we expected to attain modification of the zero-valent Pd cluster derivatives by treatment with organo-mercury compounds with insertion of an organic or organo-mercury fragment. 8-(α-Bromomercuryethyl)quinoline was chosen as a potential source of a chelating N,C-ligand due to the presence of two active centres (N and Hg atoms) in its molecule. In fact, however, the reaction proceeded along an unexpected route with elimination of the organic part R of the RHgBr molecule and insertion of the HgBr residue into the polyhedron of the new heteroatomic cluster:

$$Pd_4(CO)_5(PEt_3)_4 + C_9H_8NCH(Me)HgBr \xrightarrow[-CO]{}$$

$$Pd_4Hg_2Br_2(CO)_4(PEt_3)_4. \quad (1)$$
The formation of a neutral cluster molecule implies a homolytical cleavage of the C–Hg bond. Formally reaction (1) represents a substitution of the CO ligand for two HgBr residues. However the Hg atoms are coordinated with the $Pd_4(CO)_4(PEt_3)_4$ moiety of the resulting cluster (IV) in a most unusual fashion.

A similar reaction of phenylmercury(II) bromide with a trinuclear carbonyl hydride ruthenium complex has been studied recently:[10]

$$(C_6H_9)Ru_3(CO)_9H + C_6H_5HgBr \xrightarrow{THF}$$

$$(C_6H_9)Ru_3(CO)_9HgBr. \quad (2)$$
$$(V)$$
This interaction proceeding essentially as replacement of the hydride ligand in the starting complex resulted in the formation of the heteronuclear cluster (V) with a "butterfly" configuration, which underwent dimerization due to the formation of halide bridges. In the molecule of (V) the Hg atom is bonded to two Ru atoms (2.733 and 2.739 Å), the dihedral angle between the Ru_2Hg and Ru_3 planes in the butterfly-shaped (V) being 127°.

Bond lengths in (IV) are given in Table 1, and bond angles in Table 2. In the crystal the molecule of (IV) (see Fig. 1) occupies a special position on the two-fold symmetry axis and involves the butterfly-shaped

$Pd_4(CO)_4(PEt_3)_4$ fragment whose triangular wings are capped asymmetrically by the Hg atoms [the Hg–Pd(1) distance, 2.993(1) Å, is substantially greater than two others, Hg–Pd(2), 2.717(1) Å, and Hg–Pd(2'), 2.704(1) Å]. Tetrahedral coordination of the Hg atom is completed by the Br ligand (Hg–Br 2.544(1) Å). A dihedral angle of 100.2° between the Pd_3 planes in the $Pd_4(CO)_4(PEt_3)_4$ fragment exceeds the corresponding value in the butterfly (II) (93°),[4] being accompanied by increasing the nonbonded Pd(1)...Pd(1') distance (3.365 Å in (II) and 3.428(1) Å in (IV)). However both the last two values are close to the lengths of the "elongated" edges, 3.3–3.4 Å, in the Pd_{10} polyhedron of the cluster $Pd_{10}(CO)_{12}(PBu_3^n)_6$ (VI).[1,6] The peripheral Pd–Pd bonds of the Pd_4 butterfly in (IV) are tightened by the bridging CO ligands. The lengths of these bonds, 2.687(1) and 2.702(1) Å, are close to those of the "short" Pd–Pd edges in (V), also reinforced by μ_2-CO bridges (av. 2.056 Å[6]). The absence of a bridging CO ligand at the Pd(2)–Pd(2') bond is accompanied by its lengthening to 3.015(1) Å. In the molecule of (IV) only an average Pd–Pd bond length of 2.750(2) Å is reported.[4] Coordination of the μ_2-CO ligands in (IV) reveals a small, but distinct asymmetry (Tables 1 and 2), viz., though a difference in the lengths of the C–Pd bonds to the "peripheral", Pd(1), and "central", Pd(2), metal atoms, 2.01(1) and 2.09(1) for C(1), and 2.03(1) and 2.08(1) for C(2), respectively, is close to the experimental error, the corresponding bond angles Pd(1)CO and Pd(2)CO, 144.3(9) and 133.2(9)° for C(1), 143.7(9) and 134.5(9)° for C(2), are, in fact, significantly unequal, suggesting a stronger bonding of the bridging CO to the "peripheral" Pd atoms. Both C and O atoms of the μ_2-CO ligands are close to the plane of the corresponding Pd(1)Pd(2)Pd(2') triangle, the out-of-plane deviations in the direction from the Hg atom being 0.10(1) for C(1), 0.23(2) Å for O(1), 0.05(1) for C(2), and 0.11(1) Å for O(2). The P(1) atom bonded to the Pd(1) atom is displaced from this plane by only 0.081(3) Å, and thus, despite involvement of the peripheral Pd(1) and Pd(1') in the metallopolyhedron, they retain a predominantly planar trigonal ligand environment, the sum of the bond angles P(1)Pd(1)C(1), P(1)Pd(1)C(2) and C(1)Pd(1)C(2') being 359.1°. On the contrary, coordination of the Hg atom is close to sym-

Fig. 1. Molecule (IV) (ethyl substituents of the phosphine ligands omitted for clarity).

metrical tetrahedral, and the Br atom deviates from the HgPd(2)Pd(2') plane by 0.438(1) Å. The Hg–Hg distance, 3.251(1) Å, is close to the values found in various polynuclear mercury compounds, both in the tetramercurated methane derivatives, $C(HgX)_4$ where, probably, there is no Hg...Hg bonding interaction (X = CN, 3.280–3.398 Å;[11] X = OAc, 3.251–3.436 Å,[12]) and in the heteronuclear cluster $RH_4Hg_6(PMe_3)_{12}$ with a Hg_6 octahedron (3.131–3.149 Å) wherein four noncontiguous faces have μ_3-Rh(PMe$_3$)$_3$ bridges.[13] To conclude unequivocally

if there is any Hg...Hg bonding in (IV), one has to compare the geometrical parameters of the Pd_4 "butterfly" in (IV) and (I), a structural study of the latter being our immediate purpose.

SYNTHESIS AND CHARACTERIZATION BY IR SPECTROSCOPY AND X-RAY DIFFRACTION OF A QUINAZOLINE-COMPLEX OF DIBUTYLDICHLOROTIN(IV)

C. PELIZZI, G. PELIZZI* and P. TARASCONI

Istituto di Chimica Generale ed Inorganica, Università degli Studi, Centro di Studio per la Strutturistica Diffrattometrica del C.N.R., Via M. D'Azeglio 85, 43100 Parma, Italy

Abstract—The synthesis, the X-ray analysis and the IR spectrum of the complex $SnBu_2Cl_2(AIP)$ [AIP = 2-(2'-pyridyl)-3-(N-2-picolylimino)-4-oxo-1,2,3,4 - tetrahydroquinazoline] are reported. The coordination polyhedron can be described as a distorted pentagonal bipyramid. The AIP molecule behaves as a terdentate ONN donor ligand, with the N atoms involved in two equational weaker interactions with respect to the O atom.

INTRODUCTION

We have shown previously the structural flexibility of N,O-containing ligands in metal complexes, in connection with the nature of the metal and of the inorganic anion.[1,2] Among these ligands, 2 - (2' - pyridyl) - 3 - (N - 2 - picolylimino) - 4 - oxo - 1,2,3,4 - tetrahydroquinazoline (AIP), obtained by condensation of 2-aminobenzoylhydrazine and pyridine-2-carbaldehyde, is able to act as a ONN[3] or NNN[4] terdentate ligand when coordinating to metals.

As part of a continuing interest in the organotin(IV) complexes with ligands obtained by condensation of acylhydrazines with aldehydes or ketones,[5–7] we now report the synthesis, the X-ray analysis and the infrared spectrum of $SnBu_2Cl_2(AIP)$.

EXPERIMENTAL

Synthesis. Bu_2SnCl_2 was commercially available (Merck) and used as received. AIP was prepared as described previously.[8] The complex $SnBu_2Cl_2(AIP)$ was obtained by adding a chloroform solution of Bu_2SnCl_2 to an acetone solution of the organic ligand. After refluxing for *ca.* $\frac{1}{2}$ hr the solution was allowed to crystallize. Analytical (C, H, N, Sn) data agree with the formula $C_{27}H_{33}Cl_2$ and N_5OSn.

X-ray data collection. All X-ray measurements were performed using a computer-controlled Siemens AED three-circle diffractometer employing CuK_α radiation ($\lambda = 1.54178$ Å). The compound crystallizes in the monoclinic space group $C2/c$ with a unit-cell of dimensions: $a = 14.701(5)$, $b = 16.727(4)$, $c = 22.963(6)$ Å, $\beta = 100.38(4)°$, and $Z = 8$. Intensity data were collected with a small ($0.13 \times 0.16 \times 0.24$ mm) prismatic crystal to a maximum 2θ of $128°$ for hkl with $l = 0$–3, and of $110°$ for hkl with $l = 4$–23, a total of 3012 reflections being measured from profile analysis following the method of Lehmann and Larsen.[9] After symmetry-equivalent reflections were averaged and reflections which had $I < 2\sigma(I)$ were excluded, 1801 unique data were obtained and used in the refinement. No crystal decomposition occurred during data collection. Corrections were applied for Lorentz and polarization effects, but not for absorption ($\mu \bar{r} = 0.69$).

†Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre for inclusion in their Data Base.

Structure solution and refinement. The structure was solved by heavy-atom method except for hydrogen atom locations. Refinement was by full-matrix least-squares calculations with anisotropic thermal parameters for the Sn, Cl, O, N and for all C atoms except those of the butyl groups, since for these last anisotropic refinement resulted in physically meaningless parameters. The hydrogen atoms from the AIP molecule were inserted at calculated positions, even though some were visible on the Fourier difference map, and they were isotropically refined as "riding" atoms. The hydrogen atoms from the butyl chains were neglected. A final conventional residual index of 0.0538 resulted. The function minimized was $\Sigma w(F_o - F_c)^2$, where the weight for each reflection was unity at first, while in the last cycles the weighting scheme $w = 0.34/[\sigma^2(F_o) + 0.0082 F_o^2]$ was employed. A final difference map had peaks of up to 0.8 $e\text{Å}^{-3}$ in the region of the butyl groups. A total of 309 parameters, including one scale factor, was refined yielding a data: parameter ratio of 5.8:1.

Scattering factors used in the structure factor calculations were taken from Ref. 10 and allowance was made for anomalous dispersion.[11] All computations were performed, using the SHELX-76 system of computer programs,[12] on the Cyber 76 Computer of CINECA (Casalecchio, Bologna), with the financial support from the University of Parma.

Selected bond distances and angles are given in Table 1. Atomic positional coordinates, thermal parameters, additional bond distances and angles, and a list of observed and calculated structure factors have been deposited with the Editor as supplementary material.†

Infrared spectra. The infrared spectra were recorded on a Perkin–Elmer mod. 283 B instrument in KBr discs. Main vibrational bands (cm^{-1}) with relative assignments of AIP, $SnBu_2Cl_2$ (AIP), $Mn(AIP)Cl_2$, $Cd(AIP)Cl_2$, $Cu(AIP)Cl_2$ are listed in Table 2.

RESULTS AND DISCUSSION

The molecular structure is shown in Fig. 1, along with the numbering scheme used for the atoms. There is some difficulty in defining the geometry of the coordination polyhedron, which is quite irregular. In fact, if we consider only the immediate bonding about tin, the coordination could be described in terms of a highly distorted tetragonal pyramid, having two butyl carbon atoms, a chlorine atom (*Cl*1), and the oxygen atom of the AIP ligand at the basal corners, and the second chlorine at the apex, at a Sn–Cl distance unexpectedly shorter (0.14 Å) than the equatorial one. The atoms at the base of the

pyramid show a strong tetrahedral deformation as indicated by the deviations form the weighted least-squares plane running through them: Cl1 −0.02, O −0.25, C20 0.38, C24 0.82 Å. Alternatively, if also two more loosely bonded atoms, N1 and N2, both at 2.73(1) Å from tin, are regarded as being part of the coordination sphere, the tin environment is consistent with a geometry based on a distorted pentagonal bipyramid, whose apical sites are occupied by the two carbon atoms. The pentagonal girdle is almost planar, none of the five atoms being displaced more than 0.11 Å out of the mean plane, the sum of the angles in the girdle being 360.1°. In our opinion, the seven coordination model is to be preferred, in view of a more regularity in the coordination polyhedron. Moreover, there is also further evidence to support this conclusion. In fact, a similar mode of coordination for AIP has been found in the previously determined structures of Mn[3] and Cd[1] complexes, in which the ligand acts too as a ONN terdentate agent giving rise to two planar five-membered rings. By contrast, in the Cu[4] and Co[13] complexes a NNN terdentate ligand behaviour has been found. The two conformations AIP shown in the coordination differ by

rotation about the N–N bond and are also evident by comparing the main vibrational bands of Sn and Mn (or Cd) compounds with those of the Cu complex (Table 2). In despite of bond distances and angles in the O–C–N–N system, which are poorly influenced by the different coordinating behaviour of the ligand, significant differences occur in the CO and CN stretching mode. In fact, a positive shift of the ν(CO) value in the Cu complex (1675 cm^{-1}) and a negative shift in the Mn (1615 cm^{-1}), Cd (1630 cm^{-1}) and Sn (1635 cm^{-1}) complexes are observed with respect to the value (1650 cm^{-1}) observed for the free ligand; moreover, the ν(CO) band values in the Sn compound have stronger similarities to that of the Cd compound than to that of the Mn derivative. It can be noted also that the infrared spectrum of the Sn complex, as a whole, is very similar to that of SnPh$_2$Cl$_2$(AIP), for which a seven-membered coordination has been suggested previously.[5]

The three aromatic rings are rigorously planar within experimental errors; bond lengths and angles show no significant deviation from the standard values. The two pyridine rings are mutually inclined at 89.4°. The six-membered heterocyclic ring is slightly puckered into a *sofa* conformation with five atoms practically coplanar, the sixth atom, C7, being 0.57 Å out of this plane. The Cremer and Pople ring puckering parameters[14] are: $q_2 = 0.355$, $q_3 = 0.198$, $Q = 0.407$ Å: $\phi_2 = 236.1$ and $\theta_2 = 60.9°$.

The two butyl chains are shown to adopt different conformations, synclinal and antiperiplanar respectively, as indicated by the torsion angles: Sn–C20–C21–C22 = 166(1), C20–C21–C22–C23 = −80(2); Sn–C24–C25–C26 = −180(1), and C24–C25–C26–C27 = −168(2)°. Due to large thermal motion, some distances and angles in these chains depart from the expected values.

The crystal packing is mainly determined by the following interactions, the first of which has to be considered as hydrogen bond:

N5 ... Cl1($x - \frac{1}{2}, \frac{1}{2} + y, z$)   3.30(2) Å
N5 ... C6($\bar{x}, y, \frac{1}{2} - z$)   3.52(3) Å
C4 ... Cl2($\frac{1}{2} - x, \frac{1}{2} + y, \frac{1}{2} - z$)   3.56(2) Å
C12 ... Cl2($\frac{1}{2} - x, \frac{3}{2} - y, 1 - z$)   3.51(3) Å.

RING GEOMETRY AND SECONDARY INTERACTIONS IN A SALT OF S₃N₂Cl⁺; THE CRYSTAL STRUCTURE OF 1-CHLORO-1,2,4-TRITHIA-3,5-DIAZOLIUM TETRACHLOROFERRATE(III)

HARRISON M. M. SHEARER†, ARTHUR J. BANISTER, JOAN HALFPENNY* AND GRAHAM WHITEHEAD

Department of Chemistry, University of Durham, South Road, Durham DH1 3LE, England

Abstract—The structure of the title compound has been determined using single crystal X-ray methods. The tetrachloroferrate(III) ion is approximately tetrahedral, with three Fe–Cl bonds at 2.178(2), 2.182(2) and 2.183(2) Å, and one, Fe–Cl(2), at 2.215(2) Å, which is weakened by interactions between Cl(2) and two sulphurs of the cation. The four sulphur-nitrogen distances [1.546(6)–1.604(6) Å, mean 1.578 Å] are typical of a delocalised SN system; the two-coordinate atoms (only) are coplanar within experimental error. The S(2)–S(3) bond [2.181(2) Å] and exocyclic S(2)–Cl(1) bond [2.086(2) Å] are respectively 0.045 Å longer and 0.08 Å shorter than in S₃N₂Cl⁺Cl⁻; this is interpreted as being due to weaker cation-anion interaction in the tetrachloroferrate (III) salt. Ring angles at S(1) [105.8(3)°], N(2) [121.5(4)°], S(3) [95.6(2)°] S(2) [95.9(2)°] and N(1) [119.6(4)°] are under compression due to constraint within the small ring.

INTRODUCTION

Abnormally short intermolecular contacts between species containing a disulphur group, and one or more external atoms, have been shown to give rise to compounds of novel structural types. These interactions usually involve sulphur and atoms of similar or higher electronegativity; for instance, several three-centre examples have been described[1-3] where an organic or inorganic dithiolium cation interacts with a halide ion (e.g. I)[2] or with oxygen of an oxo-anion[3]. More recently compounds of a new structural class have been discovered, in which a pair of delocalised five-membered rings interact via their disulphur groups. For instance, in (PhCN₂S₂)₂ (II)[4] and (S₃N₂)₂²⁺ (III)[5] two five-membered rings interact respectively in *cis*(eclipsed) and *trans* configurations:
In all these compounds, the secondary interactions tend to perturb the geometry of the component rings and so, for comparison, it is of increasing importance to determine the structures of relatively unperturbed systems. In this paper we describe the crystal structure of the title compound [S₃N₂Cl]⁺[FeCl₄]⁻ and compare cation parameters with those for [S₃N₂Cl]⁺Cl⁻ where cation-anion interactions are quite strong.

EXPERIMENTAL

The title product crystalised as brown needles from a 1 : 1 molar mixture of iron(III) chloride (suspension) and tetrasulphur tetranitride in thionyl chloride solution; it was separated from other products by recrystallisation from thionyl chloride[5]. An alternative and more convenient preparation is from the reaction between iron(III) chloride and S₃N₂Cl₂ suspended in thionyl chloride[5].

Crystal data. Cl₅FeN₂S₃, [S₃N₂Cl]⁺[FeCl₄]⁻, monoclinic, *a* = 9.264(1), *b* = 10.610(1), *c* = 11.259(1) Å, *β* = 92.1(1)°, space group P2₁/n, *D*c = 2.15 Mg m⁻³ with Z = 4, *μ* = 3.07 cm⁻¹ for MoKα radiation, *λ* = 0.71069 Å.

Intensity data for 1952 unique reflections were measured with a ω − 2θ scan on a Hilger and Watts Y-290 four-circle diffractometer, using MoKα radiation. No corrections were made for absorption. The structure determination (heavy atom method) and refinement were performed with the programs of F.R. Ahmed *et al.*[6], only 1412 reflections for which I ≥ 3σ(I) being included. Least squares refinements of the atomic parameters (all atoms with anisotropic temperature factors) were terminated when the shifts on all parameters were less than 0.06 of the e.s.d. and R = 0.048. Final atomic positions, observed and calculated structure factors and anisotropic thermal parameters have been deposited as supplementary material with the Editor from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre. Bond distances and angles are listed in Table 1.

DISCUSSION

Each tetrachloroferrate anion is loosely associated with one cation as shown in Fig. 1. The convention of atom numbering for the cation is the same as that used by Zalkin *et al.*[7] for S₃N₂Cl₂. The S–N distances in the cation (average *d*SN = 1.578 Å, 1.589 Å in S₃N₂Cl₂) alternate shorter/longer round the ring as in S₃N₂Cl₂[7] and are close to those in other thiazenium cations (see the average values of 1.563 Å and 1.562 Å in [S₄N₃]₂SbCl₅[8] and [S₅N₅][S₃N₃O₄][9]). The bond angles all betray some compression due to constraint within a small ring. Correlations[10,11] between bond distances (pm) and bond angles (°) for unstrained and largely unstrained sulphur-nitrogen compounds (viz. *d*NS = 177.47−0.1421 N̂ and *d*SN = 213.14−0.4816 Ŝ) indicate compressions of the order of 10° at N(1), 25° at N(2) and 10° at S(1). These values are very approximate, because the calculation ignores the effects of the secondary interactions with the

Cl(3) - Fe - Cl(5)	108.6(1)	N(2) - S(1) - N(1)	105.8(3)
Cl(4) - Fe - Cl(5)	108.5(1)	S(1) - N(1) - S(2)	119.6(4)
		N(1) - S(2) - S(3)	95.9(2)
Fig. 1. 'View of one unit of structure of 1-chloro-1,2,4-trithia-3,5-diazolium tetrachloroferrate.'

anion, and assumes that constraint compresses angles without affecting distances. (The calculated values are also quite sensitive to errors in bond distance.) The ring angle N(1)Ŝ(2)S(3) [95.9(2)°] at the three-coordinate sulphur atom also appears to be under compression; by analogy with other trigonal–pyramidal tricoordinate sulphur compounds, the preferred ring angle at tricoordinate S(2) is likely to be 100–110°[10,12] (i.e. OŜCl = 106.3° in SOCl$_2$, and NŜN = 105.2° in CF$_3$SO$_2$N–S(Me)–N(SO$_2$CF$_3$)SnMe$_3$[13]).

Van der Waals radii for sulphur and for the chloride ion are approximately 1.8 Å[14]; non-bonded S . . . Cl distances shorter than 3.6 Å are given as Table 2. Only two [Cl(2)–(S(2) = 3.160(2) and Cl(2)–S(3) = 3.138(3) Å] are below 3.2 Å; both interactions involve Cl(2) and this would account for the long Fe–Cl(2) distance of 2.215(2) Å. The three remaining iron-chlorine distances are shorter (average 2.181 Å). The largest Cl–F̂e–Cl bond angle [112.3(1)°] in the approximately tetrahedral anion, is between the two atoms, Cl(3) and Cl(4), which are least involved in secondary interactions (Fe–Cl bond pair repulsions will tend to be highest for bond pairs closest to the iron atom).

For S$_3$N$_2$Cl$_2$, Zalkin, Hopkins and Templeton[7] reported a "polar dispersion shift" (a relative shift of light and heavy atoms along a polar direction during least squares refinement) which introduced some doubt concerning the

Table 2. Non-bonded S · · · Cl distances less than 3.6 Å

Roman numeral superscripts refer to the following equivalent positions with respect to the molecule at x, y, z:

I: -1 + x   y   z   II: -½ + x   ½ + y   ½ - z

III: -½ + x   ½ - y   -½ + z   IV: -½ + x   ½ - y   ½ + z
Fig. 2. Comparison of bond parameters in $[S_3N_2Cl]^+Cl^-$(I) and $[S_3N_2Cl]^+[FeCl_4]^-$(II). Where the difference is positive, the distance (Å) or angle (°) is larger in I than in II. Three times the sum of e.s.d.'s for the two structures are given in brackets; differences in parameters less than this are not shown.

geometry of the cation, especially the distances $S(1)$–$N(1)$ and $S(1)$–$N(2)$. (Their estimated standard deviations were about 0.005 Å on the distances and about 0.3° on the angles). Consequently the significant differences between the two structures are the angle $N(1)S(2)S(3)$ and bond distances d_{SS} and d_{SCl} (see Fig. 2).

In $S_3N_2Cl_2$, the chloride ion $Cl(2)$ makes a close approach [2.90 Å at $S(1)$, 3.04 Å at $S(2)$] to all three sulphur atoms and so this is most likely to affect the cation where there are two adjacent interaction sites (e.g. at the $S(2)$–$S(3)$ bond; this is found to be the case. Compared with $[S_3N_2Cl]^+[FeCl_4]^-$, the increased charge transfer from the anion strengthens the disulphur link (by 0.045 Å) and weakens the $S(2)$–$Cl(1)$ bond (by 0.082 Å). In a survey of the directional preferences of non-bonded atomic contacts with divalent sulphur, (XSY), Dunitz et al.[15] showed that donor atoms such as oxygen and fluorine tend to form bonds in the XSY plane. They interpreted this as being due to an interaction of the donor atoms with the LUMO's on sulphur which they identify as the antibonding orbitals associated with the SX and SY bonds. Our results, and also the observations by Gillespie et al.[16] for $(S_3N_2)^+$ and $(S_3N_2)_2^{2+}$, are in accord with this generalization. A similar situation has been found[17] for $(S_4N_3)^+$ and $(CCl_3 . CN_2S_2)^+$ where the lowest unoccupied orbital (LUMO), apart from one or two of π character, is bonding with respect to S–S and antibonding with respect to the neighbouring bonds (disulphur S to N). Consequently, electron drift into this unoccupied orbital

strengthens the disulphur link[17]. The ordering of molecular orbitals is different for some other dithiolium cations, for example in the case of 4-phenyl-1,2-dithiolium iodide and bromide increasing partial S-halogen bonding causes a very small lengthening (0.001–0.002 Å) of the S–S bond[1].

A further interesting feature of the structure of $[S_3N_2Cl]^+[FeCl_4]^-$ (and $[S_3N_2Cl]^+Cl^-$) is the shape of the S_3N_2 ring.

Deviations of atoms from least squares planes are given as Table 3. The four atoms $S(3)N(2)S(1)N(1)$ are planar within the limits of error. The three-coordinate sulphur atom $S(2)$ and the attached chlorine atom $Cl(1)$ lie 0.243 and 2.296 Å respectively above the plane through these four atoms, the $S(2)$–$Cl(1)$ bond making an angle of 112.8° with this plane. Since all ring angles are under compression (loc. cit), and any movement of $S(2)$ out of the $S(3)N(2)S(1)N(1)$ plane causes more reduction of ring angles, further bonding or repulsion forces must be operating, e.g. (i) a bonding interaction between $S(2)$ and the upper lobes of π molecular orbitals at $S(3)$ and $N(1)$, and (ii) lattice forces; secondary interactions between the chlorine atoms of the anion and the cation positions $S(2)$ and $S(3)$ have already been noted, and the fairly short $Cl(1)\ldots S(3)$ distance of 3.296(3) Å may indicate that some interaction is occurring here also.

There are four intermolecular contacts shorter than 3.6 Å (see Table 2). These very weak interactions link ions of opposite charge together throughout the structure.

This structural study shows that in $(S_3N_2Cl)^+$ salts, the geometry of the cation at the disulphur position is sensitive to secondary cation-anion interactions. Since S_3N_2 is a small and hence rather inflexible ring, we anticipate that when large-ring S/N dithiolium salts are prepared, cation-anion interactions will have a much more marked distorting effect.

STUDIES IN METAL SULPHITE CHEMISTRY—III

W. D. HARRISON, J. B. GILL and D. C. GOODALL*
Department of Inorganic and Structural Chemistry, The University, Leeds LS2 9JT, England

Abstract—Manganese(II) iodide, iron(II) iodide and copper(I) iodide each react with tetramethylammonium disulphite to form anhydrous manganese(II) sulphite, iron(II) sulphite and copper(I) disulphite respectively. Iron(II) sulphite and copper(I) disulphite react with dimethylsulphoxide–sulphur dioxide to form iron(II) disulphate and copper(II) disulphate respectively. Hydrated sulphites of manganese(II), iron(II), magnesium(II) and calcium(II) were also prepared. The properties of the sulphites were investigated using thermogravimetric and IR measurements.

INTRODUCTION

In recent years considerable study has been devoted to the preparation of anhydrous inorganic oxyanion compounds, many of which exhibit remarkable differences when comparison is made with the hydrated compounds. It is not clear how, and to what extent, the absence or presence of water of hydration affects the nature of the oxyanion in such compounds. Our studies relate to the preparation of anhydrous transition metal sulphites, few of which have been prepared and characterised,[1] and to some hydrated transition and non-transition metal sulphites, in order to ascertain the influence of metal ion and water of hydration upon the characteristics of the oxyanion.

RESULTS AND DISCUSSION

Earlier studies[1] on anhydrous transition metal sulphites have shown that it is generally not possible to prepare them by thermal dehydration of the hydrates since water and sulphur dioxide are simultaneously lost. It is necessary to make use of metathetical reactions in non-aqueous media. The metal under study, in the form of its iodide salt, was treated with tetramethylammonium disulphite in acetone. Samples of manganese(II) sulphite, iron(II) sulphite and copper(I) disulphite were prepared. These compounds are all extremely sensitive to air and water. As experienced in our earlier work,[1] it proved impossible to remove all traces of occluded tetramethylammonium salts. This difficulty arises on account of the extreme insolubility of the sulphites, which cannot thus be recrystallised or reprecipitated, and of the lack of a solvent which is suitable for the complete solution of the reactants. Anhydrous manganese(II) sulphite may also be prepared by thermal decomposition of the hydrate, but it exists only within a small temperature range (310–370°), according to thermogravimetric studies referred to later; it is very unstable, and surface decomposition commences very soon after the compound is formed, as a result of spontaneous loss of sulphur dioxide.

However, for each of the anhydrous transition metal sulphites, the metal:sulphur dioxide ratio is in accord with the formula, and two of them were converted to pure disulphates on treatment with the mixed system dimethylsulphoxide–sulphur dioxide.[2] It may be inferred from this that the original materials are essentially anhydrous metal sulphite (disulphite in the case of copper). Iron(II) sulphite gave rise to the formation of $FeS_2O_7 \cdot 6dmso$[3] and copper(I) disulphite to the formation of $CuS_2O_7 \cdot 6dmso$[3]. In the case of manganese(II) sulphite, an oily yellow product formed, which could not be characterised.

The IR bands, shown in Table 1, indicate that, in the anhydrous manganese(II) and iron(II) sulphites, the sulphite group coordinates through oxygen to the metal, very likely in the form of bridging sulphite groups, especially in view of the extreme insolubility of the compounds, which indicates some high molecular weight structure which is likely to arise from such a bridging arrangement. Copper(I) disulphite is considered to contain disulphite covalently bonded to the metal. Its IR spectrum is similar in many ways to those of $K_2S_2O_5$ and $(NMe_4)_2S_2O_5$, but it shows a complex series of bands in the region 700–400 cm^{-1}. Two bands of medium intensity, at 380 cm^{-1} and 330 cm^{-1}, in the copper compound, which are not present in the spectra of $K_2S_2O_5$ or $(NMe_4)_2S_2O_5$, probably arise from Cu–S or Cu–O bonds. It is clear that the sulphite groups in these anhydrous transition metal sulphites are not present as free ions.[1]

Four hydrated sulphites were prepared, two containing main group metals and two containing transition metals, in order to ascertain what effects both metal ion and water of hydration have on the mode of attachment of the sulphite group, and to see whether the anhydrous sulphites in these cases could be prepared by thermal decomposition of the hydrated compounds.

Much of the earlier work associated with the preparation of hydrated metal sulphites has been shown to be unreliable. Preparative methods[4,5] yielded several samples for which reproducible analytical data could not be obtained; perhaps this is in part accounted for by the fact that hydrated sulphites are extremely sensitive to oxidation, particularly the iron(II) compound. We have characterised compounds using methods of preparation developed by us which give products for which reliable analytical data were consistently obtained.

$MnSO_3 \cdot H_2O$, $CaSO_3 \cdot 0 \cdot 5H_2O$ and $MgSO_3 \cdot 3H_2O$ were all made by treating an aqueous suspension of the metal carbonate with sulphur dioxide until all the carbonate had dissolved. Excess sulphur dioxide was removed by warming the solution, and the hydrated sulphite was obtained as a crystalline solid. $FeSO_3 \cdot 3H_2O$ was prepared by treating iron(II) sulphate solution with amalgamated zinc, sodium sulphite and sulphur dioxide. If

precautions are not taken to exclude air strictly from all the operations and to work in reducing conditions, basic sulphates and thiosulphates form readily, and iron(II) easily reduces aqueous sulphur dioxide to dithionite.

Thermograms were obtained for all the hydrated sulphites prepared, and are shown in Fig. 1. $MnSO_3 \cdot H_2O$ is quite stable and only begins to lose H_2O at 255°. Anhydrous $MnSO_3$ is present from 310–370°, but some surface decomposition occurs within this range. Above 370°, loss of SO_2 occurs at an irregular rate. MnO exists beyond 750°. $FeSO_3 \cdot 3H_2O$ begins to lose H_2O at 135°. A point of inflection is observed in the thermogram at 400°, when

loss of H_2O is almost complete, and rapid irregular loss of SO_2 commences. FeO exists above 830°. No intermediate decomposition products are observed.

$CaSO_3 \cdot O \cdot 5H_2O$ is remarkably stable. It begins to lose H_2O at 400°. Anhydrous $CaSO_3$ is present from 450–710°. SO_2 is lost beyond 710°, and at this temperature, slow disproportionation of sulphite to sulphate and sulphide occurs. At 920° isothermal decomposition of sulphate to oxide and SO_3 occurs. $MgSO_3 \cdot 3H_2O$ begins to lose H_2O at 100°. Anhydrous $MgSO_3$ is evident at 310°, but very soon afterwards, a slow irregular decomposition begins, which is not complete at 1000°. Final decomposition
Fig. 1. Thermograms of hydrated metal sulphites.

products include MgO and MgS, and these probably arise from reactions similar to those occurring for the calcium compound.

Infrared bands are recorded in Table 1.

Nyberg and Larsson[6] made a detailed study of the IR spectra of a range of solid metal sulphites. Interpretation is not easy, as many of the bands are broad, and the stretching vibrations ν_1 and ν_3 in sulphite are often superimposed. However, it is usually possible to distinguish between ionic sulphite and covalently bonded sulphite.

The spectra of $MgSO_3 \cdot 3H_2O$ and $MgSO_3$ indicate that sulphite is present as the free ion, which may be loosely attached to the metal ion and hydrogen-bonded to water in the case of the hydrate.

The spectra of $CaSO_3 \cdot 0 \cdot 5H_2O$ and $CaSO_3$ are more complex than those of the magnesium compounds, and suggest some degree of interaction between the metal ion and sulphite, as well as hydrogen-bonding between sulphite and water in the hydrate. The water molecules are very strongly attached and the compound exhibits high thermal stability.

$MnSO_3 \cdot H_2O$ (pale pink) and $FeSO_3 \cdot 3H_2O$ (pale green) have colours in accord with octahedrally coordinated metal ions. The central metal ion is probably surrounded by oxygen-bonded sulphite groups and by water molecules. This is borne out by the complexity of peaks. ν_3 is most likely split and responsible for the complexity in the region $1020-880 \text{ cm}^{-1}$. If sulphite were sulphur-bonded, a simpler spectrum would be expected in this region, as ν_3 would remain a singlet and absorption would be most intense above 975 cm^{-1}.[6]

The support which IR studies give to the type of bonding in these compounds is enhanced by the thermogravimetric studies.

Both $MnSO_3 \cdot H_2O$ and $FeSO_3 \cdot 3H_2O$ decompose with loss of SO_2 at very much lower temperatures than the hydrated sulphites of calcium and magnesium, indicating some fundamental differences in structure. They decompose to give pure oxides (MnO, FeO), whereas the sulphites of magnesium and calcium decompose rather reluctantly to give mixtures of sulphides and oxides and sulphates.

The sulphites of manganese and iron should be compared with those of cobalt and nickel, which yield pure oxides CoO and NiO on heating.[1,2] The relative ease with which transition metal sulphites decompose, and the fact that they give an oxide only, favours a fairly strong metal–oxygen bond in these sulphites. The metal sulphite is easily decomposed on heating, with loss of SO_2, through fission of the oxygen–sulphur bond, which is weaker than in the free sulphite ion.

Thermogravimetric studies on transition metal sulphites also indicate that, whilst most of the SO_2 is evolved between 250° and 600°, in the cases of the hydrated sulphites $FeSO_3 \cdot 3H_2O$, $CoSO_3 \cdot 2 \cdot 5H_2O$ and $NiSO_3 \cdot 6H_2O$ further loss of SO_2 occurs at rather higher temperatures. This is probably due to the presence in these compounds of some sulphite ion as well as to covalently bonded sulphite.

Compounds containing free sulphite do not decompose substantially until higher temperatures are reached (710° in the case of $CaSO_3$ and 600° in the case of $MgSO_3$, neither being completely decomposed at 1000°). The decomposition of anhydrous $CoSO_3$ to CoO and of $NiSO_3$ to NiO is complete at 570° and no secondary loss of SO_2 is observed at higher temperatures. This, together with IR data,[1] suggests that these sulphites contain exclusively covalently bonded sulphite groups and no free sulphite ions.

EXPERIMENTAL

All operations were carried out in a closed system under dry nitrogen. Manganese(II) iodide was prepared by heating manganese(II) iodide tetrahydrate *in vacuo* over phosphorus(V) oxide at 140°C. Iron(II) iodide was prepared as described by Winter.[7] Copper(I) iodide was freshly prepared by adding sodium iodide (7.5 g) in water (150 ml) to copper(II) nitrate trihydrate (12.0 g) in water (100 ml) and passing sulphur dioxide. The white precipitate was filtered, washing with sulphurous acid, ethanol and dry ether. The product was dried *in vacuo* over phosphorus(V) oxide for 12 hr.

Manganese(II) sulphite. Manganese(II) iodide (11.0 g) was refluxed with tetramethylammonium disulphite (10.5 g), added in four aliquots, in dry acetone (250 ml) for 40 hr. The white product was filtered, dried, washing with liquid sulphur dioxide (8 × 20 ml), and finally dried at $125°/10^{-4}$ mm. (Found: Mn, 39.2; SO_2, 46.1. Calc. for MnO_3S: Mn, 40.7; SO_2, 47.5.)

Iron(II) sulphite. The method described for the corresponding manganese compound was followed. A green product was obtained. (Found: Fe, 39.7; SO_2, 45.8. Calc. for FeO_3S: Fe, 41.1; SO_2, 47.1.)

Copper(I) disulphite. Copper(I) iodide (9.1 g) and sodium iodide (5.5 g) were refluxed with tetramethylammonium disulphite (9.0 g) in dry acetone (200 ml) and the method described for the corresponding manganese compound was followed. A white product was obtained. (Found: Cu, 45.0; SO_2, 45.8. Calc. for $Cu_2O_5S_2$: Cu, 46.9; SO_2, 47.25.)

Manganese(II) sulphite monohydrate. Sulphur dioxide was passed into a suspension of manganese(II) carbonate (3.0 g) in distilled water (20 ml) until a clear solution was obtained. The solution was heated on a steam bath under a stream of nitrogen. Crystalline manganese(II) sulphite monohydrate formed. When no more sulphur dioxide was evolved, the solution was allowed to cool under nitrogen. The product was filtered under nitrogen, washed with ethanol previously boiled and saturated with sulphur dioxide, dried with ether under nitrogen, and finally dried at 10^{-4} mm for 12 hr. The product was stored in a sealed tube under pure nitrogen. (Found: Mn, 35.8; SO_2, 41.5. Calc. for H_2MnO_4S: Mn, 35.65; SO_2, 41.85.)

Iron(II) sulphite trihydrate. All solutions were prepared and stored in a stream of pure nitrogen (previously deoxygenated by passing through chromium(II) chloride solution). Iron(II) sulphate pentahydrate (3.0 g) was dissolved in distilled water (20 ml) previously boiled and cooled under nitrogen. Concentrated hydrochloric acid (0.2 ml) and a piece of zinc were added. In another portion of water (20 ml), sodium sulphite (5.0 g) was dissolved and the solution saturated with sulphur dioxide. The two solutions were mixed, the zinc removed, and sulphur dioxide passed into the solution for 15 min. The stream of sulphur dioxide was replaced with nitrogen, and the solution heated to 100°C. When no more sulphur dioxide was evolved, the solution was allowed to cool. The pale green crystals were filtered, washed with ethanol previously boiled and saturated with sulphur dioxide, dried with ether, and finally dried at 10^{-4} mm for 12 hr. The product was stored in a sealed tube under pure nitrogen. (Found: Fe, 29.2; SO_2, 33.45. Calc. for H_6FeO_6S: Fe, 29.4; SO_2, 33.7.)

Calcium(II) sulphite hemihydrate. The method described for the corresponding manganese(II) sulphite monohydrate was followed. A white crystalline product was obtained. (Found: Ca, 31.4; SO_2, 48.9. Calc. for $HCaO_{3.5}S$: Ca, 31.45; SO_2, 49.6.)

Magnesium(II) sulphite trihydrate. The method described for the corresponding manganese(II) sulphite monohydrate was followed. A white crystalline product was obtained. (Found: Mg, 15.25; SO_2, 40.2. Calc. for H_6MgO_6S: Mg, 15.35; SO_2, 40.4.)

Physical measurements. Infrared spectra were recorded on a Perkin-Elmer 457 grating spectrophotometer as Nujol mulls. Thermogravimetric curves were obtained using a Stanton thermobalance. Metals were determined gravimetrically: manganese as ammonium manganese(II) phosphate monohydrate, iron as

iron(III) oxide, copper as dipyridinedithiocyanato copper(II), and magnesium as ammonium magnesium phosphate hexahydrate.

Sulphur dioxide was determined iodometrically and gravimetrically as barium sulphate, after oxidation of sulphite with hydrogen peroxide. Calcium was determined by Mr. A. Hedley of this department.

CRYSTALLINE PHASE EFFECTS ON ESCA VALENCE BANDS OF Zr(IV) AND Ti(IV) ACID PHOSPHATES

GIOVANNI MARLETTA,* ORAZIO PUGLISI and SALVATORE PIGNATARO

Abstract—The valence bands (V.B.) of ESCA spectra of Zr(IV) and Ti(IV) acid phosphates in different crystalline phases are reported. The various bands are assigned by comparison with Li_3PO_4. Variations on changing the crystalline phase for compounds having the same M(IV) ion are found. Two types of molecular orbitals are mainly involved. One related to P–O bonds is affected by the crystalline phase. The other, related to M(IV)–O bonds and confined into the layers of the compounds, are less sensitive to crystalline environment. Variation in the symmetry of the tetrahedral type PO_4^{3-} anion are proposed to be mainly responsible of the observed effects.

INTRODUCTION

Several attempts have been made in order to characterize the electronic effects of structural variations, due to changes in the crystalline phase, by means of the ESCA technique.[1-5] The study of the binding energy shifts of core levels on going from one to another crystalline phase does not give any conclusive answer to the problem of the detectability of structural changes. This is because the variation in crystalline phase influences primarily the Madelung potential that is expected to shift all the binding energies (B.E.) of the core levels in the same sense.[6,7] The Valence Band (V.B.) region of the ESCA spectrum seems to be more appropriate to detect structural changes. Large efforts have been made in the characterization of V.B. patterns for amorphous and crystalline phases in semiconducting compounds.[8,9] In addition, changes in the V.B. pattern for metal/dielectric and semiconductor/metal phase transitions and in general for a compound before and after a temperature induced phase transition have been reported.[10-13] Changes in the V.B. pattern of samples epitaxially grown in two different crystalline structures have been described also; however this last study deals with quite simple systems such as cubic (s.c.) and face centred cubic (f.c.c.) thallous halides.[14]

No dependence of V.B. structure on the crystalline phase has been reported for complex inorganic salts having polyatomic anions.

In connection with a general program of ESCA characterization of inorganic ion-exchangers and/or solid electrolytes we are carrying out[1,15] a systematic investigation on the acid phosphates of tetravalent metals and their salt forms. It was thought that these materials could be suitable compounds to study the eventual effect of the crystalline phase variation on the ESCA spectra of V.B. In fact, the acid salts of tetravalent metals, M(IV)·(HPO₄)₂, can be obtained, other than as amorphous materials, also in two different layered structures named as α- and γ-phases.[16-18] Thus, the V.B. spectra of the phosphate group can be examined and compared in three different materials of same chemical composition, while

the effect of the tetravalent metal can be investigated by comparing the results obtained with analogous crystalline phases of different M(IV) phosphates.

In this paper the results obtained with α-, γ- and amorphous acid phosphates of Zr(IV) and Ti(IV) are reported and discussed.

EXPERIMENTAL

Amorphous zirconium phosphate was prepared by slowly mixing 1 M $ZrOCl_2$ solution with 2 M H_3PO_4 solution. Microcrystalline α-$|Zr(PO_4)_2|H_2 \cdot H_2O$ and γ-$|Zr(PO_4)_2|H_2 \cdot 2H_2O$ were obtained with the slow precipitation[19] and refluxing[20] procedures respectively. The α-$|Ti(PO_4)_2|H_2 \cdot H_2O$ and γ-$|Ti(PO_4)_2|H_2 \cdot 2H_2O$ were obtained as described in Refs. 21 and 22 respectively. The amorphous and α-phases were stored over phosphorus pentoxide while the γ-phase were conditioned in vacuum desiccator over a NaCl saturated solution at room temperature ($P/P_0 = 0.7$).

The ESCA spectra were obtained with a KRATOS ES-300 electron spectrometer. The samples were introduced in the spectrometer chamber as powder pellets, obtained under rotary vacuum pump and attached to a Ni–Cr wire with a silver glue. The measurements were performed with Al_{K_α} radiation under a vacuum of 10^{-9} Torr.

It is always very difficult to assess the behaviour of water containing materials in the high vacuum of an X-ray Photoelectron Spectrometer.[23] In our case one can think that water of crystallization may or may not be pumped away. In both cases we should not have interference with the anion spectrum. If it is pumped away the crystalline structures remain unchanged.[22] If it has not been pumped away, the water O $2p$ cross section is so low with respect to metal–oxygen bonding orbitals to ensure little contribution to the valence band.

Carbonaceous contamination, previously discussed,[1] might also influence the V.B. spectra. However the good reproducibility of the spectra taken in different experimental conditions ensures that this disturbing factor should play a negligible role.

No attempt was made to remove the residual carbon contamination by Argon sputtering since this procedure causes strong damage in the examined samples.[15,24]

RESULTS AND DISCUSSION

Figure 1 shows the V.B. region of the ESCA spectrum of the amorphous $Zr(HPO_4)_2$. In the same figure the spectrum of Li_3PO_4 is also reported for comparison. The high K.E. part of the V.B. spectra of α, γ and amorphous

Fig. 1. Valence Band region (Al_{K_α}) of ESCA spectrum of amorphous $Zr(HPO_4)_2$. The Li_3PO_4 spectrum reported for comparison is from Ref. 25.

$Zr(HPO_4)_2$ are compared in Fig. 2. Figure 3 shows the same spectra for α and γ $Ti(HPO_4)_2$.

The assignment of the various bands in Figs. 1–3 is made by comparing the amorphous $Zr(HPO_4)_2$ and Li_3PO_4 spectra.

The structure (a) in the spectrum of the amorphous zirconium phosphate (Fig. 1) is due to the photoionization of 4p electrons of Zr(IV) ions; the rather sharp shape of this band suggests that the 4p orbitals are not strongly involved in the bonding. The weak structure (c) may be due to shake-up transitions involving the bands at higher K.E.

The structures (b), (d), (e) and (f) resemble those found in Li_3PO_4. This is not surprising, since, this part of the spectrum is free from metal Zr(IV) orbitals. Thus, it must be correlated to the PO_4^{3-} moiety and can be assigned to the same type of orbitals attributed to the corresponding bands in the Li_3PO_4 spectrum.[25-30] This because also the V.B. of this last compound is free from metal orbitals.

On this basis, the band (b) is assigned to four strongly bonding O-2s orbitals which are split by tetrahedral field in $1a_1$ and $1t_2$ orbitals having some P-3s and P-3p contribution respectively.

The bands (d) and (e) are assigned to $2a_1$ and $2t_2$-like orbitals. These orbitals arise from the mixing of four orbitals P-3s and P-3p with four $O-2p_\sigma$ orbitals. These two bands correspond to the two types of P-O σ-bonding, with $2a_1$ linked to the s-symmetry and with the $2t_2$ band linked to the p-symmetry.[25,26] The $2a_1$ band is mainly due to a P-3s/O-2p bonding orbital in which the little contribution of O-2s is of opposite sign of the P-3s. The $2t_2$ band arises from O-2p with P-3p strong contribution.

The band (f) is attributed to the convolution of three structures $1t_1$, $3t_2$ and $1e_1$ that arise from the splitting in

tetrahedral field of the eight 2p π orbitals of oxygen atoms. Strong contribution of Zr 4d orbitals to $2t_2$ and to $1t_1$, $3t_2$ and $1e$ is expected.

A closer comparison of the V.B. patterns of the Li_3PO_4 and of the amorphous $Zr(HPO_4)_2$ shows some differences (Fig. 1) in the relative intensities, shapes and relative B.E.'s of the various bands. Differences are also noted in the spectra of the Zr(IV) vs Ti(IV) compounds and for the same cation comparing the different crystalline structures (Figs. 2 and 3). These differences can be interpreted considering that the Valence Band features should be influenced by the following structural factors:

(1) Bond lengths between the central atom and the oxygens of oxoanions,

(2) Symmetry of the oxoanions in the crystalline lattice,

(3) Madelung potential effect arising on the peculiar crystal packing,

(4) Nature of the cations which in turn influence bonding features as polarity, covalency percentage, lengths and orientation of the bonds.

On the basis of the above considerations the differences between Li_3PO_4 and Zr(IV) or Ti(IV) phosphates, should be due to:

(a) the higher covalent nature of M(IV)-O bonding with respect to the more ionic nature of Li-O bonds,

(b) the different P-O length in $M(IV)(HPO_4)_2$ compound compared to that in Li_3PO_4 (1.53 Å in α-$Zr(HPO_4)_2$ against 1.56 Å in Li_3PO_4[16]),

(c) the distortion from tetrahedral symmetry mainly due to the P-OH bond which is longer for example, in α-$Zr(HPO_4)_2 \cdot H_2O$, than the other P-O bonds of about 0.06 Å.[31,32]

In particular, the first factor should account for the higher intensity of the (f) band in M(IV) phosphates. This
Fig. 2. Valence Band region in expanded scale of ESCA spectra of amorphous, α- and γ-Zr(HPO$_4$)$_2$.

Table 1. Binding energies (eV) of amorphous, α and γ Zr(HPO$_4$)$_2$

	O$_{1s}$	P$_{2s}$	Zr 3d 5/2	Zr 4s	Zr 4p	(b)	(d)	(e)	(f)
					(a)				
Amorphous	533.4	193.8	185.9	56.7	34.4	26.6	15.9	12.6	9.8
α	533.3	193.4	185.5	56.8	34.2	26.4	15.8	12.4	9.4
γ	532.7	193.0	185.0	56.2	33.7	25.9	14.6	11.9	9.1
Li$_3$PO$_4$	536.6	195.5	-	-	-	29.3	17.6	15.0	11.5 - 9.0

The figures for the Zr compounds are referred to the B.E. of the Zr 3 d5/2 core level (1)

The Li$_3$PO$_4$ values are taken from ref. 25.

because the covalent nature of the bonding should give a strong contribution of Zr 4d and 5s orbitals (or Ti 3d and 4s) to the oxoanion's molecular orbitals 1e$_1$, 1t$_1$ and 3t$_2$. An increased photoionization cross-section is indeed to be expected[33] for Zr 4d (or Ti 3d) orbital contribution to the low photoionization cross section of the O-2p like orbitals.

The B.E. lowering of the (f) band (distance O 2s-(f)

band centroid: Zr(HPO$_4$)$_2$ = 16.8 eV, Ti(HPO$_4$)$_2$ = 17.7 eV; Li$_3$PO$_4$ = 19.05 eV) should be mainly due to the increase of positive charge density of the oxygen atoms covalently bonded to M(IV) ions, with respect to the PO$_4^{3-}$ moiety in the Li$^+$ salts. The trend seems to be unaltered by eventual final state effects. The increased splitting of 2a$_1$.and 2t$_2$ like components from 2.5 eV for Li$_3$PO$_4$ to 3.3 eV for α-Zr(HPO$_4$)$_2$ or 3.6 eV for α-
TI(HPO₄)₂

Fig. 3. Valence Band region of ESCA spectra of α- and γ-Ti(HPO$_4$)$_2$.

$Ti(HPO_4)_2$ should be due to the concurrent influence of the decrease of the P–O distances and distortion of the tetrahedral symmetry of PO_4^{3-} group. The shorter bonds imply a stronger crystalline field effect on the energy levels in the anionic group, which should increase the separation of the levels. On the other hand the distortion of the tetrahedral symmetry is expected to remove band degeneracies, by splitting the $2a_1$ and $2t_2$ orbitals in different components convoluted in the broad (d) and (e) bands.

Several factors may contribute to the intensity inversion of the two $2a_1$ and $2t_2$ like bands. Due to the short P–O bond in M(IV) phosphates the interactions between the P 3s–O 2s orbitals are expected to be stronger than in Li_3PO_4. As a consequence, due to the opposite sign in the molecular combination, the intensity of $2a_1$ like band is reduced with respect to that of $2t_2$. To this effect concurs the above mentioned distortion of the tetrahedral symmetry on going from the Li to the M(IV) compounds. Because of the lower symmetry, the splitting of the (d) band takes place with a consequent lowering of its intensity. On the other hand the $2t_2$ like band should have some Zr 4d or Ti 3d contribution which should increase the intensity of the (e) band for the same reasons invoked for the (f) band.

A comparison of the V.B. region of ESCA spectra of

$Zr(HPO_4)_2$ and $Ti(HPO_4)_2$ with different crystalline arrangements shows the strong importance of the phase effects versus the "chemical" effect of the substitution of Li with Zr(IV) or Ti(IV) ions. The previous hypothesis allow to interpretate these effects.

Let us first compare the V.B. region of amorphous, α- and γ-zirconium phosphates. Figure 2 shows the (d), (e) and (f) bands in expanded scale. Remarkable differences both in B.E. and in shape for the three samples can be observed. The (a) and (b) bands are instead not reported being very similar.

The distance between the maxima of (d) and (e) bands is greater in α- and amorphous than in γ-phases. The γ-phase figure is closer to that of the model compound (see Fig. 2 and Table 1). The previously hypothesized correlation of this parameter to the symmetry of the PO_4^{3-} group would suggest in this case a more regular symmetry of the anionic groups in the γ-phase.

However the (d) band of the γ-phase shows a definite component at the low K.E. side and the energy difference of the centroid of the whole band with respect to the (e) band is 3.3 eV, very close to that found for the α-phase.

The α- and amorphous phases are characterized by a distorted tetrahedral symmetry of the anionic group with the P–OH bond significantly longer than the other P–O

bonds.[31,32] Unfortunately the structure of the γ-phase is yet unknown but some indirect evidences[34-36] lead to assume that there are two kinds of $PO_3(OH)$ groups, crystallographically different. This hypothesis seems to be supported by the observation of a low K.E. component of the (d) band, the deconvolution of this band giving an approximate 2:1 ratio between the more and less intense component. These two components might then be attributed to two different types of $PO_3(OH)$ groups. The low K.E. component should be due to a distorted tetrahedral situation. The more populated high K.E. band should be due to the presence of $PO_3(OH)$ groups with a more regular tetrahedral symmetry, since its energy difference from the sharp (e) band is closer to that of the tetrahedral model compound.

The (e) band seems very sharp in shape for the γ- and amorphous phases while it is broader in the α-one. This sharpening is probably to be connected again to symmetry factors.

In particular, in a previous work,[22] it was found that the structure of the γ-macroanions is more dense than that of the α-ones. It was supposed that the dense structure of the γ-layer could arise from a linking of $PO_3(OH)$ tetrahedra to the $M(IV)O_6$ octahedra different from that observed for the α-layer. In this latter macroanion the tetravalent metal atom is coordinated to six oxygens of six different $PO_3(OH)$ groups; in the γ-one the 6-coordination may be obtained with a lower number of $PO_3(OH)$ tetrahedra, probably four.

On the other hand, one has to take into account that angular variations in a given anion structure leads to modification in the V.B. pattern,[37] so that the modification observed in the (e) band may be connected to different packing, which involves angular variations in $PO_3(OH)$ tetrahedra on changing phase. The (f) band appears to be more similar in the case of the γ and amorphous phases with respect to the α-one. In particular the (f) band seems to be broader and less close to the (e) band in the series, $\alpha > \gamma >$ amorphous.

The sharpening of the (f) band seems reasonably connected to the poor band overlap in the amorphous phase, due to the lack of any regularity in the lattice. In the γ-phase, because of the same feature of the (f) band, the presence of some distortion in the crystal lattice should be considered. Indeed, the high density of the γ-sheets, that implies the distortion of the regular octahedral symmetry of the ZrO_6^{8-} clusters could cause the missing of part of the symmetry pattern found in the α-phase. This decrease of symmetry (from general solid state band considerations) could account of the observed band sharpening.

Similar conclusion can be drawn by examinating the V.B. spectra of α- and γ-titanium phosphates (see Fig. 3). In particular, the splitting of the (d) band in two components on going from α to γ phase is much stronger. This effect gives supports to the hypothesis made for the zirconium phosphates since it is just the effect expected on the base of the differences in the molecular internal distances. It is known that the distance between the M(IV) ions, lying nearly in a plane, is 5.3 Å (Zr) and 5.0 Å (Ti) for the α-compounds[16] and 4.6 Å (Zr) and 4.4 Å (Ti) for the γ-ones.[34,38]

Also the behaviour of the (e) and (f) bands resembles that observed for Zr(IV) phosphates on going from the α- to the γ-phase. The asymmetric shape of (e) band in α-Ti(HPO$_4$)$_2$ is removed in γ-Ti(HPO$_4$)$_2$, and the (f) band has a more flat shape in the α and a well peaked shape in

the γ-phase. Furthermore, the distance between the maxima of (d) and (e) bands is very similar to that found for the α and γ-Zr(IV) compounds: i.e. 3.6 eV in the α-phase and 2.7 eV in the γ-phase.

All of this suggests that the described differences in the V.B. patterns are peculiar to the various structures and that each phase is characterized by rather well defined features. The replacement of Zr(IV) with Ti(IV) leads only to small differences.

CONCLUSION

The comparative study of the V.B. region of the ESCA spectra of acid salts of tetravalent metals, having different structures, has shown that the V.B. patterns are affected by variation in the crystalline structure.

The structural variations influence in different extent the different parts of the V.B. pattern. In particular the (d) and the (e) bands (a$_1$ and t$_2$ orbitals) are those which seems to be mainly affected by the crystalline environment. This is connected to the fact that these bands refer to orbitals, (P–O) which are external to the macroanionic layers.

On the other hand the (f) band (e, t$_2$ and t$_1$ orbitals) is less affected by crystalline environment and the consequent symmetry variations. This is connected to the fact that these bands refer to orbitals, (mainly M(IV)–O), which are inside of the macroanionic layers.

Work is in progress in our laboratories on the alkali forms of these layered ion exchangers in order to study the effect of the intercalation of the cations on their V.B. patterns.

Abstract—Novel neutral biimidazolate or bibenzimidazolate palladium(II) and platinum(II) complexes of the type $M(N-N)_2(dpe)$ [M = Pd, Pt; $(N-N)_2^{2-}$ = BiIm^{2-}, BiBzIm^{2-}. dpe = 1,2-*bis*(diphenylphosphino) ethane] have been obtained by reacting $MCl_2(dpe)$ with $Tl_2(N-N)_2$. Complexes $M(N-N)_2(dpe)$ which are Lewis bases react with $HClO_4$ or $[M(dpe)(Me_2CO)_2](ClO_4)_2$ to yield, respectively, mononuclear cationic complexes of general formula $[M\{H_2(N-N)_2\}(dpe)](ClO_4)_2$ (M = Pd, Pt; $H_2(N-N)_2$ = H$_2$BiIm, H$_2$BiBzIm) and homobinuclear palladium(II) or platinum(II) cationic complexes of the type $[M_2\{\mu-(N-N)_2\}(dpe)_2](ClO_4)_2$. Reactions of M(BiBzIm)(dpe) with $[Rh(COD)(Me_2CO)_x](ClO_4)$ render similar heterobinuclear palladium(II)-rhodium(I) and platinum(II)-rhodium(I) cationic complexes, of general formula $[(dpe)M(\mu-BiBzIm)Rh(COD)](ClO_4)$ (M = Pd, Pt; COD = 1,5-cyclooctadiene). Di- and mono-carbonyl derivatives $[(dpe)M(\mu-BiBzIm)Rh(CO)L](ClO_4)$ (M = Pd, Pt; L = CO, PPh$_3$) have also been prepared. The structures of the resulting complexes have been elucidated by conductance studies and IR spectroscopy.

INTRODUCTION

Our recent contributions to the coordination chemistry of biimidazolate (BiIm^{2-}) and bibenzimidazolate (BiBzIm^{2-}) anions have shown the ability of these ligands to form bi-,[1–4] tri-[3,4] and tetra-nuclear[3,5] complexes. Particularly, we have described[3,4] several homonuclear gold(I) or heterotrinuclear gold(I)–palladium(II) and gold(I)–rhodium(I) complexes which have been prepared starting from $Au_2(\mu-BiBzIm)L_2$ (L = phosphine) (A) as precursors, where BiBzIm^{2-} is acting as bidentate bridging ligand. These binuclear gold(I) complexes are Lewis bases, since they contain two nitrogen atoms as potential donors.

In the present paper we report the synthesis and properties of neutral mononuclear palladium(II) or platinum(II) complexes (B, C) of the type $[M(N-N)_2(dpe)]$ (M = Pd, Pt; $(N-N)_2^{2-}$ = BiIm^{2-}, BiBzIm^{2-}; dpe = 1,2-

bis(diphenylphosphino) ethane) which, similarly to the aforementioned gold(I) complexes, behave as a potential bidentate ligands. This allows the preparation of mono- and bi-nuclear palladium(II) and platinum(II) cationic complexes of the type $[M\{H_2(N-N)_2\}(dpe)](ClO_4)_2$, $[M_2\{\mu-(N-N)_2\}(dpe)_2](ClO_4)_2$ (M = Pd, Pt) as well as heteronuclear palladium(II)–rhodium(I) and platinum(II)–rhodium(I) cationic complexes of general formula $[(dpe)M(\mu-BiBzIm)RhL_2](ClO_4)$ (M = Pd, Pt; L_2 = 1,5-cyclooctadiene; L = CO), along with the monocarbonyl derivatives $[(dpe)M(\mu-BiBzIm)Rh(CO)L](ClO_4)$ (M = Pd, Pt; L = PPh$_3$).

RESULTS AND DISCUSSION

Reaction between dichloromethane solutions of $MCl_2(dpe)$ (M = Pd, Pt; dpe = 1,2-*bis*(diphenyl-phosphino) ethane) and thallium salts of BiIm^{2-} or BiB-
---

(A)   (B)   (C)

zIm^{2-} according to eqn (1):

$$MCl_2(dpe) + Tl_2(N-N)_2 \rightarrow M(N-N)_2(dpe) + 2TlCl \quad (1)$$

$$M = Pd; (N-N)_2{}^{2-} = BiIm^{2-}(I), \; BiBzIm^{2-}(II)$$

$$M = Pt; (N-N)_2{}^{2-} = BiIm^{2-}(III), \; BiBzIm^{2-}(IV)$$

lead to the precipitation of TlCl and solutions from which the mononuclear biimidazolate and bibenzimidazolate palladium(II) or platinum(II) complexes I–IV (Table 1), where the anions are acting as bidentate chelate ligands, can be obtained.

These complexes (B, C) havè two uncoordinated nitrogen donor atoms and are therefore Lewis bases. Thus, the addition of a stoichiometric amount of perchloric acid to dichloromethane solutions of I–IV (eqn 2)

$$M(N-N)_2(dpe) + 2HClO_4 \; ac. \rightarrow [M\{H_2(N-N)_2\}(dpe)](ClO_4)_2$$

$$M = Pd; H_2(N-N)_2 = H_2BiIm(V), \; H_2BiBzIm(VI) \quad (2)$$

$$M = Pt; H_2(N-N)_2 = H_2BiIm(VII), \; H_2BiBzIm(VIII)$$
produces the protonation of the basic nitrogen atoms leading to the formation of cationic complexes V–VIII, in form of the perchlorate salts. Alternatively, these complexes can also be obtained from the cationic precursors[6] $[M(dpe)(Me_2CO)_2](ClO_4)_2$ by displacement with H_2BiIm or, respectively, $H_2BiBzIm$ of the poorly coordinated Me_2CO (eqn 3)

$$[M(dpe)(Me_2CO)_2](ClO_4)_2 + H_2(N-N)_2 \rightarrow$$

$$[M\{H_2(N-N)_2\}(dpe)](ClO_4)_2 + 2Me_2Co \quad (3)$$
Since complexes (I–IV) are stronger Lewis bases than acetone, they react with the cationic complexes $[M(dpe)(Me_2CO)_2](ClO_4)_2$ (M = Pd, Pt) affording solutions of homobinuclear cationic complexes (eqn 4)

$$[M(dpe)(Me_2CO)_2](ClO_4)_2 + M(N-N)_2(dpe) \rightarrow$$

$$[M_2\{\mu-(N-N)_2\}(dpe)_2](ClO_4)_2 + 2Me_2CO \quad (4)$$

$$M = Pd; (N-N)_2{}^{2-} = BiIm^{2-}(IX), \; BiBzIm^{2-}(X)$$

$$M = Pt; (N-N)_2{}^{2-} = BiIm^{2-}(XI); \; BiBzIm^{2-}(XII)$$
from which, after partial evaporation of the solvent, complexes (IX–XII) are obtained.

The process of eqn (4) is a general one and can be extended to the synthesis of heterobinuclear complexes.

Thus, palladium(II)–rhodium(I) and platinum(II)–rhodium(I) complexes (XIII–XIV) can be prepared, according to eqn (5)

$$[Rh(COD)(Me_2CO)_x](ClO_4) + M(BiBzIm)(dpe) \rightarrow$$

$$[(dpe)M(\mu-BiBzIm)Rh(COD)](ClO_4) + xMe_2CO \quad (5)$$

$$M = Pd(XIII), Pt(XIV) \quad COD = 1,5\text{-cyclooctadiene.}$$
All the reactions take place smoothly at room temperature.

Bubbling of carbon monoxide through dichloromethane solutions of the heterobinuclear complexes XIII and XIV leads to the displacement of the diolefin and to the formation of the dicarbonyl derivatives $[(dpe)M(\mu-BiBzIm)Rh(CO)_2](ClO_4)$ (M = Pd(XV), Pt(XVI)). Addition of an equimolecular amount of triphenylphosphine to dichloromethane solutions of XV and XVI causes the substitution of one mole of carbon monoxide by the phosphine and leads to the formation of the monocarbonyl complexes $[(dpe)M(\mu-BiBzIm)Rh(CO)(PPh_3)](ClO_4)$ [M = Pd(XVII), Pt(XVIII)].

All the complexes described herein are air-stable. Table 1 lists their analytical data, decomposition points, molecular weights of the neutral complexes along with the conductivity data of the cationic complexes. The values of the slope A in Onsager's equation (nitromethane solutions) for the cationic complexes V–XVIII (see experimental) confirm that they are 1:2 (A = 427–477) or 1:1 (A = 230, 249) electrolytes supporting the proposed formulation and ruling out other possible structures (D, E) for which higher values of A should be expected.[7]

The IR spectra of the complexes (Nujol mulls) show absorption bands due to the anions BiIm^{2-} or BiBzIm^{2-} which are basically identical with those described for these ligands in other related complexes.[1,3] Nevertheless, some differences are observed in the 1300–1100 cm^{-1} region (in plane C–H bending) where the spectra of mononuclear and homobinuclear complexes I–IX and XI exhibit two absorption bands. The spectra of the cationic complexes VI–XVIII show the two absorption bands which are characteristic of the perchlorate anion[8] (Td) at *ca.* 1095(s, br) and 623(s) cm^{-1}. For the complexes $[M\{H_2(N-N)_2\}(dpe)](ClO_4)_2$ (V–VIII) these results contrast with the IR spectra of the related rhodium (I) cationic complexes $[Rh\{H_2(N-N)_2\}(diolefin)](ClO_4)$ where the corresponding absorptions of the perchlorate group (C$_{3v}$) point to a bonding via N–H ... OClO$_3$.[4,9] The stretching ν(N–H) in the complexes V–VIII appears as a strong and broad band in the 3500–3000 cm^{-1} region.

The dicarbonyl complexes **XV** and **XVI** exhibit two strong absorptions (CH_2Cl_2 solutions) due to $\nu(CO)$, as expected for *cis*-dicarbonyl derivatives whilst the spectra of monocarbonyl complexes **XVII** and **XVIII** show a single absorption band (Table 1).

EXPERIMENTAL

C, H, N analyses were carried out with a Perkin–Elmer 240 microanalyzer. The IR spectra were recorded over the 4000–200 cm^{-1} range on a Perkin–Elmer 577 spectrophotometer using Nujol mulls or CH_2Cl_2 solutions. Conductivities were generally measured in *ca.* 5×10^{-4} M acetone or nitromethane solutions with a Philips 9501/01 conductimeter. Values of A were calculated in Onsager's equation $\Lambda_e = \Lambda_0 - A\sqrt{c}$ using several concentrations in the 5×10^{-3}–5×10^{-4} M range. The molecular weights were determined in chloroform solutions with a Hitachi-Perkin Elmer 115 osmometer. Decomposition points were determined under air in a Buchi apparatus.

PREPARATION OF COMPLEXES

Mononuclear palladium(II) or platinum(II) neutral complexes: M(BiIm)(dpe) *and* M(BiBzIm)(dpe) (*I-IV*)

An equimolecular mixture of Tl_2BiIm or $Tl_2BiBzIm^1$ and $MCl_2(dpe)^{10}$ (M = Pd, Pt) (0.5 mmol) in 50 ml of CH_2Cl_2 was stirred at room temperature for 2 hr. After filtering off the TlCl, partial evaporation of the solvent and addition of ether led to the precipitation of complexes I–IV. Yield %: (I) 64, (II) 79, (III) 83, (IV) 75.

Mononuclear palladium(II) or platinum(II) cationic complexes: $[M_2(\mu\text{-BiIm})(dpe)_2](ClO_4)_2$ (*V, VII*) *and* $[M(H_2BiBzIm)(dpe)](ClO_4)_2$ (*VI, VIII*)

Method (a). To a solution of 0.173 mmol of $[M(dpe)(Me_2CO)_2](ClO_4)_2$ (M = Pd, Pt)^6 in 50 ml of acetone (obtained *in situ* by reacting 0.173 mmol of $MCl_2(dpe)$ with 0.347 mmol of $AgClO_4$ and subsequent removal of AgCl) was added 0.173 mmol of H_2BiIm or $H_2BiBzIm$.^{11} After stirring at room temperature for 3 hr solutions were filtered off yielding the respective complexes by: partial evaporation of the filtrate and addition of ether (V, VII) or evaporation to dryness and stirring the oily residue in ether (VI, VIII). Yield %: (V) 84, (VI) 82, (VII) 87, (VIII) 90, A = (V) 435, (VI) 434, (VII) 460, (VIII) 477.

Method (b). A solution of 0.1 mmol of I–IV in 60 ml of CH_2Cl_2 was treated with 0.022 ml of $HClO_4$ 60% and stirred at room temperature for 1 hr. Complexes V–VIII were isolated after partial evaporation of the solution and addition of ether. Yields %: (V) 87, (VI) 80, (VII) 88, (VIII) 82.

Homobinuclear palladium(II) or platinum(II) cationic complexes: $[M_2(\mu\text{-BiIm})(dpe)_2](ClO_4)_2$ (*IX, XI*) *and* $[M_2(\mu\text{-BiBzIm})(dpe)_2](ClO_4)_2$ (*X, XII*)

An equimolecular mixture of $[Pd(dpe)(Me_2CO)_2](ClO_4)_2$ (obtained *in situ* as described above) and Pd(BiIm)(dpe) (I) or Pd(BiBzIm)(dpe) (II) (0.157 mmol) in 50 ml of acetone was stirred at room temperature for 3 hr. Complexes IX and X were precipitated by addition of ether to the partially evaporated solution. Platinum complexes XI and XII were similarly prepared. Yields %:

(IX), 80, (X) 88, (XI) 87, (XII) 93. A = (IX) 430, (X) 424, (XI) 427, (XII) 448.

Heterobinuclear palladium(II)–rhodium(I) or platinum(II)–rhodium(I) cationic complexes $[(dpe)M(\mu\text{-BiBzIm})Rh(COD)](ClO_4)$. M = Pd, (*XIII*), Pt (*XIV*)

A mixture of $[Rh(\mu\text{-Cl})(COD)]_2^{12}$ (0.033 g; 0.068 mmol), $AgClO_4$ (0.028 gr, 0.138 mmol) and 0.136 mmol of M(BiBzIm)(dpe) [M = Pd(II), Pt(IV)] in 30 ml of $H_2CCl_2Me_2CO$ (1 : 1) was stirred at room temperature for 20 min. AgCl was filtered off and the filtrate evaporated until *ca.* 1 ml. Yellow complexes **XIII** and **XIV** were precipitated by addition of ether. Yields %: (XIII) 79, (XIV) 94. A = (XIII) 230, (XIV) 249.

$[(dpe)M(\mu\text{-BiBzIm})Rh(CO)_2](ClO_4)$ M = Pd (*XV*), Pt (*XVI*)

Carbon monoxide was bubbled through a dichloromethane solution (20 ml) of **XIII** and **XIV** at atmospheric pressure for 20 min. The resulting solutions were partially evaporated and the required orange complexes **XV**, **XVI** precipitated by addition of ether. Yields %: (XV) 92, (XVI) 91.

$[(dpe)M(\mu\text{-BiBzIm})Rh(CO)(PPh_3)](ClO_4)$ M = Pd (*XVII*), Pt (*XVIII*)

An equimolecular mixture of **XV** (0.013 g; 0.013 mmol) or of **XVI** (0.039 g; 0.036 mmol) and PPh_3 in 20 ml of CH_2Cl_2 was stirred at room temperature until CO evolution is not observed (in *ca.* 2 hr). Pale yellow complexes **XVII** and **XVIII** were isolated after partial evaporation of solutions and addition of hexane. Yields %: (XVII) 91, (XVIII) 96.

STUDIES OF THE REACTIONS OF LITHIUM ATOMS WITH METHYL CYANIDE AND METHYL ISOCYANIDE IN INERT GAS MATRICES

ZAKYA A. KAFAFI, ROBERT H. HAUGE and JOHN L. MARGRAVE†
Rice University, Department of Chemistry, Houston, TX 77251, U.S.A.

Abstract—Linear LiNC is known to be the more stable isomer when isolated in inert gas matrices at low temperatures (4–15K).[1] In an attempt to form the other geometrical isomer, LiCN, studies of the reaction of lithium atoms with CH_3CN and CH_3NC were undertaken. A new absorption in the CN stretching region was observed when lithium atoms were co-condensed with CH_3NC in solid argon and xenon matrices. Photolysis of the matrices with a medium pressure Hg lamp during deposition of Li/CH_3NC seemed to favour the formation of the more stable isomer, LiNC. Reactions of lithium atoms with CH_3CN only led to the formation of LiNC, with or without photolysis.

INTRODUCTION

Early *ab initio* Hartree–Fock calculations on the structures and stabilities of gaseous LiCN and LiNC indicated that linear LiNC should be more stable by ~9 kcal/mole than linear LiCN.[2] From the different measured isotopic shifts for the three fundamental modes of carbon-13, nitrogen-15 and lithium-6 enriched samples, IR matrix isolation studies carried out on this molecule confirmed the greater stability of LiNC. Shortly after the experimental studies, Clementi *et al.*[3] reinvestigated the LiCN and LiNC molecules in the linear configuration making use of a larger basis set in their calculations. The resulting atomization energies were found to be 310.71 and 317.63 kcal/mole for LiCN and LiNC, respectively, again demonstrating the stability of LiNC over LiCN. However the emphasis in this work was on the study of the energy surface for a lithium atom reacting with a CN radical which represents the isomerization reaction surface for conversion from LiCN to LiNC. Particular interest was paid to the height of the energy barrier between the two configurations. No energy barriers were found to exist in the conversion of LiCN to LiNC, or between the linear and non-linear configurations.

Recently it was shown[6] that if correlation effects are included in the calculations of the isomerization energy for LiNC ↔ LiCN, the molecule shows almost no energy change for rearrangement in support of the idea of the "polytopic" bond.

Lunichev and Rambidi[5] derived equations that describe nuclei distributions of LiNC molecules for lower states of deformation vibrations. It was found that on increasing the vibrational energy, the average distance of the Li nucleus from the center of mass of the NC group increases and the average arrangement of LiNC nuclei changes from near linear to triangular. The same authors[6] studied the motion of the Li atom in a LiNC molecule and these calculations showed that the LiNC nuclear framework is highly non-rigid at low vapour temperatures as reflected from the high population of excited states. However the fraction of states where pseudo-rotation of the Li atom is possible, was not large

even at rather high vapour pressures because of the low vaporization temperature (~ 800 K).

The atomization energies of gaseous alkali metal monocyanides were recently experimentally measured[7] using an atomic absorption spectrometric method. The measured atomization energy of 317.17 kcal/mole for the lithium compound compares very well with that calculated (317.63 kcal/mole) for LiNC.[3]

This paper deals with the study of the nature of reactions of lithium atoms with CH_3CN and CH_3NC in solid inert gas matrices. An end-on attack of a lithium atom on CH_3CN and CH_3NC is expected to form LiNC and LiCN, respectively, while an approach from the side should produce a mixture of the isomers.

EXPERIMENTAL

The matrix isolation apparatus used in this study has been previously described in detail.[9,10] Lithium was heated in a stainless steel crucible in the temperature range 350–400°C. The temperature of the furnace was measured with alumel–chromel thermocouple wires placed at the back of the cell. In a typical experiment, an atomic beam of the metal was co-condensed with the reactant gas, CH_3CN or CH_3NC, with excess inert gas for a period of 1 hr. The matrix surface, a polished copper mirror, was then rotated 180° and the infrared reflection spectra of the trapped species were measured with a Beckman IR-9 spectrophotometer. Absolute frequencies were usually read to an accuracy of ±0.5 cm⁻¹ and were calibrated against the standard water spectrum. A closed cycle helium refrigerator was used for cooling the copper block to the desired temperature. Photolysis of the matrix with a medium pressure short-arc mercury lamp and a water/pyrex filter was sometimes carried out during deposition.

The lithium metal, obtained from Alfa Inorganics, was of high purity (99%). An isotopically-enriched sample of metal (96% ⁶Li) was furnished by the Oak Ridge National Laboratory. Methyl cyanide (99+%) was purchased from Aldrich Chemical Company. Methyl isocyanide was prepared according to the method described in Ref. 11. Both the cyanide and isocyanide compounds were frozen at liquid N_2 temperature and pumped on for a short period of time. These freeze-thaw cycles were repeated several times until the liquids were completely degassed. Matheson argon (99.99%) was purified by passing it through hot titanium (900°C) prior to deposition. Xenon (99.99%) was obtained from Cryogenic Rare Gas Laboratories and was used without further purification. The flow rates of the reactant gases

---

†Author to whom correspondence should be addressed.

and the inert gases were separately controlled through two different needle values connected to thermocouple gauges.

DISCUSSIONS OF RESULTS

When lithium atoms were co-condensed with methyl isocyanide in excess argon, a new absorption appeared in the CN stretching region at $2230.5 \, cm^{-1}$ as shown in Figs. 1(B) and 1(B'). The frequency of this band was not altered upon substitution of lithium-6. A weak absorption was also detected at $617.4 \, cm^{-1}$ which has been assigned to the out-of-plane bending mode of the methyl radical. When photolysis of the matrix was carried out during deposition using a short arc Hg lamp, two bands appeared at 646.5 and $2080.5 \, cm^{-1}$. The frequencies of these bands are very close to the LiN ($646.4 \, cm^{-1}$) and NC ($2084.5 \, cm^{-1}$) stretching frequencies of lithium isocyanide.[1] The peak at $646.5 \, cm^{-1}$ shifts by $40 \, cm^{-1}$ when an enriched sample of the metal (96% ^6Li) is used. Again the measured frequency is very close to that of the ^6LiN ($696.5 \, cm^{-1}$) stretching frequency of ^6LiNC. These absorptions can be assigned to the molecule, LiNC.

Reactions of lithium atoms with methyl cyanide in the presence or absence of light led only to the formation of LiNC as evidenced from the absorption band due to the NC stretching mode as shown in Fig. 2. It is obvious from these spectra that photolysis of the matrix during deposition enhanced the yield of the lithium isocyanide produced. Similar results were obtained for the reactions of lithium atoms with CH_3NC or CH_3CN in xenon matrices.

The spectra measured after simultaneous co-condensation of lithium with methyl isocyanide in inert gas matrices suggest the formation of a new compound containing a CN functional group. Lithium cyanide and methyl lithium cyanide are two possible products that can be formed. If the complex CH_3LiCN were produced, one would expect to observe a large shift in the out-of-plane mode of the methyl radical by analogy to that
Fig. 1. IR spectra of the products of the reactions of ^7Li or ^6Li with CH_3NC in solid argon × A and A' Pure CH_3NC, B and B' $CH_3NC/^7Li$ and $CH_3NC/^6Li$ and C and C' $CH_3NC/^7Li$ and $CH_3NC/^6Li$ after photolysis with a medium pressure Hg lamp ($\lambda \geq 3000$ Å) for a period of 1 hr.
Fig. 2. IR spectra of the products of the reactions of ^6Li with CH_3CN in solid argon × A Pure CH_3CN, B $CH_3CN/^6Li$ and C $CH_3CN/^6Li$ after photolysis with a medium pressure Hg lamp ($\lambda \geq 3000$ Å) for a period of 1 hr.

observed in case of the methyl alkali halide complexes where the perturbed CH_3 frequency is shifted to the region between 730 and $680 \, cm^{-1}$.[12,13] This blue shift would be indicative of a methyl radical strongly interacting with a lithium cyanide molecule. A broad absorption near the peak assigned to unperturbed methyl suggested that some of the methyl groups may be undergoing weak interactions with neighbouring groups; however, the shifts were much smaller than those reported for methyl in a complex such as CH_3LiX. Thus, one concludes that an appreciable amount of essentially free methyl radical was produced which suggests that the following reaction has occurred

$$Li + CH_3NC \rightarrow LiCN + CH_3$$
where lithium has attacked the methyl isocyanide end-on from the side opposite the methyl leading to the formation of only lithium cyanide. Photolysis during deposition causes the formation of some LiNC in addition to LiCN. This result is not surprising since it is known that lithium isocyanide is more stable than lithium cyanide.[1-6]

Table 1 compares the CN stretching frequencies for the molecules HCN[14] vs HNC[15], LiCN vs LiNC[1] and CH_3CN[16] vs CH_3NC[16]. It is clear from these data that the CN frequencies for the cyanides are higher than those for the respective isocyanides. This result is not surprising since one expects the CN bond in the MCN species to have more triple-bond character and resemble closely that of CN^-.

CONCLUSIONS

This study of the reactions of lithium atoms with CH_3CN and CH_3NC supports a mechanism in which the met attacks the CN or NC groups end at the end

Table 1. Comparison between the CN and NC stretching frequencies for MCN and MNC

M	$\tilde{v}_{NC}(cm^{-1})$	$\tilde{v}_{CN}(cm^{-1})$
H	2029.2	2093.4

A SYNTHETIC ROUTE TO HETERONUCLEAR CLUSTERS CONTAINING IRIDIUM AND RHODIUM: X-RAY CRYSTAL STRUCTURES OF [IrOs$_3$(μ-H)$_2$(μ-Cl)(CO)$_{12}$] AND [Ir$_2$Rh$_2$(μ-CO)(μ_3-CO)$_2$(CO)$_4$(η-C$_5$Me$_5$)$_2$]

LOUIS J. FARRUGIA, A. GUY ORPEN and F. GORDON A. STONE

Department of Inorganic Chemistry, The University of Bristol, Bristol BS8 1TS, England

Abstract—The iridium and rhodium complexes [MCl(CO)$_2$(NH$_2$C$_6$H$_4$Me-4)] (M = Ir or Rh) react with [Os$_3$(μ-H)$_2$(CO)$_{10}$] to give the tetranuclear clusters [MOs$_3$(μ-H)$_2$(μ-Cl)(CO)$_{12}$]; the iridium compound being structurally identified by X-ray diffraction. Similarly, [IrCl(CO)$_2$(NH$_2$C$_6$H$_4$Me-4)] and [Rh$_2$(μ-CO)$_2$(η-C$_5$Me$_5$)$_2$] afford the tetranuclear cluster [Ir$_2$Rh$_2$(μ-CO)(μ_3-CO)$_2$(CO)$_4$(η-C$_5$Me$_5$)$_2$], also characterised by single-crystal X-ray crystallography.

The isolobal relationship existing between carbenes CR$_2$ on the one hand and the "carbene-like" metal fragments W(CO)$_5$, Fe(CO)$_4$, Rh(CO)(η-C$_5$Me$_5$) and PtL$_2$ (L$_2$ = cod = cyclo-octa-1,5-diene, or L = PR$_3$ or CO) on the other[1] has enabled us to prepare a variety of complexes containing heteronuclear metal–metal bonds.[2–4] Useful conceptual relationships result. Thus the PtL$_2$, Fe(CO)$_4$ and W(CO)$_5$ groups all readily added to the dirhodium compound [Rh$_2$(μ-CO)$_2$(η-C$_5$Me$_5$)$_2$], as does CR$_2$. Isolobal with the dirhodium compound is [(OC)$_4$Fe=Fe(CO)$_4$], which although unstable[5] can be complexed by Pt(cod) in the stable species [Fe$_2$Pt(CO)$_8$(cod)].[6] However, although the analogy between inorganic and organic fragments with similar electronic structures allows synthetic strategies to be developed, it does not necessarily follow that the nature of the final products are those predicted by a simple consideration of isolobal relationships. This is because an initially formed species can transform into another to gain greater kinetic or thermodynamic stability. Herein we report some examples of the apparent limitation of the isolobal analogy, but which nevertheless provide a new and useful route to heteronuclear clusters of iridium and rhodium.

The similarity of the frontier orbitals of the metal ligand fragments ML$_5$(d^n, C_{4v}) and ML$_3$(d^{n+2}, C_{2v} or T-shaped), e.g. W(CO)$_5$ vs MCl(CO)$_2$ (M = Rh or Ir), as well as the relationship between W(CO)$_5$ and PtL$_2$ or CH$_2$ allows the isolobal mapping.[1]

$$W(CO)_5 \longleftrightarrow IrCl(CO)_2 \longleftrightarrow PtL_2 \longleftrightarrow CH_2.$$
Hence, since PtL$_2$[3,7] or CR$_2$[3,8–10] fragments readily add to [Os$_3$(μ-H)$_2$(CO)$_{10}$] and [Rh$_2$(μ-CO)$_2$(η-C$_5$Me$_5$)$_2$] to give products in which PtL$_2$ or CR$_2$ groups can be identified, it was reasonable to suppose that MCl(CO)$_2$ (M = Rh or Ir) fragments, derived from [MCl-(CO)$_2$(NH$_2$C$_6$H$_4$Me-4)], would also react with these electrophilic triosmium and dirhodium compounds. Reactions readily occur, but the end products do not contain MCl(CO)$_2$ fragments.

Treatment of [Os$_3$(μ-H)$_2$(CO)$_{10}$] in dichloromethane

with one equivalent of [IrCl(CO)$_2$(NH$_2$C$_6$H$_4$Me-4)] at room temperature gave the yellow crystalline compound (1) in 70–80% yield [ν_{CO} (cyclohexane), 2087s, 2080m, 2049s, 2028m, 2014m, and 1988w cm^{-1}]. The ^{1}H NMR spectrum (CDCl$_3$) of (1) showed a characteristic resonance for the μ-HOs$_2$ hydrido ligands at $\delta -14.66$ ppm, an interesting feature of which was the observation of ^{187}Os satellite peaks [J(OsH)$_{av}$ 32 Hz]. The rhodiumtriosmium compound (2) [ν_{CO} 2078s, 2052m, 2029m, 2012m, and 2004s(sh) cm^{-1}] was similarly prepared, but in lower yield, due to concomitant formation of the complexes [Os$_3$(μ-H)(μ-Cl)(CO)$_{10}$] and [Rh$_2$(μ-Cl)$_2$(CO)$_4$]. In the ^{1}H NMR, the two hydrido ligands gave a resonance at $\delta -19.73$ ppm; failing to observe ^{103}Rh coupling establishing the absence of Rh–H bonds. A single-crystal X-ray diffraction study was carried out on (1) to establish the molecular structure.

Crystal data. C$_{12}$H$_2$ClIrO$_{12}$Os$_3$, $M = 1136.4$, Monoclinic, space group $P2_1/m$, $a = 7.364(4)$, $b = 16.157(6)$, $c = 8.659(3)$Å, $\beta = 111.39(3)°$, $U = 959.5(7)$Å^3, $Z = 2$, $F(000)$ 984, $D_c = 3.93$ g cm^{-3}, μ(Mo-K$_\alpha$) 269.2 cm^{-1}, Mo-K$_\alpha$ X-radiation, $\bar{\lambda} = 0.71069$ Å.

The structure was solved by heavy atom Fourier methods and refined using blocked cascade full-matrix least squares. For 2163 unique, absorption corrected, observed data [$I > 2.5\sigma(I)$], measured at 200 K on a Nicolet *P3m* diffractometer in the range $4 \leq 2\theta \leq 60°$, the current residual R is 0.084.

The molecule (Fig. 1) contains a "butterfly" arrangement of four metal atoms, with the non-bonded Os(1)–Os(1′) vector being bridged by a chlorine atom. As such the structure is related to that[11] of [Os$_4$(μ-H)$_3$(μ-I)-(CO$_{12}$)], with an Os(μ-I)Os bridge. Both molecules have 62 cluster valence electrons.

[MOs$_3$(μ-H)$_2$(μ-Cl)(CO)$_{12}$]
(1) M = Ir
(2) M = Rh
[Ir$_2$Rh$_2$(μ-CO)(μ_3-CO)$_2$(CO)$_4$(η-C$_5$Me$_5$)$_2$]
(3)
Because the molecule has crystallographic mirror sym-

metry, although not located directly, the two hydrido ligands in (1) must bridge the Os(1)–Os(2) and Os(1')–Os(2) edges of the butterfly. Thus Os(1)–Os(2) and Os(1')–Os(2) [2.994(1)Å] are appreciably longer than the other metal–metal bonds, and may be compared with corresponding Os(μ-H)Os separations in the butterfly clusters [Os$_3$Rh(μ-H)$_2$(acac)(CO)$_{10}$] [2.968(1)Å][7] and [Os$_4$(μ-H)$_3$(μ-I)(CO)$_{12}$] [3.055(1)Å].[11] Potential energy calculations[12] also suggest location of the hydrido ligands in (1) as bridging Os(2)–Os(1) and Os(2)–Os(1'), as do Os–Os–CO bond angle considerations. In contrast with the C_s symmetry of (1), the neutron diffraction study[11] of [Os$_4$(μ-H)$_3$(μ-I)(CO)$_{12}$] revealed that the two equivalent hydrido ligands bridge Os–Os bonds such that the molecule has C_2 symmetry.

Treatment of Rh$_2$(μ-CO)$_2$(η-C$_5$Me$_5$)$_2$] with one equivalent of [IrCl(CO)$_2$(NH$_2$C$_6$H$_4$Me-4)] in toluene (12 hr, 60 °C) gave a dark purple solution and red crystals; the latter as yet unidentified. Removal of solvent from the solution and chromatography (alumina, with dichloromethane—light petroleum as eluant) gave a purple band which afforded black crystals (20%, based on [Rh$_2$(μ-CO)$_2$(η-C$_5$Me$_5$)$_2$]), from light petroleum, of the compound (3); structurally identified by X-ray crystallography.

*ν_{max}(CO), 2 040s, 2 021vs, 2 007s, 1 847m, 1 704m, and 1 682m (cm^{-1}). NMR: ^{1}H (CDCl$_3$, 25°C), δ 1.76 (s, C$_5$Me$_5$); ^{13}C (CDCl$_3$, -80°C), δ 235.6 [t, μ_3-CO, J(RhC) 32 Hz], 180.9 (s, IrCO and Ir(μ-CO)Ir), 104.4 (C$_5$Me$_5$) and 9.3 ppm (Me).

Crystal data. C$_{27}$H$_{30}$Ir$_2$O$_7$Rh$_2$, M = 1 056.4, Monoclinic, space group $P2_1/n$, a = 11.458(2), b = 15.318(2), c = 16.837(3)Å, β = 94.75(2)°, U = 2 945.1(9)Å^3, Z = 4, $F(000)$ = 1 968, D_c = 2.35 g cm^{-3}, μ(Mo-K$_\alpha$) = 101.0 cm^{-1}, Mo-K$_\alpha$ X-radiation, $\bar{\lambda}$ = 0.710 69 Å.

The structure was solved by direct methods and refined using blocked cascade full-matrix least squares. An empirical absorption correction was applied to the 3 904 independent observed reflections [I > 2.0σ(I)] measured at 293 K on a Nicolet $P3m$ diffractometer in the range $3 \le 2\theta \le 50°$. The current residual R is 0.037 (R' 0.037).

The molecule (Fig. 2) contains a tetrahedron of two rhodium and two iridium atoms. The arrangement of ligands is very similar to the analogous 60 electron homonuclear tetracobalt cluster [Co$_4$(μ-CO)(μ_3-CO)$_2$(CO)$_4$(η-C$_5$Me$_5$)$_2$].[13] The molecule has a near perfect mirror symmetry, though not crystallographically defined. There is evidently dynamic behaviour of the terminally bound and μ_2-bridging CO ligands, as shown by the appearance of only one CO resonance for these five ligands in the ^{13}C NMR spectrum measured at -80 °C. However, in the IR spectrum* the band at 1 847 cm^{-1} may be assigned to the Ir(μ-CO)Ir group. The presence of the latter fragment is unusual, this mode of bridge bonding being uncommon for a third row transition element. The compound [Ir$_2$W$_2$(CO)$_{10}$(η-C$_5$H$_5$)$_2$], synthesised by the conventional route of treating [IrCl(CO)$_2$(NH$_2$C$_6$H$_4$Me-4)] with the anion [W(CO)$_3$(η-C$_5$H$_5$)]$^-$, has only terminal CO ligands.[14]

It is reasonable to propose that [IrCl-
Fig. 1. Molecular structure of [IrOs$_3$(μ-H)$_2$(μ-Cl)(CO)$_{10}$]. Important geometrical parameters are: Ir–Os(1) 2.803(1), Ir–Os(2) 2.749(2), Os(1)–Os(2) 2.994(1), Os(1)....Os(1') 3.636(1), Os(1)–Cl 2.435(6)Å; Os(2)–Os(1)–C(3) 114.6(7), Os(1)–Os(2)–C(7) 113(1)°; other M–M–C angles range from 87(1) to 97.2(8)°. Dihedral angle Os(1)–Os(2)–Ir–Os(1') 91.0(1)°.
Fig. 2. Molecular structure of [Ir₂Rh₂(μ-CO)(μ₃-CO)₂(CO)₄(η-C₅Me₅)₂]. Important geometrical parameters are: Ir(1)–Ir(2) 2.645(1), Ir(1)–Rh(1) 2.716(1), Ir(1)–Rh(2) 2.787(1), Ir(2)–Rh(1) 2.731(1), Ir(2)–Rh(2) 2.786(1), Rh(1)–Rh(2) 2.704(1)Å. Dihedral angle Ir(1)–Rh(1)–Rh(2)–Ir(2) 66.9(1)°.

(CO)₂(NH₂C₆H₄Me-4)] acts as a source of the fragment IrCl(CO)₂ which initially adds to the electrophilic LUMO's of [Os₃(μ-H)₂(CO)₁₀] and [Rh₂(μ-CO)₂(η-C₅Me₅)₂].[15] The reactions are complex, however, and in both cases proceed with cleavage of the Ir–Cl bond, indicating that the chloride ligand is not chemically innocent. Nevertheless, [IrCl(CO)₂(NH₂C₆H₄Me-4)] is a useful reactant for generating heteronuclear metal–metal bonds.

THE DETECTION OF TRACE AMOUNTS OF
trans-Pt(NH₃)₂Cl₂ IN THE PRESENCE OF
cis-Pt(NH₃)₂Cl₂. A HIGH PERFORMANCE
LIQUID CHROMATOGRAPHIC APPLICATION
OF KURNAKOW'S TEST

J. DEREK WOOLLINS,* ANN WOOLLINS and BARNETT ROSENBERG

Department of Biophysics, Michigan State University, East Lansing, MI 48824, U.S.A.

Abstract—Treatment of mixtures of *cis* and *trans* Pt(NH₃)₂Cl₂ with thiourea (thu) gave Pt(thu)₄Cl₂ and *trans* [Pt(NH₃)₂(thu)₂]Cl₂ which were separated and quantified by high-performance liquid chromatography using a strong cation exchange column. Several platinum–thiourea compounds have been studied by NMR (^{1}H, ^{13}C, ^{195}Pt), an increase in the coalescence temperature of the NH₂ resonances being observed as a result of co-ordination. The NMR data has also been used to show the presence of interactions between the Pt(thu)₄²⁺ and PtCl₆²⁻ ions of [Pt(thu)₄][PtCl₆] in dimethylsulphoxide solution.

INTRODUCTION

Since the discovery[1] of the anti-tumour activity of *cis*-Pt(NH₃)₂Cl₂, **1**, there has been great interest in the chemistry of simple platinum compounds. As part of our studies we have developed a high-performance liquid chromatography (HPLC) method for the detection of *trans*-Pt(NH₃)₂Cl₂, **2**, in **1**. The *trans*-isomer, **2**, which is inactive against tumours[2], is normally observed as a by-product in the preparation of **1** with tedious recrystallisations being required to purify **1** completely. The simple procedure described here allows the purity of preparations to be checked quite easily and should enable studies on *cis–trans* isomerisation in dilute solution to be undertaken. The separation we have employed makes use of derivatisation of the platinum complexes with thiourea (the classic Kurnokow test[3]) before injection into the HPLC. As part of the general characterisation of the thiourea complexes we have measured their NMR spectra (^{1}H, ^{13}C, ^{195}Pt) and note that upon co-ordination the barrier to rotation in thiourea increases significantly.

It is the twofold purpose of this paper to report an HPLC method for the trace detection of **2** in **1** and the results of a multinuclear NMR study on several thiourea complexes.

EXPERIMENTAL

All reactants and solvents were of at least reagant grade. Thiourea was purchased from Mallindrockt, *cis* and *trans*-Pt(NH₃)₂Cl₂, K₂PtCl₄ and Na₂PtCl₆ were supplied by Johnson Matthey and Engelhard Industries.

The high performance liquid chromatograph (Waters Assoc.) consisted of a 6000A pump, U6K injector and model 440 dual wavelength absorbance detector (operating at 254nm with the second electronics module being used for expanded scale recordings), together with a 4.6 × 250 mm Whatman Partisil PXS 10/25 SCX strong cation exchange column. The eluent (0.25 M NH₄H₂PO₄) was filtered through 0.47 μm filters (Millipore) and thoroughly degassed prior to use. Sample solutions were filtered through 0.22 μm filters before injection.

NMR measurements were made using a Bruker WM 250 (^{1}H and ^{13}C) and a Bruker WH 180 (^{195}Pt). Infrared spectra were obtained with a Perkin Elmer 457 spectrometer with samples prepared as pressed KBr discs.

Microanalyses were performed by Canadian Microanalytical Services, Vancouver, B.C.

Pt(thu)₄Cl₂, **3**, *trans*-[Pt(NH₃)₂(thu)₂]Cl₂, **4**, and *trans*-PtCl₂(thu)₂ (thu = thiourea) were prepared by well-known procedures.[3] The reaction of K₂PtCl₄ ·or **1** with thiourea in dimethylformamide (dmf) was also found to be a convenient route to **3** in the following manner.

Pt(thu)₄Cl₂.dmf. Thiourea (3.42 g, 45 mMol) and K₂PtCl₄ or *cis*-Pt(NH₃)₂Cl₂ (10 mMol) were stirred together in dmf (100 ml) for 16 hr. The resulting light yellow precipitate was filtered off, washed with dmf, ethanol and diethyl ether and air dried, yield 6.3 g, 98%. Conversion to Pt(thu)₄Cl₂ could be accomplished by recrystallisation from hot water (70% yield) or by dissolution of the Pt(thu)₄Cl₂.dmf in hot water and precipitation using HCl (yield 97%).

[Pt(thu)₄][PtCl₄]. Filtered aqueous solutions of K₂PtCl₄ (0.83 g, 2 mMol) and Pt(thu)₄Cl₂dmf (1.2 g, 2 mMol) were combined. The resulting light red precipitate was filtered off, washed with water, ethanol and diethyl ether and dried *in vacuo*, yield 1.25 g, 75%.

[Pt(thu)₄][PtCl₆]. Filtered aqueous solutions of Na₂PtCl₆ (0.9 g, 2 mMol) and Pt(thu)₄Cl₂dmf (1.2 g, 2 mMol) were combined. The resulting brick red precipitate was filtered off, washed with water, ethanol and diethyl ether and dried in vacuo, yield 1.4 g, 77%.

HPLC Analysis. The Pt(NH₃)₂Cl₂ mixture to be analysed was dissolved in water at a concentration of approx. 1 mg/ml acidified (50 μl of 1 M HNO₃ per ml of Pt(NH₃)₂Cl₂ solution) and then treated with thiourea (100 μl of a 20 mg/ml solution per ml of Pt(NH₃)₂Cl₂ solution), and heated at 60°C for 30 minutes. After this time the solution was filtered and injected (20 μl) into the HPLC.

Standards for calibration were prepared using pure samples of Pt(thu)₄Cl₂ and *trans*-[Pt(NH₃)₂(thu)₂]Cl₂ dissolved in water at known concentrations.

RESULTS AND DISCUSSION

HPLC analysis

A number of chemical tests[4] for distinguishing **1** and **2** are known but there does not seem to be a good method for the trace detection of **2** in **1**, although the reaction[5] with oxydiphenylenetellurium hydrogen sulphate does permit detection of minute amounts of **1** in **2**. Cleare[6] has discussed the application of spectroscopic techniques to the problem and also shown that separation of **1** from **2**

---

*Author to whom correspondence should be addressed.

may be achieved by HPLC but has not reported any details of the procedure or the detection limits.

In order to take full advantage of the HPLC technique it is preferable to have easily detected species which are well separated. Platinum diammine dichlorides are poorly soluble in water, have very low absorbances in the operating range of most HPLC detectors (i.e. 254 nm) and represent a "difficult" separation. However, treatment of the platinum compounds with thiourea using the classic Kurnakow test[3] alleviates these problems. As a result of the *trans* directing ability of thiourea 1 is converted to Pt(thu)$_4$Cl$_2$, **3**, and **2** yields *trans*-[Pt(NH$_3$)$_2$(thu)$_2$Cl$_2$, **4**, when treated with thiourea. These complexes are easily separated by HPLC and have strong absorbances in the UV.

Figure 1 shows the results of derivatisation and chromatography upon known mixtures of **1** and **2**. The chromatographic conditions employed here achieve a good separation of thiourea, **3** and **4**. The use of different concentrations of ammonium phosphate as the eluent has a marked effect upon the retention times of the platinum containing species. For example, the retention times of **3** and **4** go from 5.3 and 7.3 min. respectively when using 0.25 M NH$_4$H$_2$PO$_4$ as the eluent to 3.4 and 4.6 min. respectively when using 0.5 M NH$_4$H$_2$PO$_4$. The concentration of ammonium phosphate chosen is thus a compromise between better separation and loss of sensitivity as a result of peak broadening.

Calibrations were carried out using pure samples of **3** and **4** which had been separately prepared and analysed (Table 1). Agreement between the standards and the samples prepared *in situ* was found to be good, the chromatograms from the analysis being very clean with only bands due to thiourea, **3** and **4** being observed. Injection of an equimolar mixture of **3** and **4** showed, as expected, that **3** gave peak areas of very close to twice those of **4**. However, this is not a problem, because of the large dynamic range of the detector, detection limits of 0.01% *trans* in *cis* were obtained. We did not make
Fig. 1. HPLC of various mixtures of **1** and **2** after treatment with thiourea. Column: Partisil PXS 10/25 SCX (4.6×250 mm). Eluent: 0.25 M NH$_4$H$_2$PO$_4$. Flow rate 2 ml/min. Detector 254 nm, using the following sensitivities for expansions (a) 2.0 absorbance units full scale, (AUFS) mixture containing 25% *trans*-Pt(NH$_3$)$_2$Cl$_2$, **2**, in *cis*-Pt(NH$_3$)$_2$Cl$_2$, **1**, (b) 0.02 AUFS, 1% **2** in **1**, (c) 0.005 AUFS, 0.1% **2** in **1**, (d) 0.005 AUFS, 0.01% **2** in **1**.

any efforts to obtain detection limits for *cis* in *trans* but it should be at least as good as the above.

The results obtained here reveal the high sensitivity that the HPLC technique can achieve with the absolute

detection limit of 1 or 2 being better than 20 ng. It should also be possible using platinum atomic absorption or electrochemical detection to measure quite low levels of 1 in physiological fluids.

NMR Studies

The effect of co-ordination upon the barrier to rotation in substituted thioureas[7] has been studied by ^{1}H NMR but no reports are available for simple thiourea complexes.

The solvent used here (d^6-dimethylsulphoxide) did not allow the "no exchange" limit to be reached, and together with the linewidth of the signals (Fig. 2), this makes the data obtained unsuitable for simple thermodynamic analysis, thus only coalescence temperature (T_c) and chemical shifts are reported (Table 1).

As expected, co-ordination of the thiourea through sulphur results in a downfield shift of the proton resonances together with an increase in T_c, thiourea itself having[8] a chemical shift of 7.08 and $T_c = -40°C$ (in ethyl acetate). The rise in coalescence temperature is due to the increasing importance of resonance form B upon complexation and thus agrees well with

$$S = C \begin{matrix} \diagup NH_2 \\ \diagdown NH_2 \end{matrix} \qquad S^- - C \begin{matrix} \diagup\mkern-10mu/ {}^+NH_2 \\ \diagdown NH_2 \end{matrix}$$

$$\text{A} \qquad\qquad\qquad \text{B}$$

the sulphur co-ordination[9] of thiourea.

Platinum stacking compounds such as Magnus Green salt [Pt(NH₃)₄] [PtCl₄] and [Pt(NH₃)₄][PtCl₆] are currently widely studied and it is of interest to establish techniques for assessing solution interactions in these types of compounds. We prepared [Pt(thu)₄][PtCl₄] and [Pt(thu)₄] [PtCl₆] and note that for the mixed valence compound quite a substantial shift (relative to 3) in the NH resonance is observed. This may arise from hydrogen-bonding interactions between the chloroligands of PtCl₆²⁻ and the hydrogens on the thiourea, thus indicating some organised interaction between the PtCl₆²⁻ and the Pt(thu)₄²⁺ ions in dmso solution.

The ^{13}C spectra of the complexes all show a high field shift relative to thiourea (which has $\delta = 183.49$) and are all singlets with no Pt–C couplings being observed. The absence of Pt–C coupling is not surprising[10] at the high fields used here, whilst the lack of any other splittings indicates that the doublets in the proton spectra are correctly assigned as being due to restricted rotation about the C–N bond in thiourea and cannot be assigned as being due to isomerisations to N-co-ordinated species.

The ^{195}Pt NMR chemical shifts all fall within the range one would predict from current literature[11–13] values and show for the first time the chemical shift for a platinum atom surrounded by four donor sulphur ligands. Once again, of interest is the difference in chemical shift between 3 and [Pt(thu)₄][PtCl₆]. The observation that no such difference is seen between 3 and [Pt(thu)₄][PtCl₄] indicates the relative insensitivity of ^{195}Pt NMR to the counter-ion in simple systems and lends support to the argument that some interactions are occuring in solution for [Pt(thu)₄][PtCl₆].

The time dependence in the spectrum of *trans*-PtCl₂(thu)₂ is probably coming about as a result of replacement of the chloro ligands by dmso followed by isomerisation; similar effects have been observed for 1 in dmso by Kerrison and Sadler.[14]
Fig. 2. Temperature dependence of NH₂ resonances in the ^{1}H NMR of Pt(thu)₄Cl₂ in d^6-dmso solution.

RAMAN STUDY OF GALLIUM CHLOROSULPHIDES
IN CHLORIDE MELTS

ROLF W. BERG* and NIELS J. BJERRUM

Chemistry Department A, The Technical University of Denmark, DK-2800 Lyngby, Denmark

Abstract—The reaction between sulphur and gallium in chlorobasic melts at *ca.* 500°C was studied by visual observation and by Raman spectroscopy. The results suggest the formation of charged long chains (–GaCl₂–S–GaCl₂–S–) in these melts and the presence of the radical anion S_3^- under certain conditions.

In a continued effort[1-3] to understand the chemical behavior of the sulphide ion in molten salts, the reaction between sulphur and metallic gallium in chloride melts was studied. Previously, it has been found[1] that aluminium and sulphur in molten CsCl–AlCl₃ mixtures (with an excess of CsCl, i.e. chlorobasic melts) reacted according to $2Al + 3S + CsAlCl_4 + 2CsCl \rightarrow 3/n\ Cs_n$-$(AlSCl_2)_n$ (large n). The $[AlSCl_2^-]_n$ polymer was characterised by its polarized Raman band at ~325 cm⁻¹, and this band was assigned to the occurrence of AlCl₂–S–AlCl₂ units in chain-like ions of the type $[Al_nS_{n-1}Cl_{2n+2}]^{n-}$, or simply $[AlSCl_2^-]_n$ for large n.

The objective of this investigation was to study what happens if gallium substitutes aluminium. The qualitative similarities between the chemistry of Al(III) and Ga(III) in alkali chloride melts are well-known[4-6], but the chemistry of gallium sulphide chlorides is very little known. The formation of polymeric ions $[GaSCl_2^-]_n$ was to be expected, giving rise to a strong polarised Raman-band in the neighbourhood of 325 cm⁻¹.

EXPERIMENTAL

Anhydrous, high purity (>99.9% by weight) chemicals were used in evacuated Pyrex or quartz cells, which were equilibrated in rocking furnaces (as in Ref. 1–3). The evaporation of weighed GaCl₃ was avoided by cooling the cells to be sealed in liquid nitrogen. The Raman spectra were measured using argon-ion laser radiation and a Jeol-JRS–400D spectrometer equipped with cooled extended S–20 PM-detector and a photon counting system.

Two kinds of chlorobasic molten salts were used as solvents: (i) Cs[GaCl₄] and CsCl at compositions near a molar ratio of CsCl/GaCl₃ = 60/40, with melting points below *ca.* 400 °C. (Cs[GaCl₄], which melts congruently at 400 ± 20 °C[7,8] was obtained from equimolar amounts of CsCl and GaCl₃). (ii) Mixtures of NaCl and CsCl with a molar ratio NaCl/CsCl of *ca.* 35/65 and a melting point around 500°C[9,10]

RESULTS AND DISCUSSION

CsCl–GaCl₃ *melts as solvent*

With a molar excess of CsCl relative to GaCl₃, the pure solvent melt has been shown[4-6] to contain Ga(III) as tetrahedral $[GaCl_4]^-$ complex ions, in accordance also with the crystal structure of CsGaCl₄.[11] As for other tetrahedral ions, four Raman bands can be observed from molten CsGaCl₄: $\nu_1(a_1) \cong 343$; $\nu_2(e) \cong 120$; $\nu_3(t_2) \cong 370$ and $\nu_4(t_2) \cong 153$ cm⁻¹; ν_1 being polarised and ν_2–ν_4

depolarised.[4-6] The addition of sulphur alone to the melt did not produce any strong new Raman band; the dissolved sulphur molecules scattered negligibly relative to $[GaCl_4]^-$, see Fig. 1(C).

In melts to which small amounts of gallium metal and sulphur have been added (in near equimolar amounts), a reaction consuming these materials quickly proceeded. After approximately one hour at 400 °C no more unreacted Ga or S was left. The main reaction products were colourless when the molar ratio Ga/S was 2/3 and easily soluble in the melts. The more gallium and sulphur added, the more viscous seemed the melts and the more pronounced the tendency to foam formation. In experiments with an excess of sulphur, yellow-brown sulphur or polysulphide colours were always observed. In addition to this, sometimes a deep blue colour (similar to the one found for S_3^- in other melts[2]) was seen. In combination with the yellow colour this blue produced greenish to black colours when much excess sulphur was present. The stability of the blue species depended on a number of circumstances: The presence of excessive sulphur and sufficient free chloride, the temperature and probably also the sulphide formality. A permanent blue-green colour seems to exist only:

(1) If excessive sulphur (according to the reaction $2Ga + 3S \rightarrow$ "Ga_2S_3") is present. Even in the first stages of experiments having excessive but yet undissolved metallic gallium the blue colour has been seen.

(2) If the chlorobasicity is sufficiently large. Probably the molar ratio of CsCl/GaCl₃ needs to be at least of the order of 60/40 or larger.

(3) If the temperature is sufficiently high. When the ratio CsCl/GaCl₃ was around 66/34, the temperature should be around 500 °C or higher, otherwise only yellow–brown colours were seen.

(4) It seemed as if the total concentration of sulphide (S(-II)) had an influence on the stability of the blue species. A small sulphide concentration (e.g. in the first stages of reaction) were favourable for blue colours. The exact conditions necessary for the formation of the blue coloured solutions are very complicated and not presently understood.

The addition of GaCl₃ to a blue melt in amounts necessary to consume all free chloride, (CsCl/GaCl₃ ≅ 45/55), destroyed the colour and produced a yellow–white precipitate, which probably was "GaSCl".[12-13] The
Fig. 1. Raman spectra of basic CsCl–GaCl₃ melts with addition of gallium and excess of sulphur according to the reaction $2Ga + 3S \rightarrow 2Ga^{3+} + 3S^{2-}$: A: blue, B and C: brown. Formalities are based on an estimated density of 2.5 g/cm³. In A and B: S(O)/S(–II) = 0.2 and 1.0, respectively.

Raman spectrum of the melt over the precipitate only showed the bands at ~343 and ~366 cm⁻¹ characteristic of simultaneous presence of $[GaCl_4]^-$ and $[Ga_2Cl_7]^-$.[4-5]

The Raman spectra of the basic clear, colourless or yellow melts obtained after Ga and S had reacted, always showed in addition to the $[GaCl_4]^-$ bands a new polarized Raman band at 315–320 cm⁻¹. This is analogous to what was seen in the case of Al, which had a similar band at ~325 cm⁻¹.[1] The fact that this band appears also in the gallium case indicates that most probably –GaCl₂–S–GaCl₂– chain polymers (of formula $[Ga_nS_{n-1}Cl_{2n+2}]^{n-}$) are formed from $[GaCl_4]^-$ and S^{2-} in the same way as the polymers –AlCl₂–S–AlCl₂– of formula $[Al_nS_{n-1}Cl_{2n+2}]^{n-}$ are formed from $[AlCl_4]^-$ and S^{2-}.[1] The formation of precipitates of "AlSCl" or "GaSCl" by addition of sufficient AlCl₃ or GaCl₃, respectively, is in accordance with this opinion of analogy between the chlorosulphides of aluminium (III) and gallium (III). Probably "GaSCl" is really $[Ga_nS_{n-1}Cl_{2n+2-m}]^{(n-m)-}$ with n large and m < n.[1]

The melts with excess sulphur did not produce any new Raman bands when brown; when blue, a band at 525 cm⁻¹ was observed in addition to the bands already mentioned. This band is a clear indication that the blue color is indeed due to the radical ion S_3^-, which is known to have its resonance enhanced symmetric stretching Raman band ν_1 at ~530 cm⁻¹.[2-3] No bands due to sulphur or polysulphides were observed, which probably means that these species which are believed to be present just scatter too weakly to be seen (similar results were found in the CsCl–AlCl₃ experiments³).

NaCl–CsCl melts as solvent

The pure NaCl–CsCl solvent, like other completely dissociated, monatomic ionic liquids showed no definite Raman band. When GaCl₃ was added, Raman bands appeared due to the formation of $[GaCl_4]^-$ ions (Fig. 2A). When either GaCl₃ and Na₂S or gallium metal, GaCl₃ and sulphur were added to the solvent, the new band assigned to -GaCl₂–S–GaCl₂- appeared (like in Fig. 1 but now at ~318 cm⁻¹). As the sulphide concentration was increased (see Fig. 2), the strong $[GaCl_4]^-$ ν_1 Raman band at ~343 cm⁻¹ gradually disappeared and at the same time the 318 cm⁻¹ band increased. When the molar ratio S:Ga exceeded ~1, the ν_1 band of $[GaCl_4]^-$ was completely lost. This is analogous to the behavior in the case of aluminium,[1] showing that the reaction between the metal and the sulphur is essentially a 1:1 reaction. The observed formation of foam when shaking the melts, finds a reasonable explanation by formation of polymers.
Fig. 2. Raman spectra of NaCl–CsCl melts (NaCl/CsCl molar ratio = 34.5/65.5) with ~2F GaCl₃ and increasing formality of Na₂S. A: waterclear. B–F: increasingly bluish. Na₂S in NaCl–CsCl with no GaCl₃ added gave a yellow melt with no Raman band.

It is of interest to note that also the blue colour and the S_3^- Raman band (at 527 cm^{-1}) could be seen in the more concentrated solutions of $GaCl_3$ and Na_2S, even without addition of sulphur. Na_2S alone did not produce any blue color in the NaCl–CsCl melt. Probably the partial oxidation of S^{2-} to S_3^- is coupled to a reduction of Ga^{3+} to Ga^+. Also in experiments with gallium metal and excessive sulphur in the NaCl–CsCl melt a blue solution was obtained with a S_3^- Raman band at 526 cm^{-1}.

"Cs GaSCl₂"-glass

When gallium, sulphur, CsCl and $GaCl_3$ in the molar ratios 2/3/3/1 (i.e. as in the formula $CsGaSCl_2$) were reacted for 5 days at 600 °C, a colourless, clear and viscous melt remained, with no reactant left over. Again the Raman spectrum of the melt was dominated by a strong polarized band at ~315 cm^{-1}, which again is assigned to the $-GaCl_2-S-GaCl_2-$ skeleton. The melt formed a stable fully transparent glass when cooled to room temperature. This formation of the $[Ga_nS_{n-1}Cl_{2n+2}]^{n-}$ polymer is analogous to the behavior in the case of aluminium.[1]

CONCLUSION

In chloride melts sulphur and gallium seem to react forming $[Ga_nS_{n-1}Cl_{2n+2}]^{n-}$, i.e. long charged $-GaCl_2-S-GaCl_2-$ chains. The degree of polymerisation is unknown and the chemistry is very complicated, as the existence of crystals of $Ga_9S_8Cl_{11}$ also proved some years ago.[13] In acidic melts (with an excess of $GaCl_3$) a precipitate is formed, probably consisting of "GaSCl" or $[Ga_nS_{n-1}Cl_{2n+2-m}]^{(n-m)-}$ salts with $n \gtrsim m$.

Under certain conditions (such as presence of excessive sulphur in highly chlorobasic melts and temperatures around 500–600 °C) the S_3^--radical ion with ν_1 Raman bands at 525–527 cm^{-1} is stable in these environments, as it is in analogous aluminium substituted melts. It should be of interest to investigate if the radical is free or bound to Ga(III), (like for Al(III)[3]) in which case the ESR spectrum should show a hyperfine splitting into 4 lines due to the $I = 3/2$ state of the two natural Ga isotopes.

Our present experimental setup for measuring ESR-spectra[3] is unfortunately not well suited for operating at temperatures much higher than ca. 400 °C, but we hope soon to be able to perform such investigations.

NUCLEOPHILIC ADDITION OF THE THIOCYANATE ION TO FERROCENYL-STABILISED CARBOCATIONS

ALBERTO CECCON*, ALESSANDRO GAMBARO, DANIELE PAOLUCCI and ALFONSO VENZO

Istituto di Chimica Fisica, Università di Padova, 2, Via Loredan, 35100 Padova, Italy

Abstract— The reaction of ferrocenylmethylcarbocations with the ambident thiocyanate ion produces only the isothiocyanate isomer.

Some years ago, the reaction of secondary and tertiary ferrocenylmethyl tetrafluoborates with a variety of nucleophilic reagents was described as a convenient high-yield operation for the synthesis of ferrocenyl derivatives of great potential interest.[1] We report here the results obtained from the reaction of some ferrocenylmethyl tetrafluoborates with the ambident nucleophile, [SCN]⁻. Ferrocenylmethylisothiocyanate, which was used as a "tag" in metabolic polypeptide studies,[2] is obtained from ferrocenylmethylamine and thiophosgene;[3] moreover, a yellow product which the authors claimed to be ferrocenylmethylthiocyanate is formed on refluxing N, N - dimethylaminomethylferrocene methiodide with an aqueous solution of KSCN.[4]

The tetrafluoborates of the ions $Fc-\overset{+}{C}R_1R_2(Fc = C_5H_5FeC_5H_4; R_1=R_2=H, C_6H_5; R_1=H, R_2=C_6H_5)$ were prepared from solutions of the corresponding carbinols in Et_2O by adding fluoboric acid; the primary cation prepared by this procedure has been shown to be strongly solvated by ether molecules so that it can be considered an oxonium rather than a carbenium ion.[5] The addition of the thiocyanate ion to the salts has been made either by shaking a water solution of KSCN with a CH_2Cl_2 solution of the ferrocenylmethyl ions or by adding the nucleophile dissolved in CH_3CN to a solution of the cation in the same solvent. The results of the homogeneous and heterogeneous processes did not differ substantially, though higher yields were obtained from the heterogeneous experiments. The details of the "quenching" experiments carried out on the secondary ferrocenyl(phenyl)methyl carbenium ion will be described.

The IR analysis of the organic phase of the heterogeneous quenching and of the acetonitrile solution in the homogeneous one showed a band centered at 2079 cm⁻¹ whose position, intensity and shape are characteristic of organic isothiocyanates and not of thiocyanates which show a weaker (by a factor of 10) sharp absorption band at *ca.* 2150 cm⁻¹. Portions of this solution were sealed in vials under nitrogen and heated at 60°C for various periods of time. The IR spectrum of the solution after 20 min. heating did not show any appreciable variation with respect to the initial one, but longer heating times (1 hr) caused a definite change in the shape and frequency (2065 cm⁻¹) of the absorption band. This was attributed to the stretching of the inorganic SCN⁻ ion, by comparison with a standard solution of KSCN. Very prolonged heating (*ca.* 20 hr) afforded shining dark-brown crystals, m.p. 140°C (dec.) which were identified as thiocyanato complexes of Fe(III).

After removal of the solvent from the initial unheated solution, one obtains a yellow–brown viscous oil; its ¹H NMR spectrum contains sharp signals (s) at δ 7.30 (5 phenyl protons) at 4.26 and 4.17 (5 and 4 cyclopentadienyl protons) and at 5.64 (1 methine proton). Treatment of the oil with *n*-heptylamine in cyclohexane gave, on cooling, a yellow precipitate which after recrystallization from cyclohexane was identified as *N*-(*n*-heptyl)*N*'-(ferrocenyl(phenyl)methyl)thiourea, from elemental analysis and ¹H NMR spectrum (see Experimental). The IR spectrum of the mother solution showed the total disappearance of the band of the isothiocyanates and the absence of any other band in the region characteristic of the SCN stretching (2050–2160 cm⁻¹). Attempts to crystallise the viscous and pungent oil were unsuccessful; on the other hand, purification by column chromatography on SiO_2 gave the ferrocenyl(phenyl)methyl alcohol as the only product. The above findings allow the following conclusions: (a) the only product of the quenching of the ferrocenyl(phenyl)methyl carbenium ion and SCN⁻ is the ferrocenyl(phenyl)methyl isothiocyanate, as confirmed by IR and NMR spectra and by the formation of the corresponding thiourea; (b) the absence of the thio-isomer in the reaction mixture is proved by the lack of the band characteristic of organic thiocyanates after reaction of the crude product with the amine and by the unchanged intensity of the isothiocyanate band after short heating. On the other hand, on the basis of the data obtained for the triphenylmethyl- structure for which only the isothio isomer could be synthetised,[6] one would expect that, even if formed, the ferrocenyl thiocyanate isomerises instantaneously. In fact, since the isomerization proceeds through an electron-deficient transition state[7] this should be extraordinary stabilised by the ferrocenyl-methyl residue if one takes into account that the ferrocenyl (phenyl)methyl carbenium ion ($pK_{R^+} = +0.4$)[8] is several powers of ten more stable than the triphenylmethyl ion ($pK_{R^+} = -6.6$); (c) the thermal instability and the facile hydrolysis to the corresponding alcohol make the compound obtained an isothiocyanate of a particular nature. In fact the stability of the ferrocenyl-(phenyl)methyl carbenium ion allows, contrary to most organic isothiocyanates, the easy rupture of the carbon-to-nitrogen bond. The subsequent thermal decomposition of the organometallic cation to give thiocyanic complexes of Fe(III) probably · occurs by a mechanism very similar to that proposed for other ferrocenylmethyl salts;[9] however, an intermediate in which the iron atom interacts directly with the S-end of the SCN group (see Fig. 1) cannot be excluded.

The reactions of tertiary diphenyl and the primary
Fig. 1.

ferrocenylmethyl cations with SCN⁻ were not investigated in detail, but the conclusions which can be drawn from the IR spectra of the quenching solutions are that only the isothiocyanate isomer could be identified. A great amount of decomposition products occurred in the case of the primary ferrocenylmethyl cation probably due to the lower thermal stability[5] of this species.

EXPERIMENTAL

IR and ^{1}H NMR spectra were recorded on a Beckman IR-9 spectrophotometer and a Bruker HFX-90 spectrometer, respectively. The ferrocenylmethylfluoborates were prepared as described[5] and investigated under nitrogen.

Reaction of ferrocenyl(phenyl)methyl fluoborate with SCN⁻
The dried title salt (2 mmol) was dissolved in 20 ml of dry, cold CH₂Cl₂ and added at 0° with vigorous stirring to an oxygen-free aqueous 1.3 M solution of KSCN (20 ml). During the addition the colour of the solution changed from brown to dark yellow. The organic phase was then separated, dried with Na₂SO₄, filtered and the solvent pumped off until a brown–yellow oil was obtained. The oil was dissolved in cyclohexane and 4 mmol of *n*-heptyl amine were added slowly. The solution becomes yellow and was kept overnight at 0°C. The precipitate was filtered off, washed with petroleum ether and crystallzed from cyclohexane. (Yield 0.425 g., 47%) m.p. 105–107°C. Found: C, 66.7; H, 7.8; N = 6.1. C₂₅H₃₂FeN₂S requires: C, 66.9; H, 7.2; N, 6.2%.

NMR (in CDCl₃, δ from internal TMS): 7.38 (*s*, 5H: C₆H₅); 6.87 and 5.50 (two broad singlets, 1 H each: N–H); 4.16 (*s*, 5H: C₅H₅); 4.16 (*m*, 4H: C₅H₄); 3.96 (*s*, 1H: methine CH); 3.44, 1.16 and 0.87 (three multiplets, 15H overall: *n*-C₇H₁₅-protons).

PREPARATION AND PROPERTIES OF DINITROGEN TRIMETHYLPHOSPHINE COMPLEXES OF MOLYBDENUM AND TUNGSTEN—II†

SYNTHESIS AND CRYSTAL STRUCTURES OF [MCl(N₂)(PMe₃)₄] (M = Mo, W) AND *TRANS*-[MoCl₂(PMe₃)₄]

Abstract—Sodium amalgam reduction of the complexes [MCl₃(PMe₃)₃] (M = Mo, W) in tetrahydrofuran, under dinitrogen, yields dark red–brown suspensions from which red–orange crystals of composition *trans*-[MCl(N₂)·(PMe₃)₄] can be collected. Spectroscopic and chemical evidence indicate the compounds are best formulated as mixtures of *trans*-[M(N₂)₂(PMe₃)₄] and *trans*-[MCl₂(PMe₃)₄] species, but attempts to isolate the pure *bis*(dinitrogen) derivatives have proved unsuccessful. Single crystals of analytical composition [MCl(N₂)(PMe₃)₄] have been studied by X-ray crystallography, and the structure of *trans*-[MoCl₂(PMe₃)₄] has been determined for comparison. *trans*-[MCl(N₂)(PMe₃)₄] (M = Mo, W) and *trans*-[MoCl₂(PMe₃)₄] are all isostructural, crystallizing in the tetragonal space group I4̄2 *trans*-[MoCl(N₂)(PMe₃)₄] has $a = 9.597(5)$, $b = 12.294(6)$ Å, $D_c = 1.36$ g cm⁻³ for $Z = 2$ and was refined to a final R value of 0.021 based on 319 independent observed reflections. The tungsten analogue has $a = 9.573(4)$, $b = 12.278(5)$ Å, $D_c = 1.63$ g cm⁻³ for $Z = 2$ and was refined to R = 0.19 with 322 independent observed reflections. *trans*-[MoCl₂(PMe₃)₄] has cell parameters $a = 9.675(5)$, $b = 12.311(6)$ Å $D_c = 1.36$ g cm⁻³ for $Z = 2$ and was refined to R = 0.043 with 316 independent observed reflections. In each case the metal atom resides on a crystallographic 4̄2m position. For *trans*-[MoCl(N₂)(PMe₃)₄] (M = Mo, W) the chlorine and dinitrogen ligands are disordered. M–N distances of 2.08(1) Å (M = Mo) and 2.04(2) Å (M = W) and M–Cl bond lengths of 2.415(8) Å (M = Mo) and 2.46(1) Å (M = W) are observed. In *trans*-[MoCl₂(PMe₃)₄], where there is no disorder, the Mo–Cl distance is 2.420(6) Å.

A number of dinitrogen complexes of Group VI metals, containing tertiary phosphine ligands have been isolated, and some of them have been structurally characterized.[1,2] The range of complexes prepared is however limited, and for monodentate tri-alkyl phosphines, apparently only *cis*-[Cr(N₂)₂(PMe₃)₄] is known.[3] We have recently reported[4] that the reduction of [MoCl₃(PMe₃)₃] with dispersed sodium gives *cis*-[Mo(N₂)₂(PMe₃)₄] in good yields. Using sodium amalgam, under similar conditions, red–orange crystals of a compound we first formulated as *trans*-[Mo(N₂)₂(PMe₃)₄] on the basis of analytical and spectroscopic data (see below) were obtained. In this paper, we present evidence that indicates the proposed formulation to be incorrect, and that this compound, of composition [MoCl(N₂)(PMe₃)₄], behaves in fact as a mixture of *trans*-[Mo(N₂)₂(PMe₃)₄] and *trans*-[MoCl₂(PMe₃)₄]. We have also prepared the tungsten analogue and determined the X-ray structures of both compounds. For comparative purposes, the structure of *trans*-[MoCl₂(PMe₃)₄] is also reported.

RESULTS AND DISCUSSION

The addition of a tetrahydrofuran (thf) solution of [MoCl₃(PMe₃)₃],[5] to a suspension of sodium amalgam in thf, produces a change in colour from yellow to deep green and finally to very dark red–brown. The formation of a green solution is also observed at the early stages of the preparation of *cis*-[Mo(N₂)₂(PMe₃)₄],[4] but attempts to isolate this intermediate species from either system have been unsuccessful. The final, dark red–brown, light sensitive solution yields, after several purification operations, a red–orange crystalline material as the only isolable pure product. The workup of this solution is considerably facilitated if it is previously stirred, in daylight for 24–48 hr.

The formation of the red–orange crystals of the molybdenum dinitrogen complex from the sodium amalgam reduction of [MoCl₃(PMe₃)₃], clearly shows the complexities involved in the synthesis of transition metal dinitrogen complexes, by reduction of suitable precursors under a nitrogen atmosphere. The difficulties found in isolating the orange crystals of [MoCl(N₂)·(PMe₃)₄], are probably similar to those encountered in the preparation of other related complexes using magnesium metal as reducing agent, where isolation of the dinitrogen complex requires the use of methanol to hydrolyze some magnesium adduct.[6] On the other hand, as in other related systems,[1] the choice of precursor is also of the greatest importance, no dinitrogen species being detected from the reduction of either [MoCl₃(thf)₃] or [MoCl₃(PMe₃)₃] in the presence of an excess of phosphine, or from [MoCl₂(PMe₃)₄]. [WCl₂(PMe₃)₄] has similarly been found to be unreactive towards sodium

†For part 1 see Ref. 4.

amalgam.[7] Furthermore, the use of *in situ* solutions of [MoCl$_3$(PMe)$_3$], prepared from [MoCl$_3$(thf)$_3$] and PMe$_3$ in tetrahydrofuran,[5] and subsequent removal of the excess of PMe$_3$ yields mainly [MoCl$_2$(PMe$_3$)$_4$], together with some decomposition products, and only small amounts of the dinitrogen complex. Attempts to improve the yield of the final product in a manner similar to that used for the synthesis of *cis*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$], (addition of *ca.* 80% of the required amount of phosphine a few minutes after the appearance of the green color[4]) were unsuccessful. The only observable effect was an increase in the amounts of [MoCl$_2$(PMe$_3$)$_4$] formed in the reaction. Finally, the selection of the reducing agent is also of much importance since, while the use of sodium amalgam produces mainly [MoCl(N$_2$)(PMe$_3$)$_4$] and small amounts of *cis*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$], the sodium dispersion reduction yields the *cis* complex in *ca.* 60% yields, with very small amounts of the [MoCl(N$_2$)(PMe$_3$)$_4$].

The first sets of analytical data obtained for the red-orange crystals of the molybdenum complex, together with the results of molecular weight determinations (cryoscopically in benzene) closely fitted the composition [Mo(N$_2$)$_2$(PMe$_3$)$_4$]; this formulation was also substantiated by spectroscopic data. Thus the IR spectrum shows a strong absorption at 1930 cm^{-1}, assignable to the antisymmetric N–N stretch (A_{2u} in the assumed D_{4h} geometry for the *trans*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$] species) and a very weak band at 2005 cm^{-1} assignable to the symmetric stretch (A_{1g} in D_{4h}), in agreement with data reported for other similar complexes.[8] On the other hand, the ^{1}H NMR spectrum (C$_6$D$_6$, 35°C) shows a slightly broad singlet, centred at $\delta = 1.5$, with some fine structure on both sides, and the ^{31}P NMR is a singlet at $\delta = -0.8$ ppm.† The IR spectrum of the C$_6$D$_6$ solution used for the NMR studies displays a unique strong absorption at 1930 cm^{-1}, due to the N–N stretch. Since structural data on Mo and W dinitrogen complexes are rather scarce, and since comparison with the structure of *cis*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$][4] would be of interest, a structural analysis of the supposed *trans*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$] complex was undertaken. X-Ray studies on two different crystals (from different crops) seemed to indicate (see below) the presence of the molecule *trans*-[MoCl(N$_2$)PMe$_3$)$_4$], with the *trans*-chloro and dinitrogen ligands completely disordered. Since this situation cannot be immediately differentiated from one in which *trans*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$] and *trans*-[MoCl$_2$(PMe$_3$)$_4$] have co-crystallized, approximately in a 1:1 ratio, we attempted to solve this problem with the aid of spectroscopic and chemical studies.

Molybdenum(I) complexes are uncommon, and those containing coordinated dinitrogen are of interest since species of the type [MX(N$_2$)(dppe)$_2$] (M = Mo, W; X = Cl, Br, I; dppe = Ph$_2$PCH$_2$CH$_2$PPh$_2$) are thought to be intermediates in the alkylation reactions of co-ordinated dinitrogen in *trans*-[M(N$_2$)$_2$(dppe)$_2$] complexes.[9] In addition to the cationic Mo(I) complex, [Mo(N$_2$)$_2$(dppe)$_2$]$^+$, that can be generated by chemical or electrochemical oxidation[1] of [Mo(N$_2$)$_2$(dppe)$_2$], species of composition [MoX(N$_2$)(dppe)$_2$] (X = Cl, Br) have been claimed, although Chatt *et al.* later demonstrated[10] that a product with spectroscopic properties identical to those of [MoCl(N$_2$)(dppe)$_2$] could be obtained by mixing equimolar amounts of [MoCl$_2$(dppe)$_2$] and [Mo(N$_2$)$_2$(dppe)$_2$];

they concluded that the complexes [MoX(N$_2$)(dppe)$_2$] (X = Cl, Br) do not exist as stable species at room temperature. Other similar Mo(I) species, particularly [Mo(N$_2$)(SCN)(dppe)$_2$], were later prepared[11] and seem to be stable at room temperature. For our [MCl(N$_2$)· (PMe$_3$)$_4$] (M = Mo, W) complexes the situation is analogous to that encountered for [MoCl(N$_2$)(dppe)$_2$], and analytical, spectroscopic and chemical data, indicate that the compounds should be considered as mixtures of *trans*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$] and *trans*-[MoCl$_2$(PMe$_3$)$_4$]. This proposal is based on the following grounds.

Although the first two sets of analytical data obtained for the molybdenum complex were consistent with the initial formulation,[4] *trans*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$], as discussed above, further analytical data from different laboratories, on samples of identical properties to the initial ones, consistently gave nitrogen contents lower than the expected values for the above formulation. Furthermore, although in some cases analytical figures agree well with the formulation [MCl(N$_2$)(PMe$_3$)$_4$], they are often inconsistent, even in samples that have been recrystallized four or five times. Crystals of [MoCl(N$_2$)· (PMe$_3$)$_4$] look different from [MoCl$_2$(PMe$_3$)$_4$]. Addition of solid [MoCl$_2$(PMe$_3$)$_4$] to [MoCl(N$_2$)(PMe$_3$)$_4$] (*ca.* 5–10% in weight), followed by recrystallization from toluene, yields red–orange crystals which can hardly be distinguished from those of [MoCl(N$_2$)(PMe$_3$)$_4$]. If, on the other hand, free PMe$_3$ is added during the reduction of [MoCl$_3$(PMe$_3$)$_3$] a few minutes after the solution turns deep-green in colour (see above), red–orange crystals can be collected after workup. These are again very similar to those obtained when the reaction is carried out in the absence of free phosphine, but have a lower nitrogen content. We therefore conclude that [Mo(N$_2$)$_2$(PMe$_3$)$_4$] and [MoCl$_2$(PMe$_3$)$_4$] co-crystallize together, not only when they are present in equimolar amounts but over a wide range of composition. We also believe that the initial analytical determinations that led us to formulate the complex as *trans*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$], were incorrect.

The evidence for the existence in solution of the *trans*-dichloro and dinitrogen species is as follows: (i) the ^{1}H NMR spectrum shows, in addition to the broad singlet centred at $\delta = 1.5$, that we assign to the phosphine methyl protons in *trans*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$], a very broad hump centred at $\delta = -8.8$ which is characteristic for *trans*-[MoCl$_2$(PMe$_3$)$_4$]. At 60 MHz, this signal was observed only with difficulty but it is easily detected in the 200 MHz spectrum. Interestingly, the presence of paramagnetic *trans*-[MoCl$_2$(PMe$_3$)$_4$] does not cause significant broadening of the phosphine methyl protons resonance at $\delta = 1.5$, nor of the phosphine resonance in the ^{31}P NMR spectrum. The above indicate that it is either a mixture or it disproportionates very rapidly in solution,[10] but since the compound can be recrystallized a number of times, the latter would require the disproportionation to be reversible, which is highly unlikely. (ii) when a tetrahydrofuran solution of [MoCl(N$_2$)· (PMe$_3$)$_4$] is heated at 40–50°C for *ca.* 24 hr. in the presence of an excess of PMe$_3$, the strong IR absorption at 1930 cm^{-1} gradually disappears, and a new band arises at 1945 cm^{-1}. From the resulting solution (see Experimental) [Mo(N$_2$)(PMe$_3$)$_5$][4] and [MoCl$_2$(PMe$_3$)$_4$] can be crystallized. Since *cis*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$] readily transforms[4] into [Mo(N$_2$)(PMe$_3$)$_5$], it seems likely that under the above conditions *trans*-[Mo(N$_2$)$_2$(PMe$_3$)$_4$] isomerizes to the *cis* isomer. This process is very slow at room temperature but is accelerated by heating at 40–50°C,

---

† ^{31}P chemical shifts are to high frequency of external 85% H$_3$PO$_4$.

although, as indicated below, partial decomposition occurs. (iii) a tetrahydrofuran solution of [MoCl(N₂)·(PMe₃)₄] was stirred at 45°C, for 20 hr in the presence of an excess of KI. The resulting solution was shown to contain [MoI₂(PMe₃)₄],[12] cis-[Mo(N₂)₂(PMe₃)₄] and [Mo(N₂)(PMe₃)₅], the latter being formed at the expense of the phosphine produced in the decomposition of some of the cis complex. (iv) carbon monoxide was bubbled through a tetrahydrofuran solution of [MoCl(N₂)·(PMe₃)₄], at 50°C for 6–8 hr. A mixture of [Mo(CO)$_x$(PMe₃)$_{6-x}$] (x = 2, 3) complexes, identical to that resulting from the interaction of cis-[Mo(N₂)₂(PMe₃)₄] and CO, and pure [MoCl₂(CO)₂(PMe₃)₃][12] were obtained.

The above evidence together with the low value found for μ_{eff} (1.40 μ_B) and the absence of any ESR signals in X-band for Mo^I complexes, indicate that the products of composition [MCl(N₂)(PMe₃)₄] (M = Mo, W) should be considered as mixtures of trans-[MoCl₂(PMe₃)₄] and trans-[M(N₂)₂(PMe₃)₄]. It is possible that the trans-[MCl(N₂)(PMe₃)₄] complexes are formed at some stage during the reduction of the trichloro derivatives [MCl₃(PMe₃)₃] (M = Mo, W), but they are probably unstable under the reaction conditions, and if they form they must readily and irreversibly disproportionate to give a mixture of the M(O) and M(II) species. It is not clear why we have been unable to isolate the pure trans-[M(N₂)₂(PMe₃)₄] derivatives. Also it is difficult to rationalize that while the complexes [MoX(N₂)(dppe)₂] (X = Cl, Br) and [MCl(N₂)(PMe₃)₄] (M = Mo, W) are too unstable to be isolated at room temperature, other similar derivatives such as [Mo(SCN)(N₂)(dppe)₂] seem to be surprisingly stable[11] under the same conditions.

The molecular structures and atom numbering schemes for trans-[MCl(N₂)(PMe₃)₄] (M = Mo, W) and trans-[MoCl₂(PMe₃)₄] are presented in Figs. 1–3, respectively. Bond lengths and angles are given in Tables 1 and 2. In each the metal atom resides on a $\bar{4}2m$ crystallographic site. For trans-[MCl(N₂)(PMe₃)₄] (M = Mo, W) the Cl and N₂ ligands are disordered and in these cases it is not possible to distinguish crystallographically between trans-[MCl(N₂)(PMe₃)₄] (Fig. 1a) and a mixture of co-crystallized (Fig. 1b) trans-[MCl₂(PMe₃)₄] and trans-[M(N₂)₂(PMe₃)₄]. In both cases refinement of the Cl and N occupancy factors (see Experimental) produced no change in the R value and both occupancy factors refined to within experimental error of a 50–50% disorder.

Disorder in dinitrogen complexes is quite common,[2] e.g. in [ReCl(N₂)(PMe₂Ph)₄][13] and a related simulation has recently been reported for trans-[W(Me)(CMe)(PMe₃)₄] which is isostructural with the title compounds.[14] An unfortunate result of the crystallographic problem is a decrease in the accuracy of the bond lengths and angles. In trans-[MoCl(N₂)(PMe₃)₄] the Mo–N bond distance is 2.08(1) Å and the N–N length, 1.14(2) Å. Both of these are slightly larger than values found for similar Mo-dinitrogen complexes, 2.014 and 1.118 Å in trans-[Mo(N₂)₂(dppe)₂][2] and 2.068 and 1.087 Å in trans-[Mo(CO)(N₂)(dppe)₂]·1/2C₆H₆.[2] The Mo–N–N bond angle is symmetry constrained to be 180°. In cis-[Mo(N₂)₂(PMe₃)₄] the Mo–N lengths average 1.97(1) Å but an identical N–N average of 1.14(1) Å has been observed.[15]

In trans-[WCl(N₂)(PMe₃)₄] the W–N distance of 2.04(2) Å is shorter than found for the Mo analogue
Fig. 1(a).

(considering a difference in metallic radii of $\Delta_{W-Mo} = 0.008$ Å),[16] but is identical to the average value found in [WH(N₂)₂(dppe)₂]HCl₂·2thf.[2] All of these, however, and the N–N distance in *trans*-[WCl(N₂(PMe₃)₄] probably agree within expectations at the 3σ level.

trans-[MoCl₂(PMe₃)₄] exhibits a Mo–Cl and a Mo–P bond distance of 2.420(6) and 2.496(3) Å, respectively. Differences in the observed M–Cl and M–P bond lengths for *trans*-[MoCl(N₂)(PMe₃)₄] (2.415(8), 2.461(1) Å), *trans*-[WCl(N₂)(PMe₃)₄] (2.46(1), 2.458(2) Å and thus for *trans*-[MoCl₂(PMe₃)₄] are not significant in view of the high ESD's (which in turn have their origin in the disorder problem).

EXPERIMENTAL

Microanalyses were by Butterworth Microanalytical Consultancy Ltd., Middlesex, Pascher Microanalytical Laboratory Bonn, and Schwarzkopf Microanalytical Laboratory, Woodside, New York. Molecular weights were measured cryoscopically, in benzene, under nitrogen. The spectroscopic instruments used were a Perkin-Elmer model 577 for IR spectra, a Perkin-Elmer R12A(¹H), a Varian XL-100-12 (³¹P, F. T) and a Nicolet NT-200 (¹H, F. T) for NMR spectra. Magnetic susceptibilities were measured in solution by the Evans' method.[17]

All preparations and other operations were carried out under oxygen-free nitrogen following conventional Schlenk techniques. Solvents were dried and degassed before use.

The light petroleum used had b.p. 40–60°C. PMe₃,[18] [MoCl₃(thf)₃][19] and [WCl₃(PMe₃)₃][20] were prepared according to literature methods.

Dichlorotetrakis(trimethylphosphine)molybdenum (II)

This complex was prepared by the Zn powder reduction of [MoCl₃(PMe₃)₃].[21] Details for its preparations were as follows: [MoCl₃(thf)₃] (1.68 g. *ca.* 4 mmol) was placed in a 250 ml three-necked flask, provided with a gas-inlet and a side-arm containing 1.3 g (20 mmol) of Zn powder, activated by heating at 150°C for 4–6 hr. 80 cm³ of dry thf were added and the resulting suspension reacted with PMe₃ (1.8 cm³ *ca.* 18 mmol) for 8–10 hr. The Zn powder was then poured into the flask, the mixture stirred overnight, then centrifuged. The solvent was removed *in vacuo* and the residue extracted with toluene (80 cm³) and filtered or centrifuged, if necessary. Evaporation of the solvent to *ca.* 20 cm³ and cooling at −20°C afforded [MoCl₂(PMe₃)₄] as yellow-orange crystals. Yield 1.3 g 70%. The compound can be recrystallized from toluene, diethyl ether, acetone or tetrahydrofuran. [Found C, 31.1; H, 7.7; Cl, 14.5%; M 452. C₁₂Cl₂H₃₆MoP₄ requires C, 30.6; H, 7.6; Cl, 15.1%; M 471].

IR (KBr disc) bands at: 2980, 2965, 2900, 1435, 1425, 1420, 930, 850, 725, 705, 660 cm⁻¹. ¹H NMR data: δ = −8.8 (very broad); $\mu_{eff} = 2.75$ μ_B.

Dinitrogen complexes. The complexes of composition [MCl(N₂)(PMe₃)₄] (M = Mo, W) were prepared by reduction of the trichloro derivatives [MCl₃(PMe₃)₃] with sodium amalgam. The procedures are similar and therefore only the synthesis of the molybdenum complex is described in detail. To a suspension of [MoCl₃(thf)₃] (1.68 g, *ca.* 4 mmol) in 40 cm³ of THF, were added 1.4 cm³ (*ca.* 14 mmol) of PMe₃, and the mixture stirred at room temperature for 8–10 hr. The solvent was evaporated almost to dryness and precipitation of the yellow [MoCl₃(PMe₃)₃] achieved by the successive addition of 20 cm³ of Et₂O and 20 cm³ of petroleum, while cooling at 0°C. The solid was filtered off, washed with 20 cm³ of a 1:1 mixture of Et₂O:petroleum and dissolved in 40 cm³ of thf. The resulting solution was filtered into a 250 cm³ flask, containing 1% sodium amalgam (0.9 g Na) and 10 cm³ of thf. After stirring at room temperature for a few minutes a deep green colour developed which changed to almost black and then to very dark red–brown. This suspension was stirred for 5 hr at room temperature and then centrifuged. The solvent was evaporated to dryness and the black, tacky residue, extracted with 60 ml of toluene and centrifuged. The solvent was removed *in vacuo* until the final volume was *ca.* 5 cm³, 40 cm³ of petroleum ether were added and the flask was cooled at −20°C for 24–48 hr. The resulting solid was filtered off, washed with 2 × 5 cm³ of petroleum at −20°C, and twice recrystallized from diethyl ether. Red–orange crystals were collected in *ca.* 25% yields (referred to PMe₃). The yields vary from one preparation to another, the best results being obtained when the reduction of [MoCl₃(PMe₃)₃] is carried out in relatively small scale (1 mmol). Work up of the dark suspension, after the reaction is over, often requires a number of filtrations and/or centrifugations before a pure crystalline solid can be isolated. Five different crops of crystals were analytically determined. The following figures correspond to the crystalline material used for the X-ray studies [Found C, 31.0; H, 7.9; N, 6.2%; *M* 464. C₁₂ClH₃₆MoN₂P₄ requires C, 31.1; H, 7.8; N, 6.0%, *M* 456].

Infrared (Nujol mull) bands at: 2005 (vw), 1930, 1430, 1425, 1375, 1290, 1275, 1265, 930, 850, 840, 725, 710, 690, 650 cm⁻¹. NMR data: ¹H(C₆D₆) δ = 1.5 and −8.8 (*trans*-[Mo(N₂)₂(PMe₃)₄] and *trans*-[MoCl₂(PMe₃)₄] respectively). ³¹P(C₆D₆-toluene) δ = −0.8 ppm. μ_eff = 1.40 μ_B.

Yields for the tungsten complex were consistently lower (10–15%) [Found C, 26.6; H, 6.6; N, 6.5. C₁₂ClH₃₆N₂P₄W requires C, 26.1; H, 6.5; N, 5.1%]. These figures correspond to the material used for the X-ray studies. A second determination on an apparently identical sample gave N, 3.2%].

Infrared (Nujol mull) bands at: 1980 (vw), 1900, 1430, 1425, 1415, 1285, 1270, 1260, 920, 845, 715, 695, 680, 640, cm⁻¹. ¹H NMR data: δ = 3.8 (very broad, *trans*-[WCl₂(PMe₃)₄][20]), and 1.5 (broad singlet with fine structure, resembling a triplet, *trans*-[W(N₂)₂(PMe₃)₄]).

Reactions of [MoCl(N₂)(PMe₃)₄]

(a) *with* PMe₃ *under* He. [MoCl(N₂)(PMe₃)₄] (0.225 g, *ca.* 0.5 mmol) was dissolved in thf (20 cm³) and reacted with a large excess of PMe₃ (0.3 cm³, *ca.* 3 mmol) at 50°C, under helium or argon, for 24 hr. The solvent was removed *in vacuo* and the residue extracted with petroleum. The undissolved solid gave yellow–orange crystals upon recrystallization from ether, that were identified as *trans*-[MoCl₂(PMe₃)₄] by comparison of their IR and NMR spectra with those of an authentic sample. Additional, although small amounts of this complex, were separated from the petroleum solution by cooling at −20°C overnight. Concentration of the mother-liquor to *ca.* 2–3 cm³ and cooling at −20°C gave yellow crystals of [Mo(N₂)₂(PMe₃)₅][4] (identified by IR, ¹H and ³¹P NMR spectroscopy).

(b) *with* KI. [MoCl(N₂)(PMe₃)₄] (0.135 g, *ca.* 0.3 mmol) was dissolved in thf (15 ml) and reacted with an excess of KI (0.83 g, *ca.* 5 mmol) at 45°C for 20 hr, under nitrogen. Some decomposition took place as evidenced by the presence of small amounts of a black, finely divided solid. The mixture was allowed to cool at room temperature, the solution filtered and the solvent evaporated, precipitation of a red crystalline solid being observed when the volume of the solution was *ca.* 1–2 cm³. The residue was extracted with petroleum ether and the solution shown by IR

to be a mixture of *cis*-[Mo(N₂)₂(PMe₃)₄] and [Mo(N₂)(PMe₃)₅]. Since the *cis*-complex is very soluble in most common organic solvents and it is difficult to crystallize from dilute solutions, the petroleum solution was reacted with PMe₃ (0.2 cm³, *ca.* 2 mmol) at room temperature for 6–8 hr, whereby complete conversion to [Mo(N₂)(PMe₃)₅] took place. This latter complex was crystallized from petroleum anf characterized as in (a). The petroleum insoluble solid was dissolved in 5 cm³ of thf, the solution centrifuged and the volume reduced to *ca.* 1–2 cm³. Upon cooling at −20°C overnight, red crystals of [MoI₂(PMe₃)₄][12] were obtained.

(c) *with* CO. Carbon monoxide was bubbled through a tetrahydrofuran (40 cm³) solution of [MoCl(N₂)(PMe₃)₄] (0.45 g, *ca.* 1 mmol), at 50°C, for 6–8 hr. The solution was then cooled at room temperature and the solvent evaporated. The resulting yellow residue was treated with 2 × 20 cm³ of petroleum. The petroleum solution was filtered and shown (IR) to be identical to the mixture of carbonyls [Mo(CO)ₓ(PMe₃)₆₋ₓ (x = 2, 3) obtained from *cis*-[Mo(N₂)₂(PMe₃)₄] and CO at room temperature,[4] and it was not investigated any further. The yellow solid was dissolved in a 2:1 mixture of petroleum:dichloromethane, and the resulting suspension centrifuged. Partial removal of the solvent *in vacuo* and cooling at −20°C gave yellow-crystals of [MoCl₂(CO)₂(PMe₃)₃].[12]

X-ray data collection, structure determination and refinement for trans-[MCl(N₂)(PMe₃)₄] (M = Mo, W)—*Crystal data*

C₁₂H₃₆ClMoN₂P₄, (C₁₂H₃₆ClWN₂P₄), M = 463.7 (551.6), tetragonal, *a* = 9.597(5) (*a* = 9.573(4)), *b* = 12.294(6) (12.279(5) Å), U = 1132.3 (1125.2 Å³), Z = 2(2), Dc = 1.36 (1.63 gcm⁻³) μ(MoKα) = 9.61 (58.31 cm⁻¹), space group *I* 4̄2m. The lattice parameters were determined from a least-squares refinement of the angular setting of 15 reflections (2θ > 40°) accurately centered on an Enraf-Nonius CAD-4 diffractometer.

A crystal of dimensions 0.88 × 1.00 × 1.13 (0.38 × 0.50 × 0.45 mm) was sealed in a thin-walled capillary under a nitrogen atmosphere. Data were collected on the diffractometer with graphite crystal monochromated molybdenum radiation. The diffracted intensities were measured by the ω-2θ scan technique in a manner similar to that described previously.[22] All independent reflections in one octant out to 2θ ≤ 50°(50°) were measured; 319 (322) were considered observed [I ≥ 3σ(I)]. The intensities were corrected for Lorentz and polarization effects. The intensities for *trans*-[WCl(N₂)(PMe₃)₄] were corrected for absorption.

Calculations were carried out with the SHELX system of computer programs.[23] The function w(|Fo|-|Fc|)² was minimized. No corrections were made for extinction. Atomic scattering factors for Mo(W), Cl, P, N and C were taken from Cromer and Waber;[24] those for H were taken from Ref. 25. The scattering for molybdenum (tungsten) was corrected for the real and imaginary components of anomalous dispersion using the values of Cromer and Liberman.[26]

The existence of 2 molecules in the unit cell required that the molybdenum atom reside or a 4̄2m site. A difference Fourier map phased on the molybdenum atom readily revealed the positions of the non-hydrogen atoms and the disorder of the Cl and N₂ ligands. The Cl and 2N atoms were given half weight occupancy factors of 0.125 each initially. In a attempt to deduce the nature of the disorder, the occupancy factors were refined in the following manner: one cycle of refinement of the Cl positional and thermal parameters, one cycle of refinement of the N positional and thermal parameters and one cycle of refinement of the occupancy factors (constrained so that the sum was 0.5). No significant changes in the R factor or the bond distances and angles was noted. The occupancy factors refined to within experimental error of 0.125, 0.125 even when starting values of 0.05 and 0.45 (and vice versa) were used. A second data set was collected on a crystal of *trans*-[MoCl(N₂)(PMe₃)₄] from a different preparation with similar results. For all final refinements reported here the occupancy factors were fixed at 0.125 for Cl and 0.125 for the N atoms and were not refined.

The positional parameters for *trans*-[MoCl(N₂)(PMe₃)₄] were used as the starting point in the refinement of the tungsten analogue. Least-squares refinement with isotropic thermal

parameters led to $R = \Sigma\|F_0|-|F_c\|/\Sigma|F_0| = 0.058$ (M = Mo) and 0.068 (M = W). The methyl hydrogen atoms were located with the aid of a difference Fourier map; their positional and thermal parameters were not refined. Refinement of the nonhydrogen atoms with anisotropic temperature factors led to final R values of $R = 0.021$ for trans-[MoCl(N$_2$)(PMe$_3$)$_4$] (0.019, M = W) and Rw = 0.024 (0.023). The two nitrogen atom of trans-[WCl(N$_2$)(PMe$_3$)$_4$] could not be refined with anisotropic thermal parameters and were therefore isotropic in the final refinement. Refinement of the inverse configurations resulted in the final R values shown. Refinement prior to the conversion to the inverse configurations gave R = 0.032 (M = Mo) and 0.038 (M = W). A final difference Fourier showed no feature greater than 0.3 e-/Å^3.

The weighting scheme was based on unit weights; no systematic variation of $w(|F_0|-|F_c|)$ vs $|F_0|$ or $(\sin\theta)/\lambda$ was noted. The final values of the positional parameters are given in Tables 3 (M = Mo) and 4(M = W).[27] The thermal parameters and the observed and calculated structure factor amplitudes are given in supplementary Publications No. SUP 00000(00 pp).

X-Ray data collection, structure determination, and refinement for trans-[MoCl$_2$(PMe$_3$)$_4$].

Crystal data. C$_{12}$H$_{36}$Cl$_2$MoP$_4$, M = 471.2, tetragonal, $a = 9.675(5)$, $b = 12.311(6)$ Å, U = 1152.4 Å^3, Z = 2, D$_c$ = 1.36 gcm^{-3}, μ(MoKα) = 10.55 cm^{-1}, space group $I\bar{4}2$. The lattice parameters were determined from a least-squares refinement of the angular settings of 15 reflections ($2\theta > 40°$) accurately centred on the diffractometer. The data were obtained and treated as above.

The positional parameters for trans-[MoCl(N$_2$)(PMe$_3$)$_4$] were used as a starting point in the refinement of this compound. No evidence of any N$_2$ was located. Least-squares refinement with isotropic thermal parameters led to R = 0.065. The hydrogen atoms were located with the aid of a difference Fourier map and their parameters were not refined. Refinement of the nonhydrogen atoms with anisotropic thermal parameters led to R = 0.044. Refinement of the inverse configuration led to final values of R = 0.043 and R$_w$ = 0.051. The weighting scheme was based on unit weights; no systematic variation of $w(|F_0|-|F_0|)$ vs $|F_0|$ or $(\sin\theta)/\lambda$ was noted. The final positional parameters are given in Table 5. The thermal parameters and the observed and calculated structure factor amplitudes are given in Supplementary Publications No. SUP 00000 (00 pp).

(Received 5 August 1982)

Abstract—5,7-Dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine (dmtp) is used as a ligand for divalent metal thiocyanates. Compounds of formula $M(NCS)_2(dmtp)_2(H_2O)_x$ are formed, with $x = 2$ for M = Mn, Fe, Co, Ni and Cd and $x = 0$ for M = Zn and Hg. Infrared and ligand field spectra are discussed. The crystal structures of compounds $Cd(NCS)_2(dmtp)_2(H_2O)_2$ and $Hg(SCN)_2(dmtp)_2$ are described. $Cd(NCS)_2(dmtp)_2(H_2O)_2$ is monoclinic, C2/c, $a = 15.823(8)$ Å, $b = 8.358(7)$ Å, $c = 17.650$ Å, $\beta = 102.82(5)°$, $Z = 4$, $d_c = 1.634$ Mg · m⁻³, $R = 4.8\%$ based on 2437 reflections. Cd^{2+} is (distorted) octahedrally coordinated by two N(3)-bonded ligands (*trans*-oriented) with Cd–N = 2.366(2) Å, two water molecules (*cis*) with Cd–O = 2.344(4) Å and two N-bonded NCS ions with Cd–N = 2.259(4) Å. The molecules are held together by Van der Waals forces and OH ... S hydrogen bonds (O ... S = 3.263(2) Å).

$Hg(SCN)_2(dmtp)_2$ is triclinic, P$\bar{1}$, $a = 10.343(7)$ Å, $b = 13.225(8)$ Å, $c = 8.060(6)$ Å, $\alpha = 97.15(4)°$, $\beta = 103.43(3)°$, $\gamma = 79.01(4)$, Z = 2, $d_c = 1.941$ Mg · m⁻³, R = 7.8% based on 3218 reflections. The (distorted) tetrahedral coordination around Hg^{2+} consists of two N(3)-bonded ligands with Hg–N = 2.386(8) and 2.427(8) Å and two S-bonded tiocyanate ions with Hg–S = 2.414(4) and 2.441(4) Å; the valence angles S–Hg–S and N–Hg–N are 134.9(1)° and 98.0(3)° respectively. The crystal packing is determined solely by Van der Waals forces. The ligand geometry appears to be the same for both compounds, within experimental error.

INTRODUCTION

The coordination chemistry of heterocyclic ligands is a field of increasing interest. The study of the imidazole-type ligands and that of the purines and pyrimidines is especially rapidly expanding, due to the realisation that the interaction between such ligands and metal ions plays an important rôle in a variety of biological systems.[1,2] Examples are the imidazole ligands in many copper, zinc and iron proteins, and the interaction between "essential" ions like Mg^{2+}, Zn^{2+} and "toxic" ions as Cd^{2+} and Hg^{2+} with nucleic acids.

Usually such heterocyclic bases have more than one donor atom available for coordination, so that no straightforward prediction of their coordination mode can be made. Previous studies[3–5] on 1,2,4-triazoles have shown that either one or two of the *N*-atoms coordinate to many metal ions.

Comparative binding studies on the naturally-occurring bases in DNA have shown that the purine ligands frequently use the (imidazole-type) N(7) atom, but that also coordination can occur at N(9) (the proton residing on N(7)), N(3) or N(1).[6,7] With adenine a bidentate bridge (coordination through N(3) and N(9)) has been found for several copper(II) compounds.[8,9] Pyrimidine bases are known to use N(3) for coordination to a large variety of metal ions.[6] In addition to the naturally-occurring nucleic acid bases pyrimidine, purine and derivatives, a number

of modified bases have been studied. For instance the 8-azapurines containing the 1,2,3-triazole nucleus are of interest because of their anti-neoplastic activity.[10]

5-Azapurines contain the 1,2,4-triazole nucleus, and have no substitutions at N(9) or N(7). Therefore, additional types of coordination may be expected To study the influence of steric effects upon the coordination of this type of ligands we have developed a synthetic program towards the coordination chemistry of (modified) 5-azapurines.

The numbering of these ring systems has often caused confusion, because of the special numbering in use for the purine derivatives. In this paper we will use the IUPAC[11] numbering as depicted in Fig. 1.

Because of our earlier experience with thiocyanate salts[3–5] and because of their ambidentate character (both N and S coordination can occur) and the easy crystallisation of their coordination compounds, this first study
Fig. 1. 5,7-Dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine following IUPAC ring numbering. In purine ring numbering the sequence 1–8 becomes: 7, 8, 9, 4, 3, 2, 1, 6, 5.

deals with the transition-metal(II) thiocyanates of the new ligand 5,7-dimethyl[1,2,4]triazolo[1,5-a]pyrimidine (abbreviated dmtp) (Fig. 1). In the case of monodentate coordination, bonding through N(3) would be expected for steric reasons, but bidentate coordination through N(3) and N(4) (chelating), or through N(1) and N(3) thereby polynucleating, cannot be excluded.

In the present paper both the synthesis and characterisation of the new compounds are described. Two crystal structure determinations were performed to obtain unambiguous evidence about the coordination of dmtp.

EXPERIMENTAL

The ligand dmtp was prepared according to the method of Bülow and Haas[12] from pentanedion-2,5 and 3-amino-1,2,4-triazole.

Metal thiocyanates were prepared *in situ* by metathesis from hydrated metal nitrates and two equivalents of ammonium thiocyanate in water. The hydrated dmtp compounds were prepared by mixing the metal thiocyanate solutions (2 mmol in 20 ml of water) with a dmtp solution (4 mmol in 20 ml of water). All compounds crystallise within several hours. The anhydrous zinc and mercury compounds are rather insoluble in water. Therefore, they were prepared from commercial metal thiocyanate and dmtp in acetone solutions. Yields were generally better than 95%.

Doping of Cu^{2+} compound and of Co^{2+} in the Zn^{2+} compound was effected by the addition of 3–5% of Cu^{2+} or Co^{2+} in the form of their thiocyanates to the solutions of Cd^{2+} and Zn^{2+} respectively prior to crystallisation.

X-Ray powder diffractograms, taken on a Philips diffractometer, showed all hydrates to be mutually isomorphous.

Ligand field spectra were recorded at room temperature on a Beckman DK2-A UV-VIS-NIR spectrophotometer, in the solid state, by means of the diffuse reflectance technique.

Infrared spectra were taken on a Perkin–Elmer model 580 IR spectrophotometer as nujol mulls between KRS-5 and polythene (below 400 cm^{-1}) windows and as CsCl discs (concentration about 1%).

The cadmium and mercury compounds were recrystallised respectively from water and acetone. Monocrystals were grown easily from the solutions by cooling slowly to room temperature. For both compounds a monocrystal suitable for X-ray analysis was found.

Reflections for crystals were measured on an Enraf Nonius CAD4 diffractometer, using Mo-K$_\alpha$ radiation and a graphite monochromator. The data were corrected for Lorentz and polarisation effects, but absorption nor extinction corrections were applied. Table 1 shows the relevant crystallographic data.

The structure of compound 1 was partly solved using MUL-TAN.[13] The remainder of the atoms were found using conventional (difference) Fourier techniques. Some hydrogen atoms were placed on calculated positions.

To determine the structure of 7, only Patterson and (difference) Fourier techniques were applied.

For both molecules reflections with $I > 2\sigma(I)$ were used in the refinement, employing the Gauss–Seidel block method.[4] Counting statistics served as a basis for the weighting scheme.

During the refinement, the temperature factors of all hydrogen atoms were held fixed.

For 1 the space coordinates of the hydrogen atoms of one methyl group were fixed. No coordinates of hydrogen atoms were refined for 7. All bond distances and valence angles containing hydrogen atoms appeared to have physically realistic values.

The final residuals, defined as $R = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ are shown in Table 1. Lists of structure factors, fractional coordinates and anisotropic thermal parameters have been deposited as Supplementary Material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.[15] The atoms are numbered as given in Figs. 2 and 3.

Fig. 3. Perspective view and atom numbering for $Hg(SCN)_2(dmtp)_2$.

RESULTS AND DISCUSSION

General

Table 2 lists the compounds prepared together with their colours, relevant elemental analysis and powder diffraction types. Because of the mutual isomorphism, C, H and N analyses were determined only in one case. All compounds appear to be stable in air upon standing. With copper(II) thiocyanate several types of crystals were found, which will be the subject of future investigations.

For the characterisation several spectroscopic techniques were used, which will be described below.

Ligand field spectra

The ligand field spectra of the hydrated compounds could be interpreted on the basis of an averaged octa-hedral environment for the central metal ion. No clear splittings of the bands were observed, so that deviations from octahedral symmetry must be small. On the other hand low-symmetry splittings in distorted octahedral complexes are known to be small in case of a *cis* geometry of the weakest ligands[16] (in this case H_2O). Because of the presence of three different kinds of ligands, the symmetry must be C_{2v} or lower.

In Table 3 the experimental values of the band maxima of these compounds are listed, including the copper-doped cadmium compound (8) and the cobalt-doped zinc compound (9). The spectrum of (9) was interpreted on the basis of a distorted tetrahedral symmetry for the central metal ion.

Dq and B parameter values were calculated in accordance with the assignment given.[16-18] The Dq values

†Assignment according to octahedral geometry for (2–8), according to T_d symmetry for (9).

show that dmtp can be placed near imidazole in the spectrochemical series. For instance, using 960 cm^{-1} for Dq of $[Ni(NCS)_6]^{4-}$[19], 860 cm^{-1} for $[Ni(H_2O)_6]^{2+}$[20] and the 1080 cm^{-1} value of $[Ni(imidazole)_6]^{2+}$[21], the rule of average environment calculates Dq for 5 to be 965 cm^{-1}, in accordance with the experimental value of 970 cm^{-1}.

The Dq and B values of 9 are consistent with N coordination of the thiocyanate anion in the zinc compound.

IR *spectra*

Anion vibrations. The anion parts of the IR spectra reflect the different coordination modes of the thiocyanate ion. Especially the positions of ν_{CN} and ν_{CS} in the mercury compound are clear indications for the S-bonding mode of the thiocyanate in this compound. The absorptions relevant to the thiocyanate ion are tabulated in Table 4. The $\nu_{CN} + \nu_{CS}$ combination bands have also been listed because they are helpful in assigning the often very weak ν_{CS} absorption.

The pseudo-tetrahedral zinc and mercury compounds

show split ν_{CN} absorptions in accordance with the C_{2v} symmetry. The other compounds in which the thiocyanate ions are *cis*-oriented show only one absorption. This indicates that only small electronic coupling occurs between the CN bonds in these compounds.[22]

Water vibrations. The absorptions associated with the

vibrations of the M–O⟨H H⟩ parts of the compounds 1–5

can be assigned easily and are given in Table 5. They are rather broad as is expected because all hydrogen atoms are involved in hydrogen-bond formation with non-coordinating nitrogen atoms of the dmtp ligands and sulphur atoms of the thiocyanates, as will be demonstrated in the section about the structure determination.

There is a distinct metal dependency, especially for ρ_{MOH_2} and $\rho^w_{MOH_2}$, which parallels the Irving and Williams sequence.[23] The highly coupled $\delta^{sym}_{OH_2}$ and ν_{MO} vibrations show, however, a much less pronounced metal dependency and moreover do not follow the Irving and

Table 4. Thiocyanate IR bands (cm^{-1}) of transition metal dmtp compounds

Williams sequence, but in fact show a decrease from iron to cobalt. This decreased metal dependency is attributed to lack of deformation in the structure on going from cadmium to nickel, which opposes the decrease of the radius of the metal ion. The relatively rigid structure held together by hydrogen bonds, tends to maintain the metal-ligand distances. This effect appears to be strongest for cobalt and nickel. The smaller force constants associated with this effect lower the wavenumbers of the metal-ligand vibrations.

This same effect is observed for the metal-nitrogen vibrations, (*vide infra*).

Metal–nitrogen vibrations. The metal–nitrogen vibrations, which are expected in the far-IR region below 350 cm^{-1}, show a clear metal dependency. An assignment is not given because the absorptions of metal-thiocyanate and metal-dmtp are expected to be rather close to each other and coupled. Moreover, three vibrations of the free ligand (at 312, 280 and 230 cm^{-1}) interfere and hamper an adequate discernment. It was found, however, that the order of the metal-dependent absorptions parallels the order of the metal–oxygen absorptions.

Description of molecular and crystal structures

In compound **1** the ligands form a pseudo-octahedral configuration around the central Cd^{2+} ion. The dmtp molecules are in *trans*-position to each other apparently as a result of steric effects. They form two parallel crossing layers with a plane-to-plane distance of 3.54 Å, which is about twice the Van der Waals radius of an aromatic π-system.[24] The thiocyanate ions are mutually *cis*-coordinated *via* their nitrogen atoms to the central ion.

The compound shows relatively strong hydrogen bonding between HW(1)[x, y, z]...S[$x+\frac{1}{2}$, $y-\frac{1}{2}$, z] with HW(1)...S = 2.41(4) Å, OW...S = 3.263(4) Å, OW...HW(1)...S = 161(4)° and HW(2)[x, y, z]...

N(4)[$\bar{x}$, y, $\frac{1}{2}-z$] with HW(2)...N(4) = 2.12(4) Å, OW...N(4) = 2.879 Å and OW...HW(2)...N(4) = 147(4)°.

The ligands of **7** form a very distorted tetrahedral configuration around the metal ion. As in **1** the rings form parallel layers with a distance of twice the Van der Waals radius of the π-system. There are no hydrogen bonding interactions in this compound. The most important bond distances and valence angles for **1** are listed in Table 6. Those for **7** are presented in Table 7.

As can be seen from Tables 6 and 7 and Figs. 2 and 3 the dmtp molecules coordinate in the same way for both

compounds, i.e. through their N(3) atoms. The ligand geometry is the same for both compounds and there are no significant differences in bond lengths and angles within the ligands.

Comparing the coordination polyhedron around cadmium in 1 with those of other cadmium compounds with nucleic acid fragments it is seen that the Cd–N (ligand) distance of 2.366 Å is in the usually-observed range (2.32[25], 2.37[26] and 2.35 Å[27]) and quite normal for a Cd–N(sp^2) bondlength. The Cd–N(sp) distance to the thiocyanates is shorter, but lies in the range for other Cd–thiocyanates.[28–30] The Cd–O bond lengths of 2.344 Å too fall in the range found for related cadmium compounds: 2.24–2.34 Å.[26,28,31]

As is usually observed for mercury compounds, the SCN groups in 7 bind to the metal via the sulphur atom. The S–C and C–N bondlengths are normal. The Hg–S distances (2.447 and 2.421 Å) are well below the sum of the covalent radii of sulphur (1.04 Å) and tetrahedrally coordinated mercury(II) (1.48 Å).[32] They are among the shortest found so far for mercury(II) thiocyanates. Typical distances reported for Hg–SCN in tetrahedral units are between 2.48 and 2.58 Å.[33,34] The N–Hg–N angle (98°) is significantly below the tetrahedral angle value, while the S–Hg–S angle of 135° is much higher, tending to become linear. This again demonstrates a relatively strong covalent interaction between mercury and sulphur. As a consequence of this, the Hg–N bondlengths (2.38 and 2.42 Å) are relatively long when compared with other Hg–N bonds in mercury nucleic-base compounds.[35,36] The structure can best be compared with that of the compound 3Hg(SCN)$_2$2PyNO[37] in which mercury has a very distorted tetrahedral coordination. Here again a large S–Hg–S angle (156°) occurs

in combination with very short Hg–S bond distances (2.38 Å).

CONCLUDING REMARKS

The ligand dmtp has a clear preference for coordination through its N(3) atom in reactions with transition-metal thiocyanates. Its spectrochemical strength is comparable to that of imidazole. The thiocyanate ions coordinate via their N atom in compounds 1–6 and via S in 7 (the mercury compound).

The coordination polyhedra in 1–5 are distorted octahedra of two ligand N (trans), two thiocyanate N (cis) and two water O atoms. The zinc compound is tetrahedral, with two ligands and two thiocyanates. The coordination around mercury in 7 is distorted tetrahedral, composed of two ligands and two strongly covalent Hg–S bonds.

SYNTHESIS AND CHARACTERISATION OF NIOBIUM(V) AND NIOBIUM(IV) POLY(1-PYRAZOLYL)BORATES

LILIANE G. HUBERT-PFALZGRAF* and MITSUKIMI TSUNODA

Laboratoire de Chimie de Coordination, Université de Nice, Parc Valrose, 06034 Nice, France

Abstract—Reactions between Nb_2Cl_{10} or $NbCl_4$ and hydridotris and hydridobis(1-pyrazolyl)borate potassium salts were investigated in different ligand to metal molar ratios (R). Room or low temperature reactions between Nb_2Cl_{10} and the poly(1-pyrazolyl)borates in a $R = 1$ stoichiometry lead to niobium(V) ionic species such as $\{NbCl_5[HB(pz)_3]\}K$ and $\{NbCl_5[H_2B(pz)_2]\}K$. Reduction to niobium(IV) was observed if the preceding reactions were conducted at higher temperature or if R increased, and molecular species, which could generally also be obtained directly from $NbCl_4$, were then isolated. All the niobium(IV) molecular species: $Nb_2Cl_6[H_2B(pz)_3]_2$, $Nb_2Cl_6[H_2B(pz)_3]_2(pzH)_2$, $Nb_2Cl_4[HB(pz)_3]_4$, $Nb_2Cl_6[H_2B(pz)_2]_2(MeCN)_2$, $Nb_2Cl_5[H_2B(pz)_2]_3$, $Nb_2Cl_4[H_2B(pz)_2]_4$ and $Nb_2Cl_2[H_2B(pz)_2]_6$, were found to be diamagnetic in the solid as in solution. Their characterisation was achieved by microanalysis, molecular weight data, IR and ^1H spectroscopy.

INTRODUCTION

By virtue of their steric and electronic properties, poly(1-pyrazolyl)borates stabilize unusual coordination geometries and oxidation states.[1] The transition metal chemistry of the hydridotris(1-pyrazolyl)borate anion $[HB(pz)_3]^-$ ($pzH = C_3H_3N_2H$) is to some degree reminiscent of that of the cyclopentadienyl ion, while the hydridobis(1-pyrazolyl)borate anion $[H_2B(pz)_2]^-$ is more closely related to the β-diketonato ligands. The stabilizing effect of the $[HB(pz)_3]^-$ anion, which behaves as a η^3 or η^2 ligand, has for instance been exploited in making stable copper carbonyl[2] or molybdenum–nitrosyl[3] derivatives, as well as a variety of five-coordinated platinum compounds.[4] On the other hand, $M[H_2B(pz)_2]_2$ (M = Co, Ni, Cd, Zn...) derivatives appear as reducing agents in organic chemistry.[5] As part of a general project concerning the synthesis of molecular low-valent niobium derivatives, and because the polypyrazolylborate derivatives of group V metals were limited to $NbO(OMe)_2[HB(pz)_3]$[6] and $[H_2B(pz)_2]TaMe_3$,[7] we have investigated the reactions between niobium(V) and niobium(IV) chlorides and hydridotris and hydridobis potassium pyrazolylborate salts. Indeed, polypyrazolylborate ligands are known to be reducing agents towards early transition metal derivatives in high oxidation states.[8]

We now wish to report the synthesis and characterization in the solid and in solution of niobium(V) and niobium(IV) polypyrazolylborate derivatives $\{NbCl_5[HB(pz)_3]\}K$, $\{NbCl_4[HB(pz)_3]\}K$, $[Nb_2Cl_6[HB(pz)_3]_2$, $Nb_2Cl_6[HB(pz)_3]_2(pzH)_2$, $Nb_2Cl_4[HB(pz)_3]_4$, $\{NbCl_5[H_2B(pz)_2]\}K$, $Nb_2Cl_6[H_2B(pz)_2]_2$, $Me(N)_1$, $Nb_2Cl_5[H_2B(pz)_2]_3$, $Nb_2Cl_4[H_2B(pz)_2]_4$ and $Nb_2Cl_2[H_2B(pz)_2]_6$.

RESULTS AND DISCUSSION

Synthesis of niobium poly(1-pyrazolyl)borates

The formation of the products obtained by reacting Nb_2Cl_{10} or $NbCl_4$ with the potassium poly(1-pyrazolyl)borate salts $KHB(pz)_3$ or $KH_2B(pz)_2$ was of course influenced by the ligand to metal molar ratio R (varying from 1 to 4), but also, very drastically, by the course of

the reaction: solvent composition, reaction time, temperature, concentration. Schemes 1 and 2 summarize the various routes that allowed the isolation, despite complicated reactions, of hydridotrispyrazolylborate and hydridobispyrazolylborate niobium derivatives. Among the various solvents investigated (toluene, tetrahydrofuran, dichloromethane or acetonitrile) the two last-named, in pure form or as their mixtures, appear the most useful, as they generally allow an easy separation from the KCl precipitate, and avoid the formation of oxo derivatives, which was observed when THF was used. Acetonitrile behaves as an additional ligand when the coordination sphere is less crowded, and $Nb_2Cl_6[H_2B(pz)_2]_2(MeCN)_2$ was thus isolated.

As expected, the bulky poly(1-pyrazolyl)borate anions generally act as reducing agents towards $NbCl_5$, leading to niobium(IV) derivatives. In fact, niobium(V) compounds could only be isolated if the reaction between $NbCl_5$ and hydridotris or hydridobispyrazolylborate salts was conducted in a $R = 1$ *stoichiometry* and at low or room temperature. However, the niobium(V) derivatives obtained as major product in these conditions correspond to ionic species of formula $K\{NbCl_5[H_xB(pz)_{4-x}]\}$ (x = 1 or 2), insoluble in common organic solvents. For instance, the reaction between $NbCl_5$ and $KBH(pz)_3$ (R = 1) in MeCN at $-30°C$ leads to a precipitate of $K\{NbCl_5[HB(pz)_3]\}$ (58%), while a reduced molecular species, $Nb_2Cl_6[HB(pz)_3]_2$, was obtained from the mother liquor, but only in a low yield (17%). Evidence for the formation of ionic poly(1-pyrazolyl)borate derivatives has also been reported for uranium(IV)[9] or molybdenum(III).[10] The formation of niobium(IV) molecular complexes was favoured by proceeding at higher temperature, thus giving a KCl precipitate instead of a niobium potassium one. Finally, no molecular niobium(V) polypyrazolylborate complex could be obtained directly from $NbCl_5$, but we were able to isolate $NbCl_4[HB(pz)_3]$ by a smooth reoxidation of $Nb_2Cl_6[HB(pz)_3]_2$ formed *in situ*, using carbon tetrachloride for precipitation. It is noticeable that the hydridotrispyrazolylborate anion displays a stronger tendency to form ionic species with niobium, as compared to the hydridobis(1-pyrazolyl)borate ligand, and $\{NbCl_4[HB(pz)_3]\}K$ was also obtained from a 1:1 molar reaction between $NbCl_4(MeCN)_3$ and $KHB(pz)_3$ in

---

acetonitrile at room temperature. No ionic niobium(IV) product was obtained in the case of the hydridobis(1-pyrazolyl)borate salt. The conductivity measurements obtained for the ionic species on dimethylformamide solutions are as expected for 1:1 electrolytes.[11]

If more than one equivalent of polypyrazolylborate per metal (R > 1) was used, only molecular niobium(IV) derivatives were obtained. Another general observation is the fact that, by contrast to TiCl$_4$[8] for instance, and with regard to the behaviour of ZrCl$_4$[12] or UCl$_4$,[9] one can replace more than one chlorine per metallic center by a poly(1-pyrazolyl)borate ligand. As a result highly substituted products could be obtained. However, the yields

were often reduced by disproportionation reactions, which are favoured by the fact that the niobium(IV) species obtained are all dimeric, and small changes in the experimental procedures can lead to the isolation of several different products. For instance, the reaction between NbCl$_4$ and H$_2$B(pz)$_2$K (R = 2) in acetonitrile leads to Nb$_2$Cl$_4$[H$_2$B(pz)$_2$]$_4$ or Nb$_2$Cl$_3$[H$_2$B(pz)$_2$]$_5$ if the heating is maintained for a longer time.

Side reactions, involving the cleavage of the B–N bond, were observed, and products having pyrazole in the coordination sphere of the metal were then obtained. The pyrazole seems to interact strongly with the niobium moiety, and no displacement by a ligand such as

phenyldimethylphosphane could be achieved. Similar side reactions have already been reported in the case of the hydridotrispyrazolylborate ligand[13] as well as for the hydridobispyrazolylborate ligand.[14] Apparently these side reactions were favoured for the hydridotrispyrazolylborate anion, by the acidity of the pentahalides, and by low or room temperature reactions (a complete B–N cleavage of $HB(pz)_3^-$ was, for instance, observed in its 1:1 reaction with $TaCl_5$ at room temperature[15]). As a consequence, although highly substituted products analyzing for instance as $Nb_2Cl_2[HB(pz)_3]_6$ could be isolated, these highly crowded products are unstable in the solid and in solution, and appear (IR, NMR) as structurally different.

Characterization

The various products were characterized by elemental analysis (Table 1), magnetic susceptibility measurements, molecular weight data, IR (Table 2), mass and ^1H NMR spectroscopy (Table 3).

The IR spectra in the solid state of the isolated product show numerous absorptions due to the pyrazolyl groups. Three absorption regions corresponding respectively to the νBH, νNH and νNb–Cl stretching frequencies, are more useful for proposing a formula. First of all, the presence of νBH absorptions ranging from 2500 to 2300 cm^{-1} confirms that of poly(1-pyrazolyl)borate ligands in the coordination sphere and negates the occurrence of extensive B–N bond cleavage as well as the possibility of B–H–M interactions (which would strongly decrease the BH frequency, for instance to 2039 cm^{-1} in $[H_2B(pz)_2]PtMe_3$[16]). As generally observed, the νB–H stretching absorptions are always shifted to higher frequencies by coordination. The presence of additional absorptions in this region for $Nb_2Cl_6[H_2B(pz)_2]_2(MeCN)_2$ was attributed to acetonitrile (νC≡N 2318 and 2292 cm^{-1}). The presence of νNH absorptions around 3160 cm^{-1} for $Nb_2Cl_6[HB(pz)_3]_2(pzH)_2$ implies a neutral pyrazole ligand in the coordination sphere (νNH of the free ligand = 3540 cm^{-1}) and supports the occurrence of B–N cleavage reactions. It is noteworthy that no absorptions which could be attributed to νC–Cl vibrations, and thus to chlorination of the pyrazolyl ring, were observed (the absence of such products was also confirmed by the non-existence in the NMR spectra of singlets located around 7.5 ppm). The niobium–chlorine vibrations were found as expected below 400 cm^{-1}.[18]

Magnetic susceptibility measurements on the solid state show that all niobium(IV) derivatives are essentially diamagnetic. This suggests spin–spin interactions directly between the metallic centers or superexchange phenomena through bridging ligands in at least dinuclear units. For the most stable complexes such as $Nb_2Cl_6[H_2B(pz)_2]_2(MeCN)_2$, we were able to establish a dimeric character by vapour pressure osmometry on acetonitrile solutions ($M_{obs.}$ = 710; $M_{calc.}$ = 387.5). The good volatility of the niobium(IV) derivatives also allowed their characterization by mass spectrometry. The Nb$_2$ unit is generally retained in the gas phase. The formation of diamagnetic niobium(IV) poly(1-pyrazolyl)borate derivatives is surprising, since no counterparts have hitherto been found for niobium(IV) cyclopentadienyls or β-diketonates.[19] Bridging through chlorine is common for niobium chemistry, but polypyrazolylborates are also able to act as bridging ligands and should constitute an alternative. For instance, $[(pz)_2B(pz)_2]^-$ was assumed to ligate two Cp$_2$Ti moieties[8] and RX studies

on [HB(pz)$_3$]$_2$Cu have established that [HB(pz)$_3$]$^-$ presents two terminal pyrazolyl ligands (one to each copper) and one cross-wise bridging pyrazolyl.[20] Indeed, the value of the dihedral angle between pz groups in various polypyrazolylborate compounds varies greatly; it reflects the very flexible nature of the polypyrazolylborate ligands and their adjustable bite, which allows the adoption of a wide range of conformations for the B(pz)$_2$M ring.

The diamagnetic character of all niobium(IV) derivatives, like the convenient solubility of the molecular products (which increases with the degree of chlorine substitution), allowed us to gain structural information by using ^{1}NMR integration techniques (Table 3). The spectra were generally measured at room temperature on fresh solutions in deuterioacetonitrile (slow disproportionation reactions were sometimes observed). It should be mentioned that the nature and the quality of the solvent are very important for the NMR study of this class of complexes. Although all products are soluble in dichloromethane, its acidity favoured B–N cleavage as well as disproportionation reactions; on the other hand small amounts of water in acetonitrile again induced B–N cleavage (appearance of a NH peak while no νNH was detected by IR on the solid) as well as possible formation of B–OH bonds.[21] Therefore the ^{1}H NMR spectra were first used as a probe to confirm that the pyrazolylborate

anions are unchanged (presence of sets of two doublets and one triplet, in a 1:1:1 intensity ratio, which are always shifted to lower field with respect to the potassium salt). The spectra often display numerous resonances (Fig. 1), especially when the metal is highly substituted by poly(1-pyrazolyl)borate groups.

The spectra of the monomeric NbCl$_4$[HB(pz)$_3$] account for the presence in solution of one molecular species displaying equivalent pyrazolyl groups, as only one set of a couple of doublets (at 8.27 and 8.12 ppm) and one triplet (at 6.81 ppm; J = 2.6 Hz) are observed. The hydridotrispyrazolylborate ligand appears to behave as tridentate, the niobium atom therefore being heptacoordinated.. For all other hydridotrispyrazolylborate derivatives, which are dinuclear, niobium(IV) species, [HB(pz)$_3$]$^-$ acts as a bidentate, but exchange between coordinated and uncoordinated pyrazolyl was never observed. As also noted for instance for UCl$_2$[HB(pz)$_3$]$_2$,[9] the resonances of the uncoordinated pyrazolyl are generally more shielded, and slightly broader, than those of the coordinated one.

Thus the spectra of the solutions Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$(pzH)$_2$ and Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$ show only two sets of pyrazolyl resonances each in a constant 2:1 ratio. The main difference is due, for Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$(pzH)$_2$, to the additional resonances of the coordinated pyrazole, which appears equivalent

Table 3. ^{1}H NMR (in CD$_3$CN at room temperature)

* relative area ; ** see figure ; d : doublet ; t : triplet ; a : only one molecular species.
Fig. 1. ^{1}H NMR spectra of Nb$_2$Cl$_4$[H$_2$B(pz)$_2$]$_4$ in CD$_3$CN (0.03·10^{-3} M) at room temperature (peaks marked with the same symbol belong to the same species).

(δNH = 14.4 ppm; 7.85(d), 7.83(d), 6.60(t); J = 2.2 Hz). These data are in agreement with the presence of a single molecular species in each solution. The pattern of the pyrazole resonances indicates that the heterocycle functions as a monohapto neutral ligand, via the 2-N atom, as previously observed.[1,22] The most probable structure would be isomer A—the metal center being hexacoordinated—for Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$. For Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$-(pzH)$_2$, species having bridging or chelating η^2-hydridotrispyrazolylborates (four isomers for each one) are possible, but only one isomer is detected in its solution.

A
One molecular species mainly (95% of the total peaks area) is found for the solutions of freshly prepared Nb$_2$Cl$_4$[HB(pz)$_3$]$_4$. That species displays only two types of pyrazolyl groups, in a 2:1 area ratio, thus suggesting equivalent but η^2-hydridotrispyrazolylborate ligands, and isomer B appears as the most probable. Other species in dynamic equilibrium, but not yet determined, were found for the solutions prepared from Nb$_2$Cl$_4$[HB(pz)$_3$]$_4$ more than two months old.

B
The spectra of Nb$_2$Cl$_6$[H$_2$B(pz)$_2$]Y$_2$ (Y = MeCN or pzH) display only one type of signal for the polypyrazolylborate [doublets at 9.26, 8.07 and 8.17, 8.00 ppm; triplets at 6.81 and 6.41 ppm (J = 2.6 and 2.2 Hz) respectively]. The presence of MeCN in the coordination sphere of Nb$_2$Cl$_6$[H$_2$B(pz)$_2$]$_2$(MeCN)$_2$ was confirmed by a singlet at 2.53 ppm. The pyrazole ligand of

Nb$_2$Cl$_6$[H$_2$B(pz)$_2$]$_2$(pzH)$_2$ is characterized by a deshielded NH signal (δ = 14.1 ppm), as two doublets at 8.06 and 8.04 ppm and one triplet at 6.62 ppm (J = 2.7 Hz) in a 1:2 intensity ratio (by comparison with the pyrazolyl signals). NMR monitoring shows that Nb$_2$Cl$_6$[H$_2$B(pz)$_2$]$_2$(pzH)$_2$ could not be obtained by ligand exchange from Nb$_2$Cl$_6$[H$_2$B(pz)$_2$](MeCN)$_2$ at room temperature. The spectra of Nb$_2$Cl$_6$[H$_2$B(pz)$_2$]$_2$Y$_2$ account for the presence in solution of a single molecular species in which the pyrazolyl groups appear equivalent, as are the neutral ligands acetonitrile or pyrazole. These data are similar to those for Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$(pzH)$_2$, and the geometry of the Nb$_2$Cl$_6$[H$_2$B(pz)$_2$]$_2$Y$_2$ adducts is probably closely related to that of the former compound, in which the [HB(pz)$_3$]$^-$ ligand functions as a bidentate like [H$_2$B(pz)$_2$]$^-$.

Only one molecular species is also detected in the solutions of Nb$_2$Cl$_5$[H$_2$B(pz)$_2$]$_3$, the polypyrazolylborate groups being inequivalent in a 2:1 intensity ratio (Table 3). Only one isomer C fits these spectroscopic data:

C
Contrary to the preceding compounds, the spectra of Nb$_2$Cl$_4$[H$_2$B(pz)$_2$]$_4$ and Nb$_2$Cl$_2$[H$_2$B(pz)$_2$]$_6$ depend on the dilution, thus suggesting the presence of different molecular species, but no indications of disproportionation reactions were found, and we therefore favour the presence of geometrical isomers in equilibrium. The spectra are often complicated as a result of resonances overlapping. For instance, the spectra of Nb$_2$Cl$_4$[H$_2$B(pz)$_2$]$_4$ (Fig. 1) consist of 5 sets of pyrazolyl signals, which can be attributed (on the basis of their constant relative area for various concentrations) to three molecular species. Two species (one being always predominant—60% for a 0.3 10^{-3} molar solution) display non-equivalent hydridobispyrazolylborate ligands in a 1:1 intensity ratio. Three isomers (D, E, F) are compatible with these data, but molecular models show that the coordination sphere is less crowded for isomer D than for E or F.
D
E
F

Two molecular species are detected for the solutions of Nb$_2$Cl$_2$[H$_2$B(pz)$_2$]$_6$. The main species (80% for a 0.4 10^{-3} molar solution) presents two types of [H$_2$B(pz)$_2$]$^-$ ligand (2:1 intensity ratio). Isomer G in which the metal is heptacoordinated should be the most favoured for steric considerations, but other isomers having only chelating [H$_2$B(pz)$_2$]$^-$ groups, and for which the metal is octacoordinated, may be possible. Note that high coordination numbers are also common for niobium(IV) β-diketonates.[19]
G

EXPERIMENTAL

All manipulations were conducted under dry de-oxygenated argon, using Schlenk tubes and vacuum-line techniques. The solvents were carefully distilled over the standard drying reagents and de-oxygenated. NbCl$_4$,[23] NbCl$_4$(MeCN)$_3$[24] and the polypyrazolylborate potassium salts[25] were synthesised as described in the literature. IR spectra were recorded as nujol mulls on a Perkin–Elmer 577 spectrometer. The NMR spectra were obtained on a WH-90 Bruker spectrometer operating in the Fourier transform mode. Molecular weight data were measured on a Knauer pressure osmometer. The mass spectra (VG Micromass 70-70 spectrometer) and the microanalysis data were effected by the Service Central de Microanalyses du CNRS.

Synthesis of {NbCl$_5$[HB(pz)$_3$]}K

A solution of KBH(pz)$_3$ (1.55 g, 6.13 mmol) in 15 ml MeCN was added to a solution of NbCl$_5$ (1.66 g, 6.14 mmol) in 60 ml of MeCN maintained at −30°C. Precipitation started immediately. Stirring was continued for about one hour and the temperature raised slowly to room temperature. The reaction mixture was filtered off. After washing with CH$_2$Cl$_2$ and vacuum drying, 1.58 g (58%) of a pale yellow powder of {NbCl$_5$[HB(pz)$_3$]}K was obtained. (10^{-3} M in DMF; Λ = 75 ohm^{-1}·cm^2·mole^{-1}).

Synthesis of {NbCl$_4$[HB(pz)$_3$]}K

A solution of KBh(pz)$_3$ (0.85 g, 3.36 mmol) in 20 ml MeCN was added to a solution of NbCl$_4$(MeCN)$_3$ (1.21 g, 3.38 mmol) in 15 ml MeCN at room temperature. A slightly exothermic reaction occurred immediately, with formation of a precipitate. After 16 h stirring, 1.22 g (75%) of {NbCl$_4$[HB(pz)$_3$]}K in the form of a powder was isolated by filtration. (1.5 10^{-3} M in DMF; Λ = 72 ohm^{-1}·cm^2·mole^{-1}).

Synthesis of NbCl$_4$[HB(pz)$_3$]

A suspension of KBH(pz)$_3$ (0.71 g, 2.83 mmol) in 10 ml CH$_2$Cl$_2$ was slowly added to a solution of NbCl$_5$ (0.73 g, 2.69 mmol) in 24 ml of a mixture of CH$_2$Cl$_2$ and MeCN (4:1) at room temperature. The yellow solution rapidly became cloudy and dark orange. The reaction was completed by refluxing for 18 h. The reaction mixture was filtered at room temperature, the filtrate evaporated to dryness and extracted with CH$_2$Cl$_2$. Precipitation was obtained by adding CCl$_4$; 0.98 g (88%) of red crystals of NbCl$_4$[HB(pz)$_3$] were obtained.

Synthesis of Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$(pzH)$_2$

A solution of KBH(pz)$_3$ (1.88 g, 7.34 mmol) in 15 ml MeCN was slowly added to a solution of NbCl$_5$ (1 g, 3.74 mmol) in 50 ml MeCN at −30°C. Stirring was maintained for 12 h at −30°C, and the insoluble product was then removed by filtration. During the concentration of the filtrate, crystallisation started and was completed by storing at −30°C for 2 days. Finally 0.91 g (30%) of red crystals of Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$(pzH)$_2$ were collected. Mass spectrometry (120°C, chemical ionisation) M = NbCl$_3$[HB(pz)$_3$](pzH) (M$_2$–pzH) (1%), M$_2$–2pzH (2%), Nb$_2$Cl[HB(pz)$_3$][H$_2$B(pz)$_2$] (10%), Nb$_2$[HB(pz)$_3$][H$_2$B(pz)$_2$] (23%), Nb[H$_2$B(pz)$_2$]$_2$ (5%), NbClN$_2$[HB(pz)$_3$] (15%), pzH (100%).

Synthesis of Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$

A suspension of KHB(pz)$_3$ (1.51 g, 5.97 mmol) in 20 ml CH$_2$Cl$_2$ was slowly added to a solution of NbCl$_5$ (1.63 g, 6.05 mmol) in 60 ml of a CH$_2$Cl$_2$:MeCN (4:1) mixture, and the reaction medium was allowed to reflux for 12 h, giving a brown suspension; KCl was separated by filtration. The filtrate was concentrated to about 6 ml, and 1.789 (72%) of a reddish brown solid, Nb$_2$Cl$_6$[HB(pz)$_3$]$_2$ crystallised out and was separated by filtration. Mass spectrometry (70 eV, 150°C): [M = NbCl$_3$[BH(pz)$_3$]M (4%), M–Cl (46%), (M–Cl–$\frac{1}{2}$N$_2$) (32%), M–pzH (46%), M–pzH–N$_2$ (46%), NbCl$_2$(pz)$_2$ (72%), pzH (100%).

Synthesis of Nb$_2$Cl$_4$[HB(pz)$_3$]$_4$

A suspension of KBH(pz)$_3$ (1.75 g, 6.9 mmol) in 18 ml MeCN was slowly added to a stirred suspension of NbCl$_4$ (0.514 g, 2.19 mmol) in 34 ml MeCN at room temperature. The suspension became violet and then grey–green. The reaction was completed by refluxing 24 h and a dark red suspension was obtained. After cooling, the precipitate of KCl was separated by filtration and the filtrate evaporated to dryness. The residue was redissolved in CH$_3$CN and crystallisation was induced by adding CCl$_4$, and completed by leaving in the cold (−30°C). Finally, 0.45 g (35%) of dark red crystals of Nb$_2$Cl$_4$[HB(pz)$_3$]$_4$ were obtained.

Synthesis of {NbCl$_5$[H$_2$B(pz)$_2$]}K

Potassium hydridobispyrazolylborate (1.36 g, 7.25 mmol) in solution in 20 ml MeCN was added to a suspension of NbCl$_5$ (1.90 g, 7.04 mmol) in 40 ml CH$_2$Cl$_2$. An insoluble product formed immediately. The reaction was completed by stirring at room temperature for 12 h and refluxing for 1 h more. Filtration left 2.7 g (70%) of a grey–yellow powder. (0.8·10^{-1} M in DMF; Λ = 81 ohm^{-1}·cm^2·mole^{-1}).

A solution of KBH$_2$(pz)$_2$ (0.91 g, 4.89 mmol) in 15 ml MeCN was added to a solution of NbCl$_5$ (1.30 g, 4.81 mmol) in 50 ml MeCN at −30°C. The solution became brown–yellow, and then brown–green, and a precipitate appeared. Stirring was maintained at −30°C for 1 h and the reaction mixture was allowed to reach and stay at room temperature for 14 h. The precipitate was eliminated by filtration and washed with MeCN. The filtrate was concentrated to about 10 ml, a red–brown precipitate appeared and the crystallization was improved by storing alternately at −30° and −5°C. After 5 days, the mother liquor was separated by syringe. After washing with toluene and vacuum drying, 1.26 g (80%) of a grey–violet product were collected. Mass spectrometry (70 eV, 120°C) M = NbCl$_3$[H$_2$B(pz)$_2$](MeCN); M$_2$-MeCN (4%); M$_2$-2MeCN (8%), Nb$_2$Cl$_2$[H$_2$B(pz)$_2$]$_2$ (21%); Nb$_2$[H$_2$B(pz)$_2$]$_2$ (10%); NbClN$_2$[H$_2$B(pz)$_2$] (20%), pzH (100%).

Synthesis of Nb$_2$Cl$_6$[H$_2$B(pz)$_2$]$_2$(pzH)$_2$

KBH$_2$(pz)$_2$ (1.34 g, 7.20 mmol) in 15 ml MeCN was added to NbCl$_5$ (0.98 g, 3.6 mmol) in 50 ml MeCN at −30°C. Stirring was maintained for 2 h at −30°C and for 12 h at room temperature, giving a reddish brown suspension. The insoluble products were removed by filtration. Concentration of the filtrate to about 10 ml induced crystallisation which was improved by leaving at 0°C for 24 h. Filtration left 0.4 g (27%) of a buff colored solid, Nb$_2$Cl$_6$[H$_2$B(pz)$_2$]$_2$(pzH)$_2$. Mass spectrometry (70 eV, 150°C): M = NbCl$_3$[H$_2$B(pz)$_2$](pzH); M$_2$-pzH (1%); M$_2$-2pzH (4%), Nb$_2$Cl$_3$[H$_2$B(pz)$_2$]$_2$(pzH) 18%, Nb$_2$Cl$_2$[H$_2$B(pz)$_2$]$_2$ 15%, Nb$_2$[H$_2$B(pz)$_2$]$_2$(pzH) (11%), NbCl[H$_2$B(pz)$_2$](pzH) 12%, pzH (100%).

Synthesis of Nb$_2$Cl$_5$[H$_2$B(pz)$_2$]$_3$

A solution of KBH$_2$(pz)$_2$ (1.07 g, 5.74 mmol) in 30 ml MeCN was added to a suspension of NbCl$_4$ (1.35 g, 5.74 mmol) in 40 ml MeCN. After 2 h stirring at room temperature, the reaction mixture was refluxed for about 12 h. The KCl precipitate was separated by filtration and the yellow–brown filtrate concentrated to about 7 ml. A yellow solid started to precipitate, and the precipitation was imporved by adding a small amount of diethyl-ether. 0.76 g (33%) of yellow crystals of Nb$_2$Cl$_5$[H$_2$B(pz)$_2$]$_3$ were obtained.

Synthesis of Nb$_2$Cl$_4$[H$_2$B(pz)$_2$]$_4$

KBH$_2$(pz)$_2$ (1.72 g, 9.24 mmol) in 30 ml MeCN was added to a stirred suspension of NbCl$_4$ (1.08 g, 4.6 mmol) in 40 ml MeCN. The mixture was refluxed for about 12 h. The brown solution was separated from KCl by filtration and was concentrated to about 4 ml. Addition of diethyl-ether led to the crystallization of a brown solid, Nb$_2$Cl$_4$[H$_2$B(pz)$_2$]$_4$ (1.05 g, 50%). Mass spectrometry (70 eV, 150°C): Nb$_2$[H$_2$B(pz)$_2$]$_3$ (1%) Nb$_2$[H$_2$B(pz)$_2$]$_3$-½N$_2$ (2%), Nb$_2$[H$_2$B(pz)$_2$]$_2$(pz)Cl (3%), Nb$_2$[H$_2$B(pz)$_2$]$_2$H (2%), Nb$_2$(pzH)$_3$H (40%), NbClBN$_5$C$_6$H$_8$ (7%), pzH (100%).

A longer reaction time (16 h instead of 12 h) led to the isolation of Nb$_2$Cl$_3$[H$_2$B(pz)$_2$]$_5$.

Synthesis of Nb$_2$Cl$_2$[H$_2$B(pz)$_2$]$_6$

A solution of KBH$_2$(pz)$_2$ (2.22 g, 11.9 mmol) in 35 ml CH$_2$Cl$_2$ was added at room temperature to a suspension of NbCl$_5$ (0.77 g, 2.85 mmol) in 35 ml CH$_2$Cl$_2$. A brown suspension was obtained and the reaction was completed at reflux for 24 h. The KCl precipitate was eliminated by filtration. The filtrate was concentrated to about 5 ml; addition of pentane resulted in the formation of an oily precipitate; the mother liquor was eliminated by syringe. 1.2 g (74%) of a brown–black powder was obtained after drying under high vacuum.

The ionic products are air-stable in the solid state. Most of the

neutral products can be handled in the air for short periods, and their stability generally increases with the number of poly(1-pyrazolyl)borate groups per niobium, but the dinuclear species having an odd number of chlorine atoms remain highly air-sensitive. In solutions, all products are unstable in air.

The molecular products are insoluble in toluene, CCl$_4$, Et$_2$O, soluble but often unstable in CH$_2$Cl$_2$, more stable in MeCN. The ionic products were found to be insoluble in most organic solvents such as MeCN or acetone but slightly soluble in pyridine and in dimethylformamide.

CRYSTAL AND MOLECULAR STRUCTURE OF TETRACHLOROPHOSPHORUS(V)

HEXACHLOROURANATE(V)

ABSTRACT

The crystal structure of tetrachlorophosphorus(V) hexachlorouranate(V), $PCl_4^+ \cdot UCl_6^-$, has been solved with 2492 independent $F(hkl)$ collected by necessity from one component of a bicrystal; all crystals prepared were twinned. The structure is triclinic, space group $P\bar{1}$, with a = 7.038(4), b = 7.373(4), c = 13.706(8) Å, α = 89.38(3), β = 88.80(3), γ = 105.20(3)°, with Z = 2. The two components of the bicrystal, in the volume ratio of 2.5 to 1, had their reciprocal lattice spots sufficiently separated to allow collection of the data set from component 1 with AgKα radiation (λ = 0.5608 Å). A model was derived from the Patterson synthesis and refined by least squares to $R = \Sigma(|Fo|-|F_c|)/\Sigma|Fo| = 0.146$. The structure was confirmed by a final $(\rho_o - \rho_c)$ synthesis.

The structure is an assembly of octahedral $U(1)Cl_6^-$, $U(2)Cl_6^-$ and tetrahedral PCl_4^+ groups. The chlorine atom array is hexagonal close-packed, while the polyhedra are regular within the experimental errors. The structure is isomorphous with the transition metal analogues $PCl_5 \cdot NbCl_5$ and $PCl_5 \cdot TaCl_5$.

INTRODUCTION

Several addition compounds of UCl_5 have been reported, e.g. $UCl_5 \cdot SOCl_2$, $UCl_5 \cdot R_3PO$ (R = NMe_2, Ph or $PhCH_2$), $5UCl_5 \cdot CCl_2 = CClCOCl$, and $UCl_5 \cdot PCl_5$[1]. The latter, the subject of the present study, was first prepared by Cronander[2] in 1873. Its properties were further studied by Panzer and Suttle[3] whose optical measurements showed that the bright orange-red crystals were triclinic, and highly twinned (the twinning precluded further structural studies.) Panzer and Suttle found that $UCl_5 \cdot PCl_5$ formed the ions PCl_4^+ and UCl_6^- in non-aqueous ionising solvents, but were uncertain whether these existed in the solid. $UCl_5 \cdot SOCl_2$ is considered[4] to be $SOCl^+ UCl_6^-$. Some $UCl_5 \cdot PCl_5$ was prepared, in connection with studies in this laboratory on the volatilities of uranium complexes. As found earlier[3], all crystals showed twinning, and structural analysis was commenced, by necessity, on a fragment that was not single. The structure was solved, and is compared, in the Discussion, with analogous transition metal structures[5,6,7].

EXPERIMENTAL

The air-sensitive crystals were prepared in accordance with the method of Panzer and Suttle[3]. Preparation and manipulation were done under drybox conditions,

and crystals were sealed for study in glass capillaries. Of ten crystals mounted,
only three were unhydrolysed after several days and one of these kept for long
enough for the present data collection. Weissenberg photographs could not be
interpreted because the crystal was multiple and the irregular morphology was not
helpful in determining axial directions. All the definitive work was done on a
4-circle diffractometer with AgKα radiation (to minimise absorption, λ = 0.5608 Å),
the counter being an Si/Li solid state detector.

A scan of reciprocal lattice spots showed the crystal was essentially a bicrystal.
Two identical reciprocal lattices were observed, the volume ratio of
crystal 1:crystal 2 being approximately 2.5:1. At χ=0, the b* axis of crystal 1 at
ϕ = 139.0° was nearly coincident with the a* axis of crystal 2 (ϕ = 137.4°) while
at χ - -26°, the a* axis of crystal 1 (ϕ = 65.8°) was nearly coincident with the b*
axis of crystal 2 (ϕ = 63.4°). The c* axes of crystals 1 and 2 ran in opposite
directions. Thus the two orientations could be described as an interchange of the
a* and b* axes in the basal plane with the c* axes in opposite senses. As the
superposition was not exact, this crystal was called a bicrystal rather than a twin.
Unit cell dimensions measured for crystals 1 and 2 agreed within the experimental
errors. (hkl) intensities for crystals 1 and 2 showed general agreement, but there
were irregularities which were thought to be due to the obscuring of one crystal
component by the other. Superposition of reciprocal lattice spots was uncommon.

A set of (hkl) intensity data were collected for crystal 1. 2860 intensities gave,
on averaging equivalents, 2492 independent I(hkl). The intensities were normalised
to a standard reflexion, corrected for absorption (μ = 109 cm^{-1}) and Lorentz and
polarisation factors[8], and reduced to F(hkl) values. The crystal shape was
described by eight (hkl) planes, and transmission factors lay between 0.03 and 0.08.
The irregular shape and the uncertainty as to which parts of the crystal belonged to
crystal 1 and which to crystal 2 produced systematic errors in the absorption
corrections. Crystal data are summarised in Table 1.

TABLE 1.   CRYSTAL DATA FOR TETRACHLOROPHOSPHORUS (V)

HEXACHLOROURANATE (V)

$PCl_4^+ \cdot UCl_6^-$:   Formula weight = 1247.1, density = 3.02 g cm^{-3}(calc) = 3.02 g cm^{-3}
(obs[3]), melting point = 154°C, triclinic, P1 or P$\bar{1}$. P1 confirmed by structure analysis,
unit cell volume = 686 Å, molecules/cell = 2, volume/Cl$^-$ ion = 34.3 Å^3 (36.0 in
α-and β-UCl$_5$ and 31.6 in PCl$_5$), linear absorption coefficient = 109 cm^{-1} (AgKα)

Unit Cell Dimensions (Å and deg)

Crystal Component of Bicrystal	a	b	c	α	β	γ
Crystal 1	7.038(4)	7.373(4)	13.706(8)	89.38(3)	88.80(3)	105.20(3)
Crystal 2	7.042(14)	7.375(15)	13.736(30)	89.17(12)	88.71(7)	104.90(5)

ANALYSIS AND REFINEMENT

The space group was either P1 or P$\bar{1}$ while the unit cell volume was consistent with two formula units per cell. The reflexions with L = 2n+1 were generally weak while all others were strong. This showed the uranium atoms formed a subcell of half the c-dimension, with uranium atoms at (000) and (00$\frac{1}{2}$). A Patterson synthesis confirmed this, and showed 24 peaks, each of about one tenth the height of the U-U vectors. The latter were U-Cl and U-P vectors. The U-Cl vectors indicated octahedra about U(1) and U(2), differing in orientation. One orientation was arbitrarily fitted around U(1) and the other around U(2). Four more Cl locations were found from the map which completed a hexagonal close-packed Cl lattice. A further vector appeared to be a U-P vector to a P atom in a tetrahedral hole in this lattice. The arrangement derived was a packing of U(1)Cl$_6^-$ octahedra, and PCl$_4^+$ tetrahedra, the polyhedra being discrete (i.e. no chlorine bridging of uranium, such as that found in UCl$_5^9$). The space group was P$\bar{1}$ by the structure analysis.

The model was refined with the least-squares program LINUS[10], with neutral scattering factors for U,P and Cl and $\Delta f' = -6.7$ and $\Delta f'' = 10.6$ e for uranium. During the refinement, a trend was noticed for some reflexions to have Fo > Fc. These 33 reflexions were given reduced weights in the refinement. The 'unobserved' reflexions were given values of F = $\bar{F}$ where $\bar{F}$ is the mean calculated F_{hkl} over the unobserved reflexions. The model refined smoothly until all shifts were < 0.002 e.s.d. The final value of R = $\Sigma(|Fo|-|Fc|)/\Sigma|Fo|$ was 0.146. Although this was higher than usual, due to systematic errors caused by the bicrystal, the structure was well-determined because of the large ratio of observed reflexions to variable parameters, and a final difference synthesis confirmed its correctness. In this synthesis, there was a peak 0.8 Å from uranium of $\frac{1}{25}$ the height of the uranium peak, while elsewhere the average value of the points in the map was $\sim\pm\frac{1}{30}$ the height of a Cl atom, except for a few points where it became $\sim\pm\frac{1}{6}$ the height of a chlorine atom. Thus the final difference synthesis showed systematic errors only.

A table of positional and thermal parameters is given in Table 2 and interatomic distances and angles in Table 3. A table of Fo and Fc may be obtained from the authors on request.

DISCUSSION

The crystal structure of $UCl_5 \cdot PCl_5$ is shown in Figure 1. This analysis has shown that $UCl_5 \cdot PCl_5$ is in fact $PCl_4^+ \cdot UCl_6^-$, i.e. tetrachlorophosphorus(V) hexachlorouranate(V); thus these ions occur in the solid as well as in solution. The compound may alternatively be thought of as an arrangement of hexagonal close-packed chloride ions, with P^{5+} and U^{5+} ions in tetrahedral and octahedral holes. As the bond lengths, Table 3, are shorter than the ionic contact distances[11] (2.57 Å for U^{6+}-Cl^- and 2.12 Å for P^{5+} - Cl^-), the former description in terms of an assemblage of discrete UCl_6^- and PCl_4^+ ions is preferable. The UCl_6^- and PCl_4^+ polyhedra are regular within the experimental errors. The U-Cl distances are comparable with the U-Cl distance (average) in α- and β-UCl_5[9,12] of 2.52 Å and the P-Cl distance of 1.97 Å in the tetrahedra of PCl_5[13]. (PCl_5 consists of PCl_4^+ tetrahedra and PCl_6^- octahedra).
Figure 1. Crystal structure of UCl$_5$.PCl$_5$ as viewed
down the a-axis. Numbers shown are x-coordinates
in hundredths of a.

Kistenmacher and Stucky[6] solved the structures of the interesting compounds $[PCl_4]_2[Ti_2Cl_{10}]$ and $[PCl_4][Ti_2Cl_9]$. The first is based on PCl_4^+ tetrahedra and Ti_2Cl_{10} dimers of the type found in α- and β-UCl_5. The second is built of PCl_4^+ tetrahedra and triply-bridged Ti_2Cl_9 dimers. The structure of $PCl_4 \cdot VCl_5$[7] consists of PCl_4^+ tetrahedra and VCl_5^- bipyramids.

Structural studies by Preiss[5] of the transition metal analogues $PCl_5 \cdot NbCl_5$ and $PCl_5 \cdot TaCl_5$ were brought to our notice after the present work was complete. An examination of his data showed that these compounds were isostructural with $UCl_5 \cdot PCl_5$ but that the coordinates differed from ours as his origin was selected at $(0,0,\frac{1}{2})$ instead of $(0,0,0)$ and his long axis ran in the opposite direction. The α and γ angles of Preiss were indistinguishable from 90°, as his unit cell angles were ± 1.1°; in the present study, the errors in the angles are ± 0.03° or 37 times less. It was of interest that the actinide and transition metal analogues belonged to the same structural type, as this is not always the case[14].

Twinning was also occasionally seen in $PCl_5 \cdot NbCl_5$ and $PCl_5 \cdot TaCl_5$[5], but here the twinning there was an exact superposition, quite different to the bicrystal formation in the $UCl_5 \cdot PCl_5$ crystal. Preiss also redetermined the PCl_5 structure[15] and found a P-Cl distance of 1.90(1) Å in the tetrahedra in PCl_5. This is the same as the average P-Cl distance in $UCl_5 \cdot PCl_5$.

ABSTRACT

$UO_2(thd)_2$ CH_3OH (thd = tetramethylheptane-3,5-dione) is monoclinic, with a = 10.602(11),
b = 22.883(20), c = 12.054(11) Å and β = 105.90(3)°, Z = 4 and space group $P2_1/c$.
The structure, which is molecular, was solved by conventional Patterson and Fourier
techniques with 3173 independent (hkl) reflexions collected with MoKα radiation
(λ = 0.7107 Å), and refined to R = $\Sigma(|Fo|-|Fc|)/\Sigma|Fo|$ = 0.093. The uranium
coordination polyhedron is a pentagonal bipyramid, with U-O (carbonyl) distances
between 2.25 and 2.37 Å and a longer U-O (methanol) distance of 2.50 Å. The uranyl
group is linear (uranyl angle 179.3(8)°). The pentagon oxygen atoms and uranium do
not form a planar system, as there are deviations of up to 0.17 Å from the mean plane.
If the methanol oxygen atom O(7) is excluded from the plane calculation, the remaining
atoms are more nearly planar. The four carbonyl oxygens are coplanar, with uranium
0.08 Å from their plane. The methanol oxygen is 0.28(4) Å from this second plane.

The two (thd) molecules, excluding methyl carbons, are planar and are inclined
at 43.6° to each other in a boat form and at 29.1 and 14.5° to the pentagonal plane.
The methanol C-O bond is inclined at 133° to the U-O bond, confirming the ligand is
the neutral CH_3OH molecule, and not CH_3O^-.

INTRODUCTION

At the Lucas Heights laboratories, we have studied the crystal structures of various
uranyl chelate compounds including α- and β-$UO_2(hfa)_2$tmp (I,II)[1,2] $UO_2(hfa)_2$ (III)[3],
$UO_2(hfa)_2$ NH_3 (IV)[4], $UO_2(acac)_2$ tppo C_6H_6 (V)[5] and UO_2(3-Cl acac)$_2$tppo (VI)[5], where
hfa = hexafluoroacetylacetonate, tmp = trimethyl phosphate, acac = acetylacetonate
and tppo = triphenylphosphine oxide. Interesting structural features have emerged,
e.g. the different molecular conformations in I and II, the trimeric molecule in
III, and the hydrogen-bonded NH_3 complex in IV. A similar compound, $UO_2(hfa)_2$thf,
where thf = tetrahydrofuran, has been the subject of a structural study[6]. Another
ligand of interest is thd = tetramethylheptane-3,5-dione, a somewhat bulkier ligand
than acac or hfa. The neutral ligand used here was CH_3OH, the complex being

$UO_2(thd)_2CH_3OH$ (VII); the crystal structure of this complex is reported.

EXPERIMENTAL AND ANALYSIS

Several large crystals (3 mm x 1 mm x 1 mm) of $UO_2(thd)_2CH_3OH$ were grown from solution. As the compound was moisture sensitive, a fragment $\sim$ 600 µm thick was mounted in a glass capillary and Weissenberg photographs gave the monoclinic space group $P2_1/c$. Approximately 5000 (hkl) reflexions were measured on a 4-circle X-ray diffractometer with a Si/Li solid-state detector and MoKα radiation (λ = 0.7107 Å). The intensities were normalised to a standard reflexion and corrected for Lorentz, polarisation and absorption factors[7]. On averaging equivalents, 3173 independent (hkl) were available for analysis. The crystal was irregular in shape, but, for absorption correction, its shape was approximated by 6 (hkl) planes (Table 1). As the linear absorption coefficient was large (55.4 cm^{-1}), the absorption was difficult to calculate accurately. Crystal data for $UO_2(thd)_2CH_3OH$ are given in Table 1.

TABLE 1.   CRYSTAL DATA FOR $UO_2(thd)_2CH_3OH$

$UO_7C_{23}H_{44}$, M = 670.63, monoclinic, a = 10.602(11), b = 22.883(20), c = 12.054(11) Å, β = 105.90(3)°, U = 2812 $Å^3$, Z = 4, D_c = 1.584 g cm^{-3}, F(ooo) = 1292, space group $P2_1/c$. MoKα radiation (λ = 0.7107 Å), µ(MoKα) = 55.4 cm^{-1}. Crystal bounding planes :

A Patterson synthesis gave the uranium location in the unit cell, and the remaining atoms were located in successive $(\rho_o-\rho_c)$, structure factor cycles. The complete model was refined with the program LINUS[8], using neutral atomic scattering factors, and $\Delta f'$ = -4.9, $\Delta f''$ = 11.3 for uranium. The final value of R = $\Sigma(|Fo|-|Fc|)/\Sigma|Fo|$ was 0.093. No peaks of structural significance were observed on the final $(\rho_o-\rho_c)$ map. Positional and thermal parameters are given in Table 2 and interatomic distances and angles in Table 3. The observed and calculated structure factors may be obtained from the authors on request.

DISCUSSION

The molecular structure is illustrated in the ORTEP diagram of Figure 1, and the packing of molecules in the unit cell is shown in Figure 2. The main structural features are described below.
Figure 1.   Stereo diagram of the $UO_2(thd)_2CH_3OH$ molecule.
Figure 2.   Stereo diagram showing the packing of four
$UO_2(thd)_2CH_3OH$ molecules in the unit cell.

The U pentagonal bipyramid

The uranium coordination polyhedron is a pentagonal bipyramid formed by the uranyl
group, four carboxyl oxygens and the hydroxyl oxygen. The O(1)-U-O(2) angle is
essentially linear, 179.3(8)°. The U-O(uranyl) distances, 1.63(2) and 1.60(2) Å
are slightly shorter than the usual distance, 1.71 Å. The U-O(carbonyl) distances
lie between 2.25(2) and 2.37(2)Å, whereas the U-O bond to the methanol oxygen O(7)
is longer, 2.50(2)Å. Table 4 summarises interatomic distances of interest in the
series of uranyl chelates we have so far studied. Table 4 shows the U-O(7) bond is
weaker then the U-O bonds to the other neutral ligands in the series. This is because
the (thd) group is a weaker Lewis acid than the (hfa) group. The O-U-O angles in the
pentagon are between 65 and 78°, close to the theoretical value of 72° for a regular
pentagon.

TABLE 4   COMPARISON OF INTERATOMIC DISTANCES IN THE
PRESENT SERIES OF URANYL CHELATES

Bond	α-UO$_2$(hfa)$_2$tmp	β-UO$_2$(hfa)$_2$tmp	UO$_2$(hfa)$_2$thf	UO$_2$(hfa)$_2$NH$_3$	UO$_2$(thd)$_2$MeOH	UO$_2$(hfa)$_2$
U-O (uranyl)	1.73	1.69	1.66	1.69	1.62	1.74
U-O (carbonyl)	2.40	2.40	2.38	2.40	2.31	2.32
U-O (neutral ligand)	2.31(3)	2.26(3)	2.35(2)	2.48(6) (N)	2.50(2)	-
C=O	1.25	1.27	1.30	1.24	1.26	1.32
C-C(ring)	1.49	1.46	1.35	1.50	1.46	1.50
Ref.	1	2	6	4	this work	3

The angles O(1)-U-O(7) (81.9(7)°) and O(2)-U-O(7) (97.4(7)°) suggest that the methanol
oxygen atom O(7) is out of the plane formed by the other pentagon oxygen atoms and
uranium. The least squares plane through uranium and O(3) to O(7) is given in Table 5.
The system is not planar, with O(3), O(6) and O(7) deviating by 0.13(4), 0.17(4) and
-0.17(4)Å from the plane. The plane through uranium and O(3) to O(6) is shown in
Table 5. When O(7) is excluded from the plane calculation it is seen that the four
carbonyl oxygen atoms O(3) to O(6) lie in a plane with uranium slightly out of this
plane by 0.08 Å and the methanol oxygen 0.28(4)Å from this plane. The uranyl group,
however, is normal to the pentagon plane, as the O(1)-U-O and O(2)-U-O angles in
Table 3 both average to 90°.

TABLE 5   LEAST-SQUARES PLANES IN $UO_2(thd)_2CH_3OH$

The equation is in the form $Aax+Bb(\frac{1}{2}+y)+Ccz = D$ where x,y and z are in fractional coordinates.

The (thd) ligands

The bond distances and angles for the (thd) molecules in Table 3 are normal. The C-C bonds average 1.50 Å for thd(1) and 1.48 Å for thd(2), and the carbonyl distances lie between 1.23 and 1.28 Å. The least-squares planes in Table 5 show that thd(1) and thd(2) are (excluding methyl carbons) planar to within the experimental error. However the thd(1) and thd(2) molecular planes are tilted at 43.6(15)° to each other in the form of a boat. This is not unusual to these compounds, e.g. the interplanar

angle of 45° in α-UO$_2$(hfa)$_2$tmp[1] (boat), and the tilt of 31° in UO$_2$ (3-Cl acac)$_2$tppo[5]. The thd(1) and thd(2) groups are inclined to the pentagonal plane calculated without O(7), by 29.1 and 14.5° respectively. Tilt angles of diketonate planes in the present series of uranyl chelates are collected in Table 6.

TABLE 6   TILTS OF DIKETONATE PLANES 1 AND 2 WITH RESPECT
          TO THE UO$_5$ PENTAGONAL PLANE, AND THE TOTAL
          CONFIGURATION

Disorder was observed in the methyl groups of thd(1) but not in thd(2); four electron density maxima were observed about C(8). The extra methyl carbon location is labelled C(8)' in Table 2 and can be observed in Figure 1. In this complex, the thermal factors on the peripheral methyl carbons are large. Disorder was also observed in the CF$_3$ groups of the uranyl (hfa) complexes studied previously.[1,3,4]

(c)   The Neutral Ligand CH$_3$OH

The only atoms observed directly in this molecule are the carbon and oxygen atoms, C(23) and O(7). The C(23)-O(7) distance is 1.41 (3) Å, and the hydroxyl oxygen is weakly bonded to uranium (U-O(7) = 2.50(2) Å). Although the hydrogens were not directly observed, this analysis has established that, on the basis of bond angles, the ligand is CH$_3$OH rather than CH$_3$O$^-$. Figure 1 shows clearly the C-O bond is inclined to the U-O bond. The angle U-O(7)-C(23) is 133.2(14)°; an angle of 180° would be expected if there were no hydroxyl hydrogen attached to O(7).

RECOIL TRITIUM REACTIONS ON MONOGERMANE

M. Castiglioni[*] and P. Volpe

Institute of General and Inorganic Chemistry, University of Torino
Corso Massimo d'Azeglio 48, 10125 Torino, Italy

Abstract – The reactions of recoil tritium with germane have been studied. Excited GeH_3T molecules decompose mainly to HT. Both scavengers and moderator fail to affect the HT and GeH_3T yields. This has been attributed both to the low energy of Ge–H bonds and to the high reaction rate of H atoms with germane. Apparently there is no lack of continuity on the reactivity of T atoms with GeH_4 from hot to thermal energies.

Introduction

Gas-phase high energy tritium reactions greatly contributed to the knowledge of the "recoil chemistry"[1].

A great deal of work has been done during the last two decades and the best approach to the fundamental knowledge of the hot reactions has been obtained from very simple systems such $T + H_2$, $T + D_2$[2,3] and $T + CH_4$[4].

We already studied recoil T reactions with hydrides such SiH_4[5], Si_2H_6[6], methylsilanes[7,8,9,10] and NH_3[11] to get information on the influence of the chemical properties of the reactant on the hot reaction.

In this paper we report on the reactions of recoil T atoms with an other simple hydride of the IVth group: GeH_4, which exhibit the same molecular geometry as CH_4 and SiH_4, but longer bond distance and lower bond energy.

Experimental.

GeH_4 was prepared by reduction of GeO_2 with KBH_4, accordingly to W.L. Jolly and J.E. Drake[12], and purified by gas-chromatography. NO was prepared by reduction of diluted HNO_3 with copper wires and purified by gas-chromatography. ^3He used as target for the $^3He(n,p)T$ reaction was purchased from The Radiochemical Centre-Amersham (England). Details on samples preparation and neutrons bombardment are reported in previous papers[5,13]. Neutrons bombardment was performed in the TRIGA Mark II reactor of the University of Pavia.

Analysis was carried on by radio-gas-chromatography using Chromosorb 102 and Silicone oil 702 columns in the -10 to +150°C temperature range.

Isotopic exchange and ^{71}Ge activity. No isotopic exchange was observed on heating for 15 days at 330°K mixtures of HT and GeH_4 or H_2 and GeH_3T.

The natural abundance of ^{70}Ge is 20.55% and its nuclear cross section for the $^{70}Ge(n,\gamma)^{71}$Ge reaction is 3.9 x 10^{-24} cm^2. ^{71}Ge decays for E.C. with an half life of 11.6 d. The soft X-rays associated with the E.C. are detectable by the flow ionization chamber used as radioactivity detector. Under our experimental conditions at the end of the neutrons bombardment the calculated activity of ^{71}Ge was about of the same order of magnitude of that of tritium. This activity could seriously interfere with the measurement of any GeH_3T and Ge_2H_5T. Experiments performed bombarding $GeH_4 + {}^3He$ mixtures and pure GeH_4 showed that 25 days after bombardment the contribution of ^{71}Ge to the total activity of the sample was negligible. Each sample was then stored in the dark for thirty days at 253°K before the analysis.

Total activity and recoil loss.: The total activity of each sample was both calculated from ^3He content and measured from a butane sample filled and bombarded at the same time of GeH_4 samples.

In low pressure samples the detected activity was corrected for recoil loss using a range of 0.126 cm for tritons in GeH_4 at STP; 1.128 cm, 0.287 cm, 0.271 cm and 1.592 cm have been used as tritons ranges in Ne, O_2, NO and He respectively[14].

Results.

Decomposition of T for H substituted species often occurs in hot atom chemistry due to the energy released to the molecule by the hot reaction. The aim of the pressure dependence study is to know to what extent the decomposition of excited species could affect the primary products distribution.

Table 1 shows that at reactant pressure higher than 106 KPa the unimolecular decomposition of excited GeH_3T^* molecules becomes negligible.

The yields of GeH_3T and Ge_2H_5T are about the same as for other simple hydrides of the IV group no other Germanium-hydrides have been detected in measurable amounts. HT yield is high, more close to that from SiH_4[5] than to that from CH_4[15].

The activity detected in gas phase was always very close to the total calculated activity suggesting that the decomposition of hot products leads mainly to volatile substances.

Table 1. Yields of HT, GeH$_3$T and Ge$_2$H$_5$T in the 13-200 KPa pressure range.[a]

GeH$_4$	HT	GeH$_3$T	Ge$_2$H$_5$T	Tot. experim. Activity / Tot. calcul. Activity
200 KPa	71,2 + 3,7	25,3 + 2,2	2,1 + 0,7	1.02 + 0.03
160 KPa	72,4 + 4,0	24,1 + 1,6	1,9 + 0,6	0.97 + 0.06
106 KPa	71,7 + 4,1	24,6 + 1,8	1,8 + 1,0	0.99 + 0.02
80 KPa	74,3 + 3,2	21,5 + 0,9	2,4 + 0,9	0.95 + 0.06
40 KPa	77,0 + 2,6	17,3 + 0,8	2,9 + 1,1	1.01 + 0.09
13 KPa	81,1 + 5,2	13,6 + 1,2	3,3 + 0,9	0.98 + 0.02

[a] Yields are percentage of total activity experimentally determined from butane samples bombarded at the same time. The total calculated activity was obtained taking into account: ^{3}He content, neutron fluxes and recoil losses for each sample.

The total hot yield may be obtained using radical scavengers to clean the system from interfering reactions such reaction /1/.

$$GeH_4 + T \ (thermal) \longrightarrow GeH_3 + HT \qquad\qquad /1/$$
O_2 and NO were used because I_2 and Br_2 easily react with GeH$_4$.

Table 2 shows the effect of both O_2 and NO as scavergers on the yields of HT, GeH$_3$T and Ge$_2$H$_5$T.

Table 2. Effect of scavengers on the T* + GeH$_4$ system.[a]

GeH$_4$	Scavenger	HT	GeH$_3$T	Ge$_2$H$_5$T	Tot. experim. Activity / Tot. calcul. Activity
106 KPa	NO 1 KPa	70,6 + 5,1	23,4 + 3,0	1,8 + 0,9	0.97 + 0.02
106 KPa	O$_2$ 1 KPa	71,3 + 4,6	22,8 + 2,2	1,9 + 0,3	0.99 + 0.03
13 KPa	NO 2 KPa	79,2 + 6,1	13,2 + 0,8	2,2 + 0,3	1.04 + 0.04
13 KPa	NO 4 KPa	77,2 + 3,7	11,5 + 1,1	1,5 + 0,4	0.96 + 0.08

[a] See note on Table 1.

The effect of Ne added to the system as inert moderator for the recoiling T atoms is reported on Figure 1. In spite of its very low efficiency, NO was added in increasing amounts (from 10 to 30%) as the mole fraction of Ne increased[16].

Substitution reaction appears to be affected by the decrease of the energy of the tritium atoms (i.e. by moderation), whereas HT yield increases of about 5% in highly moderated samples.

Discussion

The possible reactions of hot T on GeH_4 give rise to HT by hydrogen abstraction /2/ and, by hydrogen substitution /3/, to GeH_3T which can be found in an excited state (GeH_3T^*):

$$T^* + GeH_4 \longrightarrow GeH_3 + HT \qquad\qquad /2/$$

$$T^* + GeH_4 \longrightarrow GeH_3T + H \qquad\qquad /3/$$
Some highly excited substituted molecules, GeH_3T^*, may decompose before collisional deactivation to GeHT (T-germylene) or HT. The decomposition to germyl radicals (GeH_2T or GeH_3) is energetically unfavourite as shown by RRKM calculations[17], Fig. 2. Further reaction of germylene-T radicals with the substrate is responsible for the formation of digermane /4/[18]

$$GeHT + GeH_4 \longrightarrow Ge_2H_5T \qquad\qquad /4/$$

Decreasing the pressure of the system from 200 to 13 KPa the yield of GeH_3T decreases of about 11% whereas HT increases of 10% and Ge_2H_5T of about 1%.

From the calculated decomposition rates (Fig. 2) it also appears that the decomposition of GeH_3T^* to HT should be less favourite than the decomposition to GeHT and hence the yield of Ge_2H_5T should increase more than HT as the pressure decreases.

The small increase of Ge_2H_5T and the 10% increase of HT suggest that only a small fraction of GeHT species survive long enougth to undergo reactive collision with GeH_4 /4/ while the larger fraction further decomposes accordingly reaction /5/

$$GeHT \longrightarrow Ge + HT \qquad\qquad /5/$$

Reaction /5/ is thermodinamically feasible, fast and probably with a low activation energy[19].

As reported on Table 2 neither O_2 nor NO show a significant effect on both HT and Ge_2H_5T. There is some uncertainty on the efficiency of the above scavengers on GeH_3 and GeH_2 radicals[18] but they are known to be good scavengers for thermal T atoms[20]. It could then be supposed that reaction /1/, which is known to be very fast[21,22], may compete with the scavenger for the reaction of thermal T atoms. On the other hand it appears from moderator experiments that the HT yield does not decreases as expected (also with high percentage of NO). The failure of moderation suggests that a different mechanism may contribute to the HT yield and that such mechanism should be insensitive to thermal radical scavengers and favoured by the decrease of the energy of the recoiling T atoms. Moreover, the increase of HT at very high moderation suggests that, besides a possible decomposition to HT of excited GeH_3T^* molecules by collision with Ne, the abstraction reaction /2/ could

occur also at very low energies consuming the T atoms which being moderated are no more able to react as in /3/ [**].

To sum up, the question arises if either the substrate molecules compete with the scavenger for thermal T atoms or monogermane exhibit a kind of shadowing effect on NO, i.e. GeH_4 reacts with both thermal and quasi-thermal(epithermal) T atoms, sharply decreasing the number at T atoms that, once thermal, could be scavenged by NO or O_2.

Although the literature data on the rate of reaction /1/ are discordant and could indicate a considerable energy dependence (different rate constants have been observed using different hydrogen atom generation methods)[21,22] it seems unlikely that the rate constant for reaction /1/ could be higher than that of scavenging reaction. Hence we suggest that the lack of scavenging effect is due to shadowing effect.

The above suggestion is upported by: a) the cross section for the abstraction reaction increases as the energy of the involved bond decreases, because the low energy threshold for the reaction decreases with the bond energy[24]. b) RRKM calculations show that the mean energy released to the GeH_3T molecule by the substitution reaction is low (only 4×10^{19} J). This implies that the mean energy of the T for H substitution is low, ·it could than be inferred that also the abstraction reaction occurs at low energy.

Conclusions.

It has been already pointed out[25] that in hot T chemistry the hot HT yield is correlated with the dissociation energy of the bond involved in the reaction. Ge-H bonds are relatively weak and therefore the HT yield should be high, however the inefficiency of scavengers towards the HT yield in GeH_4, in addition to the high reaction rate for thermal hydrogen abstraction, suggests that tritium atoms abstract hydrogen from germane without lack of continuity from hot to thermal energies. On the contrary the T for H substitution yield is apparently unaffected by bond energy: in fact the simple hydrides CH_4, SiH_4 and GeH_4, having the same molecular geometry but different bond energies and lengths, exhibit the same T for H substitution yield, i.e. about 25%.

[**]   The scavenger inefficiency prevented us to perform a complete kinetic analysis. However the second kind plot of the Estrup-Wolfgang theory[23] (obtained using: $\sigma_{T+GeH_4} = 0.44$ nm^2, $\sigma_{T+Ne} = 0.22$ nm^2, $\sigma_{T+NO} = 0.30$ nm^2 and $\alpha_{GeH_4} = 0.263 = 0.96 \alpha_{Ne}$) shows a non-linear trend with an intercept $\simeq 0.5$ α_{Ne} (other values of α_{GeH_4} have been tested with the same result). The curvature of the plot confirms that the values at higher moderation are lowered by the unimoleculaar decomposition; the extrapolation using only the values from low moderation experiments gives: $I_{GeH_3} = 0.65 \alpha_{Ne}$.
Fig. 1. Effect of Ne moderation on the products yields for the T^* + GeH$_4$ reaction. Yields as percentage of total activity. HT = ● ; GeH$_3$T = ■ ; Ge$_2$H$_5$T = ▲
Fig. 2. RRKM calculated specific rate constants for decomposition reactions: $GeH_3T \longrightarrow$ GeH_2T + H $=$———; $GeH_3T \longrightarrow GeHT$ + H_2 $=-\cdot-\cdot-$ and $GeH_3T \longrightarrow GeH_2$ + HT $=----$. The i.r. frequencies used for the calculations where taken from L.P. Lindeman and M.K. Wilson, Z. Physik. Chem. 9, 29 (1956). Activation energies from ref. 26 and 19 respectively.

POLYHEDRON REPORT NUMBER 3

MECHANISMS IN THE RACEMIZATION OF OPTICALLY ACTIVE CO-ORDINATION COMPLEXES IN THE SOLID STATE. A REVIEW

P. O'BRIEN

Department of Chemistry, Chelsea College, Manresa Road, London SW3 6LX, England

CONTENTS

1. INTRODUCTION

Although reactions of coordination compounds in the solid state have been known since the time of Werner[1] detailed studies of the kinetics and mechanism of such reactions remain (relative to solution studies) rare. Racemization (1) is a particularly simple reaction, no new chemical species need necessarily be transported to or from the reaction site for its occurrence:

$$2L \rightarrow D + L. \tag{1}$$

Various kinetic studies of the racemization of coordination compounds in the solid state have appeared, and a collection of many of these references is available.[2] The purpose of this article is to reconsider the validity of such kinetic work in relation to the complicated but well documented theory of rate processes in the solid state.

The vast majority of studies to date have modelled racemization with a simple unimolecular rate law. It is shown here that a more accurate model of the kinetics of these reactions is available in well known equations for the kinetics of solid state processes; subsequently the correlation of activation parameters with elementary chemical steps is fraught with difficulties.

The first observation of solid state racemization is usually attributed to Johnson and Mead,[3] strictly they studied the mutarotation of strychninium salts of [Co(ox)₃]. Later, a study of the racemization of $K_3[Cr(ox)_3]$ was reported.[4] There were few studies of such systems until the 1960s, when Bailar's school investigated the solid state racemization of $[Cr(en)_2X_2]$[5] and $[Co(en)_3]X$.[6] An isolated and thorough study of $K_3[Cr(ox)_3]$ appeared in 1969.[7] More recently, Yamamoto *et al.* have studied the racemization of tris(chelate) complexes of Ni(II) and Fe(II) with 2,2-bipyridyl and 1,10-phenanthroline.[8,9] In parallel to the above studies of thermal racemization a number of studies of pressure induced racemization have appeared; this work will be considered separately.

Consideration will now be given to the more relevant aspects of the theory of rate processes in the solid state and the implications of this for studies limited to formal kinetics. This will be followed by a detailed examination of reported studies of solid state racemisations.

2. STUDIES ON THE FORMAL KINETICS OF SOLID STATE SYSTEMS

Excellent reviews of the mechanisms possible for solid state processes are available.[10–13] The majority of coordination chemists studying racemization in the solid state choose a unimolecular rate

law; there seem to be two main reasons for this:

(a) analogy with solution studies (nearly always performed under first order or pseudo-first order conditions).

(b) assumptions, regarding the process occurring in the lattice based on the Scheme 2 shown below:

$$2L \xrightarrow{k_{rac}} L + D \quad \text{racemization}$$

$$L \xrightarrow{k_{inv}} D \quad \text{inversion} \quad k_{inv} = \frac{k_{rac}}{2} \tag{2}$$
(L and D are enantiomorphs, k_{inv} and k_{rac} are the rate constants for inversion and racemization, respectively). In dilute solutions prepared with achiral solvents, the above scheme is usual and correct. In the solid state the complexes racemize within an asymmetric lattice. Optically pure and racemic compounds are not isomorphous; hence simple correlations of inversion and racemization rate constants are not valid.

Alternatively, an individual optically active molecule undergoing inversion in the solid state (by whatever mechanism) is necessarily in intimate contact with its nearest neighbour. Its neighbour being chiral leads to a diastereomeric situation which might be represented as in[3]:

$$nL \rightarrow (n-1)L + D. \tag{3}$$

All molecules within the lattice do not have an equal probability of undergoing inversion, it is thus extremely unlikely that when racemization is complete, asymmetric centres will continue to invert at the same rate. The formal kinetics of a solid state process deals with exactly this kind of problem. The kinetics of solid state processes are difficult to interpret, two main approaches are available.

(a) A careful consideration of the formal kinetics of the process, observed under varying conditions should be made, (the subject of this section).

(b) Other crucial experiments, microscopic examination, morphology, texture, etc. should all be considered (the subject of the next section).

Some commonly used rate equations for solid state processes are summarized below (Table 1). These equations fall into three main classes, those based on diffusion control of reaction rate D_1, D_2 and D_4, those based on the concept of an order of reaction R_2, R_3 and F_1 and those describing nucleation and growth kinetics A_2 and A_3.[14] There are various methods of assigning rate law, a number of these are mainly of value in deciding on the type of mechanism, viz. D, R or A. Reduced time plots (plots of α (fractional reaction) vs $t/t_{0.5}$) fall into this category. Such plots have the same shape irrespective of the magnitude of the rate constant, using a master curve it is easy to compare quantities of data. The curves for $R_2 R_3$ are quite similar making delineation within this group difficult. Figure 1 shows some data for the racemization of $[K_3Cr(ox)_3]$ (anhydrous sample D[14]) compared with the theoretical curves for rate laws R_3 and A_3. The fit to R_3 is excellent; however the main conclusion from such a graph should only be that the concept of an order is appropriate.

An alternative to this method has been introduced by Sharp and Hancock.[15] Plots of $\ln-\ln(1-\alpha)$ vs $\ln$ time are used, the gradient (m) of such plots in the region $0.1 < \alpha < 0.5$ is characteristic of the type of

Table 1. Some commonly used rate equations for solid state reactions

Mechanism	Integrated form[a]	Notation[a]	m^{ab}
Diffusion control 1 dimension	$\alpha^2 = (k/x^2)t$	$D_1(\alpha)$	0.62
Diffusion control 2 dimensions	$(1-\alpha)\ln(1-\alpha) + \alpha = (k/r^2)t$	$D_2(\alpha)$	0.57
Diffusion control 3 dimensions	$(1-2\alpha/3) - (1-\alpha)^{2/3} = (k/r^2)t$	$D_4(\alpha)$	0.57
Phase boundary control 2 dimensions	$1 - (1-\alpha)^{1/2} = (u/r)t$	$R_2(\alpha)$	1.11
Phase boundary control 3 dimensions	$1 - (1-\alpha)^{1/2} = (u/r)t$	$R_3(\alpha)$	1.07
First order (random nucleation)	$\ln(1-\alpha) = -kt$	F_1	1.00
Nucleation and growth 2 dimensions	$[-\ln(1-\alpha)]^{1/2} = kt$	$A_2(\alpha)$	2.00
Nucleation and growth 3 dimensions	$[-\ln(1-\alpha)]^{1/3} = kt$	$A_3(\alpha)$	3.00

[a]Notation of Sharp et al. Ref. 14 is used.
[b]Slope of plot of $\ln-\ln(1-\alpha)$ vs $\ln t$ after Sharp and Hancock. Ref. 15.
Fig. 1. The use of a reduced time plot. Solid lines are theoretical curves for mechanisms A_3 and R_3, points are α
vs $t/t_{0.5}$ for anhydrous sample D of d-$K_3[Cr(ox_4)_3]^{37}$ (data at 242, 246 and 251°C).

mechanism. Briefly for the gradient $m \sim 1$ the concept of an order of reaction (R_2, R_3 or F_1) is valid, for $m \sim 0.5$ diffusion control (D_1, D_2 or D_4) is appropriate and $m \sim 2$ is consistent with nucleation and growth (A_2 or A_3 Avrami/Erofeyer) kinetics. The straight lines obtained in this way are only approximate, but the method seems reliable.

These two techniques help us to decide to which class a solid state process belongs. A simple inspection of the data plotted as α vs time is also worthwhile.[16] The presence or absence of an induction period should always be investigated, as this may help to rule out certain of the above mechanisms.

The problem of deciding which particular-rate law to use within a type is more difficult. If the concept of an order of reaction is valid (R_2, R_3 or F_1) we have recently advocated a differential method,[17,18] based on equation (4) as being extremely useful:

$$\frac{-(1-\alpha)}{d(1-\alpha)/dt} = (n-1)t + \frac{1}{k}. \tag{4}$$

Accurate and reliable values for the order (n), and (in the absence of a zero time error) rate constant (k) may be determined by an approximation procedure.[18]

Another possibility is simply to consider the statistical fit of the various possible integrated rate equations (care is needed with the range of values considered). When no serious zero time error is involved a comparison of theoretically predicted and observed values for the intercept on the $f(1-\alpha)$ axis is also extremely useful. Dolimore et al.[19] have suggested that the linearization of reduced time plots may be a worthwhile procedure.

A combination of the above procedures provides a useful method of screening kinetic data for solid state rate processes. In closing some brief mention must be made of the possible marked effect of particle size distribution. There have been several studies of the effect of particle size distribution,[20-23], and it should always be borne in mind that change in particle size assembly can produce as marked a change in formal kinetics as a change of mechanism.[23]

3. OTHER METHODS RELEVANT TO KINETIC STUDIES OF SOLID STATE SYSTEMS

It has been variously suggested[24-26] that a full study of the mechanism of a solid state reaction should not be limited to formal kinetics alone. The following have been itemized as being particularly informative methods.[23].

(a) Structure: the lattice (crystal structure) of both product and reactant should be known.

(b) Texture: studies of the actual crystals; grain aggregation, crystallite sizes, orientation or crystallites surface area and lattice defects.

(c) Morphology: direct observation of nucleation, subsequent reaction and behaviour of particles.

Much of this can be difficult, and racemizations have on occasions proved singularly intractable, e.g. Bailar and Kutal could observe no interface during the reaction of (+)-$[Co(en)_3]X_3$.[6]

The molecular nature of the racemization of coordination compounds in the solid state should also be
Fig. 2. Commonly proposed transition state for the racemization of tris-chelated coordination complexes.

considered. In Fig. 2 we collate some commonly suggested transition states for the racemization of tris-chelated coordination complexes. In the solid state formal kinetics does not on the whole provide a method of determining which of these mechanisms is operating; although studies of pressure induced racemization may be helpful *vide infra*. In certain cases mechanisms may be eliminated on the basis of chemical considerations, e.g. Fig. 2c is impossible for an anhydrous complex *in vacuo*.

Symmetry considerations have proved to be extremely useful in chemistry.[27-29] The reactions of coordination compounds have been considered by Eaton[30] and later more thoroughly by Whitesides.[31] Notably the racemization of tris-chelate d^3 systems by a twist mechanism, was found to be thermally allowed for weak field cases.[32-34] This lends some support to the frequent suggestions that such mechanisms operate in the solid state.

4. OXALATO COMPLEXES

Johnson and Mead first reported[4] the solid state "racemization" of [Co(ox)₃] in 1932, however as strychninium salts were used this is really not a racemization. In fact the diastereomeric strychninium salts of d and l [Co(ox)₃] showed different rates and final percentages of inversion. The majority of work reported by Johnson *et al.*[4,5,35] in the 1930s concerned such diastereoisomers, but a brief study of K₃[d-Cr(ox)₃] was carried out.

Historically these were the first solid state thermal racemizations to be studied. A number of interesting observations were made: diastereoisomers showed markedly different behaviour in the solid state, a first order model of the kinetics was found to be unsatisfactory, the racemization of anhydrous complexes was demonstrated (although in general at a rate slower than for the corresponding hydrate) and the effect of crystal size on reaction rate was investigated. This work was thorough and made the best use of the then available experimental methods.[36] Brief mention of the slow rate of solid state racemization of [Cr(ox)₃] was made by Billardon[36] but no detailed studies were carried out.

Perhaps the most thorough study of the kinetics of the thermal racemization of a co-ordination complex in the solid state was carried out by Chowdry and Harris.[7,37] Both hydrated and anhydrous forms of K₃[Cr(ox)₃] were studied, rapid racemization was observed during dehydration of the complex, in line with the earlier findings of Johnson *et al.* No real effort was made to investigate the mechanism of this rapid reaction but the possibility of expansion of the complex with lattice water (Fig. 2c) was noted. Anhydrous samples were found to racemise at a faily reproducible rate; racemization rate constants were determined from plots of $(1 - \alpha)$ vs time on logarithmic paper. A first order model with an induction period was considered appropriate. Apart from observations on dehydration, and a study of the effect of neutron irradiation this work was limited to formal kinetics interpreted as outlined above.

We have reinvestigated the data of Chowdry and Harris[7,37] in some detail. A typical set of data, (anhydrous sample D Ref. 37)† will be considered using the scheme outlined in Section 2. Plots of α vs time (or $t/t_{0.5}$) Fig. 2 are deceleratory throughout, the reduced time plot lying closest to the theoretical

line for R_3. The slope of plots of ln–ln $(1 - \alpha)$ vs ln t $(0.1 < \alpha < 0.5)$ are all close to unity (Table 2); the above suggest that the concept of an order of reaction $(R_2R_3F_1)$ is appropriate.

Delineation between these order based mechanisms is achieved in a number of ways. Plots of integrated rate equations [Fig. 3, Table 2] show R_3 to provide the best fit to the data at all temperatures. Plots of $(1 - \alpha)^{1/3}$ are colinear with the expected 0, 1 origin [Table 2, Fig. 4], not the case for R_2 or F_1.

There are unfortunately insufficient data for a proper application of our differential method;[18] orders between 0.6 and 0.8 are obtained in cases where enough data[37] for a preliminary analysis are available.

The two third order rate constants determined by these methods may be used to obtain an activation energy of 227 kJ mole^{-1} (for anhydrous sample D). This may be contrasted with the two values 570 kJ mole^{-1} (for the induction period) and 159 kJ mole^{-1} (for racemization) reported for the same sample by Chowdry.[37] Support for our interpretation of the formal kinetics of this system may be obtained by the method by Ng;[12] plots of log $t_{0.5}$ vs $1/T$ K^{-1} lead to an activation energy of 235 kJ mole^{-1}, comparing very favourably with the activation energy from our single step mechanism.

There are insufficient data on the activation energy of solid state racemization of this kind for a detailed comment on our value of $\sim$227 kJ mole^{-1}. However it is similar to others reported for phase boundary controlled reactions in the solid state. The activation energy of $\sim$500 kJ mole^{-1} reported by Harris and Chowdry,[7,37] seems unreasonably high even for nucleation in the solid state.

It seems clear that in this case there are at least two mechanisms for the solid state racemization. The first, appropriate for hydrated samples, may well involve expansion of the first co-ordination sphere with lattice water and has been little studied. The second, that of anhydrous samples, is most accurately described by phase boundary control in 3 dimensions (R_3), and possibly proceeds at the molecular level by a twist mechanism.[31] More work is needed to elucidate fully the mechanisms operating for this system.

5. COMPLEXES OF 2,2-BIPYRIDYL AND 1,10-PHENANTHROLINE

Yamamoto *et al.*[8,9] have reported on the racemization of various anhydrous salts of Ni(II) and Fe(II) with 2,2-bipyridyl and 1,10-phenanthroline. Throughout unimolecular rate laws were applied; we have again carefully recalculated fully reported data.[8] Considering each complex in turn, for [Fe(phen)$_3$] (ClO$_4$)$_2$ we find m (the slope of plots of ln–ln (1 − α)vs ln time $\sim$1 at all temperatures, suggesting that the concept of an order of reaction is valid. A statistical and graphical analysis of the results Fig. 5 and Table 3 leads to the conclusion that a phase boundary controlled process in two dimensions (R$_2$) best describes the kinetics. The results of our calculations are similar for [Ni(phen)$_3$] (ClO$_4$)$_2$, however the delineation of the mechanism between those based on order (F$_1$R$_2$ or.R$_3$) is not quite so clear as for the corresponding iron complex.

For the bipyridyl complexes the gradients of ln time vs ln–ln (1 − α) plots are much steeper (Table 3), suggesting nucleation and growth kinetics are appropriate. Yamamoto's plots of ln(1 − α) vs time are not colinear with the origin for any of these complexes, and many graphs show marked curvature. The slopes of the ln–ln(1 − α) plots lead to the conclusion that nucleation and growth in two dimensions occur for the nickel complex and in three for the iron complex. For all four complexes reduced time plots indicate that the reactions belong to the types postulated above. The quantity of data available is·

^{d}Results of Yamamoto. Ref. 9.

unfortunately rather limited both in terms of α vs time and temperature range, however it seems clear that there is little theoretical justification for the use of a first order rate law.

Yamamoto[9] also correlated variations in activation parameters, most notably for the racemization of (–)[Ni(bipy)$_3$] with the donicity of the lattice counter ions. Unfortunately in this paper full data were not reported, however activation parameters are often relatively insensitive to the rate law chosen.[13] As a first approximation published values of $\Delta H^{\ddagger}$ for the racemization of [Ni(bipy)$_3$] as the perchlorate, iodide bromide and chloride are considered. An alternative explanation for this marked variation in enthalpies of activation with counter ion could be changes in lattice energy. Lattice energies may be approximated by the Kapustinski equation[38,39] shown in its simplest form below (5):

$$U = \frac{287.2\gamma Z_+ Z_-}{d_0}\left[1 - \frac{0.345}{d_0}\right]$$

or

$$U \approx \frac{287.2\gamma Z_+ Z_-}{d_0} \tag{5}$$

(where $d_0 = r_a + r_c$ the sum of ionic radii of anion and cation).

The lattice energy with a constant cation is thus approximately inversely proportional to the radius of the anion. Figure 6 shows a plot of $(\Delta H^{\ddagger})^{-1}$ against r_a for the perchlorate, iodide, bromide, chloride of optically active [Ni(bipy)$_3$]. A clear correlation exists and although at present tentative, such ideas are probably worthy of more attention.

6. ETHYLENE DIAMINE COMPLEXES

(a) l cis-[Cr(en)$_2$Cl$_2$]Cl·H$_2$O

This complex was found[5] to racemize only during dehydration; no evidence was found for the racemization of the anhydrous complex. Bailar and Le May concluded that a scheme of the kind shown below explained their observations:

$$l\text{-}cis\text{-}[Cr(en)_2Cl_2)Cl_2]Cl \cdot H_2O \rightarrow l\text{-}cis\text{-}[Cr(en)_2Cl_2]Cl + H_2O$$

$$l\text{-}cis\text{-}[Cr(en)_2Cl_2]Cl + H_2O \rightarrow l\text{-}cis\text{-}[Cr(en)_2Cl(H_2O)]Cl_2$$

$$l\text{-}cis\text{-}[Cr(en)_2Cl(H_2O)]Cl_2 \rightarrow rac\text{-}cis\text{-}[Cr(en)_2Cl_2]Cl + H_2O.$$
Fig. 6. Correlation of activation energy and radius of anion for [Ni(bipy)$_3$]X$_2$. A plot of $\Delta H^{\ddagger-1}$ vs r_a, correlation coefficient = 0.851; the point corresponding to Cl$^-$ is well off the line and carries a large error bar (based on Yamamoto's data), excluding this point the correlation is excellent viz. correlation coefficient = 0.994. It is interesting to note that the higher values of $\Delta H^{\ddagger}$ are associated with the lower lattice energies (when calculated by Kapustinski's method). This is the opposite of our intuitive expectations. Little is known of the processes involved in racemization and at present the correlation presented is purely empirical.

Racemization occurring in the second or third steps. Interestingly X-ray powder pictures showed $d \cdot l$-cis-[Cr(en)$_2$Cl$_2$]Cl obtained by dehydrating the racemic compound to have a markedly different structure from rac-cis-[Cr(en)$_2$Cl$_2$]Cl obtained by the simultaneous dehydration and racemization of the l complex. This is the only detailed study of an optically active cis-bis-chelated complex, and in contrast to tris-chelated complexes the anhydrous complex has not been shown to racemize.

Some analogy may be drawn with solution studies of similar complexes, the rate of racemization has been found to be similar to the rate of chloride exchange, again suggesting an "aquation–anation" pathway. The solid state racemization of this complex is worthy of more attention, chloride exchange during racemization/dehydration could provide firmer evidence for the above mechanism. Isothermal studies of the dehydration of the optically active complex would be expected to show more than one mechanism of dehydration to occur. Finally, an interesting and unassigned exotherm was noticed in the DTA of l-cis-[Cr(en$_2$Cl$_2$]Cl H$_2$O, the origin of which may be significant.

(b) (+)-[Co(en)$_3$]X$_3$·nH$_2$O

The racemization of optically active [Co(en)$_3$]I$_3$ in the solid state was first reported by Dwyer et al.[40] A detailed study of this system was undertaken by Kutal and Bailar.[6] The mechanism was attributed to a twist process; the marked acceleration of racemization during dehydration at higher temperatures being attributed to disruption of the lattice. Electron microscopy revealed marked modification to the crystal after dehydration, but no interface could be detected for the racemization process.

Samples dehydrated at relatively low temperature, when heated to high temperature underwent thermal racemization. Quantitative kinetic studies for such samples were not reported, and for no samples was the reaction followed to completion. However qualitatively the rate of racemization was reproducibly found to be I$^-$ > Br$^-$ > Cl$^-$ (Fig. 7); this is exactly the order expected if lattice energy were controlling the reaction vide supra. Although no formal kinetics were studied by Kutal and Bailar this singularly thorough study used many of the techniques listed in Section 3 and as such remains unique. It is reasonable to suggest that such reactions could and should be followed to completion if possible, and that a more detailed kinetic study might reveal much new information.

(c) Other ethylene diamine complexes

d-cis-[Co(en)$_2$[H$_2$O)Cl]Cl$_2$. was shown[41] to undergo simultaneous, racemization, anation and dehydration at 100°C.
Fig. 7. Effect of counter ion on the racemization of (+)-[Co(en)₃]X₃ at 127°C.

d-cis-[Co(en)₂Cl₂]Cl·H₂O. Racemized largely after dehydration[5] (24 hr at 160°C), no conversion to the *trans* isomer was observed. Insufficient is known of these racemizations for any serious speculation regarding mechanism to be made.

7. COBALOXIME COMPLEXES

A series of papers have appeared[48-50] reporting the racemization of complexes of the kind R-α-cyanoethyl (s-α-methylbenzylamine) cobaloxime. The cyano ethyl group in this complex racemizes during X-ray exposure at ambient temperatures. The mechanism suggested for this unusual reaction is that a planar cyanoethyl radical produced by Co–C band cleavage, rotated about the CoC=N axis to face the opposite side of the plane to the cobalt atom; then recombines to give the racemic complex.

8. PRESSURE INDUCED RACEMIZATION

High pressure of the order of 10,000 atm promotes the racemization of (−) K₃[Co(C₂O₄)₃],[42,44] (+) [Ni(phen)₃] (ClO₄)₂[43,45] and (−)[Fe(phen)₃] (ClO₄)₂.[43] A first order model was used as the basis of the kinetic analysis in each of these studies; for (−)K₃[Co(C₂O₄)₃][44] the fit obtained to a first order rate law is excellent (although some unspecified correction for decomposition was made). The limited quantities of data available from such studies make verification of the rate law difficult.

In all the above cited studies negative volumes of activation [$\Delta V^{\ddagger}$] were found. It seems likely that the sign of the volume of activation will be unaffected by the choice of rate law and that these negative values are reliable. Negative values of $\Delta V^{\ddagger}$ are usually correlated with a twist type of mechanism for racemization, and this was concluded to be the case in all the above studies.[42-45] However it is difficult to make a very strong case based on negative values of $\Delta V^{\ddagger}$ alone. As pointed out by Brady *et al*.[44] lattice distortions over large distances, which may accompany local volume changes in the complex ion, make it difficult to interpret volumes of activation in terms of volume changes of the complex ion alone. Also the extrapolation of high pressure results[42] for Ni(II) and F(II) tris phenanthroline complexes to atmospheric pressure suggests a fairly high rate of racemization for these complexes in the solid state under ambient conditions; this is known not to be the case. A mechanism change at high pressures provides a possible explanation for this observation.

Perhaps analogy with solution chemistry is useful here; it has recently been shown [46,47] that negative values of $\Delta V^{\ddagger}$ may be consistent with dissociatively activated mechanisms. Thus causing earlier ideas[46] based on a simple interpretation of $\Delta V^{\ddagger}$ alone to be revised. The interpretation of the solution kinetics experiments is generally much less ambiguous than that of corresponding ones in the solid state but much caution is obviously needed in equating the magnitude and sign of volumes of activation with molecular mechanisms.

9. CONCLUSIONS

There are a number of general and specific conclusions to be drawn from this article. Firstly, well documented rate laws for solid state processes may well describe the kinetics of racemization of coordination compounds in the solid state better than the generally applied unimolecular rate law. Some methods of screening kinetic data have been briefly outlined. As the rate determining step may be rearrangements within the lattice itself, the correlation of activation parameters, etc. with molecular changes responsible for the reaction may not in many cases be possible. The kinetics of solid state reactions is a complicated and often contentious matter, studies limited to formal kinetics are not recommended, and the comment of Gomes on the application of rate laws should always be borne in mind.[51]

On a more specific level the role of lattice water in solid state racemization needs careful consideration. Frequently anhydrous and hydrated samples of a complex have been compared with no regard to the fact that during dehydration the crystal structure is much disrupted. The anhydrous sample may well contain many new defects, providing one explanation of the frequent observation,[9,44] that anhydrous complexes racemize more rapidly than hydrated ones.

In marked contrast the absence of solid state racemization when water is not present e.g. $[Cr(en)_2Cl_2]Cl^5$ may implicate water in the mechanisms. In the case of optically active $K_3[Cr(ox)_3]$ two mechanisms operate. The hydrated form racemizes rapidly, possibly by expansion of the co-ordination sphere with lattice water, the anhydrous complex more slowly by a phase boundary controlled process.

Crystallography has not yet provided the necessary structures of racemate and optically active complex needed for a better understanding of solid state racemizations. Indeed the frequent observation,[5,7] that the thermally racemized solid complex has a different crystal structure from dehydrated racemic complex needs further investigation. The crystal structures of some of these apparently simple complexes are not trivial and a recent extensive investigation[52] of d-l-$K_3[Cr(ox)_3]$ highlights this problem.

The kinetics and mechanism of solid state racemizations are as yet relatively poorly understood. Only with a proper appreciation of the complexity of solid state processes can real progress be made. In many ways the ideas expressed in this article are in line with recent suggestions (of a general nature) made by House,[53] and have been briefly outlined earlier by the author.[54]

Abstract—Equilibrium-based computer models using MINIQUAD-75 program were utilized to determine the stoichiometry and formation constants involved in the systems pyridoxamine(Pm)-glycine (Gly)-imidazole (Imd) with CO(II), Ni(II), Cu(II), Zn(II) and Cd(II) metal ions. The data were obtained from potentiometric pH titration of the various binary, ternary and quaternary systems under physiological-like conditions (0.15 M NaNO₃–37°C). Various composition ratios of metal and ligands were used. The ligand concentrations did not exceed 4 times the concentration of metal ion in the binary systems and 4 times of the metal ions in ternary systems. In case of the quaternary systems only imidazole concentrations were two or four times the concentrations of metal ions keeping those of other ligands equal to that of metal ions. The stability constants of the quaternary species are discussed in terms of binary and ternary constants as are the effect of ring size on the stability of mixed ligand species. In addition, electrostatic as well as statistical effects also are mentioned and the biological implications of these model equilibria are described.

INTRODUCTION

Considerable progress has been made in the last two decades in the treatment of many diseases by the introduction of long-term feeding regimens and/or drug treatment. For instance gastrointestinal diseases may be treated by the introduction of long-term supplementation of solutions with protidic, lipidic and glucidic compositions that have been found to be suitable for maintaining healthy tissue metabolism in patients.[1] A major concern lies in the adequate supply of essential trace metals which should be included in the regimens to avoid impairment in some biochemical processes. Supplementation of trace metal concentrations in nutritive mixtures have been made.[2] The doses appear to have been chosen somewhat randomly and very little correlation between the administered levels, plasma concentrations and overall metal ion balance was observed.[3] This may lead to the toxicity by the unknown greater concentration of an essential metal ion and the loss of the relationship between the nutritive requirement for a metal ion and its rate of excretion. A better understanding of the interactions between ligands and metal ions is essential prior to any chemotherapeutic medical treatment. Many attempts to correlate physiological responses with the 1:1 metal-ligand binary formation constants have appeared in the literature.[4] These fail to take into account a large number of other important reactions that determine the overall degree of complexation such as protonation, ternary and quaternary complex equilibria.

In this study we have investigated the equilibria which may be involved in the interaction of pyridoxamine (a vitamin B₆ compound), glycine and imidazole with some divalent metal ions. This may serve as an example of the presence of not only binary complexes but also ternary as well as quaternary complexes in biological fluids.

Moreover, glycine in combination with imidazole may serve as a model for histidine interaction with metal ions.

EXPERIMENTAL

The ligands glycine (Gly) (>99%; BDH), (99%; BDH) and pyridoxamine dihydrochloride (Pm) (>99%; Merck) were used without further purification. Imidazole (Imd) (Aldrich) was crystallized from benzene and dried under reduced pressure. The stock solutions of the ligands were kept at 5°C in dark.

Cobalt(II), nickel(II), copper(II), zinc(II) and cadmium(II) nitrates (>99%; BDH) were used as provided. The concentrations of the stock solutions were checked by potentiometric methods. The method is essentially EDTA titration of metal ions using Radiometer pH meter model pH M62 provided with Radiometer cupric selectrode type 1112 Cu as indicator electrode and Radiometer calomel electrode type K401 as a reference electrode[5].

The titrimetric data were acquired using Orion Research microprocessor ionalyzer type 901, using Radiometer combined glass electrode type GK 2301 C. The ionalyzer in the pH mode was calibrated using two Radiometer buffers at pH's 6.98 and 4.03 at 37°C. All pH-metric titrations were carried out as previously described[6]. The ionic strength of all titration solutions was adjusted to 0.15 M NaNO₃. The temperature of the titration cell was kept constant at 37°C. The titrant in most cases was a solution of 0.1 M carbonate-free NaOH which was 0.15 M in NaNO₃ and in few cases was 0.1 M HNO₃. In all titrations, purified nitrogen was passed into the solution before and during the titration time. The metal ion concentration was in the range (0.6–2.0)10⁻³ M. The ligand concentrations did not exceed 4 times the concentration of metal ions in the binary systems. In ternary systems, the concentrations of each ligands were not more than twice the concentration of metal ions except in case of imidazole where its concentration did not exceed 4 times that of metal ions. In the quaternary systems, the concentrations of each ligand was identical to that of metal ions except imidazole where its concentration was not more than 4 times that of metal ions. Multiple titrations were carried out for each system. The hydrogen-ion concentration was taken as 10⁻ᵖᴴ.

Methods

Titration data were analysed by using MINIQUAD-75 program[7]. Different equilibrium models have been tested. The results were assessed by observing the values of chi square (Xi^2),

* l, p, q, r, s are the stoichiometric coefficients corresponding to Pm⁻, Gly⁻, Imd, M^{2+}, and H^+, respectively.

⁺ The ranges of S, Xi^2 and R are $((4.37-60.0)10^{-8})$, (38-88) and (.002-.036), respectively.

crystallographic factor (R) and sum of squared residuals (S). The model which gave the lowest R values, Xi^2 value (or both) and S value has been adopted taking in consideration the errors in experimental quantities and rules for propagation of errors.

The protonation constants of Pm, and Gly were determined by titrating 25 ml of the aqueous solution of the ligands in the concentration range $(1-3)10^{-3}$ M with CO_3^{2-} free NaOH of 0.1 M. In addition, 25 ml of the aqueous solutions of Gly and Imd in the concentration range of $(0.5-1.0)10^{-2}$ M were titrated with 0.1 M HNO_3. Table 1 depicts the values of protonation constants obtained at I = 0.15 M and T = 37°C.

The conditions of measurements for the determination of the

* The values of S, Xi² and R did not exceed 1.0E-6, 261 (depending on the number of titration data) and .013, respectively.

stability constants of the binary, ternary and quaternary complex species were the same as for the protonation constants of ligands. The composition ratios of ligands to metal ions (M^{2+}) were always 1:1, 2:1, and 3:1 in case of Gly:M^{2+} and Pm:M^{2+} and 2:1 and 4:1 in case of Imd:M^{2+} binary systems. Table 2 lists the values of stability constants of the binary systems. In the ternary systems, the ratios of Pm:Gly:M^{2+} were 1:1:1, 1:2:1, 2:1:1, while the ratios of Pm:Imd:M^{2+} and Gly:Imd:M^{2+} were 1:2:1 and 1:4:1. Table 3 depicts the values of the ternary stability constants obtained in this work. In the quaternary systems, the ratios of Pm:Gly:Imd:M^{2+} were 1:1:2:1 and 1:1:4:1. The values of the stability constants are listed in Table 4.

In calculating the stability constants of the binary complexes using MINIQUAD-75 program, the protonation constants were kept constant while varying the values of the binary species. In case of ternary systems, the values of protonation constants of ligands and the stability constants of binary complex species were kept constant while varying those of ternary complex species. In case of the quaternary system the values of protonation constants of ligands, the stability constants of 1:1 binary complex species and those of 1:1:1 ternary complex were kept constant while varying those of the quaternary complex species.

The ionization of water (pK_w) was taken to be 13.38 at $I = 0.15$ and 37°C.[10]

RESULTS AND DISCUSSION

Binary metal complexes

Interactions of the bivalent metal ions Co(II), Ni(II), Cu(II), Zn(II) and Cd(II) with the ligands Pm, Gly and Imd have been the subject of many reports.[11-25] The formation constants have been re-evaluated at the ionic strength, $I = 0.15$ M and temperature of 37°C (this being isotonic with blood plasma). If allowance is made for the effect of

different reported solution media, some of the formation constants reported in this work are more or less in accord with those reported by other authors, Table 2 (a, b and c).

Although, pyridoxamine complexes of various metal ions have been studied by different investigators[6,11,15] variation in their results are mostly due to variation in experimental conditions and methods of calculation. Upon using wider pH range and different initial metal ion and Pm concentrations, revealed that Cu(II)–Pm system may exhibit somewhat different set of equilibria from what have been previously reported, Table 2(a). In the Cu(II)–Pm system, the titration data were divided into two parts at two pH ranges, 3.1–4.7 and 6.5–8.4. Upon analyzing the data at lower pH range by using MINIQUAD-75 program, protonated binary Cu(II)–Pm complexes were obtained, Table 2(a). In the 1:1:1 (Pm:Cu(II):H) species, it is believed that the proton is located on the hetero-nitrogen atom of Pm rather than on the amino group if a 6-membered chelate is assumed to be formed. In such case, the protonation constant of the hetero-nitrogen atom should be greater than that of the amino group, opposite to what one expects for the free ligand. Other protonated species may indicate that Pm can also act as monodentate ligand species. The formation constants of the non-protonated species were obtained at the higher pH range when the titration data were analysed by the same program keeping those obtained at lower pH range constant.

The other bivalent metal ions-Pm equilibrium reactions are more or less in agreement with those previously reported, Table 2(a). Moreover, it has been proved that Pm cannot form *tris*-metal complex species under the experimental conditions used.

Glycine binary metal complexes were extensively studied in the last two decades.[16] Various equilibria and their formation constants were reported. At least two unprotonated complexes were detected in the present work. Table 2(b) depicts their formation constants. Of course, 5-membered metal chelates are assumed to be formed. It has been proved that other species may also be formed. Cd(II) may form protonated complex species with glycine and Zn(II) forms soluble hydroxy glycinate complex species in solution, Table 2(b). The presence of triglycinate complexes were not confirmed under the experimental conditions used in this work, except in the Zn(II) system.

Complexes of imidazole of various metal ions were studied by several investigators.[8,24-26] It has been observed that precipitation was fast at slightly alkaline medium under the experimental conditions used in this work. This behaviour precluded our obtaining enough titration data for the determination of the formation constants of the binary complexes. However, it has been confirmed that polymerization of complexes is not the trend among the metal complexes studied except in the Cu(II) system, Table 2(c). In the latter system several polymeric complexes were detected. It has been reported that these types of Cu(II) complexes with imidazole are dependent on the ionic strength of the medium and the salt type used in its adjustment.[26] Actually there was no correlation between our work and that reported by previous other authors in case of the Cu(II) system except in the possibility of the formation mononuclear species.

Ternary and quaternary metal ion complexes.

The stability constants of the ternary metal ion complexes reported in Tables 3 and 4 are for the following equilibrium reaction.

$$1 \, Pm^- + p \, Gly^- + q \, Imd + r \, M^{2+} + s \, H^+$$
$$\rightleftharpoons M_r Pm_l \, Gly_p \, Imd_q \, H_s. \quad (1)$$
At least 20 sets of complexes for each system were examined using MINIQUAD-75 programme. Many were rejected when chi square (XI^2), crystalographic factor (R) and sum of squared residuals (S) are large or when constants had large standard deviations. Furthermore, the effect of variations in the values of protonation and binary constants on the constants of the chosen ternary model (and also ternary constants in case of the chosen quaternary model) were examined and was concluded that the choices were correct with errors in the values of the stability constants within the standard deviation shown in Tables 3 and 4.

(i) Ternary metal ion complexes

The ternary complexes involving Pm as one of the ligands are mostly protonated. Since Gly and Imd ligate metal ions when they are not protonated it may be expected to stay this way in their ternary complexes. One should expect that the protons may be located on the Pm moiety in their ternary complexes such as 1:1:0:1:1, 2:1:0:1:2, 1:2:0:1:1 and 2:0:2:1:1 species. The presence of other protonated ternary species may indicate that Pm and Gly can act as monodentate ligands. It is noted that some of the intermediate species in the Pm–Imd–M^{2+} system are absent (e.g. 1:0:2:1:sH) except in Cu(II) and Cd(II) systems. There is likely a preference to particular structures; penta-coordinated and hexa-coordinated structures in case of Co(II), Ni(II) and Zn(II) systems (e.g. 1:0:3:1:0 and 2:0:2:1:0 species) and tetra-coordinated and hexa-coordinated structures in Cu(II) and tetra-coordinated and hexa-coordinated structures in Cu(II) and Cd(II) systems (e.g. 1:0:2:1:0 and 2:0:2:1:1 species). In such complexes two or more Imd molecules are involved.

The ternary complexes not involving Pm are entirely unprotonated, (i.e. Gly–Imd–M^{2+} system), Table 3(c). Similar to the system Pm–Imd–M^{2+}, stepwise species are absent and preference to penta-coordinated structures is more obvious. In these complexes more than one Imd moiety and, in rare cases, more than one Gly moiety are involved. The presence of species containing more than one Gly molecule (in the Gly–Imd–M^{2+} system) is less than those containing more than 2 Pm molecules in the Pm–Imd–M^{2+} system. This may be explained as due to the better π-acceptor character of Pm over that of Gly. However, six-membered chelate of Pm should be expected to exert more hindrance than the five-membered chelate of Gly. This may explain why more than one molecule of Imd prefer Gly containing complexes rather than those containing Pm where steric factor is greater. In the ternary systems studied, the aquated 1:1:1 species (for Pm or Gly:Imd:M^{2+}) are stable at a certain pH range (which is usually below pH 7.0), where Imd, in particular, is not completely deprotonated.

The formation of 1:1:0:1:s or 1:0:1:1:s (Pm^-:Gly^-:Imd:sH$^+$:M:sH) ternary complex species from binary species may result from either one of the following reactions or both:

$$MLH_m + ML'H_n \rightleftharpoons M + MLL'H_s\,;$$
$$K^I = \beta_{ITH_s}/\beta_{IMLH_m}\beta_{IML'H_n} \tag{2a}$$

$$M(LH_m)_2 + M(L'H_n)_2 \rightleftharpoons 2MLL'H_s\,;$$
$$K^{II} = \beta_{ITH_s}^2/\beta_{2MLH_m}\beta_{2ML'H_n} \tag{2b}$$
where β_{ITH_s}, β_{IMLH_m}, β_{2MLH_m}, $\beta_{IML'H_n}$, and $\beta_{2ML'H_n}$ are the formation constants of the ternary complex, first and second complex species of LH$_m$ and first and second complex species of L'H$_n$, and $s = n + m$.

Table 5 lists the values of log K^I and log K^{II} (log K and log X used by Sigel[27]) for 1:1:1:0:s, 1:0:1:1:s and 0:1:1:1:0 complex species whenever the binary constants data were available. It is generally found that the formations of most ternary complexes under consideration, are favored over the formations of the bi-binary metal complexes as well as most mono-binary species. It should be kept firmly in mind that the magnitudes of log K^I and log K^{II} are strongly influenced by statistical differences in the formation of each complex as well as differences in bonding. The statistical values of log K^I and log K^{II} depend on the coordination number of the metal ion and denticity of the ligands,[28,29] e.g. for the tetragonal complex of Cu(II) with bidentate ligands the statistical value is -0.6 log units. For other situations, the statistical values may be less but is always negative. Values of log K^I and log K^{II} greater than -0.6 log units indicate that ternary metal complex formation is more favored than that of binary metal complexes. Table 5 shows that the values of log K^I and log K^{II} are mostly greater than -0.6. The log K^I values of M–Pm–Gly systems are more negative than those of M–Pm–Imd and M–Gly–Imd systems. This is not surprising since the latter systems exhibit less steric hindrance than the former.

The formation of 1:1:1:s (Pm:Gly or Imd:M:sH) ternary complex species involving Pm may also be discussed in the light of the following equations;

$$MPmH_s + L \rightleftharpoons MPmLH_s\,; \quad K^{III} = \beta_{ITH_s}/\beta_{IMPmH_s} \tag{3a}$$

$$M + PmH_s \rightleftharpoons MPmLH_s\,; \quad K^{IV} = \beta_{ITH_s}/\beta_{ITH_s}/\beta_{IML} \tag{3b}$$

(L may stand for either Gly or Imd). Table 6 lists the values of log K^{III} and log^{IV} for 1:1:1:0 and 1:1:1:1 complex species. It is obvious that the values of log K^{IV} are greater than those of log K^{III} for most metal ion complexes. This may reflect the type of bonding of Pm to these metal ions. Pm may increase the electron density in the vicinity of the metal ions rendering them less electrophilic towards the other ligands, Gly and Imd. Furthermore, upon inspecting Table 6, one may also find that the size of chelate rings affect the stability of the ternary complex species. Six (Pm), five (Gly)-membered chelates are more stable than five (Gly), five (Gly)-membered chelates. However, six (Pm), Six (Pm)-membered chlates are more stable than five (Gly), six (Pm)-membered chelates except in Ni(II) and Cd(II) systems.

Table 5. The values of log K^I and log K^{II} defined by the eqns (2a and 2b) for all ternary systems studied in this work

System	l p q r s	log K^I					log K^{II}				
		Co(II)	Ni(II)	Cu(II)	Zn(II)	Cd(II)	Co(II)	Ni(II)	Cu(II)	Zn(II)	Cd(II)

( )   Correspond to the equilibria: $M\,LH_n + LH_m \rightleftharpoons M\,L_2H_{n+m}$

*   Correspond to the equilibria: $ML + PmH \rightleftharpoons M\,Pm\,LH$

The stability enhancement of imidazole ligation in ternary complex formation may be revealed when the values of log K^{III}, Table 6, are compared with the 1:1 binary species, Table 2(c). The presence of Gly or Pm H usually enhance the nucleophilic attack of Imd to metal ions. Although, PmH has slight higher electron releasing power than Gly, yet Imd seems to prefer ligation to the mono-binary species containing PmH rather than that containing Gly. This finding may indicate that interaction between Pm and Imd is less than that between Gly and Imd.

MINIQUAD distribution diagrams for Cu(II) ternary systems, as representative example, are shown in Fig. 1(a–c). The figures compare the complex distributions of Cu(II) with Pm–Gly, Pm–Imd and Gly–Imd systems. It should be borne in mind that these distribution curves are dependent on the initial concentrations of the reactants. In selecting these diagrams for representation, we have made the choice for those showing the distribution of the greatest number of the species mentioned in Table 3.

(ii) Quaternary metal ion complexes

Table 4 lists the formation constants of the quaternary complexes represented by eqn (1). It is clear from this table that most of the complexes are protonated in solutions of the same pH range used before in case of the binary and ternary systems. Again one may expect that the protons are preferably located on the Pm moiety specially in mono and di-protonated species. In the triprotonated species, Gly may also be protonated. This protonation is an indication of a decrease in the positive character of metal ions as many ligands clustered around them. It may also indicate that ligands of multidentate nature may behave as mono-dentate is presence of other ligands. Table 4 also shows that there are no unique stoichiometry for various quaternary species among the metal ions studied. However, three species are present in

common, 1:1:1:1:3, 1:1:1:2:1:1 and 1:1:2:1:2 species. The persistence of the latter two species emphasize the preference of hexa- and penta-coordinated structure among these metal ions complexes. The chelation of the metal ions with Pm and Gly facilitate their ligation with imidazole. This may be verified by comparing the formation constants of the following

$T_{Pm} = T_{Gly} = 2\,T_{Cu} = 3.2 \times 10^{-3}M$

	PN	Gly	Cu	H
A	2	1	1	2
B	1	1	1	2
C	1	1	1	3
D	1	2	1	1
E	1	2	1	2
G	2	0	1	0

(a)

$$T_{Gly} = \frac{1}{2} T_{Imd} = 2 \, T_{Cu} = 1.6 \times 10^{-3} M$$

(b)

(c)
Fig. 1. MINIQUAD computed distribution of complex species with pH of Cu(II) ternary systems. (a) Pm–Gly–Cu(II) system. (b) Pm–Imd–Cu(II) system. (c) Gly–Imd–Cu(II) system.

equilibrium reactions;

$$M \, Pm \, Gly \, H_s + Imd \rightleftharpoons M \, Pm \, Gly \, Imd \, H_s;$$
$$K^V = \beta_{IQH_s}/\beta_{ITH_s} \tag{4a}$$

$$M \, Pm \, Gly \, H_s + 2 \, Imd \rightleftharpoons M \, Pm \, Gly \, Imd_2 H_s;$$
$$K^{VI} = \beta_{2QH_s}/\beta_{ITH_s} \tag{4b}$$
(where β_{IQH_s} and β_{2QH_s} are the formation constants of the quaternary cvomplex species $1:1:1:1:s$ and $1:1:2:1:s$ respectively) with those of the binary complexes of these metal ions with imidazole, Table 2(c). The log K^V values for $1:1:1:1:0$ species of Co(II) and Cu(II) systems are 3.86 and 4.97 which are greater than

that for $0:0:1:1:0$ species by approximately one log unit. Moreover, the log K^V values for $1:1:1:1:1$ species involving Co(II) and Ni(II) are 4.21 and 3.91 which are still greater than that of the mono-binary species of Imd by more than one log unit. The nucleophilic attack of Imd seems not to depend primarily on the diminished positive character of the central metal ions but also on the electron density of other ligands in the complex. Furthermore, the log K^{VI} values are still greater than that corresponding to the bi-binary species of Imd by more than one log unit, e.g. the log K^{VI} for $1:1:2:1:1$ of the Co(II) and Cu(II) systems are 6.99 and 7.47, respectively.

There is a tremendous number of equilibrium reactions involved in the formation of the $1:1:1:1:s$ quaternary complex. It may be formed from the combination of

three different binary species or one binary and one ternary species or from two ternary species. It has been shown, Table 5 that mono-binary species are mainly in equilibrium with the ternary species, in most cases. One should expect that the most important species in the quaternary system are the mono-binary as well as the ternary species. The formation of the quaternary species may be examined if the following equilibria are considered,

$$ML + ML'L''H_s \rightleftharpoons MLL'L''H_s + M;$$
$$K^{VII} = \beta_{IQH_s}/\beta_{IML}\beta_{IML'L''H_s} \tag{5}$$

$$ML' + MLL''H_s \rightleftharpoons MLL'L''H_s + M;$$
$$K^{VIII} = \beta_{IQH_s}/\beta_{IML'}\beta_{IMLL''H_s} \tag{6}$$

$$ML''H_s + MLL' \rightleftharpoons MLL'L''H_s + M;$$
$$K^{IX} = \beta_{IQH_s}/\beta_{IML''H_s}\beta_{IMLL'} \tag{7}$$
(L, L' and L''H$_s$ stand for Gly, Imd and Pm, respectively). Due to the lack of the formation constants of the necessary species to calculate the log K^{VII}, log K^{VIII} and log K^{IX}, only the values for few species may be obtained. It has been found that the log K^{VII}, log K^{VIII} and log K^{IX} are 0.36, 1.18 and 0.74 for the 1:1:1:1:1 species of the Co(II) system. This finding indicates that quaternary complex formation is moderately enhanced with the equilibrium reaction six more than that of 5 and 7, confirming the great affinity of Imd to ternary complexes containing Gly and Pm. Ni(II) quaternary system behaves similarly but with lower values of the log K's (−0.45, +0.71 and +0.03, respectively). For the 1:1:1:1:0 species of Cu(II) system, the values for the log K's are −1.75, −0.55 and −1.36, respectively. The negative values show that quaternary complex formation is diminished but still equilibrium reaction 6 is the least which confirm the favorable tendency of Imd to attack the ternary species involving Gly and Pm.

The formation of the 1:1:1:1:s quaternary complex species may also arise from the combination of two different ternary complex species;

$$MLL' + MLL'H_s \rightleftharpoons MLL'L''H_s + ML;$$
$$K^X = \beta_{IQH_s}\beta_{IML}/\beta_{IMLL'}\beta_{IMLL''H_s} \tag{8}$$

$$MLL' + ML'L''H_s \rightleftharpoons MLL'L''H_s + ML'$$
$$K^{XI} = \beta_{IQH_s}\beta_{IML'}/\beta_{IMLL'}\beta_{IML'L''H_s} \tag{9}$$

$$MLL''H_s + ML'L''H_s \rightleftharpoons MLL'L''H_s + ML''H_s$$
$$K^{XII} = \beta_{IQH_s}\beta_{IML''H_s}/\beta_{IMLL''H_s}\beta_{IML'L''H_s}. \tag{10}$$
It has been found that log K^X, log K^{XI} and log X^{XII} are 0.99, 0.15 and 0.59 for the 1:1:1:1:1 species of Co(II) system. The same trend was obtained for Ni(II) system except the log values are less in magnitude than that in Co(II) system, i.e. 0.61, −0.65 and 0.13, respectively. These results showed that the equilibrium reaction (9) is not favored in comparison with the reactions (8) and (10) and they reflect the high stability of the monobinary species of Gly and Pm with respect to that of Imd. The log values for K^X, K^{XI} and K^{XII} for 1:1:1:1:0 for Co(II) quaternary species are greater (0.26, 0.21 and 1.32, respectively) than that of Cu(II) system (−0.56, −1.76 and 0.28, respectively). One may conclude that the formation of quaternary species from ternary species are more

favored in Co(II) system than in that of Cu(II) system. The rationale is probably of structural origin.

The stabilization enhancement of the formation of 1:1:2:1:s complex species may be analyzed in a way similar to that discussed for the 1:1:1:1:s species. In such case lots of equilibrium reactions may be considered. However, the most important reacting species are the mono-binary and ternary species. One may consider only the following equilibria;

$$ML + 2ML' + ML''H_s \rightleftharpoons MLL'_2L''H_s + 3M;$$
$$K^{XIII} = \beta_{2QH_s}/\beta_{IML}\beta^2_{IML'}\beta_{IML''H_s} \tag{11}$$

$$ML + ML'_2L''H_3 \rightleftharpoons MLL'_2L''H_s + M;$$
$$K^{XIV} = \beta_{2QH_s}/\beta_{IML}\beta_{IML_2L''H_s} \tag{12}$$

$$2ML' + MLL''H_s \rightleftharpoons MLL'_2L''H_s + 2M;$$
$$K^{XV} = \beta_{2QH_s}/\beta^2_{IML'}\beta_{MLL''H_s} \tag{13}$$

$$ML''H_s + MLL'_2 \rightleftharpoons MLL'_2L''H_s + M;$$
$$K^{XVI} = \beta_{2QH_s}/\beta_{IML''H_s}\beta_{MLL'_2} \tag{14}$$

$$MLL' + ML'L''H_s \rightleftharpoons MLL'_2L''H_s + M;$$
$$K^{XVII} = \beta_{2QH_s}/\beta_{MLL'}\beta_{ML'L''H_s} \tag{15}$$
where β_{2QH_s} is the formation constants of the species 1:1:2:1:s. Unfortunately, not all the formation constants in eqns (11)–(15) can be evaluated due to the lack of binary as well as ternary formation constants. The formation constants K^{XIV} and K^{XVI} for the species 1:1:2:1:1 cannot be determined since we have not obtained the ternary species $ML'_2L''H_s$ and MLL'_2 except in one Cu(II) system, Table 3(b). The log values for K^{XVII} for the same quaternary species are negative for the most metal ions (−0.20, −1.35, −1.53, −0.15 for Co(II), Ni(II) Cu(II) and Cd(II), respectively). It may be noticeable that Ni(II) and Cu(II) exhibit the largest negative values for the log K^{XVII}. This finding reflects the great stability of the ternary species of both Ni(II) and Cu(II) shown in the equilibrium reaction (15). The log values for K^{XIII} and K^{XV} for the species 1:1:2:1:1 follow the same trends for all metal ions (log K^{XIII} = 0.60, −0.67, −1.71, 1.03, 2.13 and log K^{XV} = 0.83, −0.09, −2.05, 2.03, 2.92 for Co(II), Ni(II), Cu(II), Zn(II) and Cd(II). The negative values for the log K's are restricted to Ni(II) and Cu(II). The forementioned results indicated that the formation of quaternary species 1:1:2:1:1 cannot arise from just the iteraction of mono-binary species among each other or the interaction of mono-binary species with ternary species or the interaction of ternary species with each other except in Co(II), Zn(II) and Cd(II). This may lead to the conclusion that structural reasons are playing a role in such complex formation. Cu(II) and Ni(II) binary and ternary species are less apt to form the oactahedral structural quaternary species, easily allowed for other metal ions.

It is worth to mention that the values of log K's evaluated for the eqns (4)–(15) are not corrected statistically since the structures of the complexes and the magnitude of the thermodynamic *trans*-effect were unknown. However, under the assumption that these metal ions can have octahedral structures and that the thermodynamic *trans* effect is negligible, there is a statistical correction of −log 6 (−0.78) for all log K's. The log values which are greater than −0.78 will imply enhancement of quaternary complex formation.
Fig. 2. MINIQUAD computed distribution of complex species with pH of Cu(II) quaternary systems, Pm–Gly–Imd–Cu(II).

A representative complex distributions of the Cu(II) quaternary systems are shown in Fig. 2. It is clear that binary complexes are unable to compete successfully with quaternary and ternary complexes at pH's lower than 8.5 in both systems. In addition, quaternary complexes are more predominant than ternary complexes. The ternary complexes which were found to co-exist with quaternary complexes are mainly 1:1:0:1:2 species (Pm:Gly:Imd:M:sH) system. Due to the early precipitation (at pH ~ 9) in the glycine quaternary systems, one cannot predict the type of complex species which may exist at pH's higher than 9.0.

CONCLUSION

In the mammalian body, the variation in the ligand types and their concentrations exceed the various metal concentrations in such a way that a wide range of complexing species compete actively for different metal ions. In this work we have proved that not only binary and/or ternary complexes could be formed but quaternary complexes may also be formed. Clearly, mixed-ligand formation has important biological implications due to the enhanced probability of bringing of different ligands together or of facilitating enzyme-substrates interaction through a metal ion link. This was found to be true in the ternary and quaternary systems studied in this work. Generally, the presence of Pm (specially the protonated forms) in the vicinity of metal ions facilitate the further attack of other nucleophilic ligands which leads to the formation of the quaternary complex species. It also seems that the electrostatic interactions between different ligands are diminished as Pm becomes protonated. These complexes are positively charged in most cases which effectively facilitate their transport in biological fluids. However, transfer of these complexes through cell membranes requires them to be neutral, a criterion not in their favor. This is only fulfilled in case of some of the ternary complexes of Pm–Gly system.

It has been shown in this work that free metal ions cannot exist in a wide pH range (>6–9), and are mostly found in the form of mixture of ternary and quaternary complex species and hence they may be found as such in most mammalian biological fluids. However, at pH's higher than 9 or less than 6, they may exist in the form of a mixture of binary, ternary and quaternary species and are probably found as free ions at pH's lower than 4.0 (specially in Cu(II) systems).

Abstract—Ten separated oligomeric methylsiloxanes, with cyclic and linear segments of different size, have been prepared and studied. The thermal decomposition of these compounds has been investigated in the temperature range from 400–600°C. The pentasiloxy cycle proved to be more stable than the tetrasiloxy in the investigated compounds. Compounds containing the strained cyclotrisiloxy group have the lowest stability. On the basis of the pyrolysis product distributions, a general mechanism of dimethylsiloxane elimination and addition is proposed.

INTRODUCTION

The works dealing with the thermal decomposition of siloxanes were concentrated for long on siloxane polymers. Very important conclusions have been drawn concerning the decomposition of the polydimethylsiloxane to cyclic oligomers under heat treatment.[1-3] In a previous paper[4] we studied some cyclolinear methylsiloxane polymers and reported how the thermal decomposition of the macromolecular chain is influenced by the branching points regularly built in. In order to get more information about the thermally induced processes in the siloxanes at the linear and branched molecular segments, we turned to the study of volatile oligomeric siloxane compounds.

The investigated compounds are composed of two metylsilsesquioxy $(CH_3SiO_{1.5})$ and six to twelve dimethylsiloxy $[(CH_3)_2SiO]$ groups arranged so that two cyclotrisiloxanyl, cyclotetrasiloxanyl, or cyclopentasiloxanyl rings are linked by a dimethylsiloxane chain.

EXPERIMENTAL

The following examples are given to illustrate the general procedures used in the synthesis of methylbicyclosiloxanes.[5,6] The physical constants of the compounds synthetized are given in Table 1.

Bis(pentamethylcyclotrisiloxy) tetramethyldisiloxane

In a three-neck flask equipped with stirrer and thermometer 10 cm^3 of dry benzene was placed. 16.0 g (0.0958 mol) of 1,3-dihydroxytetramethyldisiloxane, 19.5 g (0.193 mol) of triethylamine in 100 cm^3 dry benzene and 9.6 g (0.0638 mol) of methyltrichlorosilane in 100 cm^3 dry benzene were added dropwise over two hours at 5°C. The mixture was kept at 20–22°C for 6 hr. The triethylamine hydrochloride was filtered off, the solution was washed with water, then distilled at 13 mbar to yield 9.6 g (51.9%) of bis(pentamethylcyclotrisiloxy)tetramethyldisiloxane at 120–122°C. Found: C, 29.25; H, 7.39; Si, 38.20; Calc. for $C_{14}H_{42}Si_8O_9$: C, 29.03; H, 7.31; Si, 38.80%.

1-(Heptamethylcyclotetrasiloxy) - 3 - (nonamethylcyclopentasiloxy) - tetramethyldisiloxane

In a three-necked flask equipped with stirrer and thermometer 9.13 g (0.045 mol) of 1,3-dichlorotetramethyldisiloxane in 50 cm^3 of dry diethyl ether was placed. 11.19 g (0.030 mol) of hydroxynonamethylcyclopentasiloxane and 3.1 g (0.030 mol) of aniline in 50 cm^3 dry diethyl ether were added dropwise over 2 hr while the mixture was kept at 20–22°C. Two hours later an additional 8.94 g (0.030 mol) of hydroxyheptamethylcyclotetrasiloxane and 3.15 g (0.030 mol) of aniline in 50 cm^3 dry diethyl ether were added. The mixture was stirred for several hours then the aniline hydrochloride was filtered off. The distillation at 0.3 mbar yielded 2.7 g of bis(heptamethylcyclotetrasiloxy)tetramethyldisiloxane (b.p. 105°C), 3.6 g of 1-(heptamethylcyclotetrasiloxy) - 3 - (nonamethylcyclopentasiloxy)tetramethyldisiloxane (b.p. 115–116°C) and 2.0 g of bis(nonamethylcyclopentasiloxy) tetramethyldisiloxane (b.p. 126–128°C).

Hydroxyheptamethylcyclopentasiloxane

In a two-necked flask equipped with stirrer and thermometer 0.9 g (0.05 mol) of water, 4.29 g (0.046 mol) of aniline and 1 g acetone in 100 cm^3 of diethyl ether were placed. 17.3 g (0.044 mol) of chlorononamethylcyclopentasiloxane in 10 cm^3 of diethyl ether was added dropwise over 1 hr, while the temperature of the mixture was kept at 5–8°C. The mixture was stirred for 2 hr, the aniline hydrochloride was filtered off. The solution was washed with water, then distilled at 20 mbar to yield 12.8 g (78.0%) of hydroxyheptamethylcyclopentasiloxane.

Chlorononamethylcyclopentasiloxane

In a three-necked flask, equipped with stirrer and thermometer 75 cm³ dry diethyl ether was placed. 30.0 g (0.0955 mol) of 1, 7-dihidroxyoctamethyltetrasiloxane and 18.1 g (0.194 mol) of aniline in 150 cm^3 of dry diethyl ether and 19.7 g (0.130 mol) of trichloromethylsilane in 150 cm^3 of dry diethyl ether were added dropwise simultaneously over 2 hr while the temperature was kept at 4–6°C. The reaction mixture was stirred for 8 hr then the aniline hydrochloride was filtered off. The mixture was distilled at 20 mbar to yield 20.9 g (56.2%) chlorononamethylcyclopentasiloxane (b.p. 65–67°C).

Pyrolysis

Pyrolysis experiments were performed at 400–600°C in evacuated and sealed Pyrex glass tubes. The sample weight was 5 mg,

the volume of the tube was about 0.17 cm³. In fused silica tubes the same degradation products were found as in pyrex glass, but the decomposition was slightly slower.

Analysis of the pyrolysis products

The analysis of the pyrolysates was performed on a Perkin–Elmer-900 gas chromatograph equipped with Flame Ionization Detector and electronic integrator PE D-26. The peak area values were converted into molar amounts with response factors measured for cyclic and bicyclic methylsiloxane standards. Identification of the pyrolysis products was based on the retention time coincidence with pure authentic materials on three gas chromatographic columns. The following columns were used:

—3.5 m, 2 mm i.d. packed column; support: 80–100 mesh Chromosorb G; phase: 5% OV-17; temperature program from 40–280°C at 6.5°/min.

—3 m, 2 mm i.d. packed column: support: 80–100 mesh Chromosorb G; phase: 3% OF-1; temperature program: from 40–220°C at 6.5°/min.

—20 m, 0.2 mm i.d. Fused silica capillary column, coated with OV-101 phase; temperature program: from 50–200°C at 6°/min.

RESULTS AND DISCUSSION

The thermal stability of the ten compounds has been compared on the basis of the amounts that remained unchanged after pyrolysis performed under similar conditions. These values, determined after pyrolysis at 500°C for 20 min, are given in Fig. 1. The following tendencies of the relation of thermal stabilities are observed in this figure:

(1) The strained cyclotrisiloxy group containing compounds have the poorest stability among the isomeric bicycles (see T_2D_6 and T_2D_9 isomers).

(2) The stability increases with ring size, if compounds composed of 3, 4, and 5 siloxane membered rings (see the full lines in Fig. 1) are considered.

(3) The more siloxane groups separate the two rings the less stable is the compound (see the dashed lines in Fig. 1).

The thermal decomposition of methylsiloxanes leads to a series of products, most of them identical for all samples. Figure 2 shows the pyrolysis product distribution of 1,3-bis(pentamethylcyclotrisiloxy)tetramethyldisiloxane at 500°C. The methylcyclosiloxane oligomers (mainly D_3 and D_4) are the more important products. Their amount increases as the pyrolysis temperature is raised. The variation of the quantity of dimethylsiloxane in cyclic pyrolysis products with the molecular composition of the pyrolysed siloxane is shown in Fig. 3 for two different pyrolysis temperatures. There is a linear relationship between the molar amount of D units, forming cyclic pyrolysis products, and the D content of the pyrolysed molecule, at both temperatures examined.

The pyrolysis products range from T_2D_3 to T_2D_{n+2} when T_2D_n separated molecules are pyrolysed. The process taking place under pyrolysis may be described by the following general formulae:

$$T_2D_n \underset{450\text{–}500^\circ C}{\overset{450\text{–}600^\circ C}{\rightleftharpoons}} T_2D_{n-x} + x[D] \quad \begin{matrix}(n = 6, 7, \ldots 12)\\(x = 1, 2, \ldots n-5)\end{matrix} \quad (1)$$

$$T_2D_n + y[D] \overset{450\text{–}500^\circ C}{\rightleftharpoons} T_2D_{n+y} \quad (y = 1, 2) \quad (2)$$
Fig. 1. The amounts remained unchanged after pyrolysis at 500°C for 20 min, characterizing the relative thermal stabilities, plotted against molecular composition. Symbols: > = D, i.e. $(CH_3)_2SiO$ >— = T, i.e. $CH_3SiO_{1.5}$.
Fig. 2. Pyrolysis products of 1,3-bis(pentamethylcyclotrisiloxy)tetramethyldisiloxane (T_2D_6, structure in frame), separated on OV-101 capillary gas chromatographic column. Pyrolysis: 500°C, 20 min. For structural symbols see Fig. 1.
Fig. 3. The number of D units produced from 100 molecules of bicyclic siloxane, forming cyclosiloxanes under pyrolysis at 500°C(+) and 580°C(x) resp., plotted against the molecular composition of the pyrolysed compounds.

$$T_2D_z \underset{500-600°C}{\overset{}{\rightleftharpoons}} T_2D_{z-1} + [D] \quad (z = 3,4,5,6) \qquad (3)$$

$$3[D] \underset{450-600°C}{\overset{}{\rightleftharpoons}} D_3 \qquad (4)$$

$$D_3 + [D] \underset{450-600°C}{\overset{}{\rightleftharpoons}} D_4 \qquad (5)$$
Reactions (4) and (5) proposed by Davidson and Thompson,[7] involving dimethylsilanone intermediate [D], explain the formation of cyclic oligomers. On the basis of the quantitative and structural analysis of the siloxanes occurring in the reactions (1)–(3), the following conclusions can be drawn:

(1) The elimination of dimethylsilanone from the separated siloxanes—reaction (1)–takes place equally from the linear separating segment and from the tetrasiloxy or pentasiloxy cycle. The reaction leads to new separated compounds containing two linked rings in which the size of the cyclic groups becomes gradually smaller and the separating chain gradually shorter. In Fig. 4. these processes are illustrated in a scheme of decomposition of the siloxane given as an example in Fig. 2.
Fig. 4. Scheme of [D] elimination and addition reactions under pyrolysis of a T_2D_9 bicyclic siloxane.

(2) The backward reaction, the readdition of dimethylsilanone happens preferably to the cyclotrisiloxy group. The same preference can be observed in the case of the addition of the dimethylsilanone to the original compound, resulting products of higher molecular mass than the parent molecule (reaction 2). Note that these reactions are important only in the lower pyrolysis temperature range.

(3) The elimination and addition from and to the bicyclic products of lower molecular mass (T_2D_{3-6}, most of them can be of cumulated structure only) seem to reach an equilibrium soon (reaction 3). We have to point out that the relative amounts of the fused-ring bicyclic products are roughly the same for all kind of methylsiloxanes examined at a given temperature. Two out of the four most important fused-ring bicyclic pyrolysis products contain a trisiloxane cycle known as a strained ring.[8] In this way the relative amounts do not reflect the relative thermal stabilities. The distribution of these products (see Fig. 2) may be interpreted as being produced by the equilibrium between elimination and addition reactions.

The above discussion of the thermally induced reactions involves only the products formed in quantities larger than 0.5% of the pyrolysate.

Smaller amounts of different tricycles (T_4D_n) have been also found in the pyrolysates above 550°C.

STEREOSELECTIVITY IN THE ADDUCT FORMATION BETWEEN CHIRAL Eu(III) β-DIKETONE COMPLEXES AND SULPHOXIDES, SULPHONES AND PHOSPHATE ESTERS

HARRY G. BRITTAIN[1]
Chemistry Department, Seton Hall University, South Orange, NJ 07079, U.S.A.

Abstract—The adduct formation which takes place when Eu(III) chelates of trifluoroacetyl-*d*-camphor and heptafluorobutyryl-*d*-camphor bind substrates has been studied. Enhancement of Eu(III) luminescence as a function of substrate concentration has been used to obtain information on the nature of the chelate/substrate adducts, and the stereochemistry of the complexes was studied by means of circularly polarized luminescence (CPL) spectroscopy. While no optical activity can be measured for, the free chelates, formation of the adduct complexes usually led to the observation of very strong chirality even though the substrates were themselves achiral. It was concluded that adduct formation causes the bulky camphorato ligands to interact and adopt a configuration of lowest energy. This process perturbs the diastereomer ratios and yields a partial resolution of these very labile complexes.

INTRODUCTION

The existence of stereoselectivity in transition metal complexes containing chiral β-diketone ligands has become well established, and studies of this effect provide interesting information regarding interligand interactions in metal chelate systems. Most of these works have involved complexes in which the β-diketone contains the camphorato moiety:
The most commonly studied systems are those of (+)-hydroxymethylenecamphor (where R = H, and abbreviated as HMC) and (+)-acetylcamphor (R = CH₃, and abbreviated as ATC). A racemic mixture of a *tris*-octahedral complex would contain four diastereomers: Δ-*cis* and Λ-*cis* (the facial isomers), as well as Δ-*trans* and Λ-*trans* (the meridional isomers).

Early work established that with kinetically inert Co(III) complexes, if (+)-R,R-HMC or (+)-R,R-ATC was used to prepare the chelates then the Λ-*trans*-diastereomer was present in the greatest excess.[2,3] It was subsequently shown through x-ray diffraction studies that the absolute configuration of Cr(+ATC)₃ was indeed Λ-*trans*.[4] Later studies determined the relative abundances of the four diastereomers in the racemic preparations of Co(+ATC)₃[5,6], Cr(+ATC)₃[5] and Ru(+ATC)₃,[7] and found that while the Λ-isomer was present in the largest excess, considerable amounts of the Δ-isomer was also produced. One general conclusion associated with all the studies was that the existence of

the two *trans*-isomers was greatly favored over the two *cis*-isomers.

In our laboratory, we have been investigating the stereoselectivity associated with the lanthanide complexes of chiral β-diketones. Recently, it was demonstrated that the optical activity of labile Tb(+ATC)₃ was profoundly affected by the solvent the material was dissolved in.[8] The lanthanide chelates differ from the transition metal analogues somewhat in that the lanthanide complexes can expand their coordination number through adduct formation, and it was found that the steric nature of the substrate in the Tb(+ATC)₃ adduct determined the particular diastereomer which dominated *even though the substrates were not themselves chiral.*[8] This behavior is quite analogous to work carried out on labile V(+ATC)₃ complexes in which the Δ-*trans*/Λ-*trans* ratio (as determined by NMR methods) could be varied from 0.31 to 0.97 depending on the nature of the solvent used.[9]

Eu(III) chelates of fluorinated camphorato β-diketones have been used in the NMR determination of enantiomeric purity,[10,11] but no attention has been paid to the effects which stereoselectivity might have on such measurements. Such effects have been shown to exist; Eu(TFAC)₃ (TFAC = (+)-3-trifluoroacetylcamphor, and has R = CF₃) shows no optical activity in noncoordinating solvents, but shows extremely intense optical activity when dissolved in dimethyl sulphoxide solvent.[12] Similar results were reported for Eu(HFBC)₃ (HFBC = (+)-3-heptafluorobutyrylcamphor, with R = C₃F₇), but the sign of the optical activity was found to be opposite to that of Eu(TFAC)₃ even though the absolute configuration of both ligands was the same.[13] Synthesis of mixed-ligand Eu(III) chelates subsequently showed that the stereoselectivity arose from the adduct formation with the substrate molecules.[14]

In the current work, we present the results of studies involving the adduct formation of Eu(TFAC)₃ and Eu(HFBC)₃ with phosphate esters, sulphoxides and sulphones. In many cases, adduct formation with these substrates leads to strong optical activity with this chirality clearly being a stereoselective effect. The optical activity was measured via circularly polarized luminescence (CPL) spectroscopy rather than the more

conventional method of circular dichroism, since the f-f absorptions of the lanthanide complexes are too weak to permit CD work except at high concentrations. Recent correlations relating the absolute configuration of trigonal Eu(III) complexes with the signs of CD and CPL peaks permitted the prediction of which particular isomer predominated in the Eu(TFAC)₃ and Eu(HFBC)₃ adduct systems.

EXPERIMENTAL

Eu(TFAC)₃ and Eu(HFBC)₃ were purchased from Aldrich, and dried for a prolonged period in a vacuum desiccator. Spectrograde CHCl₃ (dried over molecular sieves) was used as the solvent for all studies. Trimethyl phosphate, triethyl phosphate, tributyl phosphate, dimethyl sulphoxide, di-n-butyl sulphoxide, diphenyl sulphoxide, dimethyl sulphone, di-n-butyl sulphone and diphenyl sulphone were all obtained from Aldrich and used as received.

Luminescence titrations were carried out for each of the Eu(III) chelates with each of the substrates. Stock solutions of Eu(TFAC)₃ and Eu(HFPC)₃ were prepared to be 5 mM, and titrated with microlitre amounts of substrate solutions (whose concentrations ranged from 0.1 M to 0.5 M, depending on the desired ratio of substrate/chelate) which were added to 3 ml of the Eu(III) solution in the fluorescence cuvette. The total luminescence (TL) and CPL spectra of the $^5D_0 \rightarrow {}^7F_0$ (580 nm), $^5D_0 \rightarrow {}^7F_1$ (595 nm), and $^5D_0 \rightarrow {}^7F_2$ (615 nm) was followed after each addition. Reproducibility in the Eu(III) TL intensities was monitored by periodically recording the emission intensity of a piece of uranium glass.

All luminescence measurements were obtained on a medium-resolution CPL spectrometer constructed in our laboratory, and whose basic operation has been described.[15] An excitation wavelength of 365 nm was used to excite the compounds (obtained by passing the output of a 200-W Hg-Xe arc lamp through a 0.1-m grating monochromator and suitable glass filters), with a bandpass of 16-nm being used. As before, the emission was collected at 180° to the exciting light (to eliminate any possible linear polarization effects) and passed through a concentration solution of NaNO₂ to remove any unabsorbed exciting light. The emission was analyzed by a 0.5-m grating monochromator at 1-nm bandpass, and detected by an EMI 9798B photomultiplier tube (S-20 response). No attempt was made to correct the spectra for system response since the wavelength regions scanned were quite narrow and any correction would be minor at best. The TL and CPL signals were recorded simultaneously to insure that the ratio of these quantities would account for any instrumental fluctuations.

RESULTS

Irradiation of the Eu(III) chelates in the near-UV region of the spectrum results in efficient population of the excited $^5D_0$ state, and to luminescence occurring in red spectral regions. Unlike most other Eu(III) β-diketone complexes, the luminescence of free Eu(FTAC)₃ and Eu(HFBC)₃ is exceedingly weak and difficult to measure. However, on our equipment the TL is large enough to demonstrate that no CPL is present in the luminescence spectrum. This result is not surprising when one considers that in a racemic mixture of a highly labile chelate, all four diastereomers would be present and the CPL of these would approximately cancel. This has been shown for the analogous transition metal complexes, where the CD of the two cis-isomers is essentially equal in magnitude but opposite in sign to that of the two trans-isomers.[5] While for the transition metal complexes, one finds an excess of the Λ-isomers (when starting with (+)-TFAC or (+)-HFBC) in the free chelates,[5-7] the larger ionic radius of the lanthanide ions apparently allows the three β-diketone ligands to coexist without significant interaction.

Sulphoxides

The addition of dimethyl sulphoxide to a CHCl₃ solution of either Eu(TFAC)₃ or Eu(HFBC)₃ results in a modest increase in the TL intensity within the $^5D_0 \rightarrow {}^7F_J$ transitions of the Eu(III) ion. Such increases have been attributed in the past to protection of the metal ion from solvent quenching via formation of an insulating sheath,[16] and is a feature characteristic of adduct formation.[17-20] In these earlier works,[19,20] we have outlined the basic methods whereby one may use these TL intensity enhancements to obtain the association constants for the 1:1 and 1:2 adducts:

$$Eu(DK)_3 \;\; + S \rightleftharpoons Eu(DK)_3(S)$$
$$Eu(DK)_3(S) + S \rightleftharpoons Eu(DK)_3(S)_2.$$
In Fig. 1, the enhancement of Eu(TFAC)₃ and Eu(HFBC)₃ luminescence by dimethyl sulphoxide is shown for the initial portions of the titration. One may easily see that the luminescence intensity does not reach a limiting value even after the addition of 15 equivalents of substrate per mole of Eu(III) chelate, although the amount of increase tapers off substantially. Continued addition of substrate results in further increases in TL intensity, although limiting values can be eventually reached. The titration curves up to 150 equivalents of substrate may be found in Fig. 2, and the final limiting intensity was obtained by dissolving an equivalent amounts of chelate in neat dimethyl sulphoxide solvent. The tendency of the titration curves not to reach a limiting value except at very high concentrations of
Fig. 1. Luminescence titration of Eu(HFBC)₃ (upper trace) and Eu(TFAC)₃ (lower trace) with dimethyl sulphoxide. Only the initial portion of the titration is shown, and the emission intensities are given in arbitrary units.
Fig. 2. Full luminescence titration of Eu(HFBC)₃ (upper) and Eu(TFAC)₃ (lower with dimethyl sulphoxide. The intensity scale is in arbitrary units.

substrate prevented a calculation of the association constant in the usual manner.[19,20] However, examination of Fig. 2 reveals that the initial portion of the curves provides evidence for the efficient formation of the 1:1 chelate/substrate complex. The remaining portion of the titration curve probably represents formation of the 1:2 adduct, as well as geometrical rearrangements of the β-diketone ligands in the manner as has been reported previously.[19] Application of Job's method of continuous variations led to somewhat ambiguous results, but did indicate the existence of 1:1 and higher stoichiometries. Dibutyl sulphoxide was found to yield much smaller degrees of TL enhancement with Eu(TFAC)₃ and no enhancement with Eu(HFBC)₃. No sharp increases in TL intensity was noted, and the Job's plots only indicated the presence of 1:1 complexes. In fact, it was found that addition of solid dibutyl sulphoxide in large quantities never led to peaking of the TL spectra. We conclude that the 1:1 dibutyl sulphoxide adduct only forms partially, even at huge ratios of substrate to chelate. Such behavior is consistent with the existence of very weak complexation (and possibly no complexation in the case of Eu(HFBC)₃).

No data could be obtained when diphenyl sulphoxide was added to CHCl₃ solutions of either Eu(TFAC)₃ or Eu(HFBC)₃, as no TL enhancements could be measured at any concentration of this substrate. One may conclude that either this substrate does not enhance the luminescence intensity upon binding, or the degree of complexation is so small that no enhancement is seen. Given the bulkiness of the camphorato ligands, the latter possibility is quite likely.

Accompanying the TL increases associated with the dimethyl sulphoxide adduct formation is the appearance of optical activity within the Eu(III) emission bands. However, this optical activity is not observed until a

considerable amoung of substrate is added to the chelate solutions (at least 50 equivalents of dimethyl sulphoxide per mole of Eu(III) chelate is required). The CPL spectra obtained for the $^5D_0 \rightarrow {}^7F_1$ band system at high concentrations of dimethyl sulphoxide are shown in Fig. 3 for Eu(TFAC)₃ and Eu(HFBC)₃, while the spectra associated with the $^5D_0 \rightarrow {}^7F_2$ transitions are found in Fig. 4. These spectra are essentially the same as we have presented earlier for Eu(TFAC)₃[12] and Eu(HFBC)₃[13] in neat DMSO solvent. It is highly significant to note that while both β-diketone ligands are derived from the same isomer of d-camphor, the chirality experienced by the Eu(III) ion is the opposite in these two cases. This observation immediately suggests that a stereoselective mechanism is responsible for the observed optical activity, and that opposite diastereomers have been selected in the two systems.

The CPL data may be placed on a quantitative basis by computing the luminescence dissymmetry factor, a quantity which is related to the rotational strength.[21] If the emitted intensities of left- and right-circularly polarized light are represented by I_L and I_R, respectively, then the TL intensity is defined as:

$$I = 1/2(I_L + I_R)$$

and the CPL intensity is given by:

$$\Delta I = I_L - I_R.$$

The luminescence dissymetry factor is defined as:

$$g_{lum} = \Delta I/I$$

and is analogous to the Kuhn dissymmetry factor used in
Fig. 3. Circularly polarized luminescence spectra obtained for the Eu(TFAC)₃/dimethyl sulphoxide (lower trace) and Eu(HFBC)₃/dimethyl sulphoxide (upper trace) adducts in CHCl₃ solution. The spectra correspond to emission within the $^5D_0 \rightarrow {}^7F_1$ transition.
Fig. 4. Circularly polarized luminescence spectra obtained within the $^5D_0 \rightarrow {}^7F_2$ (Eu(III) transition for Eu(TFAC)$_3$/ dimethyl sulphoxide (lower trace) and Eu(HFBC)$_3$/dimethyl sulphoxide (upper trace).

circular dichroism spectroscopy. Values for the dissymmetry factors have been collected in Table 1 for the Eu(TFAC)$_3$ and Eu(HFBC)$_3$ complexes with dimethyl sulphoxide, and these results are essentially the same as those we have previously presented for studies carried out on completely different equipment.[12,13]

No CPL was found when complexing Eu(HFBC)$_3$ with either dibutyl sulphoxide or diphenyl sulphoxide. Such observations are consistent with the earlier TL enhancement results. However, very weak optical activity was found in the case of Eu(TFAC)$_3$/dibutyl sulphoxide. The CPL spectrum was identical to that obtained for Eu(TFAC)$_3$/dimethyl sulphoxide, although the dissymmetry factors (as shown in Table 1) were

significantly smaller in magnitude. All the data indicate that while dimethyl sulphoxide reacts fairly strongly with the chelates to form 1:1 and 1:2 adducts, the other sulphoxides react only weakly or not at all. In addition, adduct formation with Eu(HFBC)$_3$ is seen to be much weaker than with the adduct formation of Eu(TFAC)$_3$ in spite of the extra fluorination (and predicted increased Lewis acidity) associated with the HFBC chelate.

Sulphones

It has been established that sulphones are capable of binding to Eu(III) chelates composed of achiral[22] and chiral[11] β-diketone ligands. We find that addition of dimethyl sulphone or dibutyl sulphone to a CHCl$_3$ solution of Eu(TFAC)$_3$ or Eu(HFBC)$_3$ yields no more than a 5% increase in TL intensity, and that the addition of diphenyl sulphone yields no TL enhancement that we can measure. These very low degrees of luminescence enhancement prevented the calculation of association constants for the sulphone adducts. It is quite clear that while these substrates are capable of bonding to the Eu(III) chelates,[11,22] the mode of attachment is such that the emission intensity of the Eu(III) ion is not enhanced. These observations would imply that the sulphones form poor shields which do not adequately protect the Eu(III) ion from solvent quenching. Application of Job's method of continuous variations to the sulphone adducts yielded poor quality results due to the low TL enhancements, but apparently only 1:1 adducts form in the CHCl$_3$ solution for both the dimethyl and dibutyl sulphone substrates. This behaviour is quite different from what was observed with the sulphoxide adducts; in that situation the dimethyl sulphoxide substrate could form 1:1 and 1:2 adducts with Eu(TFAC)$_3$ and Eu(HFBC)$_3$, while dibutyl sulphoxide formed a 1:1 complex with Eu(TFAC)$_3$ and no complex with Eu(HFBC)$_3$.

However, while the TL enhancement with the sulphones is minor at best with dimethyl and dibutyl sulphone, it was found that CPL spectra could be obtained in some cases. Unlike dimethyl sulphoxide (where strong CPL and TL signals were found), with dimethyl sulphone no CPL was observed. On the other hand, CPL was obtained in the dibutyl sulphone adducts with both Eu(TFAC)$_3$ and Eu(HFBC)$_3$ (which is somewhat different from the analogous sulphoxide results). No

Table 1. Luminescence dissymmetry factors for the Eu(TFAC)$_3$ and Eu(HFBC)$_3$ adducts with sulphoxides

Adduct	$^5D_0 \rightarrow {}^7F_1$	$^5D_0 \rightarrow {}^7F_2$
Eu(TFAC)$_3$/DMSO	-0.75 (a) -1.80 (b)	+0.35
Eu(HFBC)$_3$/DMSO	+0.15 (a) +0.29 (b)	-0.040
Eu(TFAC)$_3$/DBSO	- (a) -0.081 (b)	+0.0074

Notes: (1) DMSO = dimethyl sulfoxide, and DBSO = dibutyl sulfoxide.

(2) Within the $^5D_0 \rightarrow {}^7F_1$ band, two CPL peaks are noted: peak (a) is at 587 nm and peak (b) is found at 596 nm. With the DBSO adduct, peak (a) could not be measured due to its extremely low intensity.

optical activity was noted with the diphenyl sulphone systems. Values for the luminescence dissymmetry factors of the dibutyl sulphone adducts may be found in Table 2. The CPL spectra were essentially identical in lineshape to those shown in Figs. 3 and 4, and only differed in the observed magnitudes.

Phosphate esters

Addition of either trimethyl, triethyl or tributyl phosphate to a $CHCl_3$ solution of $Eu(TFAC)_3$ or $Eu(HFBC)_3$ results in a sizable increase in TL intensity. We have used these TL increases previously to obtain association constants for the chelate/substrate adducts, and noted at that time that only 1:1 complexes were produced.[30] Addition of triphenyl phosphate resulted in very little TL enhancement, which we took to imply that adduct formation was quite weak with this substrate. Typically the TL intensity was observed to reach an apparent maximum by the time two equivalents of phosphate ester substrate had been added per mole of Eu(III) chelate, and approximately 75% of the limiting value was attained after the addition of one equivalent.[20] The data obtained at this time indicated that only 1:1 chelate/substrate complexes formed.

During the course of the present studies, it was found that the titration curves presented earlier[20] were incomplete. While the data we had presented did indeed appear to level off, addition of large excesses of neat substrate led to further increases in TL intensity. These observations parallel those just made for the dimethyl sulphoxide titrations, and also indicate that 1:2 chelate/substrate complexes form as well as the 1:1 complexes. However, it was found that the limiting TL intensity could only be reached in the neat solvent, indicating that the possible formation of the 1:2 complex is only a weak process. This observation regarding the titration curves indicated that formation constants calculated from such results would be of dubious value. As a result, they have not been obtained from the spectroscopic results.

Accompanying this rise in TL intensity was the appearance of CPL within the Eu(III) emission bands. The CPL lineshapes were absolutely identical to those already shown for the sulphoxide and sulphone adducts (which we have shown in Figs. 3 and 4). However, no CPL is observed until a considerable excess of substrate has been added, and the CPL does not reach a limiting intensity unless the chelate is dissolved in neat solvent. Values for the luminescence dissymmetry factors asso-

ciated with all Eu(III) emission bands of the chelates dissolved in neat solvents may be found in Table 3.

One very striking difference between the sulphoxide and phosphate ester results is that with the latter substrates the sign of the CPL for the $Eu(TFAC)_3$ and $Eu(HFBC)_3$ chelates is the same in every case (opposite signs were found with sulphoxide and sulphone adducts). These trends indicate that with the phosphate esters, the nature of the stereoselectivity is such that the steric nature of the ligand sidechain does not play an important role in determining the predominant diastereomer (as it does with the sulphoxide substrates).

DISCUSSION

The data presented in the earlier sections clearly show that the nature of the bonding existing between the Eu(III) chelates and the substrates used in the present work appears to be different in every case. Given the general bonding trends of lanthanide β-diketone complexes, it is quite likely that the substrate bonds directly to the metal ion via a terminal oxygen. All substrates form a 1:1 adduct:

$$Eu(DK)_3 + S \rightleftharpoons Eu(DK)_3(S)$$

while 1:2 adducts form when the substrate (S) is dimethyl sulfoxide or a phosphate ester:

$$Eu(DK)_3(S) + S \rightleftharpoons Eu(DK)_3(S)_2.$$

This behaviour is possible since it is also well known that lanthanide ions are capable of expanding their coordination number beyond six.

In a previous work, it had been found that in the titration curves of $Eu(TFAC)_3$ and $Eu(HFBC)_3$ with simple amines, 1:2 complexes formed with the substrate molecules being added in a cooperative manner.[19] It has been shown that if $K_1 = 4 K_2$, then the two substrate molecules bind with equal efficiency.[23] Non-equivalent bonding of substrates has been noted for the $Eu(FOD)_3$ (FOD = 6,6,7,7,8,8,8 - heptafluoro - 2,2 - dimethyloctane - 3,5 - dione) adducts of dimethyl sulphoxide,[24] although the cooperativity demonstrated here was opposite to that illustrated earlier.[19] The existence of positive and negative cooperativities in substrate bonding provides evidence that rearrangement of the β-diketone ligands accompanies the adduct formation.

Prior to the adduct formation, the $Eu(TFAC)_3$ and $Eu(HFBC)_3$ chelates undergo rapid diastereomer

Table 2. Luminescence dissymmetry factors for the adducts formed between dibutyl sulphone and $Eu(TFAC)_3$ and $Eu(HFBC)_3$

Chelate	$^5D_0 \rightarrow {}^7F_1$	$^5D_0 \rightarrow {}^7F_2$
$Eu(TFAC)_3$	-0.61 (a) -1.46 (b)	+0.089
$Eu(HFBC)_3$	+0.12 (a) +0.23 (b)	-0.011

Note: The two peaks within the $^5D_0 \rightarrow {}^7F_1$ band system are located at

(a) 587 nm and (b) 596 nm.

Table 3. Luminescence dissymmetry factors for the Eu(TFAC)$_3$ and Eu(HFBC)$_3$ adducts with phosphate esters

Adduct	$^5D_0 \rightarrow {}^7F_1$	$^5D_0 \rightarrow {}^7F_2$
Eu(TFAC)$_3$/TMP	-0.17 (a) -0.60 (b)	+0.040
Eu(HFBC)$_3$/TMP	-0.062 (a) -0.15 (b)	+0.011
Eu(TFAC)$_3$/TEP	-0.10 (a) -0.48 (b)	+0.051
Eu(HFBC)$_3$/TEP	-0.043 (a) -0.18 (b)	+0.013
Eu(TFAC)$_3$/TBP	-0.056 (a) -0.11 (b)	+0.026
Eu(HFBC)$_3$/TBP	-0.041 (a) -0.093 (b)	+0.015

Notes: (1) TMP = trimethyl phosphate, TEP = triethyl phosphate, and

TBP = tributyl phosphate.

(2) Within the $^5D_0 \rightarrow {}^7F_1$ band, two CPL peaks are noted: peak

(a) is found at 587 nm and peak (b) is found at 596 nm.

interconversion, and the lack of observable CPL in noncoordinating solvents indicates an approximately equal ratio of Λ (cis and trans) and Δ (cis and trans) isomers. The cooperative nature of the substrate binding is undoubtedly related to the geometrical rearrangements required to fit these substrates in the inner coordination sphere of the Eu(III) ion, and these rearrangements are seen to be critically dependent on the nature (both chemical and steric) of the substrate donor atoms. The acidity of the chelate and basicity of the substrate must also play an important role in the adduct formation process. It is clear, however, that any perturbation of the Λ/Δ isomer ratio will yield optical activity in the complex mixture, as such a process may be viewed as a partial resolution of the very labile metal complexes. The observation that addition of an achiral substrate to a solution of either Eu(TFAC)$_3$ or Eu(HFBC)$_3$ often leads to the observation of optical activity indicates that the aforementioned ligand rearrangement can be accompanied by stereoselectivity. It is equally clear that the signs of the optical activities within the CPL bands contain information regarding the absolute configuration of the Eu(III) ion, but the source of the chirality experienced by the metal must first be established. It is well established that a metal ion interacts with a dissymmetric environment through three major mechanisms: (a) the vicinal effect (chirality induced at the metal by the simple presence of an asymmetric atom on the ligand), (b) the conformational effect (additional chirality arising when the asymmetric atom is part of a chelate ring), and (c) the configurational effect (chirality due to an asymmetric disposition of chelate rings about the metal).[25]

For the Eu(III) β-diketone complexes studied here, only the vicinal and configurational effects can contribute

to the Eu(III) ion chirality, as the chelate ring is quite planar and does not contain an asymmetric atom. We have examined the nature of the vicinal effect in detail for (Eu(III) complexes containing camphorato ligands by synthesizing and studying chelates whose general formulae are Eu(DK)$_2$(CDK) and Eu(DK)(CDK)$_2$ (where DK = any achiral β-diketone and CDK = chiral β-diketone derived from d-camphor).[14] In this earlier work, it was shown that optical activity arising from the vicinal effect was at least two orders of magnitude smaller than the effects found in the present work with dimethyl sulphoxide and phosphate ester substrates. It therefore appears quite safe to conclude that the chirality experienced by the Eu(III) ion (and manifested through the CPL spectra) in the adduct complexes is configurational in nature. We believe that the adduct formation causes crowding of the bulky camphorato ligands, and these adopt the configuration which minimizes these interactions. Since the ligands are themselves chiral, the isomer which forms in largest excess must be chiral and thus the adduct formation is accompanied by a spontaneous resolution of the very labile chelate.

The mirror images of dissymmetric six-coordinate trigonal metal complexes are denoted Λ and Δ.[25] This nomenclature is not really applicable to the Eu(III) chelate adducts as these certainly are not trigonal, and do not even possess axial symmetry.[26] Nevertheless, it is possible to speak of the free Eu(III) β-diketone complexes as being six-coordinate and trigonal, and we suggest that the Λ and Δ labels might be used to identify and approximate stereochemistry for the adduct complexes.

Complicating the picture is the fact that no correlation has yet been made between the absolute configuration of a chiral Eu(III) β-diketone complex and its chiroptical spectra. However, such a correlation has been made for

Eu(oxydiacetate)$_3$ (which happens to crystallize in an optically active space group), and it has been determined that the circular dichroism associated with the $^7F_0 \rightarrow ^5D_1$ Eu(III) absorption[27,28] and the circularly polarized luminescence of the $^5D_0 \rightarrow ^7F_1$ Eu(III) emission[29] is negative in sign if the absolute configuration of the Eu(III) ion is Δ. We have used this information to correlate observed chirality with Eu(III) and Tb(III) absolute configurations in a variety of solution-phase studies where the optical activity was induced in a trigonal complex through outer-sphere association (Pfeiffer effects).[30-32]

That the optical activity associated with the Eu(III) β-diketone chelate adducts of the present study may be approximately described by the Λ and Δ nomenclature comes from examination of the CPL spectra. The CPL spectra of partially resolved Eu(DPA)$_3^{3-}$ (DPA =pyridine - 2,6 - dicarboxylate) are very distinctive and different from CPL spectra taken in a variety of studies we have made where conformational effects dominate. Since with Eu(DPA)$_3^{3-}$ we have shown that inner-sphere complexation is negligible,[31] we believe that the CPL spectra shown in Figs. 3 and 4 are indicative of trigonal, configurational optical activity (the magnitudes of the dissymmetry factors further support this assignment). Since the CPL spectra of the Eu(III) chelate adducts are absolutely identical in lineshape and of approximately the same order of magnitude as the earlier work, we conclude that the presence of negative CPL in the $^5D_0 \rightarrow ^7F_1$ luminescence band indicates that the diastereomer present in largest excess is that of the Δ-configuration.

For transition metal complexes of camphorato β-diketones, it has been generally found that if one begins with R,R-ligand then the Λ-isomer of the metal complex is formed to the greatest extent. The degree of stereoselectivity is solvent dependent for labile complexes; the Λ/Δ ratio runs from 3.2 to 1.03 for V(+ATC)$_3$.[9] In most of the Eu(III) complexes, the opposite situation is found to hold: if the chelates are prepared from R,R-TFAC or R,R-HFBC then the Δ-isomer is present in the largest amount. Only for the sulphone and sulphoxide adducts of Eu(HFBC)$_3$ does the

Λ-isomer form to the greatest extent. One also notes that the entire series of phosphate esters all stabilize the Δ-isomers, while dimethyl sulphoxide and dibutyl sulphone lead to the predominance of different isomers in the case of Eu(TFAC)$_3$ and Eu(HFBC)$_3$.

It had been noted earlier that the 596 nm component of the $^5D_0 \rightarrow ^7F_1$ Eu(III) transition of Eu(TFAC)$_3$ dissolved in neat dimethyl sulphoxide was totally circularly polarized.[12] We have now proposed that the Δ-isomers of this chelate give rise to this optical activity, and this information enables a calculation of the diastereomer abundance for this chelate. Since this band cannot contain any further optical activity, one may assume that complete conversion of the initial racemic mixture into the Δ-isomer is achieved in neat DMSO. All other solvents yield an excess of this Δ-isomer, but the observed dissymmetry factors are much lower in magnitude. This may be interpreted to imply that the complex is only partially resolved, and that the degree of resolution may be calculated from the g_{lum} factors listed in Tables 1-3. We have presented these values in Table 4, and it may be noted that increasing the steric nature of the substrate invariably results in a lower Δ/Λ ratio. No such calculations were calculated for Eu(HFBC)$_3$, as the limiting dissymmetry factors for this band is not yet established.

It has been noted that the plots of induced differential shifts, $\Delta\Delta\delta$, (obtained during the course of nmr experiments) ought to increase to a maximum as one titrates a substrate with a Eu(III) shift reagent. However, this situation is not usually observed.[11] It has been suggested that differing magnetic environments[33] or varying stoichiometries[11] produced during the experiment can account for these effects. The present study confirms that both effects may be important, as we have shown that the stoichiometry can vary with chelate/substrate ratios and that the existence of ligand rearrangements indicates varying magnetic environments. It has proven difficult in the past to obtain absolute configurations of unknown materials by nmr methods, as the proton resonances to not always appear to shift in a rational manner. The work presented in this latest investigation has provided an insight into this behaviour; if the adduct formation is

Table 4. Diastereomeric abundances obtained for Eu(TFAC)$_3$ as a function of solvent

Substrate	Mole Fraction		
	Δ-Isomer	Λ-Isomer	Δ/Λ Ratio
Dimethyl sulfoxide	0.95	0.05	19.0
Dibutyl sulfoxide	0.52	0.48	1.08
Dibutyl sulfone	0.87	0.13	6.41
Trimethyl phosphate	0.65	0.35	1.86
Triethyl phosphate	0.62	0.38	1.63
Tributyl phosphate	0.53	0.47	1.13
Chloroform	0.50	0.50	1.00

Note: The results were obtained using the 596 nm component of the $^5D_0 \rightarrow ^7F_1$ Eu(III) emission band.

accompanied by ligand rearrangements (which are in turn dictated by steric requirements), the chirality of the resulting predominant diastereomer does not necessarily have to correlate with the absolute configuration of any asymmetric atom. Further studies are under way to clarify the nature of these processes.

Abstract—The copper(I) complexes [Cu(btz)$_2$](BPh)$_4$ (I) and [Cu$_2$(bt)$_4$][ClO$_4$]$_2$ (II) have been prepared (btz = 2,2'-bi-4,5-dihydrothiazine and bt = 2,2'-bi-2-thiazoline). Crystals of (I) are orthorhombic with a = 10.927(8), b = 11.743(8), c = 15.000(6) A, Z = 2, spacegroup P2$_1$2$_1$2. Crystals of (II) are monoclinic with a = 21.928(11), b = 11.925(8), c = 14.716(11) A, β = 103.6(1), Z = 8, spacegroup C2/c. 2121 and 2204 independent reflections have been measured on a diffractometer and the structures refined to R 0.061 and 0.063 respectively. In the cation of (I) the two btz ligands are coordinated via the α-di-imine groups (Cu–N 2.010(6), 2.024(6) Å). The resulting CuN$_4$ coordination geometry is a flattened tetrahedron with a dihedral angle of 68.9° between the two "CuN$_2$" planes. It is suggested that this distortion is an intrinsic property of the molecule associated with metal-to-ligand d_π–p_π* charge transfer rather than a consequence of lattice packing effects. In the dimeric cation (II), each copper(I) ion is bonded to the α-di-imine group of one bt molecule (A) but with appreciably different Cu–N bond lengths (2.277(6), 1.999(5) Å), to one nitrogen atom of a second ligand molecule (B) in the *trans* configuration (Cu–N 1.961(5) Å) and to one sulphur atom (Cu–S 2.428(2)Å) of a third ligand molecule (C). The coordination geometry is a very distorted tetrahedron if a very weak interaction (Cu … S 3.039(2) Å) with a sulphur atom of ligand B is discounted. It is suggested that the different structures arise from the different "bites" of the two ligands.

INTRODUCTION

It is generally assumed that in the absence of ligand constraints the preferred geometry of four-coordinate copper(I) is regular tetrahedral.[1]

For the copper(II) on the other hand, which prefers higher coordination numbers, configurations based on the square plane, i.e. the square pyramid and the tetragonally elongated octahedron, are particularly common.[2] Interest in copper coordination environments intermediate between tetrahedral and "square" has been stimulated recently by the discovery of distorted tetrahedral active sites in the "blue" copper proteins plastocyanin[3] and azurin[4] and in the recognition of the dependence of copper(I)/copper(II) redox potentials[5] and, possibly also, rates of electron transfer[6] on the degree of such distortion of the reduced and oxidised species from regular tetrahedral and square respectively.

Copper(II) complexes containing the Cu(bp)$_2$ or Cu(phen)$_2$ groupings do not adopt a square planar configuration because of interligand steric interactions between hydrogen atoms α to the nitrogens.[7] Structural studies have shown that in such complexes the Cu(ligand)$_2$ moiety is tetrahedrally distorted or that the metal ion adopts an approximate trigonal bipyramidal configuration.[8–11] With copper(I) having a filled d-shell, on the other hand, there is no obvious steric or electronic reason why the two "CuN$_2$" planes should be disposed at other than an angle of 90°, but this is not always observed. Recent structural studies[12–16] of several copper(I) complexes of substituted 2,2'-bipyridine and 1,10-phenanthroline ligands of the type [Cu(ligand)$_2$]$^+$ have revealed significant flattening of the "CuN$_4$" coordination sphere (see Discussion).

In this paper we report the crystal and molecular

structures of the copper(I) complexes [Cu(btz)$_2$] (BPh$_4$) (I) and [Cu$_2$(bt)$_4$] (ClO$_4$)$_2$ (II) where btz and bt are 2,2' - bi - 4,5 - dihydrothiazine and 2,2' - bi - 2 - thiazoline respectively. These ligands have obvious similarities to

btz   bt
2,2'bipyridine but differ in that the α-di-amine group is not part of a conjugated system. Previous studies[17] on complexes with iron(II) and other divalent first row transition metal ions have shown that both ligands chelate via the α-di-imine group. In this paper we show that this also is the case for [Cu(btz)$_2$]$^+$ which also exhibits severe tetrahedral distortion. In (II) the structure is more complex involving both α-di-imine and sulphur coordination.

RESULTS AND DISCUSSION

Physical properties of the complexes

Both complexes (I) and (II) are diamagnetic. (I) is readily soluble in a range of organic solvents (acetonitrile, dimethylformamide, acetone, 1,2-dichloroethane) while (II) has much more limited solubility in the more polar solvents only. Both complexes are stable to air in the solid state but solutions slowly turn green on exposure to air. The IR spectra of both ligands show a strong ν(C=N) absorption at 1614 cm^{-1} in btz and at 1590 cm^{-1} in bt, and strong bands in the 800–1200 cm^{-1} region corresponding to skeletal vibrations of the heterocyclic rings.[17] A weak-to-medium intensity band at 650–660 cm^{-1} in both ligands may be due to the ν(C–S) vibration. There are marked changes in the IR spectra on

---

*Authors to whom correspondence should be addressed.

coordination to copper(I). In (I), the strong band at 1614 cm^{-1} has virtually disappeared being replaced by a medium intensity band at 1530 cm^{-1} while the vibration at 660 cm^{-1} tentatively assigned to ν(C–S) is relatively unchanged, now occurring more weakly at 670 cm^{-1}. These observations are fairly consistent with coordination *via* the α-di-imine group subsequently proved by the X-ray structure determination (see below). The large coordination shift (84 cm^{-1}) of ν(C=N) to lower energies together with the alteration in intensity is indicative of strong coupling between vibration modes within the Cu(N=C–C=N) chelate ring.[21,22] This could arise from metal d_π-to-ligand p_π^* back coordination. Similar effects have been observed in low-spin iron(II) complexes of α-di-imine ligands.[17,22] Significantly in the copper(II) complex [Cu(btz)$_3$] (ClO$_4$)$_2$ where little metal-to-ligand charge transfer is expected, ν(C=N) is shifted to lower frequencies only by 46 cm^{-1} and without appreciable loss in intensity.

In the case of the bt complex (II), a more complex pattern is apparent in the 1500–1600 cm^{-1} region of the IR spectrum. The single strong ν(C=N) vibration occurring at 1590 cm^{-1} in the free ligand is replaced by three medium intensity bands at 1600, 1572 and 1552 cm^{-1}. The 652 cm^{-1} vibration in the free ligand is apparent also in the spectrum of the complex though with much reduced intensity and there are also a number of other weak bands in this region. While assignment of these bands to particular vibrations is difficult and beyond the scope of this paper there is the clear indication that the coordination mode of bt in (II) is different from that of btz in (I) as confirmed by the X-ray structure determinations.

There are also notable differences in the electronic spectra of the two complexes. In the solid state (I) displays a strong broad absorption consisting of a maximum at 20,200 cm^{-1} with a pronounced shoulder at 16,900 cm^{-1} and another weaker one at *ca.* 26,000 cm^{-1}. The solid state spectrum of (II) consists of a broad unresolved absorption band centred at 25,200 cm^{-1} (Fig. 1).

The different energies of the two (presumably) Cu(I) to ligand charge transfer systems reflect the different coordination environments of the metal ion in the two com-

plexes. The much lower energy of the charge transfer in (I) may be taken as an indication of the good π-accepting capacity of the α-di-imine group. Similar low energy metal-to-ligand d_π–p_π^* charge transfer has been noted[17] in the low spin iron(II) complex [Fe(btz)$_3$]$^{2+}$. Good correspondence between the spectra of (I) obtained in the solid state and in 1,2-dichloroethane solution was obtained an apparent extinction coefficient of 1640 dm^{3}mol^{-1}cm^{-1} being observed for the absorption maximum at 20,500 cm^{-1} in this solvent. In more polar solvents such as dimethyl formamide and particularly acetonitrile marked deviations from Beer's law were found indicating extensive dissociation in dilute solution. The effect of added btz ligand was to partially restore the spectrum. Complex (II) is insoluble in 1,2-dichloroethane while in polar solvents such as acetonitrile even more extensive dissociation occurred, preventing measurement of the spectrum of the complex in solution even in the presence of a large excess of free bt ligand.

EXPERIMENTAL

Preparation of the complexes: The ligands were synthesised according to the methods described by Tomalia and Page.[18] Purification was by extraction of the crude products with hexane followed by recrystallisation from carbon tetrachloride or acetone. Complexes were prepared by addition of [Cu(MeCN)$_4$] (ClO$_4$) to an excess of the ligand in warm de-oxygenated acetonitrile under N$_2$. Orange crystals of [Cu$_2$(bt)$_4$] (ClO$_4$)$_2$ separated on cooling. Found C, 28.3, H, 3.1, N, 11.1%. [Cu$_2$(bt)$_4$] (ClO$_4$)$_2$ requires C, 28.4, H, 3.2; N, 11.0%. No perchlorate salt of [Cu(btz)$_2$]$^+$ could be isolated but the tetraphenylborate was obtained as dark brown cubes on addition of Na(BPh$_4$) to the reaction mixture. Found C 61.3, H 5.7, N 7.2% [Cu(btz)$_2$] (BPh$_4$) requires C 61.2, H, 5.7; N, 7.1%

STRUCTURE DETERMINATION

Crystal data are given in Table 1. The two crystals were mounted in turn on a Stoe STADI2 diffractometer and data was collected via variable width *w* scan. Background counts were 20 s and the scan rate of 0.033°/s was applied to a width of $(1.5 + \sin \mu/\tan \theta)$. Absorption and extinction corrections were not applied.

Both structures were solved by the Patterson method and the positions of non-hydrogen atoms found from the Fourier syntheses. The hydrogen atoms were generated in trigonal or tetrahedral positions and an overall isotropic thermal parameter was refined. Structures were refined by full-matrix least squares with a weighting scheme $w = 1/(\sigma^2(I) + 0.003 F^2)$. Final R values were 0.061 and 0.063 respectively. Calculations were carried out using Shelx76[19] at the University of Manchester Computing Centre. Atomic scattering factors and dispersion corrections were taken from Ref. 20. Important dimensions are given in Table 2. Atomic parameters, some dimensions, thermal parameters and a list of structure factors have been deposited with the editor as supplementary material; copies are available on request.

Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

The structure of [(Cu(btz)$_2$)(BPh$_4$) (I)

This compound contains discrete [Cu(btz)$_2$]$^+$ cations and [BPh$_4$]$^-$ anions. Both ions have crystallographic C$_2$ symmetry with the Cu and B atoms positioned on two fold axes. In the cation (Fig. 2) the copper atom is bonded to two btz ligands via Cu–N bonds (2.010(6), 2.024(6) Å). The two "CuN$_2$" planes intersect at an angle of 68.9° so that the coordination geometry is a distorted (flattened) tetra-
Fig. 1. The electronic absorption spectra of [Cu(btz)$_2$] (BPh$_4$) (I) and [Cu$_2$(bt)$_4$] (ClO$_4$)$_2$ (II) in the solid state.

hedron. As noted in the introduction several other copper(I) complexes, of α-di-imine ligands also show this kind of distortion. In (Cu(dmbp)$_2$)(BF$_4$),[12] (Cu(tmbp)$_2$)(ClO$_4$),[13] (Cu(dmp)$_2$)(ClO$_4$),[14] (Cu(dmbp)$_2$)(NO$_3$)[15] and (Cu(dmp)$_2$)(NO$_3$)·2H$_2$O,[16] where dmbp = 6,6' - dimethyl - 2,2' - bipyridine, tmbp = 4,4',6,6' - tetramethyl - 2,2' - bipyridine, tmp = 2,9 - dimethyl - 1,10 phenanthroline, the dihedral angles between the two planar bidentate ligands are respectively 80.9, 67.6, 81.8, 80 and 85.4°. In all these structures the Cu–N bond lengths fall within the range 2.01–2.08 Å.

In (I) five of the atoms of the six-membered heterocyclic rings are planar within experimental error. However C(3) and C(10) lie 0.66 and 0.70 Å from their respective planes. Bond distances within the rings are as expected, though it is noticeable that S(5)–C(6) and S(8)–C(7) at 1.747(6) and 1.738(6) are significantly shorter than S(5)–C(4) and S(8)–C(9) at 1.823(10), and 1.809(10) Å. There is a small twist around the C(6)–C(7) bond connecting the

two six-membered rings. Thus, the N(1)–C(6)–C(7)–N(12) torsion angle is −13.9, i.e. slightly larger than the twist angles (4.4, 5.0 and 12.3°) observed for the copper(I)-substituted bipyridine complexes referred to above.[12,13]

The only intramolecular contacts between non-hydrogen atoms of less than 3.5 Å are N(1)...N(1*) 3.46, N(12)...N(12*) 3.34 Å. There are no contacts between cation and anion less than 3.5 Å. The only intermolecular contact of note is S(8)...S(8) $(1 - x, -y, -z)$ of 3.28 Å.

It is difficult to identify the reason for the large deviation of the dihedral angle between the two "CuN$_2$" planes in (I) from 90°. Intermolecular packing effects could, of course, account for small distortions but the deviation (21°) seems large for a purely packing effect. Moreover the observation of dihedral angles ranging from 68 to 85° in all the Cu(I)-α-di-imine structures so far solved seems to suggest that there may be an intrinsic electronic origin. The assignment of the intense visible absorption in (I) to a metal-to-ligand charge transfer has been discussed above. Possibly there is some mixing of the excited state, formally a complex of Cu(II) with a ligand radical anion with the ground state. Alternatively the flattening of the tetrahedral configuration may lead to an improved d_π-p_π^* overlap.

The structure of [Cu$_2$(bt)$_4$] (ClO$_4$)$_2$ (II)

The structure consists of discrete ClO$_4^-$ anions and dimeric [Cu$_2$(bt$_4$)]$^{2+}$ cations. Each copper atom is bonded to two nitrogen atoms of one ligand molecule (A) (Cu–N 2.277(6), 1.995(5) Å). By comparison with the chelating α-di-imine groups in (I) the first Cu–N bond is lengthened by ca. 0.26 Å. The metal atom is also strongly bonded to one nitrogen N(1B) of a second ligand molecule (B) at 1.961(5) Å. This ligand molecule is in the trans configuration and the sulphur atoms S(10B) cis to N(1B) is 3.039(2) Å distant from the metal (Fig. 3). The copper atom is also strongly bonded (2.428(2) Å) to S(10B*) of a centrosymmetrically related "Cu(bt)" unit. The two nitrogen atoms of ligand A together with N(1) and S(10) of ligand B constitute an approximate square planar environment about the copper atom. Least squares plane calculations show that the metal atom is 0.49 Å out of plane in the direction of S(10B*). If S(10B) is considered to be coordinated to the metal (Cu...S 3.039 (2) Å) then the coordination geometry is a distorted square pyramid with the angles involving the axial Cu–S (10B*) bond being 102.8(2), 102.6(2), 108.7(2) and 97.0(2)°. However it is probably not realistic to consider the Cu...S contact as a conventional bond, particularly as the Cu–S (10B)–C (9B) angle is 168.1(3)°, so that the coordination geometry is better viewed as a very distorted tetrahedron the angles subtended at the metal by the four donor atoms N(1A), N(7A), N(1B) and S(10B*) ranging from 78 to 145°.

The five-membered rings of the bt ligands are nearly planar. Deviations from the plane are irregular in the four examples and we presume that there is no favoured conformation.

As in (I) the S(4)–C(5) and S(10)–C(9) bonds are somewhat shorter at 1.752(7), 1.771(8) Å, 1.747(7), 1.752(6) Å than S(4)–C(3), S(10)–C(9) at 1.813(8), 1.809(9), 1.792(11), 1.826(9) Å. The N(1A)–C(5A)–C(6A)–N(7A) torsion angle is 0.2 while that of N(1B)–C(5B)–C(6B)–S(10B) is 7.4°. The Cu...Cu distance is 3.65 Å. There are no close contacts between the two halves of the dimer nor are there any cation...anion interactions of note. There

are no Cu . . . O contacts less that 3.75 Å although there are some O . . . S and O . . . C distances of *ca.* 3.2 Å.

The widely different structures of the two complexes is unexpected. Earlier studies[17] have established that in iron(II) complexes of the type [Fe(ligand)$_3$]$^{2+}$, both btz and bt coordinate via the α-di-imine group. Copper(I) is known, of course, to have an affinity for sulphur but it is far from obvious why the two ligands should behave differently towards this metal ion. A possible answer may be found from the different sizes of the heterocyclic rings. The btz ligand chelates efficiently with the MN$_2$C$_2$ ring approximately planar. The N . . . N separation is 2.63 Å and both atoms are strongly bonded subtending an angle of 81.5° at the metal.

On the other hand, there are several indications that the N . . . N chelation of the bt ligand A in (II) is less stable. First the two bond lengths are unequal, the Cu(1)–N(1A) bond at 2.277(6) Å being particularly long. Concomitant with this is an Cu–N(1)–C(2) angle of 140.3(5)°. Even the Cu–N(7)–C(8) angle is 132.6(4)° compared to similar angles of *ca.* 124° in (I). This may be a consequence of strain in the five-membered rings. An indication of this is the C–S–C angles which range from 88.2 to 90.7°. (They are *ca.* 100 in btz in (I)). The CuN$_2$C$_2$ ring in (II) is still planar despite these distortions. The N . . . N separation in ligand A is 2.71 Å and the angle subtended at the metal is 78.3°. It would appear then that the α-di-imine group of (I) is better suited for chelation though it is not clear to what extent the Cu–N(1A) bond in (II) might be lengthened because of steric effects concomitant with the square planar arrangement of N(1A), N(7A), N(1B) and S(10B) around the copper atom.

Whatever the disadvantage in the "bite" of bt compared to btz the effect must be small enough not to influence critically the coordinating properties of the α-di-imine group towards iron(II) both ligands generating ligand fields strong enough to cause spin pairing.[17] It may be that in the case of copper(I) with its known affinity for sulphur there is a delicate balance between α-di-imine chelation and sulphur coordination so that both coordination modes occur in the same molecule.

The chelating capacity of bt in the *trans* configuration, i.e. using one nitrogen and one sulphur atom, might well be expected to be inferior since the sulphur lone pairs will not lie in the same plane as the nitrogen lone pair, in the planar ligand molecule. Thus the copper atom prefers to bond strongly with the sulphur atom of another ligand molecule in an adjacent "Cu(bt)$_2$" unit. The angles subtended at the sulphur S(10B*) by the Cu and C atoms are 88.2(3), 101.8(3), 108.8(3)°.

There are no intramolecular contacts of note in the two structures. It therefore seems unlikely that packing effects could account for the different coordination spheres in the two structures.

ENTHALPIES OF REACTION OF TRIFLUOROMETHANESULPHONIC ACID WITH VARIOUS BASES

KEITH J. FISHER

Department of Chemistry, Faculty of Education, University of Khartoum, Republic of Sudan

Abstract—The enthalpies of reaction of CF_3SO_3H with a series of bases have been measured calorimetrically in nitrobenzene. Conductivity studies have been carried out and these have indicated the complexity of the acid-base products in solution. The failure of attempts to fit the enthalpy data to the Drago E and C equation reinforce the need for caution in its use.

INTRODUCTION

The E and C equation has been reported by Drago *et al.*[1] for the correlation of a very large number of neutral acids and bases which form un-ionized adducts.

$$-\Delta H = E_A E_B + C_A C_B.$$

Non-polar solvents have been used in an attempt to reduce the possibilities of complex or ionic products, for example:

$$n B_{(sol)} + n HX_{(sol)} \rightleftharpoons (BHX)_{n(sol)} \rightleftharpoons (BHX)_{n-m(sol)}^{m-} + mH_{(sol)}^+.$$

The above system involves many energetic contributions leading to the net enthalpy, which is quite different from the gas phase enthalpy useful in Drago's equation.

Acid-base reactions which result in ionic products have often been studied in polar solvents. Drago has warned against the attempted use of these data and also the potential complexity of pK_a and pK_b data.[2] Various studies have been carried out using a strong acid such as FSO_3H as both solvent and acid.[3–5] The studies of the enthalpy of ionization of various acid-base adducts yield large variable solvation enthalpies and cannot be used in the E and C approach, and would not seem to have any understandable meaning. It seems possible that reactions in non-polar solvents could provide more meaningful results which might correlate with Drago's equation.

In order to test these ideas and the Drago equation, calorimetric measurements of the heats of reaction of trifluoromethylsulphonic acid with various bases were carried out. Trifluoromethylsulphonic acid has been shown by conductivity studies to be a stronger acid than perchloric acid.[6] It reacts with a large number of bases to give 1:1 acid-base adducts and seems likely to give ionic products, making it an ideal acid to test whether the Drago equation might be simply number fitting.

Trifluoromethylsulphonic acid, besides being extremely hygroscopic, is not soluble in non-polar solvents such as cyclohexane or carbon tetrachloride. Thus nitrobenzene, a weakly basic solvent, was chosen, as this solvent has been used in previous studies[7] and a solvent correction has enabled the data to fit the Drago equation. Drago[8] has also shown that the G value approach gives poor correlations especially with this solvent.

EXPERIMENTAL

All operations were carried out under dry nitrogen.

Baker Analysed nitrobenzene was initially dried with phos-

phorus pentoxide and then distilled at ~1 mm Hg. The middle fraction of the distillation, 50–51°, was collected and used within a few hours. Methylene chloride was dried with phosphorus pentoxide and distilled immediately before use. Trifluoromethylsulphonic acid was distilled before use and stored in a sealed flask under dry nitrogen. The bases were dried as previously described.[9]

The calorimeter used was an all-glass type used in a previous study.[10] The calorimeter was evacuated and flushed with dry nitrogen before use. The solvent (generally 100 ml) was added to the nitrogen-filled calorimeter via a syringe. Weighed amounts of the base were added to the acid solution using a calibrated Hamilton gas tight syringe which had been allowed to reach thermal equilibrium within the calorimeter. This method was found to give inconsistent results; more consistent results were obtained by the reverse addition of known amounts of acid to a solution containing excess base. The first addition of acid generally gave high results possibly due to a trace of water in the system. Subsequent additions of acid were found to give consistent results. In most cases the base concentration was about 0.5 molar and the acid additions were not greater than 0.12 molar.

In all systems the values of H' (heat evolved per increment of acid added, corrected for the heat of solution of the acid in nitrobenzene) suggested that the acid was a limiting reagent and that complete reaction had occurred ($K \geq 10^4$).

Conductivity studies were carried out in an all-glass, previously evacuated, conductivity cell. An Industrial Instrument Conductivity Bridge Model R1682 was used and the cell calibrated with potassium chloride solutions. The problem of traces of moisture reluctantly caused us to use higher solution concentrations than those considered ideal.[11] Concentrations of solutions of approximately 5×10^{-3} and 1×10^{-2} molar were used.

RESULTS

The enthalpies of reaction of various bases with trifluoromethylsulphonic acid are shown in Table 1. The values are given in kcal mol^{-1} to conform with other data in the literature.

DISCUSSION

The calorimetric data reported in Table 1 will have a contribution from the displacement of the acid from the base nitrobenzene.

$$AB' + B'' \rightarrow AB'' + B'.$$
This contribution should have a constant value and so we should employ the modified eqn[9] in the E and C fit.

$$-\Delta H + \omega = E_A E_B + C_A C_B.$$

Fitting seven enthalpies (from Table 1) with the known E_B and C_B values gives more flexibility than for the

Table 1. Enthalpies of reaction of various bases with CF_3SO_3H

Nitrobenzene solvent	
Base	**Measured** $-\Delta H$ (kcal mol^{-1})
Ether	8.95 ± 0.15
Acetonitrile	3.10 ± 0.10
Tetrahydrofuran	9.99 ± 0.25
Dimethylsulphide	5.37 ± 0.13
Dimethylsulphoxide	23.46 ± 0.30
Tetrahydrothiophene	5.54 ± 0.15
Hexamethylphosphoramide	25.20 ± 0.30
Methylene chloride solvent	
Nitrobenzene	3.99 ± 0.10
Ether	14.43 ± 0.20
Dimethylsulphoxide	25.79 ± 0.30

The conductivity studies in nitrobenzene are shown in Table 2.

normal E and C equation. Even with this extra flexibility no reasonable fit of the data could be obtained. As examples the best fit value for ω was -25.2 kcal mol^{-1}, but when the enthalpy for tetrahydrofuran was calculated using the best fit E_A and C_A values, a heat of 13.2 kcal mol^{-1} was obtained, which compares very

poorly with the measured value of 9.99 kcal mol^{-1}. Similarly, the calculated value for dimethylsulphoxide was 19.5 compared with the measured value of 23.46. These kinds of deviations are not acceptable and indicate that the E and C equation is not so heavily parameterized as to fit almost any batch of data.

The reason for this failure may be seen in the conductivity data. Several of the conductivities obtained are large enough to indicate predominantly ionic species in solution. The rather erratic nature of the results in some cases and the higher values in high base concentrations suggests a large degree of complexity of the species in solution. The problem of traces of water cannot be ruled out, but as every possible precaution was taken in this work to exclude moisture we think that water would have only a minimal effect on the data.

The conductivity studies indicate that only the interactions of the acid with diethyl ether, acetonitrile and tetrahydrofuran may be considered to give essentially non-ionic products. Using these heats would give a meaningless fit to the extended E and C equation ($-\Delta H + \omega = E_A E_B + C_A C_B$). The adducts of the acid with hexamethylphosphoramide and triphenylphosphine seem to be completely ionic but the other adducts probably contain ionic and covalent species.

In several other enthalpy studies, particularly those of Arnett,[3-5] a strong acid, FSO_3H, has been used as both acid and solvent. These studies have not been accompanied by conductivity data and one would expect significant ionic contributions to the measured data. Fluorosulphonic acid as a solvent should be a better solvating medium than nitrobenzene and it is therefore

Table 2. Conductivity studies in nitrobenzene of CF_3SO_3H adducts

	Concentration of acid ×10³ M	Concentration of base ×10³ M	Λ_m
Acid only	5.66	—	2.04
	5.66	—	2.07
	11.3	—	2.02
	11.3	—	1.92
Diethylether adduct	13.6	19.0	2.15

	11.3	13.0	29.8
	13.6	12.6	20.4

expected that complete ionization for many, but not all, of the systems will occur.

We recommend that all acid-base enthalpy studies with solvents and acids which might produce ionic products should include conductivity data, especially if the data are to be fitted into, or used to disprove, the Drago equation.

SYNTHESIS, CHARACTERIZATION AND PHOTOCHEMISTRY OF SOME MONOMETALLIC AND BIMETALLIC 2,2'-BIPYRIMIDINE COMPLEXES OF CHROMIUM AND TUNGSTEN CARBONYLS

KATHY J. MOORE and JOHN D. PETERSEN*
Department of Chemistry, Clemson University, Clemson, SC 29631, U.S.A.

Abstract—Synthesis, electronic absorption spectra, ^{13}C NMR and photochemistry are reported for the complexes $M(CO)_4$bpym (M = Cr or W) and $[W(CO)_4]_2$bpym. The electronic absorption spectra indicate, for these complexes, that the lowest lying metal-to-ligand (L) charge transfer (MLCT) excited state is lower in energy than the ligand field (LF) excited states. The ^{13}C NMR spectra showed that the chemical shifts of C(5) and C(6) for the M-bpym complexes move downfield with respect to that of the free ligand, bpym, while C(4) moves upfield upon complexation. Small, wavelength-dependent quantum yields for loss of CO were obtained upon irradiation. These quantum yields were an order of magnitude larger for the Cr-bpym complex than for the W complexes ($\Phi = 2.4 \times 10^{-2}$ quanta/min for Cr-bpym, 2.5×10^{-3} quanta/min for W-bpym and 1.1×10^{-3} quanta/min for W-bpym-W, $\lambda_{irr} = 366$ nm).

INTRODUCTION

Numerous photochemical studies have been performed for the low spin d^6 octahedral complexes $Ru(NH_3)_5L^{2+}$ [1,2] $Fe(CN)_5L^{3-}$,[3] and $W(CO)_5L^4$ (L = aromatic nitrogen heterocycle). Each of these complexes exhibit an intense metal-to-ligand (L) charge-transfer (MLCT) absorption band in the visible region of the spectrum which shifts to a lower energy as the electron withdrawing ability of L increases. Previous studies indicate that the photosubstitution behaviour of these complexes is dependent upon the nature of the lowest lying excited state.[1–4] For complexes in which the lowest, triplet, ligand-field (^{3}LF) excited state is lower in energy than the MLCT manifold initially populated, the predominant photosubstitution reaction which occurs upon irradiation is efficient dissociative loss of L owing to an increase in σ^* electron density. However, when the MLCT excited state is tuned to an energy lower than the ^{3}LF excited state by changing the substituents on L, a dramatic decrease in the photosubstitution of L results. The same behaviour was observed for a series of $W(CO)_4L_2$ complexes.[5]

Studies of complexes of the type $M(CO)_4L$ (M = Cr, Mo, or W, and L = bidentate unsaturated nitrogen donor) have been reported previously.[6,7] For each of these complexes the MLCT excited state is presumed to be lower in energy than the ^{3}LF excited state and no photosubstitution of L occurs. However, photosubstitution of *cis*-CO does occur with small wavelength dependent quantum yields.[6,7]

Complexes of the type $M(CO)_4L$, in which L = 2,2'-bipyrimidine (bpym), are of special interest to our group. By analogy to the complexes of this type previously studied and described above, this system should exhibit a visibly absorbing MLCT band and be photosubstitutionally stable with respect to loss of L. Also, for L = bpym, the possibility exists for bimetallic complex formation where bpym allows efficient communication between the two metal centers as shown for the systems $[Ru(bpy)_2]_2L^{4+}$(L = 2,2'-bpym or 4,4'-dimethyl-2,2'-bpym

and bpy = 2,2'-bipyridine)[8,9] and $[Ru(NH_3)_4]_2L^{4+}$(L = 2,2'-bpym).[10]

The stability of the bridge with respect to photosubstitution, along with the efficient communication experienced between the metal centers, are desirable characteristics which should enable us to study energy transfer reactions of various mixed-metal bimetallic systems. Upon absorption of visible light, one end of the system serves as the visibly absorbing fragment while the other end serves as the reactive fragment. In this report, the synthesis, electronic spectra, ^{13}C NMR and photochemistry of the monometallic complexes $M(CO)_4$bpym (M = Cr or W) and the bimetallic complex $[W(CO)_4]_2$bpym are presented.

EXPERIMENTAL

Materials. Analytical reagent grade compounds and solvents were used for all preparations described in this work. $W(CO)_6$, $Cr(CO)_6$ and 2,2'-bipyrimidine (bpym) were obtained from Alfa. Solvents used for ^{13}C NMR were spectro grade. Elemental analyses were performed by Atlantic Microlab, Atlanta, Georgia.

Syntheses. The complexes $M(CO)_4$bpy (M = Cr or W) were prepared by the method of Stiddard.[11] (Care was taken to shield all reaction mixtures from light.)

Cr(CO)$_4$bpym. A mixture of 0.55 g (2.50 mmol) $Cr(CO)_6$ and 0.42 g (2.66 mmol) bpym in 25 ml toluene was heated at reflux for 3 hr under nitrogen. The dark brown crystals which formed upon cooling to room temperature were collected by filtration. The product was washed thoroughly with light petroleum ether and dried under vacuum. Yield 0.72 g (89%). Anal. Calcd for $C_{12}H_6CrN_4O_4$: C, 44.74; H, 1.88; N, 17.39. Found: C, 43.51; H, 2.14; N, 16.84.

W(CO)$_4$bpym. A mixture of 0.87 g (2.47 mmol) $W(CO)_6$ and 0.41 g (2.59 mmol) bpym in 40 ml xylene was heated at reflux for 2 hr under nitrogen. The dark brown crystals which formed upon cooling to room temperature were collected by filtration. The product was washed and dried as above. Yield 0.93 g (83%). Anal. Calcd for $C_{12}H_6N_4O_4W$: C, 31.75; H, 1.33; N, 12.34. Found: C, 31.65; H, 1.25; N, 12.30.

[W(CO)$_4$]$_2$bpym. A mixture of 1.73 g (4.92 mmol) $W(CO)_6$ and 0.42 g (2.66 mmol) bpym in 50 ml xylene was heated at reflux for 4 hr under nitrogen. The dark green–black crystals which formed upon cooling to room temperature were collected by filtration. The product was washed with acetonitrile and petroleum ether and dried as above. Yield 1.84 g (100%). Anal. Calcd for

$C_{16}H_6N_4O_8W_2$: C, 25.63; H, 0.81; N, 7.47. Found: C, 26.73; H, 0.99; N, 7.38.

Spectroscopy. All absorption spectra and absorbance measurements used for the quantum yield determinations were recorded on a Bausch & Lomb Spectronic 2000 spectrophotometer. Proton-decoupled ^{13}C NMR spectra were obtained on a JEOL FX-90Q operating at 22.5 MHz using chloroform-d as a solvent and as an internal reference. Chemical shifts are reported versus external TMS using the following equation:

$$\delta_{ext\ TMS} = \delta_{int\ CDCl_3} - 77.0\ ppm.$$

Photochemistry. Photosubstitution quantum yields were determined using a continuous beam photolysis apparatus described elsewhere.[3] The incident intensity, I_0^i, of the irradiation beam was determined by ferrioxalate[12] ($\lambda_{irr} \leq 436\ nm$) or Reineckate[13] ($\lambda_{irr} > 436\ nm$) actinometry. The values of I_0^i obtained for each wavelength used were approximately 3.2×10^{17} quanta/min ($\lambda_{irr} = 366\ nm$), 2.4×10^{17} quanta/min ($\lambda_{irr} = 405\ nm$), 2.2×10^{17} quanta/min ($\lambda_{irr} = 436\ nm$), and 1.7×10^{18} quanta/min ($\lambda_{irr} = 546\ nm$).

All photolyses were carried out at 25°C in 2- or 5-cm cylindrical quartz cells in acetonitrile solutions ($\approx 10^{-4}\ M$). The solutions were thoroughly deoxygenated and transferred into the cells under nitrogen as previously described.[14] Disappearance quantum yields were calculated from absorbance changes in the electronic spectra as a function of irradiation time. All spectroscopic measurements were corrected for thermal reactions. The photolysis products formed were identified spectroscopically.

RESULTS AND DISCUSSION

Electronic spectra

The visible and near-UV electronic absorption spectral data for the complexes $M(CO)_4L$ (M = Cr or W; L = bpy or bpym) and $[W(CO)_4]_2$bpym are presented in Table 1. The spectra are shown in Fig. 1. Each complex exhibits an intense, low-energy, absorption maximum which is sensitive to the nature of L and also to the polarity of the solvent. For the monometallic complexes, as the electron withdrawing ability of L increases and the molecular orbitals of L are stabilized going from bpy to bpym, this low energy absorption maximum shifts to a longer wavelength by approx. 40 nm when CH_2Cl_2 is the solvent. For the W-bpym-W bimetallic complex, this absorption maximum is shifted to an even longer wavelength (225 nm for W-bpy in CH_2Cl_2). This dramatic shift to a longer wavelength for the bimetallic complex not only indicates that the remote metal center increases the electron withdrawing ability of bpym by acting as a Lewis acid, but also, as explained previously for bimetallic complexes,[10,15,16] the HOMO of the bimetallic complex is destabilized with respect to the HOMO of the monometallic complex and thus a lower energy transition results. The shift to a longer wavelength as L increases in electron withdrawing ability indicates, as shown previously for similar systems,[4-6,17] that the low energy absorption band has charge transfer character and is

therefore assigned as being a MLCT transition ($d_\pi \to p_{\pi^*}$).

The solvent dependence of the MLCT band for similar systems of the type $M(CO)_4L$ (M = Cr, Mo or W; L = aromatic nitrogen heterocycle) has also been investigated.[6,18] The MLCT absorption maximum shifts to a shorter wavelength as the polarity of the solvent is increased. This trend is shown in Fig. 1 for the complexes listed in Table 1 as the solvent polarity is increased from CH_2Cl_2 to CH_3CN. The bpym and the W-bpy complexes exhibit a higher energy absorption maximum in the 340–455 nm region which was also found to be slightly sensitive to the polarity of the solvent and to the nature of L. Therefore, this band is also assigned as being a MLCT transition.

The energy of the MLCT absorption maximum is dependent upon the ease of oxidation of the central metal. The general trend is an increase of oxidation potential as the energy of the MLCT transition increases

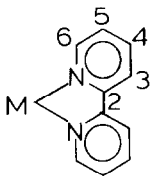
which implies a stabilization of metal molecular orbitals. From Table 1, it appears as though the energetic ordering for the metal molecular orbitals is Cr > W. A qualitative assessment of the electrochemistry corresponding to the compounds listed in Table 1 agrees with this energetic ordering. Cyclic voltammetry experiments[19] indicated that a reversible redox process occurs for Cr-bpym with an oxidation potential of 0.822 V (NHE). The anodic peak position for Cr-bpym is 0.879 V. An irreversible redox process was observed for W-bpym with an anodic peak position at 1.070 V. Two reversible redox processes were observed for W-bpym-W with oxidation potentials at 0.984 and 0.713 V and anodic peak positions at 1.040 and 0.746 V, respectively. The anodic peak positions of the W complexes occur at higher potentials than the anodic peak position of Cr-bpym. This qualitative electrochemical comparison implies that the metal molecular orbitals of the W complexes are stabilized with respect to the metal molecular orbitals of Cr-bpym, in accord with the electronic spectra.

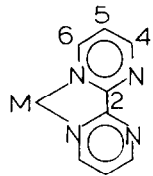
Wrighton et al.[5,6] have determined for a series of $M(CO)_4L$ (L = bidentate ligand) and cis-$M(CO)_4L_2$ (L = monodentate ligand) complexes that the lowest lying excited states are LF in character when L is an aliphatic amine. The energies of these LF excited states are relatively invariant to the nature of L and to the polarity of the solvent. Thus, the absorption maxima which occur at approximately 450 and 402 nm for each complex of this series are assigned as ^3LF ($^3A_1$, $^3B_2 \leftarrow {}^1A_1$) and ^1LF ($^1A_1$, $^1B_2 \leftarrow {}^1A_1$) transitions, respectively. For the $M(CO)_4L$ (L = aromatic nitrogen heterocycle) complexes which have lowest lying MLCT excited states, the spin-allowed LF transition is still present at approx. 400 nm. The less intense spin-forbidden transition is covered by the MLCT absorption band. Also, Stufkens et al.[20] found the LF band between 370 and 400 nm for a series of $Mo(CO)_4L$ complexes (L = unsaturated nitrogen donor chelate). From these results, we would expect to find the LF band in the 400 nm region for the complexes in this study. The shoulder which occurs at approx. 400 nm for the complexes listed in Table 1 is shown in Fig. 1 to be relatively insensitive to the polarity of the solvent and to the nature of L. We assign this shoulder as a LF ($^1A_1$, $^1B_2 \leftarrow {}^1A_1$) transition. The large extinction coefficients corresponding to these LF bands have been attributed to having some MLCT character in the transition.[6] The spin-allowed LF transition of the Cr-bpym complex is obscured by the intense MLCT band at approx. 400 nm. Also, an interesting point to note is that the higher energy MLCT absorption maximum of the monometallic complexes lies above the spin-allowed LF transition; however, for the bimetallic W-bpym-W complex this MLCT maximum is shifted below the LF transition. The lowest lying absorption band for all of the bpym complexes is lower in energy than 450 nm, thus the energetic ordering of the excited states is determined to be LF > MLCT. The significance of this ordering will be discussed below.
Fig. 1. Electronic absorption spectra of the $M(CO)_4L$ and $(CO)_4WbpymW(CO)_4$ complexes at 289 K in CH_3CN (----) and CH_2Cl_2(——). A = Cr$(CO)_4$bpy, B = Cr$(CO)_4$bpym, C = W$(CO)_4$bpy, D = W$(CO)_4$bpym and E = $(CO)_4$WbpymW$(CO)_4$.

^{13}C NMR

^{13}C NMR studies for the complexes $Ru(NH_3)_5L^{2+}$ [21] and $Fe(CN)_5L^{3-}$ [22,23] (L = aromatic nitrogen heterocycle) have been previously reported in the literature. The general trend found for these systems when compared to the ^{13}C NMR spectra of the free ligand, L, is a downfield chemical shift of the carbons ortho (C(6)) to the bonded nitrogen while the remaining carbons (C(3),

C(4) or C(5)) of the ring shift upfield. This upfield shift was related to the amount of $d\pi \to p\pi^*$ back-bonding to the ring system.[21-23] As the π-back-bonding to L increases, the shielding of these carbons (C(3), C(4) or C(5)) increases, and hence the chemical shift moves upfield. The downfield shift of the ortho carbons (C(6)) was more difficult to interpret. In a recent study of the complex $Ru(NH_3)_4bpym^{2+}$,[24] the upfield shift was attributed to a through-bond polarization toward the coordinated nitrogen or changes in electron density from changes in the σ-donating and π-accepting characteristics of L.

Table 2 lists the ^{13}C NMR data for the free ligands and the Cr and W complexes studied here. Due to compound solubility, the ^{13}C NMR of the bimetallic complex was unattainable within reasonable instrument time.[25] For each of the bpy and bpym complexes, the chemical shift of C(6) is shifted downfield with respect to the free ligand. Also, the chemical shift of C(6) for the Cr complexes occurs downfield with respect to that of the W complexes. This trend strenghtens the assumption of a through-bond polarization interaction between the coordinated nitrogen and the ortho carbon, C(6). Since Cr is more electronegative than W, Cr should inductively withdraw electrons in the σ sense through the M-N-C(6) bond system to a greater extent than W. Therefore it would be expected that C(6) of the Cr systems is more deshielded than that of the W systems. The expected trend, increasing downfield shift of C(6) with increasing electronegativity of the remote atom bonded to nitrogen, free space < W < Cr, thus corresponds with the experimental results.




The general downfield shift of C(3), C(4) and C(5) for the bpy complexes is in contrast to the upfield shift occurring for the pyridine systems previously studied.[21-23]

The bonding interaction between L and the metal center is a complex combination of σ bonding from L to M and π bonding from M back into L. For carbonyl complexes, π-back-bonding into CO also occurs and is competitive with the backbonding into L. This competitive back-bonding into CO could decrease the π electron density delocalized over the ring system with respect to the other systems studied.[21-23] Thus, for C(3), C(4) and C(5) of the bpy complexes and C(5) of the bpym complexes the inductive σ electron withdrawal upon coordination to the metal appears to be predominant although the π affects are still apparent. These shifts are slightly downfield for the W complexes in relation to the Cr complexes. This indicates that the π back-bonding into L is less for the W complexes than for the Cr complexes which is in accord with the electronic spectra. For the bpym complexes, C(4) shifts upfield relative to that of the free ligand. This is in accord with the π back-bonding model of other systems[21-23] and indicates that bpym is a better π acceptor than bpy which is in agreement with the electronic spectra. ^{13}C NMR studies of similar Mo-bpy and -bpym systems showed downfield shifts of C(3), C(4) and C(5) relative to the free ligand in all cases.[25] It appears as though the shift of C(6) is governed by an inductive σ-withdrawing interaction of M while the shift of C(3), C(4) and C(5) depends upon a combination of the σ and π interactions between M and L.

Photochemistry

The photochemistry corresponding to systems of the type $M(CO)_4L$ or $M(CO)_4L_2$ (M = Cr, Mo or W and L = unsaturated nitrogen donor) has been studied by Wrighton *et al.*[5,6] and by others.[7] Wrighton and co-workers found from their work that irradiation at 436 nm

[b]Signal too small to be extracted from noise.

of $W(CO)_4L_2$ (L = monodentate) resulted in loss of only L and not CO. The quantum yields for loss of L dramatically decreased as the MLCT excited state was tuned below the LF excited state. However, for complexes of the type $W(CO)_4L$ (L = bidentate) in which the MLCT excited state is the lowest lying excited state, no photosubstitution of L occurs upon irradiation from 313 to 436 nm. Dissociative loss of CO, however, does occur, with very small, wavelength-dependent quantum yields. The quantum yield for CO substitution was found to increase with the energy of irradiation. Therefore, it was concluded for the complexes having lowest lying MLCT excited states that the excited states responsible for the CO loss are the higher energy LF excited states, and the MLCT excited state is unreactive with respect to to loss of CO or L.

The photochemistry corresponding to the Cr and W carbonyls studied here is presented in Table 3. Figure 2 represents the electronic absorption changes as a function of time for the monometallic complex, $W(CO)_4$ bpym, using deoxygenated acetonitrile as a solvent. Air-saturated solutions of this complex were found to be very stable at room temperature if left in the dark; however, the photolysis solutions undergo degradation if not deoxygenated. As photolysis of the deoxygenated solution proceeds, the MLCT absorption bands are shifted to longer wavelengths with an isosbestic point at 412 nm. In analogy to the $W(CO)_4L$ systems previously studied[6], the phoreaction which occurs is suggested to be loss of CO as shown in reaction (1).

$$W(CO)_4bpym \xrightarrow[CH_3CN]{h\nu} W(CO)_3(CH_3CN)bpym + CO.$$
$$(1)$$
The quantum yields for CO substitution were found to be very small and wavelength dependent (λ_{irr} 366 nm, $\Phi = 2.5 \times 10^{-3}$ quanta/min; λ_{irr} 405 nm, $\Phi = 6.0 \times 10^{-4}$ quanta/min).

Photolysis of the bimetallic complex $[W(CO_4]_2$bpym is shown in Fig. 2. As for W-bpym the MLCT absorption bands are also shifted to longer wavelengths upon irradiation, with isosbestic points at 476, 574 and 688 nm. By analogy with the monometallic W complex, the reaction which occurs upon irradiation is suggested to be that of equation 2.

$$(CO)_4WbpymW(CO)_4 \xrightarrow[CH_3CN]{h\nu} (CO)_3(CH_3CN)Wbpym$$
$$W(CO)_4 + CO. \qquad (2)$$
Fig. 2. Absorption spectral changes upon 366 nm irradiation of $W(CO)_4$bpym in deoxygenated CH_3CN ($\approx 10^{-4}$ M) at 298 K.

The photosubstitution quantum yield for CO loss from W-bpym-W was also found to be small (λ_{irr} 366 nm, $\Phi = 1.1 \times 10^{-3}$ quanta/min).

The photochemistry of the monometallic complex $Cr(CO)_4$bpym differed slightly from that of the W complexes. During the initial irradiation times a well defined isosbestic point was obtained at 444 nm. However, after approx. 1 hr of irradiation, degradation took place resulting merely in a decrease in absorbance of the MLCT bands. The absorbance of the dark control solutions decreased in the same manner. As a result of this degradation, the extinction coefficient at the monitored wavelength of the photoproduct could not be calculated. Therefore, the quantum yields for CO loss corresponding to the initial irradiation times are approximated by comparing the absorption spectra of Cr-bpym to that of W-bpym and the W photo-product. Also, the quantum yields for substitution of CO upon irradiation at 366 nm are an order of magnitude larger for Cr-bpym than for the W complexes. The same reaction occured for Cr-bpym upon irradiation into the low energy MLCT band at 546 nm whereas irradiation at 436 nm of the W complex gave no reaction. Larger quantum yields for loss of CO from Cr complexes vs W complexes of the type $M(CO)_5L$ have been reported previously.[26,27]

To explain the photochemical behavior for the bpym complexes, first of all consider that only CO is substituted whereas for the complexes $W(CO)_5L$ and $W(CO)_4L_2$, loss of L predominates owing to a more labile ground state M-N bond. This difference probably results from the chelate effect of bpym.[6] Also, the quantum yields were found to increase as the wavelength of irradiation increased. Therefore, in analogy to the systems investigated by Wrighton and co-workers[5,6], the

Table 3. Photosubstitution of $M(CO)_4L(M = Cr$ or W) to yield $M(CO)_4(CH_3CN)L^a$

M	L	Φ_{546nm}	Φ_{436nm}	Φ_{405nm}	Φ_{366nm}

W	$W(CO)_4$bpym				1.1×10^{-3}

^{a}Quantum yields were determined using deoxygenated solutions of CH_3CN at 298 K.

states responsible for CO substitution are suggested to be the upper electronic LF excited states.

Stufkens and co-workers[7] have investigated the relationship between the resonance Raman spectra and the photo-substitution quantum yields corresponding to *cis*-CO loss for a series of $M(CO)_4L$ complexes. They found that irradiation into the MLCT band of these complexes resulted in an enhancement of Raman intensity of the symmetrical stretch corresponding to the carbonyls *cis* to L, $\nu_s(CO_{cis})$, whereas $\nu_s(CO_{trans})$ was not observed in the spectra. In addition, they found the photosubstitution quantum yield for *cis*-CO loss as well as the intensity of $\nu_s(CO_{cis})$ to increase as the electron density about the nitrogen which is coordinated to the metal increased. They concluded from these observations that *cis*-CO loss upon MLCT irradiation results from a delocalization of the MLCT excited state over the *cis*-carbonyls. This delocalization involves an overlap of orbitals which are localized at L and at the *cis*-carbonyls. The negative charge thus acquired by the *cis*-carbonyls reduces metal-to-CO π-back-bonding and hence weakens the M–C bond.

As can be seen from Fig. 1, the MLCT and LF excited states overlap to a large extent, so the LF excited states have a deal of MLCT character. We therefore suggest that the CO dissociation, which is assumed to occur from the LF excited state, is enhanced by the delocalization of the MLCT excited states over the *cis*-carbonyls. Good evidence for this is the difference in magnitude between the quantum yields of CO loss for the W-bpym and Cr-bpym complexes. Since Cr is smaller in size than W, the overlap of orbitals localized at L and at the *cis*-carbonyls of the Cr complex should be greater than that of the W complexes which corresponds to larger quantum yields for loss of CO from the Cr complex. Also, as shown from the ^{13}C NMR and the electronic spectra, the π-back-bonding into L is greater for the Cr complexes than for the W complexes which would result in a larger overlap of L and *cis*-carbonyl orbitals for the Cr complexes.
Fig. 3. Absorption spectral changes upon 366 nm irradiation of $(CO)_4WbpymW(CO)_4$ in deoxygenated CH_3CN ($\approx 10^{-4}\underline{M}$) at 298 K.

CONCLUSIONS

The bpym complexes were found to be stable with respect to bpym loss upon irradiation and therefore should be useful for studying energy transfer reactions in mixed metal bimetallic systems. Irradiation of these complexes did result in *cis*-CO substitution with very small, wavelength-dependent quantum yields. It was suggested that CO loss occurs from the LF excited states and is enhanced by the large degree of MLCT character of these states.

CHELATE COMPOUND STABILITY CONSTANT CALCULATIONS ON METAL DIKETONATE COMPLEXES

L. G. VAN UITERT

Bell Laboratories, Murray Hill, NJ 07974, U.S.A.

Abstract—Acetylacetone ($CH_3COCH_2COCH_3$ or Hacac) may give up a proton and chelate with a metal ion through the two oxygen atoms. The stability constant for the neutral complex (given as log β_Σ) in aqueous solution can be calculated using the electrostatic relation log $\beta_\Sigma = N_A V_c^2 e^2/(2.3RT\epsilon/d)$ when cations in $\bar{S}$ states are involved. Larger values that reflect exchange related electron correlation as well as electrostatic contributions to cohesive energy are obtained using transition metal ions. Separate values for the two energies are determined (see the text for definitions of the symbols).

INTRODUCTION

Chemical bonding is a subject of continuing interest. Understanding the nature of the interactions between chelate complexing agents and metal ions is particularly germane as this relates to life processes. The problem may be approached using molecular orbital and other complex treatments, but not without some loss of understanding of the physics involved. Indeed, considering the complexity of life related processes in general, it is well to use the simplest of analytical measures and foster an intuitive feel for the interactions of concern. Graphical analysis, though somewhat unpopular in the computer era, is one of the better ways to meet these goals. This approach, combined with easily understood principles of electrostatics, provide valuable insight if the data is resolved so as to reflect relations consistent with accepted concepts of bonding.

In this paper, it is shown that a simple ion–ion electrostatic relation can be used to calculate the (electrostatic) solution chelation energy (E_1) of complexes involving the anion (acac) of acetylacetone (Hacac, $CH_3COCH_2COCH_3$) and metal ions, particularly those that have empty valence shells in the uncomplexed state (i.e. in $\bar{S}$ states). Further, for transition metal ions, one can obtain a separate estimate of the electrodynamic contribution to cohesion (E_2). As will be shown (E_2) is dependent upon the polarization of the oxygen atoms of the anion and upon the presence of electrons in d states of the valence shell, and therefore is due to correlative interactions between the valence shell electrons of the abutting atoms. Of course, the total chelation energy in solution (E_0) equals E_1 plus E_2. Separate determination of these two energies is facilitated by the fact that E_1 is dependent on the dielectric constant (ϵ) of the medium while (as shown herein) E_2 is not.[1]

DATA

Although numerous determinations of stability constants of chelate complexes have been made over the past half century, most of the data are not suitable for the present purposes.[2–4] For example, chelate formation using neutral complexing agents, such as ethylenediamine, involves complicated ion–dipole rather than simple ion–ion interactions.[5] Also the data for most chelate complexes involving oxyanions is relatively incomplete and much of the data in the more complete sets is questionable due to hydrolysis competing with chelation in the solutions used for measurement. Further, for many

otherwise applicable data sets, large quantities of NaCl or KCl were added to the solution to be measured. ostensibly to maintain a fixed ionic strength. However, even in aqueous solutions Cl^- can complex with multivalent cations to an appreciable extent. This can lower measured values for stability constants by an order of magnitude (one log unit) or more. In addition, data measured in mixed solvents (water–dioxane, water–alcohol, etc.) cannot be employed unless corrections to obtain thermodynamic values have been made.[6,7]

To minimize such uncertainties, the data employed herein have been restricted to thermodynamic values obtained potentiometrically using the glass electrode to measure dilute perchlorate soluions that are free of extraneous salt additions, as far as practicable. Four sets of stability constants are considered. These are given as log β_Σ values (log β_Σ being the logarithm of the constant for the neutral species). The first set is for acetylacetonates using water as the solvent (see Table 1).[2–4,8,9] The second set is for dibenzoylmethanates using 25–75 water-dioxane as the solvent (see Table 2).[3,10,11] The third set is composed of Ba, Ni and Cu diacetylacetonates and ditrifluoroacetylacetonates in the same mixed solvent (divalent metal chlorides were used in obtaining this data (see Table 3)).[12] And the fourth set is for ethylacetoacetate measured using water and using ethanol as the solvent (relevant data are given in the text).[7] Ethanol is used as the second unmixed solvent (the first being water) simply because it fits the Born relation for expected changes in the primary medium effect (or the relative activity of H^+ for infinite dilution).[13] Hence, the effect of changing the medium on the stability of the chelate can be investigated without introducing new complications.

For acetylacetone (Hacac), the negative logarithm of the acid dissociation constant (pK_a) equals 9.0 in water. This value is too low to permit accurate measurements to be made for a broad range of chelates. Dibenzoylmethane (Hdbm, $PhCOCH_2COPh$) would have a greater pK_a (13.75 compared to 12.7 for Hacac in 25–75 v/o water–dioxane) but it is not soluble in water. Hence, ethylacetoacetate (Haa, $CH_3COCH_2COOC_2H_5$) for which $pK_a = 10.7$ in water and 15.8 in ethanol is used for comparing results measured using these two solvents.

COMMENTS

A number of things should be made clear:
(a) The M–O bondlength (between the metal ion and the oxygens of the ligand) in these betadiketones is

approximately equal to $r + 1.35$ angstroms, where r is the cation radius as given by Shannon.[14] The ligand oxygen radius of 1.35 Å is deduced in Refs. 15 and 16.

(b) The ion–ion electrostatic energy of association of the complex (E_1) in solution is not the energy required to separate the ions to an infinite distance from each other, but is the residual electrostatic energy of the complex. In water, the latter value is only 1.3% of the former. Further, the change with dielectric constant is in the opposite direction.

(c) The solvation state of the free ions is not of concern for the present purposes as the constants employed were derived taking the concentration of the cations or anions to be the sum of the solvated and nonsolvated species present. Indeed, the actual concentration of the unsolvated ion is exceedingly small (i.e. less by many orders of magnitude).

(d) The ionization of the M–O bond in these oxychelates is essentially 100% when $\bar{S}$ state cations are involved. This appears to favor negative charge localization on the betadiketone oxygens in such complexes and thereby facilitate the use of simple ion–ion electrostatic interactions.

(e) In addition, as H_2O molecules may orient themselves about charged particles almost as readily in mixed solvents as in water, and the activity of H_2O increases (rather than decreases) upon mixing in considerable amounts of paradioxane, one need not be surprised that the "effective" dielectric constant for much of the mixed medium is greater than the normally measured values.[13,17]

EQUATIONS

The electrostatic energy (E_1) of one mole of a 100% ionized chelate complex is:[1,5,8]

$$E_1 = N_A e^2 V_c V_a Z/(\epsilon d) \qquad (1)$$

where N_A is Avogadro's number (6.02×10^{23}), e is the charge on the electron $(4.8 \times 10^{-10}$ esu), V_c is the valence of the cation, V_a is the valence of the anion, Z is the

Table 3. Stability constants for acetylacetonates and trifluoroacetylacetonates in 25–75 v/o water–dioxane

Salt	Betadiketone	pK_a	d	log β_2	d log β_2
BaCl₂	Hacac	12.7	2.70	9.0	24.3
BaCl₂	F₃-Hacac	8.7	2.70	8.8	23.8
NiCl₂	Hacac	12.7	2.04	17.4	35.5
NiCl₂	F₃-Hacac	8.7	2.04	14.2	29.0
CuCl₂	Hacac	12.7	2.08	22.6	47.0
CuCl₂	F₃-Hacac	8.7	2.08	17.2	35.8

number of anions per cation and may be viewed as a Madelung constant derived from the location and charge of the anion oxygens surrounding the cation in each complex and $\underline{d}$ is the M–O bond length in angstroms. The electrostatic energy is reduced by changing from $\epsilon = 1.00$ for air to a medium with $\epsilon > 1.00$, while the difference in energy for $\epsilon = 1.00$ and $\epsilon > 1.00$ (e.g. the heat of solvation) increases.[1] Since $ZV_a = V_c$ for the chelates of interest and $N_A e^2 = 1387$ kilojoules/mole, for one mole of a betadiketonate chelate complex dispersed in a solvent the electrostatic contribution to cohesive energy is:

$$E_1 = 1387 V_c^2/(\epsilon \underline{d}) \text{ kJ/mole}. \tag{2}$$

In its equilibrium constant form, relation (2) becomes:

$$\log \beta_\Sigma = \frac{E_1}{2.3RT} = \frac{1387 \times 10^3 V_c^2}{5.7 \times 10^3 \epsilon \underline{d}} = \frac{243 V_c^2}{\epsilon \underline{d}}. \tag{3}$$

Here, $R = 8.31$ J/mole and temperature $T = 298$ K. Further, the difference in $\log \beta_\Sigma$ values for a complex in a medium ϵ_3 and in a medium ϵ_2 is:

$$\Delta \log \beta_\Sigma = 243 V_c^2 (1/\epsilon_3 - 1/\epsilon_2)/\underline{d}. \tag{4}$$

In addition, other things being equal, the logarithm of the stepwise stability constants for a given cation and chelating agent should be in the ratio: $1:3:5:7:9$, etc. proceeding as far as required from the last to the first. Deviations from this pattern can be related to solvation differences and/or salt anion–cation association.

FIGURES

Figures 1 and 2 depict $\underline{d} \log \beta_\Sigma$ vs the index number of the period in the periodic table in which the cation occurs for (1) acetylacetonate data taken using an aqueous medium and (2) essentially thermodynamic data for dibenzoylmethanate complexes taken using 25–75 v/o water–dioxane as the medium.[2–4,6,8–11] The horizontal guidelines fit relation (4) with $\epsilon = 78.5$ for the first figure and with $\epsilon = 30$ for the second. The vertical lines indicate displacement from the relevant horizontal line. In Fig. 1, only the points for Mg and La fit the calculated guideline. These ions are in $\bar{S}$ states and, obviously, the acac ions provide little steric hinderence. If similar data were
Fig. 2. $\underline{d} \log \beta_\Sigma$ vs period number for metal ion dibenzoylmethanates measures using 25–75 v/o water–dioxane as the solvent. The horizontal lines represent values calculated using relation (3), $\epsilon = 30$ and $V_c^2 = 1, 4, 9$ and 16 in ascending order.

available for the Na–Cs and Ca–Ba acetylacetonates, it is expected that their data points would also fit these lines. However, due to the low value of $\log \beta_\Sigma$ constants that apply when water is used as the solvent, they have not been measured.[2,3] Most of the remaining data points that fall below the dashed line that passes through the origin in Fig. 1 are for complexes that have cations with partially filled valence shells. Most of the data for the points that fall above the dashed line in Fig. 1 are of questionable value as they represent attempts to estimate constants from pH data measured in the presence of relatively large quantities of acid added to suppress hydrolysis.[2,3,9] For example, the correct positions for trivalent Fe, Ti and Ga probably lie about half way to the guideline as indicated by the arrow.

The stability constants measured using Hdbm and 25–75 v/o water–dioxane as the solvent (as shown in Fig. 2) are much larger than those measured using Hacac and water. This can be attributed to a smaller "effective" dielectric constant for the solvent; including some increase due to steric effects and (for transition metal ions) to enhanced polarization of the oxygens of the betadiketone. The increased stability of these complexes makes it possible to measure $\log \beta_\Sigma$ for all of the alkali metal and alkaline earth cations in this medium. As can be seen in Fig. 2, these data points and those for trivalent Ce and tetravalent Th as well fall on or very close to their respective guidelines. In comparison, data points for complexes in which the valence shell of the cation is partially filled fall above the relevant guideline for $\bar{S}$ state ions.

Figure 3(a) depicts $\underline{d} \log \beta_2$ for the acetylacetonates (indicated by the end groups, CH_3—CH_3) and trifluoroacetylacetonates (CF_3–CH_3) of divalent Ba, Ni and Cu vs pK_a values for the chelating agents (as measured in 25–75 v/o water–dioxane).[12] It is evident that $\underline{d} \log \beta_2$ is little affected by the change in pK_a for the $\bar{S}$ state cation (Ba^{2+}). Further, it is evident that the trifluoroacetylacetonate ions as well as the acetylacetonate ions themselves offer little steric hinderence.

Figure 3(b) depicts $\underline{d} \log \beta_2$ and $\underline{d} E_0$ for the indicated $M(acac)_2$ complexes vs $ip2$ (the second ionization potential of the metal) for data measured in water.[2] Points for V^{2+} or Cr^{3+} are not included as these ions oxidize during

measurement and therefore tend to greater values than they would have if stable.[19] The horizontal line roughly separates cohesive contributions E$_1$ (below) and E$_2$ (above).

Figure 3(c) represents Néel temperature (T$_N$) for divalent metal chromates (MCr$_2$O$_4$) and sulfates (MSO$_4$) vs ip2.[20] This figure is included to show the common dependence of E$_2$ and T$_N$ on ip2 for the Mn, Fe, Co, and Ni series. Point displaced by spin-orbital coupling are not presented in this figure.

DISCUSSION

Most expressions of cohesive energy between charged particles are in terms of the electrostatic energy given up upon consolidation.[5] Such relations predict a reduction in E$_1$ or log β_Σ values with a reduction in ϵ for the medium. However, comparison of log β_Σ values measured in ethanol ($\epsilon = 24.3$) to those obtained using water ($\epsilon = 78.5$) show the opposite to be the case.[7,8] For example. log $\beta_\Sigma = 26$ for Ni(acac)$_2$ in ethanol and $= 10.4$ in water.[7] This is in agreement with relations (3) and (4). By inserting $\underline{d} = 2.04$ (for the nickel complex), $\epsilon_3 = 24.3$ (for ethanol and $\epsilon_2 = 78.5$ (for water) into relation (4) one calculates Δ log $\beta_\Sigma = 13.5$. In comparison, the experimental difference is 13.2. Similar results can be deduced for Mg, Zn and Ca.[7,8] In general, the change in log β_Σ found employing these ions agrees with that expected using relation (4) and either $\bar{S}$ state or transition metal ions. This demonstrates that E$_2$ is little affected by changes in ϵ.

Even through relation (3) should apply, it is evident from Fig. 1 that it would be difficult to fit it to the existing data for acetylacetonates measured using water as the solvent. Much of the needed data for $\bar{S}$ state ions has not been obtained, or involves hydroxide formation, and most of the remaining cations have d states occupied in the valence shell. However, a suitable correlation is possible employing the extended data for monovalent and divalent cations in $\bar{S}$ states and the values for Ce and Th shown in Fig. 2. It is evident from this figure that the points for the indicated cations essentially fit the (V^2) position lines expected from relation (3). This strongly supports the view that bonding for these chelates is close to 100% electrostatic.

Actual values for E$_1$ and E$_2$ can be estimated for divalent transition metal cations using data measured employing water as the solvent and acetylacetone as the chelating agent as this minimizes any effects related to mixed solvents and steric factors. But first it is well to establish the nature of the electrodynamic interactions involved.

As represented in Fig. 3(a), the stability constant changes little upon going from the acetylacetonate to the trifluoroacetylacetonate of Ba^{2+} even though pK$_a$ changes by 4. This is as expected for electrostatic interactions provided steric effects are minimal for both betadiketones used. However, for Ni^{2+} and Cu^{2+}, the slope of the connecting lines increase with ip2. The relation of the three lines indicates that electrodynamic correlation effects between electrons about the oxygen atoms of the chelating agent anion and the cation depend upon the presence of electrons (principally in d states) in the valence shell of the latter as well as the ability of the cation to polarize the anion. Further, the convergence of the slopes (meeting at pK$_a = 5.0$) indicates that electrodynamic exchange also is a function of the polarization of the anion. This increases with pK$_a$.

Values of E$_1$ and E$_2$ for M(acac)$_2$ transition metal ion complexes in water can be deduced using Fig. 3(b). The horizontal (dashed) line passing close by the point for Mg(acac)$_2$ represents the $\underline{d}$E$_1$ or $\underline{d}$ log β_Σ value for all divalent S state cation complexes. As can be seen, the $\underline{d}$ log β_2 values for Mn–Cu lie above this line and tend to increase linearly with ip2. The second half of the 3d subshell is being filled in the course of this transit. Points for Zn and Cd, which have filled d^{10} sets fall at lower values as it is somewhat more difficult for d^{10} electrons to enter into spin correlation interactions with electrons in the valence shell of the anion. The line through the Mn–Cu points intercepts the electrostatic (horizontal) guideline at 13.8 eV. As shown in Fig. 3(c) the onset of

magnetic exchange in the oxides (MCr_2O_4 and MSO_4) also occurs at 13.8 eV. This indicates a common dependence on the electron affinity of the cation to foster interatomic correlative interactions. Electrodynamic interactions may occur for a lower (first) ionization potential (e.g. Ag 7.57 and Tl 6.11 eV) for non $\bar{S}$ state cations provided they are in asymmetric sites where they can polarize extensively (e.g. in monochelates). Related binding effects are expected to increase exponentially as mutual polarization overlap increases linearly. Hence, it is not surprising that $\not{d} \log \beta_1$ values for Ag^+ and Tl^+ dibenzoylmethanates are considerably larger than those for the comparable $\bar{S}$ state cations (see Fig. 2).

One ordinarily tends to think of electrostatic and electrodynamic cohesive interactions as having comparable dependences on bondlength and therefore to be difficult to separate quantitatively. Since the latter tend to decrease ionization, E_1 may be expected to decrease as E_2 increases. However, upon going from air to water E_1 decreases as the inverse ratio of the dielectric constant of the medium (to $1 \times 100/78.5 = 1.27\%$ of the former value) while E_2 is essentially unaffected. This is supported by the measurements reported above for ethylacetoacetates in ethanol and in water. Consider a complex for which E_1 is 98% and E_2 is 2% of E_0 in air. Upon dissolving the complex into water, E_1 decreases to $98/78.5 = 1.25\%$ of the air value of E_0 while E_2 remains at 2%. Clearly the value of E_1 in water is only decreased 2% by the electrodynamic interactions present, even though the ratio of E_2/E_1 may be greater than unity in the solvent. In as much as this example applies reasonably well to the data in Fig. 3(b), the horizontal line in that figure can be taken to divide $\not{d}E_0$ into $\not{d}E_1$ and $\not{d}E_2$ contributions for interactions in water.

CONCLUSIONS

Thermodynamic $\log \beta_\Sigma$ values for betadiketonates of cations that are in $\bar{S}$ states essentially fit the simple ion–ion electrostatic interaction model indicated by relation (3). In particular, the correct values for the acetylacetonates of this group should provide an excellent fit as shown by the data points for $Mg(acac)_2$ and $La(acac)_3$ in Fig. 1. Using relation (3) and a known value of $\log \beta_2$ for $Mg(acac)_2$ measured by other means (see Refs. 6 and 7), one can deduce an "effective" dielectric constant for

mixed solvents that may be employed. Using this constant and the appropriate bondlengths, one may then calculate $\log \beta_\Sigma$ values for the acetylacetonates of the remaining $\bar{S}$ state cations. When more complex betadiketones are employed, steric hinderence should be considered as well. The effects can be estimated as the difference in $\log \beta_\Sigma$ values for the new complex and the acetylacetonate of the same ion, particularly for $\bar{S}$ state cations. Further, some adjustment for anion and/or cation polarizability may also be needed when considering complexes of transition and post transition metal ions.

BIS- AND TRIS-(TRIMETHYLSILYL)METHYL
DERIVATIVES OF ANTIMONY

HANS JOACHIM BREUNIG* WALTER KANIG and ALI SOLTANI-NESHAN
University of Bremen, P.O. Box 330 440, D-2800 Bremen, Federal Republic of Germany

Abstract—Reaction of RMgCl [R = (Me$_3$Si)$_2$CH] with SbCl$_3$ affords RSbCl$_2$. Also R$_2$SbCl reacts with RLi to yield R$_3$Sb, while R'SbCl$_2$ [R' = (Me$_3$Si)$_3$C] is synthesized from R'Li and SbCl$_3$. Mass spectra of RSbCl$_2$ and R'SbCl$_2$ show that fragmentations proceed with elimination of Me$_3$SiCl. The chlorides RSbCl$_2$, R$_2$SbCl and R'SbCl$_2$ are thermally very stable.

INTRODUCTION

Silylmethyl groups like (Me$_3$Si)$_2$CH- or (Me$_3$Si)$_3$C- combine bulkiness with the capability to form strong metal- or element-carbon bonds. Therefore they have been used for the syntheses of organometallic compounds with unusual coordination numbers and chemical properties.[1] In the course of our investigations on steric effects in organoantimony synthesis,[2] we were interested in the preparation and chemistry of alkylantimony chlorides with these substituents. We hoped that a part of their chemistry might be the thermal 1,2-elimination of Me$_3$SiCl, yielding stiba-alkenes. Analogous reactions are known in phosphorus chemistry.[3]

SYNTHESES AND PROPERTIES OF (Me$_3$Si)$_3$CSbCl$_2$ (1), [(Me$_3$Si)$_2$CH]SbCl$_2$ (2), [(Me$_3$Si)$_2$CH]$_2$SbCl (3), and [(Me$_3$Si)$_2$CH]$_3$Sb (4)

Reaction of (Me$_3$Si)$_3$CLi with SbCl$_3$ in tetrahydrofuran (THF) results in the substitution of one chlorine atom (eqn 1) and formation of colourless crystals of compound 1, which are stable towards water and air but become dark brown in the sunlight. 1 is soluble in common organic solvents. It can be sublimed at reduced pressure and recrystallized from methanol.

$$(\text{Me}_3\text{Si})_3\text{CLi} + \text{SbCl}_3 \rightarrow (\text{Me}_3\text{Si})_3\text{CSbCl}_2 + \text{LiCl}. \quad (1)$$
$$1$$
Its mass spectrum shows intense signals for the ions (M$^+$-Me) and (M$^+$-Me-Me$_3$SiCl). The latter ion corresponds to a (M$^+$-Me) fragment ion of a stiba-alkene (Me$_3$Si)$_2$C=SbCl. Attempts to eliminate Me$_3$SiCl from 1 under preparative conditions have however not been successful, but proved the remarkable thermal stability of 1. Under the conditions of the synthesis of 1 used here, it was not possible to substitute a second chlorine atom in 1.

The considerably reduced steric demand of a (Me$_3$Si)$_2$CH group is shown by the substitution of one to three chlorine atoms in SbCl$_3$, which yields the complete series R$_{(3-n)}$SbCl$_n$

$$[R = (\text{Me}_3\text{Si})_2\text{CH}; 2: n = 2, 3: n = 1, 4: n = 0].$$
The dichloride 2 is prepared by the Grignard reaction (2)

$$(\text{Me}_3\text{Si})_2\text{CHMgCl} + \text{SbCl}_3 \rightarrow (\text{Me}_3\text{Si})_2\text{CHSbCl}_2 + \text{MgCl}_2$$
$$2$$
$$(2)$$
and obtained as a colourless liquid, which is thermally

very stable but sensitive to oxygen. Fragmentations of 2 in the mass spectra resemble those of compound 1. Again we observe the formation of an ion corresponding to the (M$^+$-Me) fragment of a stiba-alkene. Heating 2 to 280°C did not, however, result in elimination of Me$_3$SiCl, but caused the decomposition of the whole molecule.

The substitution of two or three chlorine atoms in SbCl$_3$ was accomplished by reactions of (Me$_3$Si)$_2$CHLi with this substrate. The chloride 3 is synthesized by reaction (3)[1b] using appropriate molar amounts of the reagents.

$$2(\text{Me}_3\text{Si})_2\text{CHLi} + \text{SbCl}_3 \rightarrow [(\text{Me}_3\text{Si})_2\text{CH}]_2\text{SbCl} + 2\text{LiCl}.$$
$$3 \quad (3)$$
3 reacts in tetrahydrofuran with one more molar equivalent of (Me$_3$Si)$_2$CHLi yielding the tertiary stibine 4.

$$[(\text{Me}_3\text{Si})_2\text{CH}]_2\text{SbCl} + (\text{Me}_3\text{Si})_2\text{CHLi}$$
$$3 \qquad \rightarrow [(\text{Me}_3\text{Si})_2\text{CH}]_3\text{Sb} + \text{LiCl}. \quad (4)$$
$$4$$
3 and 4 were isolated as liquids with considerable stability in air. They are soluble in common organic solvents. 3 is thermally stable up to 290°C whereas 4 decomposes at 180°C and cannot be distilled under reduced pressure. Attempts to eliminate Me$_3$SiCl by thermal cracking of 3 have not been successful. Mass spectra of 3 and 4 show intense molecular ions and the expected fragments. There is no elimination of a Me$_3$SiCl unit in the fragmentation of 3.

The ^{1}H-NMR spectra of 1, 2 and 4 show singlets for the Me$_3$Si groups whereas in the spectrum of 3 the Me$_3$Si signal is more complicated. This corresponds to a diastereotopic situation, which indicates configurational stability in 3. It must be noticed however, that we observe more signals than the expected two singlets. The relative positions of the signals of the tertiary stibine 4 and the dichloride 2 show the expected trend: substitution of two alkyl groups in 4 by chlorine atoms causes a downfield shift for the Me$_3$Si protons.

Preliminary results show that all these alkyl-antimonychlorides (1, 2, 3) react with Mg in THF with abstraction of chlorine atoms. There is evidence for the formation of cyclo(polystibanes) of the composition (RSb)$_n$ [R = (Me$_3$Si)$_2$CH] by dehalogenation of 2 [(18 eV, 100°C): m/z = 840 (5%) R$_5$Sb$_5$$^{+\cdot}$, 68$_1$ (5%) R$_2$Sb$_3$$^+$]. The reaction of 3 with Mg/THF yields a distibane R$_4$Sb$_2$ [R = (Me$_3$Si)$_2$CH; (25 eV, 100°C): m/z = 719 (5%) R$_3$Sb$_2$$^+$].

DISCUSSION

Because of the high steric requirements of both the $(Me_3Si)_3C$ and the $(Me_3Si)_2CH$ substituents, we observe the expected decrease of reactivity on the antimony (III) centers. This prevents the introduction of more than one $(Me_3Si)_3C$ group under the conditions of the preparation fo **1** and allows selective syntheses of the alkyl(chloro)stibines **2–4**. Similar reactions with alkyl reagents which have no steric hindrance always afford peralkylated stibines. Partial alkylation has been achieved, however, with tertiary-butyl substituents. A decrease in reactivity is also observed towards oxygen: **1, 3** and **4** are stable in air. Another unusual feature of **1–3** is their termal stability.

EXPERIMENTAL

All preparations of air sensitive compounds were carried out in an atmosphere of purified Ar and in dry solvents. The following spectrometers were used: NMR, EM 360 Varian; IR, PE 577 Perkin Elmer; MS, CH7 A, Varian MAT; mass spectral data are given for ^{121}Sb and ^{35}Cl. The peak patterns correspond to theoretical values based on the natural abundance of isotopes. Elemental analyses were carried out by Fa. Beller, Göttingen.

Tris(trimethylsilyl)methylantimonydichloride (1)

22·8 g (0·1 mol) $SbCl_3$ were added at 0°C to a solution of $(Me_3Si)_3CLi$,[4] which had been prepared by reaction of 14·4 g (0·062 mol) $(Me_3Si)_3CH^5$ with MeLi in THF. Distillation of the solvent afforded a brown oily residue, which contained unreacted $(Me_3Si)_3CH$ (b.p.$_{0·01}$ 50°C) and 8·7 g (33%) of white crystalline **1** (m.p. 196°C) which sublimed at 140°C 0.01 mm Hg and could be recrystallized from methanol.

Heating of **1** for 5 hr did not yield Me_3SiCl, but black solids were produced when the temperature reached 280°C. **1**: ^1H-NMR (C_6H_6) $\delta = 0.30$ ppm S; IR (nujol) 1250 s, 840 s, 670 m, 600 m, 330 s $\nu SbCl$; MS (35 eV, 90°C) m/z (rel. int. %): 407 (100) $(M^+ - Me)$, 299 (30) $(M^+ - Me - Me_3SiCl)$, 223 (20), 221 (100), 201 (10), 73 (100). $C_{10}H_{27}Cl_2SbSi_3$ (424·2); found: C 28·2 (28·3); H 6·2 (6·3); Cl 16·9 (16·7); Sb 28·4 (28·7)%.

Bis (trimethylsilyl)methylantimonydichloride (2)

A THF solution of $(Me_3Si)_2CHMgCl$ was prepared from 3.0 g (0.125 mol) Mg and 19·5 g (0·1 mol) $(Me_3Si)_2CHCl^7$ and added slowly to 22·8 g (0.1 mol) $SbCl_3$ in 50 ml THF at 0°C then stirred 12 hr at 0°C and 2 hr at 25°C. After removal of the solvent at reduced pressure, the residue was hydrolysed and extracted with ether. **2** was obtained by distillation at 75°C/0·01 mm Hg as a yellow liquid [yield 18·5 g (53%)]. **2**: ^1H-NMR $(CDCl_3)$ $\delta = 0.18$ ppm S (18 H), $\delta = 0.86$ ppm S (1 H). IR (film) 1255 s, 845 s, 765 w, 665 w, 330 $(\nu SbCl)$; MS (30 eV, 20°C) m/z (rel. int. %): 335 (100) $(M^+ - Me)$, 227 (40) $(M^+ - Me - Me_3SiCl)$, 129 (80), 73 (60).

$C_7H_{19}Cl_2SbSi_2$ (352·1); found: C 23·4 (23.9); H 5·2 (5·4); Cl 20·5 (20.2)%.

Bis[bis(trimethylsilyl)methyl]antimonychloride (3)[1b]

$(Me_3Si)_2CHLi^6$ was prepared from 1·4 g (0.2 mol) Li sand and 16 g (0·08 mol) $(Me_3Si)_2CHCl$,' analysed (80% conversion) and added to 6·8 g (0·03 mol) $SbCl_3$. Work up as described [1b] yielded 11·5 g (81%), Lit.[1b] 65%, of **3** as a colourless oil. b.p.$_{0·01}$ 103–105°C, Lit.[1b] b.p.$_2$ 147–149°C.

3: ^1H-NMR $(CDCl_3)$ sharp signals at $\delta = 0.15$; 0·20; 0·25 ppm 18 H; $\delta = 0.95$ ppm (1 H) *S*. IR (film): 1255 s, 840 s, 535 m, 330 m $(\nu SbCl)$ cm^{-1}. MS (30 eV, 25°C) m/z (rel. int. %): 474 (30) (M^+), 459 (80) $(M^+ - Me)$, 443 (85), 389 (30), 369 (70), 355 (10), 315 (90), 221 (30), 207 (100), 147 (80), 73 (100). $C_{14}H_{38}ClSbSi_4$ (476·0); found: C 35·7 (35·3); H 8·1 (8·1)%.

Tris[bis(trimethylsilyl)methyl]antimony (4)

A solution of 6 g (0·012 mol) **3** in 20 ml THF was added to a solution of $(Me_3Si)_2CHLi$ in THF prepared from 3·3 g (0·017 mol) $(Me_3Si)_2CHCl$ and 0·25 g (0·036 mol) Li. The solution was stirred under reflux for 12 hr, the solvent was then stripped off *in vacuo* and the residue extracted with pentane. After distillation of this solvent **4** remained as a yellow oil (3 g, 42%). Attempts to distil **4** caused decomposition. **4**: ^1H-NMR $(CDCl_3)$ $\delta = 0.15$ ppm *S* (18 H); $\delta = 0.7$ ppm *S* (1 H), IR (film: 1255 s, 840 s, 530 m. MS (20 eV, 70°C) m/z (rel. int.%): 598 (30) (M^+), 439 (100) (R_2Sb^+), 369 (10), 269 (2). $C_{21}H_{57}SbSi_6$ (600·0); found: C 42·1 (42·0); H 9·31 (9·58); Sb 19·3 (20·3).

THERMAL, SPECTRAL AND MAGNETIC STUDIES ON SOME
TRANSITION METAL COMPLEXES OF EMBELIN

K.K.ABDUL RASHEED, JACOB CHACKO AND P.N.K. NAMBISAN*
Department of Marine Sciences, University of Cochin,
Cochin - 682 016, India

Abstract - Complexes of embelin with Mn(II), Ni(II), Cu(II)
and Zn(II) have been prepared and characterised for the first
time. Spectral, thermal and magnetic studies suggest an
octahedral coordination for Mn(II), Ni(II) and Zn(II) ions
while a tetrahedrally distorted planar configuration is
proposed for the Cu(II) complex.

INTRODUCTION

Embelin (2,5 dihydroxy-3-undecyl-2,5-cyclohexadiene-1,4-dione),
an orange pigment isolated from the berries of Indian shrub Embelia
ribes, is of great medicinal importance, because of its anthelmintic
properties[1]. However, only very scant information is available on
metal chelates of embelin[2,3], which could function as possible basis
for anthelmintic drugs. We have, therefore, undertaken a systematic
study on the synthesis and structure of transition metal complexes of
embelin and here in report the results of our investigation. Complexes
of Mn(II), Ni(II), Cu(II) and Zn(II) with embelin have been synthesised
and characterised by elemental analysis, IR spectra, reflectance spectra,
thermal and magnetic studies.

EXPERIMENTAL

Preparation of the ligand

Pure natural embelin was prepared by the method of Fieser and
Chamberlin[1]. The crushed embelia ribes were extracted with solvent
ether in a soxhlet apparatus. The crude embelin thus isolated was
purified by defatting twice with petroleum ether (60-80°C) and
recrystallizing twice from absolute alcohol. Pure embelin (mp 142°C)
was obtained in ∼ 2% yield.

Preparation of the complexes

Aqueous ethanolic solutions of the corresponding metal acetates
and ethanolic solutions of the ligand in 1:1 molar ratio (with the metal
salt in slight excess) were mixed together and refluxed on a water bath

---

*for correspondence

for 20-30 minutes. The metal complexes precipitated out and were washed repeatedly with aqueous ethanol to remove excess metal ions. The complexes were dried in vacuum over P_2O_5.

Elemental analysis and physical measurements

The complexes were decomposed with a mixture of HCl and HNO_3 and manganese, copper and zinc were analysed complexometrically and nickel gravimetrically[4]. IR spectra (4000-600 cm^{-1}) were recorded as KBr pellets on a Beckman Acculab 7 IR spectrophotometer. Simultaneous TGA-DTA of the samples were carried out on a Stanton Redcroft TR-01 Thermobalance with a DTA attachment. Magnetic susceptibilities were measured by the Gouy method using mercury tetra-thiocyanato cobaltate (II) as the calibrant[5]. As the complexes were found to be insoluble in most of the common organic solvents, conductance measurements and molecular weight determinations could not be carried out. The electronic spectra were recorded in the solid state using a Schimadzu SP 200 spectrophotometer with a reflectance attachment using magnesium oxide as the reference.

RESULTS AND DISCUSSION

The insolubility of the complexes in most of the common organic solvents indicates a polymeric nature. All the complexes are mildly hygroscopic and hence experimentally determined values of the metal content (Table I) are slightly lower than those theoretically expected for a 1:1 polymer. Such variations in analytical data were observed by earlier workers too[6,7].

IR spectra

The important IR frequencies of the ligand and of the metal complexes are presented in Table I. The O-H stretching frequency is observed as a strong band at 3300 cm^{-1} for embelin. The disappearance of this band in the spectra of the complexes indicates that the phenolic hydrogens present on the ligand molecule are lost on chelation. The broad, medium intense peak occurring between 3300 and 3450 cm^{-1} in the spectra of Mn(II), Ni(II) and Zn(II) complexes may be attributed to the O-H stretching frequency of the coordinated water molecules. The O-H bending frequency is observed as a weak band at 1650 cm^{-1} for Mn(II), Ni(II) and Zn(II) complexes.
EMBELIN

Table I

Analytical, magnetic and spectral data of Embelin and its complexes

Compound	Colour	% metal found	% metal calcd	μ_{eff} (BM)	Reflect-ance spectra λ_{max} (cm^{-1})	Assignments of important i r spectral bands ν_{O-H} Phenolic (cm^{-1})	ν_{O-H} Coord water (cm^{-1})	δ_{O-H} Phenolic (cm^{-1})	δ_{O-H} Coord water (cm^{-1})	$\nu_{C=O}$ (cm^{-1})
Embelin $C_{17}H_{26}O_4$	Orange-yellow				17800 28570 33330	3300		1640		1610

Em = $C_{17}H_{24}O_4^=$

Both these bands are absent in the spectra of the Cu(II) complex indicating the absence of any water molecules. Vibrational bands, in the 880–650 cm^{-1} region, characteristic of coordinated water molecules[8] could not be located owing to strong ligand absorptions in this region. The carbonyl stretching frequency, observed as a strong peak at 1610 cm^{-1}, is found shifted to 1520 cm^{-1} in the spectra of Mn(II), Ni(II) and Zn(II) complexes and to 1460 cm^{-1} in the case of the copper complex. The Cu(II) complex of 2,5-dihydroxy-2,5-cyclohexadiene-1,4-dione is also known to exhibit a similar enhanced shift for the carbonyl stretching frequency[6,7]. Thus the assignments of the spectral bands indicate that embelin acts as a tetra dentate ligand coordinating through its phenolic and carbonyl oxygens.

Electronic spectra

      Reflectance spectra of the complexes in the region (900–200 nm) were studied (Table I). Ligand absorptions and charge transfer transitions complicate the assignment of bands observed in the UV region.

      Being spin and multiplicity forbidden, the d-d transitions of the Mn(II) complex have very low intensities. The band at 19230 cm^{-1} could be assigned to the $6A_1 \longrightarrow 4T_2(G)$ transition and that at 23800 cm^{-1} to the $6A_1 \longrightarrow 4E(G)$, $6A_1 \longrightarrow 4A_1(G)$ doublet. The $6A_1 \longrightarrow 4T_1(G)$ transition, expected around 17000 cm^{-1}, is probably obscured by the fairly strong ligand absorption at $\sim$ 17800 cm^{-1}. The observed spectral bands of the Mn(II) complex thus suggest an octahedral symmetry[9,10].

      The absorption bands observed for the Ni(II) complex at 17240 cm^{-1} and at 25000 cm^{-1} may be assigned to the spin allowed transitions from the ground state $3A_{2g}(F)$ to $3T_{1g}(F)$ and $3T_{1g}(P)$ levels respectively. This is in conformity with the expected d-d transitions for octahedrally coordinated Ni(II) complexes[11].

      In the case of Cu(II) complex, the d-d transition bands are seen to undergo a red shift and are located at 11460 cm^{-1} and 14700 cm^{-1} and an asymmetric and weak LF band is observed at $\sim$ 20000 cm^{-1}. This suggests a tetrahedrally distorted planar configuration[12], especially in view of the steric hindrance caused by the bulky embelin molecules. Copper complexes with other bulky ligands too have been known to exhibit similar spectral and magnetic behaviour[13]. The observed band at 22720 cm^{-1} may be ascribed to a charge transfer transition[14].

      Since no ligand field transition is expected for a d^{10} configuration, the observed bands in the spectrum of the zinc complex are due to ligand absorptions and/or charge transfer transitions.

Magnetic properties

      The room temperature magnetic moment of 5.84 BM (Table I) for the Mn(II) complex indicates an octahedral environment for the metal ion[15].

Table II

*   Theoretical value in brackets

**   Theoretical value, based on metal oxide composition, in brackets.

The Ni(II) complex has a μ_{eff} value of 3.2 BM and is quite expected for an octahedrally coordinated Ni(II) ion with an orbital contribution arising from a second order process[11]. Cu(II) complexes, in general, have μ_{eff} values between 1.75-2.2 BM and magnetic moments, strictly, cannot be used to distinguish between the stereochemistries of the complexes. Nevertheless, lower magnetic moments (<1.93 BM) are frequently attributed to square planar configurations[16]. Since tetrahedral distortions are expected to lead to increased magnetic moments[13], a μ_{eff} value of 2.12 BM further supports the stereochemistry proposed on the basis of the electronic spectral behaviour. The Zn(II) complex is diamagnetic as expected.

Thermal behaviour

Thermal studies on the metal complexes of embelin were carried out under static air conditions. Thermo-analytical data obtained from TG, DTG and DTA curves and independent pyrolysis are presented in Table II. The thermograms for the Mn(II) and the Zn(II) complexes indicate two clear cut stages: the first corresponding to the dehydration of the coordinated water molecules and the second to the decomposition process. In the case of the Ni(II) complex, the dehydration step is seen to merge with the decomposition process resulting in a single extended stage. The temperature ranges for the dehydration step, in this case has, therefore, been deduced from the DTG curve and the percentage mass loss corresponding to this range has been attributed to the loss of water molecules. The Cu(II) complex shows only a single stage, being devoid of any water molecules. Dehydration peaks in the DTG for Mn(II), Ni(II) and Zn(II) complexes are parallelled by corresponding endothermic DTA peaks. Exothermicity of the decomposition peaks may be attributed to the concomitant oxidation reactions of the ligand. Final residues of independent pyrolysis (upto 700°C) of the complexes were subjected to chemical analysis[4] and were found to have metal contents corresponding to the compositions of Mn_2O_3, NiO, CuO and ZnO. On the basis of the procedural decomposition temperatures, the complexes are seen to follow the stability sequence Zn > Ni > Mn > Cu which is in good agreement with the order of thermal stabilities observed for the coordination polymers[6]. However, the increased shift in the carbonyl frequency of the Cu(II) complex suggests an extra stability which is portrayed in terms of the initial stability range of the complex in the TG curve.

NOTES

Synthesis, molecular structure and electrochemistry of pentagonal bipyramidal nickel(II) complexes of quinquedentate macrocyclic ligand incorporating a 2,2':6',2"-terpyridyl moiety

Abstract—The synthesis and single crystal X-ray structure of the pentagonal bipyramidal nickel(II) complex [Ni(L)(EtOH)$_2$](BF$_4$)$_2$ involving the quinquedentate terpyridyl macrocyclic ligand L is reported; the electrochemical reduction of such complexes yields, in solution, d^9 nickel(I) species.

INTRODUCTION

We have recently reported structural[1] and electrochemical[2] studies on transition metal complexes of pentadentate macrocycles incorporating 2,2'-bipyridyl or 1,10-phenanthroline units. The stabilisation of low valent metal species in these systems has been correlated with the π-acceptor properties and stereochemical requirements of the diimine macrocyclic ligand. It has been demonstrated that similar π-acceptor properties are shown by higher diimine chelates such as terpyridyl[3] and quinquepyridyl[4] derivatives. We have therefore undertaken to incorporate such higher diimine units into macrocyclic arrangements and to study their subsequent stereochemical and redox behaviour.

In this communication we report the synthesis and single crystal X-ray structure of the pentagonal bipyramidal nickel(II) complex [Ni(L)(EtOH)$_2$](BF$_4$)$_2$, the first macrocyclic complex incorporating a 2,2':6',2"-terpyridyl moiety, and the electrochemical reduction of such complexes to the corresponding d^9 nickel(I) species.

EXPERIMENTAL

The template condensation of 6,6"-bis(methylhydrazino)-4'-phenyl-2,2':6',2"-terpyridine[5] with glyoxal in the presence of Ni(OAc)$_2$·4H$_2$O in refluxing methanol yielded, on addition of [n-Bu$_4$N]$^+$[BF$_4$]$^-$, yellow micro crystals of [Ni(L)(MeOH)$_2$](BF$_4$)$_2$. Recrystallisation of this product from ethanol gave single crystals of [Ni(L)(EtOH)$_2$](BF$_4$)$_2$ a single crystal X-ray structural determination of which was undertaken to confirm its stereochemistry.

Electrochemical measurements were recorded on a Princeton Applied Research Electrochemistry System Model 170. Cyclic voltammetric studies were carried out using a three-electrode potentiostatic system with platinum wire as auxiliary and working electrodes and an Ag–AgNO$_3$ reference electrode at a scan rate of 1 V sec^{-1}. All readings were taken in acetonitrile with 0.1 mol l^{-1} [n-Bu$_4$N]$^+$[BF$_4$]$^-$ present as base electrolyte. Controlled potential electrolysis experiments were carried out using platinum gauze as the working electrode, a salt bridge being incorporated to separate oxidised and reduced species. ESR spectra were measured as glasses in acetonitrile at 77 K. All solvents were distilled, dried and degassed before use.

RESULTS AND DISCUSSION

Crystal data: [C$_{29}$H$_{33}$N$_7$NiO$_2$]$^{2+}$ (BF$_4^-$)$_2$, M = 743.93, monoclinic, a = 14.271(3), b = 17.365(5), c = 12.364(4) Å, β = 98.03(3) Å, U = 3033.95 Å^3, D$_c$ = 1.628 g cm^{-3}, Z = 4, Cu-K$_\alpha$ radiation, λ = 1.5418 Å, μ(Cu-K$_\alpha$) = 8.09 cm^{-1}, F(000) = 764,

†Copies of atomic co-ordinates, thermal parameters and F$_o$/F$_c$ values have been deposited as Supplementary material with the Editor, from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

space group C2/c. 2773 intensities were recorded on a Syntex P2$_1$ diffractometer (2θ$_{max}$ = 125°) using graphite monochromated Cu-K$_\alpha$ radiation and a ω/2θ scan technique. The data were not corrected for absorption, but were averaged to give 1944 unique observed reflections [F > 3σ(F)]. The structure was solved by a combination of direct method and Fourier difference techniques and refined by blocked-cascade least squares to R = 0.068 and R$_w$ = 0.067 [w = {σ^2(F) + 0.0008|F|^2}$^{-1}$]. Anisotropic temperature factors were introduced for all the non-hydrogen atoms except for the carbon atoms of the coordinated ethanol molecules. The hydrogen atoms, with the exception of the unique hydrogen atom lying on the two-fold axis, were constrained to refine in geometrically idealised positions 1.08 Å from the relevant carbon atoms. The methyl groups were treated as rigid bodies. Common isotropic temperature factors were introduced for each type of hydrogen atom; the hydrogen atoms of the ethanol ligands were not located.†

The structure of the cation is shown in Fig. 1, together with some important bond parameters, the hydrogen atoms and the tetrafluoroborate anions having been omitted for clarity. The cation lies on a crystallographic two-fold axis which passes through the atoms C(14), C(10), N(4) and Ni(1).

The X-ray analysis confirms the presence of the seven co-ordinate pentagonal bipyramidal nickel(II) centre. The five nitrogen donor atoms of the macrocyclic ligand occupy the equatorial plane (deviations from planarity N(3): +0.0064 Å, N(4): −0.0101 Å) with two axial ethanol molecules. The non-coordinated nitrogen atoms N(2) and N(2') are planar sp^2 hybridised, the sum of the bond angles around these atoms being 359.6°. The phenyl group subtends an angle of 14.9° to the terpyridyl unit, the separation between the two hydrogen atoms H(9) and H(12) of 1.958 Å is significantly shorter than the sum of the Van der Waals radii. This indicates a significant π-interaction between the phenyl ring and the terpyridyl unit, and is consistent with the unusually short bond length of 2.015 Å for Ni(1)–N(4). The molecule shows no tendency to octahedral coordination as observed for nickel(II) complexes of more flexible pentadentate macrocyclic ligands,[6] and represents one of the few d^8 complexes with pentagonal bipyramidal stereochemistry.[7]

Cyclic voltammetry of the bis-acetonitrile adduct [Ni(L)(CH$_3$CN)$_2$](BF$_4$)$_2$ in acetonitrile at platinum electrodes shows two reversible one electron reduction waves at $^1E_{1/2}$ = −1.07 V and $^2E_{1/2}$ = −1.49 V. Controlled potential electrolysis of [Ni(L)(CH$_3$CN)$_2$](BF$_4$)$_2$ at a platinum gauze in acetonitrile at −1.1 V led to the reduction of the nickel(II) complex to give a dark green solution, the e.s.r. spectrum of which as an acetonitrile glass at 77 K, shows the features of a d^9 nickel(I) product; g$_\parallel$ = 2.4390, g$_\perp$ = 2.1184. Addition of CO or P(OMe)$_3$ to the nickel(I) product gives axially substituted univalent complexes; g$_\parallel$ = 2.5008, g$_\perp$ = 2.0491 (for CO), g$_\parallel$ = 2.4177, g$_\perp$ = 2.0684 (for P(OMe)$_3$). We propose the formation of six coordinate pentagonal pyramidal or seven coordinate pentagonal bipyramidal nickel(I) complexes.
Fig. 1. The molecular structure of the $[Ni(L)(EtOH)_2]^{2+}$ cation. Bond lengths: N(1)–Ni(1) 2.234; N(3)–Ni(1) 2.104; N(4)–Ni(1) 2.015; O(1)–Ni(1) 2.084 Å.

(L)
Electrochemical reduction of $[Ni(L)(CH_3CN)_2](BF_4)_2$ at the secondary reduction potential -1.6 V yields a mauve reduction solution, the e.s.r. spectrum of which at 77 K, shows the formation of nickel(I) stabilised ligand radical species with two essentially discrete paramagnetic centres, the second electron residing on the macrocyclic ligand; $g_{||} = 2.3103$, $g_{\perp} = 2.1928$ (for d^9 nickel(I) centre), $g_{iso} = 2.0245$ (for ligand radical). The stabilisation of the nickel(I) oxidation state by L parallels the redox behaviour of related 1,10-phenanthroline based macrocyclic systems,[2] although the presence of a secondary reduction process in the terpyridyl macrocycle reflects a tendency of this diimine system to form radical species.[4,5] At present the role of the 4′-phenyl group in the bonding in both the nickel(I) and nickel(II) complexes is not clear, although we believe it plays an important part in determining the π-acceptor properties of the ligand.[3]

NOTES

A CONVENIENT ONE-POT SYNTHESIS OF o-PHENYLENE BIS(DIPHENYLPHOSPHINE)

by H.C.E. McFarlane and W. McFarlane

Chemistry Department, City of London Polytechnic,

Jewry Street, London, EC3N 2EY.

Summary. The reaction between o-difluorobenzene and sodium diphenylphosphide in liquid ammonia provides a convenient synthesis of the title compound.

The ligand o-phenylene bis(diphenylphosphine) (I) has considerable potential in transition metal chemistry[1-3], but has been used less frequently than might have been expected because its published syntheses are low yielding and/or multi-stage[3]. Thus the direct reaction[4] between lithium- or sodium-diphenylphosphide and o-dichloro- or o-dibromobenzene gives yields of less than 1%, whilst for the reportedly "optimum" synthesis[2] using the sequence (1) the overall yield is only 18% and it is necessary to isolate and purify the intermediate o-chlorodiphenylphosphinobenzene.

(1)
Other reported routes involve more stages and are similarly low yielding[3,5].

In this note we describe a simple one-step synthesis based on the reaction in liquid ammonia between sodium diphenylphosphide and o-difluorobenzene which produces (I) in yields of 35% in a straightforward way. A typical procedure is as follows, all operations being conducted with exclusion of atmospheric dioxygen. A deaerated solution of triphenyl phosphine (131 g, 0.5 mole) in dry tetrahydrofuran (250 ml) is added over a period of 1 hr to a stirred solution of sodium (23 g, 1 mole) in liquid ammonia (2 l). Solid dry ammonium chloride (26.7 g, 0.5 mole) is added in small portions over 1 hr to destroy phenyl sodium, followed by dropwise addition of a deaerated solution of o-difluorobenzene (28.5 g, 0.25 mole) in tetrahydrofuran (100 ml). The ammonia is allowed to evaporate overnight. After addition of toluene (600 ml) and refluxing for 1 hr, methanol (5 ml) is added to destroy any residual sodium and the mixture is filtered hot and the solvents are stripped. Recrystallization from EtOH/toluene then yields (I) (46.5 g, 35%) as white crystals m.p. 183-185°. (Lit. 186°).

Although the yield obtained by this route is only moderate, it is superior to that hitherto achieved and is based upon readily available and cheap starting materials. In addition, the procedure is very convenient and is easily adapted to different scales of operation; we are currently investigating other applications of fluoroaromatic compounds to the preparation of polyphosphorus ligands.

COMMUNICATION

COORDINATIVELY UNSATURATED ALKYNE COMPLEXES: SYNTHESIS OF MONO AND BIS-ALKYNE COMPLEXES OF TUNGSTEN (II)

Jack L. Davidson[*] and Giuseppe Vasapollo[†]

Department of Chemistry, Heriot-Watt University, Riccarton,
Currie, Edinburgh EH14 4AS,UK.

Summary. $[WBr_2(CO)_4]_n$ reacts with alkynes to give complexes $[WBr_2CO(RC\equiv CR)_2]_2$ (1) (R = R' = Me, Et, Ph; R = Me, R' = Ph), which react with nucleophiles L{L = $CNBu^t$, PPh_3, or $P(OMe)_3$} to give monoalkyne derivatives $[WBr_2(CO)(RC\equiv CR')L_2]$ (2).   An intermediate bis-alkyne adduct $[WBr_2CO(MeC\equiv CMe)_2(CNBu^t)]$ (3) was isolated in the reaction of $[WBr_2(CO)(MeC\equiv CMe)_2]_2$ with $CNBu^t$ illustrating that cleavage of the dimer(1) is the first stage in these reactions.

In recent years it has become clear that alkyne ligands can involve both sets of filled π-orbitals in bonding with a transition metal and thus stabilise coordinative unsaturation[1,2].   This phenomenon is particularly pronounced in divalent molybdenum and tungsten, (d^4), complexes containing one or two coordinated alkyne ligands.   Following recent indications that 4-electron donation may lead to activation of a coordinated alkyne towards nucleophilic rather than electrophilic attack,[2a,b,3] we now report the synthesis of new alkyne complexes of W(II) and their reactions with nucleophiles.

Reactions of $[WBr_2(CO)_4]_n$ with alkynes RC≡CR' (R = R' = Me, Et, Ph: R = Me, R' = Ph) in hexane at 20°C give good yields of alkyne complexes $[WBr_2CO(RC\equiv CR)_2]_n$ which according to molecular weight studies in solution are dimeric i.e. n = 2.   However the mass spectra in each case only gives identifiable peaks due to mononuclear fragments $[P/2 = CO]^+$,$[P/2 - (CO + RC\equiv CR')]^+$,$[P/2 - (CO + Br)]^+$ although very weak dinuclear ions were observed in some cases.   Spectroscopic data : e.g. $[WBr_2(CO)(MeC\equiv CMe)_2]_2$; i.r., ($CCl_4$), 2098 cm^{-1}, wm, 2060 cm^{-1}, vs; ^1H nmr., δ2.96(s, 6H) 2.33(s, 6H).   The two ^1H nmr resonances suggest two sets of inequivalent alkynes or that all four alkynes are equivalent but the two substituents are magnetically non-equivalent and on this basis structures (1a) or (1b) are proposed.   However, since alkynes are able to function as 4-electron donors an alternative structure to (1) without a metal-metal double bond is equally plausible.   Interestingly $CF_3C\equiv CCF_3$ and $[WBr_2(CO)_4]_n$ give a mononuclear complex $[WBr_2CO(CF_3C\equiv CCF_3)_2]$ under similar reaction conditions[2b] while $[Mo(SBu^t)_2(CNBu^t)_4]$ reacts with alkynes to give $[Mo(SBu^t)_2(CNBu^t)_2 (RC\equiv CR)]$ (R = H, Ph)[3].

                     Via Amendola 173,
                     Bari, Italy.
(1a)   (1b)

Mononuclear complexes $[WBr_2CO(RC\equiv CR)L_2]$, (2) were readily obtained from reactions of
(1) with nucleophiles L = PPh_3, $P(OMe)_3$ or $CNBu^t$ and in one case an intermediate bis alkyne
complex $[WBr_2CO(MeC\equiv CMe)_2(CNBu^t)]$ (3), was also isolated. Spectroscopic data:
$[WBr_2CO(MeC\equiv CMe)_2(CNBu^t)]$; i.r. ($CHCl_3$), $\nu C\equiv N$ 2218 cm^{-1}s. νCO 2092 cm^{-1}vs; ^1H nmr ($CDCl_3$),
$\delta 2.93$ (q, J = 0.79 Hz, 6H), 2.89 (q, J = 0.79 Hz, 6H), 1.80 (s 9H); mass spectrum-highest
peak $[WBr_2(MeC_2Me)_2]^+$. The presence of CH_3-CH_3 coupling in the ^1H nmr spectrum indicates
inequivalence of the CH_3 groups at either end of each acetylene rather than inequivalent
acetylene ligands and structure (3) is therefore proposed. Structures with *trans* alkynes
are also possible but six-coordinate bis alkyne d^4 metal complexes appear to prefer *cis*
alkyne ligands[2a].
(3)

Spectroscopic data: $[WBr_2CO(MeC\equiv CMe)(CNBu^t)_2]$ i.r. ($CHCl_3$), $\nu C\equiv N$ 2194 s, 2160 cm^{-1}s;
νCO 2002 cm^{-1}vs, ^1H nmr $\delta 3.16$ (s, 6H), 1.74 (s, 9H), 1.36 (s, 9H) mass spectrum –
decomposition observed in the probe. The ^1H nmr spectrum of $[WBr_2CO(MeC\equiv CMe)(CNBu^t)_2]$
indicates two inequivalent isocyanide ligands and a single acetylenic CH_3 resonance in
accord with *cis* $CNBu^t$ groups. ^1H and ^{31}P nmr spectra of $[WBr_2CO(RC\equiv CR')\{P(OMe)_3\}_2]$
similarly suggest *cis* phosphite ligands with R = R' = Me. Spectroscopic data: ^1H nmr:

δ = 3.94 (d, J_{P-H} = 9.81 Hz, 9H)   3.47 (d, J_{P-H} = 10.46 Hz, 9H) 3.03 (d, J_{P-H} = 1.77, 6H); ^{31}P[^{1}H] 119.95 (AB quartet), but *trans* P(OMe)$_3$ ligands with R = R' = Ph ^{1}H nmr δ7.75 (m, 4H), 7.48 (m, 6H), 3.61 (t, J_{P-H} = 5.42 Hz, 18H); ^{31}P[^{1}H], δ117.96 (s).   However monitoring of the spectra of [WBr$_2$CO(MeC≡CMe){P(OMe)$_3$}$_2$]revealed that isomerisation of the kinetic *cis* isomer occurs to a more stable *trans* form: ^{1}H nmr δ3.66 (t, J_{P-H} = 5.38 Hz, 18H), 3.14 (t, J_{P-H} = 1.59 Hz, 6H); ^{31}P [^{1}H], δ120.03 (s).   Variable temperature ^{1}H nmr spectra also revealed that the CH$_3$C≡CCH$_3$ doublet δ3.03 of the *cis* isomer splits into two equal intensity multiplets at low temperatures (T. coalescence = 14°C) whereas no change is observed in the spectrum of the *trans* isomer down to -85°C.   This suggests propeller rotation of the alkyne ligand but with significantly higher barriers to rotation in the *cis* isomer.   Such a conclusion is based on the proposal that in both isomers the alkyne should be in an asymmetric environment as in the illustrated structures (2a,b,c).   This follows from simple bonding arguments[1,3] which dictate that for the alkyne to function as a four electron donor ligand in (2) the CO and RC≡CR ligands must be mutually *cis* while the most stable alkyne orientation will be that in which the C≡C bond lies parallel to the M-CO bond.

(2a)
(2b)   (2c)
L = P(OMe)$_3$

    These structures are based on the premise that the phosphines are coordinated to the metal a fact confirmed by the presence of ^{31}P - ^{183}W coupling in the ^{31}P nmr spectra of the complexes.   In contrast P(OMe)$_3$ reacts with [WBr$_2$CO(CF$_3$C≡CCF$_3$)$_2$] to give a vinyl derivative as a result of addition to an acetylenic carbon[2b].   Thus, although nucleophilic attack at

an acetylenic carbon may be promoted by four-electron donation to a metal [2a,b,3] these results indicate that the presence of electron withdrawing groups (CF_3) also appears to be necessary in some circumstances.

Finally we note the increasing range of stoichiometries exhibited by d^4 Mo(II) and W(II) alkyne complexes.[1-5] Since coordinative unsaturation in d^4 complexes can also be stabilised by inorganic donor ligands[1a] it seems probable that the wide range of stoichiometries available to the alkyne complexes may be a consequence of π-donation by both the alkynes and the inorganic ligands. Thus differences in the π-donor abilities of SBu^t and Br could account for the preference for five coordination in $[Mo(SBu^t)_2(CNBu^t)_2(PhC\equiv CPh)]$[3] relative to six coordination found with $[WBr_2CO(CNBu^t)_2(PhC\equiv CPh)]$.

THE METAL COMPLEXES OF HETEROCYCLIC β-DIKETONES AND THEIR DERIVATIVES—II

LANTHANIDE CHELATES OF 1-PHENYL-3-METHYL-4-ACETYLPYRAZOLONE-5, (HPMAP)

EMMANUEL CHUKWUEMEKA OKAFOR

Coordination Chemistry Research Unit, Department of Chemistry, University of Nigeria, Nsukka, Anambra State, Nigeria

Abstract—Some lanthanide chelates of 1-phenyl-3-methyl-4-acetyl-pyrazolone-5, HPMAP, have been synthesized and investigated. Characterisation involved elemental analysis, conductivity measurements, IR and proton magnetic resonance spectra, melting points and Karl–Fischer titrations. The complexes are shown to be neutral chelates with the empirical formula $Ln(PMAP)_3 \cdot xH_2O \cdot yC_2H_5OH$ were for Ln = La, Ce and Nd, $x = 2$ and $y = 1$, and for Ln = Y, Eu, Gd, Dy, Er and Lu, $x = 2$ and $y = 0$. IR, PMR and electronic spectral data together with band assignments are presented. The Nd chelate was found to exhibit positive nephelauxetic effect and Sinha's parameters were calculated and discussed for Nd and Er.

In a previous communication[1] the synthesis and spectral properties of some anhydrous lanthanide chelates of 1-phenyl-3-methyl-4-benzoyl–pyrazolone-5, (HPMBP) were described. In continuation of this serial study, the investigation has been extended to the lanthanide complexes of 1-phenyl-3-methyl-4-acetyl-pyrazolone-5, (HPMAP).

EXPERIMENTAL

Reagents

The following Merck reagents of analytical quality were used: $YCl_3 \cdot 6H_2O$, $La(NO_3)_3 \cdot 6H_2O$, $Nd(NO_3)_3 \cdot 5H_2O$, $Eu(NO_3)_3 \cdot 5H_2O$, $Gd(NO_3)_3 \cdot 5H_2O$, $Dy(NO_3)_3 \cdot 5H_2O$, $Er(NO_3)_3 \cdot 5H_2O$, Lu_2O_3, CeO_2, H_2O_2, 1-phenyl-3-methyl-pyrazolone-5, acetyl chloride, dioxane, 95% and absolute ethanol.

1-Phenyl-3-methyl–pyrazolone-5 (17 g) was dissolved in dioxane (100 cm^3) by warming and $Ca(OH)_2$ (15 g) added. Acetyl chloride (7 cm^3) was next added, drop by drop, with stirring within 3 min. After refluxing gently for 1 hr, the orange mixture was cooled and poured with stirring into chilled 3M HCl (300 cm^3). A handful of ice–salt mixture was added and vigorous stirring continued for another 30 min, after which, the reaction mixture was kept in a refrigerator until crystallisation occurred. Filtration of the product gave 76% yield of light brown crystals, m.p. 64–65°C. Recrystallization of the product from *n*-hexane gave the yellowish enol tautomer, m.p. 66–67°C. IR (Nujol): ν_{max} (cm^{-1}), 1635 (C=O); 2200–3500, weak and broad, (O–H ... O). Anal. Calc. for $C_{12}H_{11}O_2N_2$: C, 66.65; H, 5.60; N, 12.96. Found: C, 66.58; H, 5.57; N, 12.91.

Preparation of rare earth complexes

The complexes of La, Nd, Eu, Gd, Dy, Er and Y were obtained by the following general procedure: A 0.5 M aqueous solution of sodium hydroxide (10 cm^3) was added to a solution of 1-phenyl-3-methyl-4-acetyl-pyrazolone-5, (5 mM) in 95% ethanol (45 cm^3). The reaction mixture was put aside for about 24 hr. The resulting solution of the monosodium salt of the ligand was added dropwise with constant stirring to a solution of 1.67 mM of lanthanon salt in 10 cm^3 of 95% ethanol. The reaction mixture containing precipitates was stirred magnetically for 2 hr and thereafter filtered under suction. The product was washed with aqueous ethanol (1/1), air-dried for 2 days, and stored in a desiccator over P_2O_5.

The above procedure was modified slightly in the case of Ce^{3+} and Lu^{3+} complexes. Hydrated chlorides of Ce(III) and Lu(III) (1.67 MM of each) were dissolved in 400 cm^3 and 300 cm^3 of 95% ethanol respectively. Into each filtered lanthanon salt solution, the solution of the monosodium salt of the ligand was added dropwise. The resulting reaction mixture was stirred magnetically for 2 hr and concentrated down to about 50 cm^3. The crystals which deposited on cooling were filtered and treated as described earlier.

The hydrated Ce(III) chloride was obtained from CeO_2 by treating CeO_2 first with H_2O_2, next with conc. HCl, and evaporating the resulting solution cautiously to dryness to obtain white crystals, while the hydrated Lu(III) chloride was obtained by treating Lu_2O_3 with conc. HCl and evaporating to dryness.

Physical measurements

IR spectra were recorded on a Perkin–Elmer 577 spectrophotometer. Other measurements are as described previously.[1]

Elemental analyses

Microanalyses for C, H and N were performed by the microanalytical unit of the Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, Scotland.

RESULTS AND DISCUSSION

Table 1 lists the complexes prepared together with some of their physical properties and microanalytical data.

The analytical data show that the complexes have the general formula $Ln(PMAP)_3 \cdot xH_2O \cdot yC_2H_5OH$ where for Ln = La, Ce and Nd, $x = 2$ and $y = 1$ and for Ln = Y, Eu, Gd, Dy, Er and Lu, $x = 2$ and $y = 0$. The amount of water associated with the complexes has been determined by Karl–Fischer titrations.[2] This technique was applied successfully to β-diketonate complexes of lanthanides by Wagner[3] and Springer *et al.*[4] The agreement between the Karl–Fischer determinations and the proton NMR spectral integration of the proton signals of the associated water in the case of diamagnetic complexes is excellent. The proton NMR spectra reveal the presence of ethanol molecules in the case of La, Ce and Nd (Table 3). Conductivity measurements in DMF reveal that all

the complexes are non-conducting and are therefore neutral non-ionic complexes. The complexes are very soluble in such polar solvents as acetone, DMF, and DMSO but slightly soluble in chloroform and insoluble in such non-polar solvents like benzene and *n*-hexane.

IR spectra

Previous work on 1,3-diketonates[1,5-11] have been taken into consideration in the assignment of frequencies. The IR spectrum of the enol tautomer of the ligand is considered as reference. Since these complexes have identical IR spectra, only the spectral data of the ligand and a representative complex—the lanthanum complex—are listed in Table 2, the vibrational frequencies (4000–200 cm^{-1}) with possible assignments being given. The following features of the IR spectra are of interest:

(1) The presence of coordinated water is indicated by the presence of a broad peak centred at 3400 cm^{-1} with a shoulder at 3600 cm^{-1} attributable to the OH stretching frequencies of water.

(2) The weak broad band in the 2200–3500 cm^{-1} region which has been attributed to ν_{as} (OH) of O–H...O in enols[12] is absent in the spectra of the complexes. This fact implicates deprotonated OH in bonding.

(3) The shift of the C=O stretching frequency from 1635 cm^{-1} in the ligand to ~1620 cm^{-1} (ν_{as}C $\leftrightarrows$ O) in the lanthanum complex suggests that C=O is involved in chelation.

(4) The presence of bands between 300 and 500 cm^{-1} typical of metal 1,3-diketonates (νM–O) suggests bonding through oxygen atoms.[13]

IR spectral evidence, therefore, suggest that the ligand bonds to the metal ion through the carbonyl and the deprotonated hydroxyl groups of an enol form of the ligand.

Proton magnetic resonance (PMR) spectra

Table 3 gives the PMR spectral data of the ligand and some of its lanthanide complexes together with assignment of the proton signals.

The PMR spectra of the complexes confirm IR evidence that the complexes are hydrated by revealing peaks due to water. The chemical shifts of these peaks are listed in Table 3. In the case of lanthanum, cerium and neodymium complexes, the proton NMR spectra demonstrate clearly the presence of ethanol molecule in each chelate molecule. The PMR spectra in DMF-d_7 of these C_2H_5OH adducts indicate that the C_2H_5OH molecule is not coordinated to the Ln ion since the C_2H_5OH signals are not shifted at all in the case of methyl resonances and only very slightly in the case of methylene and hydroxyl signals (Table 3) relative to the signals of the uncomplexed C_2H_5OH in DMF-d_7. These slight methylene and hydroxyl shifts could be attributed to solution (medium) effects. On the other hand, the proton signals of the associated water molecules exhibit significant shifts relative to the signal of uncomplexed H_2O in DMF-d_7 which occurs at δ 4.33 ppm indicating that the H_2O molecules are coordinated. In the case of the diamagnetic complexes, the signals of the water protons experience appreciable upfield (diamagnetic) shifts to δ (ppm): 3.13 (Y), 3.57 (La) and 3.00 (Lu) whereas in the case of the paramagnetic complexes the signals of the H_2O protons apart from experiencing some broadening suffer extensive downfield (paramagnetic) shifts to δ (ppm): 10.16 (Ce), 10.67 (Nd) and 10.73 (Eu). Our results are in agreement with the recent conclusions of Richardson and Wagner[14] that when water and an organic donor are both present, only the water is coordinated to the lanthanide ion, the organic donor molecules being hydrogen-bonded or held in the crystal by lattice forces. Careful integration of the proton signals reveals the number of H_2O and C_2H_5OH molecules associated with each complex molecule. Two water molecules are coordinated to the lanthanide in La, Nd, Ce, Eu, Lu and Y complexes whereas one C_2H_5OH molecule is associated with each molecule of La, Nd and Ce complexes.

In all the complexes, the methyl signals experience upfield (diamagnetic) shifts—δ (ppm): 2.33 (Y), 2.30 (La),

Table 3. Proton NMR spectral data of HPMAP and some of its rare earth complexes (chemical shifts in δ ppm relative to TMS)

Compound	Ligand Methyl Protons	Water Protons	Ethanol Protons			Ligand Phenyl Protons	Ligand Hydroxyl Proton	Solvent for NMR
			CH_3 Protons	-CH_2- Protons	OH Proton			
Ligand (HPMAP)	2.45(sp,s)	-	-	-	-	7.20-8.00(m)	12.27	$CDCl_3$

Lu(PMAP)$_3$.2H$_2$O	2.13, 2.33 (sp)	3.00(sp,s)				7.00-8.20(m)	-	$CDCl_3$+DMSO-d$_6$

Legend: sp, sharp; br, broad; s, singlet; tp, triplet; qt, quartet; m, multiplet; v, variable.

1.73 (Ce), 2.18 (Nd), 0.93 and 2.23 (Eu), and 2.13 and 2.33 (Lu) relative to that of the ligand (2.45 ppm). It is interesting to note that in the case of the europium complex the two methyl groups in the ligand with different environments have widely separated signals. In both the ligand and the diamagnetic complexes of La, Y, and Lu the methyl signals are sharp whereas these signals have been broadened in the case of the paramagnetic chelates of Ce and Nd. The phenyl multiplet experiences slight downfield (paramagnetic) shifts in the case of the diamagnetic complexes of Y, La and Lu (~7.00–8.30 ppm) relative to the multiplet of the ligand (7.20–8.00 ppm) whereas in the case of the paramagnetic complexes the shift is upfield—Ce (7.20–7.70 ppm), Nd (7.25–7.80 ppm) and Eu (5.20–7.00 ppm). The signal due to the hydroxyl proton in the ligand at δ 12.27 ppm is absent in the PMR spectra of all the complexes providing conclusive evidence that the hydroxyl proton is lost during complexation.

In the PMR spectra of the chelates of gadolinium, dysprosium and erbium, no proton signals were picked up at all even at very high spectral amplitudes. This might be due to huge shifts or extensive broadening of the signals or a combination of both.

Electronic spectra

The electronic spectra of the lanthanide chelates of HPMAP may be conveniently divided into three types of bands which are derived from intraligand, charge-transfer, and f–f transitions and are found at decreasing energy (and intensity). The absorption maxima together with their molar absorptivities are reported in Tables 4 and 5.

(a) *Intraligand transition.* The UV spectra of the lanthanide complexes are similar to that of the ligand and show virtually no shifts in the positions of the absorption maxima (Table 4) as was the case in the spectra of 1-phenyl-3-methyl-4-benzoyl-pyrazolone-5, HPMBP and its lanthanide chelates.[1] The absorption at 262 nm (~38,000 cm^{-1}) is ascribed to intraligand $\pi \to \pi^*$ transition.

(b) *The charge transfer transition.* HPMAP complexes are not sufficiently soluble in 95% ethanol. The visible spectra of the ligand and the complexes have therefore been recorded in DMF in which these complexes are very soluble. The complexes of yttrium, lanthanum, gadolinium, dysprosium, erbium and lutetium show L → M charge transfer bands around 23 kK (Table 4).

(c) *f–f Transitions.* Visible spectral data for the neodymium and erbium chelates are reported in Table 5 together with band (J level) assignments. The complexes of yttrium, lanthanum, cerium, europium, gadolinium, dysprosium and lutetium did not show any bands assignable to f–f transitions.

Generally, the f–f transitions are slightly affected by the immediate surrounding of the lanthanide cation and this is commonly attributed to the "buried" or shielded nature of the $4f$ orbitals by the overlying $5s^2$ and $5p^6$ shells; however, shifts, sometimes splitting and intensity enhancement of certain bands can be observed on complex formation. The nephelauxetic effect has been correlated with the covalency of the metal–ligand bonding[15,16] and Sinha's parameter[17] is usually supposed to be a measure of covalency.

The absorption spectrum of the neodymium(III) chelate shows the expected red shift, with respect to aquo-ion, of the "hypersensitive" transitions; the value of Sinha's parameter was found to be positive but smaller than unity ($\delta = 0.7$). If these shifts are effectively an accurate measure of covalent bonding the Nd(III) chelate shows weak covalent bonding. But in the case of the erbium(III) chelate, the absorption spectrum does not

Table 4. Electronic spectral data—intraligand and charge transfer transitions of rare earth complexes of HPMAP

sh, shoulder.

show any shift whatsoever with respect to aquo-ion, of the "hypersensitive" transitions; the value of Sinha's parameter was found to be zero. This would imply that the Er(III) chelate is on the border line between ionic and covalent bonding since according to Sinha[17] negative values of δ indicate ionic bonding. However, of all the synthesized lanthanon chelates of HPMAP, the Er(III) chelate has the lowest melting point, 156–157°C (Table 1) and besides, the M–O stretching frequency of ~504 cm^{-1} suggests much greater covalent bonding than in the sodium chelate with νM–O of 427 cm^{-1}. To what extent, Sinha's parameter is a good index for measuring covalency is a matter for future investigation.

Assignments of the f-f transitions of the Nd and Er chelates of HPMAP (Table 5) are based on the calculations and analysis of the electronic spectra of trivalent Nd and Er carried out by Wybourne[18] and on the term assignments recently made for the absorption

bands of Nd^{3+} and Er^{3+} in aqueous solution by Katzin and Barnett[19] and Ryan and Jorgensen.[20]

CONCLUSION

HPMAP bonds to lanthanide ions through the carbonyl and hydroxyl groups of an enol form, the hydroxyl proton being liberated during complexation. The resulting metal complex is a neutral tris chelate, each chelate molecule having two water molecules coordinated to its lanthanide atom which thereby exhibits a coordination number of eight.

MIXED LIGAND COMPLEXES OF RUTHENIUM(III), RHODIUM(III) AND IRIDIUM(III) WITH DIPICOLINIC ACID AND SOME MONOBASIC BIDENTATE NITROGEN, OXYGEN DONOR LIGANDS

S. K. SENGUPTA*, S. K. SAHNI and R. N. KAPOOR
Department of Chemistry, University of Delhi, Delhi-110007, India

Abstract—The trivalent ruthenium, rhodium and iridium complexes of dipicolinic acid and its mixed ligand complexes with several nitrogen, oxygen donor molecules, of types: $Na[M(dipic)_2] \cdot 2H_2O$ and $[M(dipic)(N-O)] \cdot nH_2O$ (where $M = Ru(III)$, $Rh(III)$ or $Ir(III)$; $dipicH_2$ = dipicolinic acid; N–OH represents different nitrogen, oxygen donor molecules, viz., picolinic acid, nicotinic acid, isonicotinic acid, glycine, aminophenol, o- or p-aminobenzoic acid), have been synthesized and characterised on the basis of elemental analyses, electrical conductance, magnetic susceptibility measurements and spectral (electronic and infrared) data. The parent dipicolinic acid complexes are found to have a six-coordinate pseudooctahedral structure, whereas for mixed ligand complexes, a polymeric six-coordinate structure has been assigned. Various ligand field and nephelauxetic parameters have also been evaluated.

Dipicolinic acid or pyridine 2,6-dicarboxylic acid is a versatile ligand and it can function as a neutral, monobasic or dibasic tridentate chelating agent. A large number of bivalent or trivalent transition metal and lanthanide(III) complexes of dipicolinic acid have been studied.[1–4] Recently, some cobalt(II) and cobalt(III) complexes of dipicolinic acid have been synthesized to explore the possibility of their use as models to explain some intricate reactions in biological systems.[5, 6] The reactions of acetylacetonates of cobalt(II), nickel(II), iron(III) and manganese(III) with dipicolinic acid have also been carried out to obtain complexes of unusual structure.[7, 8]

However, no systematic study of mixed ligand complexes of trivalent metal ions with dipicolinic acid as primary ligand together with bidentate ligands appears to have been carried out. It is, therefore, of interest to synthesize such complexes, with a view to obtaining five-coordinate ruthenium(III), rhodium(III) and iridium(III) complexes, which occur rarely. The various nitrogen, oxygen donor bidentate molecules selected for this work include picolinic acid (picH), nicotinic acid (nicH), isonicotinic acid (inicH), glycine (glyH), aminophenol (apH), o-aminobenzoic acid (oabH) and p-aminobenzoic acid (pabH). The complexes have been isolated in the solid state and structures have been assigned tentatively on the basis of their elemental analyses, and spectral and magnetic properties.

EXPERIMENTAL

The platinum metal salts used were obtained from Johnson Mathey Products, London. Commercial ruthenium trichloride, which contains some ruthenium(IV), was evaporated several times with concentrated hydrochloric acid to ensure conversion into ruthenium(III) chloride. The pyridine carboxylic acids, amino carboxylic acids and aminophenol used as ligands, were Analar grade (B.D.H. and E. Merck).

A common procedure has been adopted to prepare and isolate ruthenium(III), rhodium(III) and iridium(III) complexes.

Preparation of $Na[M(dipic)_2] \cdot 2H_2O(M = Ru(III)$ or $Ir(III)$; dipic H_2 = dipicolinic acid)

An ethanolic solution of the appropriate metal trichloride (0.01 mol) was added to a refluxing aqueous ethanolic solution of dipicolinic acid (0.02 mol) containing sodium hydroxide (0.01 mol). The refluxing was continued for ca. 2–4 hr. On concentrating the resulting solution, the coloured mass obtained was filtered, washed with water and dried in vacuo at room temperature.

Preparation of the mixed ligand complexes, $[M(dipic)(N-O)] \cdot nH_2O$ ($M = Ru(III)$, $Rh(III)$ or $Ir(III)$; N–OH represents secondary ligand)

All these complexes have been prepared by the following procedure. An aqueous ethanolic solution of the appropriate metal trichloride (0.01 mol) was added to an aqueous ethanolic solution of dipicolinic acid (0.01 mol). To this mixture was added the appropriate bidentate N,O donor compound (0.01 mol) and the solution was refluxed for ca. 4–8 hr; the coloured mass obtained was filtered, washed with ethanol and dried in vacuo at room temperature.

RESULTS AND DISCUSSION

The elemental analysis (Table 1) reveals 1:2 metal to ligand stoichiometry for the parent $M(III)$-dipicH_2 complexes, and it is 1:1:1 (metal:dipicH_2:N–O⁻) in the case of the mixed ligand complexes, where N–O⁻ represents a monobasic, bidentate nitrogen, oxygen donor molecule. The parent complexes are soluble in dimethylformamide, dimethylsulphoxide, nitrobenzene and partially soluble in ethanol and acetone, whereas mixed ligand complexes are partially soluble in dimethylformamide and dimethylsulphoxide. Thermogravimetric data indicate a loss of weight at 100–120°C corresponding to two water molecules for the parent complexes and one water molecule for the mixed ligand complexes of aminophenol, glycine, and o-and p-aminobenzoic acids, with all three metal ions. The mixed ligand complexes of ruthenium(III), rhodium(III) and iridium(III) with picolinic, nicotinic and isonicotinic acid do not show any weight loss up to 200°, indicating the absence of water molecules. The electrical conductance of the parent complexes, measured in dimethylformamide, show them to be essentially non-electrolytes. Accordingly, the parent and the mixed ligand complexes

where dipicH$_2$ = dipicolinic acid or pyridine 2,6-dicarboxylic acid,
picH = picolinic acid, nicH = nicolinic acid,
inicH = isonicotinic acid, glyH = glycine, apH = aminophenol
oabH = o-aminobenzoic acid and pabH = p-amino benzoic acid

of ruthenium(III), rhodium(III) and iridium(III) can be formulated as $Na[M(dipic)_2] \cdot 2H_2O$ and $[M(dipic)(N-O)] \cdot nH_2O$, respectively. These formulations have been further corroborated on the basis of magnetic and spectral properties of these complexes.

Magnetic moments and electronic spectra

Ruthenium(III) complexes. The room temperature magnetic moments of the ruthenium(III) complex of dipicolinic acid and of the mixed ligand complexes lie in the range 1.75–1.80 B.M. (Table 1), which are lower than the predicted value[9] of 2.10 B.M. The lowering in μ_{eff} values may arise due to low symmetry ligand fields, metal–metal interactions or extensive electron delocalization.[10]

The electronic spectra of the ruthenium(III) complex of dipicolinic acid and its mixed ligand complexes show bands at *ca.* 13000–14000, 17000–18000 and 22000–23000 cm^{-1} which may be assigned[11-14] to $^2T_{2g} \rightarrow {}^4T_{1g}$, $^2T_{2g} \rightarrow {}^4T_{2g}$ and $^2T_{2g} \rightarrow {}^2A_{2g}, {}^2T_{1g}$ transitions, in increasing order of energy.

The electronic spectra of these complexes are further rationalised[12] in terms of ligand field parameters (10 Dq) and interelectronic repulsion parameters (B and C). The values of these parameters along with that of β given in Table 2, are comparable to those reported for other ruthenium(III) derivatives involving nitrogen, oxygen donor molecules.[11,14,15] The B values are about 74–86% of the free ion value in the ruthenium(III) complexes. The considerable decrease in the value of the Racah

interelectronic repulsion parameter B from that of the free ion suggests that strong covalent bonding occurs between the ligands and the metal atom.[12] The overall effect of some covalent bonding will be an increase in the observed value of Dq; high values of Dq are usually associated with considerable electron delocalization.[10]

Rhodium(III) complexes. Rhodium(III) complexes are diamagnetic as expected. This is consistent with an octahedral arrangement of the donor atoms around the metal ions, producing a strong field.[9]

The electronic spectra of rhodium(III) complexes show bands at *ca.* 17000–17800, 20000–21000 and 24000–25000 cm^{-1}. These spectra resemble those of other six-coordinate rhodium(III) complexes[12, 15–17] and may be assigned[18] to $^1A_{1g} \rightarrow {}^3T_{1g}$, $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ transitions, in increasing order of energy. The electronic spectra of these d^6 complexes can be used[19] to evaluate ligand field and nephelauxetic parameters: values of 10 Dq, B and β thus calculated are given in Table 2. The values are comparable to those observed for other complexes of this metal ion with nitrogen and oxygen donor ligands[15, 16, 18]. The B values are of the order of 34–43% of the free ion values, suggesting considerable orbital overlap with strong covalency in the metal-ligand σ-bond. The decreasing values of B are associated with a reduction in the effective positive charge of the metal ion and with an increasing tendency to be reduced to the next lower oxidation state.

Iridium(III) complexes. The iridium(III) complexes are diamagnetic, with donor atoms producing a strong octahedral field.[18]

The mull spectra of these complexes show bands in the 30000–32000 and 33000–34000 cm^{-1} regions (Table 2) which can be assigned[18] to $^1A_{1g} \rightarrow {}^1T_{1g}(\nu_1)$ and $^1A_{1g} \rightarrow {}^1T_{2g}(\nu_2)$ transitions in increasing order of energy. In some of the complexes, an additional band is also observed at *ca.* 23500–24200 cm^{-1} which can be assigned[12] to a $^1A_{1g} \rightarrow {}^3T_{1g}$ transition. The ratios of ν_2 and ν_1 in the iridium(III) complexes lie in the range 1.06–1.13. These values for the present complexes having the chromophore IrN$_2$O$_4$ are slightly lower than those observed[19, 20] for IrN$_3$X$_3$ and IrO$_3$X$_3$(X = Cl, Br, I) chromophores (1.10–1.20). This is expected in view of the different positions of these donor atoms in the spectrochemical series.[12] The two transitions ν_1 and ν_2 have been used[19] to evaluate the ligand field (10 Dq or Δ) and

nephelauxetic (B) parameters. The values of these parameters along with that of β (covalency parameters) are given in Table 2, and are comparable to those reported for other iridium(III) complexes involving similar donors.[18, 20] The B values are about 18–35% of the free ion value (660 cm^{-1}). This can be taken as an indication of considerable overlap with significant covalency in the metal–ligand σ-bond.

IR spectra. The IR spectrum of dipicolinic acid shows two bands at *ca.* 1700 and 1300 cm^{-1} due to $\nu_{asym}(COO)$ and $\nu_{sym}(COO)$ vibrations, respectively. In the mixed ligand complexes, these two bands appear at *ca.* 1600–1580 and 1460–1430 cm^{-1}, respectively, indicating the involvement of the carboxylic group in bond formation with metal.[21, 22] This is also supported by the appearance of new bands at 340–300 cm^{-1}, assignable to $\nu(M–O)$ vibrations.[23, 24] However, it is worth noting that the lowering (*ca.* 100 cm^{-1}) of $\nu_{asym}(COO)$ (which is mainly due to $\nu(C=O)$ of the COOH group) and also the difference $\Delta\nu = \nu_{asym}(COO) - \nu_{sym}(COO) \sim 150$ cm^{-1} are considerable, which clearly indicates that the $\diagdown$C=O moiety of the –COOH group is also coordinated to the metal atom, resulting from loss of electrons on coordination.[8] This situation (I) is similar to that observed by Nakamoto *et al.*[25] in $[Cu_2(OAc)_4] \cdot 2H_2O(II)$ and later explained by Lever *et al.*[26]
(I)
(II)

However, in the parent dipicolinic acid complexes, the shift of the $\nu_{asym}(COO)$ band is of the order of 40–30 cm^{-1}, excluding the possibility of coordination of the $\diagdown$C=O group to an other metal atom.[27] In different pyridine or aminocarboxylic acids, these two bands appear at *ca.* 1710–1690 and 1340–1320 cm^{-1}. On complexation these bands also show similar type of changes as in the parent dipicolinic acid complex, indicating that the carboxylic group coordinates to the metal atom.

The infrared spectrum of *m*-aminophenol shows one band at 3350 cm^{-1} which may be assigned to $\nu(OH)$. However, in its mixed ligand complexes, this band disappears completely, indicating the bond formation of phenolic oxygen to metal through deprotonation.[28] In the

mixed ligand complexes of amino acids and aminophenol the shift of the $\nu(NH)$ band, which occurs at *ca.* 3300–3100 cm^{-1} in the ligands to lower frequency (~ 100 cm^{-1}) indicates the amino group coordination to the metal atom.[28] This has been confirmed by the appearance of a new band in the far infrared region at 460–420 cm^{-1} which may be assigned to a $\nu(M–N)$ vibration.[24]

Ligands containing the pyridine ring show bands at *ca.* 1610–1570, 630–590 and 430–390 cm^{-1} which may be assigned to 8a or 8b (ring deformation), 6a (in-plane deformation) and 16b (out-of-plane deformation) vibrations,[29, 30] respectively. In the complexes, these bands show an upward shift (~ 20 cm^{-1}) and in some cases the splitting of the 6a band has also been observed. The upward shift and splitting of 6a and 16b bands are consistent with coordination of the pyridine nitrogen to a metal atom[30, 31]. The bands due to $\nu(M–Py)$ are located at 280–255 cm^{-1}. In addition to the above, the parent complex of dipicolinic acid and mixed ligand complexes of *m*-aminophenol, *o*- and *p*-aminobenzoic acids and amino acetic acid show one broad band at *ca.* 3450 cm^{-1} which may be assigned to $\nu(OH)$ of the water present in the lattice.[28]

Thus, on the basis of above discussion it appears that the mixed ligand complexes are polymeric in nature, as is also supported by their limited solubility in organic solvents, and each unit of polymeric structure possesses a pseudo-octahedral stereochemistry. The electronic spectra of these complexes which are typical of octahedral ruthenium(III), rhodium(III) and iridium(III) also corroborate a polymeric structure. The $\diagdown$C=O moiety of the COOH group appears to provide the sixth coordination sites, three being provided by dipicolinic acid $(N, O^-, \bar{O})$ and two $(N, \bar{O})$ being provided by the monobasic, bidentate ligands, making these complexes polymeric. Thus the tentative structure of these complexes can be depicted as follows:
M = Ru (III), Rh(III) or Ir (III); n = 0 or 1

However, the parent complexes appear to be monomeric. If they are assigned a structure similar to that suggested for mixed ligand complexes, they would have seven-coordinate units; however this is ruled out by the electronic spectra, which support a six-coordinated structure. A polymeric structure for the parent complexes can also be ruled out on the basis of steric

arguments. Their structure can, therefore, be tentatively depicted as follows:
M = Ru(III), Rh(III) or Ir(III).

Abstract—The crystal structure of racemic $[Co(NSSSN)Cl](ClO_4)Cl$ was determined by X-ray diffraction methods. It crystallizes in the monoclinic system, space group $P2_1/c$, with cell constants of $a = 9.795(3)$, $b = 10.412(3)$ and $c = 16.323(8)$ Å and $\beta = 93.87(4)°$; $V = 1661$ Å^3 d (meas.; flotation) $= 1.85$ gm-cm^{-3}, d (calc.; $Z = 4$ molecules/unit cell) $= 1.88$ gm-cm^{-3}. The molecules, a racemic mixture, have the absolute configurations $\lambda\lambda\delta\lambda$ or $\delta\delta\lambda\delta$ at each of the four five-membered rings and resémble, in general, the so called $\alpha\alpha$ conformer already described by Snow[1] in his study of the Co(tetraen)Cl^{2+} cation. However, the torsional angles at C2, C3 and C8, C9 in the two terminal C–C–NH$_2$ fragments are quite different in the two systems. For Co(tetraen)Cl^{2+} they are 44.7° and −20.2° respectively, whereas for Co(NSSSN)Cl^{2+} the values −52.3° and −44.6° obtain. Also, the ring Co–S1–C3–C2–N1 does not have the classical, low energy conformation found in Co(tetraen)Cl^{2+}. The presence of the larger Co–S bonds causes the two terminal –NH$_2$ groups to be pushed toward each other, and to minimize steric hindrance between adjacent –NH$_2$ hydrogens and ligand twists C2 down and staggers the terminal hydrogens. We visualize the propagation of these distortion effects in solution as being transferred from one side to the other across the entire ligand chain with concomitant effects on the activation of the precursor complex in electron transfer reactions, resulting in ~10^7 rate enhancement over the Co(tetraen)Cl^{2+} system. Kinetic data for the reduction of Co(NSSSN)X^{2+} and Co(NSNSN)X^{2+} (X = Cl$^-$, Br$^-$) by Fe(II) is also presented and discussed.

From a crystallographic standpoint, it is challenging to study the geometrical details of substances which, though closely related in composition and even stereochemistry, are sufficiently different so that other physical properties, such as reactivity, rates of electron transfer and/or ligand exchange, etc... differ by significant orders of magnitude. The hope is, of course, that stereochemically significant changes in these substances can be assigned as the origin of the alteration of properties under consideration. Such is the case of previous work we have conducted in collaboration with Prof. Dobson in elucidating the stereochemical reasons for changes in the rates of ligand exchange in metal carbonyls.[2,3] The availability of data on the pair of related substances [Co(NSSSN)Cl](ClO$_4$)Cl and [Co(tetraen)Cl](ClO$_4$)Cl[1], where NSSSN = 1,11 - diamino - 3,6,9 - trithiaundecane and tetraen = 1,3,6,9,11 - pentaazaundecane, now permits their comparison as well. Based on all available chemical evidence[4,5] we inferred that the so-called $\alpha\alpha$ conformer is present in the NSSSN, as in Snow's[1] compound. One perplexing question related to Co(NSSSN)Cl^{2+} and Co(tetraen)Cl^{2+} was, why is Co(NSSSN)Cl^{2+} reduced by Fe(II) at a rate ~10^7 times faster than the amine analog if they both possess the same geometry? Is this rate enhancement due to a structural *trans* effect as being researched by Deutsch *et al.*[6,7] for Co(en)$_2$X$_2$$^{n+}$ type

complexes, or is it due to an electronic ground state effect due to the nature and presence of the thioether donors as suggested earlier,[8,9] or is there a structural driving force that promotes activation of the Co(NSSSN)Cl^{2+} complex?

In this work we report and discuss the results of an X-ray structural determination for [Co(NSSSN)Cl](ClO$_4$)Cl in conjunction with several kinetic studies involving the Fe(II) reduction of octahedral cobalt(III) complexes derived from both N–S–S–S–N and N–S–N–S–N type pentadentate ligands.

EXPERIMENTAL

X-Ray study

Crystals of [Co(C$_8$H$_{20}$N$_2$S$_3$)Cl](ClO$_4$)Cl were grown from an aqueous HClO$_4$ solution of recrystallized [Co(NSSSN)Cl] [ZnCl$_4$]. The crystal structure was determined from 3891 reflections collected by X-ray diffraction methods using a computer-controlled diffractometer equipped with a Mo-target tube whose radiation was monochromatized by a dense graphite crystal. Table 1 summarizes the experimental data collection and processing parameters. Tables of atomic positional and thermal parameters and F$_0$/F$_c$ values have been deposited as supplementary data with the Editor, from whom copies are available on request.†

Materials

All common laboratory chemicals were of reagent grade. Stock solutions of aqueous iron(II) perchlorate, perchloric acid and lithium perchlorate were prepared using triply distilled water and standardized using methodologies reported earlier.[10] The complexes [Co(NSNSN)Cl](ClO$_4$)$_2$, [Co(NSNSN)Br](ClO$_4$)$_2$, [Co(NSSSN)Cl](ClO$_4$)$_2$, and [Co(NSSSN)Br](ClO$_4$)$_2$ were pre-

R $\quad$ $\Sigma \left\| \left\|F_o\right\| - \left\|F_c\right\| \right\| / \Sigma \left\|F_o\right\|$	0.030
R $\quad$ $[\Sigma_w (\left\|F_o\right\| - \left\|F_c\right\|)^2 / \Sigma_w \left\|F_o\right\|^2]^{\frac{1}{2}}$	0.031
Weights	$\sigma(F)^{-2}$

pared as reported in the literature.[4,11,12] All complexes ($\Delta_m = 190-225 \, \Omega^{-1} \, cm^2$) were recrystallized from dilute HClO$_4$–NaClO$_4$ and their C, H, N, and S analyses, as determined by Chemalytics Inc. of Tempe, Arizona, verify the above analytical formulations.

Kinetic procedures

Predetermined volumes of deoxygenated stock solutions were delivered into a 5.0 cm cell under argon and the cell allowed to equilibrate at the desired temperature. Thermostated iron(II) solution was then added to the cell by syringe. The cell was shaken and absorption measurements using a Cary-14 were begun. Temperature was maintained at ±0.1°C and monitored using the apparatus described previously.[10]

Pseudo-first-order conditions were maintained by having iron(II) consumption less than 10% of the total iron(II). Rate constants were obtained from computer calculated least-squares slopes of plots of ln $(D_t - D_x)$ vs time. Such plots were found to be linear over 95% reaction. Data were collected by having triplicate determinations for k_t at any given set of conditions. The error limits reported are standard deviations. Reactions were followed at λ_{max} for the low energy d–d envelope observed for each complex. Visible UV Spectral characteristics $\lambda_{max}(\epsilon)$ are as follows: Co(NSNSN)Cl^{2+}, 565(207), 505(159), 278(15,260); Co(NSNSN)Br^{2+}, 586(242), 505(148), 281(21,950); Co(NSSSN)Cl^{2+}, 548(351), 380(390), 288(15,440); Co(NSSSN)Br^{2+}, 566(364), 370(790), 299(14,960).

RESULTS AND DISCUSSION

Structure description of [Co(NSSSN)Cl]ClO$_4$)Cl

As can be seen in Fig. 1, the Co(NSSSN)Cl^{2+} cation closely resembles the $\alpha\alpha$ isomer of Co(tetraen)Cl^{2+} which was investigated by Snow,[1] in that the central

sulfur donor (S2) is the one *trans* to chlorine. The absolute configuration shown in Fig. 1 is designated $\lambda\lambda\delta\lambda$ (starting from N1) according to IUPAC convention,[13] although the $\delta\delta\lambda\delta$ racemate is also present in the lattice since the compound was unresolvable[4] and crystallizes in a centrosymmetric space group. A tabulation of bond distances is presented in Table 2, and intramolecular bond angles are given in Table 3. The averages of the essentially chemically equivalent bond distances in Table 2 are as follows: Co–S = 2.235(1), Co–N = 1.973(2), C–S = 1.820(3), C–N = 1.489(4), C–C = 1.499(4) Å. Two of the C–S bonds, namely S1–C4 and S3–C7, are markedly shorter than the other four, and since they are in similar positions in the ligand one is tempted to suggest and assign some electronic phenomenon to this observation. In this case however, there is no such ready explanation available. Excluding the bonds to sulphur, the remaining bond averages are insignificantly different from those reported by Snow,[1] and also from those found in other related compounds both with sulphur ligands[7,16] and without.[14,15] The Co–S distances are in good agreement with previous results,[7,16] and there is no indication of any *trans* effect in either the Co–S2 bond or the Co–N bonds. In compounds exhibiting a structural *trans* effect, the Co–N bond length increases to about 2.00 Å. Also, according to Deutsch *et al.*, only in those ligands where the sulfur atom carries a formal negative charge will a significant *trans* effect be observed upon chelation,[17] and this is not the case in the present compound. The Co–Cl

bond distances in $Co(NSSSN)Cl^{2+}$ and $Co(Tetraen)Cl^{2+}$ are 2.268(1) and 2.263(3) Å respectively, eliminating the idea of a sulfur induced structural *trans* effect influencing the reactivity of groups positioned across the octahedron from sulfur.

The crystal lattice structure $[Co(NSSSN)Cl](ClO_4)Cl$ is held together by an extensive system of hydrogen bonding which can be seen in Figs. 2 and 3. The close intermolecular contacts are listed in Table 4. Both the chloride and the perchlorate anions, separately, bridge adjacent cations through the amino hydrogens. The perchlorate anion links pairs of cations, and these pairs

are themselves linked by pairs of chlorides into infinite chains parallel to the *a* axis. The separate chains are segregated from one another by C–H/C–H repulsions, although there may be some weak electrostatic attractions between the perchlorate oxygen lone pairs and the empty *d* orbitals on the sulfurs. These contact distances are listed in Table 4, and the orientation of the S1 and S3 atoms to O4 can be seen in the two packing diagrams. The O1 type oxygens and the ligated chlorine atoms serve no role in the intricate hydrogen bonding scheme.

Since chemical reactivity studies have shown appreciable differences between $Co(NSSSN)Cl^{2+}$ and

Co(tetraen)Cl^{2+}, it is of interest to compare the major structural features of the two complexes for a possible explanation. To this end we employed a program written by Liu[18] to produce Fig. 4, which overlays the two cations by minimizing the Co, Cl, N1 and N10 distances. It is quickly seen that the basic framework involving the sulfurs of NSSSN and the -NH groups of tetraen are the same, given the longer Co–S bond length. The two terminal C–C–N fragments, however, are quite different in the two molecules. In the tetraen complex, the C2, C3 and C8, C9 torsion angles are 44.7° and −20.2°, respectively, while in the NSSSN compound the corresponding angles are −52.3° and −44.6°. A comparison of selected torsion angles for both molecules is presented in Table 5. The differences in both sign and magnitude of rotation are important, showing that Co(NSSSN)Cl^{2+} is somewhat more buckled, and with the opposite sense with regard to C2, C3. The configuration of Co(tetraen)Cl^{2+} is

*The signs of the angles have all been reversed for purposes of comparison, since the two molecules are of opposite chirality.

$\delta\lambda\delta\lambda$ instead of $\lambda\lambda\delta\lambda$ as found in $Co(NSSSN)Cl^{2+}$. The main consequence of this divergence in configuration of the Co-S1-C3-C2-N1 ring is to effectively stagger the terminal amino hydrogen atoms of NSSSN, while they remain eclipsed in tetraen. The reason behind the divergence is most probably the longer Co-S bond distance, which forces the amino hydrogen atoms more toward each other. To relieve this interaction the ligand twists C2 down and staggers the terminal hydrogens. By manipulating an accurate scale model of aa-$Co(NSSSN)Cl^{2+}$ into the $\delta\lambda\delta\lambda$ configuration,[19] there appears to be an even more strained contact between H2A and H5A than between H1B and H10B, and this certainly accentuates the driving force toward the $\lambda\lambda\delta\lambda$ configuration.

This structure determination is in accord with our earlier aa geometric assignment for complexes of $Co(NSSSN)X^{2+}$ based then on indirect chemical evidences. Although we as yet have not been able to grow $[Co(NSNSN)Cl](ClO_4)_2$ crystals of suitable quality for a structure determination, we are confident that they also possess the aa configuration due to the stereochemical constraints required by the donor atoms in the NSNSN ligand[5] and the complexes' very close chemical and physical similarity to the $Co(NSSSN)X^{2+}$ series.[4]

Kinetic studies

The Fe(II) reduction of $Co(NSSSN)X^{2+}$ and $Co(NSNSN)X^{2+}$ (X = Cl⁻, Br⁻) was examined under a variety of complex concentrations, Fe(II) concentrations, acidities and temperatures. In all cases, the total $[ClO_4^-]$ was adjusted to 1.0 M using appropriate volumes of standardized $LiClO_4$-$HClO_4$. Table 6 summarizes the conditions and values of k_t obtained. Pseudo first-order conditions were employed in which consumption of Fe(II) was negligible, thus $k_t = k_{obs}/Fe(II)$. From this

[b]Variations in k_t are given in standard deviations from the average

data we conclude that reduction of all four complexes is first order in Co(III) and Fe(II) and follows the common acid independent $(0.20\,M < H_3O^+ < 0.90\,M)$ rate law:

$$-d[\text{complex}]/dt = k_t[\text{Co(III)}][\text{Fe(II)}].$$

It has been established generally that similar Fe(II)–Co(III) systems undergo reaction via an inner-sphere electron transfer mechanism,[20] and we assume that basic mechanism in this work.

Activation parameters for the iron(II) reduction of the Co(NSSSN)X^{2+} and Co(NSNSN)X^{2+} complexes are presented in Table 7 along with the corresponding values for the analogous halopenta–aminecobalt(III) species.

Previous studies demonstrated that the placement of thioether donors *trans* to potential inner-sphere bridging groups enhanced the reduction rate by factors of $\sim 10^2$–10^3 as compared to nitrogen donors similarly placed in the coordination sphere.[3,9] The exact nitrogen analog to Co(NSSSN)Cl^{2+} and Co(NSNSN)Cl^{2+} is Co(tetraen)Cl^{2+}. Second order Fe(II) reduction rate constants at 25°C are $0.193\,M^{-1}\,s^{-1}$, $0.226\,M^{-1}\,s^{-1}$ and $\sim 1 \times 10^{-8}\,M^{-1}\,s^{-1}$ respectively. The latter value is an estimate because the Co(tetraen)Cl^{2+}–Fe(II) reaction was found to be extremely slow.[21] Reactivity trends in k_t have been attributed to the circumstance that the oxidant acceptor orbital (probably dz^2) is made more available by simultaneously removing the bridging ligand and the donor group *trans* to it. Experimentally one observes that k_t is significantly reduced as chelation is increased in a series of cobalt(III) complexes when NH$_3$'s are replaced by ethylenediamine, triethylenetetramine and tetraethylenepentaamine respectively.[8] Presumably increased chelation reduces the ability of a *trans* donor to stretch along the axis of inner-sphere interaction and thus we would expect any complex derived from a pentadentate ligand to exhibit the greatest reduction in k_t. In this work, with the presence of thioether donors, the above decrease in k_t is not observed; instead we have a $\sim 10^7$ fold rate enhancement.

From the structure data on Co(NSSSN)Cl^{2+} and Co(tetraen)Cl^{2+} we clearly must exclude any structural *trans* effect, the Co–Cl bond distances in both being almost identical (2.268(1) and 2.263(3) Å respectively). We believe a major factor contributing to the increased reduction rate begins with the fact that the Co–S1–C3–C2–N1 ring does not have the classical low energy conformation as found in the tetraen derivative. In Co(NSSSN)Cl^{2+} one of the two adjacent terminal – NH$_2$'s must be twisted to assume a position in which the

hydrogens on the two amino groups are staggered, minimizing hydrogen–hydrogen steric effects. Since the ligand is symmetrical, this phenomenon must alternate from one side to the other in solution, inasmuch as the mirror image molecule must have the distorted ring on the opposite side from that shown in Fig. 4, and the enantiomers are in equilibrium. Therefore, one can visualize this phenomenon as a propagation of the distortion from one side to the other across the entire chain with concomitant effects on the activation step associated with the precursor complex, and the observation of enhanced k_t.

Another feature to consider is the possibility of an Fe(II)–S–Co inner-sphere reduction path. Deutsch *et al.* have demonstrated that Cr(II)–Sulphur bridges to Co(III) centers are fairly common.[6,7] Several observations suggest that in our case Fe(II) does not favour such a bridge. In Table 6 we find that the reduction rate of Co(NSNSN)X^{2+} in several orders of magnitude greater than the corresponding Co(NSSSN)X^{2+} species, even though the latter has more sulphur atoms available for possible interaction with Fe(II). With Fe(II) as reductant the bridging efficiency of Cl$^-$ is greater than that of R–S–R and if both paths were operative to varying degrees one would observe nonlinear $\ln(D_t - D_\infty)$ vs time plots. Such is not the case as the graphs are exceptionally linear over 95% of reaction demonstrating reaction singularity. In previous work[9] complexes of the type Co(NSSN)-diamine were observed to be unreactive, even at high Fe(II) concentrations, demonstrating the Fe(II)–Thioether bridge is an unfavourable path for electron transfer. Preliminary experiments with Co(NSNSN)NCS^{2+} and Fe(II) gives $k_t \sim 6 \times 10^{-5}\,M^{-1}\,s^{-1}$, again demonstrating the disdain Fe(II) has for inner-sphere sulphur bridges. It has been noted elsewhere that a large ratio of k_{N_3}/k_{NCS} is suggestive of an inner-sphere Fe(II) reduction path and reflects the affinity of Fe(II) for nitrogen rather than sulphur bridges. The ratio of the azide rate constant[8] to the N-thiocyanato rate constant is $1.35\,M^{-1}\,sec^{-1}/6 \times 10^{-5}\,M^{-1}\,s^{-1}$ or $\sim 2 \times 10^5$, consistent with our assignment of a bridged inner-sphere mechanism not involving the thioether donor atoms.

Examination of Tables 6 and 7 shows that the Co(NSSSN)X^{2+} complexes are reduced slower than the Co(NSNSN)X^{2+} analogs in which the central thioether donor has been replaced by a CH$_3$–N moiety. The slight increase in k_t due to this structural modification may imply that the methyl group via solvation interactions is

Table 7. Activation parameters for the Fe(II) reduction of cobalt(III) complexes

Oxidant	$k_t\ M^{-1}s^{-1}$ $25°C$	$\Delta H^{\ddagger}$ kcal/mole	$\Delta S^{\ddagger}$ e.u.	$\Delta G^{\ddagger}$ kcal/mole

pulled into the bulk solvent, thus facilitating expansion of the cobalt radius along the critical axis as the reduction process proceeds with Co(III) becoming Co(II). The presence of CH_3-N physically causes a marked increase in solubility between the two series of complexes. In Table 6, a noticeable feature is the consistently more negative entropy of activation for $Co(NH_3)_5X^{2+}$ and $Co(NSSSN)X^{2+}$ species, again suggesting a less stringent structural ordering in the activated complex for reduction of $Co(NSNSN)X^{2+}$ complexes. In each case the bromo complex is reduced at a rate considerably slower than observed for the chloro derivative. This may be a manifestation of soft–hard (Br–Fe^{2+}) vs the favored hard–hard (Cl–Fe^{2+}) interaction in forming the precursor complex.

In this and previous studies we observed that placement of thioether donors *trans* to potential bridging groups greatly enhances the reduction rate compared to comparable complexes with amino donors. The exact reasons for such rate enhancement ($\sim 10^2$–10^7) are not easily isolated because of the difficulty in systematically controlling or varying only one of the numerous contributory features present in a molecule. Several emerging investigative routes include the synthesis of new molecules having specific stereochemistries and structural studies to examine the role of bond lengths, angle and ring conformations in conjunction with the reduction rate. The possible role of ground state electronic effects, especially in sulphur-containing ligands such as NSSN, NSNSN and NSSSN awaits theoretical and/or photochemical investigation.

THE DISTRIBUTION OF CERIUM (III) CATIONS BETWEEN AQUEOUS AND NITROBENZENE PHASES IN THE PRESENCE OF DICARBOLIDE ANIONS

I. PODZIMEK, M. KYRŠ,* J. RAIS and P. VAŇURA

Nuclear Research Institute, 250 68 Řež, Czechoslovakia

Abstract—Extraction of micro- and macroquantities of Ce^{3+} ($C^o_{Ce} = 10^{-6}$–10^{-1} mole/dm^3) with a nitrobenzene solution of dicarbolide ($C^o_{H^+B^-} = 0.04$–0.5 mole/dm^3) from a nitric acid solution ($C^o_{HNO_3} = 0.1$–0.3 mole/dm^3) was investigated. Coextraction of water and simultaneous extraction of Ce^{3+} and Ba^{2+} ($C_{Ce^+} + C_{Ba} = 0.3$ mole/dm^3) from 0.3 and 0.5 M HNO$_3$ was also studied. It was found that the reaction $Ce^{3+} + 3\bar{H} \rightleftharpoons \overline{Ce^{3+}} + 3H$ ($K_{Ce/3H}$) takes place in all cases. The dependence of the apparent exchange extraction constant $K_{Ce/3H}$ on the initial composition of both phases was determined and the effect of the composition of the aqueous phase on the values of $K_{Ce/3H}$ and $K_{Ba/2H}$ was discussed. The stability constant of the $CeNO_3^{2+}$ complex and the hydration number of the Ce^{3+} cation in the organic phase ($h_{Ce^{3+}} = 16.2 \pm 2$) was determined and a linear correlation between individual extraction constants of mono-, bi- and trivalent cations and the hydration numbers in the nitrobenzene phase was found using data from the present paper and values given in literature.

In the previous paper[1] the reasons were given for the investigation into solvent extraction of barium in the title system. In this work an analogical study has been performed on cerium III cations. This particular choice of cation is based upon the presence of cerium among nuclear fission products and because the system has been proposed for the isolation of radioactive cesium and strontium from radioactive wastes generated in Purex reprocessing of irradiated nuclear fuel.[2] Furthermore, cerium was selected as a suitable representative of trivalent cations which have almost been up to now ignored in investigations of similar solvent extraction systems based upon the presence of the bulky hydrophobic dicarbolide anion acting as the extractant.

The simultaneous extraction of barium and cerium in this system was studied also with the aim of investigating a possible mutual interaction of these two cations in the solvent extraction process.

EXPERIMENTAL

The experimental technique, e.g. the determination of water and proton concentrations in the organic phase, followed rather strictly the experimental pattern described previously.[1] For the determination of the distribution ratios of tracer amounts of cerium (D_{Ce}) tracing with ^{144}Ce was used and the ratioactivity of aliquots of the two phases was measured after reaching (in 2 hr) radioactive equilibrium between ^{144}Ce and the daughter element ^{144}Pr. In experiments where Ba and Ce were simultaneously present two parallel sets of experiments were performed in which the chemical composition of the extraction systems was exactly equal, but one set was labelled with ^{144}Ce in order to determine the D_{Ce} values, the other one with ^{133}Ba. Weighable amounts of Ce in the stock solution were determined using a complexometric method (pH 4.4, indication with xylenol orange).

RESULTS AND DISCUSSION

The dependence of D_{Ce} values for tracer amounts of Ce upon the concentration of HNO$_3$ in the aqueous phase and upon the concentration of the reagent in the organic phase is given in Fig. 1. Similarly to analogical

results[1] obtained with Ba, the values of log D_{Ce} depend linearly upon the initial acidity of the aqueous phase $c^o_{HNO_3}$ (at constant initial reagent concentration in the organic phase (c^o_{HB})), the slope being this time -3. For constant $c^o_{HNO_3}$ values in the aqueous phase log D_{Ce} values increase linearly with c^o_{HB} the slope being approximately $+3$. Accordingly, the prevailing equilibrium underlying the solvent extraction process can be formulated as follows: $Ce^{3+} + 3H^+_{org} \rightleftharpoons Ce^{3+}_{org} + 3H^+$ ($K_{CE/3H}$).

In order to investigate if the same simple reaction takes place also when weighable amounts of cerium are extracted systematic experiments were performed in which the initial concentrations of the threee components varied in the ranges: 0.1–0.3 mole/dm^3 HNO$_3$; 0.04–0.5 mole/dm^3 HB; 10^{-6}–10^{-1} mole/dm^3 Ce and distribution ratios of Ce and equilibrium concentrations of protons in both phases were determined. The total number of these distribution experiments was 124. The method of calculating the $K_{Ce/3H}$ values was analogical to that described previously.[1] The values $K_{Ce/3H}$ showed no dependence upon the concentration of the reagent in the whole range investigated and upon the concentration of Ce in the range 10^{-6}–10^{-2} M Ce. On the other hand, a slight decrease in $K_{Ce/3H}$ values was observed with increasing aqueous acidities. For low concentration of Ce (< 0.01 M) the empirical relationship is valid log $K^{Ce}_{3M} = 1.49 - 0.26c^o_{HNO_3}$.

In the whole concentration range a rather complicated empirical relationship has been derived:[3]

$$\log K^{Ce}_{3H} = 1.31 - 0.19\, c^o_{HNO_3} + 1.21\, c^o_{H^+B^-} - 3.63\, c^o_{Ce}$$
$$+ 0.34\, c^o_{H^+B^-}c^o_{HNO_3} - 0.77\, c^o_{H^+B^-}c^o_{Ce}$$
$$+ 1.35\, c^o_{HNO_3}c^o_{Ce} - 2.32(c^o_{H^+B^-})^2 - 0.059$$
$$\times (c^o_{HNO_3})^2 + 8.02(c^o_{Ce})^2.$$

The fact that the $K_{Ce/3H}$ values vary only slightly when the initial concentrations of the three components of the solvent extraction system change in wide ranges can be considered as a corroboration of the validity of the chemical model of the extraction proposed (no asso-

ciation of the extracted species and the extractant in the organic phase, no association of the ions Ce^{3+} and B^- in the aqueous phase, no extraction of HNO_3).

Another evidence in favour of the proposed main chemical reaction of the extraction process can be inferred from the data on the proton transfer from the organic phase into the aqueous phase during the solvent extraction of weighable amounts of cerium (Table 1). It can be seen that the coincidence of calculated and experimentally found values of the increase of H^+ concentration in the aqueous phase (Δ_{aq}) and its decrease in the organic phase ($-\Delta_{org}$) is fairly good. The average value from all data available is $\Delta_{aq}/[Ce^{3+}]_{org} = 3.12 \pm 0.15$ and $-\Delta_{org}/[Ce^{3+}]_{org} = 3.14 \pm 0.17$ which is very close to the theoretically expected value of 3 protons per cerium cation.

For the interpretation of the results obtained the behaviour of cerium (III) nitrate complexes might be of importance.[4,5] Therefore the effect upon Ce^{3+} extraction was investigated of the type of the anion of the mineral acid present. In these experiments tracer amounts of Ce^{3+} were used, three concentrations (0.1, 0.2, 0.3 M) of the extractant and the initial acidity in the aqueous phase was adjusted to 0.2–2 M H^+ using alternatively the following acids: HNO_3, $HClO_4$, HCl, and H_2SO_4. With all four acids the linear dependence of log D_{Ce} upon log C_{H^+} with the slope of -3 was observed. The values of D_{Ce} increased according to the sequence $HCl \leq HNO_3 < H_2SO_4 < HClO_4$. The values for HCl were about 95%, those for H_2SO_4 140% and for $HClO_4$ 175% of the value for HNO_3 taken as reference.

These results show that in the solutions of perchloric

acid, which is known to be in most cases a noncomplexing medium, the distribution ratios of Ce(III) exhibit the highest values observed which could be interpreted as a result of the absence of complex formation between Ce^{3+} and the anion as compared to some degree of masking in the other media tested. The differences between the D_{Ce} values for different acids are small compared to the strong scattering of published stability constants[6] of the complex 1:1. Therefore, on the basis of literature data available the question whether the order of the acids according to the degree of Ce complexing is identical to that of decreasing D_{Ce} values cannot be answered with reliability.

For this reason we investigated in more detail the dependence of D_{Ce} upon $c_{HNO_3}^0$ in a medium of constant ionic strength (replacing gradually $HClO_4$ by equivalent concentrations of HNO_3). The experimental curves are given in Fig. 2.

The theoretical curves calculated on the assumption that Ce^{3+} and $CeNO_3^{2+}$ are the only species of Ce(III) in the aqueous phase and $CeNO_3^{2+}$ is nonextractible coincide satisfactorily with experimental data if the values of the stability constant of $CeNO_3^{2+}$ are assumed to be 2.19 ($\mu = 0.3$) and 2.84 ($\mu = 0.5$). The comparison of these log K_1 values with available data from the literature given in Table 2 shows that the values found in our system do not contradict values found by other authors. Therefore we are prone to ascribe the lower values of D_{Ce} in nitric acid than in perchloric to the formation of inextractible $CeNO_3^{2+}$ species. Consequently the values of $K_{Ce/3H}$ given in this paper ignoring the formation of these species must be characterized as "conditional" concen-

tration constants[7] which are valid only for the degree of the metal masking occurring in the presence of the ligand concentration, which was used in the determination of the $K_{Ce/3H}$ constant.

Thus the influence of HNO_3 concentration upon the $K_{Ce/3H}$ values found in this paper is due to two factors: changing degree of Ce^{3+} masking and changing activity coefficients of the species in the aqueous and to some extent—in the organic phase.

Since the exchange constants $K_{Ce/3H}$ and $K_{Ba/2H}$ have been found[1] to be reasonably constant in systems, where a pair of cations only was present, it seemed worthwhile to investigate the validity of this approach to systems

with the simultaneous presence of three types of cations (H^+, Ba^{2+}, Ce^{3+}).

In these types of experiments the $c^o_{HNO_3}$ and c^o_{HB} were held constant and the ration c^o_{Ba}/c^o_{Ce} was varied in a wide range maintaining the sum $c^o_{Ba} + c^o_{Ce}$ constant. In all cases the values D_{Ba}, D_{Ce} and $c^{tot}_{H_2O}$ were determined. The distribution of metals is shown in Fig. 3 for three concentrations of HB. The values of constants $K_{Ce/3H}$ and $K_{Ba/2H}$ were calculated

(a) for each $c_{H^+B^-}$ and $c^o_{HNO_3}$ separately

(b) for all $c^o_{H^+B^-}$ with constant $c^o_{HNO_3}$ together and

(c) for all $c^o_{H^+B^-}$ and $c^o_{HNO_3}$ together.

The special version of general least squares minimizing

program LETAGROP (Ref. 8) was used for this calculation involving the function

$$U = \Sigma\{[(\log D_{Ba}(exp) - \log D_{Ba}(calc)]^2$$
$$+ [\log D_{Ce}(exp) - \log D_{Ce}(calc)]^2\} \qquad (2)$$

where $D_{Ba}(exp)$, $D_{Ba}(calc)$ resp. $D_{Ce}(exp)$, $D_{Ce}(calc)$ are experimental and calculated values of distribution ratios of Ba resp. Ce. Results are summarized in Table 3.

Values of both $K_{Ce/3H}$ and $K_{Ba/2H}$ show no dependence on acidities of both the aqueous and the organic phase. The scattering of these values is probably caused by experimental errors and neglecting the changes of activity with component concentration during constant calculation. Both $K_{Ce/3H}$ and $K_{Ba/2H}$ are approximately three times lower than these found in the systems containing Ba^{2+} resp. Ce^{3+} in microamounts. This difference may be caused by changing of activity coefficients in one or even both phases.

For the discussion of this difference in $K_{Ce/3H}$ values it is useful to start with the obvious relationship:

$$K_{Ce/3H} = K_{Ce/3H}^{th} \times \frac{\bar{\gamma}_H^3 \times \gamma_{Ce}}{\bar{\gamma}_{Ce} \times \gamma_H^3}.$$

The assumption can be made that the ratio $\bar{\gamma}_H^3/\bar{\gamma}_{Ce}$ does not depend significantly on the composition of the aqueous phase and on the ionic strength of the organic phase. This is indicated by the fact (see Table 3) that the dependence of $K_{Ce/3H}$ and $K_{Ba/2H}$ on the value of c_{HB}^o are very feeble.

As for the activity coefficient of the protons or acids, we assume that they are practically equal for both cases, i.e. 0.3–1.0 M HNO_3 or 0.3 M $HNO_3 + 0.3$ M ($Ce(NO_3)_3$–$Ba(NO_3)_2$). This assumption is based upon an analogy with the systems $BaCl_2 + HCl$ (Ref. 9) and $Nd(NO_3)_3 + HNO_3$ (Ref. 10). In the latter case values almost constant were found for the acidity range 0.1–1.0 mole/kg and practically independent of Nd concentration in the range 0–0.2 mole/kg. In the former similarly constant values of γ_{HCl} are reported.

Thus, the change of $K_{Ce/3H}$ would mainly be ascribed to the change in γ_{Ce}. In the case of microamounts of Ce the value of γ_{Ce} can be assumed to be close to unity in

extraction systems with nitrobenzene and dicarbolide anion. This statement is based on the observed independence of $K_{Ce/3H}$ constant on the acidity of aqueous phase (Fig. 1).

In the case of both multi-charge cations (Ba^{2+} a Ce^{3+}) present in weighable amounts in the aqueous phase rather low values of γ_{Ce} and γ_{Ba} should be anticipated (~ 0.2–0.35) based on the analogy with the systems containing $Ba(NO_3)_2$ or $La(NO_3)_3$ and $Pr(NO_3)_3$ (see Refs. 11, 12) which is in accordance with observed decrease of $K_{Ce/3H}$ and $K_{Ba/2H}$ for macroamounts of Ce and Ba.

In an attempt to ascertain the hydration of Ce^{3+} ions in the nitrobenzene extract the overall concentration of water in the extract was determined in dependence on the equilibrium concentration Ce^{3+} ions ($[Ce^{3+}]_{org}$) in the organic phase (Fig. 4). The calculation of the hydration number of Ce^{3+} in the organic phase ($h_{Ce^{3+}}$) was performed using the simplified procedure discussed previously,[1] based upon the balance:

$$c_{H_2O}^{tot} = c_{H_2O}^o + h_{H^+} \times [H^+]_{org} + h_{Ce^{3+}} \times [Ce^{3+}]_{org},$$

where $c_{H_2O}^o$ is the solubility of water in the pure solvent, h_{H^+} was determined previously and $[H^+]_{org}$ and $[Ce^{3+}]_{org}$ values were determined by the analytical methods mentioned.

From the fact that the curves in Fig. 4 run almost parallel to the lines of constant $c_{H_2O}^{tot}$ values it can be seen that the values of $h_{Ce^{3+}}$ should correspond to $3h_{H^+}$ since one Ce^{3+} replaces three H^+ cations during extraction.

In our previous paper the h_{H^+} values found amounted to 5.2–7.6 so that the expected range of $h_{Ce^{3+}}$ values is about 15.6–23. Unlike for h_{H^+} no correlation between the actual $h_{Ce^{3+}}$ value and the composition of the extraction system could be found and therefore the $h_{Ce^{3+}}$ values for the various points in Fig. 4 were included in the calculation of an average overall value $h_{Ce^{3+}}$, which was found to be 16.2 ± 2 mole of H_2O/mole Ce^{3+}. The limitations to the precision and accuracy of h values calculated in this way has been discussed previously in connection with the determination of $h_{Ba^{2+}}$.

Comparing the value 16.2 ± 2 for Ce with 11.5 ± 1 found[1] for Ba one can conclude that the exchange reac-

tion 3 Ba^{2+} + 2 $Ce_{org}^{3+} \rightleftharpoons 3$ Ba_{org}^{2+} + 2 Ce^3 should be accompanied with a very little change in overall cation hydration in the extract ([(3 × 11.5–2 × 16.2)/2 × 16.2] × 100 = 6.5%) which is well within the uncertainty of the hydration numbers found. Since in all experiments also the concentration of water in the extract was determined, the anticipated independence of $c_{H_2O}^{tot}$ upon f_{Ba} in the whole range of f_{Ba} values could be checked. The results (Fig. 5) corroborate the above reasoning. The fact that a practically

linear dependence of c_{H_2O} upon c_{HB}^o values was found is in coincidence with the observation that for hydration numbers of both Ba^{2+} and Ce^{3+} no dependence on c_{HB}^o values could be found.

It is interesting to compare the hydration number value of Ce in the extract with the hydration numbers of the same cation in aqueous solution since some authors[13,14] came to the conclusion that the hydration numbers of anions in nitrobenzene extracts "should be considered
Fig. 6. Correlation between individual extraction constants of cations from water to nitrobenzene and their hydration numbers in nitrobenzene. Data for Ce from this work, other data see Ref. 1.

only lower limits to the first-shell coordination numbers as they represent average values for distributions that may well range from 0 (unhydrated anions) to 4 or even 6 water molecules (the first—shell coordination number)". As a matter of fact a remarkable similarity was found between the organic phase hydration numbers of Cl^- and Br^- to the values found in aqueous solutions by compressibility and ionic vibration methods.[14]

For Ce^{3+} the following hydration numbers in aqueous phases have been found: 6.7 by diffusion measurements and 7.5 by volume fraction statistics,[15] 8 in sulphate media from thermodynamic parameters,[16] 9 spectrophotometrically,[17] 9 from molar volumes and 13 by compressibility method.[18] Similarly to Ba^{2+} behavior[1] these are much lower than the above $h_{Ce^{3+}}$ value found in nitrobenzene which shows again that the assumption of the first-shell coordination number being a higher limit to organic phase hydration number cannot be considered to be of general validity. The reasons for the possibility of the organic phase hydration number exceeding markedly that in the aqueous phase have been discussed in connection with Ba^{2+} hydration.[1]

The determination of the hydration number of Ce^{3+} in nitrobenzene offers an opportunity of testing the validity of the correlation between hydration number values in nitrobenzene and individual solvent extraction constants. Combining data given in Fig. 8 in Škarda and coworkers paper,[19] (Fig. 5) from the previous work,[1] and the value of $h_{Ce^{3+}}$ found herein we obtain the presently most general correlation plot (Fig. 6) which shows that the correlation is valid both for investigated cations of charge $+1$, $+2$, and $+3$ and investigated anions with charge -1.

REACTIONS OF COORDINATED COMPOUNDS. CHELATE-INDUCED ACCELERATION OF METHYL-PROTON DISSOCIATION FROM ACETOPHENONES

TOSHIO KAWATO

Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810, Japan

Abstract—Rate constants of acetyl-proton exchange of alkali acetylphenolates and related acetyl aromatics were measured and compared in D_2O and in CD_3OD. The results exhibited chelate-induced activation of acetyl C–H bonds. A palladium complex with N,N,N',N'-tetramethylethylenediamine turned out to catalyze the acetyl proton exchange of *o*-hydroxyacetophenone due to chelation.

Reactions of coordinated molecules have been investigated widely, while little has been studied about the reactivity of C–H bonds outside chelate rings. In a previous work, kinetics of proton dissociation from acetyl groups of β-dicarbonyl compounds were measured and discussed in connection with chelate effects.[1] In such a system, however, there was some uncertainty in measuring the kinetics because hydrolysis (C–C bond cleavage in the ligands) occurred during measurement. The chelate effect on the rate of acetyl-proton exchange was successfully observed by use of a series of hydroxy-acetophenones. This paper will expand the original communication[2] and describe the chelate-induced acceleration of proton dissociation from acetyl groups as well as a catalytic character of a palladium complex.

EXPERIMENTAL

General comments

UV absorption spectra were measured on a Hitachi EPS-3T spectrophotometer using H_2O and N,N-dimethylformamide (DMF) solutions. IR spectra were recorded on a Hitachi EPI-S2 spectrophotometer in nujol mulls or neat films. NMR spectra were determined at 60 MHz on a Hitachi R-24 spectrometer using $CDCl_3$, CD_3OD, or D_2O solutions with TMS or sodium 2,2-dimethyl-2-silapentane-5-sulfonate as the internal standard. Rate of proton dissociation was expressed by rate of disappearance of NMR peaks due to acetyl–methyl protons in D_2O or in CD_3OD. Kinetic measurement and calculation were performed by a general method described in the previous paper.[1]

Materials

o-, *m*-, and *p*-Hydroxyacetophenone(Hooa, Hmoa, and Hpoa, respectively) and other acetyl compounds were commercially available; the purity was confirmed by IR and NMR spectra. Sodium *o*-acetylphenolate, Na(ooa), has been prepared in the previous work.[1] Other alkali–metal salts were obtained similarly by mixing of solutions of hydroxyacetophenones in methanol and aqueous alkali hydroxides. The purity of the salts was confirmed by elemental analyses (Table 1); sets of small letters represent anions derived from corresponding hydroxyacetophenones.

Palladium complex with N,N,N',N'-tetramethylethylenediamine (tmen) and Hooa, [Pd(tmen)(ooa)]ClO₄

When an aqueous $K_2[PdCl_4]$ was treated with N,N,N',N'-tetramethylethylenediamine(tmen), a water-insoluble complex, $[Pd(tmen)Cl_2]$, was produced as orange–yellow crystals.[3] To a suspension of $[Pd(tmen)Cl_2]$ (0.3 g) in water (30 cm³) was added a solution of $AgClO_4$ (0.4 g) in water (10 cm³) with vigorous stirring. The mixture was stirred at 80°C for 10 min and filtered. To the cold filtrate was added a solution of Na(ooa) (0.15 g) in water (10 cm³). After stirring the mixture for 10 min, the resulting yellow crystalline powder was collected and recrystallized from water to yield (almost theoretical %) yellow needles of the desired complex, $[Pd(tmen)(ooa)]ClO_4$: NMR(CDCl₃) $\delta 2.66$(s, COCH₃, 3H), 2.81 and 2.83 (2s, NCH₃, 12H), 3.07(s, NCH₂, 4H); IR(nujol) 1607(m, C = C), 1573(s, C = O), 1525(m, C = C) cm⁻¹. Found: C, 36.80; H, 5.02; N, 6.11. Calc for $C_{14}H_{23}N_2O_6ClPd$: 36.78; H. 5.07; N, 6.13%.

RESULTS AND DISCUSSION

Rate constants, k_{H-D}, of acetyl-proton exchange of sodium salts of *o*-hydroxyacetophenone(Hooa), *m*-hydroxy–acetophenone(Hmoa), and *p*-hydroxy-acetophenone(Hpoa) in D_2O are shown in Table 2. By use of a mixture of the three salts in D_2O, the rate constants for the salts could be measured simultaneously under the same conditions: the rate constants obtained from the mixture are shown in parentheses in Table 2. The fact that each of the values measured in the mixture is larger than the corresponding rate constant obtained from the single solution is attributable to higher concentration of an OD^- ion in the mixture. The order of the rate constants, Na(ooa) > Na(moa) > Na(poa), in both series can be ascribed to the effect of conjugation in the *p*-isomer and neighbouring hydroxyl-group participation in the *o*-isomer similarly to the case of thallium(I) salts described before.[1] Carbonyl stretching vibrations in IR spectra: 1647 and 1637 cm⁻¹ for Hooa and Na(ooa), 1666 and 1687 cm⁻¹ for Hmoa and Na(moa), 1649 and 1652 cm⁻¹ for Hpoa and Na(poa), exhibit the considerable enhancement of the polarity of the carbonyl bonds resulting from the resonance in Hooa, Hpoa, and their salts.

Table 1. Analytical data of alkali acetylphenolates

Compound	Formula	Colour	Found(Calcd)	
			C	H
Li(ooa)	$C_8H_7O_2Li$	Yellow	67.60 (67.63)	4.98 (4.97)
Li(poa)	$C_8H_7O_2Li$ $1/6H_2O$	White	66.12 (66.22)	5.13 (5.10)
Na(moa)	$C_8H_7O_2Na$ $1/5H_2O$	Pale yellow	59.36 (59.41)	4.40 (4.61)
Na(poa)	$C_8H_7O_2Na$	White	60.53 (60.76)	4.44 (4.46)
K(ooa)	$C_8H_7O_2K$	Yellow	55.39 (55.15)	4.16 (4.05)
K(poa)	$C_8H_7O_2K$ $1/8H_2O$	White	54.68 (54.44)	4.44 (4.14)

Table 2. Exchange-rate constants (k_{H-D}, min^{-1})† at 36°C, concentration (M)†, chemical shifts(δ) of acetyl-proton resonances of alkali acetylphenolates in D_2O

Compound	Conc.(M)	$COCH_3(\delta)$	$k_{H-D}(min^{-1})$
Li(ooa)	0.14	2.60	4.0×10^{-2}
Li(poa)	0.13	2.45	1.6×10^{-4}
Na(ooa)	0.13 (0.11)	2.63	5.0×10^{-2} (9.3×10^{-2})
Na(moa)	0.12 (0.11)	2.58	1.2×10^{-2} (2.7×10^{-2})
Na(poa)	0.13 (0.13)	2.45	1.6×10^{-4} (1.7×10^{-3})
K(ooa)	0.13	2.63	5.4×10^{-2}
K(poa)	0.11	2.45	1.6×10^{-4}

†Values obtained from a mixture of the three sodium salts are designated in parentheses.

The presence of intramolecular bonding in alkali–metal salts of Hooa in solution can be confirmed by cation and solvent effects on UV absorptions according to the method of Zaugg and Schaefer.[4] Ultraviolet absorption spectra of the salts of Hooa and Hpoa were measured in dimethylformamide (DMF) and in water: $\pi - \pi^*$ transition energies of acetylphenolate anions were characterized by strong absorptions ($\epsilon_{max} \simeq 10^4$). In Fig. 1, the wave numbers ($\bar{\nu}$ in cm^{-1}) of the corresponding absorption maxima are plotted on the abscissa vs the inverse cation radii($1/r$ in A^{-1}). The cation effects observed in the salts of Hooa markedly in DMF and slightly in water are attributable to the association or the incomplete dissociation of the ooa salts in the solutions. The absence of such a cation effect for the salts of Hpoa shows clearly that the salts are ionized almost completely in solution. The linear correlations of the inverse cation radii with the transition energies show the absence of appreciable covalent interactions between the anions and the alkali metal ions. From Fig. 1, the absorption maxima

for the free solvated anions, ΔE_0, were obtained by extrapolation of the $\bar{\nu}$ values to infinite cation radius($1/r = 0$) followed by conversion of the resulting $\bar{\nu}_0$ to its energy equivalents (Kcal/mol). The hypsochromic shifts observed in going from DMF to water, $\Delta E_0^{H_2O} - \Delta E_0^{DMF}$, were 8.1 Kcal/mol for Hooa and 7.0 Kcal/mol for Hpoa, respectively. These values were then plotted against their respective aqueous pKa values, 10.82[5] for Hooa and 8.05[6] for Hpoa(Fig. 2). The plot for Hpoa fell close to the straight line which had been proposed by Zaugg et al.,[4] showing that the energy of the anionic ground-state-hydration was proportional to the anion

Fig. 1. Correlation of absorption maxima($\bar{\nu}$) with cation radii(r). O(●), Alkali(ooa) in DMF(in H₂O); □(■), Alkali(poa) in DMF(in H₂O).
Fig. 2. Plots of anion basicities(pKa) vs ground-state hydration. 1, phenol; 2, p-chlorophenol; 3, p-nitrophenol, 4, dimedone; 5, acetylacetone; 6, dibenzoylmethane. For the values of 1−6, see Ref. 4.

basicity like many phenols and enols with no chelating ability. For Hooa, like β-diketones capable of forming chelate compounds, such a plot deviates from the line. Because of the association with cations in solution, the anionic ground state of Hooa is not stabilized by hydrogen bonded solvation to the extent that the basicity would indicate.

Figure 3 shows cation effects on the exchange-rate constants, k_{H-D}, of alkali–metal salts of Hooa and Hpoa. The presence of a marked cation effect in the salts of Hooa can be taken as a strong evidence of the partial association of Hooa anions with alkali–metal ions in water and, indirectly as an evidence of chelation of Hooa with the cations. The rate constants of the salts of Hooa were found to be inversely proportional to the cationic radii. It was thus suggested that the reactivity of the acetyl-methyl groups in the alkali–metal salts of Hooa was proportional to the magnitude of the ionic or electrostatic interaction between the o-acetylphenolate anion and the alkali–metal ions.

The other type of the cation effects on the exchange rate constant for Na(ooa) was exhibited by a mass action effect from the addition of sodium ion to a solution. Figure 4 shows the change of the exchange-rate constants when various equivalences of sodium iodide were added to 0.13 ± 0.01 M solutions of Na(ooa) in D_2O. The rate constant of Na(ooa) decreases with increasing sodium ion concentration: a limiting constant, 3.7×10^{-2} min^{-1}, is finally reached.

The cation effects on the exchange-rate in this study should be discussed by considering the relative amount of associated and dissociated species in the equilibrium of the salts in D_2O. The order of relative abilities of alkali–metal ions to form chelates, Li > Na > K, has been found for related systems.[7,8] From these results and the data in Figs. 3 and 4, the acetyl–methyl group in the dissociated o-acetylphenolate anion seems to be more active than that in the associated ion pair. However, this phenomenon should be accounted for by change in the amount of an OD$^-$ ion due to the solvation of the anion in the reaction mixture.

The limiting k_{H-D} value, 3.7×10^{-2} min^{-1}, can be taken as the H-D exchange rate constant for the chelated form of Na(ooa). On the other hand, the rate constant for the dissociated form of ooa-anion must be same as or a little larger than the k_{H-D} value of K(ooa), 5.4×10^{-2} min^{-1}. On the basis of these values and the observed rate constant, 5.0×10^{-2} min^{-1} for Na(ooa), the relative
Fig. 4. Plots of exchange-rate constant (k_{H-D}) of Na(ooa) vs mole ratios [NaI]/[Na(ooa)].

amount of associated species in the equilibrium of the salt in D_2O can be estimated to be more than 24% under these conditions. However, the dissociation constant of the salt is not available because of a lack of ideality due to the high concentration and changing ionic strength. When a few equivalents of lithium chloride were added to a 0.13 M solution of Li(ooa) in D_2O, a pale yellow precipitate of Li(ooa) separated out because of its poor solubility in water. Therefore, the NMR spectra of the lithium salt were taken at 0.045 M in D_2O solution; the rate constant changed from about 4×10^{-2} to 3.5×10^{-2} min^{-1} when 10 equivalents of lithium chloride were added. Thus the relative amount of associated species for Li(ooa) could be estimated to be about 75%.

In order to determine the effects of coordinated metal ions other than alkali–metal ions, a mixed ligand complex of palladium(II) with N,N,N',N'-tetramethylethylenediamine (tmen) and Hooa, [Pd(tmen)(ooa)]ClO$_4$, was prepared. This complex was slightly soluble in water and soluble in methanol. The proton exchange of the acetyl group in the Pd(II) complex was complete in CD$_3$OD within 10 hr. The rate constants, k'_{H-D}, of Na(ooa) and Na(moa) in CD$_3$OD solutions (0.11 M) were measured to be 4.6×10^{-1} and 1.8×10^{-2} min^{-1}, respectively. The proton exchange is faster in CD$_3$OD than in D_2O.

By use of mixtures of two or more acetyl compounds in basic CD$_3$OD, the H-D exchange rate of their acetyl–methyl groups could be compared with each other. The decreasing order of the rate constants was observed as follows. The chemical shifts of the acetyl groups are designated in parentheses.

[Pd(tmen)(ooa)]ClO$_4$(δ 2.70) > 4-acetylpyridine (δ 2.64) > 3-acetylpyridine(δ 2.64), p-nitroacetophenone (δ 2.65), o-nitroacetophenone(δ 2.55) $\gtrsim$ m-nitroacetophenone(δ 2.66) > Hooa(δ 2.60) > 2-acetylpyridine(δ 2.68) > acetophenone(δ 2.58) $\gtrsim$ m-methoxyacetophenone(δ 2.57) $\gtrsim$ Hmoa(δ 2.55) > o-methoxyacetophenone(δ 2.57), p-methoxyacetophenone(δ 2.54) > Hpoa(δ 2.42).

Replacement of the hydroxyl group of Hooa by a methoxy group inhibits intramolecular bonding of the molecule, thus the chelate effect disappears. On the other hand, introduction of a nitro group on the benzene ring of acetophenone increases the rate constant of the methyl proton exchange due to decreasing electron density of the aromatic ring. The most important point is the largest rate constant for [Pd(tmen)(ooa)]ClO$_4$. This is

Fig. 3. Correlation of exchange-rate constants(k_{H-D}) with cation radii(r). ●, Alkali(ooa); ■, Alkali(poa).
Fig. 5. NMR peaks of acetyl groups of [Pd(tmen)(ooa)]ClO$_4$ (A), Hooa (B), acetophenone (C), and Hmoa (D) measured at appropriate time intervals(hr) after being mixed in CD$_3$OD.

ethylene and methyl protons of "tmen" under a different situation appeared at δ 2.66 and δ 2.58 with time.

The rate constant of the methyl–proton exchange of the Schiff base of Hooa with methylamine, 2-(N-methylacetimidoyl)phenol (or N-methyl-2-hydroxy-acetophenimine), in CD$_3$OD was measured to be 6×10^{-1} min^{-1}, which is extremely large and cannot bear comparison with that of Hooa under the neutral conditions. This can be understood from analogy with ketimine intermediates in amine-catalyzed enolization of acetone.[9] However, it is worthwhile noting that the Schiff base in this study possesses an appreciable amount of a nonaromatic keto amine form in solutions.[10]

The simple application of NMR spectroscopy used in this study turned out to be very effective in revealing chelating ability of acetyl compounds and equilibrium problems of their salts. The chelation of o-hydroxy-acetophenone with alkali-metal ions in water was thus characterized.

attributable clearly to the electron-withdrawing effect of the coordinated metal ion.

Figure 5 shows the NMR peaks of a mixture of [Pd(tmen)(ooa)]ClO$_4$, Hooa, acetophenone, and Hmoa in CD$_3$OD. The singlet at δ 2.96 and two singlets at δ2.81 and δ2.79 were assigned to the ethylene protons and methyl protons of (tmen), respectively. The others are due to the acetyl methyl protons. Without the Pd(II) complex, the H–D exchange of the acetyl group of Hooa did not occur appreciably within a week. The activation of the acetyl protons of Hooa by the Pd(II) complex is ascribed to a slow exchange of the coordinated (ooa) anion. The ligand exchange seemed to be fast when the concentrations of Hooa and OD$^-$ ion in the reaction mixture were high; the acetyl-proton exchange of Na(ooa) in CD$_3$OD was accelerated by the addition of the Pd(II) complex. In a highly basic solution of [Pd(tmen)(ooa)]ClO$_4$ in CD$_3$OD, however, the Pd(II) complex decomposed and new NMR peaks due to the

Abstract—1:1 complexes of 1,7,10,16-tetraoxa-4,13-diazacyclooctadecane (2,2) with Ag^+ and Tl^+ have been determined by potentiometric pAg measurements in several polar nonaqueous solvents at 25°C. A comparison of the results with those for the cryptand (2,2,2) including alkali metal ions shows that interactions for a given ion with the two ligands are similar but differ considerably for different ions. The free energies of transfer of ligand (2,2) and its complexes have been determined from distribution measurements and are around zero between acetonitrile and aprotic solvents.

The complexes of the monocyclic diaza-polyether ligand, 1,7,10,16-tetraoxa-4,13-diazacyclooctadecane (2,2) with alkali metal ions in water and in methanol[1–4] are less stable than the corresponding complexes of 18-crown-6 (18C6)[4–6] and the bicyclic cryptand (2,2,2)[2,7,8], whereas the stability constants of Ag^+ complexes with (2,2) and (2,2,2) are quite similar and several orders of magnitude larger than the stability constants of the Ag^+ complex with 18C6[2,5–7].

A comparison of the results for these three macrocyclic ligands is of some interest because of certain similarities between them. The monocyclic ligands (2,2) and 18C6 are very similar in structure and have ring cavities of almost equal size, which are formed by a nearly planar, centrosymmetrical arrangement of bonding groups around a cation of appropriate size. Thus a comparison of stability constants for these ligands should show the difference in bonding of ether oxygen and nitrogen. The cavities of (2,2) and (2,2,2) also have almost equal diameters, but (2,2,2) forms a three-dimensional, spherical cavity which is much less flexible in dynamic complexation and decomplexation processes with cations of a given size than the ring cavity of (2,2).

In previous investigations the stability constants, K_s, of (2,2) complexes with alkali metal ions, the silver ion and the thallous ion have been measured in nonaqueous solvents using mainly NMR and conductance measurements.[3,4] These methods are useful for the determination of stability constants for complexes with $K_s \leq 10^5 M^{-1}$, and to complement this work we have carried out potentiometric measurements with the silver electrode in order to obtain stability constants $> 10^5 M^{-1}$ for complexes of (2,2) with mainly Ag^+ and Tl^+. A comparison of the stability constants for metal ion complexes of (2,2) and (2,2,2) shows that interactions for a given ion with the two ligands are similar in nature, but differ considerably

for the different ions, including Ag^+, Tl^+ and alkali metal cations.

In this paper we also report the free energies of transfer of the ligand (2,2) between acetonitrile and various solvents. These values have been used, together with stability constants, to estimate free energies of transfer of $M(2,2)^+$. Among aprotic solvents both $\Delta G_{tr}(2,2)$ and $\Delta G_{tr}(M(2,2)^+)$ are around zero, but in water and methanol the ligand is more strongly solvated and the metal ion complexes less strongly solvated than in acetonitrile.

EXPERIMENTAL AND RESULTS

The macrocycle (2,2)-$HN(CH_2CH_2OCH_2CH_2OCH_2CH_2)_2NH$— was purchased from Merck. Potentiometric titrations showed that the purity of the samples was better than 99%.

Acetone (Baker) was dried over molecular sieves and distilled at atmospheric pressure.

Nitromethane (Baker, Gold Label), hexadecane (Merck) and glycerine (Fluka) were used without further purification. The origin and handling of all other solvents and electrolytes as well as the preparation of solutions has been described previously.[8,9]

The stability constant K_s, of $Ag(2,2)^+$, i.e. the equilibrium constant for the complexation reaction (1) was determined by

$$Ag^+ + (2,2) \rightleftharpoons Ag(2,2)^+ \qquad (1)$$
pAg–potentiometry in a direct titration of a silver perchlorate solution with (2,2) using a three compartment cell.[9,10] Total Ag^+ and (2,2) concentrations were around 1×10^{-3} M and 2×10^{-3} M respectively. The solvent used in the preparation of the bridge solution (0.1 M Et_4NClO_4) and the reference solution (1.0×10^{-3} M $AgClO_4$) was always the same as that in the reaction vessel. The ionic strength was varied using Et_4NClO_4 in order to study the effect of ionic strength and ion-pair formation, especially in solvents of low donor number,[11] such as acetone and nitromethane. It was found, however, that the stability constants differed by only 0.3 log K_s units when measured in solutions of low ionic strength ($\leq 10^{-3}$ M) containing only $AgClO_4$ and (2,2) and in solution of ionic strength I = 0.1 M. The stability constants of $Ag(2,2)^+$ are given in Table 1. The accuracy is ± 0.05 in log K_s for the solvents of better solvating ability.

The stability constants of $Ag(2,2)^+$ have been used in con-

The results are also given in Table 1, and the accuracy in solvents of high donor number is ±0.1 in log K_s.

In order to study the contribution of ligand solvation to the thermodynamics of equilibria (1) and (3), the distribution of (2,2) between hexadecane and various polar solvents, S, has been measured. A solution of known concentration of (2,2) in S was brought into contact with hexadecane, the volume of which was five times larger than that of S, except in the case of S = propylenecarbonate when equal volumes were used. The initial concentration of (2,2) in S was in the range 1×10^{-3} M to 1.5×10^{-2} M. Equilibrium was obtained by vigorous stirring for at least 4 hr at 25.0 ± 0.1°C. The solutions were then allowed to stand for at least 2 hr before three samples from each phase were taken and analyzed by pH-metric titrations with aqueous 10^{-3} M HNO_3 in water using a Metrohm Dosimat E507. A centrifuge was used to separate the phases in distribution experiments with glycerine (see below) and with hexadecane when the densities of the polar solvent (methanol) and hexadecane were similar. In experiments with protic solvents, only the proportion of (2,2) in the hexadecane phase was determined directly. The titration of the hexadecane samples were carried out sufficiently slowly to allow the ligand to reach equilibrium at all stages.

The distribution of (2,2) between hexadecane and water has been analyzed by two different methods. The first method involved equilibration of the hexadecane phase with an aqueous solution of (2,2) containing sufficient tetraethylammonium hydroxide to prevent any significacant protonation of (2,2), followed by analysis of the hexadecane layer using pH-titrations as described above. Since the distribution strongly favoured the aqueous layer, an alternative method of analysis was also used in which the concentration of (2,2) in the hexadecane layer was determined spectrophotometrically as the $Tl(2,2)ClO_4$ complex ($\epsilon = 4950$ M^{-1} cm^{-1} at 237 nm). In this case the separated hexadecane samples were brought into contact with dry $TlClO_4$. This latter method was used for experiments in which the aqueous layer contained no tetraethylammonium hydroxide, and the concentration of unprotonated (2,2) in water was calculated using the known protonation constant (pK = 9.2).[12]

In all cases the partition coefficient, P, of (2,2) between hexadecane (hex) and polar solvent, S, (eqn 4) was determined

$$P = \frac{[2,2]_{hex}}{[2,2]_S} \qquad (4)$$

for at least three different total concentrations of (2,2) and P was found to be independent of concentration. The results are given in Table 2, together with the free energies of transfer of (2,2) from acetonitrile (AN) to the remaining solvents.

$$\Delta G_{tr}(2,2) = -RT \ln ([2,2]_S/[2,2]_{AN}). \qquad (5)$$

It was not possible to determine the free energy of transfer to acetone directly by this method because of the high solubility of acetone in hexadecane. To avoid this problem the partition coefficients of (2,2) between glycerine and (a) acetone (9.4 ± 1.2) and (b) nitromethane (1.31 ± 0.06) were determined and used with the ΔG_{tr} value of nitromethane in Table 2 to calculate the free energy of transfer of (2,2) from acetonitrile to acetone.

DISCUSSION

Inspection of the stability constants in Table 1 shows that they depend upon the properties of the solvents as reflected in the solvation energies of the metal ions (Table 3). In most cases they decrease in the order $Ag^+ > Tl^+ > Li^+ > Na^+ > Cs^+$ but there is an indication that in solvents which are good donors, complexes of Li^+ are less stable than those of the other alkali metals (e.g. in DMSO).

The stability constants of complexes between Ag^+ and (2,2) are almost 6 orders of magnitude larger than those of the corresponding Tl^+ complexes, because of the strong bonding between Ag^+ and the two nitrogen atoms of the ligand. The only exception is in acetonitrile where a competition between the nitrogen atoms of the ligand and solvent for Ag^+ results in the formation of a weaker complex with a stability constant which approaches that for $Tl(2,2)^+$. The stability constants of the Tl^+ complexes, however, are still larger than those of the alkali metal ion–(2,2) complexes. This suggests the presence of an effective covalent interaction in addition to the purely electrostatic interaction assumed to dominate in the formation of alkali metal complexes. The thallous ion does not show any pronounced preference for bonding to nitrogen as opposed to oxygen atom of (2,2), because the thallous ion complexes with (2,2) and 18C6 have stability constants of almost the same magnitude.

The stability constants of the (2,2) complexes in Table

Table 2. Partition coefficients P for the distribution of (2,2) between hexadecane and various polar solvents at 25°C and related free energies of transfer from acetonitrile to the other solvents

Solvent	$10^2 P$	$\Delta G_{tr}(2,2)\,kJ\,mol^{-1}$
Nitromethane	1.28 ± 0.08	-1.2 ± 0.4
Acetonitrile	2.05 ± 0.20	0.0
Propylenecarbonate	3.06 ± 0.22	$+1.0 \pm 0.4$
Acetone		$+3.7 \pm 0.7^a$
Dimethylformamide	2.26 ± 0.18	$+0.2 \pm 0.4$
Dimethyl sulphoxide	2.63 ± 0.05	$+0.6 \pm 0.3$
Methanol	0.72 ± 0.01	-2.6 ± 0.3
Water	0.168 ± 0.007^b; 0.13	-6.2 ± 0.4^b; -6.8

(a) Calculated from the distributions of (2,2) between glycerine and acetone, nitromethane.

(b) Determined spectrophotometrically.

1 may also be compared with those of the corresponding complexes of the macrobicyclic cryptand (2,2,2).[8] A sufficient number of data is available to allow quite reasonable comparison to be made for Ag^+, Tl^+, and Cs^+ cations. The presentation in Fig. 1 shows that the silver ion complexes with (2,2) and (2,2,2) have very similar magnitude, due to the dominant influence of bonding of Ag^+ with the nitrogen atoms of the ligands. The stability constants in all cases are greater than 10^6, and the correlation between them is good, tending to pass through the origin. Although there is some scatter, there is no indication that an increase in the number of oxygen atoms on going from (2,2) to (2,2,2) has a significant effect. A similar correlation exists for Tl^+ complexes, but in this case shifted by 4 to 5 orders of magnitude in K_s below the line for the Ag^+ complexes. This represents the difference in stability between (2,2) and (2,2,2) complexes with Tl^+. The correlations for Tl^+ and Ag^+ in Fig. 1 hold for both protic (filled symbols) and aprotic solvents (open symbols).

Data for the alkali metal complexes are more sparse. However, it may be seen (Fig. 1) that for Cs^+, although only weak complexes are formed, an excellent correlation exists between (2,2) and (2,2,2) complexes, shifted from the origin by 1.4 units. These results are more difficult to interpret because Cs^+ is too large to fit into

the ring and spherical cavities. In an exclusive complex[13] between Cs^+ and (2,2,2), the Cs^+ can presumably interact with only four oxygen atoms, as in the (2,2) complexes. However, the extra stability of Cs^+-(2,2,2) complexes suggests that the third ether bridge does play a role. Where comparison is possible for the smaller alkali metal cations, the results show a significant increase in stability on going from (2,2) to (2,2,2) ligands. In acetonitrile, for example, (2,2,2) complexes of Li^+, Na^+, K^+ and Rb^+ are between 3 (Li^+) and 7 (K^+) orders of magnitude more stable than those of (2,2). A smaller effect for Li^+ (also observed in comparisons between Li^+ and Na^+ complexes in other solvents) probably results from the fact that Li^+ is too small to interact effectively with all of the oxygen atoms in the ligand bridges.

Overall, the comparison between (2,2) and (2,2,2) complexes suggests that except where specific interactions such as between Ag^+ and nitrogen exist, the addition of an extra ether bridge to (2,2) has a strong influence on the stabilities of the complexes, but not on the variation of stability with solvent. The effects may be as large as 6-7 orders of magnitude for cations such as Na^+, K^+, and Tl^+ which are of an appropriate size for the ligand cavities.

The free energies of transfer of the uncomplexed ligand from acetonitrile to the various polar solvents (Table 2) are around zero for aprotic solvents and are negative for transfer to methanol ($-2.6\,kJ\,mol^{-1}$) and water ($-6.2\,kJ\,mol^{-1}$). The stronger solvation of (2,2) in water and methanol relative to the aprotic solvents is probably because of hydrogen bonding between (2,2) and the protic solvents. The ΔG_{tr} values of ligand and metal ions (Tables 2 and 3) have been combined with the stability constants in Table 1 to calculate the free energies of transfer of the complexes, ΔG_{tr} $[M(2,2)^+]$ between acetonitrile (AN) and solvent S as in equation (6).

$$\Delta G_{tr}[M(2,2)^+] = \Delta G_{tr}(2,2) + \Delta G_{tr}(M^+) - RT \ln\{K_s(S)/K_s(AN)\}. \quad (6)$$

The results in Table 3 demonstrate that ΔG_{tr} $[M(2,2)^+]$ values are around zero for transfer among acetonitrile, propylene carbonate, acetone and dimethylformamide. Dimethyl sulfoxide seems to be an exception to this behaviour with ΔG_{tr} values grouped around $-8.5\,kJ$ mol^{-1}, although only three results are available. The complexes $M(2,2)^+$ in methanol and particularly in water are in a higher free energy state than in acetonitrile
Fig. 1. Comparison between stability constants (log K_s) of (2,2) and (2,2,2) complexes with Ag^+, Tl^+ and Cs^+ in several solvents. (protic solvent: filled symbols; aprotic solvents: open symbols).

and in this respect are solvated like large organic ions. The only exception to this is Li(2,2)$^+$ in methanol.

The data do not indicate any noticeable contribution to the free energies of transfer of the complexes from a direct interaction between that part of the metal ion in the M(2,2)$^+$ complexes which is not covered by the ligand. Taking the extremes of dimethyl sulphoxide as a very good cation solvator and nitromethane as a very poor solvent for cations, it is possible to see evidence of some dependence of ΔG_{tr} [M(2,2)$^+$] on the metal ions, but in general there is little correlation between ΔG_{tr} [M(2,2)$^+$] and ΔG_{tr}(M$^+$) values. Ion association involving the uncomplexed cations may provide an obvious explanation for the more positive ΔG_{tr}[M(2,2)$^+$] values observed for transfer to nitromethane, although the slight variation in log K_s with changes in ionic strength argues against this.

ETHYLPHOSPHINEDIACETIC ACID: SYNTHESIS, CHARACTERIZATION AND COORDINATING BEHAVIOUR TOWARDS Ca(II), Ni(II) AND Hg(II) IONS IN SOLUTION†

D. NOSKOVÁ and J. PODLAHOVÁ*

Charles University, Department of Inorganic Chemistry, 12840 Prague, Czechoslovakia

Abstract—The new ligand, ethylphosphinediacetic acid, H_2Z, was synthesized and characterized by spectral methods. The Z^{2-} anion is protonated in three steps with the pK values of 6.10 (phosphorus atom), 2.75 and 0.9 (carboxyl groups). The ligand is highly selective for soft metal ions as demonstrated by the stability constants of the water-soluble complexes $CaHZ^-$ (log β_{CaHZ}^{HZ} 0.73), NiZ_2^{2-} (log β_2 9.06) and HgZ_4^{6-} (log β_4 40.9). The differences in behaviour compared to related phosphineacetic acids are mainly consequences of the high basicity of the phosphorus atom.

Tertiary phosphines bearing a second functional group of the hard donor type, which are frequently called "hybrid" ligands[1,2] possess interesting potential capabilities, e.g. in homogeneous catalysis.[3] With properly chosen hard donor groups, a further potential advantage of the designed ligands can be achieved, namely the solubility of the ligands and/or their complexes in polar solvents including water. Such a class of compounds is represented by two series of phosphineacetic acids synthesized and studied in this laboratory:[4] (C_6H_5)$_{3-n}$ P(CH$_2$COOH)$_n$ ($n = 1^{4a}$, 2^{4b}, 3^{4c}) and (C_6H_5)$_{2-m}$ (HOOCCH$_2$)$_m$PCH$_2$CH$_2$P(CH$_2$COOH)$_m$(C_6H_5)$_{2-m}$ ($m = 1^{4d}$, 2^{4e}). The presence of the phenyl groups in these ligands, which is advantageous in synthetic respects, however, considerably lowers both the σ-basicity of phosphorus and the solubility of the ligands in water. It was the aim of this work to investigate the influence of the ethyl group as a less sterically and electronically demanding substituent on the coordinating properties of the –P(CH$_2$COOH)$_2$ portion.

EXPERIMENTAL

All synthetic work and manipulation with solutions were carried out under inert gas (nitrogen or argon) with solvents dried and degassed before use.

The chemicals used were products of the firms Lachema, Merck and Pierce Inorganics and were purified by appropriate methods where necessary. Metal perchlorate solutions containing a slight excess of perchloric acid were prepared from CaCO$_3$, basic nickel carbonate or HgO by dissolving them in 30% perchloric acid and heating to expel CO$_2$. They were analyzed for the metals by EDTA titration and for excess acid by the Gran method. Sodium perchlorate was purified following the recommended procedure.[5] Triply distilled mercury was used for polarographic measurements.

Physical measurements and data treatment were described previously.[4e,6]

Ligand synthesis

A solution of ethyl bromzincacetate was prepared[7] from 66.0 g zinc (1.01 mol; 200 mesh, activated with iodine) and 167 g ethyl bromoacetate (1.00 mol; freshly distilled) in 250 cm³ ether. Ethyl-

dichlorophosphine[8] (58.9 g; 0.45 mol) in 100 cm³ ether was added dropwise at −35 to −40°C. After allowing the mixture to warm to room temperature, the excess organometallic was destroyed with 150 cm³ water and the ether layer was washed with water and dried over sodium sulphate. Distillation at 126–127°C/90 Pa gave ethylphosphinediacetic acid bis(ethyl ester) as a colourless liquid in 67% yield. The ester is slowly oxidized in air, $n_D^{25} = 1.4671$. For $C_{10}H_{19}O_4P$ found C, 50.54; H, 8.21; P, 12.95; calc. C, 51.28; H, 8.18; P, 13.22. IR (neat): 460w ν(PC), 580w, 662w, 855w, 953w, 1038m, 1120vs ν_s(COC), 1272vs ν_{as}(COC), 1370–1470w δ(CH$_2$, CH$_3$), 1743vs ν(C=O), 2880–2990m ν(CH$_2$, CH$_3$). ^{1}H-NMR (CDCl$_3$): 1.00 ppm, 3H, triplet, ^{3}J(H, H) 7 Hz, PCH$_2$C*H*$_3$; 1.25, 6H, triplet, ^{3}J(H, H) 7, OCH$_2$C*H*$_3$; 1.48, 2H, overlapping doublet of quartets, ^{2}J(P, H) 11, ^{3}J(H, H) 7, PC*H*$_2$CH$_3$; 2.57, 4H, doublet, ^{2}J(P, H) 6, PC*H*$_2$COO; 4.17, 4H, quartet, ^{3}J(H, H) 7, OC*H*$_2$. ^{31}P{^{1}H}-NMR (CDCl$_3$): −23.15 singlet.

The ester (70.0 g; 0.30 mol) was dissolved in 500 cm³ petroleum ether (40–60°C) and the solution of sodium hydroxide prepared from 20.7 g sodium metal (0.90 mol) and 500 cm³ 96% ethanol was added. After several hours at *ca.* 0°C, the crude disodium salt was filtered, washed with ethanol and dried *in vacuo* yielding 54.6 g of a white powder. According to TLC, IR and NMR, the salt contained small amounts of phosphine oxide and unhydrolyzed ester groups as impurities. The crude salt (54.0 g) was vacuum-evaporated at 40°C with 85 cm³ 48% HBr and the product was extracted into 600 cm³ hot acetonitrile. The filtrate was vacuum-evaporated to dryness and the resulting oil was crystallized from acetic acid to obtain 46.6 g ethylphosphinediacetic acid hydrobromide as colourless hygroscopic crystals of m.p. 74°C (sealed capillary). The compound is stable in dry air and fairly soluble in water. For $C_6H_{12}BrO_4P$ found C, 28.01; H, 4.83; P, 11.85; Br, 30.60; alcalim. equiv. 86.5; calc. C, 27.82; H, 4.67; P, 11.96; alcalim. equiv. 86.35. IR (nujol, hexachlorobutadiene): 455m ν(PC), 656s, 792m, 820m, 910s, 944s, 1028w, 1275s δ(COH), 1372w δ(CH$_3$), 1390w δ(COH), 1470w δ(CH$_2$), 1735vs ν(C=O), 2410m, ν(PH), 2910w ν(CH$_2$), 2950vs,b ν(OH), 2970w ν(CH$_3$), 3400s,b ν(OH). ^{1}H-NMR (H$_2$O): 1.29, 3H, doublet of triplets, ^{3}J(P, H) 19, ^{3}J(H, H) 8, CH$_3$; 2.50, 2H, overlapping doublet of quartets, ^{2}J(P, H) 13, ^{3}J(H, H) 8, PC*H*$_2$CH$_3$; 3.72, 4H, doublet, ^{2}J(P, H) 13, PCH$_2$COO. ^{31}P{^{1}H}-NMR (D$_2$O): 5.02 singlet.

The hydrobromide (21.0 g; 0.081 mol) was dissolved in a slight excess of 5M-NaOH and the pH was carefully adjusted to 8.0 with a HBr solution. The solution was added dropwise with stirring to a mixture of 250 cm³ methanol and 250 cm³ ether. The precipitated disodium salt was filtered off, washed thoroughly with methanol and dried *in vacuo*. Yield 17.6 g (98%) of a white powder, soluble in water, stable under inert gas, limitedly stable in air (oxidation to phosphine oxide with $\tau_{1/2}$ *ca.* 4 months). For $C_6H_9Na_2O_4P$ found C, 32.51; H, 4.20; Na, 20.55; P, 13.77; calc. C, 32.45; H, 4.08; Na, 20.67; P, 13.49. IR (nujol, hexachlorobutadiene): 449m ν(PC), 623w, 665w, 817w, 936m, 1132s, 1382s

ν_s(COO), 1390–1450w δ(CH$_2$, CH$_3$), 1590vs ν_{as}(COO), 2880–2970w ν(CH$_2$, CH$_3$). ^{1}H-NMR (D$_2$O): 1.06, 3H, overlapping doublet of triplets, ^{3}J(P, H) 16, ^{3}J(H, H) 7, CH$_3$; 1.51, 2H, overlapping doublet of quartets, ^{2}J(P, H) 7, ^{3}J(H, H) 7, CH$_2$CH$_3$; 2.47, 4H, doublet, ^{2}J(P, H) 2, PCH$_2$COO. ^{31}P{^{1}H}-NMR (D$_2$O): −24.68 singlet.

RESULTS AND DISCUSSION

The synthetic procedure followed a general method used before.[4b,c,e] The ligand was isolated with a total yield of 40% as the well-crystallizing hydrobromide and the disodium salt. Numerous attempts to obtain the free acid met with no success.

The protonation of the Z^{2-} anion is described by the constants given in Table 1. The constant K$_3$ = [H$_3$Z]/([H][H$_2$Z]) was determined by spectrophotometry with p-nitroaniline as indicator[9] at I = 1.0(H, K)Cl because of the high acidity required for the protonation. The mechanism of the proton uptake follows clearly from the IR and NMR spectra of the ligand in D$_2$O solutions of various acidity.

The ν_{as}(COO) region of the IR spectra is presented in Fig. 1. The four possible forms of the carboxyl group absorb in three separate regions[10]: R$_2$PCH$_2$COO$^-$ at ca. 1575 cm^{-1}, R$_2$P$^+$(H)CH$_2$COO$^-$ at 1615 cm^{-1} and R$_2$PCH$_2$COOH together with R$_2$P$^+$(H)CH$_2$COOH at ca. 1720 cm^{-1}. It is obvious from the spectra that the first proton added is bonded completely to the phosphorus atom and the second to the carboxyl. The ratios of the computer-separated areas under the peaks agree within experimental error with those calculated from the proton association constants (after an appropriate correction of the pH-readings in D$_2$O). The protonation of the second carboxyl group could not be followed by IR spectra because of poor transmittance of strong DCl solutions in the cells used.

The proposed mechanism is strongly supported by the
Fig. 1. The IR spectra of 0.2M solutions of Na$_2$Z in D$_2$O at various pD.

NMR spectra. Control ^{1}H spectra were always taken in H$_2$O because of the fast exchange[11] of the PCH$_2$COO protons with deuterium in acid solution. The exchange at pH 2 is essentially complete within 20 min at room temp. Fig. 2 summarizes the shifts of various hydrogen atoms and of the phosphorus atom with acidity. The results are in complete accordance with the conclusions following from the IR spectra and, in addition, confirm the bonding of the third proton to the second carboxyl group. Besides the chemical shifts, the P, H coupling constants are also acidity-dependent but, as usual,[12,13] with no readily interpretable trends. The extensive broadening of the phosphorus resonance during the uptake of the first proton indicate a relatively slow (in the NMR time scale)

Fig. 2. The dependence of the chemical shifts of hydrogen atoms (lower scale) and phosphorus (upper scale) on acidity.

exchange of protons between the phosphine and the phosphonium structure of the ligand.

The mechanism of the proton uptake can be summarized as follows:

$$C_2H_5P(CH_2COO^-)_2 \overset{H}{\rightarrow} C_2H_5\overset{|}{P^+}(CH_2COO^-)_2 \rightarrow$$

$$\overset{H}{\underset{\rightarrow C_2H_5P^+}{|}}\diagup{CH_2COO^-}\diagdown{CH_2COOH}$$

$$\overset{H}{\rightarrow C_2H_5\overset{|}{P^+}(CH_2COOH)_2}.$$
Hence, no tautomerization equilibria typical for the closely related ethylenediphosphinetetraacetate anion[10] take place for Z^{2-}.

For the investigation of the coordinating behaviour of the ligand, the Ca(II), Ni(II) and Hg(II) ions were selected as typical representatives of the hard, intermediate and soft type, respectively. Table 2 summarizes the stability constants of the complexes which describe best the experimental data accumulated in the regions given.

The stability of the complexes in solution clearly demonstrates the highly selective behaviour of the ligand towards metal ions, depending on their softness. In general, this behaviour is similar to that of the phosphineacetates studied previously but markedly different from the nitrogen analogue of the ligand.[14,15]

The hard Ca(II) ion is probably bonded only to the carboxyl group(s) with the phosphorus atom remaining uncoordinated and protonated. From this point of view, the lowering of pH on complex formation between Ca(II) and HZ^- must be only inductive in origin and does not reflect a direct competition of Ca^{2+} and H^+ ions for the phosphorus atom. This concept is supported by the similarity of the constant β_{CaHZ}^{HZ} to those of Ca complexes of α, ω-dicarboxylic acids.[16] For example, Ca(II) glutarate, which is structurally analogous but contains the CH_2 group instead of phosphorus, has the $\log \beta_1$ value of 0.55 to 1.06 depending on the experimental conditions.[17,18]

Nickel(II) as a typical representative of borderline ions forms complexes with Z^{2-} in which the coordination of phosphorus must be assumed as the factor mainly res-

ponsible for their stability. As can be seen from the disappearance of the yellow colour, the nickel-phosphorus bond remains intact in the region of the protonation of phosphorus in the free ligand (pH ca. 6) and of the first carboxyl group (pH ca. 4.5) but breaks down at pH < 3.5, where both carboxyl groups became protonated. Clearly, the ligand cannot coordinate to nickel in aqueous solution through phosphorus alone but can only chelate together with, most probably, one carboxyl group. This situation is markedly different from that of P,P-chelating bis(phosphine)acetates[6,19] but similar to monophosphineacetates.[4a,20,21] The most closely related ligand of this kind, phenylphosphinediacetic acid, yields also a 1:2 nickel complex[21] which is, however, considerably less stable ($\log \beta_2$ 6.49) despite the fact that it is octahedral with terdentate ligands. The stability, diamagnetism and the UV-visible spectrum of the NiZ_2^{2-} complex strongly support a square-planar structure with P,O-bidentate ligands. The uncoordinated carboxyl groups are readily protonated without noticeably changing the coordination environment of nickel. The obvious explanation for this specific behaviour of the Z^{2-} ligand is the higher basicity of phosphorus producing a stronger ligand field which forces spin-pairing in the complex.

The typically soft mercury(II) ion forms a highly stable 1:4 complex with the ligand studied. Its 1:4 analogues with other phosphineacetates are either of considerably lower stability or cannot be detected at all. Again, the evident reason is the higher basicity and lower steric requirements of the ethyl-substituted phosphorus atom. Most probably, the ligand is coordinated to mercury in a monodentate fashion through the phosphorus atom, and the carboxyl groups are protonated quite independently without any noticeable influence on the HgP_4 core.

PRECIPITATION AND COMPLEX FORMATION IN THE SYSTEM Mn(ClO₄)₂–Na₄P₂O₇–pH (295 K, $I = 0.5$ AND $I \approx 0$ mol dm⁻³)*

HALKA BILINSKI

Department of Physical Chemistry, "Ruder Boškovic" Institute, Zagreb, Yugoslavia

Abstract—The precipitation of manganese from aqueous solution of manganese perchlorate and sodium pyrophosphate was investigated in a broad concentration range of both precipitation components and at various pH values, at 295 K and $I = 0.5$ mol dm⁻³. Tyndallometric technique was used. A soluble range has been observed in ten-fold excess of pyrophosphate and at $7 < pH < 10$, where manganese forms complex with pyrophosphate. In the precipitation range the following precipitates were identified: $Na_2MnP_2O_7$, $Mn_2P_2O_7$ and MnO_x. Quantitative solubility experiments have been performed at $I \approx 0$ mol dm⁻³.

From experimental data the following values for equilibrium constants have been obtained:

$$\log [Mn^{2+}]^2 \cdot [H_2P_2O_7^{2-}] \cdot [H^+]^{-2} = -1.39$$

$$\log [MnP_2O_7^{2-}]^2 \cdot [P_2O_7^{4-}]^{-1} = -4.22$$

$$\log [MnP_2O_7^{2-}][Mn^{2+}]^{-1} \cdot [P_2O_7^{4-}]^{-1} = 6.51.$$

A brief and the most complete survey of the work on complex formation between different metal ions and pyrophosphate ion is given in Tables of Stability constants by Sillén and Martell[1] and by Martell and Smith.[2] The chemistry of pyrophosphate was extensively investigated after 1964. Miller and Parris[3] have synthetized pyrophosphate at low temperature, using compounds with high free energies of hydrolysis that might have occurred on the primitive earth. They suggested that pyrophosphate may have played an important part in polymerisation and dehydration reactions of organic compounds leading to the origin of life. Baltscheffsky and Stendigk[4] have investigated inorganic pyrophosphate in connection with biological energy transformations. They suggested that inorganic pyrophosphate may serve as energy donor in phosphorylating electron transport system. Zell et al.[5] have found that degradation of DNA by H_2O_2 producing methylhydrazines was stopped by pyrophosphate. This effect was attributed to complex formation of manganese ions with pyrophosphate, which prevented the formation of the catalytically active ternary complex. Equilibrium constant of soluble complex has according to our knowledge not yet been determined.

Solid $Mn_2P_2O_7$ is applied in number of industries as on synthesis of high polymers,[6] in ceramic materials,[7] in textiles[8] and in plastic technology,[9] but its solubility constants has not been determined. The pyrophosphates of calcium[10] and zinc[11,12] whose atomic numbers are close to that of manganese have been more investigated.

The aim of this work was to find concentration and pH conditions where manganese forms precipitate or soluble complex with pyrophosphate ligand and to determine the stability constant of the complex formed.

EXPERIMENTAL

Chemicals. Solutions were prepared by dissolving the following reagent grade chemicals in twice distilled water: $Mn(ClO_4)_2 \cdot 6H_2O$, $NaClO_4$ anhydrous, $HClO_4$ (G. Frederick Smith Chemical Co., Columbus, Ohio); $Na_4P_2O_7 \cdot 10H_2O$ (J. T. Baker Chemical Co., Phillipsburg, New Jersey); NaOH (Reagent A. C. S. Code 2255 Gen. Chem. Div. Morristown, New Jersey). Stock solutions were standardized.

Qualitative precipitation experiments were performed using the method described earlier by Tezak et al.[13] in the following way: Samples were made up in glass tubes by mixing 5 cm³ of diluted manganese perchlorate of constant concentration in each series and 5 cm³ of sodium pyrophosphate of various concentrations. Both precipitation components varied in concentrations. In another series of qualitative experiments the influence of pH was studied at constant concentration of manganese perchlorate in all samples. Sodium hydroxide or perchloric acid were added to various concentrations of sodium pyrophosphate. Constant ionic strength $I = 0.5$ mol dm⁻³ was adjusted by adding sodium perchlorate. For determination of solubility of $Mn_2P_2O_7$(s) and for determination of stability constants of the formed complex, samples were prepared in 250 cm³ volumetric flasks, aged 10–12 days, centrifuged and analyzed for manganese and pH. Soluble pyrophosphate was calculated as $[P_2O_7]_{sol} = [P_2O_7]_{tot} - ([Mn]_{tot} - [Mn]_{sol})/2$

Instruments. "Precipitation bodies" have been determined by observing the Tyndall effect in the beam of strong light or by Zeiss tyndallometer attached to a Pulfrich photometer. Crystals were detected by naked eye. X-ray diffraction patterns of some characteristic precipitates were used to distinguish various manganese salts. Precipitates were separated from supernatants using Beckman Model L-2 ultracentrifuge with 28000 RPM for 30 min. Soluble manganese was determined by Beckman Model D U Quartz Spectrophotometer with quartz cells of 1, 2, 5 and 10 cm, using formaldoxime method.[14] The concentration of [H⁺] was determined by a Radiometer 25 pH-meter with a glass and calomel electrode.

RESULTS

Figure 1 presents one type of "precipitation body" of manganese pyrophosphate system, when both precipitation components varied in concentration. Ionic

---

*The work has been performed in part at Department of Environmental Health and Engineering, California Institute of Technology, Pasadena, CA, U.S.A.
Fig. 1. The ground plan of a three-dimension concentration tyndallogram. The solubility limit after 24 hr of ageing is plotted vs the log. concn. of manganese perchlorate and sodium pyrophosphate. The metastable range of phase A became broader after 10 days. ($I = 0.5$ mol dm^{-3}, 295 K).

strength is 0.5 mol dm^{-3} (NaClO$_4$ was added). After 24 hr of ageing two types of precipitate have been observed and identified:

(a) Na$_2$MnP$_2$O$_7$ and   (b) Mn$_2$P$_2$O$_7$.

Upon standing 10–12 days, range A became much broader. It is evident from Fig. 1 that both salts of manganese pyrophosphate readily dissolve with increasing concentration of pyrophosphate. The effect can be attributed to the ability of pyrophosphates to form soluble complexes with a number of cations.

In Fig. 2 is presented the precipitation diagram observed after 24 hr, for constant manganese concentration $1 \cdot 10^{-3}$ mol dm^{-3}, for various pyrophosphate concentrations in the range from $2 \cdot 10^{-5}$ to $6 \cdot 10^{-2}$ mol dm^{-3} and for pH values from 1.5 to 11.5. The solid phase corresponds to Mn$_2$P$_2$O$_7$. Narrow range of soluble complexes exists at pH from 7 to 10 at pyrophosphate concentrations that are at least, ten times higher than that of manganese. It indicates that the most stable complex of manganese is with completely dissociated pyrophosphate ligand. Upon ageing the range of soluble complexes became narrower, due to the slow formation of Na$_2$MnP$_2$O$_7 \cdot 4$H$_2$O crystals, for pyrophosphate concentrations up to $2 \cdot 10^{-2}$ mol dm^{-3}. Curve 0 in Fig. 2 separates systems in which HClO$_4$ was added toward lower pH values, and NaOH toward higher pH values than in the pure systems. Curve 1 separates white precipitate of Mn$_2$P$_2$O$_7$ from the brown one, where oxidation of manganese took place in a visible amount.
Fig. 2. The ground plan of a precipitation diagram formed in mixtures with Mn(ClO$_4$)$_2$ = 1 × 10^{-3} mol dm^{-3}, Na$_4$P$_2$O$_7$ = various, pH = various, after 24 hr.
Fig. 3(a). Graphical determination of $\log K_{S1} = \log [MnP_2O_7^{2-}]^2 \cdot [P_2O_7^{4-}]^{-1}$ from experimental data in Table 1. $(I \approx 0$ mol dm^{-3}, 295 K). (b). Graphical determination of $\log K_{SO} = \log [Mn^{2+}]^2 \cdot [H_2P_2O_7^{2-}] \cdot [H^+]^{-2}$ from experimental data in Table 1. $(I \approx 0$ mol dm^{-3}, 295 K).

Quantitative experiments of solubility and complex formation constants in manganese pyrophosphate system were performed in distilled water to avoid the formation of sodium containing solid phase.

Table 1. shows results of quantitative determination of soluble manganese in equilibrium with $Mn_2P_2O_7(s)$ and corresponding pH values. Three series of samples have been prepared with constant concentration of total manganese. At the minimum of solubility curve very stable negatively charged colloids exist, which could be removed from solution only by ultracentrifuge.

At total concentrations of pyrophosphate higher than $3 \cdot 10^{-2}$ mol dm^{-3}, crystals of the composition $Na_2MnP_2O_7 \cdot 4H_2O$ are formed.

The dissolution of $Mn_2P_2O_7(s)$ in excess of manganese can be presented as

$$Mn_2P_2O_7(s) + 2H^+ = 2Mn^{2+} + H_2P_2O_7^{2-}$$
with solubility product

$$K_{SO} = [Mn^{2+}]^2 \, [H_2P_2O_7^{2-}] \, [H^+]^{-2}.$$

Dissolution in excess of pyrophosphate can be expressed as

$$Mn_2P_2O_7(s) + P_2O_7^{4-} = 2MnP_2O_7^{2-}$$
with solubility product

$$K_{SI} = [MnP_2O_7^{2-}]^2 \cdot [P_2O_7^{4-}]^{-1}.$$

In Fig. 3 is presented graphical determination of the

two solubility constants, using experimental data from Table 1. Concentration of $H_2P_2O_7^{2-}$ and $P_2O_7^{4-}$ ions are calculated from total soluble pyrophosphate, pH value and acidity constants for pyrophosphoric acid, determined by Davis[15] (log $\beta_1 = 9.25$, log $\beta_2 = 15.85$; and log $\beta_3 = 18.21$). The obtained values from the intercepts of the two straights lines are:

$$-\log K_{SO} = 1.39$$
$$-\log K_{SI} = 4.22.$$

From these two solubility constants and from log β_2 value it is possible to calculate equilibrium constant for complex formation:

$$K_1 = [MnP_2O_7^{2-}] \cdot [Mn^{2+}]^{-1} \cdot [P_2O_7^{4-}]^{-1}$$

$$\log K_1 = 6.51 \quad (I = 0 \text{ mol dm}^{-3}).$$

This value cannot be compared directly with the corresponding literature values as they are not to our knowledge available. However, it can be compared with the values for other elements.

In Fig. 4 are the values for log K_1 for various monovalent and bivalent ions[1,2] plotted vs, atomic number of these elements. Data fit two straight lines. The value for log K_1 determined for manganese is very close to the values for calcium and zinc and fits perfectly to the straight line obtained for bivalent ions. Therefore it might be concluded that the value obtained in this work for stability constant of manganese pyrophosphate is a realistic one.

MIXED HALIDE DIALKYLDITHIOPHOSPHATE
DERIVATIVES OF ARSENIC(III) AND ANTIMONY(III)

H. P. S. CHAUHAN, G. SRIVASTAVA and R. C. MEHROTRA*

Department of Chemistry, University of Rajasthan, Jaipur-302004 India

Abstract—Mixed chloride dialkyldithiophosphates of arsenic(III) and antimony(III), $[(RO)_2PSS]_nMCl_{3-n}$ (M = As, Sb; n = 1, 2; R = C_2H_5, $n-C_3H_7$, $i-C_3H_7$ and $i-C_4H_9$) have been synthesized for the first time by the reactions of metal chlorides with sodium dialkyldithiophosphates or alternatively by co-disproportionation reactions of metal chlorides with metal tris(dialkyldithiophosphates) in different stoichiometric ratios. Mixed halide dialkyl-dithiophosphates of antimony(III) have also been prepared by the cleavage reactions of antimony tris(diisopropyl-dithiophosphate) with bromine or iodine. Hydrolysis reactions of a few of these compounds have also been studied.

The new compounds have been characterized by elemental analyses, molecular weight determinations (cryoscopic) as well as IR and NMR (^1H, ^{31}P) data; chelated structures with bidentate dialkyldithiophosphate groups are proposed.

Dialkyldithiophosphate ligands exhibit bidentate[1,2] as well as monodentate[3,4] behaviour and form stable complexes with transition as well as main group elements. In spite of an extensive literature on derivatives of arsenic(III) and antimony(III) with sulphur-containing ligands,[5–13] studies on the corresponding dialkyldithio-phosphate derivatives have been limited. A variety of tris-derivatives[14–18], $M[S_2P(OR)_2]_3$ (M = As, Sb) have been synthesized in a number of laboratories, and Raman spectra,[18] photometric properties[14] and analytical applications[14,19] of some of these have also been reported. The utility of these compounds as lubricant additives[17,20,21] and for regeneration of cracking catalysts[22,23] has also been pointed out. The X-ray electron spectrum[24] of $[(BuO)_2PSS]_3Sb$ has been studied and the crystal structure[25] of $[(EtO)_2PSS]_3Sb$ has been reported. We have recently reported the synthesis of 2-dialkyldithiophosphato-1,3,2-dioxarsolanes and arsenanes.[26] The corresponding halide dialkyl-dithiophosphate derivatives of arsenic(III) and anti-mony(III) are still unknown. In view of the exciting chemistry of mixed halide dithiocarbamates[9–11] of arsenic(III) and antimony(III) it was thought of interest to synthesize a number of mixed halide dialkyl-dithiophosphate derivatives of arsenic(III) and anti-mony(III) and characterize them by various physico-chemical techniques.

EXPERIMENTAL

Materials

Moisture was carefully excluded throughout experimental manipulations. Solvents (benzene, petroleum ether, chloroform) and alcohols (ethanol, n-propanol, i-propanol and i-butanol) were dried by standard methods. Arsenic trichloride (b.p., 130°) and antimony trichloride (b.p., 223°) were distilled before use. Arsenic and antimony isopropoxides,[27] dialkyldithiophosphoric acids[28–31] and their sodium[26] and ammonium[29] salts were prepared by previously reported methods.

Product analyses

Sulphur was estimated gravimetrically as barium sulphate.[3] Arsenic and antimony isopropoxides,[27] dialkyldithiophosphoric pound by sulphuric acid followed by oxidation of As(III) and

Sb(III) to As(V) and Sb(V) respectively by heating with $KMnO_4$; excess $KMnO_4$ was decolourized by H_2O_2 and excess H_2O_2 was removed by evaporation. The remaining solid mass was dissolved in HCl, KI was added and liberated iodine was titrated against standard sodium thiosulphate solution using starch as an internal indicator.

Measurements

Molecular weights were determined cryoscopically in benzene. IR spectra using CsI cells were recorded as neat liquids or in the form of Nujol mulls (in case of solid products) on a Perkin-Elmer 577 spectrometer in the range 4000–200 cm^{-1}. ^1H NMR spectra in CCl_4 or $CDCl_3$ were recorded on a Perkin-Elmer R 12 B spectrophotometer using tetramethylsilane as an external standard; ^{31}P NMR spectra in $CDCl_3$ solutions were recorded on a Varian XL-100A spectrophotometer using H_3PO_4 as an internal standard.

General methods of preparation of various dialkyl-dithiophosphates of arsenic(III) and antimony(III)

(a) *Reaction of metal oxide with dialkyldithiophosphoric acid in 1:6 molar ratio.* A mixture of metal oxide (As_2O_3 or Sb_2O_3) and dialkyldithiophosphoric acid in 1:6 molar ratio in benzene or alcohol was heated under reflux (~4h) until a clear solution was obtained. Solvent was removed under reduced pressure and the product so obtained was crystallized from aqueous alcohol.

(b) *Reaction of metal isopropoxide with dialkyl-dithiophosphoric acid in 1:3 molar ratio.* The reaction of metal (arsenic, antimony) isopropoxide with dialkyldithiophosphoric acid in 1:3 molar ratio in refluxing benzene for about 4 hr (completion of the reaction was checked by estimating the iso-propanol collected azeotropically with benzene) yielded a yellow crystalline solid on removing volatile solvent. The product was purified by crystallization from aqueous isopropanol.

(c) *Reaction of metal chloride with dialkyldithiophosphoric acid in 1:3 molar ratio.* Metal (arsenic, antimony) trichloride and dialkyldithiophosphoric acid in 1:3 molar ratio were mixed in benzene and heated under reflux for about 4 hr till the liberation of HCl ceased. On removing the solvent under reduced pressure, a yellow crystalline solid was obtained, which was crystallized from aqueous alcohol.

(d) *Reaction of metal chloride with sodium(ammonium) dialkyldithiophosphate in different (1:1, 1:2 and 1:3) molar ratios.* Metal (arsenic, antimony) trichloride and sodium(am-monium) dialkyldithiophosphate in different stoichiometric ratios (1:1, 1:2 or 1:3) were mixed and stirred with slight heating for about 2 hr. Precipitated sodium(ammonium) chloride was removed by filtration, followed by removal of the solvent, giving the desired product.

(e) *Co-disproportionation reaction of metal chloride or metal isopropoxide with metal tris(diisopropyldithiophosphate) in* 1:2 *or* 2:1 *molar ratio.* Metal (As, Sb) trichloride or antimony isopropoxide and metal *tris*(diisopropyldithiophosphate) in 1:2 or 2:1 molar ratio in benzene were stirred with heating for about 2 hr. Solvent was removed under reduced pressure to give the desired product.

(f) *Reaction of antimony tris(diisopropyldithiophosphate) with halogens in* 2:1 *molar ratio.* To the antimony *tris*(diisopropyldithiophosphate) in carbon tetrachloride or benzene was added halogen (bromine or iodine) in 2:1 molar ratio and stirred for about half an hour. Solvent was removed under reduced pressure and the products, *monohalo* antimony *bis*(diisopropyldithiophosphate) and *bis*(diisopropylphosphorothionyl) disulphide, were separated by fractional crystallization in light petroleum (b.p., 60–80°).

RESULTS AND DISCUSSION

Tris(diisopropyldithiophosphates) of arsenic(III) and antimony(III) have been prepared by the reactions of diisopropyldithiophosphoric acids with corresponding metal oxide, isopropoxide or chloride in refluxing benzene:

$$M_2O_3 + 6(i\text{-}C_3H_7O)_2PSSH \rightarrow$$
$$2[(i\text{-}C_3H_7O)_2PSS]_3M + 3H_2O \uparrow \quad (1)$$

$$MX_3 + 3(i\text{-}C_3H_7O)PSSH \rightarrow [(i\text{-}C_3H_7O)_2PSS]_3M + 3HX \uparrow$$
$$(2)$$
(M = As, Sb; X = Cl, i-C$_3$H$_7$O).

All these reactions are exothermic and quite facile in the initial stages. As the reactions tend to slow down towards the end, the reactants were refluxed to ensure the completion of the reactions which were further facilitated by simultaneous removal of water, isopropanol or hydrogen chloride.

In view of the difficulties of purifying dialkyldithiophosphoric acids (even freshly distilled samples are generally contaminated with disulphide to an extent of ~ 5%) further syntheses were carried out by the reactions of sodium or ammonium dialkyldithiophosphates with metal chlorides:

$$MCl_3 + 3(RO)_2PSSM' \rightarrow [(RO)_2PSS]_3M + 3M'Cl \downarrow$$
$$(3)$$
(M = As, Sb; M' = Na, NH$_4$; R = C$_2$H$_5$, n-C$_3$H$_7$, i-C$_3$H$_7$, i-C$_4$H$_9$ and C$_6$H$_5$).

Mixed chloride dialkyldithiophosphate derivatives were prepared by the reactions of metal chlorides with sodium dialkyldithiophosphates in stoichiometric ratios and also by co-disproportionation reactions of metal *tris*(dialkyldithiophosphates) with metal chlorides

$$MCl_3 + n(RO)_2PSSNa \rightarrow [(RO)_2PSS]_nMCl_{3-n} + nNaCl \downarrow$$
$$(4)$$

$$MCl_3 + 2[(RO)_2PSS]_3M \rightarrow 3[(RO)_2PSS]_2MCl \quad (5)$$

$$2MCl_3 + [(RO)_2PSS]_3M \rightarrow 3[(RO)_2PSS]MCl_2 \quad (6)$$

13.	$[(C_6H_5O)_2PSS]_3As$	d	91	Yellow sticky solid	-	-	18.32 (18.18)	20.89 (21.00)

All the above reactions (3–6) are even more facile and appear to be completed at room temperature simply by stirring the reaction mixture in benzene for 2–3 hr.

Mixed alkoxide (isopropoxide) diisopropyl-dithiophosphates of antimony(III) were prepared by the co-disproportionation reaction of antimony isopropoxide with antimony $tris$(diisopropyldithiophosphate) in $1:2$ and $2:1$ molar ratios in benzene:

$$Sb(OC_3H_7-i)_3 + 2[(i-C_3H_7O)_2PSS]_3Sb \rightarrow$$
$$3[(i-C_3H_7O)_2PSS]_2Sb(OC_3H_7-i) \quad (7)$$

$$2Sb(OC_3H_7-i)_3 + [(i-C_3H_7O)_2PSS]_3Sb \rightarrow$$
$$3[(i-C_3H_7O)_2PSS]Sb(OC_3H_7-i)_2. \quad (8)$$
Antimony $tris$(diisopropyldithiophosphate), [$(i$-C_3H_7O)_2PSS]_3Sb, reacts with halogens (bromine and iodine) in $2:1$ molar ratio to give monohalo antimony bis(diisopropyldithiophosphate) and bis(diisopropyl-

phosphorothionyl) disulphide, which are separated by fractional crystallization in light petroleum (b.p., 60–80°).

$$2[(i-C_3H_7O)_2PSS]_3Sb + X_2 \rightarrow$$
$$2[(i-C_3H_7O)_2PSS]_2SbX + [(i-C_3H_7O)_2PSS]_2 \quad (9)$$
Arsenic $tris$(diisopropyldithiophosphate), [$(i$-C_3H_7O)_2PSS]_3As, also appears to react with halogens in a similar manner but only bis(diisopropyl-phosphorothionyl)disulphide is crystallized from light petroleum (b.p., 60–80°), and monohalo arsenic bis(diisopropyldithiophosphate) could not be obtained in a pure form.

Mixed chloride diisopropyldithiophosphate derivatives of arsenic and antimony in isopropanol on treatment with an excess of water give the corresponding metal (arsenic and antimony) $tris$(diisopropyldithiophosphates) and oxides:

$$6[(i-C_3H_7O)_2PSS]_2MCl + 3H_2O \rightarrow$$
$$4[(i-C_3H_7O)_2PSS]_3M + M_2O_3 + 6HCl \quad (10)$$

$3[(i\text{-}C_3H_7O)_2PSS]MCl_2 + 3H_2O \rightarrow$

$\qquad [(i\text{-}C_3H_7O)_2PSS]_3M + M_2O_3 + 6HCl. \qquad (11)$
On treatment of diisopropyldithiophosphate derivatives of arsenic and antimony with an excess of ammonia in aqueous media, only insoluble metal oxides are obtained;

$2[(i\text{-}C_3H_7O)_2PSS]_3M + 6NH_4OH \rightarrow$

$\qquad M_2O_3 + 6(i\text{-}C_3H_7O)_2PSSNH_4 + 3H_2O. \qquad (12)$
Compounds of the type $Cl_2Sb[SSP(OR)_2]$ on heating disproportionate into $SbCl_3$ and $[(RO)_2PSS]_2SbCl$; the latter appear to decompose further into products which could not be identified. This was confirmed by heating a sample of $[(RO)_2PSS]_2SbCl$, synthesized as mentioned earlier. The reaction can be represented by the following equation on the basis of the amount of $SbCl_3$ liberated:

$2[(RO)_2PSS]SbCl_2 \rightarrow SbCl_3 + [(RO)_2PSS]_2SbCl.$

$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (13)$
It is interesting to note that the compounds of the type $R_2SbS_2CNR_2$ have been reported[12] to disproportionate spontaneously into 1:1 mixtures of R_3Sb and $RSb(S_2CNR_2)_2$.

Dialkyldithiophosphate derivatives of arsenic and antimony are generally yellow crystalline solids or pale yellow oily viscous liquids soluble in common organic solvents like benzene, chloroform, carbon tetrachloride, acetone, hexane, ether, light petroleum, alcohols etc. The *tris* derivatives are insoluble in water and can be crystallized from aqueous alcohols. Mixed chloride derivatives are sensitive to moisture and solid compounds

amongst these can be crystallized from light petroleum (b.p., 60–80°). Molecular weight determinations in freezing benzene indicate the monomeric nature of these derivatives. All these compounds are non-volatile even under reduced pressure, and tend to decompose at ~120°C.

IR spectra of these new derivatives have been measured in the range $4000\text{--}200\ cm^{-1}$ and assignments have been made on the basis of earlier reports.[1,3,26] The bands in the regions, 1025–975 and 890–745 cm^{-1} are assigned to (P)–O–C and P–O–(C) stretching modes respectively. A strong band due to $\nu(P = S)$ observed in the region 680–620 cm^{-1} in the spectra of dialkyldithiophosphoric acids and their sodium and ammonium salts is shifted to lower frequencies by ~30 cm^{-1} in the corresponding antimony derivatives. This probably indicates a strong bidentate chelation of the ligand with antimony. In the case of arsenic derivatives the shift in the $\nu(P = S)$ peak appears to be small or negligible. Bands of medium intensity present in the region 580–500 cm^{-1} are due to P–S asymmetric and symmetric stretching vibrations. Bands of medium intensity present in the region 400–250 cm^{-1} are due to M–S[27] and M–Cl[32] stretching vibrations.

The PMR spectra (Tables 3 and 4) show the characteristic proton resonances of the corresponding alkoxy groups. The ^{31}P NMR spectral data (Table 5) for only a few representative compounds could be obtained. In proton-decoupled spectra, only one peak for each compound in the range of 89.0 to 91.8 ppm is obtained, which indicates[33] the bidentate behaviour of dialkyldithiophosphate ligands in all these derivatives.

For the sake of comparison, it may be recorded here that the X-ray crystallographic data show that

tris(dialkyldithiocarbamates)[7,8] of arsenic(III) and antimony(III) possess distorted octahedral geometry whereas the monobromo bis(diethydithiocarbamate) of arsenic(III)[9] possesses a distorted square pyramidal structure with Br$^-$ at the apex. $Br_2As(S_2CNEt_2)$[11] is reported to be monomeric in solution, while in the solid state it exists as a loosely held centrosymmetric dimer with bridging bromine ions: the geometry around 5-coordinate As(III) is intermediate between square pyramid and trigonal bipyramid with a stereochemically

active lone pair occupying one site in a distorted octahedral coordination.

The available X-ray crystallographic data of $[(EtO)_2PSS]_3Sb$[25] show a distorted capped octahedral environment around antimony with a stereochemically acitve lone pair at the capping position.

The spectroscopic data discussed earlier in this paper for the newly-synthesized halide dialkyldithiophosphates of arsenic(III) and antimony(III) indicate the chelating nature of the dithiophosphate moieties. Considering the

monomeric nature of all these derivatives, the mono-halide *bis*(dialkyldithiophosphates) should contain a 5-coordinate metal atom and possess a distorted octahedral geometry with the stereochemically active lone pair occupying one of the positions. The corresponding dihalide derivatives having a 4-coordinate metal atom may similarly possess a distorted trigonal bipyramidal geometry. Efforts are being made to obtain X-ray crystallographic data for some of these interesting compounds.

MAGNETIC AND EPR PROPERTIES OF Mn(II), Fe(III), Ni(II) and Cu(II) COMPLEXES OF THIOSEMICARBAZONE OF α-HYDROXY-β-NAPTHALDEHYDE

YUDHVIR K. BHOON

Sri Venkateswara College, Dhaula Kuan, New Delhi, 110021, India

Abstract—Mn(II), Fe(III), Ni(II) and Cu(II) complexes of the thiosemicarbazones of α-hydroxy-β-naphthaldehyde have been isolated. Ni(II) complex is diamagnetic, Cu(II) is planar involving metal–metal interactions, Mn(II) complex ($\mu_{\text{eff}} = 3.86$ B.M) has been assigned a planar structure with $S = 3/2$ while Fe(III) complex is five coordinated with $S = 3/2$.

Thiosemicarbazide ($NH_2 \cdot CS \cdot NH \cdot NH_2$) and thiosemicarbazones ($NH_2 \cdot CS \cdot NH \cdot N = CR_1R_2$) usually react as chelating ligands with transition metal ions by bonding through the sulphur and hydrazinic nitrogen atoms, although in a few cases, they behave as monodentate ligands and bond through the sulphur atom only. Since Domagk's original report[1] on the anti-tubercular activity of thiosemicarbazones, the number of papers on the pharmacology of these compounds has expanded dramatically. They have also been found to be active against influenza,[2] protozoa,[3] smallpox[4] and certain kinds of tumour[5] and have been suggested as pesticides[7] and fungicides.[6] Their activity has frequently been thought to be due to their ability to chelate trace metals. These findings have led recently to an increased interest in the chemistry of transition metal chelates of thiosemicarbazones. Thiosemicarbazone of α-hydroxy-β-napthaldehyde abbreviated as, HNATSC(I), is a newly synthesized compound. Mn(II), Fe(III), Ni(II) and Cu(II) complexes of HNATSC, have been prepared and characterized by magnetic susceptibility (from RT to 4 K) and ESR spectral measurements in the powdered state.

I
EXPERIMENTAL

Preparation of HNATSC, I

The thiosemicarbazone of α-hydroxy-β-baphthaldehyde was prepared by mixing the equimolar ethanolic solutions of thiosemicarbazide and α-hydroxy-β-naphthaldehyde.

The resulting solution was refluxed for about 1 hr and the thiosemicarbazone was separated out as grannular buff coloured compound which was filtered off and washed with cold alcohol and dried in a vacuum desiccator over silica gel. (Found: C, 58.43; N, 16.84; H, 4.01 and S, 12.83%. HNATSC requires: C, 58.77; N, 17.14; H, 4.49 and S, 13.06%).

Preparation of complexes

For preparing the complexes, equimolar solutions of metal halides and the thiosemicarbazone in DMF were mixed and the resulting solution was refluxed on a water bath for about 1 hr. Excess of the solvent was distilled off under reduced pressure and water was added to the concentrate. In each case, the complexes were precipitated, washed with hot water and acetone and finally dried in a vacuum desiccator over P_2O_5. The complexes are insoluble in water, ethanol, chloroform and acetone. The results of microanalysis on the complexes are presented in Table 1.

Physical measurements

The magnetic susceptibility measurements on powdered samples were carried out by Gouy's method using $Hg[Co(CNS)_4]$ as the calibrant. The results of measurements are presented in Table 1.

RESULTS AND DISCUSSION

(a) Copper(II)-HNATSC

The susceptibility measurements on the complex at room temperature yield magnetic value to be 1.54 B.M

Table 1. Micro-analytical and magnetic susceptibility data of complexes

Complex	% C Found (Calcd.)	% N Found (Calcd.)	% M Found (Calcd.)	% S Found (Calcd.)	% Cl Found (Calcd.)	μ_{eff} (B.M)
Cu(HNATSC)Cl	41.80 (41.97)	12.01 (12.24)	18.30 (18.52)	9.40 (9.33)	10.20 (10.35)	1.54
Ni(HNATSC)Cl	42.40 (42.57)	12.10 (12.47)	17.24 (17.35)	9.43 (9.46)	10.06 (10.49)	—
Mn(HNATSC)Cl	42.64 (43.05)	11.98 (12.55)	15.64 (16.42)	9.43 (9.56)	10.12 (10.61)	3.86
Fe(HNATSC)Cl$_2$	38.62 (38.83)	12.41 (12.67)	14.83 (15.06)	8.50 (8.63)	18.79 (19.14)	—

which is much below the spin only value of 1.73 B.M for mononuclear Cu(II) complexes. In view of the terdentate character of the thiosemicarbazone and chemical composition, planar stereochemistry may be proposed for the complex. Since the planar Copper(II) complexes are more prone to the metal–metal interaction along the axial positions, the lowering in magnetic moment could obviously be due to these interactions.

(b) Nickel(II)-HNATSC

The complex is diamagnetic and therefore, planar structure may be proposed for it. The planar structure for the complex also confirms the terdentate character of the thiosemicarbazone.

(c) Iron(III)-HNATSC

The results of magnetic susceptibility measurements on the powdered sample down to liq. helium temperature are presented in Table 3.

The magnetic behaviour of simple mononuclear high spin iron(III) complexes is generally uncomplicated. High spin iron(III) complexes ($S = 5/2$) with $^6A_1$ as the ground state have magnetic moment values around 5.92 B.M independent of temperature. Low-spin iron(III) complexes with strong ligands have magnetic moments corresponding to one unpaired electron. The ground state in such complexes is $^2T_2$ and the magnetic moment is temperature dependent.[8] It is interesting to note that if the geometry of the complexes is either octahedral or tetrahedral the possibility for the quartet state $^4T_1$ as the ground state with $S = 3/2$ is excluded by ligand field theory.[9] However, for d^5 configuration, this restriction does not necessarily apply to lower symmetry situations. Thus, an $S = 3/2$ ground state ($^4A_2$) has been established for a series of five coordinated iron(III) dithiocarbamates[10,11] and in the present studies, the iron(III) complex also seems to be a pentacoordinated with the square-pyramidal configuration and $S = 3/2$.

The detailed magnetic susceptibility measurements (Table 3) carried out on the powdered sample at different temperatures by SQUID susceptometer described earlier,[20] yield magnetic moments for the complex to be continuously rising from near 3.00 B.M at 4.2 K to 4.46 B.M at 143.4 K. This seems to be a slightly unusual behaviour if it is in fact a genuine $S = 3/2$ iron(III) compound because they have a moment of 3.9 B.M and independent of temperature.[8] Therefore, this compound

seems to be a 5 coordinate ($S = 3/2$) in which the excited states must be close enough to raise the moment to 4.47 B.M at room temperature which gets support from the EPR spectra recorded in the polycrystalline state both at room temperature and liquid nitrogen temperature. Very few compounds of iron(III), where the ground state has three unpaired electrons, have been subjected to EPR studies. Mono-chlorophthalocyaninato iron(III) is perhaps the first of this kind for which ESR studies were made by Gibson et al.[13] Among the series, $Fe(R_2 dtc)_2X$ polycrystalline ESR spectra are reported[14] for $Fe(Et_2 dtc)_2X$ where $X = Cl$, Br, I and NCS. Complete analysis of the EPR spectra in the present case has not been possible because of failure to obtain single crystals but it has definitely supported the 5 coordinated stereochemistry for the complex as the appearance of the signals at $g \simeq 4$ and $g \simeq 2$ could be explained by this geometry only. The ESR results for the systems with $^4A_2$ ground state can be described by the spin Hamiltonian,[14-17]

$$\mathscr{H} = D\left[\hat{S}_z^2 - \frac{1}{3}S(S+1)\right] + E(\hat{S}_x^2 - \hat{S}_y^2) + g\beta H \cdot S$$

with $S = 3/2$ and $g = 2.00$. When $E = 0$ and also when $D \gg h\nu$, there are two Kramers doublets $M_s = \pm 3/2$ and $\pm 1/2$, with effective g-tensor principal values $g_x = g_y = 0$; $g_z = 6$ and $g_x = g_y = 4$; $g_z = 2$ as shown below.

$D \gg h\nu$, $E = 0$

For the ($\pm 1/2$) doublet ignoring orbital contribution (since Fe(III) is $^6S_{5/2}$, $L = 0$)

$$g_{xx} = g_{yy} = 2\left\langle +\frac{1}{2}|S_\perp| - \frac{1}{2}\right\rangle$$

$$= 2\left\langle +\frac{1}{2}|(S_+ + S_-)2| - \frac{1}{2}\right\rangle$$

$$= 2\sqrt{\left(\frac{3}{2} + \frac{5}{2} - \left(\frac{1}{2} + \frac{1}{2}\right)\right)}$$

$$= 2\sqrt{(4)} = 4$$

$$g_\perp = 4$$

$$g_\parallel = 2\left\langle \frac{1}{2}|2S_z|\frac{1}{2}\right\rangle$$

$$= 2 \times 2 \times \frac{1}{2} = 2$$

50.5	0.04019	4.03
89.57	0.0237	4.16
106.9	0.02100	4.24
143.4	0.01733	4.46

For the $(\pm 3/2)$ *doublet*

$$g_\perp = 2\left\langle +\frac{3}{2}|2S_\perp|-\frac{3}{2}\right\rangle$$

$$= 2\left\langle +\frac{3}{2}|S_+ + S_-|-\frac{3}{2}\right\rangle$$

$$= 2\times 0 = \underline{0}$$

$$g_{zz} = g_{||} = 2\left\langle +\frac{3}{2}|2S_z|+\frac{3}{2}\right\rangle$$

$$= 2\times 2\times\frac{3}{2} = \underline{6}.$$

The compound under investigation show identical ESR properties (Fig. 1) which may be described by the above

Hamiltonian for E = 0. Such a system should give rise to g value of 6, 4 and 2. For the compound under study, $g \approx 2$ signal is quite broad and $g \approx 4$ signal is comparatively strong while $g = 6$ signal is not observed, as it is not expected to be populated appreciably.

(d) *Manganese(II)-HNATSC*

As discussed above, crystal field theory specifically excludes the possibility of a quartet ground state (S = 3/2) for Mn(II) (d^5) configuration in octahedral geometry but not for the low symmetry. As S = 3/2 ground state has been established for a series of five coordinated iron(III) dithiocarbamates and manganese(II) phthalocyanin,[12] manganese(II)-HNATSC also appears to have a
Fig. 1. ESR spectra of Fe^{III} (HNATSC) in polycrystalline state (a) RT (b) LNT.
Fig. 2. ESR spectra of $Mn^{II}(HNATSC)Ci$ in polycrystalline state (a) RT. (b) LNT.

quartet ground state since the magnetic moment value is very close to the spin only value of 3.88 B.M in a square planar environment.

Infrared spectra

The selective IR spectral bands observed in the spectra of HNATSC and its corresponding complexes are presented in Table 2 along with the assignments. The IR spectra of Fe(III) (HNATSC) Cl_2 has provided additional information regarding the configuration of five coordinated complex.

Trigonal bipyramid(II) and square pyramid(III) are the 2 possible arrangements for the 5 coordinated molecule and they will differ in their IR spectral behaviour. In TBP, as the two chlorine atoms are trans to one another, one will expect only one ν_{Fe-Cl} band while in SP structure, the two Fe–Cl positions are different, the molecule is expected to give two ν_{Fe-Cl} bands as a result of splitting due to C_{2v} symmetry and the complex under study also shows two strong bands at 410 and 405 cm^{-1} which could be assigned to Fe–Cl. Thus on the basis of IR spectral data a square pyramidal structure could be assigned to the complex.

II

III
ESR spectral studies

High spin (S = 3/2) manganese complexes have been extensively studied by ESR technique but the reports on the complexes with S = 3/2 are not many.[18,19] Mn(II) phthalocyanine seems to be the first manganese(II) complex with a quartet ground state (S = 3/2) which was studied by ESR. The complex showed a very broad signal centered around g = 2.00. The manganese(II) complex under discussion also yields a similar ESR signal

(Fig. 2) in the polycrystalline state both at RT and LNT. The g value very close to that of DPPH (g = 2.0023) indicate that there is little orbital contribution which is in agreement with the results of magnetic susceptibility measurements which give the value of magnetic moment at RT to be 3.86 B.M, very close to the spin only value (3.88 B.M).

PREPARATION AND CHARACTERISATION OF COPPER, COBALT AND NICKEL COMPLEXES OF TETRADENTATE N₆ MACROCYCLIC LIGAND

WAHID U. MALIK,† R. BEMBI and RANDHIR SINGH*
Department of Chemistry, University of Roorkee, Roorkee-247672, U.P., India

Abstract—Macrocyclic complexes of copper, nickel and cobalt were synthesised via template reactions. These 14-membered N₆ tetradentate macrocyclic complexes were characterised by magnetic, conductance, electronic and IR spectral studies. The macrocyclic ligand coordinates through the four azomethine nitrogen atoms which are bridged by 2,3-butanedione moieties, but far IR spectra suggest that the pyridine nitrogens are not coordinated. These macrocyclic complexes are considered to have distorted octahedral configurations.

Considerable attention has been paid to the characterisation of macrocyclic complexes prepared by the condensation of ketones with transition-metal complexes of tetraamines.[1–3] The relationship of electronic properties and reactivities of these synthetic macrocyclic complexes to those of naturally occurring macrocycles, such as porphyrins and corrins, continues to promote great interest in their design and preparation. Much work in this field has resulted in substantial progress in the development of cyclisation reactions, usually involving metal ions, which has led to a variety of macrocyclic complexes.[4] The effect of varying the macrocyclic ring size has also received attention; 16-membered macrocyclic complexes have been reported.[5]

In the present paper the preparation and properties of a number of copper(II), nickel(II) and cobalt(II) complexes of 14-membered macrocycles and their derivatives are reported.

EXPERIMENTAL

Preparation of the complexes. All the chemicals employed were reagent grade and used without further purification. 2,6-Diamino-pyridine (0.02 mol) and 2, 3-butanedione (0.02 mol) were mixed in a minimum quantity of MeOH and a MeOH solution of the metal salt (0.01 mol) was added; the mixture was refluxed on a water bath. After refluxing for about 12 hr hydrochloric acid (1 cm³) was added and refluxing was maintained for a few more hours. The mixture was concentrated to half volume on a rotary evaporator and kept as such for 2 days. The greenish brown crystals were filtered off and washed with methanol and ether and dried in vacuum. The complexes so obtained are stable upto 200°C and are soluble in methanol, water, dimethyl sulphoxide and acetonitrile whereas copper complexes are partially soluble in these solvents. The derivatives of these complexes were prepared by metathesis by stirring and adding slowly NaBr and NH₄CNS solutions to an ethanolic solution of metal chloride, and the NaCl or NH₄Cl, formed during the exchange reaction, was filtered off. The nitrate complexes were prepared from metal nitrate salts. The metal contents were determined by spectrophotometric methods while halides were estimated by Volhard's method and nitrate as nitron salt.

Magnetic and spectral measurements: Magnetic measurements were carried out using a Princeton Applied Research Model 155

vibrating sample magnetometer incorporating a digital readout. The electromagnet current was maintained using a Polytronic Constant Current Regulator Type CP-200. The instrument was calibrated using a standard pure nickel pallet and cross checked against Hg[Co(CNS)₄] as calibrant.

Absorbance measurements (DMF solutions) were carried out on a Carl Zeiss Specord UV.-VIS spectrophotometer using 10 mm glass cells. Conductance measurements of 1.0 mM solutions were made using the solvent acetonitrile which had been distilled from calcium hydride under nitrogen atmosphere and a Systronics Conductivity Meter Type 302 at 25 ± 1°C using a dip type conductivity cell. IR spectra were recorded on Beckmann IR-20 spectrophotometer in KBr pellets in 4000–600 cm⁻¹ range and in Nujol mulls in the 650–200 cm⁻¹ range on a Beckmann IR-12 spectrophotometer. The molecular weights of soluble complexes (MeOH solution) were determined cryoscopically.

RESULTS AND DISCUSSION

The analytical data (Table 1) show that the macrocyclic complexes can be represented as [M(C₁₈H₁₈N₆)X₂] where M = Ni(II), Co(II), Cu(II) and X = Cl, Br, NO₃ and NCS. The conductance measurements show their non-electrolytic nature and molecular weights of the nickel and cobalt complexes showed that they are monomeric (Table 2).

IR *spectral and magnetic studies.* The IR spectra of all compounds do not contain any band that could be assigned to C=O or NH groups.[6] The spectra of the condensation product of these compounds show various vibrations of the pyridine ring,[7–9] and azomethine[10] and 2,3-butanedione moiety.[7] By comparing the spectra with those of the amine, a strong band at *ca.* 1625 cm⁻¹ and a shoulder at *ca.* 1610 cm⁻¹ may be assigned to symmetric and asymmetric ν (C=N) vibrations, respectively. The absence of bands at *ca.* 3300–3200 cm⁻¹ indicates that all amino groups of 2,6-diaminopyridine have condensed with 2,3-butanedione. This contention is supported by the presence of bands at *ca.* 2925 cm⁻¹, *ca.* 1355 cm⁻¹, *ca.* 1270 cm⁻¹ and 680 cm⁻¹ characteristic of the 2,3-butanedione moiety and may be assigned to ν(CH₃), ν(C–CH₃), Sym(CH₃) and ring deformation modes.[6] However, some changes are observed in the spectra of these complexes. The spectra do not show any change in pyridine ring vibrations and it appears that in these complexes the nitrogen atom of pyridine does not participate in coordination.

It is apparent from the spectra that both the amino groups of 2,6-diaminopyridine react with oxygen atoms of 2,3-butanedione forming a two-carbon atom bridge between the two amino groups, similar to those reported in coordinated amines.[11] The absence of stretching and bending (C–O) group vibrations at ca. 1525 cm^{-1} and ca. 1280 cm^{-1} also indicate the absence of this group in these macrocyclic complexes. The frequencies of the ν(C=N) vibrations indicate coordination through this site.[13] Thus in the presence of metal salts, a quadridentate macrocyclic complex is formed which coordinates through azomethine nitrogens while pyridine nitrogen does not take part in coordination. These observations are in accordance with the idea that the formation of quadridentate macrocycles is easier than hexadentate or quinquedentate macrocycles.[12] It is also evident that azomethine nitrogen, being equally active, excludes coordination through pyridine nitrogen perhaps because this would involve the formation of unstable four-membered rings.

The far IR spectra of these complexes show some new bands at ca. 310 cm^{-1}, ca. 280 cm^{-1} and 275 cm^{-1} which can be assigned to ν(Co–Cl), ν(Ni–Cl) and ν(Cu–Cl) vibrations,[13] respectively. Similarly bands in bromocomplexes are observed at ca. 225 cm^{-1} and ca. 210 cm^{-1} for cobalt and nickel complexes and can be assigned to ν(Co–Br) and ν(Ni–Br) vibrational modes. The single bands observed and their regions are consistent with the octahedral nature of the complexes.

In nitrato complexes the spectra show some new bands at ca. 1265 cm^{-1}, ca. 1010 cm^{-1} and ca. 860 cm^{-1} which can be assigned to the monodentate nature of the nitrate group.[6] In thiocyanato complexes, some strong bands appear at ca. 2110 cm^{-1} (ν_1) ν(C=N), ca. 480 cm^{-1} (ν_2) NCS bending and ca. 830 cm^{-1} (ν_3), ν(C=S) of the NCS group, respectively in accord with the monodentate N-bonded thiocyanato group. The appearance of new bands at ca. 225–245 cm^{-1} support the coordination of nitrate and thiocyanate groups, which are assignable to ν(M–O) of the nitrate group and ca. 260–280 cm^{-1} assignable to ν(M–NCS), respectively. The appearance of bands in the region 430–495 cm^{-1} implies ν(M–N) (azomethine) vibrational modes and confirms the involvement of azomethine nitrogen. The data from the magnetic measurements of these complexes are given in Table 2. The magnetic moments of cobalt, nickel and copper complexes lie in the ranges 4.81–5.12, 3.24–3.35 and 1.75–1.86 B.M. respectively, at room temperature. The magnetic data are in accord with the high-spin nature of the nickel and cobalt complexes and indicate a pseudo-octahedral enviroment around the metal ions.[13] The distorted octahedral environment arises due to the steric interaction of the 2,6-diaminopyridine rings with methyl substituents on the macrocyclic ring. The resulting strain is relieved through a distortion of the ring to give a non-planar structure. The strain is relieved through the twisting of the torsional angles about the C–N bonds on the N$_6$-ring, which is the most readily deformable site. The extent of deviation from the dihedral angle in an ideally planar structure depends on the single and double bond characters of the various bonds in the macrocyclic ring. In this distorted structure, the four nitrogens lone pairs of the macrocyclic ring are directed[14] out of the N$_6$-plane, so that the metal "sits atop" and not inside the N$_6$-cavity. The macrocycle is distorted such that the metal ion is lying outside the nitrogens' plane on the side opposite the folding. Thus

the ligand field exerted by the nitrogen system is very weak, which results in high-spin complexes even with strong donor ligands.

Electronic spectral studies: The electronic spectra of complexes of copper show a maximum at ca. 17810–19315 cm^{-1} and a shoulder at ca. 14540–17110 cm^{-1}. This indicates that these macrocyclic complexes are distorted octahedral.[15] The shifting of bands is towards higher energy in the order NCS > NO$_3$ > Br > Cl, i.e. in order of weakening interaction of the metal ion with the anions. Assuming tetragonal distortion in the molecule, the energy level sequence for these complexes may be, $x^2 - y^2 > z^2 > xy > xz > yz$ and the shoulder can be assigned to $z^2 \rightarrow x^2 - y^2 (^2B_{1g} \rightarrow {}^2B_{2g})$ and the broad band contains both the $xy \rightarrow x^2 - y^2 (^2B_{1g} \rightarrow {}^2E_g)$ and $xz, yz \rightarrow x^2 - y^2 (^2B_{1g} \rightarrow {}^2A_{2g})$ transitions.[16] The separation of bands in the spectra of these complexes is of the order of 2520 cm^{-1} which is in accord with the proposed geometry of the complexes.[17]

The nickel complexes show three strong bands at ca. 10610–12355, 15000–17000 and 25000–28100 cm^{-1} with a shoulder at ca. 8500–9510 cm^{-1} towards the low energy side of the first band. The spectral bands are well within the range for hexacoordinate octahedral complexes of nickel reported earlier.[18] The first two bands result from the splitting of one band, ν_1, and can be assigned to $^3B_{1g} \rightarrow {}^3E_g(\nu_1)$ and $^3B_{1g} \rightarrow {}^3B_{2g}(\nu_2)$ assuming the effective symmetry[16] to be D_{4h} (components of $^3T_{2g}$ in O$_h$ symmetry) and the other two higher bands can be assigned to $^3B_{1g} \rightarrow {}^3A_{2g}$(F), $^3F_g(\nu_3)$ and $^3B_{1g} \rightarrow {}^3A_{2g}$(P). The intense higher energy band appeared at ca. 35060 cm^{-1} can be assigned to a $\pi \rightarrow \pi^*$ transition of the C = N group. A regular pattern is not followed by various bands and this seems to be anion independent. The spectral data are consistent with the distorted octahedral nature of these macrocyclic complexes. The values calculated for Dq^{xy} and Dq^z are given in Table 2. Thus, all the complexes studied herein show pseudooctahedral geometry conforming to D$_{4h}$ symmetry. On the basis of symmetry arguments, Lever[18] has given a theory applicable to D$_{4h}$ molecules. This newly-developed theory is called normalised spherical harmonic Hamiltonian theory (NSH). This theory correlates ligand field parameters to NSH absolute ligand field parameters, DQ, DS and DT. Dq is a measure of the in-plane ligand field while DQ is a measure of the average ligand field experienced by the metal ion. The DT/DQ ratio gives the information about the distortion of the molecule. The values given in the Table 2 indicate that these macrocyclic complexes are moderately distorted and the distortion increases in the order: NCS > NO$_3$ > Br > Cl.

The spectral bands at ca. 8255–8750 cm^{-1} (ν_1) and 15750–16260 cm^{-1} (ν_2), with a broad band at ca. 21050 cm^{-1} (ν_3) can be assigned to Co(II) complexes,[18] reported to be distorted octahedral with D$_{4h}$ symmetry. These macrocyclic complexes exhibit a band in the visible region which shows a structure and splitting due to low symmetry fields. The splitting causes band overlap and some broad bands are observed. Thus, assuming the effective symmetry to be D$_{4h}$, these bands observed can be assigned to $^4T_{1g} \rightarrow {}^4T_{2g1}$, $^4T_{1g} \rightarrow {}^4A_{2g}$ and $^4T_{1g} \rightarrow {}^4T_{1g}$(P) at ca. 8510, 1620 and 20060 cm^{-1}, respectively. The first band (ν_1) is in the visible region and the assignment of the visible band to $^4A_{2g}$ cannot be spin forbidden. The values of Dq, B, β and ν_2/ν_1 ratio are given in Table 2.

On the basis of above discussion the following structure (A) may be proposed for these macrocyclic complexes:
M = Cu(II),Co(II),Ni(II)

X = Cl,Br,NO₃,NCS

RATE OF HYDROLYSIS OF Na₄P₂O₇ AND Na₅P₃O₁₀ AT 100°C AND THE EFFECT OF UREA

JOHN EMSLEY and SHAHIDA NIAZI

Department of Chemistry, King's College, Strand, London WC2R 2LS, England

Abstract—^{31}P NMR analysis has been used to measure the rates of hydrolysis of $Na_4P_2O_7$ and $Na_5P_3O_{10}$ at 100°; the rate constants are 6.07×10^{-3} and 2.24×10^{-1} hr^{-1} respectively. The presence of urea has a catalytic effect on the former but an inhibiting effect on the latter. These observations are explained by the hydrogen-bonding capabilities of urea.

Urea is known to have a profound effect when heated with phosphoric acid or ammonium hydrogen phosphates—it causes polymerization to cyclic or linear polyphosphates, P_n, depending upon the temperature.[1,2] In these reactions it behaves as a dehydrating agent and can cause condensation $nP_1 \rightarrow P_n$ at temperatures as low as 100°C. The products from such reactions are suggested as fertilizers, etc.[3] in which case their hydrolysis to monophosphate would be an essential prerequisite to absorption by plants. The urea in these products is also a source of nitrogen for plants. The effect of urea on the hydrolysis of P_n has not been investigated. As model systems for such an investigation tetrasodium diphosphate $Na_4P_2O_7(P_2)$ and pentasodium triphosphate $Na_5P_3O_{10}(P_3)$ have been chosen.

The hydrolysis of P_n has been studied over many years and the catalytic effect of various countercations has been noted.[4] Even sodium has a slight catalytic effect[5] compared to Et₄N$^+$ but is much weaker than most other cations especially those of divalent and transition metals.[6] Other factors also have a profound influence on the rate of hydrolysis especially the solvent[7] and pH.[5] In this paper we report on the effect of urea.

EXPERIMENTAL

Na₅P₃O₁₀ was reagent grade from Hopkin & Williams purified as in Ref. 5. Urea and Na₄P₂O₇ were analytical grade from Fisons and were used without further purification.

^{31}P NMR analysis

As a method of analysis this is not as accurate as conventional methods but it has the advantage of convenience and the technique has been successfully used in following the hydrolysis of diphosphate in the presence of a cobalt(III) complex.[8] Moreover the rate constant for the hydrolysis of Na₄P₂O₇ at 100°C reported here is 6.07×10^{-3} hr^{-1} which compares favourably with that reported in the literature for this temperature; 6.12×10^{-3} hr^{-1}.[9]

Broad band decoupled ^{31}P NMR spectra were recorded at 36.43 MHz on a Bruker HFX90 spectrometer at 300 ± 3k. Peak positions were measured from 85% H₃PO₄ as an external standard and P_1, P_2 and P_3 signals were integrated to determine the concentrations in solution. Machine settings were: filter band width 7500 Hz; sweep width 6000 Hz; sweep offset 4500 Hz with no systematic noise reduction; Fourier transform (pulse width 12.5 μsec, 8K data points, 30° flip angle, time constant—2 sec). The observation that ammonium polyphosphate solutions, prepared from urea-phosphate heated in excess urea,[1] were more stable than normal, prompted this investigation. Na₅P₃O₁₀ was chosen as a model system for the investigation because of its commercial importance and because both it and its hydrolysis products can be clearly distinguished by ^{31}P NMR analysis.

Samples were drawn from the reaction mixtures, cooled and their pH (Pye meter) and ^{31}P NMR spectra recorded; the latter after the addition of an equal volume of D₂O. The averaged results of two runs under various ratios of P_2: urea and P_3: urea are given in Table 1. The temperature of 100°C was chosen to give a relatively rapid rate of hydrolysis of P_2 and P_3 under the slightly alkaline conditions of their sodium salts. The solutions studied were 5% w/v solutions, and they were not buffered to show whether the effects were due to pH changes.

DISCUSSION

Adding urea to an aqueous solution of Na₄P₂O₇ at 100°C increases the rate of hydrolysis three-fold; the first order rate constants are 6.07×10^{-3} hr^{-1} and 21.5×10^{-3} hr^{-1} for the non-catalyzed and catalyzed reactions respectively. The factors which enhance polyphosphate hydrolysis have been identified as (i) lowered (acid) pH; (ii) complexation by metal cations, and (iii) ring formation.[10]

Change of pH does not explain the results reported here, nor does a change in complexation, so that the third factor, cyclization, seems the most appropriate. Can urea have this effect?

Urea and phosphoric acid form a strongly hydrogen-bonded complex $CO(NH_2)_2 \cdot H_3PO_4$ of structure (I).[11] In aqueous solution at pH 8.5 the anion of Na₄P₂O₇ will be $H_2P_2O_7{}^{2-}$ so that a cyclic hydrogen bonded system can be envisaged, e.g. (II).

(III)
This might then serve to encourage nucleophilic attack at either phosphate centre by drawing away electron density towards the hydrogen bonds. Even a cyclic hydrogen bonded arrangement at only one phosphate as in (III) may serve the same purpose.

If this is the explanation of the enhanced rate of hydrolysis of diphosphate by urea it cannot serve to explain the behaviour of triphosphate, hydrolysis of which is *inhibited* by urea, see Table 1. The rate constants for this hydrolysis are 2.24×10^{-1} (no urea); 7.49×10^{-2} (1:0.25 ratio $Na_5P_3O_{10}$: urea); 1.30×10^{-1} (1:0.5); 1.17×10^{-1} (1:1.25); 1.36×10^{-1} (1:6) hr^{-1}. Thus a low ratio of urea decreases the rate by a factor of 3 but larger amounts of urea do not have a correspondingly larger effect. Again the changes in pH are not sufficient to cause this effect. The rate constant for the hydrolysis of P_3 at 100° agrees well with other values reported in the

literature for $60°C(0.45 \times 10^{-3})^5$, $70°(0.43 \times 10^{-3})^{12}$ and $90°(1.52 \times 10^{-1})^5$. A determination at 80° by us gave a value of 2.21×10^{-2}.

Displacing Na^+ from around the anion should reduce the rate of hydrolysis, but this explanation would apply also to diphosphate.† Cyclization may also occur as in (I) or (II) but again this should enhance the rate of hydrolysis. An explanation, also involving hydrogen bonding may be possible even though it involves cyclization. In aqueous solution the triphosphate ion will be chiefly $H_2P_3O_{10}^{3-}$ at pH 8 with the two protons attached to the terminal oxygens. These may then be involved in hydrogen bonds to urea, with each urea attracting several triphosphate ions. This has some basis of support since crystals of composition $CO(NH_2)_2 \cdot 2Na_5P_3O_{10}$ grow from these solutions. That the minimum rate was observed for the $1:0.25(P_3:$urea) ratio suggests that in such solutions several triphosphate ions can cluster around one urea molecule and that such clusters are less susceptible to nucleophilic attack by water by virtue of their macrostructure.

Unlike complexation to metal ions, when there is a marked chemical shift change of the phosphate signals,[13] the chemical shift changes in the presence of urea are small. Even with a P_3:urea ratio of 1:6, the end groups shift only from -5.39 to -5.55 ppm and the middle groups from -19.98 to -20.10 ppm, while J_{POP} remains the same. Hydrogen bonding does not have a profound effect on ^{31}P chemical shift of phosphates which are more susceptible to other effects such as pH.

The discovery reported here may have commercial implications. Already urea-ammonium polyphosphate

---

†Although many substances are known to enhance diphosphate hydrolysis few will retard the process. One such compound however is the polyelectrolyte polyethyleneimine ($-CH_2CH_2NH-$), which is thought to act via an electrostatic interaction with P_2: D. Turyn, E. Baumgertner and R. Fernandez-Prini, *Biophys. Chem.* 1974, **2**, 269.

mixtures are used in solution as liquid fertilizers and urea may have a two-fold effect—as a nitrogen fertilizer in its own right plus as a stabilizer for the soluble polyphosphates. Similarly the use of Na$_5$P$_3$O$_{10}$ as a detergent "builder" may be improved by the addition of urea which would preserve the triphosphate throughout more of the wash cycle especially in hot water laundering.

IR SPECTROSCOPIC STUDIES ON SUBSTITUTED PYRIDINE N-OXIDE COMPLEXES OF TIN(IV) CHLORIDE IN ACETONITRILE

C. L. WILD†, M. SPAHIS†, R. D. BLANKENSHIP†, J. W. ROGERS and R. J. WILLIAMS*

Department of Chemistry, Midwestern State University, Wichita Falls, TX 76308, U.S.A.

Abstract—Complexes of eleven substituted pyridine N-oxide donors with stannic chloride in acetonitrile solution were investigated ultizing IR spectroscopy. Two distinct types of behaviour were noted: (1) Pyridine N-oxide donors containing electron releasing substituents generally form strong complexes with SnCl₄ and exhibit maxima in continuous variation plots at a 2:1 ligand-to-metal ratio. Little or no free ligand is detected in these solutions until this ratio is exceeded. Ligands exhibiting this behaviour include the 2-methyl-, 3-methyl-, 4-methyl-, 4-methoxy- and 4-phenylpyridine N-oxides.

(2) Pyridine N-oxide donors containing electron neutral to electron with-drawing substituents generally form weaker complexes with SnCl₄ and exhibit maxima in continuous variation plots at a 1:1 ligand-to-metal ratio. Free ligand is evident in these solutions even at ligand-to-metal ratios as low as 1:3. Formation plots for these complexes indicate the possibility that 1:2 and 1:1 ligand to metal complexes exist in the concentration ranges studied. Ligands exhibiting this behaviour include the 4-chloro-, 4-nitro-, 3 and 4-acetyl-pyridine N-oxides and 2-pyridine methanol N-oxide.

The complex of 2,6-lutidine N-oxide with SnCl₄ exhibits behaviour characteristic of the 1:1 complexes even though the substituents are electron releasing. This ligand contains the most sterically crowded N–O group in the series, however, and steric factors are invoked to explain this behavior.

These results are rationalized in terms of an equilibrium model which includes the postulated existence of oxygen bridged dimers comprising a dominant species in solutions containing the 1:1 complexes. Some supporting ¹H NMR and polarographic data are also presented and discussed.

A number of solid complexes of SnCl₄ with N, O, P and S donor atom ligands have been synthesized and characterized recently.[1–5] For the most part these complexes are reported to be monomeric and to exhibit octahedral geometries. When the ligands are unidentate, 2:1 complexes (all ratios given are ligand-to-metal) with SnCl₄ are the rule and a number of studies of the possible cis-trans isomerism in these complexes have been reported.[6–9] Some unidentate ligands have been reported to give 1:1 complexes,[10–12] presumably with trigonal bipyramidal geometries. Glutaronitrile is reported to form cis-2:1 octahedral complexes bridged through glutaronitrile to form a one dimensional polymer.[13] Attempts to predict the stoichiometry and geometry in these compounds based upon steric and bond strength arguments have thus far been largely unsuccessful.

Fewer studies of SnCl₄ complexes in solution have been reported. Stannic chloride has been shown to form a cis-2:1 complex with acetonitrile (ACN)[14,15] and a 1:1 complex with 2,2'-bipyridine with a log k > 7.[16] Complexes of SnCl₄ with substituted benzonitriles are reported to be 2:1 unless the substituent has a large electron withdrawing effect, whereupon the monoamide complex is favored over the diamide.[17]

Recent work in these laboratories has focused upon the electrolyte and complex formation behaviour of SnCl₄[18] and SnCl₂[19–22] in ACN solutions. These studies indicate SnCl₂ is only slightly dissociated in ACN and forms the stable SnCl₃⁻ species upon addition of

chloride ion and 1:1 complexes upon addition of a substituted pyridine N-oxide ligand. Stability constants of these complexes were determined utilizing an IR technique[22] and were found to range in value from 22 to 243 depending upon the nature of the substituent.

Polarographic studies show that SnCl₄ is also essentially a non-electrolyte in ACN solution but forms the stable SnCl₆²⁻ species upon addition of chloride ion. These studies also show that stable complexes of SnCl₄ form in ACN when a substituted pyridine N-oxide ligand is added. This present study was undertaken to further characterize these complexes.

EXPERIMENTAL

Chemicals. 2, 3 and 4-picoline N-oxides; 2,6-lutidine N-oxide; 4-methoxy-, 4-phenyl- and 4-nitropyridine N-oxides; and 2-pyridine methanol N-oxide were obtained from Aldrich Chemical Company. The 3 and 4-acetyl pyridine N-oxides were obtained from Ennox Chemical Company. These compounds were purified by sublimation or vacuum distillation before use. 4-chloro-pyridine N-oxide was synthesized and purified by standard methods[23] (m.p., 132–5°C).

SnCl₄.5H₂O was obtained from Pfaltz & Bauer and utilized without further purification. Found: Cl, 40.48; O, 22.44; H, 2.88; Calc.: Cl, 40.45; O, 22.82; H, 2.88%. Gold label acetonitrile was obtained from Aldrich Chemical Company and used without further purification.

Solutions. All solutions were prepared in class A volumetric flasks. Two sets of solutions were prepared for each study and IR spectra obtained from each solution. One set, containing ligand in ACN in the concentration range 0.003 to 0.012 M, was utilized to assign the N–O stretching frequency for each ligand. The absorbances from this set of solutions were also utilized in Beer's Law plots to determine the molar absorptivities at the frequency of the N–O stretching band for each free ligand.

The other set conisted of six to eight mixed solutions in ACN of SnCl₄·5H₂O and ligand in continuous variation concentration ratios of 0.002M metal + 0.010M ligand to 0.01M metal + 0.002M ligand. Two to five complete studies were utilized for each ligand.

Instrumentation. IR spectra were obtained in Wilks Scientific KBr precision sealed cells utilizing a Perkin–Elmer Model 283 grating IR spectrophotometer. In some cases matched cells were used to compensate for solvent absorption. Proton NMR spectra were obtained utilizing a Perkin–Elmer Model R32 spectrometer.

Method. ACN has a transmission window in the IR region between approx. 1300 and 1100 cm⁻¹. Fortunately this is the region, in which the very strong stretching absorption band of N-oxides appears. Coordination of N-oxides to metals causes a shift to lower frequencies of this absorption by 255–150 cm⁻¹.[21,22] Thus it is possible to determine free ligand concentrations and relative complexed ligand concentrations from measurements of absorbances of these bands. Details of these methods were given earlier.[22]

RESULTS

Table 1 contains a listing of the assigned N–O stretching frequencies of free and complexed ligands from this study. IR spectra of the ligand solutions were recorded and absorbances of the N–O stretching band, at the frequency for free ligand noted in Table 1, were determined utilizing the base line method.[23] Beer's Law plots of absorbance versus concentration were linear for all ligands.

IR spectra of the ACN solutions containing ligand and SnCl₄ were also recorded. The total concentration was limited to 0.012M due to the restricted solubility of the complexes. The concentration of free ligand in these solutions was determined from the measured absorbances of the free ν(N → O) band and the results of the Beer's Law plots. Relative concentrations of complexed ligand were determined from the absorbances of the complexed ν(N → O) band at the frequencies listed in the second column of Table 1. Continuous variation plots in the form absorbance at the frequency of the complexed band vs the mole fraction of ligand were then made for each complex.

Complex formation occurred in all cases but two distinct types of behaviour were observed. The 2, 3- and 4-picoline, 4-methoxy- and 4-phenylpyridine N-oxides were observed to form relatively strong complexes and exhibit maxima in continuous variation plots at a 2:1 ratio. Typical absorption spectra of these 2:1 type complexes in he 1100–1300 cm⁻¹ region are illustrated by those of the 2-picoline N-oxide complex shown in Fig. 1(a). The spectrum of the free ligand is shown in Fig. 1a(1). Two ligand bands appear superimposed upon the ACN spectrum in this region; an intense band at 1254 cm⁻¹, assigned to the predominantly N–O stretching mode, and a weaker band at 1222 cm⁻¹, assigned to C–H in-plane deformation.[24–27] Addition of SnCl₄·5H₂O causes a band at 1254 cm⁻¹ to appear as shown in Fig. 1a(2). Since solutions of SnCl₄·5H₂O are transparent in this region, this band is assigned to the N–O stretching mode of complexed ligand. As the ligand-to metal ratio is increased but the total concentration kept fixed, this band grows and reaches a maximum at a 2:1 ratio and diminishes thereafter as shown in Figs. 1a(2)–(4). Free ligand in these solutions is not detectable until a 2:1 ratio is exceeded.

Representative continuous variation plots for this series of complexes are shown in Fig. 2(a). Maxima occur close to a mole fraction of ligand corresponding to a 2:1 ratio. Some of these plots have rounded or irregular shapes possibly indicative of two or more absorbing species present in the solutions.

On the other hand, the 3 and 4-acetyl-, the 4-nitro- and the 4-chloropyridine N-oxides, the 2,6-lutidine N-oxide and the 2-pyridine methanol N-oxide ligands appear to form weaker complexes and exhibit maxima in continuous variation plots at a 1:1 ratio. Typical of complexes exhibiting this behaviour is the 4-acetylpyridine N-oxide complex. IR spectra in ACN for this ligand exhibit an assigned N–0 stretching band at 1262 cm⁻¹ and a C–H in-plane deformation band at 1170 cm⁻¹ as shown in Fig. 1(b)(1). Additions of SnCl₄·5H₂O to this ligand in ACN causes a relative decrease in the free N–O stretching absorbance and the appearance of an absorption band at 1212 cm⁻¹ attributable to the complexed N–O stretching band. Contrary to the former complexes, free ligand is detected in all complex mixtures studied. As the ligand-to-metal ratio is increased at constant total concentration, the absorbance of the band at 1212 cm⁻¹ increases, reaching a maximum at a 1:1 ratio and diminishing thereafter as shown in Figs. 1b(2)–(4).

Table 1. Assigned N–O stretching frequencies in cm⁻¹ of free ligand and ligand complexed to SnCl₄ in ACN solution

Ligand	(N→O) free	(N→O) complexed
2-picoline N-oxide	1254	1196
3-picoline N-oxide	1282	1255
4-picoline N-oxide	1259	1212
2,6-lutidine N-oxide	1250	1190
4-chloropyridine N-oxide	1258	1205
4-phenylpyridine N-oxide	1260	1215
4-methoxypyridine N-oxide	1230	1201
4-nitropyridine N-oxide	1287	1211
3-acetylpyridine N-oxide	1216	1184
4-acetylpyridine N-oxide	1262	1212
2-pyridine methanol N-oxide	1252	1210 & 1200

Some representative continuous variation plots of these complexes are shown in Fig. 2(b). All show maxima at 1:1 ratio and are less rounded than those from the complexes exhibiting 2:1 behaviour. There is some tailing of these plots at higher ligand mole fraction indicating the possible presence of small amounts of 2:1 or higher complexes in these solutions.

Table 2 gives the fraction of the total ligand that is uncomplexed, β, for various ligand-to-metal ratios for representative systems. For the 1:1 type complexes it can be seen that approximately 1/3 of the ligand remains uncomplexed at a 1:1 ratio while generally 1/2 and 2/3 remains uncomplexed at 2:1 and 3:1 ratios respectively. For the 2:1 type complexes no uncomplexed ligand is detected at a 1:1 ratio, and only approximately 15% and 40% remain uncomplexed at 2:1 and 3:1 ratios respec-

Fig. 2. Continuous variation plots for substituted pyridine 4-oxide complexes of $SnCl_4 \cdot 5H_2O$ in ACN solutions. 2a: representative complexes exhibiting 2:1 behavior: O, 4-picoline N-oxide complex; △, 2-picoline N-oxide complex; ×, 4-phenylpyridine N-oxide complex; ● data from integrated ^1H NMR spectra of 4-picoline N-oxide-$SnCl_4 \cdot 5H_2O$ complexes in 25% DMSO, 75% ACN. 2b: representative complexes exhibiting 1:1 behavior: O, 4-acetylpyridine N-oxide complex; △, 4-chloropyridine N-oxide complex; ×, 4-nitropyridine N-oxide complex.

tively. The distinction between the two types of complex behaviour is not always sharp. For example, 4-phenyl-pyridine N-oxide exhibits intermediate behaviour. It appears this ligand may form stronger 1:1 complexes than the typical 1:1 type complex but weaker 2:1 and higher complexes than the typical 2:1 type complexes.

Some independent investigations utilizing proton NMR and polarographic techniques provide some confirmation for the IR results and further insights into the behaviour of these systems. The solubility of these complexes in pure ACN is limited to approx. 0.02M but the concentration and, therefore, the sensitivity of the NMR probe may be enhanced ten-fold in a mixed solvent consisting of 25% dimethylsulphoxide (DMSO) and 75% ACN.

However, this solvent mixture does introduce high concentrations of DMSO, an excellent Lewis base.

These NMR studies were limited to 4-substituted pyridine N-oxide ligands due to the ease of interpretation of the spectra in the aromatic proton region. In all cases tetramethylsilane (TMS) was added as an internal standard and all chemical shifts are reported relative to TMS.

The NMR spectrum of 0.1 M 4-picoline N-oxide (4PNO) in ACN in the aromatic proton region exhibited the characteristic pair of doublets due to two pairs of equivalent ring protons with chemical shifts of 7.09, 7.16, 7.92 and 8.00 ppm. NMR spectra of solutions containing 0.01M $SnCl_4 \cdot 5H_2O$ and 0.02, 0.03, 0.04, 0.05 and 0.06M 4 PNO exhibited resonances characteristic of free ligand

Table 2. The fraction of the total ligand, β, that is uncomplexed in $SnCl_4 \cdot 5H_2O$-substituted pyridine N-oxide solutions in ACN for 1:1, 2:1 and 3:1 ratios

Ligand	Complex Type	$\beta 1:1$	$\beta 2:1$	$\beta 3:1$
2-picoline N-oxide	2:1	0.00	0.15	0.35
4-picoline N-oxide	2:1	0.00	0.09	0.38
4-phenylpyridine N-oxide	2:1	0.00	0.20	0.44
4-chloropyridine N-oxide	1:1	0.27	0.48	0.56
4-acetylpyridine N-oxide	1:1	0.26	0.56	0.64
4-nitropyridine N-oxide	1:1	0.32	0.62	0.76
2,6-Lutidine N-oxide	1:1	0.42	0.55	0.68

and an additional pair of doublets shifted downfield with chemical shifts of 7.55, 7.63, 8.48 and 8.56 ppm. The latter resonances were assigned to the aromatic protons of 4PNO complexed to $SnCl_4$. Chemical exchange processes are, therefore, relatively slow and aromatic proton environments on all complexed ligands appear either identical or very similar. Significant amounts of free ligand are detected only after the ligand to metal ratio exceeds 2:1. For example, a solution containing 0.03M 4PNO and 0.01M $SnCl_4$ exhibited a ratio of complexed to free ligand of approx. 1:1. The sensitivity of this technique was too low at these concentrations to obtain reliable quantitative data from integrated peak areas.

In the DMSO-ACN mixed solvent the solubility of the complexes is greatly enhanced and more reliable NMR data may be obtained. A series of solutions of 4PNO and $SnCl_4 \cdot 5H_2O$ in this solvent mixture were prepared with ligand and metal concentrations ranging from 0.04 to 0.20 M but with a total concentration of 0.24M as in a continuous variation study. Proton NMR spectra of these solutions in the aromatic proton region are shown in Fig. 3. Again a pair of doublets is observed for the free ligand in this region with chemical shifts close to those of 4PNO in pure ACN, 7.14, 7.21, 7.99 and 8.07 ppm. Addition of $SnCl_4 \cdot 5H_2O$ produces another pair of doublets due to complexed ligand with chemical shifts of 7.61, 7.69, 8.52 and 8.60 ppm respectively. Integration of each pair of doublets yields approximate concentrations of free and complexed ligand. These along with initial concentrations of metal and ligand and values of β are given for these solutions in Table 3.

A continuous variation plot of concentration of complex vs mole fraction ligand is superimposed on the plots from the IR results in Fig. 2(a), and is seen to be quite similar with a maximum at a 2:1 ratio. Similar results were obtained with 4-methoxypyridine N-oxide, which also exhibited behaviour characteristic of the 2:1 type complexes.

However, similar studies of solutions of $SnCl_4 \cdot 5H_2O$ and 4-nitro- or 4-acetylpyridine N-oxide in the mixed solvent indicated only free ligand was present, regardless of the ligand-to-metal ratio. The characteristic set of doublets in the aromatic proton region of the NMR spectrum due to free ligand showed no change in intensity and no change in chemical shift upon addition of $SnCl_4 \cdot 5H_2O$. Evidently these ligands, which exhibited behaviour characteristic of the 1:1 complexes in the IR study, form weaker complexes with $SnCl_4$ than do DMSO, 4PNO or 4-methoxypyridine N-oxide.

Polarographic studies of these systems in ACN at concentrations around one millimolar indicate the same two types of behaviour.[28] For those complexes exhibiting 2:1 behaviour, there is one reduction wave due to complexed ligand at approximately -0.33 V relative to a saturated calomel electrode (SCE) and significant free ligand is not detected until a 2:1 ratio is exceeded. For those complexes exhibiting 1:1 behaviour there is one reduction wave due to complexed ligand at approx. -0.29 V relative to the SCE and significant free ligand is

0.20	0.04	0.000	0.040	0.00

detected at a 1:1 ligand-to-metal ratio. All polarographic and NMR results are consistent with those from the IR studies.

DISCUSSION

It is somewhat surprising to find two fairly distinct types of behaviour for a series of complexes of a single metal species with ligands so similar to one another. Two generalizations may be drawn from the data collected and analyzed thus far: it appears that substituents on a pyridine N-oxide ring that are electron withdrawing to electron neutral induce the observed 1:1 behaviour while those that are electron releasing induce the 2:1 behaviour. Also the IR and NMR results indicate that ligands exhibiting 2:1 behaviour form stronger complexes with $SnCl_4$ than those exhibiting 1:1 behaviour. It is apparent that complexes containing 2:1 or higher ligand to metal ratios may exist for ligands exhibiting either type of behaviour. However, ligand molecules in these complexes appear to have identical or very similar environments as only one type of complexed species is detected by IR, NMR or polarographic techniques.

The application of standard methods[29] of determining stability constants assuming a simple model consisting of stepwise formation of 1:1 followed by 2:1 complexes was unsuccessful. Formation plots of $\bar{n}$ (total bound ligand/total metal)vs pL (negative logarithm of free ligand concentration) over the very limited concentration ranges studied revealed small plateaus for the 1:1 complexes at $\bar{n}$ values of 0.5 to 0.7 and at $\bar{n}$ values of 1.0–1.2. Formation plots for the 2:1 complexes could not be made for the concentrations utilized since free ligand was generally not detected until a 2:1 ratio was exceeded. Graphical elimination methods[30] assuming $N = 2$ gave scattered, inconsistent values of stability constants. It is apparent from these calculations that this simple model is invalid and the possibility of multi-nuclear complexes cannot be ruled out.

Recently a series of solid adducts of $SnCl_4 \cdot 5H_2O$ and various substituted pyridine N-oxides have been synthesized from tetrahydrofuran solution, purified and partially characterized in these laboratories.[31] The ligands studied include those exhibiting both 1:1 and 2:1 behavior in ACN solutions as described above. Elemental analyses indicate all complexes have a 2:1 ligand-to-metal ratio in the solid state. No water was observed in any of the adducts.

It is assumed that all 2:1 complexes exhibit an octahedral geometry and, therefore, consideration of *cis*-

trans isomerism is important. IR studies in the cesium bromide region may allow isomeric assignments for these complexes and the newly synthesized solid adducts and these studies are planned for the near future. However, a single crystal X-ray diffraction structure determination of the tetrachlorobis(4-picoline N-oxide) tin(IV) compound, presenttly in progress, has shed some light on this question. Density, space group and Patterson function determinations require the tin and oxygen atoms to occupy special positions which would require a *trans*-octahedral geometry. This complex in ACN solution exhibited the 2:1 type behaviour discussed above and it is assumed that it maintains the *trans*-octahedral geometry in solution.

It is felt that some elements of a model for this sytem may be gleaned from these results. The presence of two distinct types of behaviour suggests that consideration of *cis*–*trans* isomerism may be important. The evidence for multi-nuclear complexes suggests that bridging by chlorine atoms or the N-oxide oxygen atoms between two or more tin atoms may exist. Bridging by N-oxides to form dimers or polymers is known in some transition metal systems.[32-34]

The importance of $d\pi$–$p\pi$ bonding in tin complexes must also be considered. This bonding has been considered significant in some tin(II) and tin(IV) complexes but insignificant in others.[35] Evidence for multiple bonding in $SnCl_2$ complexes of substituted pyridine N-oxides includes very large red shifts in the N–O stretching frequencies upon coordination. These are attributed primarily to a weakening of the N–O bond due to donation of electron density from the d-orbitals of the Sn(II) species to a π^* orbital on the ligand.[21,22] $SnCl_4$ complexes of substituted pyridine N-oxides exhibit smaller shifts even though the d-electrons is $SnCl_4$ should be more stable than those in $SnCl_2$. This could be attributed to poorer orbital energy matching in $SnCl_4$ complexes between the d orbitals of tin and the lowest lying π^* orbital of the ligand, i.e. the π^* orbital is too high in energy for effective overlap. If this is the case electron withdrawing substituents on the pyridine N-oxide ring may destablilize the highest occupied bonding molecular orbital but stabilize the lowest unoccupied antibonding molecular orbital, enhancing $d\pi$–$p\pi$ bonding. If this bonding is an important component of the metal ligand bond, the *cis*-isomer would be favoured for octahedral complexes. This effect then could cause the ligands with electron withdrawing substituents to form *cis* 2:1 complexes while causing those with electron

neutral or donating substituents to form sterically less hindered *trans* 2:1 complexes.

The first step in the complex formation equilibrium scheme is undoubtedly replacement of an ACN molecule by the pyridine N-oxide ligand (L):

$$SnCl_4 \cdot 2ACN + L \rightarrow SnCl_4 \cdot L \cdot ACN + ACN. \quad (1)$$
Complexes resulting from step (1) containing those ligands with electron neutral or withdrawing substituents could then either add another ligand *cis* to the first, (2), or add another $SnCl_4$ group to form a bridged 1:2 complex, (3):

$$SnCl_4 \cdot L \cdot ACN + L \rightarrow SnCl_4 \cdot 2L(Cis) + ACN \quad (2)$$

$$SnCl_4 \cdot L \cdot ACN + SnCl_4 \cdot 2ACN \rightarrow (SnCl_4 \cdot ACN)_2 \cdot L + ACN. \quad (3)$$
Either of the resulting species from steps (2) or (3) could then form a bridged dimer:

$$SnCl_4 \cdot 2L(Cis) + SnCl_4 \cdot 2ACN \quad (4)$$

$$(SnCl_4 \cdot ACN)_2 L + L \quad (5)$$
where Py stands for a substituted pyridine ring.

The dimer, could be stabilized by multiple $d\pi$-$p\pi$ bonding involving two d-orbitals on each tin atom. The dimer could be destroyed by addition of further ligand to form a *cis*-octahedral complex:

$$(SnCl_4 \cdot L)_2 + 2L \rightarrow 2SnCl_4 \cdot 2L \ (Cis). \quad (6)$$

There is evidence from the formation plots for species such as that produced in step (3) and if the dimer formed from steps (4) and (5) is stable, this may explain why these ligands exhibit maxima in continuous variation plots at a 1:1 ratio. This proposed model would also allow the tin atom to maintain its favoured octahedral coordination geometry in all complex formation steps.

Complexes from step (1) containing those ligands with electron donating substituents would not be significantly stabilized by $d\pi$-$p\pi$ back bonding and so would form the *trans*-complex upon addition of another ligand molecule:

$$SnCl_4 \cdot L \cdot ACN + L \rightarrow SnCl \cdot 2L(trans) + ACN. \quad (7)$$
These complexes might also bridge to form multinuclear one-dimensional polymeric species

$$n(SnCl_4 \cdot L \cdot ACN) \rightarrow (SnCl_4 \cdot L)n + nACN. \quad (8)$$

However, if the *trans*-octahedral monomer is very stable, one would expect maxima in continuous variation plots at a 2:1 ratio as observed.

The 2,6-lutidine N-oxide molecule is the only ligand with severe steric crowding around the N-oxide oxygen atom. Examination of space filling models indicates it

would be very difficult for the N-0 bond in this ligand to maintain any double bond character while bonding to tin through sp^2 type orbitals. This would mean $d\pi$-$p\pi$ back bonding would be very unlikely in this complex. The fact that 2,6-lutidine forms 1:1 type complexes even though it contains electron releasing substituents may be due to the existence of a relatively stable 5-coordinate 1:1 complex which is favoured because it is sterically less hindered than the expected *trans*-2:1 complex.

The determination of the validity of this model awaits further experimental results. Experiments are presently planned to attempt to synthesize and characterize solid 1:1 adducts of these complexes and to determine the number of significant species in these solutions and the stability constants of these species utilizing more precise experimental techniques.

KINETICS OF THE PHOTOAQUATION OF HEXACYANOFERRATE(II) ION

VILMOS GÁSPÁR and MIHÁLY T. BECK*

Institute of Physical Chemistry, Kossuth Lajos University, H-4010 Debrecen, Hungary

Abstract—Kinetics of the photoaquation of hexacyanoferrate(II) ion in aqueous solution were studied potentiometrically and spectrophotometrically. Supposing the simplest mechanism (see Fig. 3. in text), the photoaquation in alkaline medium can be well described. The value of the constants at pH = 11.0 are: $\phi = 0.8$–1.0, $k_6 = (3.0 \pm 0.5) \times 10^{-8} \text{ s}^{-1}$ and $k_{-6} = 1.5 \pm 0.2 \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$. To describe the photoaquation in neutral medium the scheme was extended ($k' = 3.33 \times 10^2 \text{ mol}^{-1} \text{ dm}^3 \text{s}^{-1}$). The quantum yield in acidic medium can be calculated by combination of ϕ values of different protonated complexes. The reversibility of photoaquation in alkaline medium is also explained by the scheme.

The photosensitivity of different cyanocomplexes is well known. The kinetics and mechanism of these photochemical reactions have been intensively studied for a long time.[1] Nevertheless, the reversible photoaquation of hexacyanoferrate(II) ion is still an unsolved problem. The following primary photoprocess was established:

$$[Fe(CN)_6]^{4-} \xrightarrow[H_2O]{h\nu} [Fe(CN)_5H_2O]^{3-} + CN^-.$$
On illumination the concentration of aquapentacyanoferrate(II) ion reaches to a well-defined value, but after interrupting the illumination the concentration decreases.[2] Illuminating an alkaline or a neutral solution of the complex, the pH increases due to the hydrolysis of cyanide ion formed. In the next dark period the pH decreases. According to Asperger[3] the characteristic changes in the concentration of complex and in pH are totally reversible while MacDiarmid and Hall[4] found only partial reversibility.

Asperger followed the changes of pH and established some qualitative conclusions, namely:

—the initial rate of photoprocess and the maximum concentration of free cyanide ion increased with increasing initial concentration of complex,

—the initial rate of reversible dark (thermal) reaction decreased with increasing total concentration of complex.

Different quantum yields (ϕ) were determined with different methods (Table 1). Explanation of the dependence of ϕ on the pH has not yet been given.

The reasons for the contradictions are as follows:

(a) *The light was not monochromatic.* The authors should have taken into account the disturbing effect of photooxidation. On illumination with light of shorter wavelength than 330 nm, only the photooxidation occurs according to Stein.[5] The photoaquation takes place on illumination with longer wavelength light.

(b) *The atmosphere was not inert*, and the effect of thermal oxidation was not eliminated. Toma[7] found that trace amounts of iron(II) ion strongly catalysed the oxidation of aquapentacyanoferrate(II) ion even in the dark.

(c) *The reagents used* (sodium azide,[7] nitrosobenzene,[2] 2,2'-dipyridyl and 1,10-phenanthroline[8]) *considerably*

influenced the studied systems since they react with the components of them.

Under such experimental conditions the kinetic data calculated from the concentration versus time curves are contestable. One cannot separate the effects of different reactions such as thermal dissociation, thermal and photochemical oxidation, photoaquation, reversible thermal reaction between the products and the substitution reactions with reagents.

Sodium aquapentacyanoferrate(II) monohydrate (the so-called Hofmann salt) is the reference compound for spectrophotometric determination of the concentration of primary product. The preparation and purification of the complex are further problems since it is not very stable in the solid state.[7] In an inert atmosphere, sodium azide cannot be used as a reagent according to the results of Jaselkis[9] and Swinehart.[10] They indicated that the reaction between azide ion and aquapentacyanoferrate(II) ion does not occur in the absence of oxygen.

Nitrosobenzene is not a suitable reagent, either. In the standard procedure, mercuric chloride is used as a catalyst since the mercuric ion accelerates and reaction between the primary product and nitrosobenzene. The problem here is that the velocity of the catalysed reaction depends on pH and the negative effect of chloride ion must also be considered according to Hadjiioannou.[11] Moreover, some investigations[12] indicated that the uncatalysed reaction between the aquapentacyanoferrate(II) ion and the reagent strongly depends on pH and there is also a slow reaction between hexacyanoferrate(II) ion and nitrosobenzene.

By the use of monochromatic irradiation (365 nm), an inert atmosphere (argon) and potentiometric monitoring of pCN⁻ and pH, the reaction could be followed in alkaline medium without perturbing the system. In nearly neutral solutions the processes were followed by a pH potentiometric method since the cyanide ion-selective electrode shows anomalous behaviour at lower pH[13]. In acidic medium the reaction was followed by measuring the absorbance of primary product.

EXPERIMENTAL

The light source was a HANOVIA 6515–36–A type medium-pressure mercury lamp (preheated for 15 min). The light was filtered with a solution filter system containing two solutions such as 0.31 mol dm⁻³ copper sulphate and 3.1×10^{-4} mol dm⁻³ tris-phenanthrolineiron(II) ion in acetate buffer at pH = 4.0. The two solutions were divided by a glass wall as in the presence of

copper(II) ion the iron(II) complex decomposes on illumination. The transmission of the filter system has a maximum at 365 nm. The intensity of light was measured by the ferrioxalate method.[14] Its value was 5.0×10^{-11} mole of photons (365 nm)/cm^{2}s^1.

The solutions were kept under argon atmosphere in a dark glass cuvette ($5 \times 3.7 \times 9.8$ cm) that was thermostatted (298 ± 0.1 K). A magnetic stirrer was used. The volume of irradiated solutions was constant (120 cm^3). The distance between the lamp and the cuvette was 13 cm.

Before following the photoaquation in alkaline medium, the pH values of the nearly neutral aqueous solutions were set to 10.5–11.0 by adding a few drops of 1.0 mol dm^{-3} carbonate-free sodium hydroxide solution. The free cyanide concentration was monitored potentiometrically by using an OP–711–D–I Radelkis ion-selective electrode and radiometer Type K 401 saturated calomel electrode with an OP–205 Radelkis mV-meter (reproducibility was ± 0.5 mV). The pH was measured by a combined glass electrode (GK 2301 B Radiometer) and PHM 51 Radiometer mV-meter (reproducibility was ± 0.1 pH).

The solutions were prepared in acetate buffer (pH = 4.0) for following the photoaquation in acidic medium. A Hitachi-Perkin-Elmer 139 single beam spectrophotometer was used for actinometry and determination of the concentration of primary product ($\epsilon_{440\,nm} = 640$ mol^{-1}dm^3). The optical length of the flow cell was 0.51 cm.

RESULTS AND DISCUSSION

In aqueous solution of hexacyanoferrate(II) at pH values from 10 to 12, there is a slow aquation reaction even in the dark. On illumination the rate of aquation increases. If the illumination period is short, the increase of cyanide ion concentration continues in the dark until the equilibrium state is attained. If the illumination period is long enough, the concentration of cyanide reaches a higher value than that which corresponds to the dark equilibrium (Fig. 1). The system returns to the equilibrium state when the illumination is interrupted. This alternating increase and decrease of cyanide concentration can be repeated several times.

The pH changes similarly in nearly neutral solution (pH = 7–7.5) of hexacyanoferrate(II) ion on illumination (Fig. 2). If the dark period is long enough, after illumination the pH decreases to the initial value. If the system was in thermal equilibrium before illumination, the change of pH is completely reversible.

The behaviour of this system can be quantitatively described by the following scheme (Fig. 3): where I_c is the average number of moles of photons (365 nm) absorbed by the complex per unit volume and unit time. In our experiments it amounts to 1.5×10^{-8},* as the excited complex ion, k_6, k_{-6} is the reaction rate constants (rrc) of thermal reactions, k_r is the rrc of the recombination reaction, k_f is the rrc of the products forming reaction, K_d is the dissociation constant of hydrogen cyanide at a certain ionic strength.[13]

Introducing the quantum yield as $\phi = k_f/(k_f + k_r)$ and applying the steady-state approximation for the concentration of the excited complex, the following rate equation is obtained:

$$-\frac{d[Fe(CN)_6]^{4-}}{dt} = \frac{d[Fe(CN)_5H_2O]^{3-}}{dt} = \phi I_c + k_6[Fe(CN)_6]^{4-} - k_{-6}[Fe(CN)_5H_2O]^{3-}[CN^-].$$

If the total concentration of cyanide (T_{CN}) is known at a certain time, the concentrations of hydrogen cyanide, cyanide ion, hydroxide ion and proton can be calculated as the components of an acid-base equilibrium system. T_{CN} is always equal to the concentration of aquapentacyanoferrate(II) ion.

On illumination, the system approaches the photostationary state when the following equation is valid:

$$\phi I_c + k_6[Fe(CN)_6]^{4-} = k_{-6}[Fe(CN)_5H_2O]^{3-}[CN^-].$$

In the dark, changes occur towards thermal equilibrium.

The exact values of the constants (ϕ, k_6, k_{-6}) were calculated by a least-squares method from the linear algebraic system of equations given for the parameters. The calculation of kinetic curves was based on the required combination of the fourth-order Runge–Kutta and the Newton–Raphson numberical methods.[15]

As shown in Fig. 4, there is excellent agreement between the experimental (full circles) and calculated (line) concentrations of cyanide ion, when ϕ, k_6 and k_{-6} are 0.8–1.0, 1.5 ± 0.2 mol^{-1}dm^{3}s^{-1} and $(3.0 \pm 0.5) \times 10^{-8}$ s^{-1}, respectively.

To characterize the conversion of the aquation process it is convenient to introduce the kinetic mean coor-
Fig. 1. The change of e.m.f. in hexacyanoferrate(II) solution C: 0.1 mol dm^{-3}, pH$_0$ = 10.75, (a) on irradiation (365 nm), (b) after interrupting the illumination.
Fig. 2. The change of pH of hexacyanoferrate(II) solution. C: 0.1 mol dm^{-3}, pH$_0$ = 7.85, (a) on irradiation (365 nm), (b) in the dark reaction, after illumination.
Fig. 4. Experimental (●) and calculated (line) cyanide ion concentrations in 0.1 mol dm^{-3} hexacyanoferrate(II) solution at pH$_0$ = 10.75 on illumination and in the next dark period. Dashed line: the change of the kinetic mean coordination number ($\bar{n}_t$). Values of ϕ, k_6 and k_{-6} are 1.0, 3.0×10^{-8} s^{-1} and 1.5 mol^{-1} dm^{3}s^{-1}, respectively.

Fig. 3. The scheme of photaquation reaction.

dination number ($\bar{n}_t$):

$$\bar{n}_t = \frac{T'_{CN} - CN_t^-}{T_{Fe}},$$

where T'_{CN} and T_{Fe} are analytical concentrations and CN_t^- is the free cyanide concentration at a certain moment.

The conversion both of the photo and the thermal (dark) reaction is extremely small (0.112 and 0.045%, respectively). Nevertheless, these very small changes of $\bar{n}_t$ can be quite exactly determined because of the high sensitivity of the cyanide ion-selective electrode and the
Fig. 5. The change of pH of hexacyanoferrate(II) solution. C: 0.1 mol dm^{-3}, pH$_0$ = 7.0 *on*: on illumination, *off*: after illumination E: experimental, B: calculated curve using the constants determined in alkaline medium (Fig. 4), M: calculated by the extended scheme.

large total concentration of the complex. The very small value of conversion is responsible for the fact that no satisfactory kinetic investigation was made earlier. It follows from the kinetic data that the stability constant of the sixth complex (K_6) is $(5.2 \pm 1.5) \times 10^7$ mol^{-1} dm^3. This value differs somewhat from that predicted theoretically (1.41×10^6)[16] or earlier determined experimentally (2×10^9).[18]

Because of the differences between the experimental and calculated (based on the constants determined in alkaline medium) curves in nearly neutral medium, the scheme should be extended by the following reaction:

$$[Fe(CN)_5H_2O]^{3-} + HCN \xrightarrow{k'} [Fe(CN)_6]^{4-} + H_2O + H^+,$$
$k' = 3.33 \times 10^{-2}$ mol^{-1} dm^3 s^{-1}. The correlation between the experimental and calculated photostationary pH-values is good. The quantum yield of hydroxide production (0.17) agrees with the literature value.[1]

When illuminating an acidic solution (pH = 4.0) of the complex, a photostationary state was not reached. After interrupting the illumination, the absorbance of primary product did not decrease but slowly increased. The reason for this situation is the continuous formation of hydrogen cyanide that is continuously taken away by the bubbled argon gas.

Figure 6 shows a typical absorbance versus time curve at 0.01 mol dm^{-3} complex concentration. Assuming zero order photodecomposition, the calculated ϕ value is 0.85–0.95 at pH = 4.0 and, in the range of complex concentration 0.01–0.015 mol dm^{-3}, in good agreement with Ohno.[7]

From a comparison of the curve relating quantum yield in acidic medium (ϕ_a) to pH with the distribution curves of the different protonated hexacyanoferrate(II) complexes,[17] it seems possible that the decrease of ϕ_s with decreasing pH is connected with the occurence of differently protonated complexes.

Introducing the $\bar{n}_H/\bar{n}_{H,max}$ ratio to characterize the degree of protonation, the ϕ_a values can be calculated by the following expression:

$$\phi_a = \phi_b \left(1 - \frac{\bar{n}_H}{\bar{n}_{H,max}} \right)$$

where ϕ_b is the quantum yield determined in alkaline solution at the same concentration of complex, and $\bar{n}_{H,max}$ equals 4.

The calculated and determined values agree, considering the experimental error of measuring the protonation constants and ϕ (Fig. 7).

Comparing the ϕ_s vs pH curve with the distribution curves it follows that $\phi_{H_1} \sim 0.8$, $\phi_{H_2} \sim 0.6$, $\phi_{H_3} \sim 0.5$ and $\phi_{H_4} \sim 0$.

The ϕ_a value at a certain pH is the weighted average of the ϕ_{H_i} values ($i = 1,.., 4$).

ACID-BASE STUDIES OF SOME
SILYLAMINES RNHSiMe₃

KEITH J. FISHER*
University of Khartoum, Sudan, Africa

and

CHIKE E. EZEANI[1]
University of Lagos, Nigeria, Africa

Abstract—The interactions of silylamines with phenol and iodine have been studied. Enthalpies of reaction have been determined and used to calculate E and C values for these bases. The calculated enthalpies with chloroform and trimethylaluminium indicate that the alkylsilylamines may not be weaker bases than corresponding aliphatic amines.

There have been several studies involving the acid-base interactions of organosilylamines (R_3SiNHR' and R_3SiNR_2') with Lewis acids.[2-6] The major acid studied has been chloroform; enthalpies of mixing, NMR shift data and C-D IR shift data have been produced.

The heat of mixing of the base using chloroform as both acid and solvent is not a simple property, and the results would differ markedly from those of a study of the chloroform base interaction in an inert solvent. Drago[7] has shown that C-D IR stretching frequencies cannot be used as a reliable estimate of the enthalpy of adduct formation with a wide variety of bases. Drago[7] has also shown that NMR data can also be an unreliable measure of enthalpy. In one NMR study[5] carbon tetrachloride was used as solvent. This solvent is known to have a specific interaction with amines and our study has shown that this is the case for silylamines.

Since many spectroscopic studies have been carried out with iodine and phenol, we set out to investigate these acids with silylamines. As the silylamines are sensitive to hydrolysis exceedingly dry conditions were used. The solvents chosen were hexane and cyclohexane which could be dried thoroughly and acted as non-interacting solvents. Iodine-silylamine studies indicated a 1:1 interaction but on standing over several hours secondary changes occurred. Freshly prepared and mixed solutions were used throughout this study. Similarly, IR studies with phenol indicated the initial formation of an adduct but on standing the adduct disappeared.

Enthalpy data were obtained for the interaction of several silylamines with these acids, and the Drago equation[7] was used to calculate E and C values for the bases.

EXPERIMENTAL

All operations were carried out under either dry nitrogen or under vacuum.

Hexane and cyclohexane were stored over sodium, distilled before use and further stored over Linde 4A molecular seives.

Phenol and iodine were sublimed under vacuum before use. Pyrrole was fractionally distilled and stored over Linde 4A molecular seives.

The secondary amines, RNHSiMe₃ were prepared by the reaction of chlorotrimethylsilane with primary amines and were distilled before use. Hexamethyldisilazane and N, N-diethyltrimethylsilylamine were purchased from Aldrich Chemical Company and distilled before use. All physical properties of the amines corresponded to literature values and gas chromatography was used as a further check on purity.

Phenoxytrimethylsilane was prepared by the reaction of phenol with trimethylchlorosilane.

Infrared studies were carried out using 1 cm pathlength solution cells with sodium chloride windows. Scale expansions were used when measurements of $\Delta\nu_{OH}$ were being made. As the O-H absorption band was generally weak and well removed from the free O-H absorption of phenol, no problem of overlap was experienced. Generally solutions of approximate concentrations of 1 to 5×10^{-3} molar were used. Similar measurements were made with pyrrole.

Visible studies of iodine with the bases were carried out on a PMQ3 spectrophotometer at 525 nm. Acid and base solutions of varying concentrations were used to determine equilibrium constants. Enthalpies were determined by carrying out the reactions at seven temperatures in the range 290–330°K. The results were treated by the least-squares method to obtain the slope of log K vs 1/T, and correlation coefficients were calculated.

RESULTS AND DISCUSSION

The values of $\Delta\nu_{OH}$ for the interaction of the amines with phenol and those for $-\Delta H$ (kcal mol⁻¹) determined from $\Delta\nu_{OH}$ are shown in Table 1. Also shown in Table 1 are the equilibrium constants for the interaction of iodine with the amines at 303°K in cyclohexane. The enthalpy values calculated from a Van't Hoff plot are also shown in Table 1.

The IR studies with phenol indicated the initial formation of an adduct but on standing the absorption for the adduct disappeared. This reaction was investigated and the final products of the reactions were shown to be a primary amine and $(CH_3)_3SiOC_6H_5$. $(CH_3)_3SiOC_6H_5$ was prepared by another method and gas chromatography was used to show that this was a product of the reaction. Cyclohexane was chosen as solvent after studies in carbon tetrachloride indicated lower equilibrium constants and lower heats of about 1.2 kcal per mole. This indicates that, as with pyridine,[7] there is an interaction of the silylamines with carbon tetrachloride (slightly greater than that with pyridine).

Using pyrrole as acid only two adducts were observed, with hexamethyldisilazane and with PhNHSiMe₃. The

C$_6$H$_5$NHSiMe$_3$	195	5.18	37.2	5.65

a) Erratic results giving a correlation coefficient of only 0.84.

b) Results with this base were inconsistent.

shifts of the N–H vibration of pyrrole, $\Delta\nu_{NH}$, were 130 and 97 cm^{-1} for hexamethylsilazane and PhNHSiMe$_3$ respectively. These lead to heats of interaction of 3.54 and 3.13 kcal mol^{-1}.

Some studies were carried out with p-chlorophenol and these gave similar results to phenol. As p-chlorophenol is not a significantly different acid from phenol, the data was not used quantitatively but used to indicate the reliability of the phenol data.

The visible spectra studies with iodine were also conducted in cyclohexane and selected results in hexane gave similar values. Studies with the amines and iodine indicated an isobestic point at approximately 485 nm. As with the phenol studies, fresh solutions were used in the measurements, as on standing a secondary reaction seemed to occur. Initial iodine concentrations of 1×10^{-3} molar and varying concentrations of base of approx. 3×10^{-3} molar were used in the studies. The data for change of equilibrium concentration with temperature were treated by a least-squares method and gave results shown in Table 1. With the exception of the isobutyl derivative and hexamethyldisilazane, they gave correlation coefficients of 0.99. With the isobutyl compound, there was a correlation coefficient of only 0.84. Hexamethyldisilazane gave inconsistent results and so $-\Delta H$ was not calculated for this base.

Early work in this area by Jarvie[2] examined the heats of mixing of various alkylamines and silylamines with chloroform using chloroform as both solvent and reference acid. The conclusion drawn was that "the alkylsilylamines are in general weaker bases than aliphatic amines". The problem is that the acid as solvent complicates the data as shown in the following Born–Haber cycle:

$$A_{(g)} + B_{(g)} \xrightarrow{\Delta H_{AB}} AB_{(g)}$$
$$\Delta H' \uparrow \qquad \uparrow \Delta H'' \qquad \downarrow \Delta H_{(solv)}$$
$$A_{(solv)} + B_{(solv)} \xrightarrow{\Delta H_0} AB_{(solv)}.$$
The observed enthalpy in solution ΔH_0 will be the sum of all the other terms.

$$\Delta H_0 = \Delta H_{AB} + \Delta H_{(solv)} + \Delta H' + \Delta H''.$$

Thus if ΔH_0 is approximately to equal the gas phase

enthalpy of adduct formation, ΔH_{AB}, the sum of $\Delta H_{(solv)}$, $\Delta H'$ and $\Delta H''$ must be approximately zero. $\Delta H''$ will differ markedly with the base used, but $\Delta H'$ will remain constant and $\Delta H_{(solv)}$ should not be a large term and remains fairly constant unless some specific interactions are occurring.

To highlight this problem, the enthalpy of triethylamine (one of the amines measured in Jarvie's study) with chloroform in an inert solvent has been measured.[8] Jarvie obtained a value of 0.87 kcal mol^{-1} whereas the later measurement gave a value of 4.8 kcal mol^{-1}. This discrepancy throws into doubt the work of Abel[4] where a correlation of the heat of mixing with the proton dilution shift gave a straight line.

Andrianov[5] et al. confirmed that NMR measurements of proton shifts of silylamines in chloroform do not correlate with estimated values of pKa; after assuming the heats of mixing correlated with proton shifts. Kelling[6] et al. have attempted a correlation of $\Delta\nu_{C-D}$ and $\Delta\nu_{N-H}$ values as a measure of the basicity of similar silylamines. Drago[7] has shown that C–D infra shifts do not correlate with other data such as the O–H shift with phenol and the N–H shift with pyrrole.

Thus all the previous studies have only been able to show the basic conclusion given by Jarvie, "the alkylsilylamines are weaker bases than aliphatic amines".

Using our data we may calculate E and C values (Table 2) and compare them with other aliphatic amines. We may also use these values to calculate possible enthalpies with acids not measured and compare those values with the enthalpies available for the interaction with aliphatic amines with those acids. Having only two sets of data for two different acids allows an easy solution of the E and C equation but these values must be regarded as only tentative until more data is available.

Our data produce only one test of the calculated E and C values and that is the heat of interaction of pyrrole with PhNHSiMe$_3$. The value obtained was 3.13 kcal mol^{-1} and that calculated from the E and C values was 3.27 kcal mol^{-1}. Although the difference is slightly greater than 0.1 kcal mol^{-1} it shows that the E and C values calculated are of the correct order of magnitude.

One observation from Table 2 is that Jarvie's statement is questionable. Two very different acids, CHCl$_3$

Table 2. E and C values for amines and calculated heats of interaction of the amines with chloroform and trimethylaluminium

Compound	$E_B{}^a$	$C_B{}^a$	$-\Delta H{}^b$ CHCl₃	$-\Delta H{}^b$ Al(CH₃)₃

c) Values taken from ref. 8.

and Al(CH₃)₃, give similar interactions with the aliphatic amines and the silylamines. The only silylamine that stands out as being markedly weaker is the phenyl derivative. The changes of E_B and C_B show no distinct pattern: the aliphatic amines show an increase in the C_B value on going from a secondary amine to a tertiary amine but the reverse seems to be the case for EtNHSiMe₃ and Et₂NSiMe₃. The silylamines show an increase in E_B and a decrease in C_B as the alkyl group changes from methyl to ethyl to isopropyl, but the t-butyl derivative shows a marked decrease in E_B with an increase in C_B.

SYNTHESIS AND CHARACTERIZATION OF A NEW IRON (II)—DINITROGEN COMPOUND WITH PDTA AS LIGAND

M. CARMEN PUERTA,* M. F. GARGALLO and F. GONZALEZ-VILCHEZ

Departamento de Química Inorgánica, Facultad de Ciencias, Universidad de Cadiz, España

Abstract—A new dinitrogen complex of formula $Na_2[Fe(PDTA) (N_2)] (H_2O)_2$ has been synthesized in aqueous solution from [Fe(H-PDTA) (H_2O)], $3/2H_2O$ and NaN_3. The complex has been characterized by chemical analysis, IR and electronic spectra, and magnetic measurements. The thermal decomposition process has been studied by using DTA and TG techniques. The evolution of gases was followed by Gas Chromatography.

Since Allen and Senoff[1] isolated the first dinitrogen complex in 1965, a great interest has been awakened in the clear possibility of carrying out the "fixation" of this molecule by means of coordination compounds.[2-4]

It is a well-known fact that the enzymological fixation of nitrogen requires the presence of Fe and Mo and that the means of the reaction is water. For this reason in chemical nitrogen-fixing systems the synthesis of nitrogen complexes in an aqueous medium is of great interest at the present time.

Numerous works[5-8] have been published on dinitrogen compounds with ligands of a simple aminic type $[M(NH_3)_5(N_2)]^{2+}$, but there are no bibliographical antecedents on dinitrogen compounds which contain complexones as ligands. Only Diamantis[9] showed recently and during the course of our own investigations, the great avidity of the complexone EDTA to act as a pentadentate ligand in dinitrogen complexes, obtaining the species $[Ru(EDTA) (N_2)]^{2+}$ and $[(EDTA)Ru-N_2-Ru(EDTA)]^{4+}$ in an aqueous solution.

In our work a general method of synthesis has been used based on the conversion to coordinate N_2 of a ligand which has a nitrogen-nitrogen link,[10] and the compound $Na_2[Fe(PDTA) (N_2)]^2(H_2O)$ from [Fe(H-PDTA) (H_2O)] $3/2H_2O$ using sodium azide (NaN_3) in an aqueous solution has been synthesised.

EXPERIMENTAL

$Fe(NO_3)_3 \cdot 9H_2O$ and NaN_3 were obtained from Merck, and PDTA-H_4 from Fluka BDH Chem. Ltd. Both of them were used without further purification.

DTA was performed in a Stanton Redcroft 673-4 thermobalance, and TG in a Cahn RG electrobalance. The gases evolved were analysed in a Hewlett-Packard 5700 A chromatograph.

IR spectrum was recorded in the 4000–$400 \, cm^{-1}$ region using a Perkin–Elmer 577 double beam instrument. The sample was prepared as KBr pellet.

Electronic spectrum was recorded on a Perkin–Elmer 124 spectrophotometer using 2 cm quartz cells, and water as reference.

A Gouy balance was used for magnetic measurements at room temperature. The ESR spectrum at room temperature and 77 K were recorded at the Instituto de Catálisis y petroquímica Rocasolano (C.S.I.C.), Madrid.

C, H, and N analysis were performed at the Departamento de Microanálisis del Instituto de Química Orgánica General del C.S.I.C., Barcelona. Iron was determined by gravimetry and by

atomic absorption spectrometry. Sodium was determined by Flame spectrophotometry. The water content was determined in a Karl–Fischer titrator, and confirmed by TG.

Synthesis of $Na_2[Fe(PDTA) (N_2)] \cdot 2H_2O$

0.750 g. of [Fe(H-PDTA) (H_2O)], $3/2H_2O$,[11] were dissolved in 25 cm³ of water heated in double saucepan at 40°C. To the resulting green solution, 0.750 g. of solid NaN_3 were added, precipitating then a reddish compound that dissolved almost immediately. The mixture was heated in a double saucepan at 50°C for 3 min, cooled in the refrigerator and when the first microcrystals appeared, 25 cm³ of absolute ethanol were added. The orange-coloured microcrystalline product was filtered and washed with absolute ethanol, and dried on phosphorous pentoxide. Found: Fe, 11.8; Na, 9.6; C, 28.2; H, 3.2; N, 12.0; H_2O, 7.7. Calc.: Fe, 11.9; Na, 9.7; C, 28.2; H, 3.8; N, 12.0 H_2O, 7.7%.

RESULTS

Thermal behaviour

The DTA curve (Fig. 1) obtained in an atmosphere of He, shows the existence of several endothermic effects. The first of these, at 130°C, probably corresponds to the elimination of water of crystallization. The second effect is registered at 220°C and can be attributed to the loss of the coordinated dinitrogen molecule, since decarboxylation in these conditions takes place at higher temperatures, according to what can be remarked in the remaining endothermic effects in the diagram.

The thermogravimetric curve (Fig. 2), shows two not very pronounced jumps between 120 and 240°C to which there corresponds loss of weight of 7.7 and 5.9% respectively, so they can be associated with the elimination of hydration water and coordinated dinitrogen. From 300°C pyrolysis of the compound begins and continues up to 500°C.

These results were corroborated by means of gas chromatography and by volumetric determination of dinitrogen in the complex, following a similar method to that used by Allen,[8] and whose results are included in Table 1. The determinations performed with the recently prepared complex (A) and after three months in a desiccator (B), allow us to deduce that the compound decomposes slowly on contact with air, although long periods of time are necessary for the decomposition to be significant.

IR spectra

In Fig. 3 the IR spectrum of the compound $Na_2[Fe(PDTA) (N_2)] \cdot 2H_2O$ is represented, and in Table 2 the most significant data of the same are shown.

At $3400 \, cm^{-1}$ a wide band can be observed which

corresponds to the vibrations of symmetrical and asymmetrical stretching of the O–H link of the crystallization water.

The bands which correspond to the stretching vibrations of the methylene groups have a similar intensity, which suggests an analogous character among all the methylene groups of the ligand.

The characteristic absorption of the dinitrogen complexes which appears between 2100 and 1900 cm^{-1}, corresponds to the stretching vibration of N $\equiv$ N. The intensity and frequency of this band indicate the degree of covalency of the metal–nitrogen link.[12,13] The said band is registered in this compound at 2030 cm^{-1} with medium intensity, which seems to suggest a moderate overlapping of the metal "d" orbitals with the π^* of the N_2 and as a result of this a not very pronounced degree of covalency for the metal–dinitrogen link.

At 1620 cm^{-1} a band appears which can be attributed to the assymetrical stretching vibration of the carboxylate groups. The difference between the latter and the most intense peak which corresponds to the symmetrical vibration of the $-COO^-$ groups which is recorded at 1390 cm^{-1}, (225 cm^{-1}), suggests a moderately covalent link in the carboxylate–metal combinations.

UV and visible spectra

The Fe(II) in the $Na_2[Fe(PDTA)(N_2)] \cdot 2H_2O$ complex, is a d^6 system of low spin and fundamental term $^1A_{1g}$. The formation of this type of compound (t_{2g}) of low spin is favoured by ligands with an intense field, which facilitate besides the reduction of the electronic density on the metal, that is to say the electronic back-bonding from the "d" orbitals of the metal to the empty (π^*) orbitals of the ligand.

The absorption spectrum in an aqueous solution (Fig. 4) shows a not very intense band at 460 nm (21700 cm^{-1}), $\epsilon = 71$, due probably to the transition $^1A_{1g} \rightarrow {}^1T_{1g}$. In the UV region there appears a band at 38500 cm^{-1} and another in the form of a shoulder, at 221 nm (45400 cm^{-1}) which through their energy and intensity can be considered as charge-transfer bands.

Study of the magnetic properties

In the Fe(II) compound of low spin, there exists no Zeeman effect of the first order ($J = S = 0$) and the magnetic susceptibility is due therefore the Zeeman effect of the second order.

The corrected magnetic molar susceptibility of the diamagnetism of the ligand, of the ion Na^+ and of the water molecules, has a value of 78.3 X_M to which there corresponds an effective magnetic momentum of 0.38 B.M.

The diamagnetism of this compound has been checked in addition by spectroscopy of ESR, which only registers a very weak signal due perhaps to the impurities of Fe^{3+}.

OPTICAL ABSORPTION SPECTRA OF PRASEODYMIUM ACETATE COMPLEXES IN SOLUTION

S. V. J. LAKSHMAN* and S. BUDDHUDU

Spectroscopic Laboratories, Department of Physics, S. V. University, Tirupati 517 502, India

Abstract—Results of analyses of the solution spectra of Pr^{3+} in the acetates of praseodymium, magnesium, calcium and cadmium complexes are presented. Slater–Condon (F_2, F_4 and F_6), configurational interaction (α, β), spin–orbit (ζ_{4f}), nephelauxetic ($\bar\beta$), bonding (δ) and Judd–Ofelt (T_2, T_4 and T_6) intensity parameters are evaluated. Judd–Ofelt intensity relationship has been used in the calculation of electric dipole line-strengths. Theoretical evaluation of predicted radiative lifetimes (τ_R) of the electronic excited states $^3P_1$, $^3P_0$ and $^1D_2$ of Pr^{3+} in four different hosts has been carried out.

Carnall et al.[1] correlated the experimental and theoretical (Judd–Ofelt) intensities of the solution absorption spectra of Pr^{3+} in ethyl acetate. Paramagnetic resonance studies on the mixed complexes of praseodymium acetate have been reported by Maiti et al.[2] Surana et al.[3] have studied the solution absorption spectrum of Pr^{3+} in haloacetates and reported the interacting, bonding and intensity parameters.

Since the optical absorption studies have not previously been reported in the literature for Pr^{3+} in $Mg(C_2H_3H_2)_2$, $Ca(C_2H_3O_2)_2$ and $Cd(C_2H_3O_2)_2$ complexes, the authors have carried out this investigation. For the first time, the second derivative spectra of these Pr^{3+} complexes have been studied.

EXPERIMENTAL

One mole% of praseodymium acetate (99.99% purity) was introduced into the saturated solutions of magnesium acetate, calcium acetate and cadmium acetate. One mole% praseodymium acetate was also separately prepared for the present investigation.

The UV-visible spectra from 3500 to 6500 Å were recorded on a Perkin–Elmer 551 recording spectrophotometer. Using a derivative accessory, second derivative spectra were also recorded in this wavelength region. The NIR spectra from 11,000 to 5000 cm^{-1} were recorded on a Carl–Zeiss Specord 61 recording spectrophotometer. Since there is no derivative accessory for this instrument, only normal spectra were recorded in this wavelength region.

The refractive indices of the solutions studied have been measured on a PZO Warszawava 3275 refractometer. The oscillator strengths of the bands were measured from their profiles.

RESULTS AND ANALYSIS

Energy levels

The observed spectrum of $Pr^{3+}:Pr(C_2H_3O_2)_3 3H_2O$ is shown in Figs. 1 and 1(a). The observed band maxima positions and their assignments are presented in Table 1 for all the four praseodymium acetate complexes.

The energy E_j of the jth level may be written in a Taylor series expansion as

$$E_j = E_{0j} + \sum_{K=2}^{6} \frac{dE_J}{dF_K}\Delta F_K + \frac{dE_J}{d\alpha}\Delta\alpha + \frac{dE_J}{d\beta}\Delta\beta + \frac{dE_J}{d\zeta_{4f}}\Delta\zeta_{4f}\ldots \quad (1)$$

where E_{0j} is the zero-order energy of the jth level and (dE_J/dF_K), $(dE_J/d\alpha)$, $(dE_J/d\beta)$ and $(dE_J/d\zeta_{4f})$ are the partial derivatives. Using the experimental energy levels for E_j and the numerical values of zero-order energy and partial derivatives,[4,5] a number of linear equations equal to the number of observed levels were formed. By employing the least-squares fit method, the values of the correction factors ΔF_K, $\Delta\alpha$, $\Delta\beta$ and $\Delta\zeta_{4f}$ were calculated. These were added to the zero-order parameter to obtain the parameters F_2, F_4, F_6, α, β and ζ_{4f} for the Pr^{3+} complexes studied. Thus

$$F_2 = F_2{}^0 + \Delta F_2; \quad \alpha = \alpha^0 + \Delta\alpha$$
$$F_4 = F_4{}^0 + \Delta F_4; \quad \beta = \beta^0 + \Delta\beta$$
$$F_6 = F_6{}^0 + \Delta F_6; \quad \zeta_{4f} = \zeta_{4f}{}^0 + \Delta\zeta_{4f}$$

where $F_2{}^0$, $F_4{}^0$, $F_6{}^0$, α^0, β^0 and $\zeta_{4f}{}^0$ are the zero-order parameters.[4,5] These zero-order parameters, zero-order energies and the partial derivatives are given in Table 1(a). The calculated values of Slater–Condon (F_2, F_4 and F_6), configurational interaction (α, β) and spin–orbit (ζ_{4f}) parameters for the Pr^{3+} complexes studied are presented in Table 2. The r.m.s. deviation is calculated from the formula

$$\sigma = \left(\sum \frac{\Delta_i{}^2}{N}\right)^{1/2} \quad (3)$$

where Δ_i is the deviation of the ith level and N is the number of levels fitted. The small r.m.s. deviations found suggests a good fitting of the energy levels.

Spectral intensities

The intensity of an absorption band is measured by its oscillator strength which is directly proportional to the area under the absorption curve. The oscillator strength (f) can be expressed in terms of the molar absorptivity ϵ and the energy of the transition in wavenumbers (ν) by the following relation.[6]

$$f = 4.32 \times 10^{-9} \int \epsilon(\nu)\,d\nu. \quad (4)$$

Here (f) is a dimensionless quantity. The molar absorptivity (ϵ) at a given energy is computed from the Beer–Lambert law[6]

$$\epsilon = \frac{1}{cl}\log\frac{I_0}{I} \quad (5)$$

where c is the concentration of the lanthanide ion in moles/litre, l is the light path in the solution (cm) and $\log(I_0/I)$ is the absorptivity or optical density. Some magnetic dipole mechanism though responsible for a few transitions (f_{md}), an induced electric dipole mechanism (f_{ed}) must be invoked to account for the intensities of most lanthanide absorption bands. The weak intra f^N transitions are accounted for by assuming that a small amount of the character of higher lying opposite parity configurations is mixed into the f^N states via the odd terms in the potential due to the ligand field.[7] Neglecting higher multipole mechanism such as electric quadrupole

etc., we have

$$f = f_{ed} + f_{md} \qquad (6)$$

According to Judd–Ofelt[8,9] theory

$$f_{ed} = \sum_{\lambda=2}^{6} T_\lambda \nu (\psi J \| U^\lambda \| \psi' J')^2 \qquad (7)$$

where ν (cm^{-1}) is mean energy of the transition $\psi J \to \psi' J'$, U^λ is a unit tensor operator of rank λ, the sum running over the three values $\lambda = 2, 4$ and 6 and T_λ are the parameters which can be evaluated from the experimental data. The values of reduced matrix elements $\|U^\lambda\|^2$ have been evaluated for Pr^{3+} complexes[5] by using the following relation.

$$(f^N \alpha SLJ \| U^\lambda \| f^N \alpha' SL'J)$$
$$= (-1)^{S+J+L'+\lambda} [(2J+1)(2J'+1)]^{1/2}$$
$$\begin{Bmatrix} J & J' & \lambda \\ L' & L & S \end{Bmatrix} (f^N \alpha SL \| U^\lambda \| f^N \alpha SL').$$
$$(8)$$

The matrix elements on the right hand side of the above equation were taken from the tables of Nielson et al.[10] The values of 6j symbols were taken from the tables of Rotenberg et al.[11] From the above equation, it is found that the sign of the numerical value depends on the S, L', J' and λ values. The sign of the value does not play any significant role in the LS basis because we are always using squared values of $\|U^\lambda\|$. But in the intermediate coupling case the sign plays a dominant role because the states of f^N electronic configuration are taken as linear combinations.

$$|f^N \psi J\rangle = \sum_{\alpha, S, L} C(\alpha SL) |f^N \alpha SLJ\rangle \qquad (9)$$

where $C(\alpha SL)$ are the numerical coefficients resulting

from the diagonalization of the matrices. The eigenvalues and eigenvectors for Pr^{3+} complexes have been computed by diagonalizing complete energy matrices of $4f^2$ configuration on an IBM 370/155 computer using the parameters E^1, E^2, E^3, α, β and ζ_{4f}. The reduced matrix elements have been transformed from LS basis states to the physical coupling scheme prior to being squared and substituted in eqn (7). The squared values of U^2, U^4 and U^6 were substituted in eqn (7) and using f_{expt} for f_{ed} (neglecting for the moment f_{md} as it is very small compared to f_{ed}), the values of T_λ parameters were evaluated by the least squares fit method and presented in Table 2.

Theoretical estimation of the oscillator strength (f) has been carried out by the method of electric (s_{md}) and magnetic (s_{md}) dipole linestrengths[6]

$$f^{e \cdot m} = \frac{8\pi^2 mc\nu}{3he^2(2J+1)} \left[\frac{(n^2+2)^2}{9n} S_{ed} + n S_{md} \right] \qquad (10)$$

where n = refractive index of the medium, S_{ed} = electric dipole linestrength, S_{md} = magnetic dipole linestrength, m = mass of an electron, c = velocity of light, h = Planck's constant, e = energy of the electron in coloumbs, ν = energy of the band in (cm^{-1}), and J = value of the initial J level.

The values of electric (S_{ed}) dipole linestrengths were evaluated using the formula[6]

$$S_{ed} = e^2 \sum \Omega_\lambda (\psi J \| U^\lambda \| \psi' J')^2 \qquad (11)$$

where

$$\Omega_\lambda = [(1.085) \times (10^{11}) \times (n(n^2+2))/9]^{-1}(2J+1)T_\lambda \qquad (12)$$

and T_λ ($\lambda = 2, 4, 6$) are the Judd–Ofelt parameters. The values of the magnetic (S_{md}) dipole linestrength were obtained with the following relation[4]

$$S_{md} = \frac{e^2 h^2}{16\pi^2 m^2 c^2} (\psi J \| L + 2S \| \psi' J')^2. \qquad (13)$$

The experimental spectral intensities (f) and theoretical estimates of spectral intensities obtained from Judd–Ofelt (f^{J-O}) and electric–magnetic dipole linestrength (f^{e-m}) methods for the Pr^{3+} complexes have been given in Table 3. The calculated values of the parameters S_{ed} and S_{md} for Pr^{3+} complexes are presented in Table 4.

Bonding

The nephelauxetic ratio β is given by[12]

$$\beta = \nu_c/\nu_a \qquad (14)$$

where ν_c and ν_a refer to the energies of the corresponding transition in the complex and aquo ions respectively. The β values for all the observed transitions were computed and their average value $\bar\beta$ was used to estimate the bonding parameter (δ). The bonding parameter (δ) is given by[12,13]

$$\delta = \frac{1-\bar\beta}{\bar\beta}. \qquad (15)$$

The bonding will be covalent or ionic depending upon the positive or negative nature of the δ value. In all the Pr^{3+} complexes reported here (Table 2) since the δ value is found negative, the nature of the bonding in these complexes is ionic.

From Table 2, it is found that the Judd–Ofelt parameter T_2 has negative values for Pr^{3+} in $Cd(C_2H_3O_2)_2$ and $Ca(C_2H_3O_2)_2$. A similar result has been found for Pr^{3+} in yttrium aluminate by Weber.[14] He has suggested that the reason for such behaviour in praseodymium complex may be due to the proximity of the $5d$ band of Pr^{3+} to $4f$ and of strong $f - d$ mixing.[15,16]

$^1D_2$ Term splittings

Second derivative spectrum of praseodymium acetate complexes have exhibited a splitting of the $^1D_2$ level into two components. The observed splittings of $^1D_2$ term in the second derivative spectrum of these complexes are presented in Table 5.

Since the crystal field splitting has been observed only in the $^1D_2$ level no calculation of crystal field parameters was attempted.

Radiative lifetimes (τ_R)

Theoretical radiative lifetimes of certain electronic excited states of praseodymium ion have been very extensively studied by several authors.[17–19] Carnall *et al.*[6,20] have evaluated radiative lifetimes for $^3P_1$, $^3P_0$ and

Table 5. The observed crystal field splitting of $^1D_2$ term in the second derivative spectrum of Pr^{3+} complexes in solution

	16710	16738	16725	16720

Table 6. Predicted lifetimes τ_R (μ sec) for the $^3P_1$, $^3P_0$ and $^1D_2$ states of Pr^{3+} complexes in solution

Complexes $\tau_R(\mu\,Sec)$	Pr^{3+}: $Pr(C_2H_3O_2)_3 3H_2O$	Pr^{3+}: $Mg(C_2H_3O_2)_2$	Pr^{3+}: $Ca(C_2H_3O_2)_2$	Pr^{3+}:$Cd(C_2H_3O_2)_2$
$^3P_1$	41	117	172	145
$^3P_0$	137	379	188	177
$^1D_2$	351	1020	2070	1700

$^1D_2$ states of Pr^{3+} in solutions. The calculation of radiative lifetimes for the above excited states of praseodymium acetate complexes have been carried out in the present work.

The squared reduced matrix elements $\|U^\lambda\|^2$ between $^3P_1$, $^3P_0$ and $^1D_2$ and all the next lower lying levels were calculated for praseodymium aquo ion.[5] Reisfeld[18] and also Riseberg[21] have pointed out that the resulting matrix elements exhibit only small differences and hence $\|U^\lambda\|^2$ values obtained for one host may generally be used for the other hosts. In view of this and in view of lack of computer facilities in the university, the calculation of matrix elements $\|U^\lambda\|^2$, were carried out only for praseodymium aquo ion.[5] The same reduced matrix elements were used for calculation of electric dipole linestrengths of lines of Pr^{3+} in $Mg(C_2H_3O_2)_2$, $Ca(C_2H_3O_2)_2$ and $Cd(C_2H_3O_2)_2$ complexes. Following Carnall et al.[22] the total radiative transition probability $A(\psi J; \psi'J')$ was calculated using the intensity parameters (T_2, T_4, T_6) evaluated in the absorption measurements.

$$A(\psi J; \psi'J') = \frac{64\pi^4\nu^3}{3h(2H+1)}\left[\frac{n(n^2+2)^2}{9}S_{ed} + n^3 S_{md}\right].$$
(16)

The total radiative relaxation (A_T) was evaluated using the expression

$$A_T(\psi J) = \sum_{\psi'J'} A(\psi J; \psi'J')$$
(17)

where the sum runs over all $\psi'J'$ lower in energy than ψJ. The radiative lifetime (τ_R) of a state is given as

$$\tau_R(\psi J) = [A_T(\psi J)]^{-1}.$$
(18)

Predicted radiative lifetime (τ_R) of $^3P_1$, $^3P_0$ and $^1D_2$ states for the Pr^{3+} acetate complexes studied, are given in Table 6. From this table it is found that the predicted lifetimes of the excited states $^3P_1$, $^3P_0$ and $^1D_2$ are in the increasing order in the following manner.
$^3P_1$: $Ca(C_2H_3O_2)_2 > Cd(C_2H_3O_2)_2 > Mg(C_2H_3O_2)_2$
$> Pr(C_2H_3O_2)_3 3H_2O$

$^3P_0$: $Mg(C_2H_3O_2)_2 > Ca(C_2H_3O_2)_2 > Cd(C_2H_3O_2)_2$
$> Pr(C_2H_3O_2)_3 3H_2O$
$^1D_2$: $Ca(C_2H_3O_2)_2 > Cd(C_2H_3O_2)_2 > Mg(C_2H_3O_2)_2$
$> Pr(C_2H_3O_2)_3 3H_2O$.

IMPROVED SYNTHESES OF Ru(CO)$_2$(O$_3$SCF$_3$)$_2$(BIDENTATE) COMPLEXES
AND THEIR CONVERSION INTO NEW [Ru(CO)$_2$(BIDENTATE)$_2$]$^{2+}$ COMPLEXES

DAVID ST.C. BLACK, GLEN B. DEACON* and NICHOLAS C. THOMAS

Chemistry Department, Monash University, Clayton, Victoria, Australia, 3168

Abstract – Reaction of the complexes Ru(CO)$_2$Cl$_2$L [L = 2,2'-bipyridyl (bpy) or 1,10-phenanthroline (phen)] with trifluoromethanesulphonic acid under carefully controlled conditions yields Ru[cis-(CO)$_2$][cis-(O$_3$SCF$_3$)$_2$](bidentate) complexes. From reactions of the trifluoromethanesulphonates with the appropriate bidentate ligands, the new complexes [cis-Ru(CO)$_2$-L(L')]$^{2+}$ (L as above; L' = 4,4'-dimethyl-2,2'-bipyridyl or 4,4'-diisopropyl-2,2'-bipyridyl) as well as the known [cis-Ru(CO)$_2$L$_2$]$^{2+}$ and [cis-Ru(CO)$_2$bpy(phen)]$^{2+}$ have been prepared.

INTRODUCTION

The complexes Ru(CO)$_2$(O$_3$SCF$_3$)$_2$phen (phen = 1,10-phenanthroline) and [Ru(CO)$_2$(MeCN)$_2$L]$^{2+}$ [L = phen or 2,2'-bipyridyl (bpy)] readily undergo substitution with uncharged bidentate ligands to give the novel dicarbonyls [Ru(CO)$_2$L$_2$]$^{2+}$ and [Ru(CO)$_2$L(L')]$^{2+}$ (L' ≠ L = phen, bpy or 3,4,7,8-tetramethyl-1,10-phenanthroline)[1,2] (subsequently, alternative syntheses of [Ru(CO)$_2$L$_2$]$^{2+}$ have also been reported[3,4]). The route to Ru(CO)$_2$(O$_3$SCF$_3$)$_2$phen and [Ru(CO)$_2$-(MeCN)$_2$L]$^{2+}$ complexes from the convenient reagents Ru(CO)$_2$Cl$_2$L involves conversion into Ru(CO)$_2$(O$_2$CMe)$_2$L derivatives and then reaction with trifluoromethanesulphonic acid either alone (giving the first complex, but unsuccessful for the bpy analogue) or in acetonitrile.[1,2] We now report a one-step synthesis of Ru(CO)$_2$(O$_3$SCF$_3$)$_2$L (L = phen *and* bpy) complexes and their conversion into new [Ru(CO)$_2$bidentate$_2$]$^{2+}$ derivatives.

RESULTS AND DISCUSSION

The complexes Ru(CO)$_2$(O$_3$SCF$_3$)$_2$L are conveniently prepared by heating the analogous chloro derivatives with trifluoromethanesulphonic acid.

$$Ru(CO)_2Cl_2L + 2CF_3SO_3H \rightarrow Ru(CO)_2(O_3SCF_3)_2L + 2HCl \qquad (1)$$
Careful control of the conditions is needed for L = bpy to prevent decomposition into (bpyH)$^+$[O$_3$SCF$_3$]$^-$. The chloro complexes are more labile than the corresponding acetato derivatives in reactions with trifluoromethanesulphonic acid, since conversion of RuCl$_2$(CO)$_2$bpy into Ru(CO)$_2$(O$_3$SCF$_3$)$_2$bpy occurs under conditions (Experimental Section) which permit only partial replacement of acetate by trifluoromethanesulphonate.[2]

The trifluoromethanesulphonato complexes are considered to have structure (1) on the basis of two ν(CO) frequencies and ^{1}H n.m.r. spectra (Experimental Section) indicative of unsymmetrical coordination of the bidentate ligands. Their formation by reaction (1) involves a stereochemical change since the chloro-complexes have structure (2a).

(1)

(2)
(1a)	N̑ N̑ = bpy	(2a)	N̑ N̑ = phen or bpy, X = Cl, n = 0
(1b)	N̑ N̑ = phen	(2b)	N̑ N̑ = phen, X = OSO_2CF_3, n = 0
		(2c)	N̑ N̑ = phen or bpy, X = OCOMe, n = 0
		(2d)	N̑ N̑ = phen or bpy, X = MeCN, n = 2
This contrasts with retention of stereochemistry in the formation of $Ru(CO)_2(O_3SCF_3)_2phen$ with structure (2b) [cf (1b) from reaction (1)] from $Ru(CO)_2(O_2CMe)_2phen$ [structure (2c)] and trifluoromethanesulphonic acid.[1,2] Although (1b) is obtained under milder conditions than (2b), it cannot be isomerized into the latter on being heated in CF_3SO_3H under conditions used to obtain (2b) from (2c).

Reactions of the new trifluoromethanesulphonates (1) with 2,2'-bipyridyl, 1,10-phen-anthroline, 4,4'-dimethyl-2,2'-bipyridyl (Me_2bpy), and 4,4'-diisopropyl-2,2'-bipyridyl (Pr_2bpy) give the known $[Ru(CO)_2L_2]^{2+}$ (L = phen or bpy)[1-4] and $[Ru(CO)_2bpy(phen)]^{2+}$ [1,2] as well as the new complexes $[Ru(CO)_2L(L')]^{2+}$ (L = phen or bpy; L' = Me_2bpy or Pr_2bpy),

e.g. $Ru(CO)_2(O_3SCF_3)_2L + L' \rightarrow [Ru(CO)_2L(L')]^{2+} + 2CF_3SO_3^-$.
The infrared spectra of the new compounds, isolated as hexafluorophosphates, showed two $\nu(CO)$ frequencies and the [1]H n.m.r. spectra unsymmetrical coordination of the bidentate ligands, indicative of structure (3). Since the new $Ru(CO)_2(O_3SCF_3)_2L$ complexes (1) are as reactive towards bidentate ligands as (2b) or the acetonitrile derivatives (2d) and are more readily prepared, they should supersede them as a source of $[Ru(CO)_2L_2]^{2+}$ or $[Ru(CO)_2L(L')]^{2+}$ complexes.

(3) N̑ N̑ = phen or bpy, N̑' N̑' = phen or bpy Me_2bpy or Pr_2bpy
(3)
EXPERIMENTAL

(a) *General*

Microanalyses were by the Australian Microanalytical Service, Melbourne. Infrared spectra were recorded with a Perkin-Elmer 180 spectrophotometer. Compounds were examined as Nujol or hexachlorobutadiene mulls (4000 - 650 cm^{-1}). Silver chloride plates were used for trifluoromethanesulphonato complexes. Uncharged complexes were also examined in CH_2Cl_2 (2400 - 1800 cm^{-1}). [1]H n.m.r. spectra were recorded with a Bruker WH-90 spectrometer. Proton chemical shifts are in ppm downfield from internal tetramethylsilane. Uncharged and charged complexes were examined in $CDCl_3$ and $(CD_3)_2SO$ respectively. Integrations were satisfactory for the proposed compositions and are not listed. Mass spectra were obtained with a VG Micromass spectrometer. The m/e values correspond to the most intense peak (containing [102]Ru) of a cluster with the correct isotope pattern. Conductivities of solutions

(0.9 - 1.2 x 10^{-3} mol dm^{-3}) in nitromethane were measured at 20-25°C with a Wayne Kerr B221A bridge using a cell of standard design fitted with shiny platinum electrodes.

(b) Reagents

Ru(CO)$_2$Cl$_2$L (L = phen or bpy) complexes were prepared as previously reported.[2] 4,4'-Dimethyl-2,2'-bipyridyl and 4,4'-diisopropyl-2,2'-bipyridyl were supplied by Dr. W.H.F. Sasse, Division of Applied Organic Chemistry, CSIRO, Melbourne. Trifluoromethanesulphonic acid (3M) was distilled (0.1 mm, 26°C) before use.

(c) Trifluoromethanesulphonatoruthenium(II) Complexes

a,b-(2,2'-Bipyridyl)-c,d-dicarbonyl-e,f-bis(trifluoromethanesulphonato)ruthenium(II)   (1a)

2,2'-Bipyridyldicarbonyldichlororuthenium(II) (0.60g) was heated in trifluoromethane-sulphonic acid (2 cm^3) for 1h at 105°C under nitrogen. The mixture was cooled in ice and ether was slowly added. The white precipitated product was collected, washed with water to remove any 2,2'-bipyridinium trifluoromethanesulphonate, and recrystallized from methylene chloride/ether under nitrogen (0.40g, 40%), m.p. 202-204°C (Found: C,27.3; H,1.4; N,4.5). C$_{14}$H$_8$F$_6$N$_2$O$_8$RuS$_2$ requires C,27.5; H,1.3; N,4.6%). Mass spectrum: m/e 584[8%,(M-CO)$^+$], 556[38,(M-2CO)$^+$], 463[4,(M-CF$_3$SO$_3$)$^+$], 407[23,(M-2CO-CF$_3$SO$_3$)$^+$]. ^{1}H n.m.r. spectrum: 7.57-7.73, m,H5'; 7.84-8.00,m,H5; 8.12-8.42,m,H3,3',4,4'; 8.79,m,^{3}J5.6Hz,H6'; 9.04,m,^{3}J5.6Hz,H6. Infra-red absorption: 3020w, 2104s and 2024s[ν(CO)], 1603w, 1476m, 1455m, 1332s[ν(SO$_3$)], 1230s[ν(CF)], 1195s[ν(CF)], 1158vs(br)[ν(SO$_3$) + ν(CF)], 1009s[ν(SO$_3$)], 993s, 771s, 726m, 620s cm^{-1}. In CH$_2$Cl$_2$: 2082, 2020[ν(CO)]cm^{-1}. Mol. cond. (MeNO$_2$), 20.8 Scm^{2}mol^{-1} (134 after 48h owing to solvolysis).

a,b-Dicarbonyl-c,d-(1,10 phenanthroline)-e,f-bis(trifluoromethanesulphonato)ruthenium(II)   (1b)

Dicarbonyldichloro(1,10-phenanthroline)ruthenium(II) (1.10g) was heated with trifluoro-methanesulphonic acid (2 cm^3) under nitrogen for 2h at 110°C. The mixture was cooled and ether (50 cm^3) was slowly added and was allowed to stand until precipitation of the white product was complete. This was filtered off, washed with water and recrystallized under nitrogen from methylene chloride/ether (1.08g, 65%), m.p. 263-265°C (Found: C,30.4; H,1.6. C$_{16}$H$_8$F$_6$N$_2$O$_8$RuS$_2$ requires C,30.6; H,1.3%). Mass spectrum: m/e 636[2%,M$^+$], 608[16,(M-CO)$^+$], 580[100,(M-2CO)$^+$], 431[40,(M-2CO-CF$_3$SO$_3$)$^+$]. ^{1}H n.m.r. spectrum: 7.88-8.03,m,H8; 8.14-8.29, m,H3,5,6; 8.69-8.91,2d(overlapping),^{3}J8.4 and 8.7Hz,H4,7; 9.12,d,^{3}J5.3Hz,H9; 9.36,d,^{3}J5.0Hz, H2*. Infrared absorption: 3000w, 2098s and 2038s[ν(CO)], 1632w, 1603w, 1587w, 1521w, 1430s, 1372s, 1325s[ν(SO$_3$)], 1242s, 1228s[ν(CF)], 1180vs(br)[ν(SO$_3$) + ν(CF)], 1148s[ν(CF)], 1010s[ν(SO$_3$)], 991s(sh), 852s, 788w, 770w, 753w, 730w(sh), 722s cm^{-1}. In CH$_2$Cl$_2$: 2091, 2034[ν(CO)] cm^{-1}. Mol. cond. (MeNO$_2$), 15.5 Scm^{2}mol^{-1} (158 after 48h).

(d) Preparations of [Ru(CO)$_2$(bidentate)$_2$]$^{2+}$ Complexes

The complex Ru(CO)$_2$(O$_3$SCF$_3$)$_2$L (L = phen or bpy) (1a,b) (ca. 0.2g) and the bidentate ligand (bpy, phen, Me$_2$bpy or Pr$_2$bpy) (ca. 0.2g) were heated in ethanol (20-40 cm^3) under reflux for 1h in an atmosphere of nitrogen. The solvent was evaporated to dryness, and the residue was dissolved in hot water. After filtration, addition of aqueous ammonium hexafluorophosphate gave a yellow precipitate, which was recrystallized from acetone/ethanol and then acetone/ ether to give the required complex as white crystals. In assignments of ^{1}H n.m.r. spectra of [Ru(CO)$_2$L(L')]$^{2+}$ complexes, the nitrogen atoms *trans* to each other [see (3)] are designated N1.

---

*H2 (N1 *cis* to two CF$_3$SO$_3$ groups) and H9 are tentatively assigned on the basis that the environment of N1 rather than N10 is more similar to that of the nitrogens in the previously characterized[1,2] isomer [structure (2b)].

Dicarbonyl(4,4'-dimethyl-2,2'-bipyridyl)(1,10-phenanthroline)ruthenium(II) hexafluorophosphate

Yield 55% (Found: C,37.9; H,2.2; N,7.0. $C_{26}H_{20}F_{12}N_4O_2P_2Ru$ requires C,38.5; H,2.5; N,6.9%). ^1H n.m.r. spectrum: 2.46,s,4'-Me; 2.78,s,4-Me; 7.28,d,$^3J5.0Hz,H9$; 7.52,d,$^3J6.0Hz$, H6'; 7.93-8.08,m,H5',8; 8.22,m,$^3J5.0Hz,H5(Me_2bpy)$; 8.35-8.59,m,H3,5,6(phen); 8.69,m,H3'; 8.86,m,H3(Me_2bpy); 9.00,d,$^3J8.0Hz,H7$; 9.25,d,$^3J8.0Hz,H4$; 9.38,m,$^3J6.0Hz,H6(Me_2bpy)$; 9.91,d, $^3J5.0Hz,H2(phen)$. REACTION OF HEXABORANE(10) WITH EXCESS TRIMETHYLPHOSPHINE

Mitsuaki Kameda and Goji Kodama*

Department of Chemistry

University of Utah

Salt Lake City, Utah 84112, U.S.A.

Abstract—Bis(trimethylphosphine)-hexaborane(10), $B_6H_{10} \cdot 2P(CH_3)_3$, reacted with trimethylphosphine and gave a solid with the total composition "$B_6H_{10} \cdot 6P(CH_3)_3$" which consisted of twice the number of moles of the original $B_6H_{10} \cdot 2P(CH_3)_3$. The solid was inert to excess $P(CH_3)_3$. When treated with HCl, it gave a 1:2 mixture of $BH_3 \cdot P(CH_3)_3$ and $BH_2Cl \cdot P(CH_3)_3$. The framework of $B_6H_{10} \cdot 2P(CH_3)_3$ appeared to be cleaved and converted by $P(CH_3)_3$ into $B_2H_4 \cdot 2P(CH_3)_3$ and $B_4H_6 \cdot 4P(CH_3)_3$, and into two $B_3H_5 \cdot 3P(CH_3)_3$.

INTRODUCTION

Pentaborane(9) reacts with trimethylphosphine to give the bisphosphine adduct of the borane, $B_5H_9 \cdot 2P(CH_3)_3$[1]. This adduct of B_5H_9[2] further reacts with $P(CH_3)_3$, and the five-boron framework is cleaved into two fragments:
Hexaborane(10) also reacts with $P(CH_3)_3$ to give $B_6H_{10} \cdot P(CH_3)_3$[3] and $B_6H_{10} \cdot 2P(CH_3)_3$[4]. Thus, the pyramid-shaped structure of B_6H_{10}[5] undergoes a series of transformation and changes to a belt-shaped structure:
It was of interest to us to see how the bisphosphine adduct of B_6H_{10} would further react with $P(CH_3)_3$ and to compare the reaction with that of the B_5H_9 adduct.

RESULTS AND DISCUSSION

When B_6H_{10} was mixed with a large excess of $P(CH_3)_3$ at $-80 \sim -60^\circ C$, and the mixture was allowed to warm to room temperature, the formation of the mono- and bisphosphine adducts occurred in rapid succession. The bisphosphine adduct further reacted slowly with $P(CH_3)_3$. The same reaction occurred when dichloromethane or acetonitrile was used as the solvent. The
Figure 1. ^{11}B NMR spectra, ^{1}H-spin decoupled, at 25°C in dichloromethane. H, T and D denote the signals of $B_6H_{10}\cdot 2P(CH_3)_3$, $BH_3\cdot P(CH_3)_3$ and $BH_2Cl\cdot P(CH_3)_3$, respectively.

(b) The same solution as in (a), 4 hours later.

(c) The reaction solution "$B_6H_{10}\cdot 6P(CH_3)_3$" + 4HCl in CH_2Cl_2.

(d) The sublimation residue.

last phase of the change as observed on the ^{11}B NMR spectra is shown in Figures 1a and 1b. When the volatile components were removed from the resulting solution at $-23\sim0$°C by pumping, a white solid with the composition "$B_6H_{10}\cdot\underline{5.9\sim6.3}P(CH_3)_3$" was left behind. The solution of the solid in dichloromethane gave the ^{11}B NMR spectrum identical with that in Figure 1b. Its ^{31}P NMR spectrum indicated that free $P(CH_3)_3$ was present in only a small amount (less than 4% of the total P in the sample.) Other signals of ^{31}P were overlapped in the region of $0\sim3.6$ ppm [85% H_3PO_4 standard, low field shifts being taken as positive], indicating that the phosphines were attached to the boron atoms. When the solid residue was treated with anhydrous HCl in dichloromethane, $BH_3\cdot P(CH_3)_3$ and $BH_2Cl\cdot P(CH_3)_3$ were produced in a 1:2 molar ratio. Only insignificant amounts of side products were detected in the ^{11}B spectrum of the resulting solution. See Figure 1c.

Shown in Figure 2 is the vapor pressure depression data of trimethylphosphine solution of B_6H_{10}. The data points are compared with the curve calculated for the two-fragment formation in which six moles of $P(CH_3)_3$ are utilized per mole of B_6H_{10}. Two other lines are drawn for two hypothetical fragmentation patterns. See the caption of the figure. Thus, the curves for most of other patterns of fragmentation would appear outside of the shaded area. The $P(CH_3)_3$ solution stayed clear and colorless during the entire period of the measurements (3 days) at 18.5°C.
Figure 2. Vapor Pressure depression of trimethylphosphine solutions of Hexaborane(10). Middle curve; calculated for two-fragment formation with the use of six $P(CH_3)_3$. Upper curve; calculated for three-fragment formation with the use of two $P(CH_3)_3$. Lower curve; calculated for 1.5-fragment formation with the use of six $P(CH_3)_3$.

In Figure 3 the ^{11}B spectrum of the final products (Figure 1b) is expanded and compared with that of $B_2H_4 \cdot 2P(CH_3)_3$. The presence of $B_2H_4 \cdot 2P(CH_3)_3$ in the B_6H_{10} cleavage products is evident. When the above mentioned solid residue was subjected to sublimation under vacuum at room temperature, $B_2H_4 \cdot 2P(CH_3)_3$ was obtained as the sublimate in a yield of 0.55~0.78 mole per mole of the B_6H_{10} used. The residue of the sublimation was a complex mixture of boron compounds containing a significant amount of $B_6H_{10} \cdot 2P(CH_3)_3$. See Figure 1d. The intensity of the $B_6H_{10} \cdot 2P(CH_3)_3$ signal was estimated to be about 15% of the total ^{11}B signal intensity in the spectrum.

The reaction of B_5H_9 with excess $P(CH_3)_3$ gave a 1:1 mixture of $B_2H_4 \cdot 2P(CH_3)_3$ and $B_3H_5 \cdot 3P(CH_3)_3$. The spectrum of the mixture is shown in Figure 3b. A similarity between this spectrum and that of the B_6H_{10} cleavage product (Figure 3a) is noted. Subtraction of the $B_2H_4 \cdot 2P(CH_3)_3$ spectrum (in an intensity 2) from the spectrum in Figure 3b (in an intensity 5) gave the spectrum for $B_3H_5 \cdot 3P(CH_3)_3$. When a similar operation was performed on the spectrum in Figure 3a by adjusting the intensity ratio 2:6, an inverted image of the $B_2H_4 \cdot 2P(CH_3)_3$ signal was produced in the resulting difference spectrum. Apparently, the amount of the diborane(4) adduct in the products was less than that expected for a simple cleavage into $B_2H_4 \cdot 2P(CH_3)_3$ and $B_4H_6 \cdot 4P(CH_3)_3$. If it is assumed that the B_6-framework was cleaved into two fragments, and that any of the fragments did not undergo further reactions, except for combining with $P(CH_3)_3$, the cleavage into two units of $B_3H_5 \cdot 3P(CH_3)_3$ would be another possible reaction. The cleavage into $BH_3 \cdot P(CH_3)_3$ and $B_5H_7 \cdot 5P(CH_3)_3$ would have to be excluded from the consideration, since $BH_3 \cdot P(CH_3)_3$ was not found in the products. The presence of $B_6H_{10} \cdot 2P(CH_3)_3$ in the sublimation residue may be due to the recombination of the B_3 units, as such was observed when $B_2H_4 \cdot 2P(CH_3)_3$ was sublimed from the cleavage products of B_5H_9.

The molecules with the formula $B_nH_{n+2} \cdot nP(CH_3)_3$ are electron sufficent. The addition of n numbers of the phosphine to a B_nH_{n+2} unit removes the electron deficiency of the unit, and the valence bond structure of the molecule can be expressed without the use of two-electron three-center bonds. Thus, $B_2H_4 \cdot 2P(CH_3)_3$ and $B_3H_5 \cdot 3P(CH_3)_3$ are inert to $P(CH_3)_3$.

The $-\overset{|}{\underset{|}{B}}-\overset{|}{\underset{|}{B}}-$ bond, however, is reactive to hydrogen chloride, and is cleaved readily into $-\overset{|}{\underset{|}{B}}-H$ and $Cl-\overset{|}{\underset{|}{B}}-$ even at $-80^\circ C$. The ^{11}B chemical shifts for $B_2H_4 \cdot 2P(CH_3)_3$ and $B_3H_5 \cdot 3P(CH_3)_3$ appear within a range of ± 2.0 ppm from the shift of $BH_3 \cdot P(CH_3)_3$ which is another member of the series. Accordingly, $B_4H_6 \cdot 4P(CH_3)_3$, the next higher member, would also be reactive to HCl, and its ^{11}B shifts would appear also in the same range. So far, the separation of the products, except for $B_2H_4 \cdot 2P(CH_3)_3$, has been unsuccessful due to the instability of the compounds above $0^\circ C$ in the absence of excess $P(CH_3)_3$. However, the observations presented in this paper may suggest that the belt-shaped framework of $B_6H_{10} \cdot 2P(CH_3)_3$ was cleaved by $P(CH_3)_3$ into two fragments in two ways:

→ 600 Hz ←

$$B_6H_{10} \cdot 2P(CH_3)_3 \begin{cases} \overset{a}{\longrightarrow} B_2H_4 \cdot 2P(CH_3)_3 + B_4H_6 \cdot 4P(CH_3)_3 \\ \overset{b}{\longrightarrow} 2B_3H_5 \cdot 3P(CH_3)_3 \end{cases}$$

Figure 3. ^{11}B NMR spectra, ^{1}H-spin decoupled. (a) "$B_6H_{10} \cdot 6P(CH_3)_3$" in dichloromethane. (b) "$B_5H_9 \cdot 5P(CH_3)_3$" in acetonitrile. (c) $B_2H_4 \cdot 2P(CH_3)_3$ in acetonitrile.

EXPERIMENTAL

The sources of chemicals and the general methods of experimental procedures were de-
scribed elsewhere.[2,3]   Teflon valves and o-ring joints were used throughout. The NMR spectra
were recorded on a Varian XL-100-15 spectrometer, operating at 32.1 and 40.5 MHz for ^{11}B and
^{31}P nuclei, respectively.

The reaction of B_6H_{10} with $P(CH_3)_3$ proceeded uncontrollably fast unless a special care
was taken. Samples of B_6H_{10} and $P(CH_3)_3$ were measured out first. Then, a portion of the
B_6H_{10} sample was condensed near the botton of a reaction tube (10 mm o.d. Pyrex) as a thin
layer at $-197^{\circ}C$, and a portion of the $P(CH_3)_3$ sample was condensed above the layer. The
tube was allowed to warm slowly to about $-60^{\circ}C$ (slightly above the melting point of B_6H_{10})
and the mixture was shaken well at that temperature. Then the tube was cooled to $-197^{\circ}C$, and
next portions of B_6H_{10} and $P(CH_3)_3$ were condensed in and treated likewise. This procedure
was repeated until all of the B_6H_{10} sample was transfered into the tube. Finally the
remainder of the $P(CH_3)_3$ sample was condensed in the tube, and the tube was allowed to warm
slowly to room temperature while the mixture was agitated. A total of 0.3~0.5 mmole sample
of B_6H_{10} was used for the preparation of each reaction mixture.

Abstract – The action of elemental sulfur with
vanadium (II) porphyrins complexes $\left[V^{II}(por)(THF)_2\right]$
(por = porphyrinate) affords the thiovanadyl porphy-
rins $\left[V^{IV}(por)(S)\right]$. EXAFS spectroscopy at the V K-edge
of $\left[V^{IV}(oep)(S)\right]$ confirms the axial symmetry of these
complexes.

Although complexes containing the vanadyl ion,
$V=O^{2+}$, are well known, there are very few studies of
vanadium compounds in which the thiovanadyl ion is
present[1,2]. K.P. Callahan et al[1]. recently have deve-
loped a synthetic route to the previously unknown
thiovanadyl species, V=S Ln, which involves reaction
of V=O Ln with B_2S_3. As such thiovanadyl species are
of likely relevance to certain industrial catalysts in
petrochemistry[3], we report here a convenient procedure
for the isolation of thiovanadium (IV) porphyrins
$\left[V^{IV}(por)(S)\right]$ (por = oep, tpp, tmtp or tptp)[+] by reac-
tion of low-valent vanadium porphyrins with elemental
sulfur. EXAFS spectroscopy at the V K-edge provides
convincing evidence for the monomeric nature of the
complexes, as well as the multiple V=S bond.

Reduction[++] by zinc amalgam (1g) of a dry oxygen

[+]Abbreviations used : por = porphinato ; oep = octae-
thylporphinato ; tpp = meso-tetraphenylporphinato ;
tmtp = meso-tetra-m-tolylporphinato ; tptp = meso-
tetra-p-tolylporphinato.

[++]All operations were carried in Schlenk tubes under
purified argon and with dried oxygen free solvents.

[+++]THF = tetrahydrofuran.

free tetrahydrofuran[+++] solution (60 cm^3) containing
$\left[V^{IV}(tptp)(Cl_2)\right]$[4], (1d)(0.65g, 0.8 mmol) led to a
brown solution of $\left[V^{II}(tptp)(THF)_2\right]$[5] after 24 h of
vigourous stirring at room temperature. Excess of zinc
amalgam was filtered and elemental sulfur (0.1g,3 mmol)
was added to the filtrate. The mixture was then stir-
red for 5 h at room temperature and concentrated in
vacuum. The excess sulfur was then sublimated (0.1mm
Hg) at 110-120°C. The obtained residue was purified by
chromatography on an aluminium oxide column (eluent :
toluene) and recrystallized in a mixture of toluene-
heptane (1/2) $\Big(0.27$ g, 45% yield of $\left[V^{IV}(tptp)(S)\right]$,
(2d)$\Big)$[6].

The analytical results and the mass-spectral data
agree perfectly with the proposed molecular formula
$\left[V^{IV}(por)(S)\right]$. The parent peak corresponds either to
the molecular peak $\left[V^{IV}(por)(S)\right]^{+\cdot}$ or to the recombi-
nation ion $\left[V^{IV}(por)(S)+H\right]^+$. The IR spectra of these
complexes show a medium to strong intensity band in
the 550 – 565 cm^{-1} range ; this band corresponds to
the V=S stretching vibration[2]. The isotropic EPR
spectral parameters g_{av} and A_{av} as well as the prin-
cipal components of the <g> tensor and the hyperfine
interaction tensor <A> for the thiovanadyl complexes
(2) – are given in Table 1.

The complexes (2) exhibit eight-line isotropic
solution spectra, indicative of a d^1 V(IV) nucleus.
The tensor components calculated from spectra measured
on frozen solutions correspond to axially symmetric
compounds. EXAFS spectroscopy at the V K-edge confirms
this square – plane pyramidal molecular structure.

For the sake of comparison we have reproduced on
the same plots the FT-EXAFS spectra of both
$\left[V^{IV}(oep)(O)\right]$ and $\left[V^{IV}(oep)(S)\right]$: the power spectra
$\left|\tilde{x}_1(R)\right|$ and the imaginary part $Im\tilde{x}_1(R)$ being respec-
tively displayed in figures 1a and 1b. It is worth
mentioning here that according to a now standard
procedure detailed elsewhere[4,7,8], these FT – spectra
were corrected for both the amplitudes and phase-
shifts of the V ...N shell which we expected to be the
dominant signal of a typical porphyrinic pattern. As
illustrated by figures 1a/1b the contributions of the
carbons of the porphyrinic ring are fairly identical,
for both compounds, whereas a strong destructive
interference effect is clearly detected in the case
of $\left[V^{IV}(oep)(S)\right]$, as a direct consequence of the
scattering phase shift difference between S and N.
As the geometry of the porphyrinic ring remains iden-
tical, for both compounds a difference FT – spectrum
gives (Fig 2) the negative contribution of the V=O
shell ($R_1 \approx 1.6$Å) together with the unknown V=S signal
($R_2 = 2.06 \pm 0.02$Å) . The latter distance is in excellent
agreement with the V=S distance reported for another
compound[1].

The reaction of elemental sulfur with low-valent organometallic systems led normally to chair-like metal pentasulfide molecules ; in contrast, reaction of the low-valent vanadium (II) porphyrins with excess sulfur led to the thiovanadyl complexes. We plan to report further studies on the catalyst deactivating agents during petroleum hydrodesulfurization ; these agents contain sulfur and vanadium, also, thiovanadyl petroporphyrins are very interesting models for the catalyst poisons.

NOTES

Mössbauer studies of solid state photolysis of barium and strontium tris(oxalato) ferrates (III)

Abstract—Solid state photolysis of strontium and barium tris(oxalato) ferrate(III) was done under a medium pressure lamp and investigated with Mössbauer spectroscopy. The product $[Fe^{II}(C_2O_4) (H_2O)_2]^{2-}$ formed during photolysis is found to be quite stable and does not convert to ferric state on long standing in air.

The photolysis of potassium tris(oxalato) ferrate(III) in solid state and solutions[1–4] and recently the Mössbauer study of the solid state photolysis of alkali tris(oxalato) ferrate(III) have been reported[5] indicating the effect of cation on photoinduced decomposition. Mössbauer study of solid state photolysis of sodium pentacyanonitroferrate(II) monohydrate has been done.[6] Thermal decomposition of barium and strontium tris(oxalato) ferrate(III) has also been reported.[7] In the present study the solid state photolysis of barium and strontium tris(oxalato) ferrates(III) has been investigated with the help of Mössbauer spectrosopy.

EXPERIMENTAL

Barium and strontinum tris(oxalato) ferrates(III) were prepared by standard method and characterised by IR, chemical analysis and thermal analysis techniques.

Mössbauer spectrometer MBS-35 (ECIL, India) coupled with MCA-38B, constant acceleration drive was employed to record the spectrum. A 2.5-mi $^{57}Co(Rh)$ source was used. The values of isomer shift are reported with respect to natural iron. All the spectra were recorded at temp. (25 ± 2°C). A sample containing approx. 10 mg/cm^2 of the natural iron was taken for each measurement. All the spectra have been fitted to Lorentzian line shape using a programme and fitting procedures on computer ICL 2960, IIT Delhi. Mössbauer spectra were almost symmetrical. Slight deviation may be due to powdered random samples and due to spin lattice relaxation effect.[8] For photoirradiation, powdered samples spread over a glass plate were exposed to medium pressure 250 W mercury lamp for 50, 100, 200 and 300 hr.

RESULTS AND DISCUSSION

The Mössbauer spectrum of strontium tris(oxalato) ferrate(III) at room temperature (25 ± 2°C) exhibits a doublet having isomer shift 0.25 mm/sec and quadrupole splitting 0.40 mm/sec (Fig. 1a) while barium tris(oxalato) ferrate(III) gives a broad single absorption band (Fig. 2a) indicative of spin relaxation effect.[9] The isomer shift to barium tris(oxalato) ferrate(III) is 0.31 mm/sec^{-1}.

*Authors to whom correspondence should be addressed.

Barium and strontium tris(oxalato) ferrate(III) were exposed to radiations up to 300 hr. The Mössbauer spectrum of the sample irradiated for 50 hr is shown in Fig. 1(b). This shows a asymmetrical doublet, the first band is due to the overlapping of two bands, one due to parent complex and the other due to the new product formed during photolysis. The isomer shift and quadrupole splitting values are 1.28 and 2.61 mm sec^{-1} in case of barium tris(oxalato) ferrate(III) photolysis while 1.18 and 2.30 mm sec^{-1} in case of strontium tris(oxalato) ferrate(III) photolysis.

On irradiation for 200 hr the Mössbauer spectrum shown in Fig. 1(c) clearly indicates that the decomposition increases with the increase of the irradiation time. Mössbauer spectrum shows a quadrupole doublets with isomer shift and quadrupole splitting 1.07 and 2.57 mm sec^{-1} in case of barium tris(oxalato) ferrate(III) and 1.26 and 2.25 mm sec^{-1} in case of strontium tris(oxalato) ferrate(III):

On irradiation for 300 hr Mössbauer spectrum shown in Fig. 1(d) shows almost complete decomposition to a product having isomer shift and quadrupole splitting 1.28, 2.20 and 2.61 mm sec^{-1} in case of strontium tris(oxalato) ferrate(III). The value of isomer shift and quadrupole splittings show that the product formed contains Fe(II) in high spin state.

The value of isomer shift 1.22 mm sec^{-1} and quadrupole splitting 2.53 mm sec^{-1} for $Fe^{II}(C_2O_4)_2(H_2O)_2^{3-5}$ are very close to the products formed during photolysis of the barium and strontium tris(oxalato) ferrate(III), indicating that the products are $M[Fe^{II}(C_2O_4)_2(H_2O)_2]$ (M = Ba^{2+}, Sr^{2+}). The high value of quadrupole splitting in the case of barium tris(oxalato) ferrate(III) irradiated for 300 hr is indicative of more distortion in the product (II) than the product (I) formed in strontium tris(oxalato) ferrate(III). Values are given in Table 1. The rate of decomposition (Figs. 1(d)) is more in the case of strontium complex than in barium complex which may be due to the different nature of cation. Intermediate $K_6[Fe_2^{II}(OX)_5]$ formed during the photolysis of potassium tris(oxalato) ferrate(III) gets converted to $K[Fe^{III}(C_2O_4)_2(H_2O)_2]$ on long standing in air.[4,5] While in the case of other alkali tris(oxalato) ferrate(III) ferrous oxalate was formed which on long standing in air gets oxidised to ferric state. The product $[Fe^{II}(C_2O_4)_2(H_2O)_2]^{2-}$ formed during the photolysis of barium and strontium tris(oxalato) ferrate(III) is found to be quite stable and does not convert to ferric state. This clearly

On the Pauling electronegativity scales—I

Abstract—It is shown that the Pauling electronegativity scale χ is closely related to the electrostatic potential near the physical meaningful boundary between the core and valence regions in an atom, and is well reproduced by the relationship:

$$\chi = \frac{(N_v + 1)}{2} f(n),$$

where N_v is the valence electron number and the factor $f(n)$ is empirically given by

$$f(n) = \left[1 - \frac{2}{9}(n-1)^{1/2}\right]; \quad n \geqq 1,$$

n being the periodic number.

There have been many theoretical studies[1–9] of the electronegativity,[10] of which the recent proposal of Parr *et al.*[1–3] that equates the electronegativity to the negative of the chemical potential within the context of the density functional theory of Hohenberg and Kohn[11] is of special interest. In the present study, it is shown from a quite different point of view with the above that the Pauling electronegativity scale[10] is closely related to the electrostatic potential near the core-valence boundary in an atom.

It has been shown by Politzer and Parr[12] that the outermost minimum in the radial density defines a physically meaningful boundary between the core and valence regions of a ground state atom. In order to investigate in detail the electrostatic potential V near such a boundary, we expand that potential with a radial distance r from the nucleus;

$$V(r_m + \Delta r) = V(r_m) + \left(\frac{\partial V}{\partial r}\right)_{r_m}(\Delta r) + \frac{1}{2}\left(\frac{\partial^2 V}{\partial r^2}\right)_{r_m}(\Delta r)^2 + \cdots \quad (1)$$

where r_m is the radial distance at which the radial density function $4\pi r^2 \rho(r)$ has the outermost minimum, and the partial differentials with respect to r are evaluated at the position r_m. To a first approximation, we may take the first and second terms truncated after the higher order terms, i.e.

$$V(r_m + \Delta r) = V(r_m) + \left(\frac{\partial V}{\partial r}\right)_{r_m}(\Delta r). \quad (2)$$

Here, we note the elegant relationships derived by Politzer[13,14] who has studied the electrostatic potential-electronic density relationships in an atom;

$$\left(\frac{\partial V}{\partial r}\right)_{r_m} = -\frac{2V(r_m)}{r_m}, \quad (3)$$

and

$$V(r_m) = \int_{r_m}^{\infty} \frac{\rho(\mathbf{r}')}{|\mathbf{r}_m - \mathbf{r}'|} d\mathbf{r}' = \frac{N_m e}{2r_m}, \quad (4)$$

where ρ is the electron density, e is the electronic charge, and N_m is the electron number which is located beyond the radial distance r_m from the nucleus. Introducing equations (3) and (4) into eqn (2), we have

$$V(r_m + \Delta r) = \frac{N_m e}{2r_m}\left[1 - \frac{2(\Delta r)}{r_m}\right], \quad (5)$$

which is the approximate electrostatic potential produced at the near outermost minimum by the nucleus and the electrons N_m. There is no doubt that this potential is a good measure of the electronegativity in an atom.

We now define conveniently the electronegativity χ from eqn (5) as

$$\chi = \int \frac{r_m}{e} V(r_m + \Delta r)\, dr = \int_{-\Delta r_m}^{\Delta r_m} \frac{N_m}{2}\left[1 - \frac{2(\Delta r)}{r_m}\right] dr, \quad (6)$$

and, to obtain the Pauling electronegativity scale,[10] we take the following integration range:

$$\Delta r_m = \frac{N_m + 1}{2N_m}. \quad (7)$$

The integration result is simply given by

$$\chi = \int \frac{r_m}{e} V(r_m + \Delta r)\, dr = \frac{N_m + 1}{2}. \quad (8)$$

Since r_m and N_m may be replaced by the core radius r_c and the valence electron number N_v,[12,14] eqn (8) becomes

$$\chi = \int \frac{r_c}{e} V(r_c + \Delta r)\, dr = \frac{N_v + 1}{2}, \quad (9)$$

which means that the Pauling electronegativity .scale[10] can be expressed with the valence electron number or the valence electronic charge.

It will be simply verified that eqn (9) works completely as it is for atoms (Li, Be, B, C, N, O, F) in the first period. However, for atoms belonging to the other periods, eqn (9) needs a slight modification taking into accocunt the periodicity. Such a modification may be accomplished by slightly varying the integration range of eqn (7). Introducing a correction factor $f(n)$ into eqn (7),

$$\Delta r_m = \frac{(N_m + 1)}{2N_m} f(n), \quad (10)$$

and then integrating similarly eqn (6), we have

$$\chi = \int \frac{r_m}{e} V(r_m + \Delta r)\, dr = \frac{(N_m + 1)}{2} f(n)$$

$$= \frac{(N_v + 1)}{2} f(n), \quad (11)$$

which is the desired result. Here, $f(n)$ may be assumed empirically as

$$f(n) = \left[1 - \frac{2}{9}(n-1)^{1/2}\right]; \quad n \geq 1 \qquad (12)$$

n being the periodic number.

We can easily confirm by numerical calculations that eqn (11) combined with eqn (12) reproduces well the Pauling electronegativity scales[10] for most atoms except for the hydrogen atom. The results are shown in Table 1. It may therefore be concluded that the electrostatic potential near the physical meaningful boundary between the core and valence regions in an atom is closely related to the Pauling electronegativity scale.[10]

It is well known that the Pauling electronegativity scales[10] are proportional to Mulliken electronegativities[15] which can be calculated from ionization potentials (IP) and electron affinities (EA) using (IP + EA)/2. It is also of interest to investigate the relation between the Pauling electronegativity scale[10] and the negative of the chemical potential. This will be reported in the near future.

Temperature dependence of the Mössbauer spectrum and magnetic susceptibility [Fe(uridine)Cl₂]∞: Novel magnetic ordering of transition metal complexes based on nucleoside ligands

Abstract—The zero-field Mössbauer spectra and magnetic susceptibility of a polycrystalline sample of the polymeric material [Fe(uridine)Cl₂]ₓ have been measured in the temperature range 1.7–300 K. The compound exhibits two magnetic transitions. The isomer shift and quadrupole splitting indicate a distorted pseudo-octahedral FeCl₄O₂ chromophore resulting from condensation to a network structure via chloro and uridine ligand bridging.

The title compound was synthesized by the method of Goodgame[1] who characterized a number of first transition series complexes based on the simple nucleosides, uridine (Fig. 1) and thymidine. The empirical formula suggests either coordinative unsaturation, e.g. pseudo-tetrahedral monomer or association to polymer or network structure via chloro and/or nucleoside ligand bridging. As part of our continuing program of detailed studies of the cooperative magnetic behavior of novel high spin ferrous systems, we now present some new results for [Fe(uridine)Cl₂]ₓ.

MAGNETIC SUSCEPTIBILITY

We find a maximum in χ'_M vs T at 22.6 K suggesting 3-D antiferromagnetic (AF) ordering and a sharp minimum in χ'_M vs T at 12.5 K suggesting a spin reorientation transition (probably canting of the AF sublattices). These are most clearly seen in the corresponding minimum and maximum observed in the reciprocal susceptibility (Fig. 2c). The overall decrease in magnetic moment (5.24 μ_B 298 K to 1.55 μ_B at 1.73 K Fig. 2b) and high critical temperature (~23 K) indicate surprisingly strong anti-ferro-

which is the desired result. Here, $f(n)$ may be assumed empirically as

$$f(n) = \left[1 - \frac{2}{9}(n-1)^{1/2}\right]; \quad n \geq 1 \qquad (12)$$

n being the periodic number.

We can easily confirm by numerical calculations that eqn (11) combined with eqn (12) reproduces well the Pauling electronegativity scales[10] for most atoms except for the hydrogen atom. The results are shown in Table 1. It may therefore be concluded that the electrostatic potential near the physical meaningful boundary between the core and valence regions in an atom is closely related to the Pauling electronegativity scale.[10]

It is well known that the Pauling electronegativity scales[10] are proportional to Mulliken electronegativities[15] which can be calculated from ionization potentials (IP) and electron affinities (EA) using $(IP + EA)/2$. It is also of interest to investigate the relation between the Pauling electronegativity scale[10] and the negative of the chemical potential. This will be reported in the near future.

magnetic exchange interactions ($\theta = -15.9$ K). As we do not know the details of molecular geometry, we cannot comment on the exact nature of these interactions at present. However, the foregoing magnetic transitions appear to be clearly mirrored in the temperature dependence of the zero-field Mössbauer spectra.

MÖSSBAUER SPECTRA

Between 2.2 and 23.0 K the Mössbauer spectrum shows fully resolved magnetic hyperfine splitting corresponding to one metal site and confirming cooperative 3D magnetic ordering, Fig. 3 (a–c). The magnetic splitting appears to reach saturation value at ~ 13 K, $H_n \approx 260$ kG, Fig. 3 (d–g). Below this temperature, what appear to be clearly resolved $\Delta m_I = \pm 2$ transitions steadily decrease in intensity and vanish. See Fig. 3(h–j). The combined effect of a quadrupole interaction and magnetic hyperfine splitting are obvious in the low temperature spectra. The fact that the normally forbidden $\Delta m_I = \pm 2$ transitions are observed at all implies substantial *lack of axial symmetry*, i.e. $\eta \neq 0$, for the electric field gradient at the ferrous sites.[2] This in turn suggests inequivalent metal halogen distances for the structure we have proposed in Fig. 1.

The isomer shift ($\delta_{Fe=0}$) and quadrupole splitting in the paramagnetic temperature range (T > 23.0 K) are 1.27 mms^{-1} (77 K) and 2.55 mms^{-1} respectively. These values are consistent with *six-coordinate* high-spin Fe^{2+} centers and a polymeric structure. In particular, the relatively large positive isomer shift is noteworthy. We believe that this indicates partial *oxygen* ligation in a chromophore such as $FeCl_4O_2$. In the absence of single crystal

X-ray diffractometry study, we can only speculate on the molecular structure of $Fe(uridine)Cl_2$. In their original spectroscopic characterization, Goodgame and Johns did not propose a specific structure. A plausible partial structure consistent with the results of this work and the previous characterization, i.e. six coordination of iron, a ligand to metal stoichiometry ratio of 1:1 and a condensed structure capable of sustaining cooperative, three dimensional magnetic order is proposed in Fig. 1. Primary coordination of the uridine via the carbonyl oxygen of C-4 (Fig. 1) is suggested by the IR studies of Goodgame.[1] Further *association* of chlorobridged "chains" might then occur by coordination of the ribose sugar hydroxyl groups of bridging uridine ligands. To test these ideas, we are initiating detailed studies of other members of the $M(uridine)\chi_2$ series.

BROMINE NQR STUDY OF STRUCTURE AND MOLECULAR TORSIONAL MOTION IN $N_4P_4Br_8$ AND $N_3P_3Br_6$

K. R. SRIDHARAN and J. RAMAKRISHNA*

Department of Physics, Indian Institute of Science, Bangalore 12, India

Abstract—The bromine NQR spectrum of tetrameric bromocyclophosphazene, $N_4P_4Br_8$, has been studied in the temperature range from 77 to 300 K. The negative temperature coefficients of the resonance frequencies have been analysed using Bayer–Kushida–Brown equations. Torsional modes in the frequency range 10–15 cm^{-1} are shown to characterise the observed motional averaging and are only slightly temperature dependent. The multiplicity and relative intensities of resonances in the trimer, $N_3P_3Br_6$, have been correlated with the known electron density distribution. The results for the bromo-derivatives are compared with those reported for the corresponding chloro-derivatives.

The compounds under investigation belong to a family of inorganic ring systems called cyclophosphazenes and have the representative structures shown in Fig. 1. There have been several studies of chlorine NQR of cyclophosphazene derivatives which have demonstrated the potential of the quadrupole resonance technique in elucidating the structural features of these compounds in the solid state.

The first observation of Br NQR in cyclophosphazenes was reported by the authors[1] earlier wherein we obtained the resonance frequencies at 77 K and at room temperature for $N_4P_4Br_8$ and $N_3P_3Br_6$. In the present paper, we discuss (i) the temperature dependence of Br NQR in $N_4P_4Br_8$ in the temperature range from 77 to 300 K and (ii) the correlation of electron charge density values at the halogen sites with the Br NQR spectrum in $N_3P_3Br_6$.

The samples were prepared by the methods described in the literature. A home-made (push–pull, tuned transmission-line) SRO spectrometer (140–380 MHz) was used to make the measurements. A 2-turn sample coil (14 SWG/1 cm dia.) was found adequate. A liquid nitrogen cryostat facilitated low-temperature studies and the sample temperature was measured with a copper–constantan thermocouple to an accuracy of ±0.5 K.

2. RESULTS AND DISCUSSION

2.1 *Temperature dependence of* Br NQR *in* $N_4P_4Br_8$

The spectrum consists of two equally intense signals in the range 195–200 MHz and two more in the range 235–245 MHz. The two pairs belong to the two isotopes of Bromine, the high frequency pair belonging to ^{79}Br in view of its larger quadrupole moment. The presence of two, equally intense signals in this compound is consistent with the presence of two inequivalent but equally populated Br sites in the crystal unit cell.[2] The ^{79}Br signals have been studied as a function of temperature in the range 77–298 K. The frequencies decrease with increase in temperature and are plotted in Fig. 2. A small discontinuity in the slope, $(d\nu/dT)$, of the curves was noted at ~230 K for both the signals. No discontinuity in the frequency has been observed. This observation might represent a small structural transition of the II order type.

It is well known that the temperature dependence of the nuclear quadrupole interaction in molecular solids is mainly due to the averaging of the electric field gradient (EFG) by the molecular librational (torsional) modes. Bayer's equation[3] for the temperature dependence of NQR frequency as modified by Tatsuzaki *et al.*[4] is given below:

$$\nu_Q(T) = \nu_0 \left[1 - \frac{3h}{8\pi^2 c} \sum_i \frac{\sin^2 \alpha_i}{A_i f_i} \left(\frac{1}{2} + \frac{1}{e^{(hcf_i/kT)} - 1} \right) \right].$$

Here, ν_0 is the NQR frequency for the stationary molecule, f_i is the frequency (cm^{-1}) of the ith torsional mode, A_i is the corresponding moment of inertia, α_i is the angle between the axis of the ith torsional mode and the

Fig. 2(b). Temperature dependence of ^{79}Br NQR frequency of
Line II in N$_4$P$_4$Br$_8$.

principal z axis of the EFG tensor, and T is the absolute
temperature.

The molecule is non-planar. The three axes that are
indicated in Fig. 1(a) could be considered as the principal
axes of the moment of inertia tensor. A three-mode
analysis would be ideal but the numerical solution
becomes complicated; a two-mode analysis has therefore
been carried out. The axes 1 and 2 have been considered
in view of the correspondingly larger values of the
weighting factor, $(\sin^2 \alpha_i)/A_i$. The P–Br bond direction

has been considered as the principal z-axis of the EFG at
the corresponding bromine.

The torsional frequencies, f_1 and f_2, have been evalu-
ated using a procedure similar to the one used by Vijaya
and Ramakrishna.[5] The frequencies are found to fall in
the very low range of 10–15 cm^{-1} and exhibit a rather
small temperature dependence (Table 1).

The temperature coefficients of NQR frequencies in
the bromo-compounds are smaller than those observed in
chloro-cyclophosphazene derivatives.[6] In this context,
the close Br...Br intermolecular contacts of less than
the sum of van der Waals' radii, and P–Br...Br linear
arrays observed in the unit cell packing, are relevant.
This closer packing implies smaller thermal amplitudes
and would explain the smaller temperature coefficient of
the Br NQR frequency.

Regarding the temperature dependence of torsional
frequencies (due to volume expansion), Brown's linear
equation

$$f_i = f_i^0(1 - g_i t)$$

is used.[7] Brown expressed the average temperature
coefficient $\langle g \rangle$ in terms of the first and second derivatives
of ν_Q vs t. In order to evaluate these derivatives and to
compare different descriptions of the functional depen-
dence of ν_Q vs T, the following equations were con-
sidered for least-squares fitting:

(i) $\nu_Q = A' + B'(T - T_0) + C'(T - T_0)^2$ Brown's
                                                   "parabolic"
                                                   equation

(ii) $\nu_Q = A + BT + CT^2 + DT^3 + ET^4$

                                                   a fourth-order
                                                   polynomial

(iii) $\nu_Q = a + bT + c/T$ Kushida's high
                                                   temperature
                                                   expression.

                                                            (8)

The parabolic and fourth-order equations are found to
provide equally good fits to the experimental curves as
shown by the mean square deviations given in Table 2.
The high temperature expression of Kushida provides a
poor fit. Since the quadritic equation can be obtained
from Kushida's equation[8] by assuming a linear tem-
perature dependence of the torsional frequencies, our
results show that the volume expansion effects are not

$$\Delta = \text{mean square deviation in } (KHz)^2.$$

negligible, similar to our observations in other cyclophosphazenes.[9]

These results for $N_4P_4Br_8$ can be compared with the ^{35}Cl NQR results for $N_4P_4Cl_8$[10,11]. The spectrum of the bromo-compound is similar to that of the K-form of $N_4P_4Cl_8$. Secondly, X-ray investigations[2] of $N_4P_4Br_8$ at 120°C reveal that there is no phase transition to any other structure, unlike the chloro-derivative which undergoes a metastable-to-stable phase transition at 63°C[11]. Thirdly, we observe a divergence of the two ^{79}Br frequencies as temperature is lowered to 77 K unlike the behaviour of the isostructural K-form of $N_4P_4Cl_8$. This shows that the two Br sites are distinct even in the stationary molecule (in the absence of thermal motions).

2.2 Frequency assignment in $N_3P_3Br_6$

Br NQR signals in $N_3P_3Br_6$ could be observed only at 77 K using phase sensitive detection. Corresponding to the ^{81}Br isotope there are two signals, at 201.319 MHz and 202.415 MHz, with relative intensities 1:2 (respectively) and two more signals near 198 MHz. The frequencies of the latter two signals could not be fixed more accurately because of overlapping sets of sidebands of the SRO but are within 200 KHz of each other and they also differ in their intensities by 2:1 (as ν_Q increases). A similar pattern of two well-separated signals, at 241.035 and 242.290 MHz, and two other signals near 236.5 MHz, has been observed for ^{79}Br.

The crystal structure of this compound has been investigated by several groups.[12–14] The crystal is orthorhombic, of space group P_{cmn}, containing 4 molecules in the unit cell. The molecule is slightly non-planar and the asymmetric unit consists of two $NPBr_2$ groups (Fig. 1). Thus, there are four inequivalent Br sites. The occupancies of these four sites in the unit cell are as 4:4:8:8 from Br(1) to Br(4) in the crystal structure notation.

Table 3. Assignment of ^{81}Br NQR in $N_3P_3Br_6$

Site	Electron density e.Å^{-3}	Population in Unit cell	NQR frequency (MHz)	Observed relative intensity
Br(3)	28.71	8	202.415	2
Br(2)	29.91	4	201.319	1
Br(4)	32.57	8	~198.2	1
Br(1)	32.71	4	~198	2

The observation of four signals in the ^{81}Br (as well as ^{79}Br) spectrum is consistent with the number of inequivalent Br sites. Secondly, the result that the signals are not all of the same intensity is understandable since the site populations are different. However, as all the P–Br bond lengths are identical within experimental error,[14] no site assignment of frequencies is possible on the basis of bond lengths.

We have tried to make an assignment of NQR frequencies based on site electron density maxima available from the crystal structure (F_c differential synthesis) analysis of Giglio and Puliti.[12] It is known that in molecular solids the NQR frequency is directly related to the electron distribution in the vicinity of the quadrupolar nucleus.[15] From simple quantum mechanical treatments of halogen bonding and NQR frequencies, it is known that the electric field gradient (i.e. NQR frequency) is decided by the p-electron density. Furthermore, we ascribe the differences in the electron density at the four inequivalent Br sites to differing σ bond populations of the various halogens, since the bond lengths point to negligible π character of P–X bonds in cyclophosphazenes. As it is known that the lower the σ bond population the higher is the NQR frequency,[15] we arrive at an assignment of the spectrum as detailed in Table 3.

The observation of a well-separated pair of signals of intensity ratio 2:1 (as ν decreases) is in very good agreement with the expected result. The observation of a close-lying doublet at the lower frequency of 198 MHz is in conformity with the nearly *equal* and relatively *higher* electron densities of Br(4) and Br(1). However, individual site assignment of this doublet cannot be reliably made since the two electron densities differ by an amount much less than the standard deviation error ($\sigma(\rho_0) = 0.40 \text{ e A}^{-3}$) quated in the X-ray work.

Department of Chemistry, University of the West Indies, Kingston 7, Jamacia

Abstract—The formation kinetics of Ni(1-nitroso-2-naphthol-6-sulphonate) are reported in the temperature range 20–30°C at an ionic strength of 0.1 M. Both the acidic (HL^-) and basic (L^{2-}) forms of the ligand react with nickel ions, the latter at a much higher rate. The rate constants are similar in magnitude to those observed with 1-nitroso-2-naphthol-3, 6-disulphonate and variation of rate constant with respect to temperature is reproduced by the equation

$$k_b = 4.01 \times 10^{13}(1\ mol^{-1}\ sec^{-1}) \exp(-12,900/RT).$$

Ortho-nitroso-naphthols are powerful complexing agents.[1] The parent compound 1-nitroso-2-naphthol and two sulphonated derivatives are well known[2] for their chelating properties.

These ligands react with Ni(II) ions in aqueous solution at rates which are convenient for stopped-flow spectrophotometry. In previous studies[3-5] it was found that the dissociation rates of certain nickel nitroso-naphthol complexes depend on the relative positions of the -NO and -OH groups and on the number and position of sulphonate group substituents. Also the formation rate of nickel (1-nitroso-2-naphthol-3, 6-disulphonate), (NiNRS), shows an unusual pH dependence in that the rate, instead of approaching a limiting value at low pH decreases as the pH is decreased.[8] In the dissociation of this complex there is also an expected and not fully explained lack of dependence of the rate constant on ionic strength. In order to gain further information about these reactions we studied the formation rate of Ni(1-nitroso-2-naphthol-6-sulphonate), (NiL), over the temperature range 20–30° over a range of acidities and at ionic strength 0.1 M.

EXPERIMENTAL

Reagents
Freshly prepared glass-distilled water was used throughout.

*Author to whom correspondence should be addressed.

The ligand was prepared by nitrosation of sodium 2-naphthol-6-sulphonate at 0°C. The yellow sodium salt which formed was recrystallized several times from water and air-dried. Solutions of nickel(II) nitrate were prepared and analysed as described previously.[5] Ionic strengths were maintained constant by use of
1-nitroso-2-naphthol
1-nitroso-2-naphthol-6-sulphonate

1-nitroso-2-naphthol-3,6-disulphonate

lithium nitrate and 2,6-lutidine/nitric acid mixtures were used for pH control.

Kinetics
Kinetic measurements were carried out as described previously.[3] After each run the pH of the reaction mixture was measured on an Orion 801A ion analyser fitted with a combination glass electrode. Temperature control was better than ±0.2°.

RESULTS AND DISCUSSION
The mechanism of the reaction can be written as

$$Ni^{2+} + HL^- \rightleftharpoons NiL + H^+ \qquad (1)$$

$$Ni^{2+} + L^{2-} \rightleftharpoons NiL \qquad (2)$$

where HL^- and L^{2-} represent the acidic and basic forms of the ligand respectively. The rate equation for the formation of NiL is then

$$\frac{1}{[Ni^{2+}]} \frac{d[NiL]}{dt} = k_{obs}[L_T] \qquad (3)$$

$$= k_a[HL^-] + k_b[L^{2-}] \qquad (3)$$

L_T is the total concentration of ligand and k_b and k_a are the formation rate constants for the reactions of L^{2-} and HL^- respectively. Equation (4) is equivalent to

$$\frac{k'}{[Ni^{2+}]}\left(1+\frac{K}{\{H^+\}}\right) = k_a + k_b \frac{D}{\{H^+\}} \quad (5)$$

where k' and K are the pseudo- first order rate constant and the dissociation constant respectively of the ligand. Hydrogen ion activities rather than concentration are used since K is a "mixed" constant.

The measured pK values at 0.1 M ionic strength are: 15°C, 6.79; 25°C, 7.06. These values were used to obtain values of K at 20 and 30° to match two of the temperatures used in the kinetics work by use of eqn (6):

$$K = 1.494 \times 10^{-15} \exp\frac{(10594)}{(RT)}. \quad (6)$$

The values of K which were used are shown in Table 1. Table 2 contains the kinetic data for the formation reaction at three temperatures.

The data in Table 2 were fitted by the linear least squares method to eqn (5) using the respective pKa values in Table 1. The results are shown in eqns (7)–(9):

At 20°C; $k_{obs}(1 + K/\{H^+\}) = 2.97(1.8) \times 10^2$
$$+ 9.95(0.18) \times 10^3 \frac{K}{\{H^+\}} \quad (7)$$

Table 3. Formatation rate constant (k_b) for Ni and NiNRS⁻

Temp/°C	NiL[a] $k_b/10^4$ M^{-1} s^{-1}	NiNRS⁻[b] $k_b/10^4$ M^{-1} s^{-1}
15	-	1.17
20	0.99	1.54
25	1.57	1.96
30	2.06	-

(a) I, 0.10 M   (b) I, 0.50 M (Ref.3)

At 20°C; $k_{obs}(1 + K/\{H^+\}) = 1.84(0.12) \times 10^3$

$$+ 1.57(0.023) \times 10^4 \left\{\frac{K}{\{H^+\}}\right\}. \quad (8)$$

At 30°C; $k_{obs}(1 + K/\{H^+\}) = 3.70(0.62) \times 10^3$

$$+ 2.06(0.08) \times 10^4 \left\{\frac{K}{\{H^+\}}\right\}. \quad (9)$$

The terms in brackets are standard deviations.

Because $k_a \ll k_b$ the intercepts cannot be regarded as accurate. The values are of the right order of magnitude however, since a combination of, for example, the value of k_a at 25° with the dissociation rate of 2240 l m^{-1} sec^{-1} obtained at the same ionic strength and temperature[4] gives an equilibrium constant for reaction (1) of 0.78 is reasonable agreement[6] with the measured value of 0.32.

The best fit to eqn (5) was also obtained by varying K to produce a minimum sum of squares of the deviations between k_{obs} and k_{calc}. This yielded the value of pK shown in the final column of Table 1 and provides some additional justification for the mechanism accepted.

The slopes of the least squares lines give reasonably accurate values at k_b. These values, which are summarized in Table 3, give, when fitted to an Arrhenius type equation, the following temperature variation:

$$k_b = 4.01 \times 10^{13} \exp -(12,900/RT) \quad (10)$$

Also shown in Table 3 are some formation rate constants for NiNRS⁻ and these are seen to be similar to those for NiL, although the conditions of measurement were somewhat different. The 3-sulphonate substituent therefore has no marked effect on the formation rates in the pH range available for experimental study. The k_b values reported here are also of the same order of magnitude observed for a variety of ligands, both monodentate and bidentate.[7]

The features indicate that the ring closure is not rate determining and that the removal of water from the coordinaton sphere of $Ni(H_2O)_6^{2+}$ is the controlling process.

BINUCLEAR TUNGSTEN(V) OXO-COMPLEXES
WITH 1,1-DITHIOLATE LIGANDS

R. LOZANO,* E. ALARCÓN, A. L. DOADRIO and A. DOADRIO

Departamento de Química Inorgánica, Facultad de Farmacia, Universidad Complutense de Madrid, Madrid (3),
Spain

Abstract—In this paper we report the synthesis of some new oxo and sulphido bridged tungsten(V) complexes with
N-ethylanilindithiocarbamate and N,N-methylcyclohexyldithiocarbamate as ligands. These complexes have been
characterised by analytical, magnetochemical and spectral methods. The results permit us to assign the formulae:
$W_2O_3(LL)_4$, $W_2O_4(LL)_2$, $W_2O_2S_2(LL)_2$ and $W_2O_3S(LL)_2$. The low magnetic moments observed in these complexes,
are due either to an interaction through the bridging atoms or to a direct spin-spin interaction. IR and
electronic absorption spectra of these complexes are sensitive to substitution of sulphur atoms into the bridge
system. The systematic changes upon bridge modification are useful in characterizing the compounds and in
clarifying assignments of W–O and W–S bridge stretching frequencies. The results are discussed on the basis of
structural information available for tungsten complexes.

In recent years, considerable interest has grown in sulphur-containing compounds of molybdenum with respect to the biochemical implications of their redox behaviour.[1] Synthesis and structure of mononuclear and binuclear molybdenum complexes were previously reported.[2–4]

Tungsten often presents very close properties to molybdenum, but such binuclear compounds are not so numerous in tungsten chemistry.

The object of the present study, has been to obtain binuclear complexes of tungsten(V) with N-ethyl-anilindithiocarbamate and N,N-methylcyclohexyl-dithiocarbamate as ligands

In this paper, we describe the isolation and characterization of four different dimeric complexes of tungsten(V).

(a) Tungsten(V) oxo-complexes with a monoxo bridge—$W_2O_3(LL)_4$.

(b) Tungsten(V) oxo-complexes with a dioxo bridge—$W_2O_2(LL)_2$.

(c) Tungsten(V) oxo-complexes with a disulphido bridge—$W_2O_2S_2(LL)_2$.

(d) Tungsten(V) oxo-complexes with oxo-sulphido bridge—$W_2O_3S(LL)_2$.

We have proved too that the 4 kinds of binuclear tungsten(V) complexes that have been obtained here, have the same structure and characteristics as the dimeric complexes of molybdenum(V) obtained by us, showing that tungsten and molybdenum present a very similar behaviour.

EXPERIMENTAL

(a) *Materials*

$Na_2WO_4 \cdot 2H_2O$ was Merck commercial product used as supplied. Sodium N-ethylanilindithiocarbamate and sodium N,N-methyl-cyclohexyldithiocarbamate, were prepared by the reaction of sodium hydroxide with carbon disulphide and N-ethylaniline in water or N,N-methylcyclohexylamine in alcohol respectively, and were recrystallized from alcohol. The solvents used to prepare the complexes were Carlo Erba or Merck; the solutions for absorption spectra were prepared with dimethylsulphoxide (DMSO) and CH_2Cl_2 spectral grade Merck–Uvasol.

(b) *Analytical procedures*

Elemental analyses were performed by "Instituto de Química Orgánica" C.S.I.C., Madrid, Spain. Tungsten was determined by atomic absorption spectrophotometry, with a Perkin–Elmer model 430 atomic absorption spectrophotometer after the complex had been decomposed by heating with concentrated sodium hydroxide.

Analytical data are given in Table 1.

(c) *Methods*

Magnetic susceptibility was determined by the Gouy method at room temperature in a Mettler H-51 A.R. balance and a type C Newport electromagnet. Molar susceptibilities given are corrected for the diamagnetism of the constituent atoms.

The magnetic moments were calculated according to the formula $\mu = 2.84(\chi_M \cdot T)^{0.5}$ B.M., where χ_M is the corrected molar susceptibility.[5]

Table 2 shows the results obtained.

The IR spectra have been registered on a Perkin–Elmer recording spectrophotometer model 283. The samples were run as KBr pellets. Important IR absorption peaks for the complexes prepared in this study are listed in Table 3.

The visible-near UV spectra of the compounds, were measured in the range 200–900 nm on a Perkin–Elmer recording spectrophotometer model 554, over dissolutions of the complexes in DMSO and CH_2Cl_2. We have registered the same peaks for both solvents, however we give in Table 4 the results obtained in DMSO as solvent, because all the complexes have a limited solubility in CH_2Cl_2.

(d) *Preparation of the complexes*

All the compounds prepared in this study were susceptible to air oxidation, therefore all manipulations and reactions were carried out in a nitrogen atmosphere dry box or on a vacuum line.

$W_2O_3(S_2CNC_8H_{10})_4$. $Na_2WO_4 \cdot 2H_2O$ (1.65 g) was dissolved in water (30 cm^3) and it was treated with concentrated sodium hydroxide to avoid the polymerization. This solution was added to a solution of sodium N-ethylanilindithiocarbamate (2.35 g) in water (35 cm^3) with vigorous stirring. The resulting yellow solution, was added to a solution (freshly prepared) of sodium dithionite (0.5 g) in water (20 cm^3). Lastly, drop by drop, glacial acetic acid was added till reaching pH = 5. There was an immediate dark-violet precipitate. The suspension was set aside for 1 hr and then filtered *in vacuo*. The residue was washed with a boiling water–ethanol mixture (50%) and dried over P_2O_5. Yield: 52%.

$W_2O_4(S_2CNC_8H_{10})_2$. A solution of $Na_2WO_4 \cdot 2H_2O$ (3.30 g) in water (40 cm^3) was treated with concentrated sodium hydroxide. The resulting solution was added to a solution of sodium N-ethylanilindithiocarbamate (2.35 g) in water (35 cm^3). A solution of sodium dithionite (1.0 g) in water (20 cm^3) was prepared and this

solution was added to the previous one, and the resulting solution takes a brown color. Dilute hydrochloric acid was added dropwise until precipitation of the complex was complete. The precipitate was filtered by suction and the violet residue was washed with hot water and absolute ethanol, and dried *in vacuo* over P_2O_5. Yield: 70%.

$W_2O_2S_2(S_2CNC_8H_{10})_2$. 3.30 g of $Na_2WO_42H_2O$ was dissolved in water (40 cm³) and to this was added 10 ml of concentrated sodium hydroxide. The resulting solution, was treated with sodium N-ethylanilindithiocarbamate (2.35 g) in water (35 cm³). Hydrogen sulphide was passed through the resulting solution with simultaneous cooling in freezing mixture for 30 min. The solution gradually takes a brown color. Drop by drop, glacial acetic acid was added till reaching pH = 6, and a brown solid precipitates. The suspension was heated, cooled and filtered. The brown residue was washed with hot water and dried *in vacuo* over P_2O_5. Yield: 75%.

$W_2O_3S(S_2CNC_8H_{10})_2$. A solution of $Na_2WO_4 \cdot 2H_2O$ (3.30 g) in 2M sodium hydroxide (40 cm³), was treated with dilute hydrochloric acid till reaching pH = 6. Hydrogen sulphide was bubbled slowly through the resulting solution for 1 hr. The solution gradually takes a reddish brown color, and it was added to a solution of sodium N-ethylanilindithiocarbamate (2.35 g) in water (35 cm³). Lastly, glacial acetic acid was added dropwise until the precipitation of the complex was complete. The precipitate was filtered *in vacuo* and the brown residue was washed with hot water and dried over P_2O_5. Yield: 72%.

A similar preparation was carried out for the complexes with N,N-methylcyclohexyldithiocarbamate as ligand.

RESULTS AND DISCUSSION
Preparation of complexes
The analytical data shown in Table 1 and the spectroscopic data to be presented later, are consistent with the formation of four series of μ-oxo, di-μ-oxo, μ-oxo-

μ-sulphido and di-μ-sulphido tungsten(V) complexes. The preparative procedures described in the Experimental Section are simple.

If we start from $Na_2WO_4 \cdot 2H_2O$ solution and make it react with a solution of the ligand in water, and reduce W(VI) to W(V) with sodium dithionite, such reactions precipitate complexes of dimeric structure in an acid medium.

If we effect the precipitation at pH = 5, with acetic acid, the complexes obtained present a monoxo bridge, the thoichiometry is 2:1 and the tungsten is six-coordinated. The formula which most closely fits the analyses is $W_2O_3(LL)_4$. We suggest that the structure for these complexes should be as follows:

However, if we precipitate the complexes at pH = 2, the stoichiometry of the compounds is 1:1, the tungsten is five-coordinated and these complexes present a dioxo bridge. The formula which we assign to these complexes is $W_2O_4(LL)_2$ and we suggest that the compounds

present the following structure:
The complexes obtained when bubbling H_2S upon the solution of $Na_2WO_4 \cdot 2H_2O$ and the ligand in water, present a stoichiometry 1:1, the tungsten being 5-coor-

dinated. The union between two atoms of tungsten is made by means of a disulphido bridge. The formula which we assign to these complexes is $W_2O_2S_2(LL)_2$, and the structure should be as follows:
The complexes synthesized when bubbling H_2S into $Na_2WO_4 \cdot 2H_2O$ in dilute hydrochloric acid, followed by addition of the ligand, present a oxo-sulphido bridge, the stoichiometry is 1:1 and the tungsten is 5-coordinated. The formula which most closely fits the analyses is $W_2O_3S(LL)_2$ and we suggest that the structure for these complexes should be as follows:
Magnetic properties

The low values of magnetic susceptibilities and magnetic moments, suggest the presence of dimeric species for these complexes.

The complexes of formula $W_2O_3(LL)_4$ gave values for the magnetic moments of 0.58 B.M. and 0.55 B.M. (see Table 2) respectively for the complexes with monoxo bridge and N-ethylanilindithiocarbamate and N,N-methylcyclohexyldithiocarbamate as ligands. These low magnetic moments then arise by interaction through the oxide bridge. Similar behaviour occurred in molybdenum(V) oxo-complexes with a monoxo bridge.[2-4]

The magnetic moments found for the complexes of formulas $W_2O_4(LL)_2$, $W_2O_2S_2(LL)_2$ and $W_2O_3S(LL)_2$, which present a dimeric structure with dioxo bridge, disulphido bridge and oxo-sulphido bridge respectively, 0.25 B.M.–0.01 B.M. (see Table 2), are lower than the magnetic moments of the dimeric complexes with a monoxo bridge. This is due to the possible formation of a direct metal–metal bond, which is more favorable to the dioxo, disulphido and oxo-sulphido bridge than to the monoxo bridge, due to the shorter bond length between the tungsten atoms, as it has been proved for molybdenum(V) oxo-complexes.[6]

IR *spectra*

The IR spectra of the four different kinds of complexes studied, exhibit a very strong band in the range 940–952 cm⁻¹, which we attribute to the vibration of the symmetric stretching mode of the terminal W=O bond. The antisymmetric stretching mode has not been detected. However, the appearance of the symmetric stretching mode, is sufficient to designate, in the dimeric complexes, a *cis* disposition of the two terminal W=O.[6]

Although the terminal oxygen–metal bonds are very sensitive to the variations produced in the metal donor atom, as it is habitual in all oxocation complexes of metal-oxo group, we have not observed any particular change for the frequency of the W=O terminal bonds. The IR spectra of the complexes with monoxo bridge, dioxo bridge and oxo-sulphido bridge, exhibit two bands between 815 and 440 cm⁻¹, which we attribute to the vibration of the antisymmetric and symmetric stretching mode, respectively, of the W–O bridge bond.

Upon comparing the IR spectra of the complexes with monoxo bridge and the IR spectra of the complexes with dioxo bridge, one observes no differences for the vibration frequency of the antisymmetric stretching mode in contrast to what was claimed by other workers,[7] who tried to solve the problem of differentiating the monoxo and dioxo bridge by means of the IR spectra.

The IR spectra of the complexes with disulphido and oxo-sulphido bridge, show two bands over 470 and 365 cm⁻¹, which we attribute to the vibration of the antisymmetric and symmetric stretching mode, respectively, of the W–S bridge bond.

If we compare the IR spectra of tungsten(V) dithiocarbamates complexes with the IR spectra of sodium dithiocarbamates, we observe that tungsten(V) complexes exhibit in the IR spectra the band of the stretching mode of the C–N bond displaced to higher frequencies than sodium dithiocarbamates. The IR spectra of tungsten(V) complexes exhibit this band in the range 1527–1512 cm⁻¹ (see Table 3), while the IR spectra of sodium N-ethylanilindithiocarbamate and sodium N,N-methylcyclohexyldithiocarbamate exhibit this band at 1460 and 1445 cm⁻¹ respectively. This difference may be attributed to a substantial contribution of resonance form:
Fig. 1. Resonance form A.

in tungsten(V) dithiocarbamates complexes, while in sodium dithiocarbamates, the following resonance forms take place:[8]
Fig. 2. Resonance forms B.

Consequently, the frequencies of the stretching mode of the C–S bond must be lower in tungsten(V) dithiocarbamates complexes than in sodium salts, because the C–S bond is not so strong in tungsten(V) complexes due to the stronger C–N bond. The IR spectra of tungsten(V) dithiocarbamates complexes exhibit the band of the C–S stretching mode in the range 1137–1119 cm⁻¹ while in the IR spectra of sodium N-ethylanilindithiocarbamate and sodium N,N-methylcyclohexyldithiocarbamate, this band appears at 1145 and 1170 cm⁻¹, respectively.

The IR spectra of all dithiocarbamate complexes show also other absorptions, over 335–345 cm⁻¹, attributed to tungsten–sulphur frequencies. The results of the present work are in good agreement with the assignments reported by Nieuwpoort and Steggerda[9] for eight-coordinated 1,1-dithio ligand complexes of W(IV).

Electronic spectra

The electronic spectra of the dimeric complexes with monoxo bridge and formula $W_2O_3(LL)_4$ exhibit two bands in the 715–590 nm region, which we attribute to d–d transitions $^2B^2 \rightarrow {}^2E(I)$ and $^2B_2 \rightarrow {}^2B_1$ respectively, according to the Balhausen–Gray scheme[10] for an octahedral structure. These complexes exhibit two other bands in the 470–420 nm region which we assign to a charge-transfer of the ligand-to-metal.

In the electronic spectra of the dimeric complexes with

dioxo bridge, oxo-sulphido bridge and disulphido bridge, we cannot observe appreciable differences between them, and that is why we propose the same structure for all these complexes. These complexes exhibit two bands over 640 and 560 nm that we attribute to $^2B_2 \rightarrow {}^2E(I)$ and $^2B_2 \rightarrow {}^2B_1$ transitions, respectively, for a possible square-pyramidal structure.[11]

In the visible region, we can detect two other bands over 470–420 nm, which we attribute to charge-transfer transitions.

The dimeric complexes with disulphido and oxo-sulphido bridges, present another transition over 450–440 nm which we assign to a charge-transfer as we have observed in similar complexes of molybdenum(V).[12,13]

On comparing the visible spectra of the dimeric complexes with monoxo-, dioxo, disulphido and oxo-sulphido bridges, one observes that the change produced in the d–d transitions on varying the coordination and passing from an octahedral structure for the six-coordinated complexes with monoxo bridge, to a square pyramidal structure for the complexes with 5-coordination and dioxo, disulphido and oxo-sulphido bridges.

The electronic spectra of tungsten(V) dithiocarbamate complexes, prepared in this study, show, in the ultraviolet region, three bands over 340, 300 and 260 nm. The electronic spectra of the sodium dithiocarbamates exhibit also three bands at the same wavelength. The differences are not significant. We attribute these bands to intraligand transitions. The first to a $n \rightarrow \pi^*$ transition, the second to a $\pi \rightarrow \pi^*$ transition and the last to a $n \rightarrow \sigma^*$ transition.

MULTINUCLEAR MAGNETIC RESONANCE AND RELATED STUDIES ON SOME ORGANOTIN(IV) COMPLEXES OF DITHIOCARBAZATES

ANIL SAXENA† and J. P. TANDON*

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

Abstract—Synthesis, characterization and geometrical features of pentacoordinated dibutyltin(IV) dithiocarbazate complexes of the type n-Bu$_2$Sn L {(where L = dianion of S-methyl-B-N (2-hydroxy-phenyl) methylene and methyl dithiocarbazate} are described. These are obtained as viscous oils from the reactions of n-Bu$_2$SnO with equimolar proportions of the ligands in benzene. On the basis of UV, IR, NMR (^{1}H, ^{13}C, ^{119}Sn) spectra along with the mass spectral fragmentation pattern a trigonal bipyramidal geometry is proposed. The N atom probably occupies the axial site, while the remaining two donor atoms O and S and the dibutyl groups rest in an equatorial plane. These complexes are active against P.388 Lymphocyte leukaemia system.

The number and diversity of S N chelating agents used to prepare new coordination and organometallic compounds has increased rapidly during the past few years. The pronounced biological activity[1,2] of the metal complexes of ligands derived from dithiocarbazic acids has created considerable interest in their coordination chemistry. Complexes of dithiocarbazates with many different transition metal ions[3,4] have been studied extensively over the last years and only limited information on the bonding and structural features is available for the tin(IV) complexes.[5] Our continuing interest in chelated tin(IV) derivatives[6] has led us to describe the synthetic and stereochemical features of some dibutyltin(IV) dithiocarbazate complexes.

EXPERIMENTAL

Materials and methods. Chemicals and solvents used were dried and purified by standard methods, and moisture was excluded from the glass apparatus using CaCl$_2$ drying tubes. The ligands were prepared by the literature method.[7] The complexes were prepared, purified and analyzed by methods similar to those reported in our earlier publications.[5]

Spectral measurements. The electronic spectra were recorded in methanol on a Pye-Unicam-SP-8-100 spectrophtometer. Infrared spectra were obtained on a Perkin–Elmer 577 grating spectrophotometer an Nujol mulls or in benzene solution. ^{1}H NMR spectra were recorded on a Perkin–Elmer RB-12 spectrometer in CDCl$_3$ using TMS as an internal standard at 90 MHz. ^{13}C NMR spectra were recorded on Bruker HFX-90 spectrometer in CHCl$_3$ using TMS as internal standard at 25.15 MHz. Coupling constants were obtained from between 1000 and 12000 pulses and the assignments are based on off-resonance decoupling and satellite peaks. ^{119}Sn NMR spectra were recorded on a Bruker HFX-90 spectrometer in CHCl$_3$ using TMT as external standard at 22.7 MHz. Mass spectra were recorded on VG Micromass-7070 F spectrometer at 70 eV with ionization chamber at 220°C and calibrated using perfluorokerosene.

RESULTS AND DISCUSSION

The reactions of dibutyl tin oxide with the ligands proceed smoothly with the elimination of water, which

was removed azeotropically with benzene:

$$Bu_2SnO + H_2L \rightarrow Bu_2SnL + H_2O. \quad (1)$$

The derivatives so isolated are highly viscous oils, miscible with most organic solvents and hydrolyzable in nature.

In the electronic spectra of the ligands,[8] a band at ca. 216 nm is observed which may be assigned to ^{1}B band of the phenyl ring. This shifts to higher wave length on complexation and is observed at ca. 222 nm in the complexes. Also the ligand chromophore >C=N, which absorbs at ca. 290 nm, shifts to a higher wavelength and is observed at ca. 298 nm in the complexes. Three sharp bands are observed in the region, 250–270 nm and assigned as change transfer bands, suggesting the formation of σ-bonds[9] and (p → d) bonds[10] between p-orbitals of O and S and vacant 5d orbitals of tin.

The IR spectra of the ligands[11] show a broad and strong band in the region, 3300–2850 cm^{-1} attributable to ν(OH) and ν(NH) modes and no band is observed at ca. 2570 cm^{-1}, showing the absence of ν(SH). However, it does appear in the solution spectra with the disappearance of ν(NH) and ν(C=S) bands. This suggests the existence of a tautomeric equilibrium[12] between the two forms of ligand as shown below:

(thione)

(thiol) (2)
In the IR spectra of the complexes, all νOH or νSH bands are absent, showing the bonding of oxygen and

sulphur to the metal by the loss of thiolic and phenolic protons of the ligands. A band of medium intensity at *ca.* 1585 cm^{-1} in the complexes may be assigned to ν(C=N) vibration, and which originally appears in the ligand at *ca.* 1605 cm^{-1} in both the solution and solid states. The shift of this band to the lower energy indicates the coordination of the azomethine nitrogen to the tin atom[13] Two bands at *ca.* 600 and 510 cm^{-1} are also observed and which may be assigned to (Sn–C) asymmetric and symmetric modes respectively and thus indicating the presence of a bent C–Sn–C moiety.[14]

Besides this, several new bands observed at *ca.* 565, 425 and 325 cm^{-1} in the complexes may be assigned to ν(Sn–O), ν(Sn–O) and ν(Sn–S), respectively and thus lending support to the proposed coordination in the complexes.

In the ^{1}H NMR spectra, a broad signal at δ 7.15 ppm is observed in all the complexes owing to the phenyl protons of the salicylaldehyde and *o*-hydroxyacetophenone residues. A further sharp signal is observed at δ2.50 ppm attributable to the –CH$_3$ protons of dithiocarbazate moiety. In the complexes, the disappearance of the signals at *ca.* δ11.20, 4.35 and 10.05 ppm assigned to OH, SH and NH protons, respectively, in the spectra of the ligands clearly indicates their deprotonation. Signals at δ8.7 ppm in complex (I) and δ2.8 ppm in complex (II) occur owing to the –CH and –CH$_3$ protons, respectively. These are shifted downfield as compared to their positions in the ligands owing to the coordination of C=N group with the metal atom. The complexes show additional signals at δ 0.7–1.8 ppm owing to the protons of butyl group.

The mass spectral fragmentation scheme of the compound Bu$_2$Sn[OC$_6$H$_4$.C(CH$_3$):N.N.CS(SCH$_3$)] is shown in Fig. 1. The molecular ion peak due to ^{119}Sn isotope is observed at *m/e* 471. The peaks at *m* + 1 and *m* – 1 have also been observed due to the presence of ^{118}Sn and ^{120}Sn isotopes. The fragmentation starts with the simple cleavage of Sn–Bu bond eliminating Bu of 57 a.m.u. leading to the formation of a three coordinate Sn fragment ion[15]. The base peak is observed at *m/e* 352. However, the Sn–S bond is more readily cleaved than the Sn–O bond. Some low abundance ions containing Sn–S at *m/e* 151 are also obtained by the processes not involving cleavage of bonds[16]. The last step in the fragmentation is the removal of HCN molecule, which is characteristic of the Schiff base complexes.[17]

^{13}C NMR data have been recorded for both the ligands
Fig. 1. Mass spectrum of C$_{18}$H$_{28}$S$_2$N$_2$OSn.
Fig. 2. Structure of organotin complex.

and the complexes. The shifts in carbons attached to O, S and N indicate the involvement of O, S and N atoms in coordination. The α(C) shifts and ^{1}J(^{119}Sn–^{13}C) values of 555 and 561 Hz indicates the five coordination around the tin atom in these complexes. Domazetis *et al.*[18] have reported a value of 560 Hz for Bu$_2$Sn complexes of thioamino acids and which are further supported by Mitchell *et al.*[19]

These complexes give sharp signals at δ-130.4 and – 156.7 ppm in ^{119}Sn NMR spectra and which strongly support the five coordination around tin in a trigonal

CONDENSATION OF β,δ-TRIKETONE DERIVED FROM DEHYDROACETIC ACID WITH ALIPHATIC AMINES AND COPPER(II) COMPLEXES OF THE SCHIFF BASES

V. DREVENKAR, A. DELJAC and Z. ŠTEFANAC*
Department of Chemistry, Faculty of Science, University of Zagreb, Strossmayerov trg 14, YU-41000, Zagreb, Yugoslavia

and

J. SEIBL
Department of Organic Chemistry, Swiss Federal Institute of Technology, Zürich, Switzerland

Abstract—The condensation of ethyl-2-hydroxy-4-oxo-4-(4-hydroxy-6-methyl-2-pyrone-3-yl)-2-butenoate with primary aliphatic monoamines occurs at 4-hydroxy group of the pyrone ring according to ^{1}H NMR and mass spectrometric data. The ketamine tautomeric form of the prepared Schiff bases is predominantly present in chloroform solutions. Isolated crude copper(II) complexes of the condensation products are shown to be mononuclear with the 1:2 metal to ligand ratio.

Several possibilities of applying ethyl - 2 - hydroxy - 4 - oxo - 4 - (4 - hydroxy - 6 - methyl - 2 - pyrone - 3 - yl) - 2 - butenoate as an analytical reagent have been reported previously.[1-4] Chelate complexes with numerous cations are formed owing to the predominantly present bisenolic form of this β,δ-tricarbonyl compound.[4] Generally, the Schiff bases prepared by condensation of β-hydroxy-, β-di- and β-tri-ketones with mono- or diamines act as potentially di-, tri- or polydentate ligands, so that the preparation plays a distinctive role in the specific design of new complexing agents.[5] Considering such an approach for the oddly substituted tricarbonyl system of the reagent we performed the condensation with primary aliphatic monoamines and studied the structural characteristics as well as the complexation behaviour of the obtained Schiff bases using copper(II) complexes as a model system.

EXPERIMENTAL

Apparatus

The UV/VIS spectrophotometer Varian Techtron Series 635D was used throughout the experiments. The IR spectra were taken in KBr pellets with a Perkin–Elmer model 257 or 167 Grating spectrophotometer. The ^{1}H-NMR spectra were recorded on a Varian A-60 or EM-390 90 MHz spectrometer in CDCl₃ with TMS as internal standard. The mass spectra were taken on a Varian MAT CH7 or a CEC 21-110C instrument.

Materials

Dehydroacetic acid, purum 98%, cyclohexylamine p.a. and n-hexylamine, puriss. were purchased from FLUKA AG (Buchs, Switzerland) while dimethyloxalate, purum, was obtained from the same firm as a gift gratefully appreciated by the authors.

2,2 - Dimethylthio - 1 - amino - ethane was prepared following the procedure described previously.[6]

All other chemicals and solvents were p.a. products of Kemika (Zagreb, Yugoslavia).

Procedures

Preparation of dehydroacetic acid derivatives. Ethyl - 2 - hydroxy - 4 - oxo - 4 - (4 - hydroxy - 6 - methyl - 2 - pyrone - 3 - yl) - 2 - butenoate (I) was prepared elsewhere by condensation of

3-acetyl-4-hydroxy-6-methyl-2-pyrone (dehydroacetic acid) with diethyloxalate in the presence of sodium ethoxide as catalyst. The raw product kindly donated by the authors[7] was purified by recrystallisation from ethanol, dried at room temperature and checked by IR, ^{1}H NMR and mass spectra.[4]

Methyl - 2 - hydroxy - 4 - oxo - 4 - (4 - hydroxy - 6 - methyl - 2 - pyrone - 3 - yl) - 2 - butenoate (II) was obtained by the following procedure.

A suspension of 6.72 g (0.04 mole) of dehydroacetic acid in 15 cm³ of tetrahydrofuran followed by a solution of 4.72 g (0.04 mole) of dimethyl oxalate in 20 cm³ of tetrahydrofuran was slowly added from the separatory funnel to sodium methoxide prepared from 2 g of metallic sodium and 3.2 cm³ of absolute methanol in 25 cm³ of tetrahydrofuran.

The mixture was stirred over a period of 24 hr. The precipitated sodium salt was sucked off, dried in the air and then dissolved in deionized water. The water solution, mixed on a magnetic stirrer, was acidified by addition of Amberlite IR-120 ion exchanger until a yellow precipitate appeared. The solution was filtered and methyl - 2 - hydroxy - 4 - oxo - 4 - (4 - hydroxy - 6 - methyl - 2 - pyrone - 3 - yl) - 2 - butenoate was separated from ion exchanger beads by dissolution in hot ethanol.

For purification the crude product was recrystallized from ethanol.

Compound II, C₁₁H₁₀O₇, yellow powder, m.p. 137–139°C. Found (Calc.): C 51.93 (51.98); H 4.54 (3.97)%. IR-spectrum, $\bar{\nu}$ cm⁻¹ rel. intensity: 3440 b, 3140 w, 2960 w, 1740 vs, 1710 s, 1650 s, 1625 s, 1615 s, 1585 s, 1550 sh, 1540 s, 1455 m, 1430 m, 1250 s, 1230 s, 1120 s, 1000 m. ^{1}H NMR spectrum, δ ppm (multiplicity, comprised H): 2.30 (singl. 3H), 3.90 (singl. 3H), 5.90 (singl. 1H), 7.75 (singl. 1H), 13.00 (broad, 1H), 15.23 (singl. 1H). Mass spectrum, m/e (rel. intensity, %): 254 (9), 239 (4), 212 (15), 197 (6), 195 (39), 166 (5), 153 (100), 126 (4), 111 (11), 85 (23), 69 (38), 43 (50).

Preparation of Schiff bases. An equimolar quantity of the aliphatic amine was added to a solution of compound I (0.006 mole) in abs. ethanol (50 cm³), refluxed on a water-bath during 3 hr whereby the reaction course was pursued by thin-layer chromatography using chloroform/ether (1:1) as mobile phase.

The solvent was evaporated to 25 cm³, the precipitate formed by cooling down the solution was separated and recrystallized from ethanol. The following condensations were performed: compound I with n-hexylamine afforded a yellow woollen precipitate (III) (R_f 0.55, yield 44%) and with cyclohexylamine yellow crystals IV (R_f 0.53, yield 30%); according to thin-layer chromatograms (CHCl₃ as mobile phase) two products were

formed in the course of the condensation of compound **I** with 2,2-dimethylthio-1-amino–ethane. However, after prolonged refluxing (4 hr) only brown needle-shaped crystals of compound **V** were obtained (R_f 0.45, yield 38%).

The condensation of compound **II** with *n*-hexylamine performed analogously yielded Schiff base **VI** as a yellow powder.

Characterization of Schiff bases. Compound **III**, $C_{18}H_{25}O_6N$, light yellow crystals, m.p. 105–106°C. Found (calc): C 61.05 (61.54); H 7.55 (7.12); N 4.54 (4.49)%. IR spectrum, $\bar{\nu}$ cm^{-1} rel. intensity: 3440 b, 2940 m, 2870 w, 1750 s, 1730 sh, 1655 m, 1595 m, 1530 vs, 1360 m, 1240 vs, 1130 w. ^{1}H NMR spectrum, δ ppm (multiplicity, comprised H): 0.90 (tripl, 3H), 1.05–1.90 (multipl. 8H), 1.38 (tripl. 3H), 2.18 (singl. 3H), 3.34 (quart. 2H), 4.35 (quart 2H), 6.53 (singl. 1H), 6.82 (singl. 1H), 10.73 (broad 1H), 19.10 (singl. 1H). DISCUSSION

Unsymmetrical β,δ-triketones can take triketo, two different monoenol and bisenol forms in their tautomeric equilibrium.[5] In the case of ethyl - 2 - hydroxy - 4 - oxo - 4 - (4 - hydroxy - 6 - methyl - 2 - pyrone - 3 - yl) - 2 - butenoate (compound **I**)[4] and the corresponding methyl ester (compound **II**) the prevalence of the bisenol form is in accordance with the recorded spectroscopic data. The IR absorption bands in the region 1800–1500 cm^{-1} correspond to lactone and chelate ring $\nu_{C=O}$ and α-pyrone nucleus $\nu_{C=C}$ vibrations of dehydroacetic acid[8] accompanied by ester and chelate ring carbonyl bands at frequencies analogous to those of ethyl and methyl-diacetoacetate[9] (Table 1). Similarly the ^{1}H NMR spectra might be compared with those of diacetoacetates supplemented with the signals of dehydroacetic acid protons. Instead of acetyl methyl protons $\delta = 2.6$ ppm the singlet $\delta = 7.8$ ppm appears corresponding to the proton of the methyne group that links both enolic moieties. The hydroxyl proton $\delta = 16.6$ of dehydroacetic acid[8] and $\delta = 18.55$ of ethyl diacetoacetate[9] shifted to $\delta = 13.08$ (13.00) and $\delta = 15.22$ (15.20) ppm respectively in compound **I** (**II**) confirm that the bisenol form is predominantly present: 80–90% based on the signal area (Table 2).

Congruence of the mass spectra confirms also analogous structures of compounds **I** and **II**: fragmentation of the ester group results in both cases in *m/e* 195 ion which is followed by an identical series of fragments.[4] The condensation of β,δ-triketones with amines takes place on the terminal carbonyl groups but not on the central group of heptane-2,4,6-trione[10] and in the case of benzoylacetylacetone, anisoylacetylacetone, p-toluylacetylacetone and p-bromobenzoylacetylacetone only on the carbonyl group with the methyl in the α-position.[11]

These regularities could not apply to our case because of the dissimilarity of the triketone. Therefore all carbonyl groups, except lactone and ester carbonyl, have been considered as possible condensation sites paying attention also to the predominantly present tautomeric form of the condensation product.[12]

Considering the central carbonyl group of triketones **I** and **II** as the condensation site, the spectroscopic characteristics of α-pyrone part in obtained Schiff bases are expected to be congruent with those of products of the reaction between dehydroacetic acid and alkyl-amines. Namely, the latter condensation takes place on acetyl carbonyl and the presence of the ketamine tautomeric form has been confirmed by ^{1}H NMR data.[13,14] Spectroscopic characteristics of condensation products as related to dehydroacetic acid can be assembled in the following way. The wavenumber of lactone carbonyl IR absorption bands is decreased for ~20 cm^{-1} and is accompanied by increase of $\nu_{C5=C6}$ value for ~ 30 cm^{-1}.[13,15] Chemical shift δ-values in ^{1}H NMR spectra of Schiff bases for C-5, C-6 methyl and hydrogen

n-Hexyl (VI)	10.2 (triplet)	3.32 (app. quartet ; 2H triplet split to doublets)	$J_{CH_2-CH_2N}$ J_{CH_2NH} 6Hz

* Obviously not AB$_2$ (8 lines) but AB$_2$X spin system incompletely resolved.

bounded enolic proton are reduced by 0.25, 0.20 and 2.82 ppm, respectively. The unambiguous evidence for the ketamine tautomeric form resulted from the presence of a bonded amino-proton signal (δ = 13.78 ppm) and from the observed coupling with alkyl substituents[13] as well as from the correlation of the associated coupling constant (J = 5.00 Hz) with that for the N-methyl group in N-methylacetamide.[14]

Analogously the predominant presence of the ketamine form can be deduced for the Schiff bases of triketones I and II (Table 3). As far as the central carbonyl group as condensation site is concerned the changes of spectroscopic data accompanying the conversion of triketones I and II are not in conformity with those occurring along with the condensation of dehydroacetic acid. Thus apart from incomplete splitting of the lower band (overlapping with ester carbonyl) there is no remarkable change in lactone carbonyl band position

and the wavenumber of $\nu_{C_5-C_6}$ vibrations is increased by not more than $10-15\,cm^{-1}$. Moreover, the increase of C-5 proton chemical shift amounts to $0.59 > \Delta\delta \geq 0.50\,ppm$, an increment suiting better the replacement of substituent in greater proximity.

Additional evidence excluding as the condensation site not only the central carbonyl but also the one next to the ester group has been derived from the mass spectroscopic fragmentation scheme. The base peak m/e 153 corresponding to 3-carbonyl-4-hydroxy-6-methyl-α-pyrone cation characteristic of the mass spectra of triketones I and II is reduced to a much smaller share in the case of Schiff bases and appears as attendant of the more pronounced m/e 152 fragment. This fact eliminates the condensation with amines at the ester terminus of the triketo system because in such a case the fragment m/e 153 should be abound and m/e 152 ion absent. The series of fragments m/e 194, 152 and 84 might come from the fragmentation of molecular ions if condensation at either

C-3 carbonyl or C-4 hydroxyl group on α-pyrone nucleus is proposed (Scheme I). However, fragment m/e 168 in the mass spectrum of compound III can be explained only by fragmentation of the species that arises from condensation at hydroxyl group on α-pyrone ring. The more so as the measured mass 168.1396 is congruent with elemental formula $C_{10}H_{18}ON$. Ethoxy rearrangement as another explanation for the origin of ion m/e 168 (Scheme II) has been eliminated by synthesizing the methyl ester (II) and its Schiff base (VI). The presence of m/e 168 in the mass spectrum of compound VI is a definite proof that condensation occurs at α-pyrone hydroxyl group. Correspondent fragment m/e 166 is present in the mass spectrum of condensation product IV (Scheme III).

Fragments with unbroken (unimpaired) pyrone ring still bearing a carbonyl group and an N-alkyl substituent are also recorded as ions m/e 236 for compounds III and VI and m/e 234 for compound IV. More aboundant ions

m/e 238 and m/e 237 in the mass spectrum of Schiff base VI corresponding to m/e 252 and m/e 251 of Schiff base III very probably have origin in the N-alkyl residue cleavage from molecular ion.

Apart from the different ester groups, Schiff bases III and VI have the same structures affording a series of fragments exactly alike, with m/e values less than 200.

In the case of compound V primary fragmentation is predetermined by the –CH(SCH₃)₂ group mass 107), leading at first to fragments m/e 280 (M⁺ – 107) and m/e 107 (M⁺ – 280). From here the origin of the base peak m/e 138 can very well be documented by metastable ion

m* 68.0. The transition $280 \xrightarrow[m^*]{-142} 138$ can be interpreted as the cleavage of the whole ketoester residue accompanied by H-rearrangement to the pyrone ring substituted with N-methylene but not hydroxyl group.

The ligand-to-metal ratios of the species present in ethanolic solutions pursued by UV/VIS spectrophotometric measurements and continuous variation method with Schiff bases III, IV and V used as ligands did not afford regularly shaped curves thus indicating the simultaneous presence of more than one species.

Crude copper(II) complexes however, isolated from

Fig. 1. Lower frequency region 600–200 cm^{-1} of IR spectra of crystalline species in KBr pellets recorded on a Perkin–Elmer Model 580B spectrometer: (A) compound III (curve a) and corresponding Cu(II) complex (curve b); (B) compound IV (curve c) and corresponding Cu(II) complex (curve d); (C) compound V (curve e) and corresponding Cu(II) complex (curve f).

the ethanolic medium at room temperature and at 40°C steadily have given identical elemental analyses and IR spectra.

Mononuclear complexes of compounds III, IV and V isolated from ethanolic solutions in crude form are conformable to the 2:1 ligand-to-metal ratio as confirmed by the presence in field desorption mass spectra of ions m/e 763, m/e 759 and m/e 835, respectively. The coordination site of copper in complexes with acyclic Schiff bases derived from triketones has been characterized by the presence or absence of definite absorption bands.[10,11]

The distinction of the pointed out bands from ester and α-pyrone $\nu_{C=O}$ or $\nu_{C=C}$ bands of the latter moiety is not possible in the IR spectra of copper complexes with Schiff bases III, IV and V.

More convincing is the comparison with copper complexes of triketones (Scheme IV) justified by the following facts. Copper is coordinated to oxygen in synthesized acyclic Schiff bases and to nitrogen and oxygen only if the acyclic complexes are obtained by hydrolysis of the initially cyclic ligands.[11] Electronic spectra of prepared complexes in chloroform solution show low intensity
Scheme IV.

maxima at λ = 580–590 nm corresponding better to the value for bis(benzoylacetonato)copper(II) than for bis(acetylacetone)ethylenediimino copper(II).[11] Increased intensity of the band at about 1600 cm^{-1} and the appearance of a very strong band at 1500 cm^{-1} (Table 4) allow matching of coordination sites with those proposed for the mononuclear copper complex with 2-acetoacetylphenol to be at the acetoacetyl group and characterized by appearance of new bands at 1570 and 1515 cm^{-1}.[16]

Direct information about the structure of the complexes and the nature of the metal–ligand bonds is provided by the metal–ligand vibrations in the low-frequency region. However, as ligand and lattice vibrations appear in this region too (Fig. 1) the assignment is far from being simple and straightforward. The idea to undertake a thorough study by applying one or the other of the specific methods used to assign the metal–ligand vibrations[17,18] has been neglected because the realization in our circumstances would raise remarkable difficulties.

Thus reliable information on structural features of crude complexes is still lacking the more so as the attempts to prepare crystalline forms appropriate for X-ray analysis have been unsuccessful so far.

Abstract—The pyrolysis products of bi-, tri- and poly-cyclic methylsiloxane oligomers were studied using gas chromatography; it was concluded that reversible elimination and addition of dimethylsilanone groups led to the observed product distribution. Polycyclic siloxane oligomers were pyrolysed together with cyclic dimethylsiloxanes in order to investigate the addition reactions. The splitting of the polycycles into bicycles containing only two branching points was observed as a consequence of dimethylsiloxane addition above 500°C.

Thermal decomposition of branched-chain methylsiloxane polymers results in a series of cyclic, bicyclic and polycyclic volatile products. For the better understanding of the processes taking place in polysiloxanes at high temperature we have studied the thermal decomposition of bicyclic and polycyclic methylsiloxane oligomers. In our previous work[1] a series of compounds with two cyclosiloxane units separated by a dimethylsiloxane chain were pyrolysed. The following general mechanism of elimination and addition of a dimethylsilanone intermediate was proposed to explain the distribution of the pyrolysis products:

$$T_2D_n \rightleftharpoons T_2D_{n-x} + x[D] \quad (n = 6, 7, \ldots x = 1, 2, \ldots) \quad (1)$$
where $T = CH_3SiO_{1.5}$ (methylsilsesquioxy group) and $D = (CH_3)_2SiO$ (dimethylsiloxy group). Similar reactions were described by other authors dealing with the pyrolysis of cyclosiloxane oligomers,[2,3] such as:

$$D_n \rightleftharpoons D_{n-1} + [D] \equiv (n = 4, 5). \quad (2)$$
In the present work we have extended the investigations to fused-ring bicyclic derivatives and to tricyclosiloxanes and polycyclosiloxanes as well.

RESULTS AND DISCUSSION

Decomposition products of bicyclic siloxanes

According to the thermal decomposition mechanism of the cyclosiloxane units separated by a dimethylsiloxane chain (reaction 1), a series of new bicycles is formed under pyrolysis. At higher degradation conversions the cyclosiloxanes and fused-ring bicyclosiloxanes of lower molecular mass predominate in the pyrolysates. We observed[1] that the relative amounts of the cumulated bicyclic products are roughly the same when pyrolysing any kind of dimethylsiloxane chain linked cyclosiloxanes at a given temperature.

If the pyrolysis is carried out in the inert gas stream of a pyrolyser coupled to gas chromatograph, a low conversion of decomposition is observed only, because the largest portion of the investigated sample has evaporated from the heated boat prior to decomposition. Nevertheless, we can elucidate the primary decomposition products: they are T_2D_3 and T_2D_4 of structure (III) and (V), respectively, shown in Fig. 1. Both compounds contain cycles of four siloxane members only. Figure 1 illustrates all the reactions of elimination and addition of [D] dimethylsilanone intermediate leading from the primary products (in frame) to the quasi-equilibrium of product distribution found in the pyrolysates.

In the scheme of Fig. 1, the contribution of T_2D_2 molecule is assumed, although it could not be identified directly due its instability. If the pyrolysis is carried out on line with a gas chromatograph, a product appears with the retention expected for T_2D_2.

Thermal decomposition of fused-ring bicycles

The mechanism given in Fig. 1 is confirmed by pyrolysing the fused-ring bicyclosiloxanes of structure (III) and (V). The distribution of fused-ring bicyclic products is given in Table 1. The first and second columns refer to pyrolystates of compounds with two cyclosiloxane units separated by a dimethylsiloxane chain. The product dis-
Fig. 1. Scheme of [D] elimination and addition reactions under pyrolysis of cumulated bicyclosiloxanes (starting compounds are in frame).

*Author to whom correspondence should be addressed.

tribution of T_2D_4 (structure V) is similar to these, although the amount of the pyrolysed compound remained yet higher than the other products after 10 min. pyrolysis at 560°C. Pyrolysing T_2D_3 (structure III) together with D_6 cyclosiloxane, the decay of the pyrolysed bicyclic compound takes place faster, the distribution of the resulting fused-ring bicycles becomes similar to the above (see Table 1).

Thermal decomposition of tricyclic methylsiloxanes

The molecule of the methylsiloxane oligomers containing four branching points (T groups), which form three separated cycles, splits into two bicyclic parts under pyrolysis above 500°C. Further decomposition follows according to the reactions of the bicyclosiloxanes. Thus the product distribution of T_4D_8 [1,5-bis(heptamethylcyclotetrasiloxy) hexamethylcyclotetrasiloxane:
and T_4D_{14}(1,5-bis[(heptamethylcyclotetrasiloxy) hexamethyltrisiloxy] hexamethylcyclotetrasiloxane:
is similar to that of T_2D_6[(heptamethylcyclotetrasiloxy) heptamethylcyclotetrasiloxane] and T_2D_9 [1,5-bis(heptamethylcyclotetrasiloxy)hexamethyltrisiloxane], respectively.

When fused-ring tricyclic compounds containing fewer D groups are pyrolysed, new tricycles are formed according to the scheme given in Fig. 2, by elimination and addition of D groups. In the pyrolysate at 560°C of T_4D_3 (structure X), two isomers of T_4D_2, two additional isomers of T_4D_3 and a T_4D_4 compound were the main products. In addition small amounts of D_3, D_4 cyclosiloxanes and T_2D_{3-5} bicyclosiloxanes and T_8 polycyclosiloxane (octamethyloctasilsesquioxane) were also formed. The fused-ring bicyclosiloxanes were only byproducts, mainly T_2D_3 (structure II) was found (see Table 1).
Fig. 2. Scheme of [D] elimination and addition reactions under pyrolysis of T_4D_3 (structure X, in frame).

In consequence of [D] addition, the fused-ring tricyclosiloxane molecules may reach a size that is able to split into two stable bicyclosiloxanes, as follows:
$$T_4D_x + y[D] \rightleftharpoons T_2D_z + T_2D_u$$
(3)
$$(x = 2, 3, \ldots; \quad y = 4, 5, \ldots; \quad z = 3, 4, \ldots; \quad u = 3, 4, \ldots;).$$

This reaction proved to be reversible; some tricyclosiloxanes appear in the pyrolysates of T_2D_3 and of T_2D_4 although they are minor products.

If the pyrolysis of T_4D_3 is carried out in the presence of D_6, the possibility for [D] addition—consequently for reaction (3)—increases. That is why the amount of tricyclosiloxane pyrolysis products decreases considerably and the distribution of the fused-ring bicyclosiloxanes produced becomes similar to that of T_2D_4, demonstrated in Fig. 3 (see also Table 1).

We pyrolysed T_8 as well, in the presence of D_6, in order to see whether [D] addition could occur onto a polycyclosiloxane built up of T groups only. A process similar to reaction (3) takes place after the addition of at least four D groups, i.e. then the molecule splits into two

parts. A possible scheme for this reaction is given in Fig. 4. Nevertheless, the thermal decomposition does not stop at D_4T_2, but in the presence of cyclosiloxanes, reaction (3) leads to the same fused-ring bicyclosiloxanes as found in the pyrolysates analysed so far and the distributions of which are given in Table 1.

CONCLUSION

Results of pyrolysis experiments on different methylsiloxane oligomers containing branching groups show that the decomposition process involves elimination and addition of dimethylsiloxane groups. The pyrolysed oligomer gradually releases its D content until the residue becomes a fused-ring compound. The eliminated [D] intermediates partly form cyclosiloxanes, and is partly incorporated into other molecules. The [D] addition to cumulated polycyclosiloxanes results in compounds of larger cycles. When the cycles become large enough, the polycyclosiloxane may split into two stable parts both containing branching points.

Summarizing the observed processes, the separation of D and T units takes place under pyrolysis of the branched methylsiloxane oligomers. The D content of the molecule is eliminated to form cyclosiloxanes while the fusion of T units results in polycyclosiloxanes. However, these processes may be reversed by introducing an excess of cyclosiloxanes into the system. In this case [D]

addition expands the fused-ring polycyclosiloxanes so much that they split into smaller products containing less T and more D in their molecules.

EXPERIMENTAL

Starting materials

1,5 - bis(heptamethylcyclotetrasiloxy)hexamethyltrisiloxane (T_2D_9) and (heptamethylcyclotetrasiloxy)heptamethylcyclotetrasiloxane (T_2D_6) were prepared and analysed according to published methods.[1,4]

Octamethylbicyclo [3.3.3]-pentasiloxane (T_2D_3, structure III.) and decamethylbicyclo [5.5.1]-hexasiloxane (T_2D_4, structure V) and decamethyltricyclo [5.5.1.3[3.9]]-hexasiloxane (T_4D_3, structure X) were isolated from the pyrolysate of a branched chain methylsiloxane polymer by preparative scale gas chromatography and analysed by mass spectrometry[5] and ^{29}Si NMR spectroscopy.[6] The structures of the first two compounds were confirmed by X-ray diffraction[7] and by electron diffraction[8] as well.

Synthesis of 1,5-bis(heptamethylcyclotetrasiloxy)hexamethylcyclotetrasiloxane (T_4D_8)

3.37 g (0.010 mol) of 1, 5-dichlorohexamethylcyclotetrasiloxane in 50 cm³ dry diethyl ether was added with stirring to 7.45 g (0.025 mol) of hydroxyheptamethylcyclotetrasiloxane and 2.02 g (0.020 mol) of triethylamine in 100 cm³ dry diethyl ether at 20–22°C. Stirring was continued for several hours, then the triethylamine hydrochloride filtered off. The solution was washed with water, distilled at 0.25 mbar to yield 5.3 g (61.6%) of an oily liquid at 137–138°C ($n_D^{20} = 1.4090$, $d_4^{20} = 1.0620$, MW = 861.7). Found: C, 28.41; H, 7.00; Si, 38.95; Calc. for $C_{20}H_{60}Si_{12}O_{14}$: C, 27.88; H, 7.01; Si, 39.12%.

Synthesis of 1,5-bis[(heptamethylcyclotetrasiloxy)hexamethyltrisiloxy]hexamethylcyclotetrasiloxane (T_4D_{14})

The synthesis was carried out according to the aboves, starting from 1-hydroxy-5-(heptamethylcyclotetrasiloxy) hexamethylcyclotrisiloxane. After filtration the solution was boiled for 5 hr, then washed with water and distilled. The b.p. of the yielding oil (53.5%) was 210–215°C at 0.1 mbar ($n_D^{20} = 1.4080$, $d_4^{20} = 1.0319$,
Fig. 4. An example of the splitting of T_8 polycyclosiloxane into two tricyclosiloxanes after [D] addition.

MW: 1306.6). Found: C, 29.72; H, 7.40; Si, 38.08; Calc. for $C_{32}H_{96}Si_{18}O_{20}$: C, 29, 29.41; H, 7.39; Si, 38.70%.

For 1 - hydroxy - 5 - (heptamethylcyclotetrasiloxy)hexamethyltrisiloxane synthesis 13.60 g (0.043 mol) of heptamethylchlorocyclotetrasiloxane[1] in 100 cm³ dry diethyl ether was added with stirring to 15.6 g (0.065 mol) of 1,5-dihydroxyhexamethyltrisiloxane and 6.05 g (0.065 mol) of aniline in 100 cm³ dry diethyl ether at 5–8°C. When the reaction was completed aniline hydrochloride was removed. The solution was washed with water and distilled at 13 mbar yielding 9.1 g (40.7%) of 1-hydroxy-5-(heptamethylcyclotetrasiloxy) hexamethyltrisiloxane at 90–100°C.

Synthesis of octamethyloctasilsesquioxane (T_8)

The method of Barry *et al.*[9] was used. Found: C, 18.04; H, 4.54; Si, 41.82; Calc. for $C_8H_{24}Si_8O_{12}$: C, 17.89; H, 4.50; Si, 41.85%, MW: 536.

Pyrolysis

The pyrolysis experiments were performed in the temperature range of 460–560°C for 5–60 min in evacuated and sealed quartz tubes. The sample weight was 1–5 mg, the volume of the tube 0.17 cm³. Additional pyrolyses were also carried out for 10–30 s in a tantalum boat and open quartz tube in a flowing inert atmosphere, on line with the gas chromatograph.

Analysis of the pyrolysis products

Product analysis was performed on a Perkin–Elmer gas chromatograph with Flame Ionization Detector and a PE D–26 Electronic Integrator. The products were identified by comparison of retention time on three different columns with authentic samples. The following columns were used:

—3.5 m, 2 mm i.d packed column; support: 80–100 mesh Chromosorb G; phase: 5% OV–17; temperature program from 40 to 280°C at 6.5/min.

—20 m, 0.2 mm i.d. fused silica capillary column, coated with OV–101 phase; temperature program from 50 to 300°C at 6°/min.

—20 m, 0.2 mm i.d. glass capillary column, coated with OV–225 phase; temperature program from 50 to 220°C at 6°/min.

STABILITY, SPECTRA AND STRUCTURE OF THE COPPER(II) CHLORIDE COMPLEXES IN ACETIC ACID

M. A. KHAN, J. MEULLEMEESTRE, M. J. SCHWING and F. VIERLING*
E.N.S.C.S., Laboratoire de Chimie Physique ERA No. 166 1, rue Blaise Pascal, 67008 Strasbourg, France

Abstract—The stability constants and the electronic spectra of four molecular chlorocomplexes formed in acetic acid solutions have been calculated. The spectrophotometric measurements were performed at wavelengths ranging from 260 to 500 nm and, in the near IR from 600 to 1400 nm. The matrix rank treatment of more than 1000 spectrophotometric data demonstrates a minimum of five absorbing species: the solvated copper(II) acetate and four chlorocomplexes. The overall stability constants of $Cu(OAc)Cl$, $CuCl_2$, $LiCuCl_3$ and $LiCuCl_4$ are respectively: $\log \beta_1 = 3.38$; $\log \beta_2 = 5.57$; $\log \beta_3 = 7.36$; $\log \beta_4 = 7.83$. The structure of the monochlorocuprate with the Cu–OAc bonding in the primary coordination sphere is supported by near-IR evidence. The bathochromic shift of the absorption maxima of the d–d transition bands indicates structural changes of the complexes with a square planar configuration for $Cu(OAc)Cl$ promoted to a flattened tetrahedron for Li_2CuCl_4.

An exhaustive study of the copper(II) chloride complexes in aqueous solution was carried out by Schwing and Khan[1,2] who concluded the presence of four mononuclear successive complexes, calculated their equilibrium constants and discussed briefly the structure of the $CuCl_4^{2-}$ ion in aqueous solution. The emphasis now seems to have shifted to the study of these copper(II) chlorocomplexes in nonaqueous solutions. This is mainly because of very small values of the overall equilibrium constants, β_j, in water, in contrast to their very high values in nonaqueous solvents. Moreover in water there is an overlapping of the characteristic bands of the complexes, which are well separated in the latter solvents.

Furlani and Morpurgo[3] suggest a flattened tetrahedral (D_{2d} symmetry) structure for tetrachlorocuprates after studies in solid state and such organic solvents as acetonitrile, nitromethane, ethylalcohol, dimethylformamide (DMF) and dimethylsulphoxide (Me$_2$SO). Manahan and Iwamoto[4] have proposed very high values for the equilibrium constants of $CuCl^+$ and $CuCl_2$ in acetonitrile.

Gutman *et al.* have shown spectrophotometrically the existence of four chlorocomplexes in DMF[5] in acetonitrile and in trimethylphosphate[6] at the same time postulating a very small equilibrium constant for $CuCl_2$. On the other hand Courtot *et al.*[7] using potentiometric and spectrophotometric means propose three copper(II) chlorocomplexes, $CuCl^+$, $CuCl_2$, $CuCl_3^-$ in Me$_2$SO. Scharff as also proposed the existence of these complexes in propylene carbonate.[8]

Very recent work published from our laboratory confirms the presence of three complexes postulated by Gutman *et al.* in DMF but with $CuCl^+$, $CuCl_3^-$ and $CuCl_4^{2-}$.[9]. The absence of the dichlorocomplex in this model is due to similar solvent and ligand donor numbers, inducing dissociation of $CuCl_2$ and autocomplex formation of $CuCl^+$ and $CuCl_3^-$.[10] The same [1, 3, 4] model, i.e. $CuCl^+$, $CuCl_3^-$ and $CuCl_4^{2-}$ is found in

Me$_2$SO instead of [1–3], i.e. $CuCl^+$, $CuCl_2$ and $CuCl_3^-$ suggested in Ref.[7], but the [1–4] model, i.e. $CuCl^+$, $CuCl_2$, $CuCl_3^-$ $CuCl_4^{2-}$ is clearly established in propylene carbonate[11] against the unsatisfactory [1–3] proposed in the same medium by Scharff.[8]

Beside these dissociating solvents, the non-dissociating acetic acid has also been used for the study of the copper(II) chlorocomplexes. Eswein *et al.*[12] suggest an equilibrium between the D_{4h} (square planar) and D_{2d} symmetry species for the tetrachlorocomplex in acetic acid, assigning the peak at 450 nm to D_{2d} and that at 375 nm to D_{4h} configuration. They identify the absorption maximum at 670 nm as that of cupric acetate in acetic acid but it is surprising that they do not observe any isosbestic point.

Sawada *et al.* have studied in detail the equilibria of copper(II) acetate in acetic acid with perchloric acid and lithium acetate[13] and with hydrochloric acid and copper(II) chloride.[14] They suggest that the characteristic absorption maximum of copper acetate in acetic acid is at 685 nm and observe isosbestic points at 360 and 440 nm and postulate the presence of tri- and tetrachlorocomplexes. However their work is limited to the interpretation of data obtained only at two wavelengths.

This work pertains to the formation of copper(II) chlorocomplexes in acetic acid at 25°C. The number of complexes present in the solution and their equilibrium constants were determined after a spectrophotometric study in the UV and visible region, from 270 to 500 nm and in the near-IR from 600 to 1400 nm. A quantitative interpretation of the whole spectrum (UV, vis., IR) was undertaken. All data were taken into account to calculate the equilibrium constants and the variation of the extinction coefficients of the individual copper(II) chlorocomplexes. Tests for different models of complexes present in the solution were performed in accordance with the results of the matrix rank method, mentioned in our discussion.

EXPERIMENTAL

Anhydrous acetic acid, pro analysis (Merck) was used after adding calculated amount of acetic anhydride, p.a. (Merck), with the addition of three drops of 0.001 M perchloric acid, 70% p.a.

---

*Author to whom correspondence should be addressed.

(Merck) and letting the solution stand overnight.[15] Copper solutions were prepared from a stock solution of copper(II) acetate, p.a. (Merck). Lithium chloride p.a., (Merck) was used without any purification.

The final analytical concentration of copper was 5×10^{-4} M for measurements in UV-vis. and 3.75×10^{-3} M in IR region. In these spectrum regions chloride concentrations were varied from 5×10^{-4} to 1 M, with $l = 0.5$ cm, and from 2.5×10^{-3} to 1 M, with $l = 2$ cm, respectively.

Acetic acid was the spectrophotometric reference solution. The final solutions of copper and chloride were prepared just before the measurements. The optical densities were obtained with a CARY 17D instrument with digital interfacing and a Periferic Zip 30 rapid printer and puncher. The numerical analysis was performed on a UNIVAC 1110 computer.

RESULTS AND DISCUSSION

Acetic acid is a molecular solvent, its dielectric constant being 6.2, and therefore non-ionic in character. However two series of measurements were carried out. One with lithium perchlorate to keep the molecular environment constant and equal to 1 M and the other, without lithium perchlorate. The absorption spectra of the two series in UV, visible and IR being identical, the simpler of the two equilibria, i.e. the direct mixing of copper(II) acetate and lithium chloride solutions was retained for the study.

(a) Spectra of copper(II) chloride in acetic acid

When chloride is added to the copper(II) solution in acetic acid the colour changes from blue to greenish yellow, and eventually to bright yellow with the increase in chloride concentration. The absorption variations with respect to the chloride concentration in UV, visible and IR are presented in Fig. 1.

The free solvated copper(II) acetate has an absorption maximum at about 252 nm. The addition of chloride shows the formation of a peak at 300 nm which undergoes a hypsochromic effect as the chloride concentration increases with a shift to 280 nm. This maximum is not

Gaussian suggesting a superposition of two maxima. For chloride concentrations much higher than 0.02 M there appears a maximum at 445 nm and for concentrations higher than 0.05 M another at 380 nm. These two maxima coalesce at 385 nm at still higher concentrations. Three isobestic points are observed at 302, 357 and 437 nm. Sawada et al.[14] have reported only two isobestic points at 360 and 440 nm whereas the work of Eswein et al. is conspicuous by its statement that "no isobestic points are observed". It is to be remarked that this latter work was carried out by preparing chloride solutions by dissolving the chloride salt first in small quantity of water before adjusting the volume with acetic acid. In our case it was observed that the addition of small quantities of water has a profound effect on the complexation, a few drops being sufficient to render the solution colourless from greenish yellow or bright yellow. This aquation effect has also been noted by Sawada and Tanaka.[16]

In the IR region the characteristic maximum of copper(II) acetate in acetic acid is observed at 680 nm $(198 \, M^{-1} \, cm^{-1})$. This peak which has been variously reported at 650[15], 670[12] and 685 nm[14] disappears as the chloride concentration increases and shifts to 1060 nm. This shift of 380 nm of the solvated copper(II) ion in acetic acid, from 680 to 1060 nm, is remarkably similar to the bathochromic shift in DMF,[9] propylene carbonate and Me₂SO.[11]

(b) Equilibrium in solution

Copper(II) acetate in acetic acid has been reported to have a maximum at 365 nm which has been ascribed to copper–copper bond by Yamada et al.[17] and Martin and Whitley,[18] indicating that the salt is dimerised in solution. This is confirmed by Sawada[13] who has located this maximum at 370 nm. This maximum although not visible in our work because of low copper concentration in UV-visible, appears distinctly at 375 nm with copper concentration 3.75×10^{-3} M. In view of this and the fact that acetic acid being a non-dissociating solvent, molecular
Fig. 1. Experimental spectra of copper(II) chloride solutions: spectrum/$10^3 \times$ [Cl⁻]$_{anal}$. UV-visible: [Cu(OAc)₂]$_{anal}$. = $5 = 10^{-4}$ M; $l = 0.5$ cm 1/0, 2/0.5, 3/1, 4/2, 5/3, 6/5, 7/10, 8/30, 9/70, 10/300, 11/700, 12/1000, 13/1300. near-IR: [Cu(OAc)₂]$_{anal}$. = 3.75×10^{-3} M; $l = 2$ cm 1/0, 2/2.5, 3/5, 4/10, 5/20, 6/40, 7/200, 8/1000.

association occurs and the following equilibria are proposed:

$$Cu_2(OAc)_4 + 2LiCl \rightleftharpoons 2CuCl(OAc), 2LiOAC$$
$$Cu_2(OAc)_4 + 4LiCl \rightleftharpoons 2CuCl_2, 4LiOAc$$
$$Cu_2(OAc)_4 + 6LiCl \rightleftharpoons 2CuCl_3Li, 4LiOAc$$
$$Cu_2(OAc)_4 + 8LiCl \rightleftharpoons 2CuCl_4Li_2, 4LiOAc.$$
The copper(II) acetate has a dimeric structure in acetic acid but the copper(II) chlorocomplexes are monomeric.[14] The formulation of the monochlorocomplex as Cu(OAc)Cl is supported by the near-IR evidence and is discussed further on.

(c) Experimental data and numerical analysis

The optical density variations as a function of chloride concentration were plotted from 260 to 500 nm, at intervals of 10 nm. These plots were used to obtain N optical density values for each selected wavelength for computation. Eventually a set of 24 wavelengths in the UV-visible range with N = 28 for each wavelength were considered. In the near IR region 20 wavelengths, from 600 to 1400 nm, at intervals of 40 nm, with N = 24 for each wavelength, were taken into account.

A matrix rank treatment method was performed for determining the minimum number of absorbing species present in the solution[19] which requires a set of N × L data, where N is the number of solutions and L the number of wavelengths, with N imperatively greater than L. The interpretation of 1152 spectrophotometric data indicated a minimum of four species: the solvated copper(II) acetate and at least three copper(II) chlorocomplexis.

(d) Calculated models and equilibrium constants

The theoretical expressions and the mathematical treatment has been explained in our earlier publication.[9] The computation was performed at three different mononuclear complexes models: the [1–3], the [1, 3, 4] and the [1–4] model in accordance with the matrix rank analysis results. Table 1 summarises the results of the numerical analysis of the three different models:

The quadratic mean, σ, for the first two models has a value of 0.128 and 0.130 respectively. On the other hand a far better value of $\sigma = 0.054$ is obtained for the model [1–4]. Consequently the existence of four mononuclear successive complexes is proposed in acetic acid for copper(II) chloride solutions.

The stability of the complexes is much higher than in water but comparable to that found in other solvents such as DMF[9] or Me$_2$SO:[11] despite the different associative property of these solvents this is particularly true for the overall stability constant of the monochlorocom-

plex and the stepwise formation constant of the tetra-chlorocomplex. On the contrary, very higher β'_is were calculated in the propylene carbonate solutions for an identical [1–4] model: the associative solvent effect, predicted by the very low dielectric constant of acetic acid ($\epsilon = 6$) compared to that of propylene carbonate ($\epsilon = 69$) should be one of the factors which supports these stability differences.

Incomplete formation for each of the four species, represented in Fig. 3, is found in the acetic acid system, which render impossible the β_i determination of one separated species and explain the drastic higher value found by Sawada et al. for CuCl$_2$ (log β_2 = 15.2).[14] These authors used data at 300 nm where they do not observe any further shift of the absorption with ligand concentration increase: consequently they postulate the unique presence of Cu(OAc)Cl and CuCl$_2$. As a matter a fact, at 300 nm the absorption maximum does not change with higher chloride concentration as seen in our experimental spectra of Fig. 1. But other absorption maxima appear, particularly at 280 and 385 nm with chloride ligand increase, which is obviously consistent with the presence of one or two other complexes. The individual electronic spectra calculation shown next in Fig. 2 indicate clearly that the extinction coefficients of LiCuCl$_3$ and Li$_2$CuCl$_4$ cannot be neglected at 300 nm.

On the other hand, we found stepwise formation constants K$_3$ and K$_4$ very similar (1.78 and 0.45) to those calculated by Sawada et al.[14] (1.68 and −0.15) using data at 385 and 450 nm: at those wavelengths the absorption due to Cu(OAc)Cl and CuCl$_2$ are effectively neglegeable compared to those of LiCuCl$_4$ (Fig. 2). Another evidence for the unique presence of the latter complexes involves the presence of isobestic points at 302, 357 and 437 nm. But once again, the discussion shows the necessity to use absorption data over the whole wavelengths range for a precise determination of the best model and accurate stability constants values.

(e) Electronic spectra of the copper(II) chlorocomplexes in acetic acid

The electronic spectra of the individual chlorocomplexes for the [1–4] model in the UV, visible and the near IR are presented in Fig. 2.

Monochlorocomplex, CuCl(OAc). In the near IR there is a peak at 680 (1970 M^{-1} cm^{-1}) which is obviously due to the acetate ion associated with the complex. This transition is clearly characteristic of the copper–acetate bond as it is located at the same wavelength as that observed for the copper(II) acetate solution, with a comparable extinction coefficient (680 nm— 198 M^{-1} cm^{-1}; spectrum 1—Fig. 1). Therefore the formulation of the monochlorocomplex is proposed as

Table 1. Results of the numerical analysis of the theoretical models for the acetic acid–copper(II) chloride solutions

	[1,2,3]	[1,3,4]	[1,2,3,4]
log β_1	3.20	8.97	3.38
log β_2	5.66	–	5.57
log β_3	7.46	14.26	7.36
log β_4	–	15.93	7.83
σ(uv-vis)	0.128	0.130	0.054
Fig. 2. Calculated electronic spectra of the copper(II) chlorocomplexes in acetic acid.

CuCl(OAc). This complex may also present a maximum at 260 nm as in water[2] and DMF.[9] Unfortunately this absorption maximum could not be ascertained because of absorption interference due to solvent below 270 nm.

It may be pointed out here that copper acetate was used instead of copper perchlorate because with the latter, at copper concentrations greater than 10^{-3} M precipitation occurs for higher chloride concentration, especially in the presence of lithium perchlorate. Had copper perchlorate been used it would have rendered difficult the exploration of the spectrum in the near IR region where, for copper concentration less than 10^{-3} M the absorption is very low.

Dichlorocomplex, $CuCl_2$. The absorption maximum of this complex is centred at 300 nm ($455 \, M^{-1} \, cm^{-1}$) in the UV region and can be compared to that at 315 nm in propylene carbonate. In the IR, $CuCl_2$ has a $\lambda_{max} = 800$ nm ($65 \, M^{-1} \, cm^{-1}$).

Trichlorocomplex, $CuCl_3Li$. It presents three maxima,

one each in UV, visible and IR, at 300 ($3150 \, M^{-1} \, cm^{-1}$), 450 ($900 \, M^{-1} \, cm^{-1}$) and 910 nm ($85 \, M^{-1} \, cm^{-1}$). The peaks in UV and visible are comparable to those in DMF and Me_2SO, but differ by 20 nm from those in propylene carbonate.

Tetrachlorocomplex, $CuCl_4Li_2$. The tetrachlorocomplex has an intense absorption maximum at 280 nm ($5160 \, M^{-1} \, cm^{-1}$) and another at 388 nm ($2170 \, M^{-1} \, cm^{-1}$). These two bands, with slight differences, have been widely reported in many previous works. It is probable that the differences in the position of these bands are due to different solvents used in each work. There seems to be another hidden band of feeble intensity at 490 nm ($180 \, M^{-1} \, cm^{-1}$). In the IR the tetrachlorocomplex peaks out at 1080 nm ($120 \, M^{-1} \, cm^{-1}$).

(f) Isosbestic points

A very good harmony is noted between experimental and calculated isosbestic points.
Fig. 3. Formation curves of the copper(II) chlorocomplexes in acetic acid.

Isosbestic points (λ in nm)	
Experimental	Calculated
302	303
357	354
437	437

(g) Formation and structure

Figure 3 represents the formation curves of the four copper(II) chlorocomplexes showing a very different pattern than either in water or in propylene carbonate. It is seen that for dilute solutions, chloride concentrations as low as 0.025 M, the fourth complex begins to form in appreciable quantities.

It is proposed that the tetrachlorocomplex has a D_{2d} symmetry in acetic acid. This can be inferred by the presence of a probable charge transfer band at 490 nm and the absence of any d-d transition band below 1000 nm. It is recalled that the ion of D_{4h} symmetry presents normally two bands in this region, one between 700 and 800 nm and the other between 900 and 950 nm whereas the configuration D_{2d} presents absorption maxima at 1100 nm and above.[20] The presence of a band at 1080 nm and the absence of any band between 700 and 950 nm are favorable arguments for a D_{2d} structure of the tetrachlorocomplex in acetic acid.

REACTIONS OF DIIODO(NITROSYL){TRIS(3,5-DIMETHYL-PYRAZOLYL)BORATO}MOLYBDENUM WITH o-DISUBSTITUTED BENZENES CONTAINING OH, SH AND/OR NH₂ GROUPS, THE FORMATION OF MONO-ARYLAMIDO AND MONO-THIOLATO COMPLEXES, AND THE STRUCTURE OF [Mo(NO)(3,5-Me₂C₃HN₂H)₃(O₂C₆H₄)]I₃, THE PRODUCT OF A DEBORONATION REACTION

HARRY ADAMS, NEIL A. BAILEY,* A. STEPHEN DRANE and JON A. McCLEVERTY*†
Department of Chemistry, The University, Sheffield S3 7HF, England

Abstract—Reactions of Mo{HB(Me₂pyz)₃}(NO)I₂ {HB(Me₂pyz)₃ = HB(3,5-Me₂C₃HN₂)₃} with o-C₆H₄(NH₂)₂, o-C₆H₄(NH₂)(OH), o-C₆H₄(NH₂)(SH) and 3,4-C₆H₃Me(SH)₂ afforded the non-substituted species Mo{HB(Me₂pyz)₃}(NO)IX where X = NHC₆H₄NH₂, NHC₆H₄OH, NHC₆H₄SH and SC₆H₃Me(SH). Reaction of the diiodo complex with o-C₆H₄(OH)₂ afforded [Mo(NO)(C₃HMe₂N₂H)₃(O₂C₆H₄)]I₃, whose structure was established by X-ray crystallography.

We have previously described the reactions of Mo{HB(Me₂pzy)₃}(NO)I₂ {HB(Me₂pyz)₃ = HB(3,5-Me₂-C₃H · N₂)₃; (1, X = Y = I)} with thiophenol[1] and with aniline and phenol derivatives[2] in which complexes of the type (1, X = I, Y = SPh), (1; X = I, Y = NHAr) and (1, X = I, Y = OAr) were formed. In some cases we were able to remove the second I atom, affording species such as (1, X = Y = SPh), and (1, X = OR, Y = NHAr; R = alkyl). It occurred to us that we might induce (1; X = Y = I) to react with o-disubstituted benzenes such as o-phenylenediamine, catechol or toluene-3,4-dithiol, forming complexes where the ligand was bidentate towards the metal, both I atoms having been displaced. Such reactions would parallel that of [Mo(η⁵-C₅H₅)(NO)I₂]₂ with toluene-3,4-dithiol, in which [Mo(η⁵-C₅H₅)(NO)(S₂C₆H₃Me)]₂ is formed.[3]

Synthetic studies

Reaction of o-phenylenediamine and o-aminophenol with (1; X = Y = I) afforded the brown or black mono-iodo complexes 1; X = I, Y = o-NHC₆H₄NH₂ or o-NHC₆H₄OH (analytical data, Table 1). NHC₆H₄SH and SC₆H₃MeSH complexes were prepared in

refluxing solutions, but in no case was there any evidence of removal of the second I atom, to afford chelated species e.g. Mo{HB(Me₂pyz)₃}(NO)NHC₆H₄S. Treatment of the reaction mixture containing (1; X = Y = I), C₆H₃Me(SH)₂ and Ag(OAc) afforded a green powder, but we were unable to characterise this compound satisfactorily. From the method of synthesis which we have used to make (1, X = Y = SR)[1], the colour of the compound and the value of ν(NO), we think that Mo{HB(Me₂pyz)₃}(NO)SC₆H₃MeS may have been produced, but in such an impure form that we could not characterise it effectively by elemental analyses.

The reaction with o-catechol followed a different course. In conditions under which we successfully prepared (1; X = I, Y = OPh) and (1; X = Y = OPh), and even in refluxing benzene, we observed no reaction between C₆H₄(OH)₂ and (1; X = Y = I). However, overnight in boiling toluene, a red–brown solution was formed from which we ultimately obtained [Mo(NO)(C₃HMe₂N₂H)₃(O₂C₆H₄)]I₃. This reaction had clearly resulted in the sequestration of the B atom, presumably as B₂(O₂C₆H₄)₃ or [B(O₂C₆H₄)₂]⁻, and, since the complex was obtained in good yields, we presume it was isolated as a mixture of mono- and tri-iodide salts. The complex was actually characterised first by crystallographic methods but finally reasonably good elemental analytical and spectroscopic data were obtained.

†The inaccuracy of this determination may have been due to insufficient degradation of the I₃⁻ ion.

Spectroscopic studies

The IR spectra of the tris(pyrazolyl)borate complexes exhibited (Table 2) the expected absorptions due to the HB(Me$_2$pyz)$_3$ ligand [*ca.* 2500 cm^{-1} due to ν(BH) and *ca.* 1400 cm^{-1} associated with the pyrazolyl ring]. The complex (1; X = I, Y = *o*-NHC$_6$H$_4$NH$_2$) exhibited three ν(NH) bands, at 3280, 3390 and 3490 cm^{-1}, (due to NH and NH$_2$) while (1; X = I, Y = *o*-NHC$_6$H$_4$OH) contained two absorptions, at 3200 cm^{-1} [probably ν(NH)], and 3500 cm^{-1} (broad) [probably ν(OH)]. We were unable to detect ν(SH) in (1; X = I, Y = SC$_6$H$_3$MeSH).

The NO stretching frequencies of those complexes containing NHAr groups occurred in the range normally observed for this class of compound, i.e. 1655–1675 cm^{-1}, and that for (1; X = I, Y = SC$_6$H$_3$MeSH) in the range for mono-arylthiolato species, i.e. *ca.* 1690 cm^{-1} (Ref. 1).

The complex [Mo(NO)(C$_3$HMe$_2$NH)$_3$(O$_2$C$_6$H$_4$)]I$_3$ does not, of course, exhibit ν(BH), but the NO stretching frequency is not substantially different from that of (1; X = Y = OPh).[2]

[a] Spectrum measured in CDCl$_3$ (TMS internal standard); relative areas of peaks in parentheses.

NHC$_6$H$_4$NH$_2$), and (1; X = I, Y = SC$_6$H$_3$MeSH) contain the expected three signals due to the inequivalent C(4)-H protons of the pyrazolyl ring. The fact that these signals in the spectra of (1; X = I, Y = o-NHC$_6$H$_4$SH) appear as two lines of relative intensity 2:1 is probably due to accidental degeneracy. All complexes exhibit resonances due to the methyl groups of the pyrazolyl rings, and we were also able to observe signals due to NH$_2$ and SH in those complexes containing these groups, and in these complexes with NHAr groups. δ(NH) of the amido group appeared in the range 12.90–13.24 ppm, consistent with previous observations.

It is quite clear from the combined spectroscopic data, and from a comparison of complexes of the type (1; X = I, Y = NHAr), (1; X = OR, Y = NHAr) and (1; X = NHAr, Y = SR), that none of the foregoing species actually contains a chelated ligand, i.e. that species of the type [Mo{HB(Me$_2$pyz)$_3$}(NO)QC$_6$H$_4$EH]^z (Q = O, E = N; Q = E = S or N; $x = 0$, $z = 0$, $x = 1$, $z = +1$) are not formed, confirming our synthetic findings.

The ^{1}H NMR spectrum of [Mo(NO)(C$_3$HMe$_2$NH)$_3$(O$_2$C$_6$H$_4$)]$^+$ was consistent with the structure in the solid state. Thus, it is clear from the C(4)-H resonances that one pyrazolyl ring is magnetically inequivalent to the other two. The signals due to the NH protons appeared as a broad signal at $\delta = 11.05$.

Crystallographic studies

The structure of the cation is illustrated in the Fig. 1 with the atom labelling used in the corresponding tables. Important bond lengths and angles (together with estimated standard deviations) are given in Table 3. Tables comprising all bond lengths and angles with estimated standard deviations and details of planar fragments have been deposited.

The cation possesses a distorted octahedral geometry about the molybdenum with three unidentate dimethylpyrazole ligands in a meridional arrangement, the remaining sites being occupied by a nitrosyl and a biden-
Fig. 1. Structure of the cation [Mo(NO)(3,5-Me$_2$C$_3$HN$_2$H)$_3$(O$_2$C$_6$H$_4$)]$^+$ showing the atom labelling.

tate catecholate ligand. The three dimethylpyrazole ligands have similar and conventional geometries, although it is perhaps worth noting that the external bond angles at the donor nitrogen atoms are very different, Mo-N-C being some 20° greater than Mo-N-N. The three molybdenum-nitrogen(pyrazole) bond lengths are similar, with those to the mutually trans ligands being marginally (2.5σ) shorter than that to the pyrazole which is trans to an oxygen of the catecholate ligand. The planes of two of the pyrazole rings are each approximately perpendicular to the meridional plane; the third pyrazole is inclined at 74°: thus, the three pyrazole planes each approximately eclipse the nitrosyl group. Each pyrazole ring is closely planar with coplanar methyl substituents; the molybdenum atom lying to varying extents (up to 0.2 Å) out of the mean planes. The catecholate ligand is also closely planar with the molybdenum atom lying in the mean plane. The two molybdenum-oxygen bonds differ greatly in length, that trans

to the nitrosyl ligand being 0.16 Å longer than that *trans* to pyrazole, reflecting the much greater competitive π-accepting capacity of nitrosyl for the available π-electrons. The molybdenum–nitrosyl system is essentially linear. The triiodide anion is also linear but the bond lengths differ markedly (by 0.17 Å, approx. 100σ) although there are no particularly short interactions to the cation.

Conclusion

It appears that the diiodo complex, (1; X = Y = I), is unwilling to form chelated complexes of the type Mo–XC$_6$H$_4$Y. On the basis of our earlier inability to synthesise complexes of the type (1; X = Y = NHR), we were not wholly surprised at our failure to prepare *o*-phenylenediimine complexes. However, we have obtained mixed complexes of the type (1; X = OR, Y = NHR) and (1; X = SR, Y = NHR). It has to be said, however, that none of these mixed species contained NHAr substituents. These observations may be related to the overall mechanism of reaction for the formation of these complexes. We have proposed[4] that the first step in the formation of (1; X = Y, Y = NHR) from (1; X = Y = I) is the one-electron reduction of the latter, giving [(1; X = Y = I)]$^-$ (and of course, RNH$_2^+$). This paramagnetic species dissociates giving [1; X = I, Y = solvent] and I$^-$, and the solvated species is believed to react with NHR (from RNH$_2^+ \rightarrow$ RNH$^\cdot$ + H$^+$) or NHR$_2$, giving the amido complex. If this mechanism is generally applicable, then a second substitution involving a prior electron transfer will involve reduction of (1; X = I, Y = NHR). We know from other studies, that the one-electron reduction of (1; X = I, Y = NHAr) is much more difficult to achieve than that of (1; X = Y = I) (*ca.* −2.0V vs +0.11V),[5] and this probably cannot be achieved by ROH, RSH or RNH$_2$. Consequently, the inability to effect removal of both I atoms, without the assistance of Ag$^+$, is perhaps not so surprising.

The reaction with catechol took a different course, presumably because of the affinity of boron for catecholate ligands. Indeed, sequestration of the B atom in HB(Me$_2$pyz)$_3$ complexes of Mo has been noted by us before, in the reaction between (1; X = Y = I) and acetone or diacetone alcohol.[6] Fragments of this reaction, in particular the bicyclic salt which must be derived from pyrazole, can presumably only be produced after removal of the B atom, presumably by the bidentate O–O' ligand diacetone alcohol.

EXPERIMENTAL

The complex Mo{HB(Me$_2$pyz)$_3$}(NO)I$_2$ was prepared as described previously.[7] All reactions were carried out under N$_2$ in thoroughly degassed solvents. All yields are quoted relative to the metal-containing starting material. IR and ^{1}H NMR spectra were measured using PE 197, PE 180 and PE R34 instruments.

Mo[HB(Me$_2$pyz)$_3$](NO)I(NHC$_6$H$_4$NH$_2$). (1; X = I, Y = *o*-NHC$_6$H$_4$NH$_2$). To a solution of Mo{HB(Me$_2$pyz)$_3$}(NO)I$_2$ (0.5 g) in dichloromethane (20 cm^3) was added *o*-phenylenediamine (0.15 g). The mixture was stirred at room temperature for 2 h during which time a brown solution formed. The solvent was reduced *in vacuo* to *ca.* 5 cm^3, diethylether was added causing precipitation of a white solid (probably C$_6$H$_4$(NH$_2$)$_2$HI), and the filtrate partially evaporated *in vacuo*. On standing at −5°, the *complex* formed as black microcrystals (0.31 g, 63%).

Mo{HB(Me$_2$pyz)$_3$}(NO)I(SC$_6$H$_4$MeOH); (1; X = I, Y = *o*-NHC$_6$H$_4$OH). This complex was prepared in the same way as its *o*-phenylenediamido analogue above, affording a green–brown solution in dichloromethane, from which the *complex* was isolated as a brown powder (0.22 g, 45%).

Mo{HB(Me$_2$pyz)$_3$}(NO)I(NHC$_6$H$_4$OH); (1; X = I, Y = *o*-NHC$_6$H$_4$SH). A mixture of Mo{HB(Me$_2$pyz)$_3$}(NO)I$_2$ (0.3 g), *o*-aminothiophenol (10 drops) and silver acetate (0.1 g) was refluxed in *n*-heptane (40 cm^3) overnight. The purple solution which had formed was cooled and filtered, a black powder being collected. This was dissolved in chloroform, filtered, and to the filtrate *n*-hexane was added. The mixture was slowly evaporated *in vacuo* until crystallisation apparently began. The *complex* was obtained as a dark purple powder (0.15 g, 49%).

Mo{HB(Me$_2$pyz)$_3$}(NO)I(SC$_6$H$_3$MeSH); (1; X = I, Y = *o*-SC$_6$H$_3$MeSH). A mixture of Mo{HB(Me$_2$pyz)$_3$} (NO)I$_2$ (0.5 g) and toluene-3,4-dithiol (0.2 g) was refluxed overnight in *n*-heptane (30 cm^3). The purple solution which had formed was cooled, filtered and a black powder collected. This was washed with methanol and *n*-pentane, affording the complex (0.39 g, 74%).

[Mo(NO)(Me$_2$C$_3$HN$_2$H)$_3$(O$_2$C$_6$H$_4$)]I$_3$. A mixture of Mo{HB(Me$_2$pyz)$_3$}(NO)I$_2$(0.5 g) and *o*-catechol (0.1 g) was refluxed overnight in toluene (30 cm^3). The red–brown solution which formed was then evaporated *in vacuo*, the residual oil being dissolved in dichloromethane. Addition of *n*-hexane to the solution caused preciptation of a red–brown oil which slowly crystallised over three days, giving the *complex* as black needles (0.40 g, 62%).

Crystallographic studies

Crystal data. [Mo(NO)(C$_3$HMe$_2$N$_2$H)$_3$(O$_2$C$_6$H$_4$)$^+$[I$_3$]$^-$; C$_{21}$H$_{28}$I$_3$MoN$_7$O$_3$; M = 903.11, crystallises from dichloromethane/hexane as black, elongated plates; crystal dimensions 0.40 × 0.05 × 0.18 mm. Triclinic a = 10.276(2), b = 10.814(3), c = 15.948(4) Å, α = 106.14(2), β = 86.88(2), γ = 113.14(2)°, U = 1562.3(7) Å^3, D_m = 1.90, D_c = 1.920 g cm^{-3}, Z = 2, space group $P\bar{1}$ (assumed and confirmed by the analysis), Mo K_α radiation ($\bar{\lambda}$ = 0.71069 Å), μ(Mo K_α) = 33.74 cm^{-1}, F(000) = 856.

Three-dimensional X-ray diffraction data were collected in the range $3.5 < 2\theta < 50°$ on a Nicolet/Syntex R3 diffractometer by the omega-scan method. 2437 Independent reflections for which I/σ(I) > 3.0 were corrected for Lorentz and polarisation effects. The structure was solved by superposition, Patterson and Fourier methods and refined by block-diagonal least-squares. Hydrogen atoms were detected and were placed in calculated positions (C–H 0.97, N–H 0.92 Å, C–C–H(methyl) 112°); their contributions were included in structure factor calculations (B = 8.0 Å^2) but no refinement of positional parameters was permitted. Refinement converged at R=0.0443 with allowance for anisotropic thermal motion of all non-hydrogen atoms and for the anomalous scattering of iodine and molybdenum. Tables of atomic positional parameters and anisotropic thermal vibrational parameters each with estimated standard deviations, predicted hydrogen atom positional parameters and observed structure amplitudes and calculated structure factors have been deposited.† Scattering factors were taken from Ref. 8; unit weights were used throughout the refinement; computer programs formed part of the Sheffield X-ray system.

ZINC(II), CADMIUM(II) AND MERCURY(II) COMPLEXES OF 4,6-DIMETHYL-PYRIMIDINE-2(1H)-ONE

RAFFAELE BATTISTUZZI* and GIORGIO PEYRONEL

Istituto di Chimica Generale e Inorganica, Università di Modena, 41100 Modena, Italy

Abstract—The following zinc(II), cadmium(II) and mercury(II) complexes of 4,6-dimethylpyrimidine-2(1H)-one (L) have been prepared and investigated by conductometric, IR and Raman methods: MX_2L_2 (M = Zn, X = Cl, Br(CHCl_3), I(CHCl_3), CF_3COO; M = Cd, X = Cl, Br, CF_3COO; M = Hg, X = Cl, CF_3COO), $Cd_2L_4L_3$, $Hg_3X_6L_2$ (X = Cl, Br), $Hg_3X_6L_4$ (X = Br, I), $MX_2L_4·6H_2O$ (M = Zn, Cd, X = ClO_4, BF_4; M = Hg, X = ClO_4). The ligand is principally bonded through the unprotonated nitrogen atom and in some complexes also through the carbonylic oxygen atom. The zinc halide complexes are tetrahedrally coordinated, the trifluoroacetate ion is coordinated as a monodentate ligand.

A problem relating to the binding of metal ions to nucleic acid components[1,2] is concerned with the coordination by exocyclic atoms of derivatives of the base pyrimidine. In previous work we have shown that in most of the zinc(II), cadmium(II) and mercury(II) complexes of neutral and deprotonated 4,6 - dimethylpyrimidine - 2(1H) - thione,[3] the ligand is strongly bonded through the unprotonated nitrogen atom and more weakly bonded through the exocyclic sulphur atom. In all the investigated copper(I) and copper(II) complexes of 4,6 - dimethylpyrimidine - 2(1H) - one[4] the ligand is bonded through the unprotonated nitrogen atom and the carboxylic oxygen atom. Only two zinc and two cadmium complexes of this last ligand have been previously described and partially investigated by IR spectroscopy.[5] We were interested in investigating more systematically, by IR and Raman spectroscopy and conductometric methods, the complexes of this ligand with zinc(II), cadmium(II) and mercury(II) ions.

EXPERIMENTAL

The ligand 4,6 - dimethylpyrimidine - 2(1H) - one (L) was prepared by the method previously reported.[4] The complexes were prepared as follows:

$ZnCl_2L_2$ and $ZnX_2L_2·CHCl_3$ (X = Br, I). A solution of the metal halide (4 mmol) in acetone (3 ml) was added with stirring to a suspension of 8 mmole of the ligand in 15 ml of $CHCl_3$ and 3 ml of acetone. The products precipitated on standing overnight and were washed with $CHCl_3$/acetone (3 : 1).

CdX_2L_2 (X = Cl, Br) and $Cd_2I_4L_3$. The solid metal halide (2.5 mmol) in 10 ml of H_2O (chloride) or EtOH (bromide) was added with stirring to a concentrated aqueous solution (10 ml) of L (5 mmol). The compounds precipitated immediately and, after standing for 2 hr, were washed with EtOH and ethyl ether.

$Hg_3X_6L_2$ (X = Cl, Br). A solution of the metal halide (2.5 mmol) in 10 ml of H_2O (chloride) or EtOH (bromide) was slowly added to a stirred aqueous solution (8 ml) of the ligand (5 mmol). The products precipitated after standing overnight and were washed with H_2O and EtOH.

$HgCl_2L_2$ and $Hg_3Br_6L_4$. An ethanolic solution (5 ml) of the metal halide (2.5 mmol) was added to a stirred solution of L (5 mmol) in 1:1 acetone + $CHCl_3$ (20 ml) and the products were washed with the same mixture.

$Hg_3I_6L_4$. The solid ligand (5 mmol) was dissolved in a solution of HgI_2 (2.5 mmol) in 30 ml of acetone. The resulting solution was concentrated to a small volume (10 ml) *in vacuo* and the light yellow product was washed with EtOH.

$MX_2L_4·6H_2O$ (M = Zn, Cd, X = ClO_4, BF_4; M = Hg, X = ClO_4) and $M(CF_3COO)_2L_2$ (M = Zn, Cd, Hg). An acetone solution (5 ml) of the metal salt (2 mmol) was added to a hot solution of 8 mmol of L (4 mmol for the trifluoroacetates) in 20 ml of 1:1 acetone + $CHCl_3$. Upon concentrating or cooling the solutions the products crystallized and were washed with 1:3 acetone + $CHCl_3$.

All the complexes are white or slightly yellow. They were dried *in vacuo* over KOH. The analyses of the metal ions were carried out by complexometric titration of EDTA[6] and for carbon, hydrogen and nitrogen by microanalysis. Conductivity measurements were performed on freshly prepared DMF solutions with a WTW conductivity bridge type L.B.B. (Table 1).

Infrared spectra were recorded on the solids as Nujol mulls or KBr disks (4000–250 cm⁻¹) and on polythene (600–60 cm⁻¹) with a Perkin–Elmer 180 spectrophotometer. Raman spectra (20–600 cm⁻¹) were recorded on the solids with a Jobin Yvon Ramanor HG2S spectrometer equipped with a Spectra-Physics 165 argon ion laser (514.5 nm line) using a rapidly rotating sample holder. The spectra were calibrated by means of the plasma lines of the laser. Satisfactory Raman spectra could not be obtained for the perchlorates, for all the mercury complexes, and for the zinc fluoroborate complex because these compounds were unstable or highly fluorescent under the laser beam. The spectra are reported in Table 2.

The molecular weights of the halide and trifluoroacetate complexes could not be determined because of their very low solubility or insolubility in all the solvents suitable for cryoscopic or osmometric measurements.

RESULTS AND DISCUSSION

The molar conductivities indicate that the halide complexes behave as non-electrolytes in DMF solution, excepting the zinc iodide complex which has a 1:1 electrolyte conductivity ($\Lambda_M = 65$–90),[7] probably due to solvolysis. The molar conductivity of the $Hg_3Br_6L_4$ complex ($\Lambda_M = 40$) excludes an ionic constitution such as [HgL_4][Hg_2Br_6] or [Hg_2Br_2L_4][HgBr_4]. The molar conductivities of $Cd_2I_4L_3$ ($\Lambda_M = 40$) and of the trifloroacetate complexes ($\Lambda_M = 54$–60), just under the lower limit of the 1:1 electrolyte conductivities, may indicate a partial solvolysis. The perchlorate and fluoroborate complexes have molar conductivities ($\Lambda_M = 133$–158) corresponding to those of 1:2 electrolytes ($\Lambda_M = 130$–170).[7]

In the IR spectra of the $ZnX_2L_2·CHCl_3$ (X = Br, I) complexes, two very strong bands at 758 and 750 cm⁻¹ may be assigned to the chloroform deformation mode (ν_5, E).[8]

In the 1750–1600 cm^{-1} region the ligand and its L·HCl derivative show several bands which are more distinct for the spectra recorded in Nujol mulls and in CHCl₃ solution than those recorded in KBr disks. Only the frequencies recorded in Nujol mulls will be considered for the ligand and its complexes:

L (CHCl₃ solution)	1720 m,
L (Nujol mulls)	1738 m,
L. HCl (Nujol mulls)	1740 vvs.

In the ZnX_2L_2 complexes, which are tetrahedral, the ligand is certainly monodentate. These complexes clearly show a blue shift of the ligand band at 1667 cm^{-1} to 1685–1675 cm^{-1} and a red shift of the ligand band at 1628 cm^{-1} to 1620–1610 cm^{-1}. These frequency shifts agree well with an electronic shift such as that resulting from the following resonance forms:
in which the coordination of the unprotonated nitrogen atom gives an increased C=O and a decreased C=N double bond character. In the pyrimidine - 2 - one

hydrochloride the protonation of the unprotonated ring-nitrogen atom gives rise to a shortening of the C=O and an elongation of both the C—N—C bonds.[9,10]

Consequently a predominantly ν(C=O) character may be assigned to the band at 1667 cm^{-1} and a predominantly ν(C=N) character to the band at 1628 cm^{-1},

1680 ms,	1655 vvs,	1625 vvs	cm^{-1}
1692 m,	1667 vvs,	1628 vvs	
1715 s,	1682 ms,	1625 vvs.	

even if this mode is coupled with other ring vibration modes.

A red shift is observed for the band at 1628 cm^{-1} for all the complexes of this series. A blue shift of the band at 1667 cm^{-1} is observed for all the zinc complexes, while for the cadmium complexes and the mercury perchlorate, fluoroborate, and trifluoroacetate complexes two very strong bands appear at 1687–1660 and 1670–1650 cm^{-1}.

In the far IR spectra of the complexes new mostly strong bands are observed in the 320–270 cm^{-1} region. Similar freqeuncies were observed for the ν(MN) bands of the 4,6 - dimethylpyrimidine - 2(1H) - thione complexes of zinc (II), cadmium(II) and mercury(II) ions[3] and other cations[11,12] and also for the Cu(I) and Cu(II) complexes of 4,6 - dimethylpyrimidine - 2(1H) - one.[4]

Halide complexes

The ZnX_2L_2 (X = Cl, Br, I) complexes show two ν(ZnN) and two ν(ZnX) bands, all IR and Raman active, supporting a (2N, 2X) tetrahedral coordination. The ν_{Br}/ν_{Cl} (0.83–078) and ν_I/ν_{Cl} (0.67–0.65) ratios are almost in the range accepted for complexes having similar coordination environments.[13] The ν(ZnBr) and ν(ZnI) frequencies are close to many other literature values

while the ν(ZnCl) frequencies are slightly lower than most of those reported in the literature, and this explains the rather high ν_X/ν_{Cl} ratios. However, ν(ZnCl) frequencies close to the present values are also reported in the literature: 270,266 cm^{-1} [14] and 276,264 cm^{-1} [15].

The CdX$_2$L$_2$ (X = Cl, Br) and Cd$_2$I$_4$L$_3$ complexes show two ν(CdN) and two ν(CdX) bands, all IR and Raman active, with ν(CdX) frequencies in agreement with many other literature values for terminal Cd–X bonds. The ν_{Br}/ν_{Cl} (0.82–0.76) and ν_I/ν_{Cl} (0.72–0.65) ratios are in an acceptable range for similar coordination environments. A substantially tetrahedral coordination may therefore be assigned to these complexes. However, because of the tendency of cadmium ion to adopt six coordination, a flattened 2N, 2X tetrahedron with axial interactions may also be possible for the CdX$_2$L$_2$ complexes. The dinuclear Cd$_2$I$_4$L$_3$ complex has terminal Cd–I bonds and probable (N, O)-bridging ligand molecules. The fact that in

these complexes the ligand ν (CO) band at 1667 cm^{-1} gives rise to two very strong bands, one of which is at a lower frequency, indicates that the carbonyl oxygen atom is involved in the coordination.

The HgCl$_2$L$_2$ complex shows one ν(HgN) band corresponding to trans-coordinated ligand molecules and two ν(HgCl) bands whose low frequency values correspond to bridging metal–chloride bonds. For the Hg$_3$X$_6$L$_2$ (X = Cl, Br) and Hg$_3$X$_6$L$_4$ (X = Br, I) complexes an ionic constitution may be excluded on the basis of their molar conductivities.

Perchlorate, fluoroborate and trifluoroacetate complexes

Some of the IR bands of the perchlorate, fluoroborate and trifluoroacetate ions, and particularly the ν_1 band of the perchlorate ion, are superimposed on ligand bands and may only tentatively be assigned:

ClO_4^-	Zn	1125 sh,	1110 vs,	1065 vs,	(927 ms),	623 vs	cm^{-1}
	Cd	1095 vs,	(910 mb),	623 vs			
	Hg	1095 vs,	(915 sh),	622 vs			
BF_4^-	Zn	1080 vs,	765 wm				
	Cd	1090 s,	1054 vs,	1025 s,	760 w,	518 m	

CF_3COO^-	Zn	1715 vs,	1700 vs,	1437 s,	1425 sm,	$\Delta(CO_2) = 278, 275$
	Cd	1745 sh,	1687 vs,	1444 s		301, 243
	Hg	1745 sm,	1430 sm			315

The slight distortion from T_d symmetry for the perchlorate and floroborate ions[16] may be attributed to hydrogen bonds. The $\Delta(CO_2)$ separations for the trifluoroacetate ions correspond to unidentate behaviour.[17]

The $MX_2L_4 \cdot 6H_2O$ (X = ClO_4, BF_4) complexes show at 3500–3400 cm^{-1} a medium strong broad band associated with $\nu(OH)$ modes of lattice water. No characteristic bands of coordinated water could be recognized in the 880–500 cm^{-1} region.[18] These complexes show four new bands attributable to $\nu(ML)$ modes, the anions and the water molecules being very likely not coordinated. Probably some of the ligand molecules are bonded through the ring nitrogen and the carbonylic oxygen atoms. This point of view is supported by the fact that in the cadmium and mercury complexes the $\nu(CO)$ band at 1667 cm^{-1} gives rise to two very strong bands instead of one.

In the $M(CF_3COO)_2L_2$ (M = Zn, Cd, Hg) complexes the anion is coordinated in a monodentate fashion. The very strong band at about 275 cm^{-1} may be superimposed in the zinc and cadmium complexes on the medium or weak band of the trifluoro-acetate anion appearing in the 270–280 cm^{-1} region[19] which is distinctly observed at 277 cm^{-1} in the mercury complex. Two $\nu(MN)$ and two $\nu(MO)$ bands, all IR and Raman active, indicate a tetrahedral (2N, 2O)-coordination for the zinc trifluoroacetate complex, for which bridging ligand molecules may be excluded because a single very strong $\nu(CO)$ band is observed at 1673 cm^{-1}. For the cadmium trifluoroacetate complex, three bands assignable to metal-ligand stretching modes, all IR and Raman active, indicate that the carbonyl oxygen atom is also involved in the coordination. This probably occurs also for the mercury trifluoroacetate complex. For both these complexes, indeed, the $\nu(CO)$ band at 1667 cm^{-1} gives rise to two very strong bands at 1687 and 1670 cm^{-1} for the cadmium and at 1680 and 1652 cm^{-1} for the mercury complex.

The ligand acts therefore preferably as N-monodentate for the zinc ion and more frequently as N,O-bidentate for the cadmium and mercury(II) ions.

COPPER(I) AND SILVER(I) COMPLEXES OF
2-AMINO-1,3,4-THIADIAZOLE AND
2-ETHYLAMINO-1,3,4-THIADIAZOLE

ANTONIO C. FABRETTI, GIORGIO PEYRONEL*, ALEARDO GIUSTI and ALINE F. ZANOLI

Istituto di Chimica Generale e Inorganica, Università di Modena, 41100 Modena, Italy

Abstract—The following copper(I) and silver(I) complexes of 2-amino-1,3,4-thiadiazole (*atz*) and 2-ethylamino-1,3,4-thiadiazole (*eatz*) have been prepared and studied by conductometric, IR and Raman methods: CuXL(X = Cl, Br, I; L = *atz, eatz*), CuXL$_3$(X = ClO$_4$, NO$_3$; L = *atz, eatz*), AgClO$_4$·1.5*atz*·1/3 EtOH, AgNO$_3$·2.5*atz*, AgClO$_4$·3*eatz*, AgNO$_3$·*eatz*. The ligands are bonded through the amine nitrogen atoms with ν(MN) bands in the 520–410 cm^{-1} region. The CuXL complexes have a trigonal (N, 2X$_b$) coordination with a probable weaker axial interaction. The CuXL$_3$ and AgClO$_4$·3*eatz* complexes probably have a trigonal pyramidal (3N, O) coordination. In the *atz* complexes of silver perchlorate and nitrate some ligand molecules are bridging. The AgNO$_3$·2.5*atz* complex is likely to have a dimeric structure with tetrahedral coordination of the silver ion.

The copper(I) and silver(I) complexes of 2-amino-1,3,4-thiadiazole (*atz*) and 2-ethylamino-1,3,4-thiazole (*eatz*) have been prepared and studied in order to compare the coordination behaviour of these ligands which differ from each other only by the presence of an ethyl substituent in the amine group.

EXPERIMENTAL

The ligands *atz* (Fluka), *eatz* (Eastman Kodak) and the other reagents were of the best commercial grade. The compounds were prepared as follows.

CuXL(X = Cl, Br; L = atz, eatz)

A warm solution of CuCl$_2$·2H$_2$O (or CuBr$_2$) (0.5 mmol) in EtOH (2 cm^3) was slowly added to a warm solution of L (3 mmol) and hydroquinone (3 mmol) in EtOH (8 cm^3). The compounds precipitated instantaneously and were stirred in their mother solutin for about 1 hr. Then they were filtered and washed with EtOH and dried *in vacuo* on KOH.

CuIL and CuClO₄L₃(L = atz, eatz)

A solution of Cu(NO$_3$)$_2$·3H$_2$O (0.5 mmol) or Cu(ClO$_4$)$_2$·6H$_2$O (0.5 mmol) respectively, in H$_2$O (1 cm^3) was slowly added, with stirring, to a solution of L (3 mmol) and KI (0.5 mmol) (for the iodides) or NaClO$_4$ (0.5 mmol) (for the perchlorates) and hydroquinone (0.5 mmol) in EtOH (2 cm^3) and H$_2$O (8 cm^3). The instantaneous precipitates were stirred for some time in their mother solution, filtered and washed with a mixture of EtOH and H$_2$O (1:4) and EtOH.

CuNO₃L₃ (L = atz, eatz)

A solution of Cu(NO$_3$)$_2$·3H$_2$O (1 mmol) in EtOH (5 cm^3) was added, with stirring, to a solution of L (1 mmol) and hydroquinone (2 mmol) in EtOH (8 cm^3). The instantaneous precipitates were stirred for some time in their mother solution, filtered and washed with EtOH.

AgNO₃·2.5atz, AgClO₄·1.5atz, AgNO₃·eatz, AgClO₄·3eatz

A solution of the silver salt (0.5 mmol) in EtOH (3 cm^3) was added to a warm solution of L (1.5 mmol) in EtOH (3 cm^3). The instantaneous precipitates were stirred for some time in their mother solution, filtered and washed with EtOH. The compounds

could not be recrystallized but they appeared as homogeneous and pure crystals under the microscope.

The compounds are white excepting the cooper iodide and the silver perchlorate complexes which are light brown. Any attempt to prepare the solid silver halide complexes was unsuccessful. The silver halides dissolve in a DMF solution of the ligands, indicating that complexes are formed in solution, but are reprecipitated by other solvents such CHCl$_3$, C$_6$H$_{12}$, or C$_6$H$_6$.

The compounds were analysed by standard methods (Table 1). Molar conductivities were determined with a WTW conductivity bridge. IR spectra (Table 2) were recorded in KBr disks (4000–250 cm^{-1}) and as Nujol mulls on polythene (600–60 cm^{-1}) with a Perkin–Elmer 180 spectrophotometer. The IR spectra of the silver complexes were also recorded in the 4000–250 cm^{-1} region as Nujol mulls on KBr disks in order to avoid any reaction of the silver ion with potassium bromide. The Raman spectra were recorded with a Jobin–Yvon Ramanor HG 2S spectrometer equipped with a Spectrophysics 165 argon ion laser using the 514.5 nm line.

RESULTS AND DISCUSSION

The ν(NH) bands shown by the ligands in CHCl$_3$ solution in the 3440–3210 cm^{-1} region are shifted to lower frequencies for the *atz*-(3370–3150 cm^{-1}) and *eatz*-complexes (3240–3100 cm^{-1}).

The very strong band at 1507 cm^{-1} for *atz* and 1517 cm^{-1} for *eatz* is assignable to ring vibration modes with a high ν(C = N) contribution[1]. This band appears at 1510–1505 cm^{-1} for the *atz* copper halides and at 1527–1514 cm^{-1} for the other *atz* complexes and shifts to 1588–1550 cm^{-1} for the *eatz* complexes.

A ν(C–NHR) contribution may be assigned[2] to the *eatz* band at 1198 cm^{-1} which shifts to lower frequencies (1160–1148 cm^{-1}) in its complexes.

An important ν(C–S) contribution may be attributed[2] to the bands appearing at 680 and 610 cm^{-1} for *atz* and 610 cm^{-1} for *eatz*. They show increased frequencies in the *atz* (700–695 and 640–626 cm^{-1}) and *eatz* (640–622 cm^{-1}) complexes.

All these frequency shifts agree well with the electronic shifts:

due to a R_2N-coordination of the ligand to the metal.

Some new bands appearing at 511–425 and 520–442 cm^{-1} for the *atz* and *eatz* complexes, respectively, may be assigned to $\nu(MN)$ modes in agreement with the frequency values reported for an amine nitrogen coordination[3] and for the complexes of similar ligands.[4-7]

Both ligands form $CuXL(X = Cl, Br, I; L = atz, eatz)$ complexes behaving as non-electrolytes in DMF solution.[8] Their $\nu(CuX)$ frequencies are in the range of values given for bridging CuX bonds[9-11] with ν_{Br}/ν_{Cl} (0.78–0.72) and ν_I/ν_{Cl} (0.67–0.56) ratios in the range given for complexes with similar coordination environments[12]. A single $\nu(CuN)$ and two $\nu(CuX)_b$ bands, IR and Raman active (when observed in the Raman spectrum) indicate for these complexes a trigonal $(N, 2X_b)$ coordination, with a probable longer axial interaction as frequently occurs in cuprous complexes.

The molar conductivities in DMF solution of the perchlorate and nitrate complexes are mostly at the lower limit or below the values given for 1 : 1 electrolytes $(\Lambda_M = 65–90\ \Omega^{-1}\ mol^{-1}\ cm^2)^8$. Some IR bands may be assigned (Table 2) to the perchlorate and nitrate ions even if with some difficulty for the nitrates because of the superposition of the ligand bands. For most of these complexes the anion bands indicate that they are coordinated in the solid state[3] even if the molar conductivities indicate a more or less pronounced solvolysis in solution. Some new far IR bands may be tentatively assigned to $\nu(MO)$ modes.

For the $CuXL_3(X = ClO_4, NO_3; L = atz, eatz)$ complexes a trigonal pyramidal coordination with three Cu–N bonds in the base and a weaker apical Cu–O bond seems to be likely.

The same trigonal pyramidal coordination may be proposed for the $AgClO_4 \cdot 3eatz$ complex which shows two $\nu(AgN)$ bands and a $\nu(AgO)$ band localizable either at 175 or 169 cm^{-1}.

For the $AgNO_3 \cdot eatz$ complex a single $\nu(AgN)$ band, IR and Raman active, corresponds to the bond of the silver ion with the aminic nitrogen atom. No bands could be identified corresponding to bonds of the silver ion either with a ring nitrogen atom of a bridging ligand molecule or with the nitrate ion which may act as mono- or bidentate.

The *atz* complexes of silver perchlorate and nitrate have a fractional number of ligand molecules per silver ion. The $AgNO_3 \cdot 2.5atz$ complex is likely to have a dimeric $(L_2AgNO_3)_2L$ structure with a bridging ligand molecule and tetrahedral coordination of the silver ion.

POLAROGRAPHIC STUDY OF Sn(IV) CHLORIDE-PYRIDINE N-OXIDE COMPLEXES IN ACETONITRILE

A. DRTIL,† JAY MEUX,† J. W. MEUX, R. J. WILLIAMS and J. W. ROGERS*

Department of Chemistry, Midwestern State University, Wichita Falls, TX 76308, U.S.A.

Abstract—Polarograms recorded of Sn(IV) chloride in acetonitrile in the presence of controlled quantities of each of nine substituted pyridine N-oxide ligands demonstrated the formation of stable and soluble complexes with a stoichiometry dependent upon the nature and position of the ring substituent. The polarographic data associated with each complex and the free ligands are used to substantiate a proposed bonding model which explains the dependency of the complex formula on the ligand structure.

The salt $SnCl_4 \cdot 5H_2O$ was employed as a source of Sn(IV) and the complete polarographic behaviour of this salt in acetonitrile is described as a basis for the interpretation of complex reduction behaviour.

Results of IR and proton magnetic resonance studies of complexes of substituted pyridine N-oxides with $SnCl_4$ in acetonitrile (ACN) solution have recently been reported.[1] Two types of behaviour were noted. Pyridine N-oxide donors containing electron releasing substituents were generally found to form strong complexes with $SnCl_4$ and exhibited maxima in continuous variation plots at a 2:1 ligand-to-metal ratio. Pyridine N-oxide donors containing electron neutral to electron withdrawing substituents were found to form generally weaker complexes with $SnCl_4$ and exhibited maxima in continuous variation plots at a 1:1 ligand-to-metal ratio. Evidence for multi-nuclear and 2:1 or higher complexes was discussed and the results were rationalized in terms of an equilibrium model for this system.

The essential elements of the model include the assumption of octahedral geometry for all complexes of sterically unhindered N-oxide ligands and a consideration of the contribution of $d\pi p\pi$ backbonding to the coordinate bond and the effect of this bonding on the possible *cis-trans* isomerism in these complexes. The importance of $d\pi p\pi$ backbonding in these complexes should be dependent upon the degree of orbital energy matching between the d-orbitals of tin and the lowest unoccupied π^* orbital of the ligand. Electron releasing substituents on a pyridine N-oxide ring are expected to raise the energy of this π^* orbital so that it is too high in energy for effective overlap and, therefore, diminish the importance of $d\pi p\pi$ bonding in $SnCl_4$ complexes of these ligands. Complexes containing pyridine N-oxide ligands with electron releasing substituents were then expected to form stable, *trans*-2:1 complexes resulting in maxima in continuous variation plots at a 2:1 ligand-to-metal ratio.

Electron withdrawing substituents on a pyridine N-oxide ring are expected to lower the energy of the lowest unoccupied π^* orbital and enhance $d\pi p\pi$ backbonding. Assuming this backbonding is an important component of the coordinate bond, these ligands would be expected to form *cis*-2:1 complexes which were postulated subsequently to form stable, oxygen bridged dimers in solu-

tion. This would result in the observed maxima in continuous variation plots at a 1:1 ligand-to-metal ratio for these complexes.

Previously published UV spectrophotometric and electrochemical data demonstrate that tin (IV) chloride, $SnCl_4$ is a nonelectrolyte in ACN and that in this solvent the neutral complex acts as the Lewis acceptor.[2] The electrochemical reduction of $SnCl_4$ occurs *via* irreversible steps, not allowing the application of standard methods to the determination of thermodynamic properties. However, the polarographic studies have previously been shown to provide a straightforward means of specifying the electrolyte properties and stoichiometry of Sn(II) and Sn(IV) complexes in the low basicity solvent ACN.[2-4]

In an attempt to confirm the results of the IR and proton magnetic studies and to further test the proposed bonding model extensive polarographic data have been taken on solutions of $SnCl_4$ in ACN containing controlled quantities of a series of substituted pyridine N-oxides. The polarographic behaviour of a metal complex is frequently dictated by properties of the metal moiety.[5] In contrast, the data leading to the previously postulated bonding model are derived from physical properties directly associated with the ligand in complexed and noncomplexed states.

Polarographic data presented herein support the previously presented IR and proton magnetic data and the resulting conclusions and bonding model. Various substituted pyridine N-oxides are found to form complexes with $SnCl_4$ in ACN in a ligand-to-metal coordination ratio dependent on the electronic nature of the ring substituent. The polarographic test solutions were prepared from the solid pentahydrate of $SnCl_4$ as opposed to the liquid anhydrous form. The polarographic characteristics of the pentahydrate salt in ACN, not previously reported, are discussed in detail as a basis for interpretation of polarographic data relating to the complexation chemistry of Sn(IV) chloride acting as a Lewis acceptor.

EXPERIMENTAL

Chemicals. All pyridine N-oxide ligands (Aldrich Chemical Co.) were purified by sublimation or vacuum distillation before use. $SnCl_4 \cdot 5H_2O$ (Pfaltz and Bauer) was utilized without purification following confirmatory quantitative analysis. Spec-

troquality acetonitrile containing less than 0.03% water (Aldrich Chemical Co.), polarographic-grade tetrapropylammonium perchlorate and tetramethylammonium chloride (Southwestern Analytical Chemicals) were employed throughout. The supporting electrolyte, tetrapropylammonium perchlorate, was recrystallized from acetonitrile-water solutions and vacuum dried before use. All solutions were prepared and transferred under a nitrogen atmosphere.

Apparatus. The polarographic cell was of conventional design and has been described previously.[6] The polarograms were recorded on a Houston Instruments Omnigraphic 2000 X-Y plotter using a Princeton Applied Research Model 173 potentiostat and Exact Model 7050 wave form generator for potential control.

RESULTS

Polarography of Sn(IV) chloride pentahydrate in ACN

Polarographic test solutions of ACN, containing 1.0 mM $SnCl_4$ prepared from the pentahydrate salt, $SnCl_4 \cdot 5H_2O$ and 1.0 M tetrapropylammonium perchlorate, exhibited two well-defined reduction current plateaus, Fig. 1(a). The lower potential plateau exhibiting a half-wave potential of -0.08 V vs saturated calomel (s.c.e.) does not exhibit the distortion or the maximum noted in the corresponding wave of similar test solutions prepared from anhydrous $SnCl_4$.[2] The higher potential wave is very broad and preceded by an adsorption maximum. The half-wave potential of the wave appears near 1 V vs s.c.e. The ratio of the total current of both waves to the square root of the corrected mercury column head height is constant signifying diffusion control. The current constants (Id) of the low and high potential waves measured at 25°C and at 1.0 mM con-

centration are 4.01 and 9.43 respectively (DME characteristics at open circuit and 50 cm Hg head: $m = 0.049$ mg/sec, $t = 6.50$ sec). Both currents are apparently the result of irreversible electrochemical processes (slope of $\log[(id - i)/i]$ vs EDME for wave appearing at -0.08 V is 120 mV).

Addition of measured quantities of noncomplexed chloride ion in the form of tetramethylammonium chloride (TMACl) to the polarographic test solution resulted in a behaviour analogous to that exhibited by $SnCl_2$ and $SnCl_4$ solutions prepared from the anhydrous form of each.[2,3] Increasing quantities of chloride up to 2.0 mM decreased the plateau current of the lower potential wave. The total polarographic current is unaltered. The lower potential wave is no longer detectable at concentrations of added chloride exceeding a ratio of 2:1 with respect to the metal. Only at concentrations of added chloride exceeding the 2:1 ratio is the characteristic oxidation of chloride observed at positive dropping mercury electrode potentials.

The observed behaviour of polarographic test solutions prepared from $SnCl_4 \cdot 5H_2O$ in the presence of added chloride is consistent with the behaviour demonstrated by solutions prepared from anhydrous $SnCl_4$ even though the half-wave potential at the lower potential wave is significantly more negative and is not distorted. These data are consistent with an electrode reduction mechanism in which a water complex of $SnCl_4$ is reduced at the first polarographic wave, releasing free chloride thereby controlling the wave current by displacement of water and subsequent production of the hexachloro complex $SnCl_6^{2-}$, a species reducible only at potentials of the second polarographic wave.[2-4] This sequence of events may be represented in the following manner:

Lower potential wave

$$SnCl_4(H_2O)_2 + Hg + 4e^- \rightarrow Sn(Hg) + 2H_2O + 4Cl^-$$
$$SnCl_4(H_2O)_2 + 2Cl^- \rightarrow SnCl_6^{2-} + 2H_2O.$$

Higher potential wave

$$SnCl_6^{2-} + Hg + 4e^- \rightarrow Sn(Hg) + 6Cl^-.$$
Polarography of Sn(IV) chloride pyridine N-oxide complexes

The stable physical properties of the pentahydrate form of Sn(IV) chloride and the lack of distortions in its polarograms in ACN made it a desirable source of the salt for polarographic studies dealing with the Lewis acceptor properties of $SnCl_4$ in a weakly coordinating solvent. Consistent with previous studies,[1] the effects of adding controlled quantities of substituted pyridine N-oxides to polarographic test solutions prepared from $SnCl_4 \cdot 5H_2O$ in ACN containing TRAP supporting electrolyte reveal the production of complexes with stoichiometries that are dependent upon the nature and position of ring substituents.

Addition of the ligands pyridine N-oxide (pno), 3-pyridine methanol N-oxide (3-pmno), 2-picoline N-oxide (2-picno), 4-phenylpyridine N-oxide (4-phenpno), 3-picoline N-oxide (3-picno) and 4-picoline N-oxide (4-picno) in sufficient quantities to bring test solutions of 1.0 mM $SnCl_4 \cdot 5H_2O$ to ligand-to-metal ratios of 1:2, 1:1, 2:1 and 2.5:1 bring about very similar changes in the structure of the resulting polarograms. Polarograms
Fig. 1. Polarogram of (a) 1.0 mM $SnCl_4 \cdot 5H_2O$ in ACN (b) 1.0 mM $SnCl_4 \cdot 5H_2O$ in ACN containing 1.0 mM pno (c) 1.0 mM $SnCl_4 \cdot 5H_2O$ in ACN containing 2.0 mM pno.

recorded in solutions containing 0.5 mM ligand (1:2 ratio) exhibit pronounced splitting of the lower potential wave resulting in a new polarographic plateau appearing near −0.3 V vs s.c.e., Figs. 1 and 2. It is reasonable to assume that the appearance of this wave signifies the existence and subsequent reduction of a SnCl₄-pyridine N-oxide complex. Increasing ligand to metal ratios bring about an increase in this complex reduction plateau current at the direct expense of the plateau current attributable to the reduction of the substrate complex, SnCl₄·2H₂O, Fig. 2. The ratio of the complex wave current to the metal chloride substrate wave current is 1.0 at a ligand-to-metal ratio of 1.0, Fig. 2. The plateau current associated with the reduction of SnCl₄·2H₂O is not detectable at a organic ligand to metal ratio of 2:1 or greater, Fig. 2. These data obviously suggest the formation of a stable SnCl -pno adduct with the stoichiometry SnCl₄·2L.

The properties of the polarographic wave associated with the reduction of each SnCl₄·2L complex are equivalent but at variance with those of the reduction wave of SnCl₂·2H₂O. The polarographic $E_{1/2}$ of the reduction plateau of each complex is observed to be −0.33 V vs s.c.e. The complex wave deviates slightly from diffusion controlled behaviour and is significantly broadened relative to that of the Sn(IV) chloride reduction, Fig. 2. The current constant (Id) is found to be 3.64. The plateau current associated with the reduction of the $SnCl_6^{-2}$ complex is unperturbed by addition of organic ligands and subsequent complex formation, Fig. 1.
Addition of the ligands 2,6-lutidine N-oxide (lno), 2-pyridinemethanol N-oxide (2-pmno) and 4-chloropyridine N-oxide (4-Clpno) in sufficient quantities to bring test solutions of 1.0 mM SnCl₄·5H₂O to a ligand-to-metal ratio of 0.5:1 splits the lower potential polarographic plateau into two waves of equal current. Increasing the organic ligand-to-metal ratio to 1:1 brings about the complete replacement of the lower potential plateau by the complex reduction plateau suggesting the formation of a stable complex with the stoichiometry SnCl₄·L.

The characteristics of the plateau current associated with the reduction of each SnCl₄·L complex are equivalent. The polarographic $E_{1/2}$ is observed to be −0.29 V vs s.c.e. The wave is broadened relative to that of the reduction of SnCl₄·SH₂O and the observed current constant (Id) value of 3.26 is less than that of SnCl₄·2H₂O and the SnCl₄·2L complexes. The wave attributable to the reduction of $SnCl_6^{2-}$ is characteristically unaltered.

Addition of noncomplexed chloride in the form of tetramethylammonium chloride (TMACl) to test solutions containing ligand enhances the plateau current resulting from the reduction of $SnCl_6^{2-}$ at the direct expense of the wave attributable to the reduction of the complex. For example, see Fig. 3. The complex reduction current is not detectable in test solutions containing equal molar volumes of pyridine N-oxide ligand TMACl. The characteristic wave associated with the oxidation of chloride is observed only in test solutions containing TMACl in excess of the Sn(IV) chloride substrate.

Each of the nine substituted pyridine N-oxide ligands described herein exhibits a characteristic polarographic reduction plateau at potentials negative of the plateau

Fig. 2. Polarograms showing only lowest potential cathodic waves (expanded scale) of ACN solutions containing (a) 1.0 mM SnCl₄·5H₂O (b) 1.0 mM SnCl₄·5H₂O and 1.0 mM pno (c) 1.0 mM SnCl₄·5H₂O and 2.0 mM pno.
Fig. 3. Polarograms of (a) 1.0 mM SnCl₄·5H₂O in ACN and (b) 1.0 mM SnCl₄·5H₂O in ACN containing 2.0 mM pno and 2.0 mM TMACl (reduced scale).

currents associated with the reduction of all Sn(IV) species produced and described in ACN, Fig. 3. The compounds pno, 4-Clpno, 2-, 3- and 4-picno, lno and 4-phenpno each exhibit reversible one-electron reduction plateaus at -2.26, -1.88, -2.33, -2.30, -2.30, -2.43 and -2.00 V respectively. The compounds 2- and 3-methanolpyridine N-oxide exhibit a two-wave reduction process probably resulting from the reduction of the methanolic hydrogen and the subsequent reduction of the anion product.

The reduction plateau characteristic of each N-oxide is observed to be superimposed on the total current resulting from the reduction of all Sn(IV) species. The current associated with the reduction of the noncomplexed ligand varies in proportion to the concentration in the range 0.5–10 mM.

DISCUSSION

Data have been presented which demonstrate that in ACN the salt $SnCl_4 \cdot 5H_2O$ is reduced in two electrochemical steps resulting in well-defined polarographic current plateaus via a mechanism analogous to that previously reported for anhydrous $SnCl_4$.[2] This information has been used as a basis for a polarographic study of $SnCl_4$-pno complex formation in ACN. Addition of each of the six ligands pno, 3-pmno, 2-picno, 4-phenpno, 3-picno and 4-picno to test solutions containing $SnCl_4$ in a ligand to metal ratio of 2:1 brings about the replacement of the plateau associated with the reduction of the water complex of $SnCl_4$ with a current plateau that may be reasonably associated with the reduction of a pyridine N-oxide $SnCl_4$ adduct having the formula $SnCl_4 \cdot 2L$. Similarly conducted experiments employing the ligands lno, 2-pmno and 4-Clpno reveal analogous behaviour but with the formation of adducts apparently having the forlula $SnCl_4 \cdot L$. The polarographic reduction current associated with the reduction of the stable $SnCl_6^{2-}$ complex is unperturbed in all polarographic experiments conducted in this study.

The polarographic wave associated with the reduction of each 2:1 complex appears at an $E_{1/2}$ of -0.33 V and is irreversible. According to conventional criteria the wave current deviates slightly from diffusion control behaviour and the measured current constant value of 3.64 is small in comparison to most four-electron processes. Similar observations related to $SnCl_4$ electrochemistry have been discussed previously.[2,7,8]

The polarographic wave associated with the reduction of each of the three 1:1 complexes studied appears at an $E_{1/2}$ of -0.29 V and is irreversible. The measured current deviates slightly from diffusion controlled behaviour and the current constant value of 3.26 is suppressed relative to that of $SnCl_4 \cdot 2H_2O$ as well as that of the 2:1 complexes.

The destruction of the 2:1 and the 1:1 complex reduction wave as well as that of $SnCl_4 \cdot 2H_2O$ by the addition of TMACl and the concurrent enhancement of the wave associated with the reduction of the $SnCl_6^{2-}$ complex ion demonstrates the great stability of the hexachloro anion relative to each of the other complexes of Sn(IV). The unperturbable current wave and the predictably large current constant of the four-electron reduction of the $SnCl_6^{2-}$ anion also signifies its great stability and diffusion controlled reduction.

These observations may be summarized with the following set of reactions:

First Cathodic Wave (Lowest Cathodic Potential)

$$SnCl_4 \cdot 2H_2O(s) + Hg + 4e^- \rightarrow Sn(Hg) + 4Cl^-(s) + 2H_2O$$
$$SnCl_4 \cdot 2H_2O(s) + 2Cl^-(s) \rightleftarrows SnCl_6^{2-}(s) + 2H_2O.$$
Second Cathodic Wave (Complex Reduction)

$$SnCl_4 \cdot nL(s) + Hg + 4e^- \rightarrow Sn(Hg) + 4Cl^-(s) + nL(s)$$
$$SnCl_4 \cdot nL(s) + 2Cl^-(s) \rightleftarrows SnCl_6^{2-}(s) + nL(s).$$
Third Cathodic Wave

$$SnCl_6^{2-}(s) + Hg + 4e^- \rightarrow Sn(Hg) + 6Cl^-(s).$$
Fourth Cathodic Wave (Highest Cathodic Potential)

$$L + e^- \rightleftarrows L^{\cdot-}.$$
Where L is pno, 2, 3, and 4-picno, 4-phenpno and 4-Clpno.

In addition to these reactions describing the electrochemistry of $SnCl_4$ species in ACN and the current ratios which define the formulas of stable adducts, two other polarographic observations are central to the postulated bonding model[1] and its relationship to the nature of ring substituents. These are the polarographic $E_{1/2}$ values of the noncomplexed ligands and the diminished currents of the reduction waves of the 1:1 complexes relative to those of the 2:1 complexes and the $SnCl_4 \cdot 2H_2O$ complex.

It is postulated that the increased matching of metal d-orbitals with lowest π^* ligand orbitals through lowering of the π^* energy as a result of the electronic and mesomeric effects of electron withdrawing substituents enhances $d\pi p\pi$ backbonding promoting the formation of stable 1:1 complexes at the expense of the 2:1 form. The reported polarographic $E_{1/2}$ values of those ligands which undergo reversible one-electron reductions are, with the exception of lno[1], clearly consistent with the postulated substituent effect on the lowest π^* orbital. As an example, the $E_{1/2}$ values of 4-picno (2:1 complex) and 4-Clpno (1:1 complex) are -2.30 and -1.878 V respectively. It is well known that the value of the polarographic $E_{1/2}$ for a reversible electrochemical reaction is proportional to the Hückel (HMO) value of the lowest π^* energy.[9,10,11] Employing the calculations of Streitwieser[12] in which the $E_{1/2}$ values of fifty aromatic substances undergoing reversible one-electron additions in aqueous dioxane (the dielectric effects of the solvent are found to be small) are correlated with the HMO value of the lowest π^* orbital, the difference in the $E_{1/2}$ between 4-picno and 4-Clpno corresponds to a lowest π^* energy lowering by Cl-substitution of approx. 0.38 eV.

This observed sensitivity of the lowest π^* orbital of pyridine N-oxide to substituents in the 2- and 4-position is predicted by HMO calculations using generally accepted heteroatom parameters for nitrogen and oxygen exchange and Coulomb integrals.[12] Treating both 2- and 4-position substituents as Coulomb perturbations by varying the Coulomb parameter, h, of the 2- or 4-carbon in the conventional manner[12] over a range of 2.0 shifts the lowest π^* energy of 4-substituted pyridine N-oxides by 0.44 β_0 units and of 2-substituted pyridine N-oxides by 0.67 β_0 units. Treating a 3-position substituent per-

turbation in a similar manner does not alter the lowest π^* energy. The highest bonding π-orbital energy is unaltered by substitution in all calculations.

Empirical evidence presented in previous studies[1] in support of the proposed existence of 1:1 complexes in an oxygen-bridged dimeric form is indirect at best. Consequently the diminution of the 1:1 complex reduction current relative to that of the 2:1 complex reduction current appears to be quite significant but must be interpreted with caution owing to the complex nature of the electrochemical processes controlling the wave current. All polarographic wave currents are found to be proportional to the concentration of the reduced species in the range 1.0–10.0 mM and all wave currents are the result of four-electron processes. Additionally, the polarographic data suggests that the production of free chloride in the double layer and the concomitant production of $SnCl_6^{2-}$ from all $SnCl_4$ complexes diffusing to the electrode surface is rapid and irreversible. This results in a constant, current-limiting effect, on each of the current waves resulting from the reduction of a $SnCl_4$ complex. Consequently the diminished current of the 1:1 complex may be explained in terms of a diminished diffusion coefficient. This, in turn, supports the existence of a 1:1 species of larger physical dimension than the 2:1 species, i.e. a dimeric complex.

PHOTOSUBSTITUTION IN SOME CYANIDE COMPLEXES OF CHROMIUM(III)[1]

ADAM MARCHAJ and ZOFIA STASICKA*

Institute of Chemistry, Jagiellonian University, Karasia 3, 30–060 Kraków, Poland

Abstract—Photosubstitution by OH⁻ ligand was concluded from a photochemical study of the $[Cr(CN)_6]^{3-}$ and $[Cr(CN)_5OH]^{3-}$ complexes in alkaline medium. Photoaccelerated aquation was found to proceed in the case of aquocyanochromates(III): $[Cr(CN)_5H_2O]^{2-}$ and $[Cr(CN)_3(H_2O)_3]$.

Ligand-field photochemistry of hexacyanochromate(III) has been studied repeatedly.[2-11] It was concluded that the only photochemical mode arising from continuous irradiation was photosolvation of one CN⁻ ligand

$$[Cr(CN)_6]^{3-} \xrightarrow[S]{h\nu} [Cr(CN)_5S]^{2-} + CN^- \qquad (1)$$
where $S = H_2O$,[4,5,9-11] DMF,[7,9] or DMSO.[6] Photochemical solvation was reported to be followed by secondary processes leading in aqueous solutions to aquation of further CN⁻ ions by thermal[5] or photochemical[4] routes.

The photochemical behavior of aquocyanochromates(III) was not studied in detail except for the $[Cr(CN)(H_2O)_5]^{2+}$ complex. In this case photoaquation of the CN⁻ ligand

$$[Cr(CN)(H_2O)_5]^{2+} \xrightarrow[H_2O]{h\nu} [Cr(H_2O)_6]^{3+} + CN^- \qquad (2)$$
was reported to proceed with a relatively high quantum yield.[12]

In this paper the photochemical study of the $[Cr(CN)_6]^{3-}$ complex has been extended to strongly alkaline solution. To solve the problem of secondary processes, the photochemical behaviour of hexacyanochromate(III) and some relatively stable cyanochromates(III) substituted by H_2O or OH⁻ ligands, was followed using both continuous illumination and flash photolysis techniques.

RESULTS AND DISCUSSION

In all systems studied no transient species could be observed upon flashing at delay times longer than 10 μs.

The only product observed in flash photolyzed solutions of hexacyanochromate(III) was the aquopentacyanochromate(III) complex, except when pH was too high. Then, the $[Cr(CN)_5OH]^{3-}$ complex was recorded with delay times between microseconds and seconds The results obtained at lower pH values were consistent

with the reported earlier photoaquation (eqn 1) following the reactive decay of the quartet excited state.[7-9]

In strongly alkaline medium, the photosubstitution by OH⁻ ligand

$$[Cr(CN)_6]^{3-} \xrightarrow[OH^-]{h\nu} [Cr(CN)_5OH]^{3-} + CN^- \qquad (3)$$
or rapid deprotonation of the aquopentacyanochromate(III) complex was considered. The latter path is supported by the value of the protonation constant of $[Cr(CN)_5OH]^{3-}$, reported[13] to be about 10^9. However, unlike the thermal aquation,[14] the photosubstitution was found to be accelerated by an increase in pH. The photosubstitution quantum yield values measured in this as well as in other studies (Table 1) increase nearly linearly with an increase in pH†. The correlation strongly suggests that the photosubstitution by OH⁻ ligand (eqn 3) is effectively competing with photoaquation in alkaline solutions of the hexacyanochromate(III) complex.

From the data presented in Table 1 the influence of spectral range on the photosubstitution quantum yield can also be followed. In accordance with the previous report[5] this seems to be insignificant although its importance seems greater at higher pH. Moreover, in alkaline solutions of hexacyanochromate(III) in the presence of oxygen, a quite new photochemical mode[15] was found to accompany the photosubstitution upon exposure to radiation with $\bar{\nu} > 33 \times 10^3$ cm⁻¹.

Prolonged irradiation of the $[Cr(CN)_6]^{3-}$ solution leads to a substitution of further CN⁻ ligands by H_2O molecules or OH⁻ ions, depending on pH. To solve the problem of secondary processes, thermal and photochemical behaviour of the $[Cr(CN)_5H_2O]^{2-}$ and $[Cr(CN)_5OH]^{3-}$ complexes has been compared. Thermal substitution of the latter complex was found to proceed slightly more slowly than that of the aquo-complex. For both complexes substitution was shown to be considerably photoaccelerated, as illustrated in Fig. 1. However, in both cases, the first possible substitution product, $[Cr(CN)_4(H_2O)_2]^-$ or $[Cr(CN)_4(OH)_2]^{3-}$, was never observed.‡ Instead, $[Cr(CN)_3(H_2O)_3]$ was the first product recorded both in thermal and photochemical aquation of aquopentacyanochromate(III), while a mixture of hydroxocyanochromates(III) was observed upon exposure of the $[Cr(CN)_5OH]^{3-}$ complex. Due to lack of any transient species even at 20 μs upon flashing, no suggestions about the detailed mechanism could be made. In alkaline medium, an additional difficulty arose

Absorption changes recorded at $\bar{\nu}_{max}$ of substrates (upper curves) and products (lower curves) during photochemical (——) and thermal (---) reactions proceeding in 5×10^{-3} M solutions of: (a) $[Cr(CN)_5H_2O]^{2-}$ in acetate buffer at pH 5.8, (b) $[Cr(CN)_5OH]^{3-}$ in 1 M KOH, (c) $[Cr(CN)_3(H_2O)_3]$ in acetate buffer at pH 5.8.

from fast thermal reactions of the $[Cr(CN)_{6-x}(OH)_x]^{3-}$ complexes (where $x > 1$) leading within a few hours to the complete substitution of all the CN^- ligands.

The photosubstitution quantum yield (Table 1) was found to be relatively low in the case of the $[Cr(CN)_5H_2O]^{2-}$ complex, but considerably higher for the hydroxo-complex. This suggests again the direct photosubstitution by OH^- ligand proceeding in alkaline solutions. The influence of spectral range on the Φ values could be

followed only in the case of the $[Cr(CN)_5OH]^{3-}$ complex and appeared to be more significant than that for hexacyanochromate(III). Similarly to the alkaline solutions of $[Cr(CN)_6]^{3-}$, photosubstitution of the $[Cr(CN)_5OH]^{3-}$ complex was accompanied by another photochemical reaction upon exposure to radiation from CT bands in the presence of oxygen.[15]

Continuous irradiation with polychromatic light of the $[Cr(CN)_5H_2O]^{2-}$ complex led to the generation of a mix-

ture of the $[Cr(CN)_{6-x}(H_2O)_x]^{3-x}$ complexes (where $3 \leqslant x \leqslant 6$), with the aquo-complex of chromium(III) as major product.† The same products were found to be generated in thermal or photochemical aquation of the $[Cr(CN)_3(H_2O)_3]$ complex. In this case, the increased rate of thermal aquation made it difficult to determine accurate values of quantum yield. Nevertheless, the effect of photoacceleration was evidently observed [see Fig. 1(c) and Table 1]. Despite fast thermal substitution, the effect of photoacceleration was also noticed for the $[Cr(CN)_{6-x}(OH)_x]^{3-}$ complexes, where $x > 1$.

EXPERIMENTAL

Materials. Potassium hexacyanochromate(III), $K_3[Cr(CN)_6]$, was prepared according to the literature method[17] and recrystallized several times from aqueous solution. Its purity was checked by chemical analysis and infrared and ultraviolet spectroscopy. The aquocyanochromates(III), $[Cr(CN)_5H_2O]^{2-}$ and $[Cr(CN)_3(H_2O)_3]$, were obtained in aqueous solution following the procedure of Schapp *et al.*[14] For further experiments only those samples were used whose electronic spectra fitted those reported earlier.[14,18] The hydroxopentacyanochromate(III), $[Cr(CN)_5OH]^{3-}$, was obtained from its parent aquo-complex by deprotonation in 1 M KOH solution. Its purity was tested spectrally.[13] Other chemicals were best available commercial reagents used without further purification.

Apparatus and procedure. Flash photolysis apparatus was that described earlier.[19] Continuous irradiations were carried out using a high-pressure (HBO 200, Narva, DDR) or a medium-pressure (ASH 400) mercury lamp. For quantum yield measurements, glass filters (Schott, Jena, DDR) were used to isolate 436, 366 and 313 nm wavelengths, and an interference filter (KIF 265, C. Zeiss, Jena, DDR) for 265 nm radiation. Irradiations were performed in a thermostated rectangular quartz cell ($d = 1$ cm) at 295 ± 0.5 K with a continuous flow of nitrogen. The reaction progress was followed by means of a Specord UV–VIS or VSU 2P spectrophotometer (both C. Zeiss, Jena, DDR). Concentrations were chosen to assure a large excess over the minima required for $>99\%$ absorption of light at the desired wavelengths. Irradiations were limited to less than 10% conversion. Due to considerable contributions from thermal processes, the photoreaction progress was calculated from differences in optical density between the irradiated sample and one kept in the dark under precisely the same conditions. Moreover, quantum yield values were corrected for inner filter effect.[5,20] Actinometry was carried out with trisoxalatoferrate(III).[21]

---

†In acetate buffer solution, anation by the CH_3COO^- ligand[16] was also observed.

THE PREPARATION AND ELECTROCHEMISTRY OF MANGANESE(II) COMPLEXES OF AN UNSATURATED PENTADENTATE MACROCYCLIC LIGAND

CHRISTOPHER W. G. ANSELL, JACK LEWIS*, JOHN N. RAMSDEN
and MARTIN SCHRÖDER
University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, England

Abstract—The preparation of a series of six and seven coordinate manganese(II) complexes $[Mn^{(II)}(L)X]^+$, and $[Mn^{(II)}(L)X_2]^{2-}$ (X = halide, water, triphenylphosphine oxide, imidazole, 1-methyl imidazole and pyridine) incorporating the pentadentate planar macrocylic ligand L is described. Cyclic voltammetry of these complexes in acetonitrile each shows a reversible one-electron reduction wave near -1.4 V vs a Ag/AgNO₃ reference electrode. Quantitative reduction of these complexes by controlled potential electrolysis at a platinum gauze at -1.4 V yields the corresponding one-electron reduction products which have been shown by ESR spectroscopy to be manganese(II)–ligand radical species, the electron being thought to reside on the di-imino pyridine moiety of the macrocyclic ligand. No metal reduced species could be isolated even in the presence of π-acceptor ligands such as CO or phosphines.

We have recently reported work on the redox properties of nickel(II)[1] and cobalt(II)[2] complexes of the pentadentate unsaturated macrocyclic ligand L and in particular the electrochemical reduction of these complexes to give univalent metal species. We now wish to report, as a continuation or our previous studies on manganese(II) complexes of L,[3,4] the electrochemical redox behaviour of pentagonal pyramidal and pentagonal bipyramidal manganese(II) macrocyclic complexes of L.
(L)

The reduction of transition metal complexes of potential π-acceptor macrocyclic ligands such as L is of interest because of the possibility of forming either metal reduced species, e.g. metal(I) or metal(O), or metal stabilised ligand radical species in which the electron resides mainly on the macrocyclic ligand. We and others[1,2,5–10] have previously shown that the redox properties of macrocyclic complexes may be highly dependent on the axial ligation, net π-acceptor axial ligands stabilising metal reduced species. We have therefore carried out studies on the redox chemistry of manganese(II) complexes of L in the presence of a series of

axial ligands to determine whether variations in redox properties might be observed.

RESULTS AND DISCUSSION

The manganese(II) macrocyclic complex $[Mn^{(II)}(L)Cl]^+$ was prepared by condensation of 2, 9-di(N-methyl)hydrazino-1,10-phenanthroline with 2,6-diacetyl pyridine in the presence of manganese(II) dichloride in refluxing water.[3,4] Halide coordination could be varied by changing the manganese halide starting material. Treatment of $[Mn^{(II)}(L)Cl]^+$ in refluxing water with AgBF₄, filtration and addition of NaBF₄ yielded the pentagonal pyramidal aquo complex $[Mn^{(II)}(L)H_2O]^{2+}$. The IR spectrum of this product showed a band near 3400 cm^{-1} assigned to the O–H stretching vibration, ν_{O-H}, of the coordinated water molecule. This complex was used as the starting material for the synthesis of a series of axially substituted adducts. Solutions of $[Mn^{(II)}(L)H_2O]^{2+}$ were treated with excess of axial ligand X in refluxing methanol to give products $[Mn^{(II)}(L)X_2]^{2+}$ (X = triphenylphosphine oxide, imidazole, 1-methyl imidazole and pyridine). The complexes are all high spin d⁵ species, conductivity measurements in dmso confirming that they are 2:1 electrolytes in that solvent. Table 1 lists analytical data for these complexes.

Cyclic voltammetric measurements on the above manganese(II) complexes in acetonitrile all show a reversible or quasi-reversible reduction wave near $E_{1/2} = -1.4$ V at a platinum electrode relative to a Ag/AgNO₃ reference. Coulometric measurements confirm that, in the absence of water, these reductions are one electron processes. The fact that the value of the half-wave potential $E_{1/2}$ remains essentially constant with variations in axial ligand suggest that the reduction occurs at the macrocyclic ligand; variation of axial ligand would be expected to have dramatic effect on the value of $E_{1/2}$ for a metal redox process.[1,2] To confirm that the reduction is indeed centred on the macrocyclic ligand, the complexes were quantitatively reduced by controlled potential electrolysis at -1.4 V in acetonitrile at a platinum gauze electrode and the reactions followed by

Table 1. Analytical data for manganese(II) macrocyclic complexes

^{a} Measured with 10^{-3} M solutions in DMSO at room temperature.

ESR spectroscopy. On reduction, the orange solution of the manganese(II) starting material darkened with concomitant development of an isotropic signal in the ESR spectrum at $g = 2.002$ (measured at 77 K as an acetonitrile glass) assigned to unpaired electron density on the macrocyclic ligand.

The broad manganese(II) ESR signal[11] at $g_{av} = 2.960$ remained essentially unchanged during the course of the reaction. The ESR data are consistent with the formation of manganese(II) stabilised ligand radical species. In the presence of water [for example in the reduction of $[Mn^{(II)}(L)(H_2O)]^{2+}$] more than one equivalent of electrons was consumed during the course of the reaction with no ligand radical species being detected in the ESR spectrum. The IR spectrum of the dark brown product obtained from this reduction showed bands near 3100 cm^{-1} assigned to N–H stretching vibration ν_{N-H} of a reduced macrocycle ligand. In addition a marked decrease in the intensity of the C=N stretching vibration of the imino functions at 1620 cm^{-1} was noted. We assign these spectral data to a product in which the diimine bonds of the macrocyclic ligand have been fully reduced. This suggests that in the manganese(II)–ligand radical species described above, the electron resides on the di-imino pyridine moiety; this is consistent with results obtained for other metal stabilised di-imino ligand radical species.[5-9]

The extreme rarity of manganese(I) complexes stabilised by nitrogen donor macrocyclic ligands led us to investigate the possibility of stabilising metal reduced species in the above electrochemical reductions. Addition of $P(OMe)_3$ or CO to solutions of $[Mn^{(II)}(L)(CH_3CN)_2]^{2+}$ in the electrochemical cell showed essentially no shifts in the value of $E_{1/2}$ for the above reduction process, although some loss of reversibility was observed. No manganese(I) species could be detected in the quantitative reductions of such solutions. This is in contrast to the redox properties of nickel(II) and cobalt(II) complexes of L in which the stabilisation of

metal(I) has been readily achieved in the presence of CO or phosphine ligands.[1,2]

The electrochemical results described above are analogous to the redox properties observed for d^{10} zinc(II) complexes of L in which reduction occurs also at the macrocyclic ligand centre.[13] Current work is directed to the investigation of the redox properties of manganese(II) complexes involving macrocycles derived from terpyridine and related open chain complexes.[14]

EXPERIMENTAL

Infrared spectra were measured as Nujol mulls between potassimum bromide discs using Perkin–Elmer 257 and 457 spectrometers over the range $400-4000 \text{ cm}^{-1}$. Conductance measurements were made with a Wayne–Kerr Universal bridge. Magnetic moments were recorded on a Newport–Gouy balance and the readings corrected for ligand and inner-core diamagnetism by using Pascal's constants.[17] Microanalyses were performed by the University Chemical Laboratory Microanalytical Department.

Electrochemical measurements were performed on a Princeton Applied Research Electrochemistry System Model 170. All readings were taken using a three electrode potentiostatic system in acetonitrile with 0.1 moles/l of $nBu_4N^+BF_4^-$ present as supporting electrolyte. Cyclic voltammetric studies were carried out using platinum wires as auxiliary and working electrodes and a $Ag/AgNO_3$ reference electrode. Controlled potential electrolysis experiments were carried out using a platinum gauze as the working electrode, a salt bridge being incorporated to separate oxidised and reduced species. ESR spectra were measured as glasses in acetonitrile or as solid samples at 77 K on a Varian E109E. For the reduction products described, all solvents were distilled, dried and degassed before use and air-sensitive compounds handled under a nitrogen or argon atmosphere using Schlenk tube techniques. 2, 6-Diacetyl pyridine was used without further purification (from Aldrich) and 2, 9-di(1-methyl hydrazino)-1, 10-phenanthroline was prepared by the published procedure.[15,16]

Preparation of $[Mn^{(II)}(L)Cl](BF_4)^4$

Manganese dichloride hexahydrate (0.087 g, 0.44 mM) was dissolved in refluxing water (50 cm^3) and solid 2, 9-di(1-methyl-

hydrazino)-1, 10-phenathroline (0.11 g, 0.44 mM) was added with vigorous stirring. When all the solid had dissolved, 2, 6-diacetyl pyridine (0.07 g, 0.44 mM) was added with a few drops of concentrated HCl. The reaction mixture was refluxed under nitrogen for 2 hr and allowed to cool to 60°C. Addition of excess of $NaBF_4$ with stirring and cooling gave the complex $[Mn^{(II)}(L)Cl]-$(BF_4) as an orange crystalline product which was recrystallised from water by the addition of $NaBF_4$, washed copiously with diethyl ether and dried in vacuo Yield:- 70%.

Preparation of $[Mn^{(II)}(L)(H_2O)](BF_4)_2$

The complex $[Mn^{(II)}(L)Cl](BF_4)$ (0.1 g, 0.17 mM) was dissolved in refluxing methanol (50 cm³) and $AgBF_4$ (0.049 g, 0.25 mM) added. The solution was refluxed under nitrogen for 2 hr and filtered hot to remove precipitated AgCl. On cooling the filtrate and addition of $NaBF_4$, the aquo adduct $[Mn^{(II)}(L)(H_2O)](BF_4)$ was obtained as a dark orange product which was recrystallised from water by the addition of $NaBF_4$. Yield:- 80%. This complex was used as the starting material for the formation of axially substituted adducts with pyridine, imidazole, 1-methyl imidazole and triphenyl phosphibe oxide. The preparation of the pyridine adduct $[Mn^{(II)}(L)(C_5H_5N)_2](PF_6)_2$ is typical.

Preparation of $[Mn^{(II)}(L)(C_5H_5N)_2](PF_6)_2$

The complex $[Mn^{(II)}(L)(H_2O)](PF_6)_2$ (0.05 g, 0.07 mM) was dissolved in refluxing methanol (20 cm³) and excess of pyridine (0.02 g, 0.3 mM) was added. The solution was refluxed under nitrogen for 2 hr. On cooling and addition of diethyl ether orange crystals of the pyridine adduct $[Mn^{(II)}(L)(C_5H_5N)_2](PF_6)_2$ were obtained. The product was recrystallised from methanol and diethyl ether containing pyridine. Yield: 70%.

ORGANOMERCURY DERIVATIVES OF ARYLAZOBENZOIC ACIDS

K. K. SARKAR, T. K. CHATTOPADHYAY and B. MAJEE*
Department of Chemistry, North Bengal University, Darjeeling-734430, India

Abstract—A number of organomercury derivatives of arylazobenzoic acids have been prepared and characterised by analytical, IR, PMR and electronic absorption spectral data. In the 3-coordinated organomercury complexes the N→Hg bond appears to be weak. The 4-coordinated complexes obtained from the terdentate ligands *o*-(2-hydroxybenzene-azo) benzoic acids show a large bathochromic shift of the π–π* transition of the ligand indicating a much stronger N→Hg bond.

o-Arylazobenzoic acids and related compounds (I) have been widely used as ligands in transition metal chemistry.[1-6] Ease of synthesis, favourable steric arrangement and variability of the number of donor sites with suitable substituents make this group of compounds excellent ligands for synthesising many interesting complexes.[7]
This prompted us to undertake the synthesis of organomercury complexes of these ligands and study

their spectral and structural characteristics. The organomercury derivatives of the *p*-carboxy compounds (II) were also prepared and their spectral characteristics compared with those of (I) to ascertain the effect of N→Hg coordination on the absorption spectra.

10–12 and 16 were prepared from the corresponding hydroxy compounds by methylation with dimethyl sulphate followed by hydrolysis with 5% aqueous sodium hydroxide.

The purity of the compounds were checked by analytical data, m.p., IR spectra and mass spectra.

(b) *Preparation of organomercury derivatives of arylazo benzoic acids*

A few typical preparative details are given below:

(i) PhHgL[1]. A mixture of L[1]H (3 g) in 75.2 cm³ of ethanolic NaOH (0.148N) and phenylmercuric acetate (3.75 g) in 125 cm³ ethanol was refluxed for 6 hr. Ethanol was removed by evaporation, the product extracted with benzene and crystallized from benzene and petroleum ether (60–80); yield 95%.

(ii) PhHgL[2]. A mixture of equivalent amounts of L[2]H and phenylmercuric hydroxide was refluxed for 16 hr in dry benzene. The solution was concentrated and petroleum ether was added to separate out the crude product. Repeated crystallisation from benzene and petroleum ether (60–80) gave the pure product; yield 55%.

(iii) p-Tol·HgL[2]. A mixture of 0.5 g of p-tolylmercuric chloride and 0.9 g of the Ag-salt of L[2]H in 100 cm³ dry benzene was refluxed for 8 hr. The solution was filtered, the filtrate concentrated and hot petroleum ether added. On cooling, the crude product separated out as a gummy mass which was purified by repeated crystallisation from benzene and petroleum ether (60–80). p-Tol·HgL[2] was obtained as a red powder; yield 40%.

(iv) PhHgL[5]. A mixture of 3.4 g of phenylmercuric acetate and 2.8 g of Na-salt of L[5]H in 160 cm³ of methanol was refluxed for 8 hr. The solution was concentrated by distillation, then cooled, when red crystals separated. Recrystallisation from benzene and petroleum ether (60–80) afforded the pure product; yield 90%.

All solvents used for spectral studies were of Uvasol (E. Merck) grade. The absorption spectra were measured with a Beckman DU-2 spectrophotometer.

RESULTS AND DISCUSSION

The formulae of the ligands and their abbreviations are given in Table 1.

(a) *Method of preparation of the organomercury derivatives*

In principle, organomercury derivatives of o-aryl-azobenzoic acids may be prepared by any of the following reactions:

$$RHgCl + L \cdot Na \rightarrow RHgL + NaCl \qquad (1)$$

$$RHgCl + L \cdot Ag \rightarrow RHgL + AgCl \qquad (2)$$

$$RHgOAc + L \cdot Na \rightarrow RHgL + NaOAc \qquad (3)$$

$$RHgOH + L \cdot H \rightarrow RHgL + H_2O. \qquad (4)$$
(L·H = o-arylazobenzoic acid).
However, the yield and purity of the desired product depend to a great extent on the particular reaction employed. For example, reaction (1) does not occur even on prolonged refluxing. On the other hand, reaction (2) is quite general though the yield is usually low, thus making it unsuitable as a preparative method.

Reaction (3) is found to be the most satisfactory. The yields are 75–95%, depending on the ligand. The presence of an –OH group at the 4-position in the coupling moiety hinders this reaction, presumably due to the hydrazone form[2,8-11] (III) which destroys the planarity of the molecule in the azo form. This is expected to affect the stability of the chelated structure adversely.

(III)
In such cases, reaction (4) has been used successfully, though the yields are low.

Another point which merits some comment is the facile hydrolysis of the acetyl group in L[8]H or L[9]H during reaction with phenylmercuric hydroxide. In both cases, complete hydrolysis of the 4-acetyl group occurred, resulting in 4-hydroxy compounds.

The products, m.p. and yields are summarised in Table 2. Analytical data are given in Table 3.

(b) *IR spectra*

The IR spectra of the organomercury arylazocarboxylates are very complex and a complete assignment of the absorption bands is not possible. The frequencies of the important vibrations that could be assigned are listed in Table 2.

Asymmetric OCO vibrations in the organomercury derivatives have been identified by comparison of the IR spectra with those of the free ligands. Due to overlapping of ν_{as}(OCO) with the ring vibrations[7] at ~ 1600 cm^{-1}, the exact position of this band is somewhat uncertain in some cases. In fact, the compounds are characterised by a rather broad and intense band around ~ 1600 cm^{-1} with distinct shoulders.

The lowering of the asymmetric carboxylate stretch in the organomercury derivatives may be ascribed to the canonical structure (IVB) because intermolecular polymerisation involving the –COO group may be ruled out

* Ph = C_6H_5; Tol = $CH_3.C_6H_4$.

as ν_{as} (OCO) is found to be nearly the same in the solid and in solution.

(IVA)

(IVB)
This is also consistent with ν_{as}(OCO) in PhHgL[1] being lower in frequency ($\sim$1580 cm^{-1}) than that in PhHgL[12] (1615 cm^{-1}) where such resonance is not possible.

The symmetric OCO stretch in the carboxylates reported here occurs as a medium to strong intensity band in the 1360–1320 cm^{-1}.

(c) *PMR spectra*

The low solubility of the azo compounds and their organomercury derivatives in common solvents made it difficult to obtain good PMR spectra except in a few cases. The chemical shifts of interest in these compounds are given in Table 2.

Of the two benzene rings present in the arylazobenzoates, the chemical shifts of the protons on ring B(I) and the substituents attached to it provide more useful information.

In general, the observed shift of the side chain protons, e.g. -NCH₃, -NCH₂CH₃, -OCH₃, Ar–CH₃ etc. present in the substituents X, Y and Z are readily identified by their position, multiplicity and relative intensities. The observed chemical shifts agree closely with the reported shifts in other azo dyes.[12,13]

The PMR spectrum of compounds with Y = – NR₁R₂ are characterised by two signals at $\delta \sim$ 6.50–6.7 and $\delta \sim$ 6.66–6.79 corresponding to one proton each. From a comparison with the available data,[12,13] these two signals can be assigned to protons at 3 and 5 positions respectively on ring B.

The signal at $\delta \sim$ 2.16 in compounds with Y = -NHR, -NHCH₃ or -NHC₂H₅ is absent in fully alkylated compounds (Y = NR₁R₂) and therefore, arises from the amino proton. The amino proton in the azo compounds is thus more shielded compared to other aromatic amines[14] ($\delta \sim$ 2.9–4.8). The data given in Table 2 show that the signals of the side chain protons undergo an upfield shift in the phenylmercury derivatives of bidentate ligands (X = H in I) compared to that in the free ligand. The signals of protons at 3 and 5 positions show a similar high field shift of about 0.06–0.1 ppm in the mercury derivatives. On the other hand, terdentate ligands (X = OH in I) and their organomercury derivatives have almost identical chemical shifts for the side chain and ring protons. The apparently anomalous results are readily
Fig. 1. Probable structure of 3-coordinate trigonal organomercury complex (the plane of the ring D is perpendicular to the plane containing the rings A, B and C).
Fig. 2. Probable structure of 4-coordinate organomercury (sp^3) complexes.

explained in terms of 3- and 4- coordinated structures for the organomercury derivatives.

Bidentate ligands are expected to form 3-coordinated organomercury complexes having trigonal planar geometry. A model of a 3-coordinate complex using bond lengths for Hg–C, Hg–N and Hg–O observed in amino acid derivatives[15] and standard bond lengths for the bonds in the azo system[16] is shown in Fig. 1. Because of the planarity of the O, N, C and Hg atoms in the three-coordinate planar geometry, the benzene ring (D) attached to the mercury atom would orient itself preferably in a direction perpendicular to the plane of the ring B to avoid steric interaction. Because of this, the protons on ring B, particularly the side chain protons at the 4 position which lie above the plane of ring D, would be more shielded due to ring current effects.[17] The observed upfield shift in the organomercury derivatives, therefore, provides strong evidence in favour of a 3-coordinate structure. Absence of such upfield shift in the organomercury derivatives of the p-arylazobenzoic acids where similar coordination is not possible supports this interpretation.

The absence of a similar high field shift in the organomercury derivatives of terdentate ligands (X = – OH in I) which can form 4-coordinate complexes provides further support. The geometry of 4-coordinated mercury is known to be tetrahedral. In the tetrahedral 4-coordinate organomercury chelates (Fig. 2), the benzene ring attached to the mercury atom lies in a direction perpendicular to the plane of the azo system. The organomercury group is, thus, expected to have little effect on the protons on ring B in the 4-coordinate complexes. The experimental data confirm this.

(d) *Electronic absorption spectra*

The electronic absorption spectra of the organomercury (aryl azo) benzoates can be explained in terms of the π–π^* transition characteristic of the azo compounds.[16,18] The spectral data are given in Table 2.

The absorption spectra of the organomercury 4-hydroxybenzeneazobenzoates are characterised by two solvent-dependent overlapping absorption maxima in the

340–390 nm region. That the two bands arise from azo-hydrazone type equilibrium (eqn 5), well-known in many 0- and p-hydroxy azo compounds,[2,8–11] is shown by the electronic absorption spectra of the methylated derivatives and the corresponding organomercury derivatives.

Methylation of the 4-OH group which eliminates the possibility of azo-hydrazone tautomerism results in a single absorption maximum in the visible region. Thus, both $L^{10}Me$ and PhHgL[10] have a single absorption at ~360 nm while the corresponding hydroxy compounds have an additional band at longer wavelengths. Clearly, the ~360 nm band arises from the azo form while the ~450 nm band present in the hydroxy compounds L^6Me and PhHgL[6] must originate from the hydrazone form which generally absorbs at longer wavelength than the corresponding azo form.[19] Interestingly, the free acids L^6H and $L^{10}H$ have only a single absorption maximum which undergoes a considerable hypsochromic shift (~35 nm) on esterification of the –COOH group. The same behaviour is shown by the 2-methyl derivatives also. Esterification of the –COOH group is not expected to have a significant effect on the absorption spectra unless some intra- or inter-molecular interaction involving the –COOH group exists. For example, absorption maxima of the p-carboxy compounds, $L^{15}H$ and $L^{15}Me$ differ by only 5 nm.

In the o-carboxy compounds, intramolecular H-bonding as shown in (V) is possible. Esterification of the –COOH groups is then expected to result in a large hypsochromic shift of the absorption maximum because the π^*-level will certainly be lower in energy in the H-bonded form due to a shift of electron charge cloud from the N atom towards to H atom.[18] Thus the observed hypsochromic shifts are consistent with intramolecular H-bonding. Such bonding is not favoured in the corresponding hydrazone from which, consequently, is much less stable in the free acid. Because of this the free acids show only a single absorption peak corresponding to the azo form.
azo form
hydrazone form   ······(5)
(V)

A bathochromic shift of the longest wavelength $\pi-\pi^*$ transition is expected due to $N \rightarrow Hg$ coordination and electron withdrawal from the N-atom[18,19] relative to the compound in which no such interaction is present, e.g. the methyl ester (comparison with the free acid is not possible due to the presence of intramolecular hydrogen bonding). The small bathochromic shift ($\sim 5-10$ nm) of the absorption maxima in the organomercury derivatives relative to those in the corresponding esters, therefore, indicates the formation of a weak $N \rightarrow Hg$ bond. Such weak $N \rightarrow Hg$ interaction is a common feature of 3-coordinated mercury complexes.[20]

The organomercury derivatives of the *o*-2-hydroxybenzeneazobenzoic acids show larger bathochromic shifts of the $\pi-\pi^*$ transition indicating stronger coordination in this case. Unlike the 4-hydroxybenzeneazobenzoates, the absorption spectra are not greatly affected by solvents showing the absence of azo-hydrazone tautomeric equilibria in such cases. This is presumably due to the formation of more stable 4-coordinate complexes (Fig. 2) with the 2-hydroxybenzeneazobenzoic acids which can act as terdentate ligands.

As expected, the organomercury derivatives of the *p*-arylazobenzoic acids (II) have absorption spectra closely similar to those of the free ligands, as the derivatives in such cases are comparable to the corresponding alkyl esters.

MÖSSBAUER STUDY OF THE AFTER-EFFECTS OF THE CONVERTED ISOMERIC TRANSITION IN ^{119m}Sn IN FROZEN SOLUTIONS OF SnCl$_2$ AND IN SOLID ADDUCTS OF SnCl$_2$· AND SnBr$_4$ WITH ORGANIC DONOR MOLECULES

SUMIO ICHIBA* and MASAAKI YAMADA

Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730, Japan

Abstract—As an after-effect of the converted isomeric transition in ^{119m}Sn, about 30% yield of the oxidised aliovalent species Sn^{4+} was observed in Mössbauer spectra of frozen solutions of ^{119m}SnCl$_2$ in organic solvents such as dimethyl sulphoxide and methanol. On the other hand, the reduced aliovalent species Sn^{2+} was observed in the emission spectra of crystalline solid adducts of ^{119m}SnBr$_4$ with dimethyl sulphoxide and other donors. As a mechanism for the stabilization of the oxidized aliovalent species observed in the emission spectra of the frozen solutions, it is proposed that the electrons released by Auger processes are trapped in imperfections of the glassy matrices of the medium. On the other hand, a possible mechanism for the formation of reduced species from adducts of ^{119m}SnBr$_4$ is that reducing radicals are formed by dissociative electron capture in autoradiolysis of the closest ligands within the molecules. The large yields of the oxidized aliovalent species Sn^{4+} observed in the emission spectra of the crystalline solid adducts of ^{119m}SnCl$_2$ with dimethyl sulphoxide, pyridine N-oxide, and pycoline N-oxides are also to be understood in terms of dissociative electron capture in autoradiolysis of the ligand.

After-effects of nuclear transformations, mainly those of electron capture, EC, ^{57}Co and converted isomeric transition, CIT, in ^{119m}Sn have been studied by Mössbauer emission spectroscopy, or source experiments.[1-3] Both EC in ^{57}Co and CIT in ^{119m}Sn are followed by Auger processes in which vacancies in the outer atomic shells are developed by a vacancy cascade and the decayed atoms are left in highly charged states at the Mössbauer level. The fate of the hot atoms thus created in the solids is very interesting, and the lifetime of the highly charged atomic state and the stable charge state of the daughter atoms in various matrices have been studied by Mössbauer emission spectroscopy.

Friedt *et al.* have investigated complex ligand compounds by Mössbauer emission spectroscopy and proposed a model of autoradiolysis of the ligands for the stabilization of the aliovalent species in the host matrix.[4-6] On the other hand, Bondarrevskii *et al.* have proposed a model of competing acceptors for the electrons between hot atoms and surrounding medium to explain the aliovalent species observed in the emission spectra of the rapidly frozen solutions containing ^{119m}Sn.[7-9]

We have reported previously a large yield of the oxidized aliovalent species of Sn^{4+} in the adducts of SnCl$_2$ with some oxygen- and nitrogen-containing donor molecules as ligands.[10,11] In the present work, source experiments on frozen solutions of ^{119m}SnCl$_2$ in some organic solvents and on crystalline solid adducts of ^{119m}SnBr$_4$ with organic ligands were performed, to study the mechanisms for the stabilization of the aliovalent species observed in the emission spectra.

EXPERIMENTAL

Preparation of sources. The sources containing ^{119m}Sn were prepared from ^{119m}Sn metal purchased from New England

Nuclear. Radioactive tin metal was dissolved in hydrochloric acid, and anhydrous stannous chloride was obtained by heating the solution to dryness under a nitrogen gas flow. The anhydrous stannous chloride obtained was dissolved in the organic solvent to be examined at a concentration of 10^{-2} M. The adducts of SnBr$_4$ labelled with ^{119m}Sn were synthesized as follows. About 30 mg of tin powder which contained 0.2 mCi ^{119m}Sn was reacted with bromine in chloroform solution. SnBr$_4$ was isolated by evaporating the solvent. Making use of radioactive SnBr$_4$, the source adducts were prepared according to the method described by Philips *et al.*[12]

Measurements. The Mössbauer absorption spectra of the adduct sources were measured with a CaSnO$_3$ source to identify the sample compounds. The absorption spectra of the SnCl$_2$ solutions were measured for other samples prepared from natural tin because radioactive tin contains mainly ^{118}Sn. The emission spectra were measured against the ^{119}Sn-enriched CaSnO$_3$ absorber (2.0 mg ^{119}Sn/cm^2) at room temperature. Both the absorption and emission spectra were measured by cooling the sample in a liquid helium flow type cryostat. Mössbauer parameters were deduced from Lorentzian curves computer-fitted to the spectra by the least-squares method.

RESULTS AND DISCUSSION

Both the absorption and emission spectra of the frozen solutions of SnCl$_2$ in dimethyl sulfoxide (DMSO) and methanol are shown in Figs. 1 and 2 as examples. The Mössbauer parameters deduced from the absorption and emission spectra are shown in Tables 1 and 2, respectively. The parameters for the emission spectra were deduced by the least-squares method by constraining all the line widths to be equal in the spectrum and setting the isomer shift of Sn^{2+} to the value obtained from the absorption spectrum. The data for solid adducts with tetrahydrofuran, DMSO, and pyridine(Py) are also shown in the Tables.

In Table 1, the values of both the isomer shift and the quadrupole splitting were higher for the solutions
Fig. 1. Mössbauer absorption and emission spectra of a frozen solution of SnCl$_2$ in dimethyl sulfoxide.

than those for the solid adducts. In the solid adducts, tin has trigonal pyramidal coordination, with one tin–ligand and two Sn–Cl bonds.[13,14] In an aprotic solvent such as acetonitrile, however, electrochemical studies indicate that the predominant species in solution is the SnCl$_2$ molecule.[15] If discrete SnCl$_2$ molecules exist in these solutions without forming Sn–

[c]Ref. 11, solid adduct.

ligand bonds, the tin atoms will have more electrons than those in the solid adducts, because formally tin electrons are used for the covalent bond between tin and ligand and acquire some ligand character in the solid adducts. The observed increases of isomer shift and quadrupole splitting are compatible with those increases of electron density at tin in the discrete SnCl$_2$ molecules in the solutions.

In Table 2, about 30% of the yield of the oxidized aliovalent species Sn^{4+} was observed in the emission spectra of the ^{119m}SnCl$_2$ solutions examined, though the yield of Sn^{4+} in the solid adducts of SnCl$_2$ was 48% in ^{119m}SnCl$_2$·2DMSO and zero in ^{119m}SnCl$_2$·2Py, as shown in Table 2. Temperature dependence of the yield was not observed in experiments using dimethyl sulfoxide solutions. Bondarevskii et al. have studied the after-effects of CIT in ^{119m}Sn and EC in ^{57}Co in frozen solutions of some organic solvents and acids.[7-9] Perfiliev et al. have also studied the after-effects in glassy solutions of sulphuric, perchloric, and nitric acids.[16] They have explained the stabilization of the aliovalent species observed in the emission spectra of the frozen solution by the model of competition between hot atoms and other components of the solution to capture the Auger electrons. Our data are reasonably consistent with their results except in the case of the methanol solutions, for which their data showed reduced yields of the oxidized aliovalent species.[9] A mechanism for the stabilization of the aliovalent species observed in the frozen solutions will be proposed, based on the capture of the Auger electrons by the medium so that the charge relaxation does not proceed to the original valence state. It seems that in those organic solutions the Auger electrons are trapped in imperfections of the glassy matrices (as is well known in the radiolysis of glassy frozen alcohol, ether, and other polar organic solvents), because the capturing yield does not depend on the properties of the solvents, such as electron scavenging.

Both the absorption and emission spectra of ^{119m}SnBr$_4$·2DMSO and ^{119m}SnBr$_4$·2DPSO are shown in Figs. 3 and 4, respectively. Though the absorption spectra showed that the samples were purely tetravalent, the reduced aliovalent species of Sn^{2+} were observed in the emission spectra. The Mössbauer parameters for the adducts of ^{119m}SnBr$_4$ with the ligands of organic donor molecules are shown in Table 3 along with the area ratios of Sn^{2+} to total.

^{b}Ref. 11, solid adduct.

The parameters were deduced from the spectra by the least-squares method as a superimposition of a Sn^{4+} singlet peak and a Sn^{2+} doublet peak without constraining the width.

Sanchez et al. have reported reduced aliovalent species of Sn^{2+} in the emission spectra of $^{119m}SnBr_4 \cdot 2Py$ and $^{119m}SnBr_4 \cdot Bipy$. They have discussed the results in terms of an autoradiolysis model. The radicals created by the autoradiolysis of the closest ligands of pyridine and bipyridine during Auger processes stabilize aliovalent charge states, depending on their reducing properties. Our result for the pyridine adduct is in good agreement with that of Sanchez et al. In the case of dimethyl sulphoxide, it

is well known that this compound decomposes to methyl radical-methanosulphenate anion pairs formed by dissociative electron capture in γ-irradiated crystalline solids according to:[17]

$$(CH_3)_2SO + e^- \rightarrow CH_3SO^- - - - - - \cdot CH_3.$$

The methyl radicals thus created reduce the tetravalent tin in $SnBr_4 \cdot 2DMSO$. However, it seems likely that in the case of the crystalline solid adducts the autoradiolysis by Auger electrons is effective only with the closest ligand molecules, because reduction by methyl radicals was not observed in solutions of dimethyl sulphoxide in which discrete molecules of

[a]Mössbauer absorption parameters.

$SnCl_2$ exist. The small yield of Sn^{2+} from the adduct of $^{119m}SnBr_4$ with diphenyl sulphoxide (DPSO) must result from the high radiation stability of the phenyl group on the ligands. The temperature dependence of the area ratio of Sn^{2+} to total will also confirm the occurrence of the reducing reaction by radicals, which will change the environment of the tin atoms from the original one.

In our previous work, a large yield of the oxidized aliovalent species was observed in the emission spectra of the adducts of $^{119m}SnCl_2$ with oxygen- and nitrogen-containing donor molecules.[10,11] The mechanism for the stabilization of the oxidised aliovalent species in those compounds can also be described in the same way as the above discussion. The relevant data are reproduced in Table 4. The ligand molecules diphenyl sulphoxide, pyridine N-oxide, and picoline N-oxide would be equal to dimethylsulphoxide as good electron scavengers in autoradiolysis of the crystalline solids.

In the adduct with dimethyl sulphoxide the highly charged hot atoms, Sn^{n+}, created by Auger processes are rapidly relaxed to Sn^{4+} by recapturing electrons

from their surroundings. However, further electron capture by Sn^{4+} to give the original valence state of Sn^{2+} would not proceed as a result of the capturing of Auger electrons by the ligands. Methyl radicals generated by the dissociative electron capture of the ligands would reduce a portion of Sn^{4+} to Sn^{2+}. Thus the yield of the oxidized aliovalent species in $^{119m}SnCl_2 \cdot 2DMSO$ is lower than that in $^{119m}SnCl_2 \cdot 2DPSO$, because the phenyl groups involved in the ligand of DPSO are stable in radiolysis.

The results for adducts with pyridine N-oxide and the series of picoline N-oxides as ligands are also explained in the same way. In these adducts, the Auger electrons are also captured by the ligand molecules. Methyl radicals will be formed by processes of dissociative electron capture in the autoradiolysis of picoline N-oxides. The methyl radicals formed, in their order of closeness to the tin atom, i.e. in the order: α-, β-, and γ-positions, will reduce Sn^{4+} to Sn^{2+} in accordance with the order of decreasing yields of Sn^{4+}. The yield of Sn^{4+} in the adduct with γ-picoline N-oxide was almost the same as the value for the adduct with pyridine N-oxide, so that the radicals formed at the γ-position, i.e. at the longest distance, are not effective in reducing the tin atoms.

These autoradiolysis mechanisms for stabilization of aliovalent species observed in the Mössbauer emission spectra as the after-effects of CIT in ^{119m}Sn probably have a short life-time related to the Mössbauer time-scale $(10^{-8}–10^{-7}$ s) at low temperatures.

INFLUENCE OF CATIONS ON ZINC(II) INCORPORATION INTO CROWN PORPHYRINS

V. THANABAL and V. KRISHNAN*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-560012, India

Abstract—The decrease in rate constants of Zn(II) incorporation into fully and partially benzo-15-crown-5 meso substituted porphyrins in the presence of cations has been explained on the basis of cation complexation ability of the crown ether cavities rather than steric effects.

Recently we designed cavity-bearing porphyrins with crown ether units derived from benzo-15-crown-5, appended at the 5-, the 5- and 10-, the 5-, 10- and 15-, and the 5-, 10-, 15- and 20-positions of the porphyrin skeleton for studying their cation complexation behaviour.[1] It occured to us that these compounds can be used to study the effect of cations, bound in the ether voids, on the rates of metal insertion reactions into crown porphyrins. The factors that contribute to the rates of porphyrin metallation reactions are the basicity of the free-base porphyrins, the relative ease of deformation of the porphyrin skeleton and the ease of deprotonation as a consequence of desolvation;[2] however, the role played by cations in such reactions remain unclear. As this study will show, the presence of alkali and alkaline-earth cations in the ether voids decreases the rates of Zn(II) incorporation into the porphyrin moiety and the relative ease of access of metal ions in determining the geometric disposition of the ether voids in the crown porphyrins. The rate data obtained here are of significance in view of the structural resemblance between the cation-bound crown porphyrins and meso-tetrapyridyl porphyrin with four positively-charged $C_5H_5N^+$ groups or cation salts of meso-aryltetracarboxylato and tetrasulphonato-porphyrins where the cations are ionically bound with the peripheral groups.

Tetra(benzo-15-crown-5) porphyrin(TCP) (1) was synthesised by condensing a mixture of 4'-formyl benzo-15-crown-5 and pyrrole in 1:1 proportions in refluxing propionic acid. By changing the mole proportions, the tris (2), cis and trans-di (3), and mono (4) crown ether-substituted porphyrins have been prepared. The structural integrity of these cavity-bearing porphyrins (Fig. 1) is established using ^{1}HNMR, optical absorption and emission spectral methods.

The Zn(II) incorporation into the free base porphyrins in a $CHCl_3$:CH_3OH (1:1) mixture at 25°C was studied using an optical absorption spectral method. The decrease in absorption of the Q band at 515 nm of TCP as a function of time was monitored. A representative plot of $\ln(OD_t - OD_\infty)$ vs time (t), where OD_t and OD_∞ represent absorbance at time ($_t$) and at the completion of the reaction, respectively, for a given concentration of Zn(II), is given in Fig. 2. The values of k_{obsd} were calculated from the slopes of the plot. The metallation reaction follows a second-order rate law, first order with respect to porphyrin and to Zn^{2+} ion. The concentration of crown porphyrin was held constant (5.0×10^{-5}M) and the concentration of Zn(II) acetate was varied from 1.0×10^{-3} to 2.0×10^{-2} maintaining pseudo first-order conditions (see Fig. 2 inset). The experiments are carried out in the presence of various cations and the rate data

for Zn(II) incorporation into crown porphyrin are given in Table 1.

An inspection of Table 1 reveals that the rate of Zn(II) incorporation into crown porphyrin is about 2.5 times greater than that into tetraphenyl porphyrin (TPP) under the same experimental conditions. This enhanced rate can be ascribed to the possible deformation of the porphyrin ring as a result of attachment of the four macrocyclic crown ether moieties at the 5-, 10-, 15-, and 20-positions of the porphyrin core. Such a deformation can promote easy deprotonation of the H-H groups[2], thereby increasing the metal incorporation rates. Alternately, the substitution of crown ether moieties in the phenyl ring at meta and para positions can be viewed as meta, para-disubstituted TPP, in which case TCP will be
Fig. 1. Chemical structure of tetra(benzo-15-crown-5) porphyrin. The partially-substituted crown porphyrins are shown. The full circle represents the porphyrin, while the ellipse and the line denote the substitutents, benzo-15-crown-5 cavity and phenyl rings respectively, in the methine positions.

Table 1. Rate data for Zn(II) incorporation into TPP and crown porphyrins at 25°C in CHCl$_3$:CH$_3$OH (1:1) solvent mixture

Porphyrin	Cation[a]	$10^3 \times K_{obs}$sec^{-1}
TPP	tBuAP(0.1M)	1.0
TPP	NaClO$_4$(0.1M)	1.1
TPP	Mg(ClO$_4$)$_2$(0.1M)	1.1
TCP (1)	tBuAP(0.1M)	2.7
TCP	NaClO$_4$(0.1M)	1.9
TCP	tBuAP(0.1M) + NaClO$_4$(5.0 × 10^{-4}M)	2.1
TCP	Mg(ClO$_4$)$_2$(0.1M)	1.9
TCP	tBuAP(0.1M) + Mg(ClO$_4$)(5 × 10^{-4}M)	1.9
TrisCP (2)	tBuAP(0.1M)	2.8
TrisCP	NaClO$_4$(0.1M)	2.0
cisDCP (3)	tBuAP(0.1M)	2.7
cisDCP	NaClO$_4$(0.1M)	2.2
MCP (4)	tBuAP(0.1M)	2.7
MCP	NaClO$_4$(0.1M)	2.4

[a]tBuAP = Tetrabutylammonium perchlorate; the value in parenthesis denotes the concentration of the cation employed in the study.

more basic than TPP since -OR group is an electron-donating group. Cyclic voltammetry of the crown porphyrin shows a marginal increase in the first reduction potential compared to TPP and we believe the enhanced rates of Zn(II) incorporation arise from the electronic effects. Construction of CPK models of the crown porphyrins show that the deformation of the porphyrin ring is minimal.

Interestingly, the presence of Na$^+$, Ca^{2+} and Mg^{2+} ions reduces the rate of Zn(II) incorporation to about 30%. Normally the rate differences in porphyrin metallation reactions in the presence of cations are explained either in terms of the formation of SAT complexes[3] or by an introduction of an ususal anion term in the rate law.[4] In the present study we did not observe the characteristic SAT visible spectra of the free-base porphyrins in

presence of cations, and a change in the anions (counterparts of cations) does not significantly alter the rates of Zn(II) incorporation into crown porphyrins. We attribute the observed decrease in the Zn(II) incorporation rates to cation complexation effects by crown ether voids. An explanation for the present finding is traced to the encapsulation of cations by the ether oxygens which induces an electron-withdrawing effect in the phenyl rings, and a transmission of this effect results in the decreased bascity of the N-H protons thereby reducing the rates of Zn(II) incorporation into the porphyrin macrocycle. The cation complexation by the peripheral crown ether oxygen atoms[3] is evidenced by the downfield shifts (~ 0.40 δ) of the ether proton and aryl proton resonances.[1] The decrease in the basicity of the porphyrin ring on addition of cations is also demonstrated in the small changes of the redox potentials as observed in the cyclic voltagramms of the cation complexes of TCP. That these cation complexation effects on the rates of Zn(II) incorporation are real and of significance is further supported by the reduced rates of Zn(II) incorporation (to about 30%) in the systems containing TCP, tBuAP (0.1M) and cations ($\sim 10^{-4}$M). Despite the close resemblance the cation-bound freebase crown porphyrins bear with *meso* N-methyl-tetrapyridyl-porphyrins and cation complexes of *meso* tetraaryltetra-carboxylato or tetrasulphonato porphyrins, the observed rates for the Zn(II) insertion reactions in the present study are distinct and different. In the former the observed rates are predominantly dictated by the differential solvation term[2] and we tend to believe the influence of these may be negligible in the crown porphyrins.

The cations K^+, NH_4^+, Ba^{2+}, and Cs^+ induce dimer formation of the free base porphyrins[1] and the metal incorporation rates could not be followed using optical absorption spectral methods.

In crown porphyrins, the crown ether moieties are oriented perpendicular to the porphyrin plane and do not sterically hinder the access of metal ions into the porphyrin core. However, in the sterically crowded tetrapivalylamidophenyl porphyrin of Collman *et al.*,[5] it has been found that the rate of metal insertion is lowered compared to that of TPP.[6] The observation that the less substituted porphyrins (tris, *cis* and *trans* DCP) exhibit rates of Zn(II) incorporation not significantly different from that observed for TCP provides further support for the absence of steric effect.

The present results show the influence of bound cations (in the peripheral positions of porphyrin) on the rates of Zn(II) incorporation. The nature of the cations apparently has no percepitable effects on the rates, since the recognition of cations by the host ethers are primarily governed by the relative sizes of the ether cavity and the cations.

THE GENERATION OF THE GERMANIUM DIHALIDES

S. M. VAN DER KERK

Department of Physical Chemistry, Free University, De Boelelaan 1083, 1081 HV Amsterdam, The
Netherlands

Abstract—A method is described for the generation of GeX_2 ($X = F$, Cl, Br, I) as uncoordinated monomers in the gas phase, free from impurities. These species were identified by UV photoelectron spectroscopy and mass spectroscopy.

Being formal carbene analogues, the divalent compounds of the group IV A elements other than carbon have, during the past decades, elicited interest in quite different fields of chemistry. However, the more stable, and thus the more accessible the compounds MX_2 are, the less is their actual carbene-like character, whether the latter be considered from a synthetical or from a more theoretical point of view. For an unambiguous assessment of their carbene-like properties, the MX_2 molecules should be studied in a monomeric, uncoordinated state.

The methods used for the synthesis of germanium dihalides[1,2] can be roughly divided into two categories.

(a) Methods which yield the dihalides in the gas phase in an uncoordinated, monomeric form.

(b) Methods which yield the dihalides in a polymeric form (i.e. coordination polymers) or in a coordinated form (e.g. to a solvent).

From a PE spectroscopical point of view, the latter methods are not suitable. Heating of the polymeric dihalides generally does not produce the monomers without interference from oligomeric species.[3] For spectroscopic purposes, GeF_2, $GeCl_2$, and $GeBr_2$ are often synthesized by reaction between elemental germanium and the germanium tetrahalide:

$$Ge + GeX_4 \rightleftarrows 2GeX_2 \quad (X = F, Cl, Br).$$
Further, $GeCl_2$ and $GeBr_2$ are formed in the thermal decomposition of the corresponding trihalogermane:

$$HGeX_3 \rightarrow GeX_2 + HX \quad (X = Cl, Br).$$

The obvious disadvantage of these methods is that the wanted product (made *in situ*) is invariably accompanied by other products which, in the case of PE spectroscopy, may obscure its spectrum.

In 1978, Feltz and Dresler[4] reported the isolation (by sublimation) of polymeric $GeCl_2$ upon reaction of a powdered Ge_2S_3 glass with eutectic mixtures of $KCl/AgCl$, $PbCl_2/AgCl$, or $KCl/CuCl$ at temperatures of 250–350°C *in vacuo*. They proposed the following reaction equation:

$$Ge_2S_3 + 2AgCl \rightarrow GeCl_2 + GeS_2 + Ag_2S.$$

In the same paper[4] it was briefly stated that crystalline germanium monosulphide also reacts with a eutectic $KCl/AgCl$ mixture at a temperature of 310° to form $GeCl_2$.

It was decided to study the latter reaction as, in our opinion, it offered the possibility of generating the germanium dihalides as uncoordinated, monomeric species in the gas phase, according to:

$$GeS + 2AgX \rightarrow GeX_2 + Ag_2S \quad (X = F, Cl, Br, I).$$

All experiments were performed in sealed tubes and in the PE spectrometer as well. It proved rather difficult to free germanium monosulphide, synthesized according to the Inorganic Synthesis method[5] (in this way, red, amorphous GeS is obtained) from all traces of water. Moreover, Schumb and Smyth[6] have established that GeS synthesized in this fashion may contain up to 20% of chloride. Therefore GeS was synthesized (in brown–black, crystalline form) by heating an equimolar mixture of GeS_2[5] and germanium powder to 550–600° under nitrogen and by subsequent sublimation of the GeS formed in vacuo at temperatures up to 650°.

In the first experiments, crystalline GeS was heated with a eutectic $KCl/AgCl$ mixture. However, only germanium tetrachloride was formed. Next, excess GeS, intimately mixed with AgCl, was heated. PE spectroscopy showed that a small amount of $GeCl_2$ was formed, together with $GeCl_4$ (at 280–310°). With a mixture of excess GeS and AgBr the same result was obtained (at temperatures of 230–270°): the tetrahalide was formed predominantly. Only a trace of $GeBr_2$ was observed. These phenomena suggested that the following redox reaction was occurring:

$$Ge^{II} + 2Ag^{I} \rightarrow Ge^{IV} + 2Ag^0.$$
This idea was borne out by the fact that upon heating a mixture of GeS and AgF at 170°, a fiercely exothermic reaction took place, in which metallic silver was formed. In order to avoid the possibility of a redox reaction, but to retain the advantage of forming a stable, non-volatile sulphide, lead(II) halides were used instead. In this way, using excess crystalline GeS with the corresponding lead(II) halide, GeF_2, $GeCl_2$, $GeBr_2$ and GeI_2 could be generated in the gas phase as uncoordinated monomers, in the case of $X = F$, Cl, Br virtually free from impurities, as was proven by PE spectroscopy. The PE spectra of these species will be published separately.[7–9]

The mass spectra of the germanium dihalides were obtained by heating the GeS/PbX_2 mixtures in the direct insertion probe of the mass spectrometer. The resulting mass spectra of GeF_2, $GeCl_2$, $GeBr_2$ and

GeI_2 are shown in Figs. 1(a), 2(a), 3(a) and 4(a), respectively. For comparison, the mass spectra of GeF_4,[10] $GeCl_4$,[11] $GeBr_4$ and GeI_4 are given in Figs. 1(b), 2(b), 3(b) and 4(b), respectively. The strength of the germanium–fluorine bonds in GeF_2^+ is illustrated by the fact that in the mass spectrum of GeF_2 the parent peaks (naturally occurring germanium is composed of five isotopes) form the base peaks, while in the mass spectra of the other dihalides the base peaks are those of GeX^+. In the mass spectra of $GeCl_2$ and GeI_2 the peaks corresponding to GeX_3^+ and $GeX_4^+\cdot$ could be observed. It is improbable that the odd-electron ions $GeX_4^+\cdot$ are formed by a recombination reaction in the ionization source. In our opinion the ions $GeX_4^+\cdot$ and GeX_3^+ derive from the tetrahalides, which are formed in a redox reaction between GeS

and PbX_2, in quantities depending on the experimental conditions. This supposition is, in the case of the iodine compound, supported by the PE spectroscopic results.[9] In the mass spectra of the tetrahalides the $GeX_2^+\cdot$ ion peaks have a very low intensity. Further, in the mass spectra of GeF_2 and $GeBr_2$ no ions $GeX_4^+\cdot$ and GeX_3^+ are found. Therefore it can be stated that the germanium dihalides have been positively identified not only by means of PE spectroscopy[7-9] but by mass spectrometry as well.

GeF_2 (from $Ge + CaF_2$[12]), $GeCl_2$,[13-15] and $GeBr_2$[15] (the latter two from $Ge + GeX_4$) have been studied by mass spectrometry before.

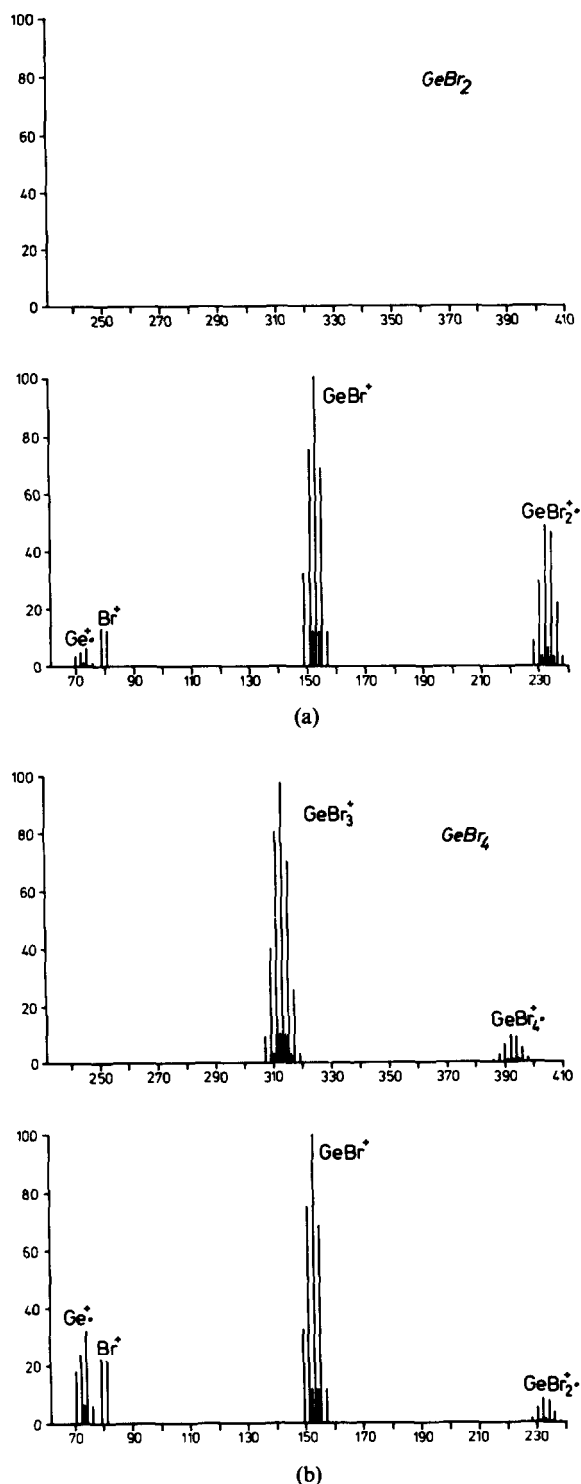
It should be noted that both in the PE and in the mass spectroscopic experiments, contamination of the spectrometer was a serious problem.
Fig. 1. (a) Mass spectrum of GeF_2. (b) Mass spectrum of GeF_4.[10]
Fig. 2. (a) Mass spectrum of $GeCl_2$. (b) Mass spectrum of $GeCl_4$.[11]


Fig. 3. (a) Mass spectrum of GeBr$_2$. (b) Mass spectrum of GeBr$_4$.

An attempt was made to generate germanium dicyanide by heating a mixture of crystalline GeS and CuCN. However, only formation of cyanogen was observed. This might be explained by the occurrence of the following redox reaction:

$$Ge^{II}S + 2CuCN \rightarrow Ge^0 + (CN)_2 + Cu_2S.$$

Preliminary experiments have indicated that the apparatus, used by Timms and others for the reaction of metal atoms with various substrates[16,17] is very well suited for the reactions of monomeric germanium dihalides, generated as described here, with suitable substrates. Only moderately high temperatures (250–350°) are needed and relatively large quantities of the pure dihalides can be produced.

EXPERIMENTAL

He(I) PE spectra of GeF_2, $GeCl_2$, $GeBr_2$, and GeI_2 were recorded on a home-built PE spectrometer described previously.[18]

Mass spectra of GeF_2, $GeCl_2$, $GeBr_2$, GeI_2, $GeBr_4$, and GeI_4 were obtained using a Finnigan 3100 D Mass Spectrometer with 6110 Data System.

Experiments were carried out under an atmosphere of dry, oxygen-free nitrogen in Schlenk vessels equipped with an inserted, water-cooled cold finger. All solids were finely ground and were thoroughly dried (if necessary) prior to use by heating in vacuo. In the syntheses of the compounds GeX_2 (X = F, Cl, Br, I) GeS was always used in excess. Reaction temperatures were dependent on reaction conditions (particle size, degree of mixing). Reaction took place between 250 and 350° for all four halides, at pressures of ca. 0.1 Torr.

After formation, the germanium dihalides (eventually) polymerized to form solids. GeF_2 is slowest in polymerizing. $[GeF_2]_n$ condenses as colourless droplets which slowly turn into a waxy yellowish white solid. $[GeCl_2]_n$ condenses as a colourless viscous fluid which turns into a white solid considerably faster than the fluoride. $[GeBr_2]_n$ directly sublimes as a solid, in the form of white needles. $[GeI_2]_n$ sublimes as a yellow–brown solid, faster so than the bromide. All four solid germanium dihalides thus formed are hygroscopic, especially the fluoride.

FORMATION OF PROTONATED SALICYLATE COMPLEXES OF Cd(II) AND Zn(II)

KYU SUN BAI

Department of Chemistry, Soong Jun University, Sang-Do Dong, Seoul, Korea

Abstract—The formation constants of the protonated complexes of Cd(II) and Zn(II) with salicylic acid (H_2Sal) and the equilibrium constants for the extraction of these complexes into cyclohexane containing tributyl phosphate (TBP) have been determined. For the complex formation:

$$M^{2+}_{aq} + HSal^-_{aq} \xrightleftharpoons{K_{11}} MHSal^+_{aq}$$
$\log K_{11}$ is 1.9 for Cd(II) and 1.4 for Zn(II) at 30°C and 0.1 M $NaClO_4$. For the extraction:

$$M^{2+}_{aq} + 2H_2Sal_{aq} + 2TBP_{org} \xrightleftharpoons{K_{ex}} M(HSal)_2TBP_{2org} + 2H^+_{aq}$$

$\log K_{ex}$ is -1.6 for Cd(II) and -2.2 for Zn(II).

In solvent extraction studies of metal ions, it is a standard procedure to plot the logarithm of the metal distribution coefficient against the pH of the aqueous phase or against the logarithm of the concentration of the extractant in one phase or the other. From analysis of slopes of such plots, the compositions of the extracting species and the extraction equilibrium constants of such reactions may be determined . Even if linear plots are obtained, the values of the slopes may or may not be integers. Many investigators commonly assume such fractional slopes to be the nearest integers in order to simplify the interpretations.[1–5]

In a recent paper,[6] a method for quantitatively interpreting such noninteger slopes has been presented. It is not only unnecessary to assume fractional slopes to be the nearest integer slopes, but also more accurate values of the constants are obtained by not making such assumptions.

In an extreme case,[3] even slopes closer to 1 than to 2 were considered to be 2 in order to explain the experimental results according to the proposed extraction model. In the present paper, the method[6] has been modified and applied to some published data[3] on the distribution of Cd(II) and Zn(II) between aqueous salicylates and cyclohexane containing tributyl phosphate.

As far as the author is aware, the present paper is the first report of the formation constants of the protonated complexes of Cd(II) and Zn(II) with salicylic acid.

DISTRIBUTION EQUILIBRIA

In systems of metal ion extraction with complexing agents, a series of complexes may be formed between the metal ion and the complexing extractant in the aqueous phase. In the case of salicylic acid as the extractant, both the "ordinary" complexes and the protonated complexes may be formed. The following reactions take place in such systems for Cd(II) and Zn(II) ions:

$$M^{2+}_{aq} + HSal^-_{aq} \xrightleftharpoons{K_{11}} MHSal^+_{aq}$$

$$M^{2+}_{aq} + 2HSal^-_{aq} \xrightleftharpoons{K_{22}} M(HSal)_{2aq}$$

$$M^{2+}_{aq} + Sal^{2-}_{aq} \xrightleftharpoons{K_1} MSal_{aq}.$$
The species extracted in the presence of TBP in the organic phase (cyclohexane) have been identified as the $M(HSal)_2(TBP)_2$ type, where M is Zn(II) or Cd(II).[3] This type has also been identified for Zn(II)[7] and for some other divalent metal ions.[7,8] The equation for the extraction of these metal ions may then be represented as:

$$M^{2+}_{aq} + 2H_2Sal_{aq} + 2TBP_{org} \xrightleftharpoons{K_{ex}}$$
$$M(HSal)_2(TBP)_{2org} + 2H^+_{aq}. \quad (1)$$
The equilibrium constant for this reaction is given by:

$$K_{ex} = \frac{[M(HSal)_2TBP_2]_{org}[H^+]^2_{aq}}{[M^{2+}]_{aq}[H_2Sal]^2_{aq}[TBP]^2_{org}}$$

$$= \frac{[M(HSal)_2TBP_2]_{org}K^2_{H2}}{[M^{2+}]_{aq}[HSal^-]^2_{aq}[TBP]^2_{org}}$$

where K_{H2} is the first acid dissociation constant of salicylic acid. The metal distribution coefficient is given by:

$$D = \frac{[M(HSal)_2TBP_2]_{org}}{[M^{2+}]_{aq} + [MHSal^+]_{aq} + [M(HSal)_2]_{aq} + [MSal]_{aq}}.$$

Using the various equilibrium constants shown above, this equation may be expressed as:

$$D = \frac{K_{ex}[HSal^-]^2_{aq}[TBP]^2_{org}}{(1 + K_{11}[HSal^-]_{aq} + K_{22}[HSal^-]^2_{aq} + K_1[Sal^{2-}]_{aq})K^2_{H2}}.$$

Hence

$$\log D + \log F_x = \log K_{ex} - 2\log K_{H2} + 2\log [HSal^-]_{aq}$$
$$+ 2\log [TBP]_{org} \quad (2)$$

where F_x may be called a formation function and is

defined by:

$$F_x = 1 + K_{11}[HSal^-]_{aq} + K_{22}[HSal^-]^2_{aq} + K_1[Sal^{2-}]_{aq}.$$

(3)

If the higher terms in F_x are neglected, eqn (2) becomes:

$$\log D = \log K_{ex} - 2 \log K_{H2} + 2 \log [TBP]_{org}$$
$$+ 2 \log [HSal^-]_{aq}.$$

This is the equation used by Singh and Tandon,[3] and was derived assuming that the complex formation of the metals with an excess of salicylic acid is negligible.

RESULTS AND DISCUSSION

Singh and Tandon[3] first carried out quantitative studies on the extraction of Zn(II) and Cd(II) with salicylic acid and TBP. Some of their results are shown in Figs. 1 and 2 (Graphs 1A and 2A). The slopes of these distribution curves indicate that aqueous complex formation in such systems is not negligible. In fact, complex formation between the metal ions and salicylic acid occurs in the aqueous phase to a large extent.

In order to explain the experimental data on the distribution of the metals, slopes even smaller than 1.5 were considered to be 2.[3] Actually, the difference between the number of charges on the metal ion and the experimental slope of such plots is a measure of the extent of complex formation in the aqueous phase.

In the case of uranyl ion extraction with anthranilic acid in the presence and in the absence of TBP, a similar situation was observed.[6] When log D was plotted against pH or against the logarithm of the acid concentration, linear relationships were obtained but the slopes were all between 1.6 and 1.8. It was found that uranyl ion formed binary complexes with anthranilic acid in the aqueous phase. Therefore, separate experiments were carried out to determine the binary complex formation constants. In
Fig. 2. Distribution of Zn(II) salicylate between aqueous 0.1 M NaClO$_4$ and TBP-cyclohexane at 30°C. Graph 1. 0.5 M TBP. Graph 2. 1.0 M TBP. Initially $1 \times 10^{-4} M$ Zn(II); Equilibrium pH 6.0. The ordinate is log D for Graphs 1A and 2A which are reproduced from Ref. 3. Slopes. 1A, 1.55; 1B, 1.94; 2A, 1.83; 2B, 2.05.

the extraction systems, allowances were then made for the presence of the aqueous complexes using the formation constants so determined. When this was done, slopes of 2 corresponding to the charge on the metal ion were obtained when log D plus log formation function was plotted against pH or against the logarithm of the acid concentration.

In the present paper, the formation constants of the protonated binary complexes are calculated from the distribution data. The extraction constants are also calculated from the same distribution data.

The extraction constants calculated assuming that the metals are present only as the aquo M^{2+} ion in the aqueous phase depend on the level of HSal$^-$ concentration. For the data in Table 2(a) of Ref. 3, the value of log K$_{ex}$ calculated for Cd(II) using eqn (1) of Ref. 3 regularly varies from −1.85 to −2.39 in going down the column. The value of pK$_{H2}$ = 2.88 for 30°C and 0.1 ionic strength[9] was used in these calculations. Had Singh and Tandom entered all the values of K$_{ex}$ in their table (Ref. 3, Table 2(a), column 4), the changing trend would have been obvious. The same changing trend may also be seen by entering all the values of K$_{ex}$ in column 4 of Table 2(b) of Ref. 3.

In the case of Zn(II), a similarly changing trend may be noticed by entering all the values of K$_{ex}$ in column 4 of Table 1 of Ref. 3. Only when the slopes of such plots are integers corresponding to the charge on the metal ion, are identical values of K$_{ex}$ obtained from all regions of the distribution curve.

In the extraction systems, salicylic acid is present in large excess of the metal ions, and the amount of salicylates combined with the metals may be neglected. The Sal^{2-} ion is also negligible under the experimental conditions employed. The mass balance for salicylates is then given by

$$[Sal]_t = [H_2Sal]_{aq} + [HSal^-]_{aq} + [H_2Sal]_{org}$$
$$+ 2[(H_2Sal)_2]_{org}.$$

By introducing the first acid dissociation constant (K$_{H2}$), the partition constant (P$_x$), and the dimerization constant

Th^{4+}	4.25		

*This work; all other values from Ref. 12 (mostly for 25°C and 0.1 ionic strength).

(K_{dim}) of salicylic acid in the organic phase, the following equation is obtained and may be solved for $[HSal^-]_{aq}$ for each experimental point.

$$\frac{2K_{dim}P_s^2}{K_{H2}^2}[H^+]_{aq}^2[HSal^-]_{aq}^2 + \left[1 + \frac{1+P_s}{K_{H2}}[H^+]_{aq}\right][HSal^-]_{aq}$$

$$= [Sal]_t.$$

The values of the constants used are $pK_{H2} = 2.88$, $P_s = 0.14$, and $K_{dim} = 580$ for cyclohexane. The values of the last two constants were obtained by interpolating the data of Banewicz et al.[10] Singh and Tandon[3] reported the value 0.585 as the partition constant of salicylic acid between cyclohexane and water. The difference between the two values of P_s for salicylic acid did not materially affect the calculation for $[HSal^-]_{aq}$, however. The calculations revealed that practically all the salicylate is present as $HSal_{aq}^-$.

The values of the protonated complex formation constants were determined using eqns (2) and (3) by systematically varying these parameters until slopes of 2 were obtained. Allowances for the presence of MSal alone as complex did not explain the experimental results. The values of K_1 used were $10^{5.55}$ for Cd(II) and $10^{6.85}$ for Zn(II).[11] Actually MSal was completely negligible for the Cd(II) systems. For Zn(II) it was only a minor species at high ends of the distribution curves. The best value of K_{11} is $10^{1.9}$ for Cd(II) and $10^{1.4}$ for Zn(II). These values were used in constructing Graphs 1B and 2B of Figs. 1 and 2. At any given concentration of $HSal_{aq}^-$, the difference between Graphs 1B and 1A or between 2B and 2A is the correction term, log F_x.

The values of K_{22} could not be determined accurately. Only the upper limits of these constants could be estimated. The distribution curves for Cd(II) (Fig. 1, Graphs 1B and 2B) were quite insensitive to variations in the value of K_{22} when log K_{22} is less than about 2.8. The curves for Zn(II) (Fig. 2, Graphs 1B and 2B) were also insensitive to variations in the value of K_{22} when log K_{22} is less than about 2.2. Above these values of K_{22}, the distribution curves seriously departed from linearity, bending upward in the high ends.

Since $HSal^-$ is a part of the extracting species, it is quite natural that binary complexes are formed between it and the metal ions in the aqueous phase. In Ref. 11, the experimental conditions were such that only the ordinary complexes exist in the aqueous solutions. In Ref. 3, on the other hand, $HSal^-$ exists in large excess of the metals and therefore the conditions are favorable for the formation of the protonated complexes.

Owing to the electroneutrality and the large size of the organic portion of $M(HSal)_2$, this species is not expected to be water-soluble to any appreciable extent. Hence the uncertainty in the values of K_{22}.

The values of the extraction constants were calculated from Graphs 1B and 2B of Figs. 1 and 2 using eqn (2). The values of log K_{ex} obtained for Cd(II) are -1.4 and -1.7 from Graphs 1B and 2B, respectively, of Fig. 1. The average, -1.6, is taken as the best. The value for Zn(II) is -2.2 from both Graphs 1B and 2B of Fig. 2. From eqn (1) involving 2 TBP molecules, the vertical spacing between Graphs 1A and 2A or between 1B and 2B should be 0.6 log unit. In Fig. 1, it is seen that the spacing is smaller than 0.6. This is reflected as the somewhat larger uncertainty in the value of K_{ex} for Cd(II).

The values of K_{11} are smaller than the corresponding values of K_1 by several orders of magnitude. This is consistent with the monodentate nature of the ligand in $M(HSal)^+$. For the protonated complexes, the Cd(II) complex is more stable than the Zn(II) complex while the opposite is the case for the ordinary complexes.[11] These results are in accord with the coordinating tendencies usually observed with these metals. Examination of the literature[12] revealed that with many monodentate ligands the Cd(II) complex is more stable than the Zn(II) complex, while the opposite is generally the case with chelating ligands. The larger stability constant of the protonated Cd(II) complex is reflected in its better extractability. Comparison of Figs. 1 and 2 indicates that Cd(II) is extracted better than Zn(II) is; the value of K_{ex} is larger for Cd(II) than for Zn(II).

Protonated complexes are quite common for salicylic acid. In Table 1 are given stability constant data for the protonated complexes of some metals with salicylic acid. Some data for benzoic acid are included for comparison.

The constants for the protonated complexes of Zn(II) and
Cd(II) are comparable to the stabilities of the benzoate
complexes. This is as expected from the similarity of the
ligands in the two cases. The relative stabilities of the
protonated salicylate complexes of Cd(II) and Zn(II) are
the same as for the benzoate complexes of these metals.

COMPLEXES CONTAINING PHOSPHORUS LIGANDS—16[1]

NEW PHOSPHINITE, PHOSPHONITE AND PHOSPHITE DERIVATIVES OF RUTHENIUM, OSMIUM AND IRIDIUM

CLIFFORD J. CRESWELL†, STEPHEN D. ROBINSON* and ARVIND SAHAJPAL
Department of Chemistry, King's College, Strand, London WC2R 2LS, England

Abstract—The complexes [MHCl(CO)(PPh$_3$)$_3$] (M = Ru or Os) readily undergo substitution at the site *trans* to the hydride ligand to afford phosphinite-, phosphonite-, or phosphite-containing products [MHCl(CO)(PPh$_3$)$_2$L] [L = P(OR)Ph$_2$, P(OR)$_2$Ph or P(OR)$_3$ respectively; R = Me or Et]. The ruthenium complexes alone undergo further substitution to afford complex cations [RuH(CO)(PPh$_3$)$_n$L$_{4-n}$]$^+$ [n = 2, L = P(OMe)$_3$; n = 1, L = P(OR)$_3$; n = 0, L = P(OR)$_2$Ph or P(OR)Ph$_2$] which were isolated and characterised as their tetraphenylborate salts. Synthesis of the cationic complexes [IrHL$_3$][BPh$_4$]$_2$ [L = P(OR)$_3$, R = Me or Et] is also reported. Stereochemical assignments based on NMR data are given, and second order ^{31}P and high field ^{1}H NMR patterns are analysed.

In contrast to the tertiary phosphines, tertiary phosphite esters, P(OR)$_3$, and the closely related phosphonites, P(OR)$_2$Ph, and phosphinites P(OR)Ph$_2$(R = alkyl) have attracted relatively little attention as ligands in platinum metal chemistry.[2] This situation has been corrected to some degree in recent years by the incorporation of these less common phosphorus donor ligands in a series of cationic complexes which can be readily isolated as tetraphenylborate, tetrafluoroborate or hexafluorophosphate salts of relatively low solubility. Much of the early work in this area originated from our own laboratory.[3–5] We now report an extension of our studies and describe a new range of ruthenium, osmium, and iridium complexes containing phosphorus donor ligands of the type under discussion.

RESULTS AND DISCUSSION

The complexes MHCl(CO)(PPh$_3$)$_2$L (M = Ru, Os)

The hydrido complexes [MHCl(CO)(PPh$_3$)$_3$] (M = Ru or Os) react with phosphorus donor ligands [L = P(OR)$_x$Ph$_{3-x}$, R = Me or Et, x = 1 – 3] in boiling benzene or alcohol (ROH) solution to afford the uncharged monosubstituted products [MHCl(CO) (PPh$_3$)$_2$L] as air-stable, white crystalline solids, soluble in most common organic solvents. The high field proton NMR spectra of these products each comprise a doublet of triplets pattern [^{2}J(PH)$_{trans}$ = *ca.* 120–180 Hz(Ru) or *ca.* 90–140 Hz(Os); ^{2}J(PH)$_{cis}$ = *ca.* 20–22 Hz] indicative of stereochemistry (I). This assignment is similar to those made for other ruthenium complexes [RuHCl(CO)(PR$_3'$)$_2$L], prepared by analogous substitution processes, and is in accord with the known high *trans* labilizing influence of the hydride ligand.[6]

The osmium complexes do not undergo further substitution when subjected to prolonged and/or vigorous treatment in the presence of excess ligand.

However, their more labile ruthenium analogues, when similarly treated with a large excess of ligand, L, give solutions which upon addition of sodium tetraphenylborate deposit complex salts of the general stoichiometry [RuH(CO)(PPh$_3$)$_n$L$_{4-n}$] [BPh$_4$](n = 0 – 2).

The complex salt [RuH(CO)(PPh$_3$)$_2$L$_2$][BPh$_4$] [L = P(OMe)$_3$]. This product was obtained as an air-stable, white, crystalline solid, soluble in acetone, chloroform and dichloromethane, but sparingly soluble in alcohols. The proton NMR spectrum displays aryl, methyl and hydride protons in the required ratio 50:18:1. The methyl resonance, consisting of two doublets of equal intensity [^{3}J(PH) = *ca.* 10.25 Hz], establishes the presence of two non-equivalent P(OMe)$_3$ ligands. The absence of a large coupling ^{2}J(PP')$_{trans}$ from the ^{31}P NMR spectrum implies that the P(OMe)$_3$ ligands are not *trans* to triphenylphosphine. These data establish stereochemistry (IIa) for the complex. The high field proton resonance consists of a broad second order pattern which does not directly afford stereochemical information, except to confirm the location of a phosphorus donor ligand *trans* to the hydride. However, iterative analysis of the ^{31}P and high field ^{1}H NMR spectra gave the data shown below which are consistent with the proposed structure (IIa).

An isomeric product, present in small quantity (*ca.* 10%), displays a compact second order high field proton NMR pattern together with a virtual coupling triplet in the methyl region. The former implies the absence of a phosphorus donor ligand *trans* to the hydride and the latter indicates the presence of a *trans* pair of P(OMe)$_3$ ligands[7] thus establishing stereochemistry (IIb) for this minor product.

The complex salts [RuH(CO)(PPh$_3$)L$_3$][BPh$_4$] [L = P(OR)$_3$]. These products were obtained as airstable, white, crystalline solids soluble in acetone, chloroform and dichloromethane but sparingly soluble in alcohols. The proton resonance of the triethyl phosphite complex shows aryl, methylene, methyl

$\delta P^3 = -133.6 \text{ ppm}$

$^2J(HP^1) = 17.75 \text{ Hz}, \ ^2J(HP^2) = 37.9 \text{ Hz}, \ ^2J(HP^3) = -124.5 \text{ Hz}.$
$^2J(P^1P^2) = 43.45 \text{ Hz}, \ ^2J(P^1P^3) = 36.45 \text{ Hz}, \ ^2J(P^2P^3) = 38.35 \text{ Hz}.$
and hydride protons in the required ratio 35:18:27:1. The methyl resonance, comprising three triplet of equal intensity, establishes the presence of three non-equivalent P(OEt)$_3$ ligands, and the broad, second order, high field proton NMR pattern betrays the presence of a *trans* coupling $^2J(PH)$. On the basis of this evidence we assign stereochemistry (IIIa) to this product. In contrast, the proton NMR spectrum of the corresponding trimethyl phosphite complex establishes stereochemistry (IIIb). The methyl resonance comprises a doublet and a triplet (relative intensities 1:2) and the high field proton pattern consists of a complex pattern which when subjected to iterative analysis affords the following data

The complex salts [RuH(CO)L$_4$][BPh$_4$] [L = P(OR)$_x$Ph$_{3-x}$, R = Me or Et, n = 1 or 2]. These products were obtained as air-stable, white crystalline solids. Their high field proton NMR spectra each consist of a regular first order quintet pattern indicative of stereochemistry (IV). Virtual coupling patterns consistent with the presence of four equivalent P(OMe)$_x$Ph$_{3-x}$ ligands arranged in a square planar manner are observed for the methyl diphenylphosphinite and dimethyl phenylphosphonite derivatives.[8]

The complex salts [IrHL$_5$][BPh$_4$]$_2$ [L = P(OR)$_3$; R = Me or Et]. These air-stable, white crystalline solids are soluble in dichloromethane but only very sparingly soluble in chloroform and alcohols. Their proton NMR spectra show aryl, alkyl and hydride proton resonances with the correct intensity ratios, but do not distinguish between axial (*trans* to hydride) and equatorial P(OR)$_3$ ligands. The ^{31}P and high field ^{1}H NMR spectra are second order and therefore do not provide stereochemical information directly. However, iterative analysis of the ^{31}P and high field ^{1}H NMR spectra (mixed CDCl$_3$/d_6-DMSO solvent) gave the following data

High field proton NMR spectra recorded at 250 MHz were first order and yielded data for [IrH{P(OEt)$_3$}$_5$][BPh$_4$]$_2$ in good agreement with those presented above [$\delta(\text{IrH}) = -12.3 \ (\tau \ 22.3)$ $^2J(PH)_{trans} = 170 \text{ Hz}, \ ^2J(PH)_{cis} = 16 \text{ Hz}.$

Attempts to prepare the carbonyl species [IrH(CO){P(OEt)$_3$}$_4$][BPh$_4$]$_2$ by carbonylation of [IrH{P(OEt)$_3$}$_5$][BPh$_4$]$_2$ for 1½ hr in boiling ethylmethylketone gave only unchanged starting material.

The stereochemical assignments made for the ruthenium complexes (I)–(IV) establish that the ligand substitution reactions are accompanied by a carbonyl

$\delta(\text{RuH}) = -7.16 \ (\tau \ 17.16)$
$\delta P^1 = -141.7 \text{ ppm}$
$\delta P^2 = -139.7 \text{ ppm}$
$\delta P^3 = -41.4 \text{ ppm}$

$^2J(HP^1) = 21.3 \text{ Hz}, \ ^2J(HP^2) = 19.25 \text{ Hz}, \ ^2J(HP^3) = 15.65 \text{ Hz},$
$^2J(P^1P^2) = 64.2 \text{ Hz}, \ ^2J(P^1P^3) = 43.95 \text{ Hz}, \ ^2J(P^2P^3) = -330.3 \text{ Hz}$

Scheme I.
migration step. It appears that, in order to minimise the effect of the increasing number of strong π-acceptor phosphorus donor ligands, the carbonyl ligand migrates to the site *trans* to the strong σ-donor hydride ligand. The proposed substitution (S) and isomerisation (I) processes are collected in Scheme 1.

EXPERIMENTAL

Platinum metal salts and phosphorus donor ligands were obtained from Johnson Matthey and the Maybridge Chemical Co. Ltd., respectively. Platinum metal triphenylphosphine complexes were made as previously described.[9] Reagent grade organic solvents were used as purchased. All reactions were performed under nitrogen but the products were worked-up in air. Analyses, by the microanalytical laboratory, University College, London, and melting points, taken in sealed tubes under nitrogen, are given in Table 1. IR spectra were taken for nujol mulls using a Perkin-Elmer 457 grating spectrometer. Proton NMR spectra were obtained using a Perkin-Elmer R12B (60 MHz) and a Bruker HFX90 (90 MHz) spectrometer. ^{31}P NMR spectra were obtained using the Bruker HFX90 spectrometer operating at 36.43 MHz and are referenced to external H_3PO_4 in the sense that positive values are to low field. Spectroscopic data are recorded in Table 2. Iterative analyses of second order NMR data were performed using an ITRCAL programme.[10]

Carbonylchlorohydrido (*trimethylphosphite*)*bis*(*triphenylphosphine*)*ruthenium*(*II*). Carbonyl chlorohydridotris(triphenylphosphine)ruthenium (0.34 g) and trimethyl phosphite (0.12 g) in a mixture of methanol (30 cm^3) and benzene (5 cm^3) were heated under reflux for *ca*. 1 hr. The resultant clear solution was filtered while hot, concentrated under reduced pressure and set aside overnight. The crystals which separated were filtered off, washed successively with methanol and light petroleum (60–80), then recrystallised from dichloromethane-methanol to yield the required product as colourless microcrystals (0.175 g, 61%).

Similarly prepared using the appropriate ligand and alcoholic solvent were: *carbonylchlorohydrido*(*triethyl phosphite*)*bis*(*triphenylphosphine*) *ruthenium*(*II*) as colourless microcrystals (61%); *carbonylchlorohydrido*(*dimethyl phenylphosphonite*)*bis*(*triphenylphosphine*) *ruthenium*(*II*) as colourless crystals (66%); *carbonylchlorohydrido*(*diethyl phenylphosphonite*)*bis*(*triphenylphosphine*)*ruthenium*(*II*) as white crystals (63%); and *carbonylchlorohydrido*(*methyl diphenylphosphinite*)*bis*(*triphenylphosphine*)*ruthenium*(*II*) as colourless crystals (63%).

Similarly prepared from carbonylchlorohydridotris(triphenylphosphine)osmium were: *carbonylchlorohydrido*(*trimethyl phosphite*)*bis*(*triphenylphosphine*)*osmium*(*II*) as colourless crystals (83%); *carbonylchlorohydrido*(*triethyl phosphite*)*bis*(*triphenylphosphine*) *osmium*(*II*) as colourless crystals (86%); *carbonylchlorohydrido*(*dimethyl phenylphosphonite*)*bis*(*triphenylphosphine*)*osmium*(*II*) as colourless crystals (75%); *carbo-*

nylchlorohydrido(diethyl phenylphosphonite)bis(triphenyl-phosphine)osmium(II) as colourless crystals (59%); carbonylchlorohydrido(methyl diphenylphosphinite)bis(triphenylphosphine)osmium(II) as colourless crystals (90%); and carbonylchlorohydrido(ethyl diphenylphosphinite)bis(triphenylphosphine)osmium(II) as colourless crystals (72%).

Carbonylhydridobis(trimethyl phosphite)bis(triphenylphosphine)ruthenium(II) tetraphenylborate—Carbonylchlorohydridotris(triphenylphosphine)ruthenium (0.34 g) and trimethyl phosphite (0.2 g) in a mixture of methanol (20 cm^3) and chloroform (10 cm^3) were heated under reflux for 30 min. The resultant clear solution was filtered while hot, then treated with sodium tetraphenylborate (0.2 g) in methanol (5 cm^3), and stirred until precipitation commenced. The white precipitate was allowed to stand overnight then filtered off, washed with methanol and light petroleum (60–80), recrystallised from dichloromethane–methanol and dried in vacuo to yield the required product as colourless crystals (0.25 g, 61%). NMR data (see Discussion) indicate the presence of a second isomer (ca. 10%).

Carbonylhydridotris(trimethyl phosphite)(triphenylphosphine)ruthenium(II) tetraphenylborate—Carbonylchlorohydridotris(triphenylphosphine)ruthenium (0.34 g) and trimethyl phosphite (0.2 g) in a mixture of methanol (30 cm^3) and benzene (5 cm^3) were heated together under reflux for ca. 3 hr. The resultant clear solution was filtered while hot, treated with sodium tetraphenylborate (0.2 g) in methanol (5 cm^3), then concentrated to a small volume on a water bath before being allowed to cool with gentle stirring. The white

precipitate was allowed to stand for a few hours, then filtered off, washed with methanol and light petroleum (60–80), recrystallised from dichloromethane–methanol and dried in vacuo to yield the required product as colourless microcrystals (0.23 g, 64%).

Carbonylhydridotris(triethyl phosphite)(triphenylphosphine)ruthenium(II)tetraphenylborate. Similarly obtained as colourless crystals (62%) using triethyl phosphite and ethanol in place of trimethyl phosphite and methanol. Carbonylhydridotetrakis(diethyl phenylphosphonite)ruthenium(II) tetraphenylborate — carbonylchlorohydridotris(triphenylphosphine)ruthenium (0.34 g) and diethyl phenylphosphonite (1.0 g) in a mixture of ethanol (20 cm^3) and benzene (10 cm^3) were heated under reflux for ca. 2 hr. The resultant clear solution was filtered while hot, treated with sodium tetraphenylborate (0.2 g) in ethanol (5 cm^3), then concentrated to a small volume under reduced pressure and stirred until precipitation occurred. The precipitate was allowed to stand overnight then filtered off, washed thoroughly with ethanol and light petroleum (60–80), recrystallised from dichloromethane–ethanol and dried in vacuo as white crystals (0.25 g, 61%).

Carbonylhydridotetrakis(methyl diphenylphosphinite) ruthenium(II) tetraphenylborate—Carbonylchlorohydridotris(triphenylphosphine)ruthenium (0.34 g) and methyl diphenylphosphinite (1.0 g) in a mixture of methanol (20 cm^3) and benzene (5 cm^3) were heated under reflux for 1 hr. The resultant clear solution was filtered, cooled to ambient temperature and treated with a solution of sodium tetraphenylborate (0.2 g) in methanol (5 cm^3). The white precip-

XPS of coordination compounds: additive ligand effect in some copper(I) and copper(II)

chelates with 1,2 phosphino (or phosphine/oxide)-sulfido ethane ligands

by M. Bressan, C. Furlani* and G. Polzonetti*

Institute of Analytical Chemistry and CNR Center, University of Padova, and

* Institute of General and Inorganic Chemistry, University of Rome.

Summary

XPS spectra of $Ph_2P-CH_2-CH_2-S-R$ ligands, of their P-oxides and of the corresponding 1:

2 complexes with Cu(I) and Cu(II) indicate a moderate donor shift on complexation of about

0.4 eV for S, and 0.3 eV for P on the 2p signals, and confirm complete chelation for both

ligands in their metal complexes. The chemical shifts of $Cu2p_{3/2}$ b.e. values can be quant-

itatively described by a model of additive ligand contribution, for which parameter values

of -0.2 eV for -S-, and -0.5÷-0.6 eV for -O⁻ donors are proposed.

Introduction

XPS (X-ray photoelectron spectroscopy) has proved a useful tool for the elucidation of

the electronic structure of coordination compounds by allowing determination of energy levels

of both valence and inner-core orbitals of atoms belonging to the coordination sphere, and

detection of chemical shifts on the latter quantity, reflecting intra-and intermolecular

atomic charge distributions. Emphasis is now being laid on attempts at more quantitative

evaluation of XPS data; one of the most recent proposals in this direction is the model of

additive ligand contributions by Feltham and Brant[1], according to which the ligand con-

tributions are regarded as a measure of the electron donor or acceptor ability of the ligands.

Although lacking rigorous theoretical background, and although formulated so as to be valid

only on a statistical basis, the model by Feltham and Brant is nevertheless attractive in

suggesting a quantitative representation of the chemical concept of electron donor/acceptor

properties of ligands, and may prove useful for an empirical classification of ligands, not

unlike other empirical series such as the spectrochemical, nephelauxetic and X_{opt} series.

We undertook a study of XPS characterization and structural confirmation of some

chelates of Cu(I) and Cu(II) with neutral chelating agents of $R_2P-CH_2-CH_2-S-R'$ and $R_2(O)P-$

CH_2-CH_2-SR' type[2], and tried to apply the model by Feltham and Brant to the rationalization

of the b.e. data. The investigated series of compounds proved particularly well suited to

this scope, both because of the good quality of the XP spectra and of their similarity of

structure, which allows significant comparisons to be drawn, while varying in a systematic

way the nature of donor atoms in the ligands. As a result we were able to conclude that the

investigated series of chelates of copper(I) and (II) can be adequately described in this

XPS behaviour by the Feltham and Brant model[1], and to propose values of additive ligand con-

tributions for sulfur and oxygen donors, which were not included in the original classifica-

tion by Feltham and Brant[1].

Experimental

We measured the solid state X-ray photoelectron spectra of the ligand molecules (di-phenylphosphino)-ethylthioethane $(C_6H_5)_2$ P-CH_2-CH_2- SC_2-H_5 (P-SEt), (diphenylphosphino)-phenyl-thioethane $(C_6H_5)_2$P-CH_2-CH_2-SC_6-H_5 (P-SPh), and the corresponding phosphine oxides (OP-SEt and OP-SPh), and of the complexes Cu^I(P-SEt)$_2$(ClO_4), Cu^I(P-SPh)$_2$(ClO_4), $Cu^I Cu^{II}$(P-SEt)$_2$ (OP-SEt)$_2$(ClO_4)$_3$, Cu^{II}(OP-SEt)$_2$(ClO_4)$_2$ and Cu^{II}(OP-SPh)$_2$(ClO_4)$_2$. The complexes were synthesized for the first time and characterized preliminarly by one of us in a previous investigation[2]. The purity of the compounds used in the present work was checked by elemental analysis and values of physical constants, and found to be satisfactory. The coordination geometry was proposed[2] to be of tetrahedral or pseudotetrahedral type for both Cu^I and Cu^{II} species, with chromophores [Cu^I P_2S_2], and [$Cu^{II}O_2S_2$] respectively, but the known tendency of Cu^I to 3- co-ordination, and of Cu^{II} to 5-coordination suggested the utility of a further structural con-firmation; actually as we shall discuss below, XPS data for the Cu^{II} species are better com-patible with a loose 5-coordination of one anion to an enlarged pseudotetrahedral coordina-tion around Cu^{II}.

XP spectra were run on a VG ESCA-3 spectrometer equipped with AlK$\alpha_{1,2}$ source (1486,6 eV). Powder specimens were dusted as thin films onto a gold bearing plate, whose Au4f$_{7/2}$ signal at 84.0 eV was used for check of the instrument scale. Reported data are averages of repeated runs on different samples (usually three runs for three different samples of each compound), the reproducibility being seldom worse than 0.1 eV. Surface charging effects (usually in the range 1-2 eV) were corrected by referring to the C1s b.e. value taken as 285.0 eV; C1s signals were narrow and well defined, hence suitable for dependable reference, and were due to superposition of practically coincident signals from ligand carbon atoms (mostly from the phenyl groups), and contamination carbon (Santovac 5 diffusion pump oil). No detectable radiation damage by X-ray was observed, so measurements could be performed at room tempera-ture.

For each element, more than one inner-core ionization line was measured whenever pos-sible, so for Cu and S besides the more common 2pj signals also Cu3p and S2s signals were measured, the former being particularly significant for check of the effective transmission function of the spectrometer, and therefore for quantitative intensity evaluation. Only the copper LVV Auger signals around 917 eV were of poor quality, being broader and less structur-ed than in simple copper species, and therefore unsuited for exact structural characteriza-tion. Intensity measurements of the XPS bands were performed in order to check the atomic composition of the XPS sampling layers; atomic ratios were computed by the simple formula $n_i/n_j = I_i\sigma_j\lambda_j$ $S_j$exp(-d/λ_j) / $I_j\sigma_i\lambda_i S_i$exp (-d/λ_i) (cross sections from the tabulation by Scofield[3], IMFP (λ) from[4], and S values approximately $\backsim E_K^{-\frac{1}{2}}$ according to[5] and found in satis-factory agreement with elemental composition, if proper account was taken of contamination overlayers, thus confirming that surface radiation damage was negligible, and that measured XPS data were truly representative of the structure of the investigated molecular solids.

Results and discussion

XP spectral data for the investigated ligands and complexes are listed in the table,

and the shape profiles of some representative spectra are reported in the figure. The results

will be discussed first in terms of structural assignements, and subsequently from the point

of view of quantitative data evaluation in the model by Feltham and Brant[1].

The general patterns of XP spectra reproduce with considerable accuracy the typical

features of copper complexes, thus yielding further support to their structural character-

ization. Cu2p signals have, as expected, higher b.e. for Cu(II) species (935.6 eV) than for

Cu(I) (934.0 eV); a quantitative discussion of the b.e. difference will be given below. FWHM

is larger for Cu(II) (Cu2p$_{3/2}$ ca. 2.8 eV) than for Cu(I) (2.0-2.1 eV under our experimental

conditions) because of unresolved multiplet splitting due to presence of a partly filled

valence shell in Cu(II) only. In Cu(II) species there is a well-defined satellite (ΔE_{av} $\sim$ 9.8

eV) on the high b.e. side of each 2p$_j$ signals, with moderate intensity (ca. 33% of the total

area of both satellite and the main line Cu2p$_j$; (compare relative intensities of 19-25% in

copper(II) dithiocarbamates[6] or up to 40% in Cu(II) oxide systems[7]), whereas Cu(I) spectra

are fully void of 2p satellites. This latter fact is significant with regard to the long

dispute in the literature whether diamagnetic (S=0) transition metal complexes do have true

although weak 2p satellites, or are exempt from satellites, and possible accompanying signals

are due to paramagnetic impurities. Our present results show, at least for the d^{10} configura-

tion of Cu(I), a case of unequivocal total absence of satellites from diamagnetic transition

metal complexes.

The mixed species Cu$_2$(P-SEt)$_2$(OP-SEt)$_2$(ClO$_4$)$_3$ behaves, on XPS evidence, as a double salt

without specific interactions between Cu(I) and Cu(II), its XP spectrum being just the super-

position of those of the separate Cu(P-SEt)$_2$(ClO$_4$) and Cu(OP-SEt)$_2$(ClO$_4$)$_2$ species in 1:1 ratio.

B.e. and FWHM values are intermediate between those of the simple Cu(I) and (II) species,

for Cu2p and P2p signals, the difference between the two species being too small to give rise

to separate signals. Also the intensity of the Cu2p$_{3/2}$ satellite (ΔE $\sim$ 10 eV) is almost exact-

ly the half (14% of the total area of both satellite and the main peak) of the Cu(II) value;

since position, shape and intensity of 2p satellites depend critically upon the structural

environment of central atoms in transition metal complexes[8], our observed satellite intensity

can be taken as evidence for absence of strong coupling interactions between Cu(I) and Cu(II)

in the present case.

Sulfur 2p$_{av}$ b.e. values are in the range 163.8-164.5 eV, as typical for neutral or near-

ly neutral sulfur atoms[9]. No significant difference is found between the S-ethyl and the S-

phenyl ligands, nor for their complexes. ΔE between complexes and uncomplexed ligand, a

measure for the S donor effect towards copper, is in the range 0.4($\pm$0.2) eV; this is somewhat

less than observed for complexes of thiol ligands (e.g. dithiocarbamates, ΔE $\sim$0.7-1.0 eV[6,10])

as expected on the ground of the negative sulfur charge, and larger availability of electron

for σ donation in the latter case. Among neutral sulfur ligands, only thioureas and related

ligands show a higher ΔE on complexation (e.g.$\sim$ 1 eV[11]), which can be however explained by

the occurrence of thioamide resonance forms of $\begin{smallmatrix} R \\ R \end{smallmatrix}\!\!>\!\!\overset{+}{N} = C\!\!<\!\!\overset{\textstyle\diagdown}{}S^-$ type[11,12]. Also P2p b.e. values

fall in the normal range (131.1$\pm$0.1 eV for free, and 131.4 eV for ligated phosphines), with

a more pronounced shift to higher b.e. occurring on donation to oxygen in the phosphine ox-

ides (132.8$\pm$0.1 eV).

Both sulfur and phosphorus XPS signals in the copper complexes are, within experimental error, as narrow as in the free ligands (except of course phosphorus in the double salt of Cu(I), Cu(II)), and therefore indicative of only one species of S and P in the complexes: for sulfur the situation is particularly clear-cut with 2s signals which are singlets and therefore more symmetric and possibly more sensitive to such effects than the 2p doublet. XPS evidence confirms therefore that both ligands are chelated in an essentially equivalent way to the central metal atom, with minimum chromophore configurations $[Cu^{I}S_2P_2]$ and $[Cu^{II}S_2O_2]$ respectively.

As for a possible quantitative interpretation of the chemical shifts on copper b.e. values in terms of addition ligand contributions, the original paper by Feltham and Brant[1] does not quote parameter values for S and O ligands, so we shall have to make a reasonable guess for the latter quantities on the ground of our experimental results. Thus, the $Cu2p_{3/2}$ b.e. value of 934.0 eV for $Cu^{I}(P-SR')_2$ (ClO_4) results from the bare metal value of 935.6 eV[1] by adding +1.0 eV (formal oxidation state of Cu +1[1]) and subtracting the ligand contributions (2.3 eV for two chelating phosphorus atoms[1]), leaving −0.3 eV as the contribution from two sulfur ligands −S− of thioether type. This suggests, rounding to the larger figure, a contributive parameter value of about −0.2 eV for neutral sulfur ligands in the Feltham-Brant scale[1].

Using the figure just derived for the sulfur ligands in the analysis of the Cu^{II} complexes, the $Cu2p_{3/2}$ b.e. value of 935.6 eV derives from the reference value of 937.6 eV for bare Cu^{2+} minus 0.3 eV for two S ligands in the chromophore, leaving us with a contribution of −1.7 eV to be assigned to the remaining ligands. This would imply an upper limit of about −0.8 eV contribution for each oxygen ligand in an isolated, purely 4-coordinated $[Cu^{II}O_2S_2]$ chromophore; since however apparently 4-coordinated Cu(II) chromophores often reach 5-coordination either by dimerization[13] or by loose interaction with a solvent molecule or an external anion (as could be the present case), we prefer to assume that the donor effect of 1.7 eV is to attributed to three rather than two oxygen donor, each of them contributing −0.5÷−0.6 eV to the total effect.

In conclusion, the XPS characterization of the Cu(I) and Cu(II) chelates investigated here allows on the one hand further elucidation of the proposed structures, and presents further cases of applicability of the model of additive ligand contributions by Feltham and Brant[1]. Parameter values of −0.2 eV for −S− and −0.5÷−0.6 eV for −O⁻ ligands are proposed; although their validity has to be tested in future through more extended statistics, such values appears reasonable and in keeping with the donor-acceptor concept of the Feltham-Brant series, since the smaller negative value for sulfur is consistent with a lower σ-donor ability (if compared to negative −O⁻ donors), and a larger π-acceptor tendence, possibly by use of empty S3d orbitals, with respect to oxygen ligands.

Barcelona, Spain.

Abstract.– Some Ni(II) complexes with 5,7-dicloro-8-aminoquinoline
(dcaq), 5,7-dibromo-8-aminoquinoline(dbaq) and 5,7-diiodo-8-amino-
quinoline(diaq) are described. The compounds are of stoichiometry
NiL_2X_2(L= dcaq, dbaq, diaq; X= NO_3^- and L= dbaq; X= Cl^-, Br^-, I^-,
NCS^-) and $NiLX_2 \cdot H_2O$(L= dcaq, diaq; X= Cl^-). The electronic spectra
and magnetic susceptibility data at room temperature, are consistent
with octahedral geometry for the Ni(II) in each compound. I.r. spectra
show the presence of ionic and bridging nitrate groups in the com-
pounds $NiL_2(NO_3)_2$(L= dcaq, dbaq, diaq) and we assign them polymeric
structures. Polymeric structures with bridging chloride are proposed
for the compounds $NiLCl_2 \cdot H_2O$(L= dcaq, diaq) and monomeric octahedral
structures for NiL_2X_2(L= dbaq; X= Cl, Br, I, NCS).

INTRODUCTION

The ligand properties of 8-aminoquinoline have been the object of considerable attention
in the last few years.[1,2] In a previous paper, the authors reported complexes of Cu(II)
with ligands derived from 8-aminoquinoline, namely 5,7-dichloro-8-aminoquinoline(dcaq);
5,7-dibromo-8-aminoquinoline(dbaq); 5,7-diiodo-8-aminoquinoline(diaq).[3] Polymeric structures
have been proposed for all of them and they closely resemble their ethylenediamine or bipy-.
ridyl analogues.

Here we describe complexes of Ni(II) with the same ligands. The objective was to define
the ligand behaviour of these substances and to compare them with 8-aminoquinoline and
with ethylenediamine and 2,2'-bipyridyl.

RESULTS AND DISCUSSION

I.r. Spectra

Table 1 shows the frequencies of the bands assigned to vibrational modes of the NH_2 group of the ligands and their complexes. The stretching modes of the NH_2 group appear in the 3000–3500 cm^{-1} region. In all the complexes these bands appear at lower frequencies than in the free ligands. This effect is indicative of the coordination of the amine group of the ligands in all the complexes.[4]

In the 1550–1620 cm^{-1} region the free ligands exhibit a wide band with a pronounced fine structure due to the partially coupled stretching vibration $\nu(C=C)$, $\nu(C=N)$ of the aromatic rings and the deformation mode of NH_2 groups. This was shown in the case of 8–aminoquinoline by deuteration studies.[5] Coordination changes the coupling of these modes, and a clear splitting of this broad band into two components can be seen in all the complexes. The higher frequency component is assigned mainly to the $\delta(NH_2)$ mode and the other to the aromatic ring vibrations. In the 1350–1375 cm^{-1} region, there is a band corresponding to the $\nu(C-NH_2)$ stretching mode. In the 1020–1060 cm^{-1} region, there is a band corresponding to the wagging mode of the coordinate NH_2 group. This appears also in the free ligands as a weak band, due to the formation of intermolecular hydrogen bonds. This band is the most sensitive to the chemical environments of the Ni(II) ions, as observed for other complexes of 8–aminoquinoline.[2]

In the 600–800 cm^{-1} region appear the rocking and twisting bands of the NH_2 coordinated group, which are, in general, difficult to assign and have little interest. The metal–amine nitrogen stretching mode appears in the 500–600 cm^{-1} region.

Nitrate complexes

Table 2 shows the frequencies assigned to the NO_3^- group in the three complexes containing this ligand. There are bands that may be assigned to the ionic nitrate group, and others corresponding to the coordinated ligand.[4] The $\nu_3(E')$ mode of ionic nitrate can be seen to be split by coordination in two components at 1435–1440 cm^{-1} and 1300 cm^{-1}. At the same time there remains a very intense band at 1380–1370 cm^{-1} attributed to ionic nitrate. In this last region the ligands dcaq, dbaq, diaq show several bands, one of which coincides with that assigned to ionic nitrate. However, by observing the i.r. spectra with very dilute KBr pellets it is possible to detect this very intense and characteristic band corresponding to $\nu_3(E')$ mode of ionic nitrate.

In the 1000–1100 cm^{-1} region the compounds show two intense bands. One of them is due to the $\nu_1(A_1')$ mode of the coordinate group (1020–1030 cm^{-1})(Table 2). The second, of higher frequency, has been assigned to the wagging mode of the NH_2 group. This last band overlaps the one due to the ionic nitrate which also appears in this region (1050 cm^{-1}). The $\nu_2(A_2'')$

mode due to coordinated and free nitrate group is observed with medium intensity in the 820–830 cm^{-1} region. The $\nu_4(E')$ mode appears between 710–720 cm^{-1}, as a weak band and without splitting, because in this region there are several bands due to the amine-ligands.

The coordination mode of the nitrate group cannot be deduced unequivocally from these data, but the physicochemical characteristics of these nitrate complexes are compatible with polymeric linear structures with nitrate groups bridging between Ni(II) ions and with ionic nitrate groups in the lattice.

Complexes with thiocyanate

The only complex prepared with thiocyanate ligand is Ni(SCN)$_2$(dbaq)$_2$. In the ν(CN) stretching mode region there is one intense band at 1995 cm^{-1} which can be assigned to this mode. Two other bands corresponding to the ν(CS) and δ(SCN) modes can be seen at 795 cm^{-1} and 490 cm^{-1}, respectively. These spectral characteristics show a coordination via nitrogen atom of the thiocyanate group in the complex.[7] The previously reported compounds with ligands 8-aminoquinoline[2] and 6-metil-2-aminoethylpiridine[8] have a similar i.r. spectra.

Electronic Spectra

Table 3 summarises the electronic spectra of all the compounds and of the similar compounds with ethylenediamine and pyridine together with the proposed assignments. All the compounds of ML$_2$X$_2$ and also MLX$_2$ stoichiometry show the same spectral characteristics which are consistent with an octahedral environment[9,10] around the Ni(II) ion.

The first band which appears in the near infrared zone, is attributable to the transition $^3A_{2g} \rightarrow {}^3T_{2g}$ and gives the 10Dq value of the complex. The frequency of this band in the compounds: Ni(dbaq)$_2$Cl$_2$, Ni(dbaq)$_2$Br$_2$, Ni(dbaq)$_2$I$_2$, Ni(dbaq)$_2$(NO$_3$)$_2$ and Ni(dbaq)$_2$(NCS)$_2$ reflects the position of the ligands, Cl$^-$, Br$^-$, I$^-$ and NO$_3$ in the spectrochemical series. Also the 10Dq value of the compound: Ni(dbaq)$_2$(NCS)$_2$ confirms the NCS group coordination, via nitrogen atom, to the Ni(II) ion. On the other hand the low energy of this transition in the compound Ni(dcaq)Cl$_2$·H$_2$O similar to the Ni(dbaq)$_2$I$_2$, is consistent with the polymeric structure with bridging chloride proposed for it.

Generally the last band attributable to the transition $^3A_{2g} \rightarrow {}^3T_{1g}$(P) is overlapped with charge transfer bands due to the amine-ligands, except in the compounds in which the ligands are in the later part of the spectrochemical series, as I$^-$ and μ-Cl$^-$ in Ni(dbaq)$_2$I$_2$, Ni(dcaq)Cl$_2$·H$_2$O and Ni(diaq)Cl$_2$·H$_2$O, respectively.

Magnetic susceptibility measurements

At room temperature the magnetic moment is that expected for a d^8 ion in an octahedral environment and with little orbital contribution for all the compounds(Table 4). Only the

compound $Ni(dcaq)Cl_2$ was measured down to $-196°C$. It follows the Curie-Weiss law with good approximation over the investigated temperature range, with a positive Weiss constant[14,3,12] showing the existence of ferromagnetic interactions among the Ni(II) ions.[11] The non-zero value of the Weiss constant is consistent with the polymeric structure with bridging chloride proposed for it. Several others polymeric Ni(II) complexes with ferromagnetic interactions have been described in the literature.[16]

EXPERIMENTAL

The dcaq, dbaq and diaq ligands were prepared by literature methods.[13,14,15]

For the synthesis of the new complexes we used anhydrous solvents distilled twice from $CaCl_2$. The reactions were carried out in air, except in the preparation of the diaq complexes, for which, because of their ease of oxidation, a nitrogen atmosphere was employed. Analytical Data are consistent with formulae proposed for all of them.

I.r. spectra were obtained in a Beckman IR-20A spectrophotometer using KBr pellets. For the $600-250$ cm^{-1} region, the ratio of KBr to complex was c.a. 1:1 in order to assign metal-ligand bands of small intensity. Electronic spectra were measured in the solid state because of the low solubility of the complexes and the possibility of exchange of the ligand with solvent. They were obtained with a Beckman DU-2 (visible, u.v. and near i.r.) and Beckman 5230 UV (visible and u.v.) spectrophotometers. In some cases we also used diffuse reflectance measurements with a Cary 17 spectrophotometer, with an MgO reference.

The magnetic susceptibility measurements were carried out with a Cahn 2000 electrobalance sensitive to 0.001 mg, a Brucker N-177 electromagnet and an Oxford Instruments CF100 cryostat. Measurements were made for different values of magnetic field.

Complexes $Ni(ligand)X_2 \cdot H_2O$

$NiCl_2(dcaq) \cdot H_2O$.— Dcaq(1g) was dissolved in hot EtOH(40 cm^3); an ethanolic concentrated solution of $NiCl_2 \cdot 6H_2O(1.2g)$ and a drop of HCl 2M were added. The pale blue powder which precipitated was filtered and washed with EtOH and Et_2O, and let to dry in the air. Found: C, 29.9; N, 7.3; Cl, 39.4; H, 2.0; Ni, 16.2 ; Calc.: C, 29.9; N, 7.7; Cl, 39.4; H, 2.2; Ni, 16.3.

$NiCl_2(diaq) \cdot H_2O$.— To a solution of $NiCl_2 \cdot 6H_2O(0.6g)$ in the minimum quantity of hot EtOH, a hot concentrated solution of diaq(1.0g) in EtOH was slowly added. A pale green powder precipitated in the cold. Yield: 85%. Found: C, 20.5; N, 5.2; halogen, 48.2; H, 1.3; Ni, 11.0; Calc.: C, 20.5; N, 5.3; halogen, 48.3; H, 1.2; Ni, 11.2%.

Complexes $NiX_2(ligand)_2$

To a concentrated solution of ligand in hot Me_2CO, a solution of the corresponding Ni(II) salt in the minimum quantity of hot EtOH was added. The powder which precipitated in the cold was filtered and washed with EtOH and Me_2CO and allowed to dry in a desiccator.

$Ni(dcaq)_2(NO_3)_2$. Found: C, 35.5; N, 13.7; Cl, 22.9; H, 2.0; Ni, 9.6; Calc.: C, 35.5; N, 13.8; Cl, 23.3; H, 1.9; Ni, 9.6%.

$Ni(dbaq)_2(NO_3)_2$. Found: C, 27.6; N, 10.4; Br, 18.1; H, 1.6; Calc.: C, 27.5; N, 10.7; Br, 18.0; H, 1.5%.

$Ni(diaq)_2(NO_3)_2$. Found: C, 22.1; N, 8.5; I, 51.9; N, 6.0; Calc.: C, 22.2; N, 8.6; I, 52.1; Ni, 6.0%.

$Ni(dbaq)_2Cl_2$. Found: C, 29.3; N, 7.3; halogen, 29.0; H, 1.7; Calc.: C, 29.5; N, 7.6; halogen, 29.5; H, 1.7%.

$Ni(dbaq)_2Br_2$. Found: C, 26.2; N, 6.9; Br, 25.5; H, 1.5; Calc.: C, 26.3; N, 6.8; Br, 25.9; H, 1.5%.

$Ni(dbaq)_2I_2$. Found: C, 23.6; N, 5.9; halogen, 22.9; H, 1.3; Calc.: C, 23.6; N, 6.1; halogen, 23.2; H, 1.3%.

$Ni(dbaq)_2(NCS)_2$. Found: C, 30.8; N, 10.9; Br, 41.0; H, 1.4; Calc.: C, 30.8; N, 10.8; Br, 41.1; H, 1.6%.

NOTES

The optical resolution of tris(pentane-2,4-dionato)metal(III) complexes

ALEX F. DRAKE, JOHN M. GOULD, STEPHEN F. MASON,* CARLO ROSINI† and FRANCIS J. WOODLEY

Chemistry Department, King's College, London WC2R 2LS, England

Abstract—A facile large-scale optical resolution of neutral [M(pd)₃] complexes, M = Cr(III), Co(III), Ru(III), Rh(III) and Ir(III), through enantioselective complex formation with (2R, 3R)-(−)-dibenzoyltartaric acid, is described.

Liquid column chromatography is the principal method available for the optical resolution of the neutral *tris*(pentane-2,4-dionato) complexes of metal(III) ions, [M(pd)₃].[1-10] With D-(+)-lactose columns 90–480 cm in length at ambient temperature, using gravity elution, the resolutions[1-4] are generally small-scale, partial, and time-consuming, although the efficiency is improved, and the scope of the method is extended to the more optically-labile [M(pd)₃] complexes, by the use of 30 cm columns at low temperature with an elevated pressure above the mobile phase.[5] More recently, short columns of the Δ-(−)-*tris*(1,10-phenanthrolline)nickel(II) complex ion supported on anionic SP-Sephadex.[6] (10 cm) or montmorillonite[7,8] (2.5 cm) are reported to partially resolve the enantiomers of [Co(pd)₃][6,7] and of [Ru(pd)₃],[8] and partial[9] or base-line[10] chromatographic resolutions of [Cr(pd)₃] on a column of chiral *cis*(NO₂)-*trans*(N)-[Co(III)-(amino acid)₂ (NO₂)₂] complex ion salts[9] or of (+)-poly(triphenylmethyl-methacrylate) coated on silica gel[10] have been described.

An alternative stationary phase, consisting of (2R, 3R)-(−)-dibenzoyltartaric acid, (−)-DBT, adsorbed on alumina has been investigated for the optical resolution of racemic [M(pd)₃] complexes using a cyclohexane-benzene (2:1) mobile phase. With a system[11] for the simultaneous monitoring at a given analytical wavelength of the absorbance (A) and the differential circularly-polarised absorbance ($\Delta A = A_L - A_R$) of a chiral solute in the eluate from a liquid chromatography column, it was found, in the attempted resolution of racemic [Rh(pd)₃], that the optical activity of the two enantiomers in the eluate from the (−)-DBT/Al₂O₃ column do not sum to zero over the chromatogram as a whole (Fig. 1). The chromatographic resolution is partial, and, while one enantiomer, the Λ-isomer, is wholly eluted, a substantial fraction of the other (∼40%) is retained by the stationary phase, from which it is stripped, together with much of the (−)-DBT, by ethanol.

The further investigation of the strongly enantioselective complex formed by (−)-DBT with the Δ-isomer of neutral [M(pd)₃] coordination compounds afforded a general method for the large-scale optical resolution of racemic [M(pd)₃] complexes (Table 1). A typical resolution procedure is as follows: Racemic [Co(pd)₃] (3.56 g, 10 mmol), (2R, 3R)-(−)-dibenzoyl-tartaric acid monohydrate (9.4 g, 25 mmol), benzene (60 cm³), and cyclohexane (120 cm³), were stirred at ambient temperature for two days. Over this period, approximately one-half of the total [Co(pd)₃] was taken up by the formation of a solid (−)-DBT-Δ-[Co(pd)₃] phase, leaving a supernatant fluid phase containing Λ-[Co(pd)₃] with an optical purity of ∼90%, indicated by absorption and CD spectroscopy. The same result is achieved -more expeditiously by employing anhydrous (−)-DBT, rather than the monohydrate. The solid crystalline complex, (−)-DBT-Δ-[Co(pd)₃], filtered and washed with a cyclohexane-benzene (2:1) mixture, is taken up into chloroform solution, from which the (−)-DBT is extracted with aqueous sodium bicarbonate. Following the removal of the

Δ-[Ir(pd)₃]	312	9,950	362	+36.8	+7.88
	260	24,000	306	−18.8	−1.93

solvent from the dried chloroform solution and recrystallisation of the residual solid, 1.3 g of optically pure Δ-(+)₅₄₆-[Co(pd)₃] is obtained with the cd characteristics listed (Table 1).

The original filtrate, containing the corresponding Λ-isomer, is washed with aqueous sodium bicarbonate and dried. The solid remaining after the removal of the solvent is ~90% optically pure and it is difficult to enhance that percentage purity further by standard fractional crystallisation, since the solubility of the enantiomer is approximately an order of magnitude larger than that of the racemate in paraffin and chloro-solvents. However, slow recrystallisation from a 2 : 1 mixture of petroleum (b.p. 80–100°) and dichloromethane affords two sets of large morphologically-distinct single crystals, which are readily separable by hand-sorting. Each crystal of the major set contains optically-pure Λ(−)₅₄₆-[Co(pd)₃], with an optical activity equal in magnitude and opposite in sign to that of the Δ-isomer isolated from the solid crystalline complex with (−)-DBT (Table 1).

The procedure provides in addition a simple optical resolution on a >1 g scale of the racemic complexes, [Cr(pd)₃], [Rh(pd)₃], [Ru(pd)₃], and [Ir(pd)₃] (Table 1). The determination of the absolute configuration of Λ-(−)₅₄₆-[Co(pd)₃][12] and Δ-(−)-[Cr(pd)₃][13] by X-ray diffraction methods, and the corresponding cd spectra, indicate that the enantiomer selectively forming a crystalline complex with (−)-DBT is the Δ-isomer in each case. The same conclusion follows for the cases of [Ru(pd)₃] and [Rh(pd)₃] from a comparison of the cd spectra of the resolved isomers with the corresponding spectra of each of the four diastereomers, with a known configuration, of the tris[(+)-3-acetylcamphorato] complexes of Ru(III)[14] and Rh(III)[15]. The consistency between these four cases suggests that the enantiomer of other [M(pd)₃] compounds selectively forming a complex with (−)-DBT is the Δ-isomer.

The fractional optical purity of a chiral compound is measured by the dissymmetry ratio ($g = \Delta\epsilon/\epsilon = \Delta A/A$) at an analytical wavelength, relative to the corresponding g-ratio of one of the pure enantiomers. The g-ratios of the [M(pd)₃] enantiomers listed (Table 1) refer in each case to a single-crystal sample, in order to ensure enantiomeric purity. In a chromatographic optical resolution, a finite g-ratio constant with respect to elution volume

indicates that the chiral solute in the eluate is optically pure.[11] On this criterion, the chromatographic resolution of [M(pd)₃] complexes on a (−)-DBT/Al₂O₃ column is not efficient (Fig. 1), although the investigation of the method provided the basis for the more efficient large-scale procedure described. An analogous enantioselective complex formation probably underlies the partial resolution of [Co(pd)₃] by the zone-melting of a frozen solution of the racemic complex and sodium (−)-dibenzoyl-tartrate in dioxan-water.[16]

Abstract—$Rh_6(CO)_{10}[(−)DIOP]_3$ has been isolated after ligand exchange between $Rh_6(CO)_{16}$ and DIOP. The molecular cluster is an efficient catalyst for asymmetric reduction of various prochiral olefins; optical yields up to 47% have been achieved; the results are compared with those obtained with mononuclear rhodium (I) complexes.

Although polynuclear complexes constitute now a new generation of organometallic complexes, their use in catalysis is still rare.[1] Moreover, within a few exceptions,[2] there are no reported cases of true cluster catalysed reaction, although molecular clusters are often used as precursor complexes.[3] One possibility to prove the reality of a cluster catalysed reaction is to use chiral clusters[4] the chirality being due to the cluster metallic framework. However, under catalytic condition, racemization may occur, which makes it difficult to induce an asymmetric catalytic reaction.[4a] Another possibility is to use chiral ligands with chiral metallic framework. But in this latter case, interpretation of the results is more difficult. In our general approach of cluster catalysis,[1] we have recently shown that rhodium clusters of the type $Rh_6(CO)_{(6−x)} L_x^{5−6}$ are catalysts for olefin hydrogenation and spectroscopic as well as kinetic data suggested that the cluster itself could act as a catalyst. It was therefore reasonable to undertake an asymmetric hydrogenation with the same family of complexes bearing chiral ligands. In the mean time Balavoine *et al.*[7] as well as Dang *et al.*[8] reported asymmetric hydrogenation of various olefins with an *in situ* mixture of $Rh_6(CO)_{16}$ and various chiral ligands. In our approach of such asymmetric reaction, we started from the cluster $Rh_6(CO)_{10}[(−)DIOP]_3$ and found effectively an asymmetric induction in the hydrogenation of various prochiral olefins.

There are already two reported cases of asymmetric hydrogenation with Ru clusters bearing DIOP ligands such as $H_4Ru_4(CO)_8[(−)DIOP]_2$ and $Ru_6(CO)_{18}[(−)DIOP]_3$. Infrared data indicate no significant change of the structure of the cluster during the catalytic reaction.[9]

RESULTS

$Rh_6(CO)_{10}[(−)DIOP]_3$ was prepared from $Rh_6(CO)_{16}$ and 3 equivalent of (−)DIOP in boiling benzene and purified by HPLC (column: styragel 500 Å; eluent: toluene) (yield = 33%). The elemental analysis and molecular weight were consistent with the formulation $Rh_6(CO)_{10}[(−)DIOP]_3(A)$. The IR spectrum of (A) exhibits $\nu(CO)$ bands at 2073 (w), 1972 (s, br) in the linear region and 1810 and 1780 (s, br) in the bridging region. Obviously the real structure of the cluster cannot be assumed with certitude unless X-ray structure is known.[11] However, considering the structure of the parent cluster $Rh_6(CO)_{10}(dppm)_3$,[10] it is likely

that in our case, probably due to steric crowding by the chiral ligands, the bridging CO ligands are hypothetically edge bridging.

This complex is stable in the solid state in the air, but less stable in solution.

Standard hydrogenation experiments were carried out with this cluster using amino-acid precursors and itaconic acid. The optical yields achieved in our experiments are listed in Table 1.

Generally speaking, in contrast with the results obtained with mononuclear complexes of $Rh(I)(DIOP)^{12}$ the acid substrates are reduced with lower asymmetric induction than the esters. Besides although the same enantiomer is obtained using (A) or Rh(I)(DIOP) complexes, the e.e. are lower in the first case. The value obtained for α-acetamido cinnamic acid, is identical to that obtained by Balavoine *et al.*[7] using a mixture of $Rh_6(CO)_{16}$ and 3 equivalents of (−)(DIOP). The temperature seems to have no influence on the enantioselectivity, but, in presence of UV-irradiation, there is an increase of the rate of hydrogenation (80% hydrogenation in 5 hr), but a drastic decrease in the enantioselectivity.

In conclusion these preliminary results constitute the first example of an asymmetric reduction using a rhodium cluster bearing chiral ligand. Although the catalytic behavior of $Rh_6(CO)_{10}[(−)DIOP]_3$ is different from the known mononuclear complexes of the type $Rh^I[(−)DIOP]$, (rate of hydrogenation, type of substrate which are hydrogenated, e.e.). The enantiomer obtained is the same in both cases. It is therefore difficult to make a clear cut distinction between a true cluster catalysed reaction and a catalysis by a mononuclear fragment. Studies are in progress to try to understand at a molecular level the mechanism of such reaction.
EXPERIMENTAL

¹H NMR spectra were recorded on a Brucker 80 spectrometer, IR spectra were taken with a Perkin–Elmer 225 spectrometer in various solvents. The cluster was purified by HPLC using a Watters M 6000 A. The column was a micro styragel (500 Å) of 50 cm, used in semi-preparative scale (solvent: toluene flow = 1 ml/min; temperature 25°C). The rotatory powers were measured on a Perkin–Elmer 241 polarimeter. Molecular weight determination of the cluster was carried out by vapor pressure osmometry. Catalytic hydrogenations were carried in a glass batch reactor equipped with a septum for kinetic measurements and connected with a hydrogen reservoir kept at constant atmospheric pressure.

(b) Hydrogenation in the presence of U.V. irradiation. $\rangle$(max) = 365 nm

(c) Enantiomeric excesses were calculated using the specific rotation of the pure enantiomers :

N - acetyl - (R) - Phenylalanine $[\alpha]_D^{25}$ = - 46.0 (c = 1 ; EtOH) (13).

N - acetyl - (R) - Phenylalanine methyl ester $[\alpha]_D^{25}$ = - 101.5 (c = 1 ; CHCl₃) (14)

N - acetyl - (R) - phenylalanine ethyl ester $[\alpha]_D^{25}$ = - 85.9 (c = 1 ; CHCl₃) (14)

N - benzoyl (S) - phenylalanine methyl ester $[\alpha]_D^{25}$ = - 45.3 (c = 1 ; EtOH) (13)

(R) Methyl - succinic acid $[\alpha]_D^{20}$ = + 16.88 (c = 2.1 ; EtOH) (15)

Preparation of $Rh_6(CO)_{10}[(-)DIOP]_3$

In a typical experiment 1.4 g (2.8 10⁻³ mole) of (−)DIOP dissolved in 100 cm³ of C_6H_6 is introduced dropwise under stirring in 70 cm³ of a refluxing solution of benzene containing 1 g of $Rh_6(CO)_{16}$ (9.4 10⁻⁴ mole).

After cooling to 25°C, the solution is concentrated under vacuum and the cluster is precipitated by addition of 30 cm³ of *n*-pentane. Purification by HPLC yields a black amorphous solid (33% yield). Found: C, 48.08; H. 3.97; P, 7.86; Rh, 25.9; mol. wt., 2475. $C_{103}H_{96}P_6Rh_6O_{16}$ calc.: C, 51.68; H, 4.04; P, 7.78; Rh, 25.8; md. wt., 2393. IR spectrum: $v(CO)$ bonds (chloroform solution) at 2073 (w), 1972 (s, br), 1810 (s, br), 1780 (s, br).

Hydrogenation procedure

In a typical experiment 13 mg of (A) (5.10⁻⁶ mole) and 10⁻³ mole of the olefinic substrate are vigorously stirred in 25 cm³ of ethanol under 1 atm. of H_2. The reaction is monitored by the absorption of H_2 with time and by quantitative analysis of the reactants by GLC. The hydrogenated products are treated as previously described.[12]

Synthesis and structural characteristics of fac-ReCl₃[P(OEt)₃]₃ a route to the phosphite complexes

W. K. RYBAK* and J. J. ZIÓŁKOWSKI

Institute of Chemistry, Wrocław University, Joliot Curie 14, 50-383 Wrocław, Poland

Abstract—Reaction of the oxo-complex $ReOCl_3(PPh_3)_2$ with an excess of triethylphosphite yields a deoxygenated rhenium phosphite complex fac-$ReCl_3[P(OEt)_3]_3$; its structure was confirmed by ^1H NMR and IR spectroscopy.

The chemistry of rhenium phosphine complexes is well developed,[1] contrary to that of the phosphite complexes. Such complexes of rhenium and other metals have recently been given considerable attention.[2] In continuation of our studies on reactivities of rhenium phosphine complexes[3] we have been interested in synthesis of the respective phosphite complexes having in mind different properties of that ligand.

The present paper reports a convenient method for synthesis of phosphite complexes from their respective metal phosphine oxo derivatives taking the rhenium complexes as an example (reaction 1).

trans-ReOCl₃(PPh₃)₂ + 3 P(OEt)₃ → fac-

(I)

ReCl₃[P(OEt)₃]₃ + P(O)Ph₃ + PPh₃   (1)

(II)

The authors believe that this method can be used for other transition metal oxo-complexes (e.g. Tc, Mo, W), due to the strong deoxygenating properties of the phosphine ligand.[1b,4] Reaction (1) in which rhenium (V) is reduced to rhenium (III) with simultaneous substitution of the phosphine ligand is probably preceded by isomerization† of the yellow trans complex (I) to a green cis complex (I) in which the oxygen atom and phosphine ligand are in trans positions.[5]

The reaction of complex (I) (3.6 mmol) and a ten-fold excess of P(OEt)₃ carried out in boiling benzene solution (60 cm³) under nitrogen for 7 hr yields a light yellow solution containing the products of reaction (1) in about 100% yield. The excess of free P(OEt)₃ was removed by prolonged evaporation of the mixture to dryness in vacuo. P(O)Ph₃ was separated from other components of the reaction mixture as a hexane-insoluble residue. Free phosphine was separated from complex (II) by means of

column chromatography using activated silica gel (350°C for 4 hr in vacuo) as packing and hexane-benzene, benzene and finally, benzene – 10% methanol as eluents, under oxygen-free conditions. Complex (II) was recrystallized from hexane (– 15°C) [Found: C 27.1, H 5.58, P 11.7%; $C_{18}H_{45}O_9Cl_3P_3Re$ requires: C 27.22, H 5.73, P 11.74%].

The structure of the facial complex (II) is confirmed by both the IR and ^1H NMR spectra. Over the frequency range characteristic of the Re–Cl bonds, complex (II) exhibits two strong bands in the IR region at 269 and 314 cm⁻¹, which indicates C_{3v} symmetry. By comparison, we find that mer-ReCl₃(PMe₂Ph)₃, of C_{2v} symmetry, has a more complicated IR spectrum in that region. Like rhenium (III) complexes with phosphine ligands,[6a] complex (II) is paramagnetic; however, quite sharp lines are found in the ^1H NMR spectrum in deuterobenzene at 30°C. Predictably, marked isotropic shifts are also observed. The integrated spectrum contains two triplets (intensity ratio 2:1, CH₃, δ 2.25 ppm, 3H and δ 3.12 ppm, 6H) and two quartets (2:1, CH₂, δ 10.07 ppm, 2H and δ 11.15 ppm, 4H). The coupling constant for the protons of two groups ^3J (H–H) = 7 Hz. The coupling constant ^3J(P–H) of 7 Hz for free P(OEt)₃ is not observed for a coordinated ligand. This spectrum shows that all three phosphite ligands in complex (II) are equivalent, although the ethoxy groups are inequivalent to each other in a (2:1) ratio. From among three ethoxy groups for each phosphite ligand, two groups are on one side of the plane determined by the three phosphorus atoms coordinated to the rhenium atom, whereas the third ethoxy group is on the other side of that plane.

The facial geometry of complex (II) is most probably the effect of a smaller cone angle of the phosphite ligand and of its stronger π-acceptor properties as compared with the phosphine ligand which instead prefers meridional geometry in similar known ternary complexes.[6]

Complex (II) undergoes no exchange reaction of the phosphite ligand (on the NMR time scale at 80°C) but may, however, be reduced (NaBH₄/EtOH) to yield monomeric and dimeric hydride complexes.

Reductive Nitrosylation Of Tetraoxometallates. Part V[1]. Single Pot And A Virtually Single Step Synthesis Of Chromium(1) Cyanonitrosyl Derivatives Directly From Chromate(VI) In Aqueous-Aerobic Media.

R. G. Bhattacharyya,* G. P. Bhattacharjee and (Mrs.) N. Ghosh
Department of Chemistry, Jadavpur University,
Calcutta 700 032, India.

Abstract : Cyanonitrosyl complexes and their derivatives of the types $[Cr(NO)(CN)_4]^{2-}$, $[Cr(NO)(CN)_3H_2O]^-$ and $[Cr(NO)(CN)_2 LL]$ [LL = 2,2' bipyridine (bipy) or 1, 10-Phenanthroline (phen)] are synthesised directly from CrO_4^{2-} using $NH_2OH.HCl$, OH^- and CN^- and other appropriate ligands, virtually in a single step process in an aqueous aerobic medium. The compounds are characterised by IR, molar conductance, magnetic susceptibility, e.s.r, electronic spectra and thermoanalytical data.

INTRODUCTION : Single step conversion of tetraoxometallates to the cyanonitrosyl derivatives, (viz, [$M(NO)(CN)_2 LL$] where LL is a bidentate ligand or two unidentate ligands) is still unknown. Sarkar et al[2] have reported the synthesis of the cyanonitrosyl derivatives of Fe and V starting from $[Fe(NO)(CN)_5]^{2-}$ and $[V(NO)(CN)_6]^{4-}$ respectively in a boiling acetic acid medium followed by thermolysis of the anionic complexes. We have described single step synthesis of the thiocyanato nitrosyl derivatives of Cr (Ref. 3), Re (Ref. 1a) and Mo (Ref. 1b) directly from CrO_4^{2-} , ReO_4^- and MoO_4^{2-} respectively. Herein is described, for the first time, a single pot and a virtually single step synthesis of the hitherto unknown cyanonitrosyl derivatives of formally Cr(1) of the types $[Cr(NO)(CN)_2 LL]$ (LL = bipy or phen) and the anionic complexes of the types $[Cr(NO)(CN)_4]^{2-}$ and $[Cr(NO)(CN)_3H_2O]^-$ directly from CrO_4^{2-} in aqueous aerobic media.

EXPERIMENTAL :

Preparation of the complexes - In a solution of KOH (3 g in 20 ml of H_2O) were added K_2CrO_4 (0.5 g, 2.6 mmol) and KCN (2.5 g, 38.6 mmol) and the mixture was stirred for 5 min at ~ 80°. To this solution, $NH_2OH.HCl$ (2.7 g, 38.6 mmol) was added portionwise with constant stirring at ~80° and the stirring was continued for another 45 min to get a yellowish green solution. This was cooled to room temperature (pH = 10.5) (solution A) and then pH was adjusted to ~5 with 6 M HCl. (solution B).

1. $(Ph_4P)_2 [Cr(NO)(CN)_4].H_2O$ - An aqueous solution of $(C_6H_5)_4PCl$ (2.4 g, 6.4 mmol in 25 ml of water) was added to the solution B obtained above with constant stirring at room temperature to yield a bright yellow precipitate. The stirring was continued for 30 min , allowed to settle and filtered. The yellow residue was washed thoroughly with water, dried over

P_4O_{10} and then washed with ether and finally dried over fused $CaCl_2$ in vacuo. The compound was recrystallised twice from acetonitrile-ether mixture. Yield 1.65 g, 72 %. M. Pt 150°. Found : C, 71.1 ; H, 4.6 ; N, 8.3 ; P, 7.5 ; Cr, 5.2 ; H_2O (lost at 80°, exothermic), 2.2 . $C_{52}H_{40}P_2O$ $N_5Cr.H_2O$ requires C, 70.7 ; H, 4.5 ; N, 7.9 ; P, 7.0 ; Cr, 5.9 ; H_2O, 2.0 %. IR : ν_{CN} 2110 (s) , 2150 (sh) ; ν_{NO} 1670 (s) and $\nu_{Cr-N}(NO)$ 620 (w) cm^{-1}. λ_{max} 710 (sh), 448 (sh) and 340 (sh) nm. μ_{eff} = 1.9 B.M. Λ_m = 230 ohm^{-1} cm^2 mol^{-1} in acetonitrile.

2. (Me_4N) $[Cr(NO)(CN)_3$ $H_2O]$ – To a solution of $(CH_3)_4NCl$ (0.42 g, 3.8 mmol in 5 ml of water) was added the above solution (solution B) with constant stirring at room temperature for 30 min . A greenish yellow precipitate was obtained which was filtered off, washed with methanol and dried over fused $CaCl_2$ in vacuo. The dried product was further recrystallised from water-methanol mixture. Yield 0.54 g, 83 %. Found : C, 33.0 ; H, 5.1 ; N, 27.2 ; Cr, 20.1 ; H_2O (130°, exothermic), 7.0. $C_7H_{12}N_5O$ $Cr.H_2O$ requires C, 33.3 ; H, 4.8 ; N, 27.8 ; Cr, 20.6 ; H_2O, 7.1 %. IR : ν_{CN} 2120 (s) ; ν_{NO} 1665 (s) and ν_{Cr-N} (NO) 620 (w) cm^{-1}. λ_{max} 740 (30.0), 450 (105) and 344 (sh) nm . μ_{eff} = 1.7 B.M. Λ_m = 130 ohm^{-1} mol^{-1} cm^2 in water.

3. $(Me_4N)_2[Cr(NO)(CN)_4].H_2O$ – Instead of adjusting the pH of the solution A to ~5, the same was adjusted at 7.5 and this solution was added to an aqueous solution of $(CH_3)_4$ NCl (0.7 g, 6.4 mmol in 5 ml of water) with constant stirring at room temperature for 30 min. An yellowish green precipitate was obtained which was filtered, washed with methanol, ether and dried in vacuo. The dried product was recrystallised from water-methanol mixture. Yield 0.6 g, 65 %. Found : C, 41.3 ; H, 7.1 ; N, 27.4 ; Cr, 14.6 ; H_2O (85°, exothermic), 4.9 . $C_{12}H_{24}N_7O$ $Cr.H_2O$ requires C, 40.9 ; H, 6.8 ; N, 27.8 ;.Cr, 14.8 ; H_2O , 5.1 %. IR : ν_{CN} 2120 (s), 2140 (s) ; ν_{NO} 1670(s); ν_{Cr-N} (NO) 615 (w). λ_{max} 744 (30), 452 (110) and 340 (sh) nm. μ_{eff}=1.7 B.M. Λ_m= 246 ohm^{-1} cm^2 mol^{-1} in water.

4. $[Cr(NO)(CN)_2(bipy)].H_2O$ – To the solution B obtained above was added a hot aqueous solution of 2,2'-bipyridine (0.6 g, 3.8 mmol) with constant stirring for 30 min at ~80°. A brown precipitate was obtained which was filtered, washed with water, ethanol, ether and dried in vacuo. The dried product was recrystallised from dimethylformamide-ether mixture. Yield 0.46 g, 58 %. Found : C, 47.1 ; H, 2.9 ; N, 23.2 ; Cr, 16.3 ; H_2O (80°, exothermic), 5.7 . $C_{12}H_8N_5O$ $Cr.H_2O$ requires C, 46.8 ; H, 2.6 ; N, 22.7 ; Cr, 16.9 ; H_2O , 5.8 %. IR : ν_{CN} 2120 (w) and 2150 (w) ; ν_{NO} 1690 (s); $\nu_{Cr-N}(NO)$ 610(w) λ_{max} 716 (sh), 460 (sh) and 372 (sh) nm. μ_{eff} = 1.8 B.M.

5. $[Cr(NO)(CN)_2(phen)].H_2O$ – Same as described under bipy complex. Yield 0.55 g, 64 %. Found : C, 51.0 ; H, 2.5 ; N, 20.8 ; Cr, 15.4 ; H_2O (80° , exothermic), 5.2 . $C_{14}H_8N_5O$ $Cr.H_2O$ requires C, 50.6 ; H, 2.4 ; N, 21.1 ; Cr, 15.7 ; H_2O, 5.4 %. IR : ν_{CN} 2120 (w), 2150 (w) ; ν_{NO} 1690 (s); ν_{Cr-N} (NO) 620 (w). λ_{max} 716 (sh), 456 (sh); 380 (sh) nm. μ_{eff} = 1.8 B.M.

RESULTS AND DISCUSSION :

The cyano complexes very naturally undergo dissociation at a lower pH ($\sim$5) and lead to the isolation of [$Cr(NO)(CN)_3$ H_2O]$^-$ or [$Cr(NO)(CN)_2$ LL] but at a somewhat higher pH, [$Cr(NO)(CN)_4$]$^{2-}$ is formed when the cation is a tetramethyl ammonium ion. With the tetraphenyl phosphonium cation, however, [$Cr(NO)(CN)_4$]$^{2-}$ could be isolated even from a solution of pH$\sim$5, as well as at a neutral pH ($\sim$7), but not from the solution A. Also, while the potassium salt of the cyanonitrosyl complex is of the type K_3 [$Cr(NO)(CN)_5$] (Ref. 4), only the dianionic complex is formed in the case of the bulky and charge delocalised tetraphenyl phosphonium cation. Moreover, the thiocyanate analogue being a trianion, viz, [$Cr(NO)(NCS)_5$]$^{3-}$ with tetraphenyl phosphonium cation, the high π - trans effect of the NO^+ ligand prevents the formation of such a type of cyano complex with the same charge delocalised cation. These molecular formulae are also supported from the electrolytic conductance data of the complexes ; 4 and 5 being non electrolytes, 2 is a 1 : 1 and 1 and 3 are 2 : 1 electrolytes[5] in the respective solvents (see the experimental section). Only in the case of the complex 2, a single and sharp ν_{CN} band (as against two bands in all other cases) is observed and this may be due to its TBP structure containing equatorial cyano ligands. Considering the NO^+ formalism the formal oxidation state of chromium should be +1 which is evident from the magnetic moment and the e.s.r. ($g_{av} \approx 1.9$) data of all the complexes[3,6]. The $d_{(metal)} \longrightarrow \pi^*(NO)$ transition[7] in the electronic spectra of the isolated complexes are at a lower wave number region than those of the thiocyanate derivatives[3]. This may be due to larger crystal field splitting involving stronger CN^- ligand. Only the compound 2 loses water at a higher temperature (130°) compared to the other complexes (ca 80°) as revealed by their TGA, DTA and DTG curves, and so in the former complex, water is considered to be within the coordination sphere.

COMMUNICATION

COMPLEXES OF COPPER AND SILVER WITH TETRACYANOBIIMIDAZOLE

Paul G. Rasmussen* and James E. Anderson
Department of Chemistry
The University of Michigan
Ann Arbor, Michigan 48109

We have recently reported the synthesis and properties of a remarkable new ligand 4,4',5,5'-tetracyano-2,2'-biimidazole (H_2Tcbiim).[1] This acidic ligand readily binds metal ions in its dianionic form and appears to act as a strong pi acceptor. Its use as a quadridentate bridging ligand allows study of metal-metal interactions through a planar conjugated system and extends earlier work by us[2] and by Hendrickson and coworkers[3] on 2,2'-biimidazole. In this communication we report on the reactions of H_2Tcbiim with Ag(I), Cu(I) and Cu(II) salts.

The silver(I) and copper(I) complexes have the general formulae $(M_{py})_2$Tcbiim and $[M(bpy)]_2$Tcbiim where py = pyridine and bpy 2,2'-bipyridine and M = Cu, Ag. The compound $[Cu(P\phi_3)_2]_2$ Tcbiim has also been prepared where $P\phi_3$ is triphenyl phosphine. The Cu(II) compounds are $Cu(py)_2$Tcbiim, Cu(bpy)Tcbiim and $[(Cu - diene)_2$Tcbiim]$(NO_3)_2$ where diene = diethylenetriamine. All of these compounds can be made in high yield; they have been characterized by analytical, spectroscopic and magnetic techniques.

The syntheses of these compounds are straightforward. To a solution of the metal nitrate salt in acetonitrile an excess of L is added, L = bpy, py for Cu and Ag and L = $P\phi_3$ for Cu only. A stoichiometric amount of H_2Tcbiim dissolved in acetonitrile is then added, the solution is stirred for 2 hours and the resulting complexes precipitate. The Cu(I) nitrate is

*Author for correspondence

formed <u>in situ</u> in acetonitrile by the reduction of $Cu(NO_3)_2$ with Cu metal. Attempts to synthesize Ag(II) complexes containing Tcbiim^{2-} resulted in the formation of the corresponding Ag(I) complex. In a typical reaction a silver(II) salt, such as $Ag(bpy)_2S_2O_8$ would react with H_2Tcbiim in a 1:1 mole ratio to form $Ag_2(bpy)_2$Tcbiim and unidentified oxidation products.

The copper(II) compounds are made in a similar way. Copper(II) nitrate was dissolved in methanol, a excess of L is added, where L = bpy, py and diene. A stoichiometric amount of H_2Tcbiim, dissolved in methanol, is then added and after two hours the green product is collected.

The structural evidence for the dimers is clearest in the case of the $[(P\phi_3)_4Cu_2]$Tcbiim (Figure 1). C^{13} NMR shows three
Figure 1.   Proposed structure of $[(P\phi_3)_4Cu_2]$Tcbiim, phenyl rings omitted for clarity.

signals at 151.2, 119.6, and 113.4 ppm relative to Me_4Si indicating a symmetrically bridged tetracyanobiimidazole. ^{31}P NMR gives only one signal showing equivalent phosphines. The IR spectrum shows a sharp singlet due to nitrile at 2220 cm^{-1}. The low solubility of the other Cu(I) compounds precludes good NMR.

<div align="center">

(py)Cu(Tcbiim)Cu(py)   (bpy)Cu(Tcbiim)Cu(bpy)

I   II

</div>

Compound I appears from stoichiometry to contain three coordinate copper. Furthermore, the nitrile stretch in the IR at 2220 cm^{-1} is unsplit. Compound II could be three coordinate in two ways, a) monodentate bpy and symmetrically bonded to $Tcbiim^{2-}$ or b) bidentate to bpy and coordinated to $Tcbiim^{2-}$ only once. We favor case b) since the nitrile peak at 2220 cm^{-1} shows a reasonable splitting (~ 10 cm^{-1}) suggesting inequivalent nitrile groups. It appears that univalent copper is satisfied with three coordination when the strongly pi accepting phosphines are absent but increases to four when they are present. We are pursuing this model of behavior by trying to effect further syntheses. Polymeric structures cannot be ruled out however at this time.

The Cu(II) dimer is directly analogous to those synthesized by Hendrickson.[3] Since biimidazole was found to give weak magnetic coupling between the copper ions, it was of interest to see if the tetracyanobiimidazole bridge enhances the interaction. Room temperature magnetic moment measurements were used to give a preliminary assay, and the value of $\mu = 1.58 \pm .05$ BM per mole of Cu, is indication of significant interaction. A more definitive study is underway.

The fact that Tcbiim^{2-} will act as a bridging group in both
Cu(I) and Cu(II) systems is noteworthy. It suggests the possi-
bility of preparing mixed valence dimers which, if the coordin-
ation geometry is properly contrived, can sustain substantial
interaction through the bridge. Pairs of Cu(II) ions bridged by
imidazoles have been extensively reported on as models for active
sites in enzymes.[4] The compounds described here offer further
examples of such model systems, which can be synthesized under
significantly less basic conditions than those previously ob-
served. Work on both these aspects is continuing.

POLYHEDRON REPORT NUMBER 4

THE REACTIONS OF NUCLEOPHILES WITH COMPLEXES OF CHELATING HETEROCYCLIC IMINES; A CRITICAL SURVEY

EDWIN C. CONSTABLE

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, England

CONTENTS

INTRODUCTION

Coordination chemistry has traditionally been concerned with the effects that ligands may have upon the properties of metal ions, but it has become increasingly evident that coordination to a metal also results in a profound modification of the reactivity of a ligand. This review is concerned with the reactivity of α,α'-diimine complexes with nucleophiles, and endeavours to interpret the available data and mechanistic proposals in a unified manner.

It is well established that electron-deficient aza-heterocycles may react with water to form "covalent hydrates" in which the oxygen atom of the water molecule is covalently bonded to a ring carbon atom of the heterocycle (Fig. 1).[1-3]
Fig. 1.

As shown in the figure, deprotonation of the covalent hydrate may occur, to give the conjugate base. Obviously, the position of equilibrium for the formation of the covalent hydrate will depend upon the particular heterocyclic system being studied, but, in general, protonation or quaternisation of a ring nitrogen atom increases the electron-deficiency, and results in a greater equilibrium concentration of the covalent hydrate. Other nucleophiles may also attack electron-deficient heterocycles, as, for example, in the formation of a neutral pseudobase in the reaction of hydroxide ion with the 1,5-naphthyridinium cation (Fig. 2).
Fig. 2.

This is reminiscent of Meisenheimer complex formation between nucleophiles and other electron-deficient systems, such as aromatic nitro compounds (Fig. 3) and it is evident that covalent hydration, pseudobase formation and Meisenheimer complex formation are very closely related,[1-1/] although this close interrelation has only recently been explicitly stated.[10]
Fig. 3.

In recent years, Gillard and others have proposed that coordination of a heterocycle to a transition metal ion has an effect similar to quaternisation, and that such coordinated heterocycles are activated towards attack by nucleophiles.[11] These proposals have met with some criticism, and this review hopes to assess the evidence which has been presented for such activation. Much of the spectroscopic and structural evidence which has been reported relates to square-planar platinum complexes, and this review will accordingly discuss such systems in some detail. The current interest in α,α'-diimine complexes of transition metal ions as components of solar energy conversion systems has emphasised the need for an understanding of the reactions of such complexes, and the second part of the review will discuss the evidence presented for nucleophilic attack upon octahedral complexes of α,α'-diimines.

Throughout this review the following abbreviations will be used

bipy	2,2'-bipyridine
bipym	2,2'-bipyrimidine
Me$_2$bipy	dimethyl-2,2'-bipyridine
Me$_2$phen	dimethyl-1,10-phenanthroline
dmso	dimethyl sulphoxide
en	1,2-diaminoethane
5-nitrophen	5-nitro-1,10-phenanthroline
phen	1,10-phenanthroline
py	pyridine
pym	pyrimidine
terpy	2,2':6',2''-terpyridine
tpt	2,4,6-(2-pyridyl)-1,3,5-triazine

REACTIONS OF THE FREE LIGANDS

Aqueous or mixed aqueous solutions of bipy show a weak absorption band at 306 nm, which is associated with a strong fluorescence centred at 328 nm, and this has been interpreted in terms of covalent hydrate formation.[12] However, more recent studies by Kotlicka and Grabowski, have shown that this behaviour is due to the formation of an intensely fluorescent zinc complex, the metal ions being leached from the glassware.[13] No evidence has been presented for the covalent hydration of phen, and the suggestion that the well-known monohydrate might be a covalent hydrate, rather than a hydrogen-bonded system, appears to be unlikely.[11] 5-Nitrophen has been shown to undergo easy, complete reaction with nucleophiles to produce the corresponding Meisenheimer adducts, although it may be noted that these compounds are unstable, and undergo further, degradative, reactions.[14-16] It is of interest that bipy will reach with powerful nucleophiles, and treatment with alkyllithium reagents leads to the formation of 6- and 6,6'-alkyl substituted derivatives.[17-19]

A number of workers have investigated the reactions of cyclic diquaternary salts of bipy and phen with hydroxide, and the reported K_{eq} values are consistent with pseudobase formation.[16,20,21] It is perhaps relevant to note that the 1-methylphenanthrolinium cation shows no observable interaction with hydroxide ion at pH 14,[20] and that there is no evidence for the formation of pseudobases of the 1-methylpyridinium cation.[10]

Williams and his co-workers have reported the results of INDO molecular orbital calculations for a series of α,α'-diimines, and these confirm that the carbon atom adjacent to a ring-nitrogen is indeed electron-deficient, although they make no quantitative prediction of the ease of attack at this position.[22]

REACTIONS OF SQUARE-PLANAR COMPLEXES WITH NUCLEOPHILES

Substitution reactions of square-planar complexes

$$[ML_3X] + Y^- \longrightarrow [ML_3Y] + X^-.$$
Reactions of this type have been widely investigated, and it is well established that the reaction proceeds via a five-coordinate species, which may be a true intermediate, or merely a transition state.[23,24] The rate expression for such a substitution reaction is of the form:

$$\rho = k_{obs}[ML_3X]$$

where

$$k_{obs} = k_s + k_y[Y].$$

This rate dependence indicates the operation of two parallel pathways, the pseudo first-order term arising from the formation of a five-coordinate solvo-complex:

$$[ML_3X] + S \xrightarrow{k_s} [ML_3XS] \xrightarrow{fast} products$$
and the second order term from:

$$[ML_3X] + Y \xrightarrow{k_y} [ML_3XY] \xrightarrow{fast} products.$$

It is within this framework that any assessment of the addition of nucleophiles to square-planar complexes of platinum and palladium must be made, and we shall now discuss the evidence which has been presented for the reactions of such complexes.

Bis(2,2'-bipyridine)platinum(II)

Aqueous solutions of $[Pt(bipy)_2]^{2+}$ show rapid (initially) reversible changes in their electronic spectra upon the addition of hydroxide ions, changes which are associated with two isosbestic

points.[11,25-31] Similar changes in the electronic spectrum are observed on the addition of halide or pseudohalide ions to aqueous solutions or of methoxide to methanolic solutions of $[Pt(bipy)_2]^{2+}$,[30,31-33] and also upon the addition of hydroxide to aqueous solutions of $[PtL_2]^{2+}$ (L = 5,5'-Me$_2$bipy).[11,25,27,29-31] On treatment with nucleophiles, solutions of $(Pt(bipy)_2]^{2+}$ show a broadening of their ^{1}H NMR spectra, and a new feature is observed at $\sim 7 \delta$.[25,30] The early NMR studies leave a little to be desired, but more recent high-field investigations have produced spectra of excellent quality, and will be discussed shortly. Over longer periods of time, further, non-reversible changes in the electronic spectrum occur, with the formation of $[Pt(bipy)(Nu)_2]$.[26,30,31,34] Nord has investigated the kinetics of the reaction of $[Pt(bipy)_2]^{2+}$ with hydroxide, and quotes an equilibrium constant for the rapid reversible reaction with the nucleophile of $10^{4.8}$ M^{-1} at 298 K, and reports that the intermediate so produced has a half life of 480 hr.[26]

Gillard has interpreted all of these observations as evidence for the attack of the nucleophile on the coordinated ligand (Fig. 4).[25,27,28,33] In contrast, other workers have interpreted these results in terms of a five or six-coordinate intermediate (Figs. 5 and 6).[26,29-31]
Fig. 4.
Fig. 5.
Fig. 6.

Gillard has dismissed the possibility of formation of a five-coordinate intermediate, and states that neither chloride nor cyanide ions produce changes in the electronic or ^{1}H NMR spectra similar to those produced by hydroxide. It is now clear that halide and pseudohalide ions do produce changes in the electronic spectrum,[30,32,35] and as early as 1964 Livingstone and Wheelahan had demonstrated the formation of 1:1 complexes of halide with $[Pt(bipy)_2]^{2+}$ in nitromethane or nitrobenzene solution, and had also isolated compounds which were throught to possess a five or six-coordinate structure.[32] Whilst it is possible that these 1:1 complexes with halide are of the type proposed by Gillard for nother nucleophiles, it is hard to envisage such a structure persisting in solution, and a five-coordinate structure appears to be the more likely. Neither $[Pt(bipy)(py)_2]^{2+}$ nor $[Pt(py)_4]^{2+}$ show similar changes in their electronic spectra upon the addition of hydroxide ion,

and Nord has proposed that it is distortion from square-planar geometry which is responsible for the tendency of the *bis*(bipy) complex to adopt a five-coordinate geometry.[26] Such distortions were predicted by McKenzie and others[36,37] and recent crystallographic studies have confirmed that the two ligands are distorted from coplanarity in the $[Pt(bipy)_2]^{2+}$ cations.[38,39] This distortion arises as a result of the Van der Waals interactions between H_6 of the ligands, which are brought into close proximity in the complex. Whilst the strain introduced in the complex satisfactorily explains a tendency to form five-coordinate species, it would, of course, also favour the attack of nucleophiles at C_6, with the concommittant release of strain in the formation of an sp^3 carbon.

The ^1H NMR and ^{13}C NMR spectra of aqueous solutions of $[Pt(bipy)_2]^{2+}$ show that the four pyridyl rings are all equivalent on the NMR time-scale, but that they become inequivalent on the addition of hydroxide.[29] The low-field spectra published by Gillard do not lend themselves to a detailed analysis of the spectral changes produced by nucleophiles. The later studies, however, show clearly that the intermediate is formed after the addition of only one hydroxide ion, and the ^1H and ^{13}C NMR spectra reveal that the symmetry of the cation alters so as to give two pairs of magnetically equivalent pyridyl rings. Unless the hydroxide group undergoes a fast exchange between two of the four pyridyl rings, these results appear to exclude the possibility of attack at the ligand. Such an exchange process appears to be very unlikely, and it is proposed that a fluxional six-coordinate system (Fig. 7) is formed. A trigonal bipyramidal structure may also be consistent
Fig. 7.

with the NMR studies, and no final conclusion as to the nature of the solution species may yet be drawn, although it is clear that attack is at the metal and not at the ligand. The high-field resonance at $\sim 7\,\delta$, which was assigned by Gillard to the tetrahedral C–H, is now seen to be due to $H_{5'}$, which is in the deshielding region above the plane of a pyridyl ring. Similar effects are observed in the ^1H NMR spectrum of $[Ru(bipy)_3]^{2+}$.[30]

Bis(1,10-*phenanthroline*)*platinum*(*II*)

Aqueous solutions of $[Pt(phen)_2]^{2+}$ show changes in their electronic and ^1H NMR spectra upon the addition of hydroxide similar to those described for $[Pt(bipy)_2]^{2+}$.[27] Gillard has demonstrated that these spectral changes parallel those observed for the bipy system, and also described the formation of dark-coloured solids in the reaction of $[Pt(phen)_2]^{2+}$ with hydroxide. These compounds were formulated as $[Pt(phen)(phen·OH)]X$ ($X = Cl$ or Br) on the basis of their electronic, vibrational and ^1H NMR spectra.[27] More recently, Wernberg and Hazell demonstrated the formation of a 1:1 complex between cyanide ion and $[Pt(phen)_2]^{2+}$ by conductiometric methods, and also showed that the spectroscopic changes in the $[Pt(phen)_2]^{2+}/[CN]^-$ system parallel those observed for the $[Pt(phen)_2]^{2+}/[OH]^-$ and $[Pt(phen)_2]^{2+}/[SH]^-$ systems. The ^{13}C NMR spectrum of the intermediate clearly shows that the cyanide ion is directly bonded to the metal, with satellites due to $^1J_{195_{Pt}-13_C}$ of 1516 Hz (*cf.* 1029 Hz in $[Pt(CN)_4]^{2-}$), and also by the absence of coupling between the ring carbon atoms and the cyanide carbon atom when ^{13}C enriched cyanide was used. On the basis of these observations it was proposed that the cyanide ion was not bonded to the ligand, but was directly bonded to the metal to give a five-coordinate species of the type $[Pt(phen)_2(CN)]^+$. A solid product, formulated as $[Pt(phen)_2(CN)][NO_3]$ was isolated, and aqueous solutions of this solid exhibited electronic spectra identical to those of 1:1 mixtures of $[Pt(phen)_2]^{2+}$ and cyanide, and it was thus concluded that the material truly represented the solid phase corresponding to the solution intermediate. A single crystal structural analysis of this compound has shown definitively that, in the solid state, the compound is a five-coordinate platinum(II)

complex in which the cyanide is coordinated to the metal, and is not bound to the ligand (Fig. 8).[40]
Fig. 8.

The results described above establish unequivocally the formation of a five-coordinate complex in the reaction of $[Pt(phen)_2]^{2+}$ with cyanide, a structure which persists both in the solid state and in solution. It is thought that the formation of the five-coordinate intermediate is favoured by the interactions between H_2 and H_9 of the ligands, and support for this comes from a recently reported crystal structure of $[Pt(phen)_2]Cl_2 \cdot 3H_2O$, which clearly demonstrates a tetrahedral distortion of the PtN_4 unit, and a marked distortion from planarity of the phen ligand.[41] The H_2–$H_{2'}$ distance was shown to be only 1.95 Å.

The similarity in the spectroscopic changes observed in the reactions of $[Pt(bipy)_2]^{2+}$ and $[Pt(phen)_2]^{2+}$ with cyanide and other nucleophiles very strongly suggests that similar reaction pathways are followed, and that attack occurs at the metal, and not at the ligand.

The reaction of hydroxide ion with $[PtL_2]^{2+}$ (L = 5-nitrophen) in dmso has been investigated, but the published NMR spectra are of low quality, and it is not possible to determine the site of attack.[33]

Other platinum(II) complexes

It has been reported that solutions of $[PtL(CN)_2]$ (L = bipy) exhibit temperature-dependent ^1H NMR spectra. At 100° the (red) solution exhibited the spectrum expected from a $[PtLX_2]$ system, but on cooling to 25° the (yellow) solution gave a spectrum with a new feature at 6.5 δ.[42] Attempts to repeat this work have been unsuccessful,[30,31,43] and it is now evident that the earlier reports relied upon a misinterpretation of the spectrum. Specifically, the spectrum reported by Gillard appears to have a narrow sweep width, and the resonances due to $H_{6,6'}$ are outside the spectrometer window, and hence missing from, or folded into, the spectrum. As a result of this the spectrum is totally misassigned.

It is well-known that the complexes $[PtLX_2]$ (L = bipy or phen; X = halide) may exist in dimorphic forms in the solid state,[28,4–48] but it has been demonstrated crystallographically that these only differ in the crystal packing, and do not possess significant halide–ligand interactions.[47,48] A number of groups have investigated the substitution reactions of $[Pt(bipy)Cl_2]$ and have shown that the kinetics follow those expected for a square-planar complex: there has been no suggestion of attack of the incoming nucleophile upon the bipy ligand.[49–52]

The complex $[PtCl(PEt_3)_2 \text{ (phen)}] [BF_4]$ is apparently five-coordinate, but a crystal structural analysis has demonstrated that, in the solid state, the phenanthroline is monodentate (Pt–N$_1$, 2.84 Å; Pt–N$_2$, 2.24 Å).[53] This is one of the few examples of a monodentate diimine ligand, and raises the question of such structures being responsible for some of the anomalous properties of diimine complexes. The complexes $[PtL(CN)_2] \cdot xH_2O$, $[PtLCl_2] \cdot yH_2O$ and $[PtLCl_2] \cdot dmf$ (L = bipym; x = 1 or 1.5; y = 0 or 0.5) have been described, but there is no change in the bipym frequencies in the vibrational spectra of the hydrated forms, and it is likely that these compounds have structures analogous to the corresponding bipy and phen complexes.[54]

The reaction of [Pt(terpy)Cl]$^+$ with nucleophiles has been investigated, and the rate equations shown to be of the form:

$$k_{obs} = k_1 + k_2[Y]$$

as expected for attack at either the metal or the ligand. The activation parameters are consistent with an associative mechanism, and the changes in the electronic spectrum of [Pt(terpy)Cl]$^+$ on the addition of hydroxide parallel those observed with [Pt(phen)$_2$]$^{2+}$.[55] These observations suggest that a five-coordinate intermediate is involved, although Mureinik has proposed that chloride ion attacks C$_6$ of the ligand, with concommittant degradation of a pyridyl ring.[56] In particular the reported reaction:

$$[Pt(terpy)Cl]^+ \xrightarrow[\text{(ii) [SCN]}^-]{\text{(i) Ag}^+} [Pt(bipy)(SCN)_2]$$
appears to be rather unlikely, and deserves reinvestigation.[56]

Palladium complexes

Gillard has investigated a number of palladium(II) complexes of 8-hydroxyquinoline and 2,9-Me$_2$phen, and concludes that there is no evidence for covalent hydration in complexes of these types.[57] Crystal structural analyses of the complexes [Pd(phen)$_2$][ClO$_4$]$_2$[58] and [Pd(bipy)$_2$](NO$_3$)$_2$·H$_2$O[59, 60] have confirmed that the diimine ligands are considerably distorted from the idealised square-planar geometry. Power et al. have produced a considerable amount of evidence for the formation of five-coordinate complexes of palladium with substituted phenanthrolines.[61–63] Livingstone and Wheelahan have proposed that five or six-coordinate complexes are formed in the reaction of [Pd(bipy)$_2$]$^{2+}$ have halide.[32]

The complex [Pd(terpy)Cl]Cl·2H$_2$O is a 1:1 electrolyte, and a crystal structural analysis has shown that the palladium atom is displaced from the N_3Cl plane towards a nitrogen atom of a neighbouring cation, to give a pseudo-pyramidal structure (Pd-N', 3.13 Å).[64]

REACTIONS OF OCTAHEDRAL COMPLEXES WITH NUCLEOPHILES

Substitution reactions of octahedral complexes

Octahedral tris(2,2'-bipyridine) complexes of transition metals may undergo substitution reactions via mechanisms which are basically associative or basically dissociative (Fig. 9).[23] It is commonly thought that a dissociative mechanism, involving a monodentate diimine, cannot apply to phen complexes, although the crystallographic results for [PtCl(PEt$_3$)$_2$(phen)][BF$_4$] suggest that this conclusion may be premature.[53] Gillard has proposed that covalent hydrates, and the related pseudo-bases, of the coordinated diimine play a critical role in the reactions of these complexes, and has presented a considerable amount of evidence to support this claim.[11,25,65,66] It is apparent that this proposal has not met with universal accpetance, and the present, unsatisfactory, situation is highlighted in a number of recent reviews.[67–73]

In the following sections we shall discuss the evidence which has been presented for the attack of nucleophiles on coordinated diimines in octahedral transition metal complexes.

Chromium

The photochemistry of chromium(III) diimine complexes has attracted considerable attention, and the enhanced reactivity of the photochemically excited states has led to a number of kinetic investigations of these systems. Much of the available data has been reviewed recently by Serpone,[74] who has a conducted intensive studies of the ground-state and photo-assisted aquation of [CrL$_3$]$^{3+}$ (L = phen or bipy). The reader is referred to this review for an in-depth discussion of these systems, and only the mechanistic conclusions are discussed in this section. A consideration of the lifetimes of the excited doublet states $^2T_1/^2E$ led Henry and Serpone to propose a model for octahedral tris diimine complexes in which solvent molecules are sited in "pockets" between the polypyridyl ligands.[75–77] This model is closely related to that proposed for the racemization and aquation of [Fe(phen)$_3$]$^{2+}$ (vide infra), and Serpone regards it as a useful general model for the behaviour of transition metal diimine complexes. Supportive evidence comes from an NMR
Fig. 9.

investigation of $[Cr(phen)_3]^{2+}$, which revealed that the water molecules were up to 2 Å within the inner-sphere,[78] and from the crystal structure of $[Cr(terpy)_2][ClO_4]_3 \cdot H_2O$, in which the perchlorate counter-ions are observed to be deep within the inter-ligand pockets (although it must be noted that the water molecule is *not* within such a site, but is hydrogen-bonded to two perchlorate oxygen atoms).[79] The kinetics observed in the ground-state and excited-state base hydrolysis of $[CrL_3]^{3+}$ are consistent with either a Gillard pseudo-base mechanism, or with the formation of a seven-coordinate intermediate. It is thought that the $^2E/^2T_1$ state is involved in the photo-aquation of $[CrL_3]^{2+}$, and this might be expected to favour attack at the metal, rather than at the ligand. It is known that the ^2E state of *trans*-$[Cr(en)_2(NCS)_2]^+$ reacts directly with hydroxide, but this does not necessarily involve the formation of a seven-coordinate intermediate. The important point about the Gillard mechanism is that the covalent hydrate is invoked as an intermediate, and thus studies of the stable crystal forms give little direct evidence as to the location of water molecules in the transition state. Indeed, in spatial terms the difference between a water molecule in an inter-ligand pocket and one involved in a bonding interaction with a ligand is minimal, although the potential energy terms will be very different indeed. In conclusion, the majority of the kinetic studies on chromium(III) diimine complexes are interpreted by Serpone in in terms of the formation of a seven-coordinate intermediate, and not of a covalent hydrate, although, in this reviewer's opinion, it is not yet possible definitively to preclude the Gillard mechanism.

Molybdenum

This section is concerned with the reactions of $[Mo(CO)_4L]$ (L = diimine) although the majority of the studies described have also considered the corresponding chromium and tungsten compounds, which are also discussed here. The complexes $[M(CO)_4L]$ (M = Cr, Mo or W; L = diimine) are readily prepared by the thermal or photochemical reaction of $[M(CO)_6]$ with L. The reduction of $[M(CO)_4L]$ by metallic sodium leads, initially, to the formation of $[M(CO)_4L]^-$, which has been shown by esr spectroscopy to have the electron localised on the diimine ligand radical.[80,81] This indicates that the ligand π^* orbitals are at lower energy than the metal d orbitals, but does not necessarily imply that the kinetic site of attack by a nucleophile is at the ligand. Wrighton and

Moore have investigated the photosubstitution reaction:

$$[W(CO)_4L] \xrightarrow[X]{h\nu} [W(CO)_3XL]$$
with irradiation at the lowest metal–ligand charge transfer (MLCT) frequency.[82] The reaction proceeds with the formation of a single isosbestic point, and the rates for bipy and phen complexes are similar, suggesting that the intermediacy of a monodentate diimine via the chelate ring-opening mechanism is not an important factor in W–C labilisation. A nucleophile may attack $[M(CO)_4L]$ at the metal, the diimine, or the carbonyl group, and Dobson has reviewed the reactions of nucleophiles with octahedral transition metal carbonyls.[83] Angelici has investigated the reactions of $[M(CO)_4L]$ with a wide range of phosphines nad phosphites,[84–88] and has shown that with M = Cr the rate expression is of the form:

$$\rho = k_1[\text{complex}]$$

whilst for the molybdenum and tungsten complexes a second-order term becomes important, and the expression becomes:

$$\rho = (k_1 + k_2[\text{nucleophile}])[\text{complex}].$$

although $\log k_1$ correlates well with the pK_a of the ligand, the correlation with $\log k_2$ is not good, and it is not clear whether the k_2 term corresponds to attack at the ligands or the metal. It is tempting to propose that attack at the metal will be more facile with the larger molybdenum and tungsten complexes, and this might explain the absence of the k_2 term for the chromium complex. The reaction:

$$[M(CO)_3(PR_3)L] + PR_3' \longrightarrow [M(CO)_2(PR_3)(PR_3')L] + CO$$
has also been investigated, and shown to obey the rate expression:

$$\rho = (k_1 + k_2[PR_3'])[\text{complex}]$$

for all three metals, although the k_2 term is only important for 5-nitrophen complexes,[88] and even here it is a very minor contribution to the overall rate. Burgess has shown that the lowest energy MLCT bands are markedly solvatochromic, and that a linear relationship exists between the frequency of the MLCT band and the solvent parameter E_T.[89,90] Connor has shown that the ^1H NMR spectra of $[Mo(CO)_4L]$ species are also solvent-dependent.[91]

Burgess has also investigated the reaction of $[Mo(CO)_4(5\text{-nitrophen})]$ with cyanide, and shown that a two-step reaction occurs, with the first step being a rapid addition of cyanide. This almost certainly corresponds to the formation of the Meisenheimer-type adduct, and it is proposed that the second step corresponds to the transfer of the cyanide group from the ligand to the metal. It is not clear, however, whether the product is $[Mo(CO)_3(CN)(5\text{-nitrophen})]$, or whether the second step is some further reaction at the ligand.[92] This complex also reacts rapidly with $[OH]^-[OMe]^-$, and sodium diethyldithiocarbamate in a similar reaction.[94] The reaction of $[Mo(CO)_4(bipy)]$ with cyanide obeys the rate law:

$$\rho = (k_1 + k_2[CN])[\text{complex}]$$

in dmso or methanol, and at room temperature the k_2 term is dominant. Similar kinetics are obeyed for the reaction of the phen complexes with cyanide, and for both types of complex with a range of other nucleophiles. Burgess believes that the desolvation of the cyanide ion is an important factor in reactions of this type, and has investigated the activation volumes for the reaction of $[Mo(CO)_4(bipy)]$ with cyanide in methanol and dmso:

$$\Delta V^{\neq}(\text{MeOH}) \simeq +4\,\text{cm}^3\,\text{mol}^{-1}$$

$$\Delta V^{\neq}(\text{dmso}) \simeq -9\,\text{cm}^3\,\text{mol}^{-1}.$$

The cyanide ion is less solvated in dmso than methanol, resulting in the positive contribution to $\Delta V^{\neq}$ in methanol.[93,94]

Iron

The reactions of iron diimine complexes have been the subject of an enormous amount of research over the past 30 years, and there seems to be little doubt that these complexes show specific interactions, of some type, with nucleophiles. The kinetic studies of Gillard and Burgess are notable, and have established the common occurrence of rate expressions of the type:

$$\rho = (k_1 + k_2[\text{nucleophile}])[\text{FeL}_3^{n+}]$$

although mechanistic studies cannot establish the nature of the transition state or intermediate involved in the second-order term. The reactions of the diimine complexes of iron are the subject of two forthcoming reviews, and it is not proposed to discuss the matter in any depth herein.[95,96] Suffice it to say that the lability of these complexes creates added complications in their investigation, and that there are a large number of apparently contradictory reports in the literature. The kinetic stability of the ruthenium(II) complexes renders them more suitable for investigation, and these are discussed in detail in the next section.

Ruthenium and osmium

There is little doubt that $[\text{Ru(5-nitrophen)}_3]^{2+}$ salts undergo a rapid, quantitative reaction with nucleophiles such as hydroxide, alkoxides and cyanide to produce 1:1 adducts, although there is some controversy over the initial site of attack.[14,15,97-101] A recent high-field NMR study indicates that the thermodynamic product of the reaction of $[\text{Ru(5-nitrophen)}_3]^{2+}$ with $[\text{OMe}]^-$ dmso-d_6 involves attack at C_6, although initial kinetically controlled attack at C_2 or C_9 is not precluded.[14] The reaction of the complex ions $[\text{Ru(5-nitrophen)}_x(\text{bipy})_{3-x}]^{2+}$ with $[\text{CD}_2\text{NO}_2]^-$ (generated *in situ* from CD_3NO_2 and $\text{C}_5\text{D}_5\text{N}$) has been investigated, and attack shown to occur at C_6 of the 5-nitrophen in each case.[102] It is notable that there is no evidence for attack at the coordinated bipy in the above systems, although this might be expected to be competitive with a kinetically controlled attack at C_2 and C_9 of the 5-nitrophen.

The complex ion $[\text{Ru(bipy)}_2(\text{py})_2]^{2+}$ shows reversible changes in its electronic and ^{1}H NMR spectra upon the addition of alkali, and Gillard has associated these changes with the attack of hydroxide upon the ligand.[103] Similar changes are observed in the spectra of a series of mixed complexes with substituted pyridines and 2,2'-bipyridines on treatment with a range of nucleophiles. A high-field (400 MHz) NMR study has confirmed that changes do occur in the spectrum of $[\text{Ru(bipy)}_2(\text{py})_2]^{2+}$ upon the addition of alkali, but these are not associated with the appearence of a new feature at $\sim 6.5\,\delta$.[104] It is possible that these changes are associated with a specific outer-sphere interaction between the nucleophile and the complex, rather than with covalent hydration, and it si attractive to postulate a mechanism in which the nucleophile enters a "cleft" between the two rings of a bipy, and is associated with $H_{3,3'}$. A 400 MHz ^{1}H NMR study of a series of $[\text{RuL}_3]^{2+}$ species has demonstrated that the T_1 relaxation time of $H_{3,3'}$ is abnormally fast, an observation in accord with the Van der Waals interactions between these two protons.[105] The ^{1}H NMR spectra of tris(diimine)ruthenium(II) complexes are solvatochromic,[104] and it is of interest to note that Connor has demonstrated similar behaviour in the electronic and NMR spectra of $[\text{Mo(CO)}_4\text{L}]$ (L = diimine) species.[91] Bosnich and Dwyer investigated the reaction of *cis*-$[\text{Ru(phen)}_2(\text{py})_2]^{2+}$ with a number of nucleophiles, and demonstrated that first-order kinetics were obeyed, depending only upon [complex].[106,107] These observations were interpreted in terms of an unimolecular dissociative mechanism, proceeding via a solventato or five-coordinate intermiediate. In the case of azide or nitrite nucleophiles, second-order terms were involved and a π-bonding interaction of the anion with the transition-state was postulated. For those nucleophiles exhibiting first-order kinetics (Br, Cl, I or SCN] nucleophilic attack at the ligand would appear to be precluded, although the kinetics might deserve reinvestigation.

The complexes $[\text{RuL}_3][\text{CN}]_2 \cdot 6\text{H}_2\text{O}$ (L = phen or bipy) show the expected CN stretching frequencies at $\sim 2080\,\text{cm}^{-1}$, but also a second frequency at $2170\,\text{cm}^{-1}$, characteristic of a nitrile.[108] Schilt also investigated these cyanide complexes and demonstrated the protonation of

the cyanide ligand in complexes of the type $[Ru(bipy)_2(CNH)_2][ClO_4]_2$.[109] This conclusion has been confirmed by Demas et al.[110,111] It is relevant to note that the IR spectrum of anhydrous $[Ru(bipy)_2(CN)_2]$ is dependent on the method of preparation, and that the material recrystallised from chloroform exhibits a band at $2070\ cm^{-1}$.[112] It is thus evident that these cyanide complexes do exhibit unusual properties, but it is not yet certain whether these are due to an unusual interaction with the water molecules, the presence of $[RuL_2(CN)_2]$ in samples of "$[RuL_3][CN]_2$" or of a further impurity not yet characterised.

The unusual pH dependence of the redox properties of $[Ru(terpy)_2]^{2+}$ and $[RuL_3]^{2+}$ (L = phen or bipy) were interpreted by Gillard in terms of covalent hydration, and this would appear to be a satisfactory explanation[11,113] although it is possible that a strong interaction between $H_{3,3'}$ and either hydroxide or water may be involved in these complexes. Creutz and Sutin suggested that the evolution of dioxygen from alkaline aqueous $[Ru(bipy)_3]^{3+}$ solutions involved nucleophilic attack upon C_4 of the ligand,[114] although this suggestion no longer appears to be likely.[115,116] The photochemistry of $[RuL_3]^{n+}$ has been widely investigated in the past few years, and this area has been recently reviewed.[116] It is apparent that photosubstitution reactions occur, but it is thought that these proceed through achiral five or six-coordinate intermediates, arising from a dissoviative process involving a monodentate diimine. The formation of ortho-metallated species in these photoreactions does not appear to have been considered.

The treatment of $[Ru(bipy)_3]Cl_2$ with $[CD_3O]^-$ in $CD_3OD/dmso$-d_6 results in a very specific deuterium exchange reaction of $H_{3,3'}$, and this was initially interpreted in terms of nucleophilic attack at C_4, followed by deprotonation of the 3,4-dihydropyridine.[117] It is now thought that the reaction proceeds via deprotonation at C_3 to give an anion which can rearrange to give an intermediate metallated species (Fig. 10). Gillard has reported a number of puzzling observations
Fig. 10.

on the $[RuL_3]^{3+}$ system, which are consistent with the formation of covalently hydrated species,[118] but the recent results of Serpone, together with those discussed above raise the possibility that metallated species may also be involved.

$[Ru(bipym)_3]^{2+}$ reacts with hydroxide to give a product formulated as $[Ru(bipym)_2(pym)(OH)]^+$, with the concomitant formation of one mole of formate ion.[119] Similar results are obtained with azide or cyanide as the nucleophile, and it is proposed that the key step involves nucleophilic attack at C_2 of the coordinated ligand. The evidence presented for this transformation is very convincing, although the precise mechanistic details are not yet clear.

Although it is not known whether 2,2'-bipyrimidine is covalently hydrated in aqueous acidic solution, it is relevant to note that 1-methylpyrimidinium salts are converted to 1-methylpyrimidin-2(1H)-one on treatment with hydroxide,[120] and that a member of pyrimidines bearing electron-withdrawing substituents in the 5-position are 100% covalently hydrated in aqueous acidic conditions.[121]

[Ru(tpt)$_2$]$^{2+}$ reacts reversibly with hydroxide to produce a stable intermediate, in which it is proposed that the nucleophile has added to the triazine ring.[122,123] The ^{1}H NMR spectrum of the complex shows that the addition of hydroxide ion results in a loss of molecular symmetry, with the two coordinated pyridyl residues becoming non-equivalent, although no new signal at $\sim 6.5\ \delta$ was observed. This eliminates the possibility of attack at a pyridyl ligand rather than the triazine. In concentrated alkali, free tpt is precipitated from the solution. Although 1,3,5-triazine is very rapidly hydrolysed in water, the 2,4,6-triphenyl derivative requires vigorous conditions, and there is little evidence for the covalent hydration of free 2,4,6-triaryltriazines.[124,125] These observations are in marked contrast to those on the copper(II) complexes of tpt, in which reaction with hydroxide leads to hydrolysis of the triazine ring of the ligand.[126,127]

In general, osmium(II) diimine complexes resemble those of the corresponding ruthenium(II) species, and, where they have been investigated, show similar behaviour on treatment with nucleophiles. Nord has proposed a specific interaction of [Os(phen)$_3$]$^{2+}$ with water in its oxidation in aqueous conditions.[128] Although bipy is expected to metallate in the 3-position in mono-nuclear complexes, other possibilities occur in polynuclear species, and Deeming has reported the formation of the novel *triangulo* triosmium cluster [Os$_3$(CO)$_{10}$H(C$_{10}$H$_7$N$_2$)] (see Fig. 11) in the reaction of [Os$_3$(CO)$_{10}$(cycooctene)] with bipy.[129]
Fig. 11.

As a postscript, it may be added that Tobe has investigated the methoxydechlorination reaction of free and coordinated 5-chloro-1,10-phenanthroline in dmso/MeOH, and has demonstrated a considerable rate enhancement with the ruthenium(II), osmium(II) and nickel(II) complexes.[130,131] Although an S$_N$Ar intermediate of the type shown in Fig. 12 may be involved,
Fig. 12.

it is interesting to note that quaternisation of the 5-chloro-1,10-phenanthroline prevents the methoxydechlorination reaction from occurring. On the basis of NMR studies the authors concluded that pseudobase formation (at C$_2$ or C$_9$) is not involved in these reactions of the complexes, and that the pseudobases or covalent hydrates are present to an extent of less than 10% in the reaction mixture.

Cobalt and iridium

In this section we shall concentrate upon the reactions of the less labile iridium complexes, species for which a considerable amount of structural and kinetic data has been amassed. However, Gillard has shown that $[Co(5\text{-nitrophen})_3]^{2+}$ undergoes reversible reaction with hydroxide to form, presumably, the Meisenheimer adduct,[132] and that $[Co(tpy)(OH)_3]^-$ gives a pseudobase on treatment with hydroxide.[133] Aqueous solutions of $[Co(tpt)_2]^{2+}$ are stable for long periods of time,[134,135-137] but treatment with hydroxide leads to rapid pseudobase formation, followed by an irreversible loss of tpt to form $[Co(tpt)(OH)_3]^-$.[134] The crystal structure of the complex $[Co_2Cl_4(tpt)(H_2O)]\cdot H_2O$ has been reported (Fig. 13) and it is apparent that the uncoordinated water
Fig. 13.

molecule is located above the C=N bond of the triazine ring, although it does not appear to be present as a covalent hydrate.[138] This molecule may be regarded as a model for the approach of water to a coordinate heterocycle, and provides strong evidence for interactions of the type proposed by Gillard. A number of cobalt (II) triazine complexes have been described in which a water molecule is strongly associated with the ligand, and it is likely that these compounds are covalently hydrated, although there are no structural data yet available.[139]

Tris(2,2'-bipyridine)iridium (III)

The $[Ir(bipy)_3]^{3+}$ cation has had a chequered and controversial history, and has been the subject of a number of novel structural proposals. As it is one of the few examples of a diimine complex for which a single crystal structural analysis of a proposed covalent hydrate is available, the system will be discussed in some detail. Martin and Waind first reported a complex analysing as $[Ir(bipy)_3][ClO_4]_3$ in 1958, as a product of the reaction of $K_2[IrCl_6]$ with bipy,[140] and later workers confirmed that a yellow solid of this apparent formulation was indeed formed.[141] DeSimone and Drago[142] and Gillard and Heaton[66] independently demonstrated that the products of this reaction were $[Ir(bipy)_2Cl_2]^+$ salts, and that the displacement of the two remaining chloride ligands by bipy could not be easily achieved. Gillard also suggested that the phen ligands in $[Ir(phen)_2Cl_2]^+$ might be covalently hydrated.[66] The ^1H NMR spectrum of the yellow complex showed conclusively that it was a *bis*-bipyridine system, and DeSimone and Drago proposed a *cis*-$[Ir(bipy)_2Cl_2]^+$ structure.[142] Throughout the early literature there are references to the formation of a less soluble orange compound in the preparation of $[Ir(bipy)_2Cl_2]^+$ salts, a species which has been variously formulated as a trace quantity of *tris*-complex or an aquated or photoaquated

derivative. An early report concerning the luminescence of solutions of "[Ir(bipy)$_3$]$^{3+}$" almost certainly refers to [Ir(bipy)$_2$Cl$_2$]Cl.[143] In 1974, Flynn and Demas reported the preparation of [Ir(bipy)$_3$]$^{3+}$ under halide-free conditions, and demonstrated that the ^{13}C and ^{1}H NMR spectra were fully consistent with a complex of D_3 symmetry.[144] The ^{13}C NMR spectrum showed five well-resolved resonances and the ^{1}H NMR spectrum resembled those of other [M(bipy)$_3$]$^{n+}$ complexes. It was later shown that a complex of the type {Ir(bipy)$_3$Cl$_3$(H$_2$O)$_4$} could be obtained from the reaction of IrCl$_3$ with bipy in glycerol at 180°, followed by treatment with methanolic sodium methoxide and ion-exchange chromatography.[145] These authors demonstrated that the absorption spectrum of this complex shows bands at 250, 305 and 315 nm, characteristic of a coordinated bipy ligand, and also weak absorption shoulders at 360, 448 and 470 nm, the feature at 470 nm disappearing on treatment with base. In the IR spectrum the complex exhibits an N–H stretching frequency at 2650 cm^{-1}, and, in addition to the bands expected from coordinated bipy ligands, shows absorptions at 1311, 1292, 1275 and 1246 cm^{-1}, unique in *tris*-bipyridine complexes.[145,146] Treatment with hydroxide leads to the formation of {Ir(bipy)$_3$(OH)Cl$_2$} (pK ~ 3.0 ± 0.1); no protonation to {Ir(bipy)$_3$(H$_2$O)Cl$_3$H}$^{4+}$ was observed. The analyses for total halide and ionic halide were identical, thus eliminating any formulations in which a chloride ion is coordinated to the metal. It was proposed that the complex should be formulated [Ir(bipy)$_2$(H$_2$O)(bipy′)]Cl$_3$·3H$_2$O, in which bipy′ represents a *monodentate* 2,2′-bipyridine.[145] A covalently hydrated structure was rejected on the grounds that acidic and alkaline solutions of authentic [Ir(bipy)$_3$]$^{3+}$ possessed identical electronic absorption spectra.[145] The deprotonated species was formulated as [Ir(bipy)$_2$(OH)(bipy′)]$^{2+}$, and it was suggested that equilibria of the type shown in Figs. 14 and 15, could occur.[145,147] The monodentate bipy′ was thought to be
Fig. 14.
Fig. 15.

hydrogen-bonded to the coordinated water molecule, this possibly accounting for the N–H stretching frequency and the non-formation of [Ir(bipy)$_2$(H$_2$O)(bipy′H)]$^{4+}$ Gillard questioned these conclusions, and claimed that the observations were more in accord with a covalently hydrated structure [Ir(bipy)$_2$(bipy·OH$_2$)]$^{3+}$, and pointed out that the *kinetic* stability of [Ir(bipy)$_3$]$^{3+}$/H$_2$O and [Ir(bipy)$_2$(bipy·OH$_2$)]$^{3+}$ could differ.[146] This would mean that the similarity of the absorption spectrum of [Ir(bipy)$_3$]$^{3+}$ in 0.1 M acid and base need not necessarily preclude covalent hydrate formation. Gillard also reported the ^{1}H NMR spectrum of the complex, and considered that the complexity of the spectrum, combined with the observation of multiplets at ~ 6.65 and ~ 7.14 was in accord with a covalently hydrated structure. Later workers have confirmed the unexpected complexity of both the ^{1}H and ^{13}C NMR spectra,[148,149] although Spellane and Watts[149] interpret

these in terms of a structure containing a monodentate bipy ligand. In 1982, Serpone reported the crystal structure of the anomalous complex, and described it as a C-metallated species (Fig. 16). This structure is fully in accord with the basic conditions required for the formation of the complex,
Fig. 16.

explains the complexity of the ^1H and ^{13}C NMR spectra, the acidity of the compound, the presence of an N–H stretching frequency in the IR spectrum, and the inability to undergo further protonation to form tetracationic species. It is difficult to distinguish carbon and nitrogen atoms crystallographically, and the structure described above is open to criticism on these grounds, although the application of Hamilton's test fully confirms the metallated structure.[150,151] If the complex is the metallated species proposed by Serpone, it should be possible to isolate the deprotonated compound formed in the reaction:[152,153]

$$[Ir(bipy)_2(bipy'H)]^{3+} \xrightarrow{OH'} [Ir(bipy)_2(bipy')]^{2+}.$$
Serpone has now isolated such complexes, and has performed a crystallographic study, showing that the cation has an overall 2+ charge, and that there are no water molecules in the vicinity of the coordinated ligand.[151] These results indicate that metallated structures must be considered as possible intermediates or products in the reactions of tris-bipyridine complexes under forcing conditions. The reports of an anomalous $[Ir(phen)_2(phen')]^{3+}$ complex are not consistent with such a metallated structure and deserve reinvestigation.[148] Gillard has also investigated the structure of an iridium pyridine complex, and has shown that although the complex is hydrated, the water molecules form a hydrogen-bonded network rather than a covalent hydrate.[153]

Nickel and platinum

The majority of the discussion of nickel(II) diimine complexes has centred around the mechanisms for the racemisation and aquation reactions. The mechanism of racemisation of $[NiL_3]^{2+}$ (L = phen or bipy) has been the subject of intensive investigation and discussion for many years, and it is apparent that solvent effects are very important. It was initially proposed that these complexes racemised by an intramolecular mechanism, although it is now established that a dissociative mechanism is implicated.

The racemisation of $[Ni(phen)_3]^{2+}$ was first investigated by Dwyer and Davies, who demonstrated that the rate was independent of acid concentration and of added phen, although it increased in alkaline conditions.[154,155] Numerous workers have confirmed that the rate of racemisation is independent of acid concentration at moderate pH values.[156,157] Basalo showed that, in acidic solution, the rates of racemisation and dissociation were identical, and interpreted these results in terms of a dissociative mechanism.[158] Wilkins later demonstrated that the rates of racemisation and dissociation in both neutral and basic solution were also, within experimental error, identical, and proposed a dissociative mechanism under these conditions.[156] A number of groups have investigated the effect of mixed solvents upon the rate of racemisation of $[Ni(phen)_3]^{2+}$, and it is evident that solvent interactions have a dramatic effect upon ρ_{rac}.[159-162] Yamamoto has shown that the rate of racemisation may be correlated with the donor number of the solvent, and that in dichloromethane–water the rate drops to zero in the absence of water.[160-162] These results were interpreted in terms of an associative intermediate $[Ni(phen)_3(H_2O)]^{2+}$.[160,161] It was also shown that the rate of racemisation was increased by halide ions, but not by non-coordinating anions such as perchlorate.[155,161,163] In mixed CH_2Cl_2–tert–BuOH–H_2O systems it was shown that the increase in the rate of racemisation was in the order

$$ClO_4 < I < Br < Cl$$
and it was proposed that a general mechanism of the type:

$$[Ni(phen)_3]^{2+} + D^{n-} \rightleftharpoons \{[Ni(phen)_3]^{2+}D^{n-}\}$$
$$\Updownarrow$$
$$products \longleftarrow [Ni(phen)_3D]^{(2-n)+}$$
in which D^{n-} was a coordinating solvent or counter-ion, was operating. As iodide was expected to be a better nucleophile towards carbon than chloride, it was suggested that $[Ni(phen)_3D]^{(2-n)+}$ represented a seven-coordinate species, rather than a covalently hydrated structure. Gillard proposed that the role of solvent and nucleophile in the racemisation and dissociation of $[Ni(phen)_3]^{2+}$ were better accommodated in a model with nucleophilic attack at the coordinated ligand,[164] and presented evidence for the covalent hydrate being the predominant solution species over a large pH range in aqueous conditions. In alkaline solution the pseudo-base was thought to be formed.

Lawrance and Stranks have investigated the aquation and racemisation of $[Ni(phen)_3]^{2+}$ in acidic conditions, and have determined values of $\Delta H^{\neq}$, $\Delta S^{\neq}$ and $\Delta V^{\neq}$ for the reactions. It was found that $\Delta V^{\neq}$ was close to zero, which is consistent with an intramolecular trigonal twist mechanism for racemisation, but this does not provide a common mechanism for racemisation and aquation. It was thus proposed that the initial step in the reaction was an associative interaction with a water molecule, followed by the dissociation of a phen molecule later along the reaction coordinate.[165]

From the above discussion it is evident that an intimate complex-solvent or complex-nucleophile interaction is implicated in reactions of $[Ni(phen)_3]^{2+}$, which could be of the covalent hydrate type, a seven-coordinate species, or with the nucleophile in a "ligand-pocket". Nucleophilic attack of halide on a coordinated diimine seems to be unlikely, and the "ligand-pocket" model seems to be the most attractive. The intimate assocation of water with $[Ni(phen)_3]^{2+}$ seems to be more in accord with this structure than with a seven-coordinate ground state. Bosnich and Watts demonstrated Pfeiffer effects in the $[Ni(phen)_3]Cl_2$-$(-)$-2,3-butanediol system[166], and proposed a solvent complex interaction of the "ligand-pocket" type (Fig. 17), although it seems likely that the hydroxy groups would be buried deep within the cleft, rather than facing out into the bulk medium.

The importance of outer-sphere stacking interactions has been demonstrated by Cayley and Margerum, who have proposed interactions of the type shown in Fig. 18 in the reaction:

$$[Ni(phen)(H_2O)_4]^{2+} + phen \longrightarrow [Ni(phen)_2(H_2O)_2]^{2+}$$

Yamamoto and others have investigated the solid-state racemisation of $[Ni(phen)_3]^{2+}$ species,
Fig. 17.
Fig. 18.

and it has been shown that lattice water hinders the racemisation of $[Ni(phen)_3][ClO_4]_2$, suggesting that covalent-hydrate formation is not implicated in the solid state.[168,172] It was also shown that the halide salts racemised more rapidly than the perchlorates, and that the complex [Ni·(phen)$_3$][ClO$_4$]$_2$·2H$_2$O dehydrates completely before any racemisation or decomposition occurs. It seems most probably that a Bailar twist mechanism is involved in the solid-state racemisation.

The racemisation of $[Ni(bipy)_3]^{2+}$ has also been investigated, and the rate shown to increase in either acidic or basic conditions,[156,158,173] and a dissociative mechanism is proposed for this reaction also. In the solid state the racemisation is thought to proceed in a similar manner to that of $[Ni(phen)_3]^{2+}$.[168,172] A number of $[NiL_3]^{2+}$ (L = substituted bipy) complexes have been studied by ^{1}H NMR methods, and the contact-shifted spectra analysed to yield electron spin densities on the ring protons.[174] Dwyer has investigated a number of mixed bipy and phen complexes of nickel(II), and has shown that the effects of solvent, pH and added ions resemble those described for the complexes discussed above.[157]

The complexes $[Ni(terpy)(H_2O)_3]^{2+}$[175] and $[Ni(terpy)_2]^{2+}$[176] have been investigated, and it is proposed that a strong outer-sphere interaction with the incoming ligand (possibly of the stacking type) is involved in the reaction:

$$[Ni(terpy)(H_2O)_3]^{2+} + terpy \longrightarrow [Ni(terpy)_2]^{2+}$$
and also for the corresponding reaction of the manganese(II), iron(II), cobalt(II), copper(II), zinc(II) and cadmium(II) complexes.

Gillard has demonstrated the formation of an intermediate in the reaction of $[Ni(5\text{-nitrophen})_3]^{2+}$ with hydroxide, which is almost certainly the Meisenheimer adduct[132]. A crystal structure of the complex $[Ni(tptH)(H_2O)_3]Br_3·H_2O$ has been reported: the non-coordinated water molecule is part of a hydrogen bonding network incorporating the bromide ions, and is not involved in a covalent hydrate of the ligand.[177]

In recent months, there has been some controversy over the behaviour of the complex ion

$[Pt(py)_4Cl_2]^{2+}$ in aqueous solution. Gillard has reported that the complex ion forms strongly acidic aqueous solutions, and attributed this to the equilibrium:[178,179]

$$[Pt(py)_4Cl_2]^{2+} + H_2O \rightleftharpoons [Pt(py)_3(pyOH)Cl_2]^+ + H^+.$$

Nord queries these results, and suggested tha the complex was contaminated with an acidic impurity.[180] Gillard has replied to this in a convincing manner, and recent results suggest the highly purified complex gives acidic solutions, and that the pH falls before chloride ion is released from the complex.[179,181]

Uranium

A note has recently appeared in which the reaction depicted in Fig. 19 is described.[182] This might suggest that these uranium complexes activate the bipy towards attack by strong nucleophiles, but no further evidence for these systems is yet available.
Fig. 19.

CONCLUSIONS

Complexes of the diimine ligands have been known since the discovery of 2,2'-bipyridine and 1,10-phenanthroline by Blau, and have played a formative role in the development of modern coordination chemistry. I hope to have shown in this review that the reactions of complexes of these and other α,α'-diimine ligands are not as simple as previously thought, and that a variety of hitherto unsuspected mechanistic pathways are open to them. The reactions of the complexes with nucleophiles cannot be described by one all-embracing mechanism, but it is possible to distinguish various classes which are expected to react by a particular pathway. At this point it is necessary to add a warning about the interpretation of the ^1H NMR spectra of these complexes. The presence of a resonance in the 6–7 δ region has frequently been interpreted as evidence for the formation of a covalent hydrate, but it is now apparent that a number of other structural features may result in the shielding of one or more aromatic protons (e.g. formation of an orthometallated structure, shielding by an adjacent aromatic ring, Meisenheimer adduct formation). The message must be *caveat emptor*.

Ligands which are know to undergo covalent hydration in the absence of a metal ion form a class in which the.metal complexes are also expected to form covalent hydrates. Ligands in this class include bipym, triazine and possibly tpt, and Gillard has produced numerous convincing examples of complexes in this class forming covalent hydrates. It seems likely that coordination of tpt to a transition metal ion greatly activates it towards nucleophilic attack, exactly as predicted from the analogy of a complex to quaternary salt.

Complexes of 5-nitrophen form a second class in which reaction with a nucleophile results in the formation of a coordinated Meisenheimer adduct. Once again, Gillard has produced convincing evidence that 5-nitrophen is activated towards nucleophilic attack on coordination to a transition metal ion.

The final class consists of complexes of ligands which do not react with weak nucleophiles (water or hydroxide) in the absence of a metal ion. The ligands of importance are bipy, phen and pyridine, and represent the major class of complexes in which we are interested. The results with ligands in the two classes described above indicate that coordination to a metal does activate the ligand towards nucleophilic attack, but it is not apparent how great this activation is. Thus although complexes of bipy and phen undoubtedly are activated towards nucleophilic attack, attack at the ligand does not necessarily provide the lowest energy reaction pathway. This is seen

in reactions of square-planar complexes of these ligands, in whcih five-coordinate species are formed in preference to attack at the ligand. In octahedral complexes the situation is nowhere near so clearly defined, and it is quite likely that a number of mechanisms may exist. There is no doubt that octahedral complexes of bipy and phen do show unique interactions with nucleophiles, but it is not certain whether this interaction is with the metal (seven-coordination), and ligand (covalent-hydration) or the outer sphere (ligand-pockets). The only crystal structural analysis of a supposed covalent hydrate has revealed that the complex contains an orthometallated bipy.

The ligand-pocket approach would be of importance in the ground state of the complexes, but covalent hydration represents an intermediate which is not necessarily structurally similar to the gound state, and may be important in the aquation of diimine complexes. However, there is no structural evidence for the formation of covalent hydrates of transition metal complexes of bipy or phen, and the kinetic results are not unambiguous. In conclusion, it is possible that covalent hydrates are of importance in the reactions of transition metal complexes of bipy and phen, but there is, as yet, no unambiguous evidence for their formation. It is, however, more likely that stronger nucleophiles do attack bipy and phen ligands coordinated to transition metals, and this provides an opening into a new, and very interesting area of chemistry. To quote Gillard "... the link between one major branch of inorganic chemistry and a major branch of organic chemistry seems likely to offer useful explanations for .... phenomena in the highly important systems involving an N-heterocycle, a metal ion, and a nucleophile ...".[178]

Note added in proof. There have been a number of recent results bearing on the subject matter of this review, and these are briefly discussed below.

Nord has re-investigated the $[Ir(bipy)_3]^{n+}$ system, and has structurally characterised the (red) deprotonated complex $[Ir(bipy-N,N')_2(bipy-C,N')][ClO_4]_2 \cdot \frac{1}{3}H_2O$.[183] It is now apparent that there are *two* yellow *tris* complexes, one of which contains an *ortho*-metallated bipy. Gillard has reported a number of complexes of the *N*-methylbipyridinium cation, which is a model for a monodentate bipy,[184] and has shown that the platinum and palladium complexes rearrange to give species thought to contain an *ortho*-metallated ligand.[185]

LANTHANIDE PERCHLORATE COMPLEXES OF 1-PHENYL-3-METHYL-4-PHENACYL-PYRAZOL-5-ONE

V. GIRI and P. INDRASENAN*
Department of Chemistry, University of Kerala, Trivandrum 695034, India

Abstract—Complexes of lanthanide perchlorates with 1-phenyl-3-methyl-4-phenacyl-pyrazol-5-one with the general formula: $[Ln(PMPP)_5ClO_4](ClO_4)_2$ (where Ln = La, Pr, Nd, Sm, Gd and Dy) have been synthesised and characterized. The physico–chemical studies indicate that the five ligands and one of the perchlorates are coordinated to the metal ion in a monodentate fashion to give approximately octahedral geometries for the complexes.

Ligands containing the C–O group are the largest group of compounds forming complexes with the lanthanides.[1] Probably the first series of lanthanide complexes with neutral oxygen donor ligands is that of anitpyrine.[2] Since then a variety of lanthanide complexes with ligands containing the pyrazolone ring have been reported.[1,3,4] Recently, Okafor[5] reported on the synthesis of some lanthanide complexes of 1 - phenyl - 3 - methyl - 4 - benzoyl - pyrazol - 5 - one. Now we are reporting on the synthesis and structure elucidation of some interesting lanthanide perchlorate complexes of 1 - phenyl - 3 - methyl - 4 - phenacyl - pyrazol - 5 - one (hereafter abbreviated to PMPP). PMPP acts as a unidentate ligand unlike the above 4-benzoyl compound,[5] which acts as a bidentate ligand. Moreover, one of the perchlorate groups is also coordinated to the metal ions in the present complexes and in this way they are very interesting.

EXPERIMENTAL

Preparation of lanthanide perchlorates. The perchlorates of La, Pr, Nd, Sm, Gd and Dy were prepared by dissolving a slight excess of the oxide (99.9% pure) in hot 60% aqueous perchloric acid. The undissolved oxides were filtered off and the perchlorates were crystallised out by evaporation.

Preparation of the ligand. 1 - phenyl - 3 - methyl-4 - phenacyl - pyrazol - 5 - one (PMPP) was prepared by the standard method.[6] Solutions of 1 - phenyl - 3 - methyl - pyrazol - 5 - one (0.01 mole) and freshly prepared phenacyl bromide (0.01 mole) in the minimum quantities of ethanol were mixed together in presence of fused sodium acetate (5 g) and the resulting mixture was refluxed

for 2 hr. The white solid formed was filtered, washed with ethanol and then with water and dried over phosphorus(V) oxide.

Preparation of the complexes. To a clear warm solution of the lanthanide perchlorate in *n*-pentanol a slight excess of the solid ligand was added in small quantities. The reaction mixture was heated carefully up to the boiling point of the solvent (138°C) for 10 min. The green solution obtained was filtered and the filtrate was concentrated to give a viscous mass. To this, solvent ether was added and it was stirred to separate solid complex. The supernatant liquid was poured off and the solid was washed with ether and dried in vacuum over phosphorus(V) oxide.

Analysis of the complexes. The lanthanide contents in the complexes were determined gravimetrically by the oxalate–oxide method[7] and the perchlorate contents by Kurz's method.[8]

Physical measurements. The molar conductances ($\sim 10^{-4}$ M solutions) of the complexes were determined at room temperature (28 ± 2°C) using an ELICO conductivity bridge type CM82 with dip type cell (type cc-03) having platinum electrodes. Magnetic susceptibility measurements were carried out also at room temperature by the Gouy method. The IR spectra of the complexes and the ligand were taken in KBr pellets on a Perkin–Elmer 397 IR Spectrophotometer in the range 4000–400 cm^{-1}. The molecular weights of the complexes ($\sim 10^{-4}$ M solutions) were determined by the cryoscopic method in nitrobenzene.[9]

RESULTS AND DISCUSSION

All the six complexes are non-hygroscopic solids. They are soluble in acetonitrile, nitrobenzene, methanol, ethanol, *n*-pentanol and dimethylformamide and are insoluble in benzene, carbo-

Table 1. Elemental analyses and molecular weight data

Complex	% Metal		% Perchlorate		Molecular Weight	
	Found	Required	Found	Required	Found	Required
La	7.30	7.32	15.87	15.71	1845	1899
Pr	7.42	7.41	15.96	15.70	1915	1901
Nd	7.46	7.58	15.49	15.67	1895	1904
Sm	7.78	7.87	15.97	15.63	1911	1910
Gd	8.33	8.21	15.35	15.57	1910	1917
Dy	8.54	8.46	15.39	15.53	1933	1923

ntetrachloride, ether and water. The elemental analysis data (Table 1) indicate the following general formula for the complexes: $[Ln(PMPP)_5](ClO_4)_3$, where Ln = La, Pr, Nd, Sm, Gd and Dy.

The molar conductivity values (Table 2) of the complexes in nitrobenzene reveal that they behave as 2:1 electrolytes indicating that one of the perchlorate groups is coordinated to the metal ions. However, they behave as 3:1 electrolytes both in methanol and dimethylformamide indicating that the coordinated perchlorate group is replaced from the coordination sphere by the solvent molecule.

The magnetic data are also given in Table 2. The La complex is diamagnetic as is to be expected. It may be seen from Table 2 that the observed magnetic moments are generally found to agree with the theoretical values calculated by the Van Vleck formula.[10]

The important IR spectral bands are presented in Table 3. The side chain carbonyl stretching frequency in the free ligand occurs as a very strong band at $1675 \, cm^{-1}$ and the ring C=O frequency is shifted to $1610 \, cm^{-1}$. The discrepancy in the ring carbonyl frequency is due to the intermolecular H-bonding in the ligand.[11] In the complexes the side chain C=O frequency is shifted to $1655 \, cm^{-1}$

as a shoulder in the strong peak of the ring carbonyl frequency, which is practically unaltered. A lowering of $\sim 20 \, cm^{-1}$ in the side chain carbonyl frequency is attributed to the coordination of the metal ion through the side chain carbonyl oxygen rather than the ring carbonyl oxygen. It may be noted that the ring carbonyl frequency is lowered by $\sim 5 \, cm^{-1}$ and a shift of only $\sim 20 \, cm^{-1}$ is observed for the side chain carbonyl frequency on complexation. This may be explained as follows: Due to complexation the frequencies of the two carbonyl groups come closer and the coupling is more effective than in the free ligand. Hence the ring carbonyl band is lowered slightly and the frequency of the side chain carbonyl group is slightly raised, resulting in the small shift to the lower frequency region ($\sim 20 \, cm^{-1}$). The broad absorption band between $3300-2800 \, cm^{-1}$ in the spectra of the complexes as well as that of the ligand may be attributed to the H-bonding.[11] The existence of the H-bonding in the spectra of the complexes confirms that the ring carbonyl group is not involved in the coordination. Therefore, the ligand shows monodenticity coordinating through the oxygen of the side chain carbonyl group.

The IR spectra of the six complexes studied show a strong doubly split band with band maxima

Dy Complex	1655 (sh)	1605 (s)	1100 (s) 1085 (s)	925 (m)	620 (s)

Abbreviations:—s = strong; sh = shoulder; m = medium.

at 1100 and 1085 cm^{-1} which is assigned to the v_3 vibration of the perchlorate group. This splitting of the asymmetric stretch shows that the perchlorate group is coordinated to the metal ion, the coordination probably being monodentate.[12] However, the splitting of v_3 band is not so clear and in some cases they are broad bands with two maxima at 1100 and 1085 cm^{-1}. A medium band at 925 cm^{-1} and a strong band at 620 cm^{-1}, which are unsplit, are assigned respectively to the v_1 and v_4 vibrations of the perchlorate groups.[12]

Based on the above physical measurements the present series of complexes have the following formula: [Ln(PMPP)$_5$ClO$_4$](ClO$_4$)$_2$ with a coordination number of six. The molecular weight determinations show that all the six complexes are monomers (Table 1) in solid state. The five ligand molecules and one of the perchlorate groups are coordinated to the metal ion in a monodentate fashion to give presumably a distorted octahedral geometry but an X-ray crystal structure is clearly needed to determine the actual configuration.

OXIDATION OF L-CYSTEINE, MERCAPTOACETIC ACID AND β-MERCAPTOETHYLAMINE BY 12-TUNGSTOCOBALTATE(III)

G. ADEFIKAYO AYOKO and M. ADEGBOYEGA OLATUNJI*

Department of Chemistry, Ahmadu Bello University, Zaria, Nigeria

Abstract—The stoichiometries and kinetics of the reactions of 12-tungstocobaltate(III) with L-cysteine, mercaptoacetic (thioglycollic) acid and β-mercaptoethylamine have been investigated in aqueous perchloric acid solution over a wide concentration range and at an ionic strength of $1.0 \, mol \, dm^{-3}$ ($NaClO_4$). One mole each of the thiols is required to reduce 12-tungstocobaltate(III) to 12-tungstocobaltate(II) ions, with the disulphide of the thiol as the other product. The rates of reactions decrease with increasing acidity and there is no evidence for the formation of an intermediate complex of significant stability. The reactions are interpreted in terms of an outer-sphere mechanism.

INTRODUCTION

The use of heteropoly molybdates and tungstates as electron-dense stains for electron microscopy[1] has been known for a long time. In recent years, much attention has been focussed on the use of these complexes as antiviral agents[2,3] and as electron acceptors in studies of photosynthesis.[4-6] Very little work has been done on the redox reactions involving these heteropoly acids and their anions. Rasmussen and Brubaker[7] investigated the kinetics of the electron exchange between 12-tungstocobaltate(III) $[Co(III)O_4W_{12}O_{36}]^{5-}$ and 12-tungstocobaltate(II) $[Co(II)O_4W_{12}O_{36}]^{6-}$ anions, hereafter referred to as [Co(III)] and [Co(II)] respectively, while Lappin *et al.*[8] reported the reactions of $[CuW_{12}O_{40}]^{7-}$ anion with hexacyanoferrate(III) in perchlorate media. The redox reactions of [Co(III)] with ligands containing di-hydroxyl groups have also been studied by McAuley *et al.*[9] and except for the reactions of [Co(III)], the oxidant in this study, with thioureas[10] no other reaction of the oxidant with sulphur-containing organic ligands have been reported. This paper is therefore an account of the kinetic investigation of the reactions of [Co(III)] with sulphur-containing ligands such as L-cysteine, thioglycollic acid and β-mercaptoethylamine.

Previously, oxidation of many thiols by metal ions has been shown to proceed through the formation of inner-sphere complexes. In the aquo-cobaltic ion oxidation of α-mercaptocaboxylic acids,[11,12] electron transfer was preceded by the formation of transient species. Similar results were obtained in the thallium(III) oxidation of thiomalic acid,[13] Cr(VI) oxidation of L-cysteine,[14] thioureas,[15] penicillamine,[16] and gluthathione[16] and Fe(III) oxidation of mercaptocaboxylic acids.[17] However, in the ceric oxidation of α-thiols[18] and thioureas,[19] aquo-cobaltic oxidation of the thioureas,[20] and the reactions of [Co(III)] with thioureas,[10] there was no evidence for the formation of intermediate complexes prior to electron transfer. In the unlikely event that intermediate complex formation is important in the present study, the choice of thiols should make possible the investigation of the effectiveness of O, N and S as binding sites. For example, if oxygen of the carboxylic acid group is an important coordinating site, its absence in β-mercaptoethylamine should be reflected in the rate and thermodynamic parameters for complex formation.

In addition, the relative position of the various coordinating sites and in particular the size of the entire molecule may also affect these values. On the other hand, if there is no evidence for complex formation, it would be interesting to know how the mechanisms of these reactions relate to those of the same oxidant with other sulphur-containing ligands like thioureas,[10] where no evidence was found for the existence of an intermediate complex.

EXPERIMENTAL

Materials

Potassium 12-tungstocobaltate was prepared by the method of Baker and McCutcheon[12] and characterised for purity by its UV-visible spectra.[9] A stock solution of [Co(III)] was standardised using a spectrophotometric titration method. The titration was carried out with a standard solution of Fe(II) which quantitatively reduced [Co(III)] to [Co(II)].

L-Cysteine (BDH reagent), β-mercaptoethylamine hydrochloride (Koch Light) were used without further purification, but mercaptoacetic acid (Analar grade) was redistilled under reduced pressure and used as soon as possible after purification. Perchloric acid (Analar grade) was used to investigate the effect of hydrogen ions on the rates of reactions while sodium perchlorate (Fluka puriss) was employed in maintaining the ionic strength constant at $1.0 \, mol \, dm^{-3}$. Other chemicals were used as supplied.

Kinetics

The reactions of the three thiols were found to be very slow under the conditions employed in the kinetic investigation. Consequently, the rates of the various reactions were measured by following the decrease in the concentration of [Co(III)] with time at 390 nm using a Pye Unicam SP 8000 spectrophotometer. All measurements were made under pseudo-first order conditions using the following reactant concentrations:

$$[Co(III)] = 2 \times 10^{-4} \, mol \, dm^{-3}; \quad [thiol] = 2-40 \times 10^{-3} \, mol \, dm^{-3};$$

$$[H^+]_± = 0.02-0.10 \, mol \, dm^{-3} \quad and \quad I = 1.0 \, mol \, dm^{-3} \, (NaClO_4).$$

The reactions were studied at temperatures in the range 15.8–30.3°C. Temperature variation within a particular set of runs was not greater than 0.1°C.

Stoichiometry

The stoichiometries of the reactions were determined by spectrophotometric titration. Absorbances of solutions containing various concentrations of the thiols in the range $(0.80-9.60 \times 10^{-4} \, mol \, dm^{-3})$ and a constant initial concentration of [Co(III)] $(2.0 \times 10^{-4} \, mol \, dm^{-3})$ at $[H^+] = 0.05 \, mol \, dm^{-3}$ and $I = 1.0 \, mol \, dm^{-3}$ ($NaClO_4$) were measured at 390 nm after the reac-

---

tions had gone to completion. The stoichiometries were then evaluated from plots of absorbance vs thiol concentration curves. Results were found to be independent of wavelength used. Similar results were obtained when the concentration of the thiol was kept constant at 2.0×10^{-4} mol dm^{-3} and those of [Co(III)] varies between 0.4–4.8×10^{-4} mol dm^{-3} using the same values of [H$^+$]$_0$ and ionic strength as in the titrations above.

RESULTS AND DISCUSSION

For each mole of [Co(III)], 0.92 ± 0.03 moles of L-cysteine, 0.94 ± 0.02 moles of β-mercaptoethylamine and 0.94 ± 0.04 moles of mercaptoacetic acid were oxidized. These are in reasonable agreement with reaction (1) where RSH represents a thiol.

$$2[Co(III)] + 2RSH \rightarrow 2[Co(II)] + RSSR + 2H^+. \quad (1)$$

Accurate knowledge of the reactant species is a requirement for a reasonable interpretation of kinetic data. An effort was therefore made to identify the important reactant species in these redox reactions. Spectra of [Co(III)] monitored over the acid concentration range employed in the kinetic investigations indicated that there was no reactive species of oxidant other than [CoO$_4$W$_{12}$O$_{36}$]$^{-5}$. For the thiols, the pK$_a$ values corresponding to the loss of a proton from an –SH and NH$_3^+$ group[22-24] are >8, whereas those of the carboxylic acid groups are ca. 2 for cysteine[14] and ca. 4 for mercaptoacetic acid.[17] Hence, in the acidity range [H$^+$] = 0.2–0.10 mol dm^{-3} employed in this work, the carboxylic acid is the predominant species, although a small proportion of the zwitterion formed from the dissociation of monoprotonated ligand (eqn 2) is also present in solution.

$$\overset{+}{N}H_3 \qquad \qquad \overset{+}{N}H_3$$
$$| \qquad \qquad \qquad |$$
$$HS\!-\!CH_2\!-\!C\!-\!CO_2H \overset{K_a}{\rightleftharpoons} HS\!-\!CH_2\!-\!C\!-\!CO_2^- + H^+.$$
$$| \qquad \qquad \qquad |$$
$$H \qquad \qquad \qquad H \qquad \qquad (2)$$
This is in line with conclusions reached by McAuley and Olatunji,[25] working under identical experimental conditions. Attempts were also made to determine the effect of these proton equilibria on the actual concentration of hydrogen ions present using the method employed by McAuley and Olatunji.[25] No significant effect was observed. This would tend to suggest that although the protonated ligand may be formed, the effective concentration of hydrogen ions remained essentially at the initial value, [H$^+$]$_0$.

Comparison of the initial absorbances in the kinetic investigations with those for [Co(III)] when no ligand was present showed no significant difference, indicating that no detectable intermediate was formed. Plots of log $(A_t - A_\infty)$ (where A_t and A_∞ are the absorbances at time t and at the end of the reaction respectively) vs time were linear to greater than 90% completion of the reactions. The strict linearity of these plots does suggest that there is no strong inhibition of the reactions by products and that the rate is first-order in [Co(III)] in each of the reactions investigated. Pseudo-first order rate constants, k_{obs}, obtained from gradients of these plots at various values of [H$^+$]$_0$ and thiol concentrations are presented in Table 1.

On plotting k_{obs} vs [RSH]^2 (where RSH is L-cysteine or mercaptoacetic acid), straight lines were obtained, suggesting that the rates of the redox reactions are
Fig. 1. The dependence of observed rate constant (k_{obs}) on the concentration of mercaptoacetic acid (MAA) and L-cysteine (cys) at 25°C. (A) L-cysteine. (B) Mercaptoacetic acid (top coordinate). [H$^+$] = 0.04 mol dm^3 ($\triangle$). (H$^+$) = 0.08 mol dm^3 ($\square$).

second-order in these thiols (Fig. 1). Plots of gradients of these lines as a function of [H$^+$]$_0^{-2}$ gave a straight line passing through the origin at constant temperature (Fig. 2). On the other hand, when RSH is mercaptoethylamine, plots of k_{obs}/RSH vs [RSH] (Fig. 3) indicate that two pathways are concurrently operative in the reaction, one being first-order in the ligand while the other has a second-order ligand dependence. Gradients of these plots vary in a linear manner with 1/[H$^+$]$_0$ at constant temperature (Fig. 4).

If the rate of protonation of the thiols is diffusion controlled, the rate of dissociation of such protonated

Fig. 3. The dependence of observed rate constant (k_{obs}) on ligand concentration for the reaction of [Co(III)] with β-mercapto-ethylamine (MEA) at 25°C. [H$^+$] = 0.06 mol dm^3 ($\triangle$). [H$^+$] = 0.08 mol dm^3 ($\square$). (H$^+$] = 0.10 mol dm^3 ($\times$).

species may be estimated from the dissociation constant of the thiol group.[14,16]

$$RSH \underset{k_{-d}}{\overset{k_d}{\rightleftharpoons}} RS^- + H^+ \qquad (3)$$

$$K_a = \frac{k_d}{k_{-d}} \qquad (4)$$

$$k_d = 10^{10} K_a . \qquad (5)$$

Since the value of K_a for the thiols[22-24] is approx. 10^{-7}–10^{-8}, the value of k_d obtained using eqn (5) is of the order of 10^2–10^3 s^{-1}. This value is much higher than the
Fig. 4. Dependence of gradients of plots of K_{obs}/[MEA] vs [MEA] (Fig. 3) on 1/[H$^+$] for the reactions of [Co(III)] with mercaptoethylamine. T = 30.3°C (○); T = 25.0°C (△); T = 20.1°C (□).

observed rate constants, k_{obs}, for the redox steps; it is therefore reasonable to assume that dissociation of –SH precedes electron transfer.

From the observed experimental data, the mechanism below can be postulated for the reactions of L-cysteine and mercaptoacetic acid with 12-tungstocobaltate(III) ions, where the protons released are derived from the thiol group as shown above.

Mechanism I

$$2RSH \overset{K_a}{\rightleftharpoons} 2RS^- + 2H^+ \qquad (6)$$

$$[Co(III)] + RS^- \overset{K_{os}}{\rightleftharpoons} [Co(III)], RS^- \qquad (7)$$

$$[Co(III)], RS^- + RS^- \overset{k_1}{\longrightarrow} [Co(II)] + RSSR^- \qquad (8)$$

$$RSSR^- + [Co(III)] \overset{fast}{\rightleftharpoons} [Co(II)] + RSSR \qquad (9)$$
where K_{os} is the outer-sphere equilibrium constant. This reaction scheme is consistent with the rate of loss of [Co(III)] as expressed in eqn (10)

$$\frac{-d[Co(III)]_t}{dt} = \frac{k_1 K_{os} K_a [RSH]^2 [Co(III)]_t}{[H^+]^2 + K_{os} K_a^{1/2}[H^+][RSH]} \qquad (10)$$

If $[H^+]^2 \gg K_{os} K_a^{1/2}[H^+][RSH]$, then k_{obs} can be derived

$$k_{obs} = \frac{k_1 K_{os} K_a [RSH]^2}{[H^+]^2}. \qquad (11)$$

This is in good agreement with the observed data as shown in Figs. 1 and 2. Values of $k_1 K_{os} K_a = k_1'$[11] derived at different temperatures and the corresponding activation parameters are shown in Table 2.

An alternative mechanism in which dimerization of RSH with loss of protons to give RSSR^{2-} is proposed as a first step, followed by a rate-determining electron transfer reaction to give the product [Co(II)] and a dithio radical RSSR$^-$ is also in agreement with the observed data. This type of mechanism was, in fact, put forward by Carlyle[26] to explain the observed second-order dependence of the ligand HSO$_3^-$ on the rate of reduction of Fe(phen)$_3^{3+}$ ions. However, this mechanism is not likely to be operating in the present study in view of the kinetic inertness of the dithio anion[27] RSSR^{2-}. The favoured mechanism outlined above is similar to the one postulated by Olatunji[10] for the reactions of the same oxidant with the thioureas. However, the second pathway involving first-order dependence on ligand concentration observed by that author was not obtained in the present investigation.

The significance of second-order ligand-dependent processes has been discussed.[28] In a number of reactions,[14,16,26] recourse had to be made to this type of process in order to rationalize the observed kinetic parameters. For sulphur-containing one-electron reductants such as those under consideration (L-cysteine and mercaptoacetic acid), routes corresponding to such terms are considered important in providing a pathway for the generation of the disulphide product. However, a rate-determining dimerization process leading to the formation of a four-centred M$_2$S$_2$ complex[29] in the transition state, which yields the disulphide without the

Table 2. Dependence of $k_1{}^{11}$ on temperature where $k_1{}^{11} = k_1 K_{os} K_a$

L-Cysteine		Mercaptoacetic acid	
T/°C	k_1^{11}/s^{-1}	T/°C	$10^3 k_1^{11}/s^{-1}$
20.1	0.10	15.8	1.85
25.0	0.14	20.7	2.71
30.1	0.18	25.5	4.11
$\Delta H^{\ddagger}/kJ\ mol^{-1}$	42.7 ± 2		57.3 ± 3
$\Delta S^{\ddagger}/JK^{-1}\ mol^{-1}$	-113.3 ± 8		-91.7 ± 10

formation of a radical, is not deemed feasible in [Co(III)] reactions because of the structure and stability of the oxidant.

In the reaction of [Co(III)] with β-mercaptoethylamine, the two-term experimental rate law encountered appears to require two parallel reaction pathways leading to the disulphide product. Mechanisms consistent with these kinetic observations are embodied in the equations below

Mechanism II

$$[Co(III)] + RSH \overset{K_{os}}{\rightleftharpoons} [Co(III)], RS^- + H^+ \quad (12)$$

$$[Co(III)] + RSH \overset{k_2}{\longrightarrow} [Co(II)] + RS^{\cdot} + H^+ \quad (13)$$

$$[Co(III)], RS^- + RSH \overset{k_3}{\longrightarrow} [Co(II)] + RSSRH^{\cdot} \quad (14)$$

$$RSSRH^{\cdot} + [Co(III)] \rightleftharpoons [Co(II)] + RSSR + H^+ \quad (15)$$

$$2RS^{\cdot} \rightleftharpoons RSSR. \quad (16)$$
This mechanism gives the rate law:

$$\frac{-d[Co(III)]_t}{dt} = [Co(III)]_t[RSH]\left[\frac{K_{os}k_3[RSH]}{[H^+]} + k_2\right]. \quad (17)$$

From eqn (17), k_{obs} can be derived

$$k_{obs} = [RSH]\left[\frac{K_{os}k_3[RSH]}{[H^+]} + k_2\right]. \quad (18)$$

Rearranging eqn (18) gives eqn (19)

$$\frac{k_{obs}}{[RSH]} = \left[\frac{K_{os}k_3[RSH]}{[H^+]} + k_2\right]. \quad (19)$$

The linearity of the plots of $k_{obs}/[RSH]$ against [RSH] is in good agreement with this rate law (Figs. 3 and 4). Values of the rate and activation parameters derived from such plots are shown in Table 3.

Earlier results obtained from the reactions of cysteine[30,31] with $Fe(CN)_6{}^{3-}$ were also rationalized by a two-term rate expression. Interestingly, the rate constant for the first-order ligand-dependent pathway was found to increase with increasing temperature. A similar trend was observed by us in an earlier investigation of the oxidation of the thioureas[32] by $Fe(phen)_3{}^{3+}$ and $[Co(III)]$.[10]

According to Walling,[33] the values of entropy of activation ΔS^* within the range -83 to $-143\ KJ\ mol^{-1}$ obtained in the reaction of β-mercaptoethylamine with [Co(III)] suggested a mechanism involving free radicals. An obvious possibility for such a radical is $RS^{\cdot}$, but radiolysis studies have shown that thioradicals formed from cysteine[34] and a variety of thiols of simple and complex structures[35] are in equilibrium with the corresponding dithio radical anion, $RSSR^{-}$. In some instances, these species may be protonated to give $RSSRH^{\cdot}$. This is in excellent agreement with mechanism II where the radical $RSSRH^{\cdot}$ has been proposed as a shortlived product formed in reaction (14) and also in the oxidation of cysteine and related ligands[30,31] by $Fe(CN)_6{}^{3-}$.

In conclusion, the oxidations of L-cysteine, mercaptoacetic (thioglycollic) acid and β-mercaptoethylamine by [Co(III)] appear to follow a route leading to the forma-

Table 3. Dependence of k_2 and $k_3{}^{11}$ on temperature for the reaction of β-mercaptoethylamine with the oxidant, [Co(III)], where $k_3{}^{11} = K_{os}k_3$

T/°C	$k_2/mol^{-1}\ dm^3\ s^{-1}$	$10^5 k_3^{11}/mol^{-1}\ dm^3\ s^{-1}$

tion of [Co(II)] and disulphides as products without the formation of intermediate complexes of significant stability. A similarity in the modes of activation of these reactions and those of the thioureas[10] with the same oxidant is therefore implied. The thermodynamic parameters for the steps involving a second-order ligand dependence are quite similar to those obtained for the di-hydroxyl ligands[36]. This may be an indication that the mode of reactions with both sulphur- and oxygen-containing ligands are the same and independent of the active groups in these ligands. This type of behaviour would not be expected if the reactions proceeded by an inner-shpere mechanism.

METAL COMPLEXES OF SCHIFF'S BASE DERIVED FROM SALICOYLHYDRAZINE AND BIACETYLMONOXIME

M. M. MOSTAFA*, M. A. KHATTAB and K. M. IBRAHIM

Department of Chemistry, Faculty of Science, Mansoura University AR, Egypt

Abstract—Biacetylmonoxime-salicoylhydrazone (BMSH) complexes of the types [Hg(BMSH)Cl₂] and [M(BMSH-H)₂], where M = Cu(II), Co(II), Ni(III), Mn(II), Zn(II), Cd(II) and UO₂(VI), have been prepared and characterized by conventional chemical and physical measurements. The IR spectra show that the ligand usually coordinates via carbonyl oxygen (C=O), azomethine nitrogen (C=N) and phenolic OH with replacement of hydrogen by metal ions, but acts as a bidentate molecule coordinating through (C=O) and (C=N) in the Hg(II) complex. The magnetic and spectral data of the Co(II) and Ni(II) complexes support octahedral stereochemistry, whilst tetragonally distorted octahedral geometry is suggested for the Cu(II) complex.

Our earlier work[1,2] on the complexes of hydrazone-oxime has been extended to the complexes of biacetyl-monoxime-salicoylhydrazone (BMSH) with some transition metal ions. Recently, Saha *et al.*[3] have isolated the Cu(II) complex of BMSH using ammonia as a buffering agent. However, no structural studies on transition metal complexes of BMSH have been undertaken to date. In the present paper, tentative structures are proposed for some complexes on the basis of molar conductance, elemental analyses, IR, magnetic and spectral data.

RESULTS AND DISCUSSION

The IR spectrum of BMSH shows three bands at 3410, 3340 and 3260 cm⁻¹ considered to be $\nu(OH)$ (phenolic), $\nu(OH)$ (oxime) and $\nu(NH)$ respectively. The existence of bands at lower wavenumbers in the spectrum of the ligand may be due to inter- or intra-molecular hydrogen bonding.[4] The observation of two weak and broad bands entered at 2280 and 1950 cm⁻¹ due to O—H—O stretching and bending vibrations[5,6] confirms the presence of in-

tramolecular hydrogen bonding which is presumed to be form between phenolic OH and carbonyl oxygen as shown in structure (I).
(I)

The complexes of this ligand which have been isolated from absolute ethanol and in presence of sodium acetate as a buffering agent are listed in Table 1. They are insoluble in non-polar solvents but dissolve in DMF and DMSO. Molar conductivities in DMF at 25°C (Table 1) indicate[7] these complexes to be non-electrolytes in this solvent.

The phenolic OH band at 3410 cm⁻¹ is not present in the spectra of the complexes (except the HgCl₂ complex). The band at 1240 ch⁻¹ is assigned to the phenolic (C–O) vibration in the spectrum of BMSH as reported in previous assignments[8,9] but is shifted to higher wavenumbers in the spectra of the complexes suggesting that the o-hydroxy group entered into bond formation

† in cm² ohm⁻¹ mol⁻¹

with displacement of hydrogen. Moreover, spot test identification of the phenolic OH[10] in metal complexes proves the replacement of hydrogen by metal ions.

The bands at 3340, 1310 and 945 cm^{-1} in the spectrum of the ligand attributable respectively to ν(OH) (oxime), $\nu(C=\overset{2}{N}+OH)$ and ν(NO) appear more or less at the same positions for the complexes indicating that neither NO nor $C=\overset{2}{N}$ groups take part in complex formation. Also, the presence of OH (oxime) in the complexes was detected by a spot test,[11] indicating that the oxime group does not participate in coordination. Strong evidence for the presence of a free -OH (oxime) in the complexes comes from the proton magnetic resonance spectra of solutions of the diamagnetic complexes in d$_7$-DMF. In, for example, a solution of [Cd(BMSH-H)$_2$], the -OH proton signal at 10.55 ppm downfield from TMS disappears upon addition of D$_2$O.

Medium and strong bands at 1630 and 1545 cm^{-1} are due respectively to the azomethine groups of the hydrazone $\nu(\overset{1}{C=N})$ and oxime $\nu(C=\overset{2}{N})$. The $\nu(C=N)$ band suffers a negative shift, while the $\nu(C=\overset{2}{N})$ band is shifted to higher wavenumbers indicating the involvement of only azomethine from the hydrazone moiety in coordination. Also, the positive shifts of the band at 1000 cm^{-1} due to ν(N-N)[12] can be taken as an evidence for the involvement of $\nu(C=\overset{1}{N})$ in bonding. The carbonyl band ν(C=O) at 1660 cm^{-1} is shifted to lower wavenumbers in all complexes suggesting that the carbonyl oxygen is also a potential site for bonding. The low frequency bands in the regions 430–410 and 365–320 cm^{-1} are tentatively assigned to ν(M-O)[13,14] and ν(M-N)[15] respectively.

The IR absorptions due to the UO$_2$ group are observed at 930 and 860 cm^{-1} as sharp bands corresponding[16] to the asymmetric stretching frequencies ν_3 and ν_1 respectively. These observations indicate that the UO$_2$ moiety is virtually linear.[16] All these observations together with the elemental analyses suggest structure (II) for all complexes except that of Hg(II) which may have structure (III). The mercury (II) complex shows ν(Hg-Cl) at 255 cm^{-1} which is in the region typically found for tetrahedral structures.[17]
M=Cu (II), Co(II), Ni(II), Mn(II), Zn (II) and Cd (II)

[Hg(BMSH)Cl$_2$]	diamag.		
(III)

The magnetic moments and reflectance spectra of the complexes are listed in Table 2. The magnetic moment of the Cu(II) complex corresponded to the spin-only value for one unpaired electron and was in the range normally observed for Cu(II) complexes having an orbitally non-degenerate B_{1g} ground state, thereby indicating no metal–metal interaction. The electronic spectrum shows one broad band at $16,900 \, cm^{-1}$ with a shoulder at $14,600 \, cm^{-1}$ which may be assigned respectively to $^2B_{1g} \rightarrow ^2E_g$ and $^2B_{1g} \rightarrow ^2A_{1g}$ transitions. On this basis the Cu(II) complex seems to have tetragonally distorted octahedral geometry.[18] The three bands at 7,300, 11,200 and $23,100 \, cm^{-1}$ in the spectrum of the Ni(II) complex are assigned to $^3A_{2g} \rightarrow ^3T_{2g}$, $^3A_{2g} \rightarrow ^3T_{1g}(F)$ and $^3A_{2g} \rightarrow ^3T_{1g}(P)$ respectively,[19] while the band at $15,100 \, cm^{-1}$ may be assigned to the $^3A_{2g} \rightarrow ^1E_g$ transition.[20] The values of $10D_q$ and B have been calculated from the observed positions of the bands by using the equations for the d^8 system[21] which can be taken as evidence for an octahedral structure. Also, the value of the magnetic moment (3.32 B.M.) together with the ratio ν_2/ν_1 (1.53)[22] gives further support for the proposed octahedral geometry. The reflectance spectrum of the Co(II) complex shows three bands at 7700, 15,300 and $18,600 \, cm^{-1}$ which are assigned respectively to $^4T_{1g} \rightarrow ^4T_{2g}$, $^4T_{1g} \rightarrow ^4A_{2g}$ and $^4T_{1g}(P)$ transitions. The values of D_q, B and magnetic moment suggest an octahedral geometry[23,24] for the cobalt complex as well.

EXPERIMENTAL

BMSH was prepared by refluxing 1 mole of biacetylmonoxime with 1 mole of salicoylhydrazine in ethanol for 2 hr and crystallizing the product from ethanol; m.p. 250°C.

The complexes of Co(II), Ni(II), Mn(II), Cd(II), Zn(II), Hg(II) and UO$_2$(VI) were prepared using ethanolic solutions of the hydrated metal salts and adding a 2:1 mole ratio of ligand to metal salt in presence of sodium acetate as a buffering agent and heating the mixture under reflux for 30 min. The complexes were filtered hot, washed with ethanol and dried in a vacuum desiccator (CaCl$_2$). The same procedure was used in case of the Cu(II) complex but without adding sodium acetate.

The analyses for the metals and chloride were carried out by standard methods.[25] Carbon and hydrogen contents were determined by the Microanalytical Unit of Mansoura University.

The IR spectra were measured as nujol mulls between CsI discs and recorded on Pye Unicam SP.2000 and Perkin-Elmer 557 ($4000-200 \, cm^{-1}$) spectrophotometers. Electronic spectra were measured in the solid state using a Unicam SP.700 C spectrophotometer. Molar conductances in DMF were measured using a Tacussel conductivity bridge type CD6NG at room temperature (25°C). Magnetic moments were measured using the Gouy method at Liverpool University, UK, and were corrected for the diamagnetism of the component atoms using Pascal's constant.[26] Proton magnetic resonance spectra of the complexes were carried out on a Perkin-Elmer R12B (60 MHz) spectrophotometer.

Abstract—The complexes Fe(po)₂·H₂O, Fe(Ppo)₂·H₂O and Fe(Ppo)₂·2py, where poH = 3 - methyl - 4 - oxime - 1H - pyrazole - 4,5 - dione and PpoH = 3 - methyl - 4 - oxime - 1 - phenyl - 1H - pyrazole - 4,5 - dione, have been prepared. The magnetic susceptibilities and Mössbauer spectra of the complexes have been investigated.

The reactions of 2-nitrosophenols (mono-oximes of 1,2-quinones) (LH) with metal salts or with metal carbonyls give neutral metal complexes of type ML$_n$ (*n* = 2 or 3).[1-3] In certain cases deoxygenation of the ligand can occur to give heterocyclic or other organic products. We now report on the reactions of the related ligands 3 - methyl - 4 - oxime - 1H - pyrazole - 4,5 - dione (poH) (**1**; R = H, R′ = CH₃) and 3 -
methyl - 4 - oxime - 1 - phenyl - 1H - pyrazole - 4,5 - dione (PpoH) (**1**; R = C₆H₅, R′ = CH₃) with iron(II) ammonium sulphate and with iron(O) pentacarbonyl. We also report on the properties and structure of the metal complexes which arise from these reactions. Complexes of copper(II), nickel(II), zinc(II), cadmium(II) and magnesium(II) derived from ligands of type **1** (R = H, C₆H₅, 4-(NO₂)C₆H₄, 4-ClC₆H₄, 2,4-(NO₂)₂C₆H₃; R′ = H, CH₃, C₆H₅) have been reported earlier.[4-6]

EXPERIMENTAL

The ligands were prepared as described in the literature.[7]

Interaction of 3 - methyl - 1 - phenyl - 4 - oxime - 1H - pyrazole - 4,5 - dione or 3 - methyl - 4 - oxime 1H - pyrazole - 4,5 - dione with iron(II) ammonium sulphate

3 - Methyl - 1 - phenyl - 4 - oxime - 1H - pyrazole - 4,5 - dione (2.0 g, 2 mol equiv.) and iron(II) ammonium sulphate (1.9 g, 1 mol equiv.) were stirred in ethanol–water (2 : 1) (120 cm³) (1 hr). Turquoise *bis*(3 - *methyl - 1 - phenyl - 4 - oximato - 1H - pyrazole - 4,5 - dione)iron(II) - monohydrate* (1.4 g, 59%), (Found: C, 50.2; H, 4.1; Fe, 11.7;

N, 17.1. C₂₀H₁₈FeN₆O₅ requires: C, 50.2; H, 3.8; Fe, 11.7; N, 17.6%), was filtered off, washed with water (2 × 100 cm³) and ethanol (2 × 100 cm³) and dried at 30°C/0.1 mm.

Unchanged 3 - methyl - 4 - oxime - 1H - pyrazole - 4,5 - dione (88%) (identified by IR) was recovered after stirring (4 hr) with the iron(II) salt in ethanol–water.

Interaction of 3 - methyl - 4 - oxime - 1H - pyrazole - 4,5 - dione with iron pentacarbonyl

3 - Methyl - 4 - oxime - 1H - pyrazol - 4,5 - dione (2.51 g, 1 mol equiv.) and iron pentacarbonyl (19.4 g, 5 mol equiv.) were heated under reflux for 12 hr in dry tetrahydrofuran (100 cm³) under nitrogen. The mixture was filtered to give dark green *bis*(3 - *methyl - 4 - oximato - 1H - pyrazol - 4,5 - dione)iron(II) - monohydrate* (1.49 g, 54%). (Found: C, 29.9; H, 2.8; Fe, 17.1, N, 25.9) C₈H₁₀FeN₆O₆ requires: C, 29.5; H, 3.1; Fe, 17.1; N, 25.8%) which was washed with tetrahydrofuran and dried at 30°C/0.1 mm. The washings were concentrated and filtered to give orange 2,4 - *dihydro - 4 - (5 - hydroxy - 3 - methyl - 1H - pyrazol - 4 - yl)imino - 5 - methyl - 3H - pyrazol - 3 - one* (0.14 g, 8%). (Found C, 47.1; H, 4.9; N, 33.6%; C₈H₉N₅O₂ requires: C, 46.9; H, 4.8; N, 33.8%), m.p. 265–67°C sub.; *m/e* 207 (M⁺).

Interaction of 3 - methyl - 1 - phenyl - 4 - oxime - 1H - pyrazole - 4,5 - dione with iron pentacarbonyl

3 - Methyl - 1 - phenyl - 4 - oxime - 1H - pyrazole - 4,5 - dione (2.04 g, 2 mol equiv.) and iron pentacarbonyl (0.98 g, 1 mol equiv.) were heated under reflux for 12 hr under nitrogen in dry tetrahydrofuran (100 cm³). Chromatography of the mixture (silica gel) gave, with toluene as eluant 2,4 - dihydro - 4 - (5 - hydroxy - 3 - methyl - 1H - pyrazol - 4 - yl) - imino - 5 - methyl - 1 - phenyl - pyrazol - 3 - one (0.41 g 66%), m.p. 185–7°C (*lit.*,[8] 183°C), (Found: C, 67.1; H, 5.1; N, 19.2%). Calc. for C₂₀H₁₇N₅O₂: C, 66.8; H, 4.8; N, 19.5%), *m/e* 359 (M⁺). Further elution with toluene gave 1,2,5 - oxadiazole[3,4-*d*] - 6 - methyl - 4 - phenyl - 4H - pyrazole (0.04 g, 6%), m.p. 86–8°C (*lit.*,[9] 91°C), *m/e* 200 (M⁺). Methanol eluted *bis*(5 - methyl - 1 - phenyl - 4 - oximato - 1H - pyrazol - 4,5 - dione)iron(II) - hydrate, (0.11 g, 14%) (identified by IR).

Interaction of bis(3 - methyl - 1 - phenyl - 4 - oximato 1H - pyrazole - 4,5 - dione)iron(II) - monohydrate with pyridine

Bis(3 - methyl - 1 - phenyl - 4 - oximato - 1H - pyrazole - 4,5 - dione)iron(II) - monohydrate (2.6 g) and pyridine (10 cm³) were stirred for 24 hr. *Bis*(3 - *methyl* - 1 - *phenyl* - 4 - *oximato* - 1H - *pyrazole* - 4,5 - *dione*)*iron*(*II*) - *dipyridine* (2.7 g, 79%) (Found: C, 57.7; H, 4.4; Fe, 8.6; N, 17.7. $C_{30}H_{26}FeN_8O_4$ requires C, 58.2; H, 4.2; Fe, 9.0; N, 18.1%) was filtered off, washed with diethyl ether (2 × 50 cm³) and dried at 30°C/0.1 mm.

Thermal gravimetric analysis data for $Fe(Ppo)_2 \cdot 2py$

Weight of sample: 206 mg. Weight loss: 55 mg (Calc. for 2 mol of pyridine per mol of adduct: 53 mg). Temperature of loss: 172–8°C.

Measurements

Magnetic susceptibility and thermogravimetric analysis data, also IR and NMR spectra were obtained as described earlier.[1] Mössbauer spectra were recorded on a constant acceleration Mössbauer spectrometer (J and P Engineering, Reading) using a [57]Co source in a rhodium matrix (Spire Corporation). The velocity calibration was based on the inner four lines of the spectrum of natural iron.

RESULTS AND DISCUSSION

The reaction of iron(II) ammonium sulphate with PpoH in aqueous ethanol gave a turquoise complex of stoichiometry $Fe(Ppo)_2 \cdot H_2O$. In contrast poH failed to react with the iron(II) salt under similar conditions. However, the complex $Fe(po)_2 \cdot H_2O$ was obtained along with some 2,4 - dihydro - 4 - (5 - hydroxy - 3 - methyl - 1H - pyrazol - 4 - yl)imino - 5 - methyl - 3H - pyrazol - 3 - one (2; R = H) from the reaction of the oxime with iron pentacarbonyl. The reaction of iron pentacarbonyl with PpoH afforded mainly 2,4 - dihy-
