†The isomer shifts (δ) are given relative to iron foil. The errors in δ and Δ are of the order 0.02 and 0.03 mm s⁻¹ respectively.

the pyridine adduct lie between 5.2 B.M. and 5.4 B.M. and are indicative of high-spin iron(II).

The magnetic behaviour of the complexes was measured at variable field strength and at variable temperature (Table 1). All complexes follow the Curie–Weiss Law. The decreasing magnetic moment with temperature of the hydrates and their large negative Weiss constants indicate antiferromagnetic behaviour and suggest association (4). However the experimental data do not rule out the possibility of spin-orbit coupling. Some indirect support for association is provided by the insolubility of the complexes and the contrasting magnetic behaviour of the pyridine adduct. The room magnetic moment, the negligible Weiss constant and the lack of significant variation of magnetic moment within the temperature range used all suggest that the pyridine adduct is monomeric. The value of $\theta = 0$ for $Fe(Ppo)_2 \cdot 2py$ suggests that the pyridine adduct is magnetically dilute, indicating a pseudooctahedral structure. The Mössbauer parameters of all the complexes (Table) indicate that the materials are essentially free from iron(III) impurities, and are in accord with high-spin iron(II), and the structural suggestions.[12]

The high spin character of the iron complexes suggests that the ligand field exerted by po^- or Ppo^- is weak. This contrasts with the high ligand-field character of quinoneoximato ligands and is probably a consequence of the limited conjugation within chelated po^- or Ppo^- ligands.

METAL CHELATES OF 1-ACETYLPYRIDINIUM CHLORIDE-4-PHENYL-3-THIOSEMICARBAZIDE

A. A. EL-ASMY and M. M. MOSTAFA*

Chemistry Department, Faculty of Science, Mansoura University, AR. Egypt

Abstract—The metal chelates of 1-acetylpyridinium chloride-4-phenyl-3-thiosemicarbazide [(APTS)]$^+$Cl$^-$ of the type [M(APTS)X$_2$]$^+$Cl$^-$ (M = Co(II), Ni(II), Cu(II), Zn(II) or Cd(II); X = Cl, Br or $\frac{1}{2}$SO$_4$) have been prepared and characterized on the basis of elemental analysis, molar conductance, IR, electronic spectra and magnetic studies. IR spectral studies showed that the ligand coordinates via thioketo and ^{1}NH groups. Magnetic and spectral studies suggest a tetrahedral structure for Ni(II), pseudo-tetrahedral for Co(II) and square planar and/or distorted tetrahedral for Cu(II) chelates.

INTRODUCTION

Our previous study[1-5] on the ligands containing thiosemicarbazide moiety are extended to 1-acetylpyridinium chloride-4-phenyl-3-thiosemicarbazide [(APTS)]$^+$Cl$^-$. Also, we have reported[1-5] the isolation of some metal complexes both in the keto and the enol forms of the same ligand by changing the pH of the solution using sodium acetate. In contrast to this observation, we prepared herein only the keto chelates even though the pH of the solution was changed. Moreover, the ligand coordinates exclusively via the thioketo and ^{1}NH groups forming a five membered ring around the metal ion. The isolated metal chelates are characterized by conventional physical and chemical studies. Finally, the stereochemistry of the chelates is discussed on the basis of magnetic and spectral studies.

EXPERIMENTAL

All the chemicals used are BDH quality. The ligand (I) was prepared by adding slowly phenyl isothiocyanate (13.5 cm^3) to a solution of (18.5 g) Girard's reagent P (carbohydrazidopyridinium chloride) in absolute ethanol. The mixture was refluxed on a water bath for a half-hour. The white product was crystallized from absolute ethanol and dried in a vacuum desiccator over anhydrous calcium chloride; m.p., 161°C.

(I)
Preparation of the metal chelates

The metal chelates were prepared by adding equimolar amounts (10^{-2} moles) of APTS and the metal salts in absolute ethanol. The mixture was refluxed on a water bath for approximately a half-hour. The product was filtered off, washed with hot ethanol and diethylether respectively and finally dried in a vacuum desiccator over anhydrous calcium chloride. Even in presence of excess ligand attempts to prepare the bis-chelates were unsuccessful.

Analyses

Elemental analyses were carried out by the Microanalytical Unit of the Mansoura University. The metals and chloride contents were carried out by standard methods.[6]

Physical measurements

Molar conductance measurements were obtained with a Tacussel type CD6NG conductivity bridge using 10^{-3} M solutions in dimethylsulphoxide at 25°C. The electronic spectra of the metal chelates in DMSO, pyridine and nujol mull were recorded on a Pye Unicam SP.1800 spectrophotometer. The magnetic susceptibility measurements were carried out using Gouy method and HgCo(SCN)$_4$ as calibrant at Alexandria University, Egypt. Diamagnetic corrections were made using Pascal's constants.[7] IR spectra were recorded as nujol mulls on Pye Unicam SP.2000 spectrophotometer.

RESULTS AND DISCUSSION

Analytical results and some physical properties of the isolated metal chelates are listed in Table 1. The chelates [M(APTS)X$_2$]$^+$Cl$^-$ are stable in air and insoluble in common organic solvents, but quite soluble in DMF and DMSO. The molar conductance of the ligand in DMSO was found to be 54 Ω^{-1} cm^2 mole^{-1} which falls in the range reported for 1:1 electrolytes.[8] Also, the molar conductance values of the metal chelates in DMSO are in the range expected for 1:1 electrolytes (i.e. 25–70 Ω^{-1} cm^2 mole^{-1}).[8]. The relatively high value (70 Ω^{-1} cm^2 mole^{-1}) for [Ni (APTS)Cl$_2$]$^+$Cl$^-$ may suggest 1:2 electrolyte or more likely some dissociation of this complex in DMSO.

All the isolated metal chelates have the same general formula [M(APTS)X$_2$]$^+$Cl$^-$ irrespective of the divalent metal ion and the pH of the preparative mixture. The existence of the free ligand as a salt as well as the distribution of the positive charge over the cation may stabilize both the thioketo and carbonyl groups and thereby prevent the deprotonation. To explain the chelation via the thioketo and ^{1}NH and not through the carbonyl and ^{2}NH groups, we believe that the ^{2}NH is less basic than ^{1}NH. Also, the carbonyl group is under the influence of the tautomeric effect and/or hydrogen bonding which decreases the activity of the carbonyl oxygen as a coordination site. Both factors therefore favour chelation by the thioketo and

*in $ohm^{-1} cm^2 mole^{-1}$

NH groups. In contrast to this, we have found[1-5] that similar neutral ligands were easily deprotonated in the presence of sodium acetate as a buffering agent.

IR spectral studies

The infrared spectrum of $[(APTS)]^+Cl^-$ indicates that it exists mainly in the keto form; it shows $v(CO)$ and $v(CS)$ bands at 1730 and 1290 cm^{-1} respectively and no bands above 3480 cm^{-1} as well as in the region 2600–2550 cm^{-1} which would be expected for the enol forms (IV) and (V).

$$RNHC=NNHCOR' \rightleftharpoons RNHCSNHNHCOR' \rightleftharpoons RNHCSNHN=CR'$$

HS (IV) (III) OH (V)
where R = phenyl and R' = —(—CH₂—N⟨⟩)Cl⁻.

The spectra of all these metal chelates are very similar. The band at 1730 cm^{-1} in the spectrum of the ligand is essentially unchanged in the spectra of the metal chelates. Also, the band at 1570 cm^{-1} due to $v(CO + NH)$ is not affected by chelation. These observations can be taken as evidence that the carbonyl group is not involved in coordination to the metal ions. The three bands at 1540, 1500 and 1460 cm^{-1} in the spectrum of the ligand are likely due to $v(-N-C=S)$ vibrations.[9] These bands are assigned as coupled modes principally of $\beta(NH)$ and $v(CN)$.[10] Also, the bands at 1290 and 790 cm^{-1} are due to $v(C=S)$ with contribution of $v(CN)$. The negative shifts of these bands to lower wavenumbers in the spectra of all metal chelates can be taken as evidence that the ligand coordinates via the thioketo group. The three $v(NH)$ mode of vibrations undergo a negative shift in the spectra of the metal chelates indicating the involvement of at least one of the $v(NH)$ groups in bonding. This supported by the small positive shifts of the band at 1020 cm^{-1} assigned to $v(N-N)$[11] in the spectrum of the ligand and the appearance of a new band at *ca.* 335 cm^{-1} which may be attributed to $v(M-N)$.[12] In summary, all these observations to-

gether with elemental analyses suggest that the ligand acts in a bidentate manner and coordinates via its thioketo and NH groups with the formation of a 5-membered rings around the central metal ion.

The stereochemistry of the metal chelates are assigned on the basis of their electronic spectra in nujol, DMSO as well as pyridine solutions and confirmed by magnetic measurements. The results of electronic spectra together with magnetic moments are reported in Table 2. The magnetic moment of the compound $[Co(APTS)Cl_2]^+Cl^-$ is found to be 4.62 B.M., which is acceptable for either tetrahedral or five coordinate structure depending on the extent of chlorine coordination. Both the spectra in nujol and DMSO are identical and show three bands at 14,700, 16,000 and 17,850 cm^{-1} which excludes a five coordinate structure.[13] The strong band at 14,700 cm^{-1} is assigned to $^4A_2\rightarrow^4T$ (P) transition, while the band at 17,900 cm^{-1} may be assigned to spin-forbidden transition[14] which is typically found for pseudo-tetrahedral structure around Co(II). On dissolution of the Co(II) chelate in pyridine the colour changes from green to brownish red and the spectrum exhibits four bands at 14,900; 15,900; 17,900 and 18,900 cm^{-1}. These values are different from those obtained in nujol and DMSO and are similar to those reported for six coordinate Co(II) complexes.[13] The spectra of Ni(II) chelate in nujol and DMSO exhibit a split band at 14,300 and 14,900 cm^{-1} along with a weak band at 12,200 cm^{-1} which support the presence of tetrahedral structure around Ni(II) ion. Also, the value of magnetic moment $\mu_{eff} = 3.38$ B.M., for Ni(II) ion suggests a tetrahedral structure around Ni(II). The spectrum of Ni(II) chelate in pyridine shows two bands at 18,900 and 13,500 cm^{-1} which are assigned respectively to $^3A_{2g}\rightarrow^3T_{1g}$ and $^3A_{2g}\rightarrow^1E_g$ transitions in octahedral

structure.[13] Two different types of spectra were recorded for Cu(II) chelates. The spectra of copper(II) chloride and sulphate chelates show a broad band centred at *ca.* 14,000 cm^{-1} with no discernible shoulders, while the bromide chelate shows three bands at 12,000(sh), 14,100 and 19,000 cm^{-1} which suggests a square planar for the former and pseudo tetrahedral for the latter. The band at 19,000 cm^{-1} in the spectrum of Cu(II) bromide may be attributed to Π(Br)→Cu(II).[15] Also, the bands at 25,000 and 25,600 cm^{-1} in the spectra of Cu(II) sulphate and bromide respectively are assumed to arise from charge transfer M→L.[16] Finally, the solution spectra in pyridine for Cu(II) chelates were also recorded and exhibit a broad band centred at ~16,000 cm^{-1} with a low energy shoulder. On this basis all the chelates in pyridine are seen to be tetragonally distorted.[17] The values of magnetic moments for the Cu(II) chelates are in a good agreement with those reported for d^9 configuration.[18,19]

REACTIONS OF DIBORANE WITH AROMATIC HETEROCYCLES—2[1]

REACTIONS WITH NITROGEN-CONTAINING HETEROCYCLES RELATED TO PYRIDINE

PHILIP C. KELLER,[*2a] RONALD L. MARKS[2b] and JOHN V. RUND[2a]

Abstract—The reactions of solutions of B_2H_6 in ethers with a variety of aromatic heterocycles containing one or more six-membered rings with only one nitrogen per ring have been examined. Quinoline and isoquinoline form monoborane adducts which hydroborate in the presence of an excess of B_2H_6. Protonolysis gives the 1,2,3,4-tetrahydro-compounds in both cases. N-Methylquinolinium and N-methylisoquinolinium iodides both hydroborate. Hydroboration and halogen loss occur with 2-, 3- or 4-haloquinolines (chlorine or bromine). Prior to hydroboration 8-hydroxyquinoline forms a borane adduct which rapidly eliminates one equivalent of hydrogen in a probable intramolecular ring closure. Sodium 8-hydroxyquinolinate combines with B_2H_6 in an unsymmetrical cleavage reaction to form $B_2H_7^-$ or BH_4^-, and the same ring closed product formed by 8-hydroxyquinoline. Phenanthridine and N-methylphenanthridinium iodide both readily undergo hydroboration. The products formed by the latter with B_2H_6 are 5-methyl-5,6-dihydrophenanthridine–borane and an iodoborane etherate. 1,8-Naphthyridine forms a transient borane complex which rapidly undergoes hydroboration; protonolysis gives 1,2,3,4-tetrahydro-1,8-naphthyridine. 2,2′-Bipyridyl undergoes a complex reaction with one equivalent of BH_3 giving a mixture of bpy·$2BH_3$ and hydroborated products, but 4,4′-bipyridyl does not appear to hydroborate. 1,10- and 1,7-Phenanthroline both hydroborate giving a mixture of reduced products on protonolysis. Pyridine-borane and 2-phenylpyridine-borane both decompose in refluxing diglyme, but protonolysis gives no reduced products in either case.

During the past few years we have been interested in the reactions of diborane with rigid polydentate chelating ligands. In experiments with bases like 1,10-phenanthroline, 8-hydroxyquinoline and 1,8-naphthyridine we observed unexpectedly complex reactions which in most instances turned out to involve hydroboration of the heterocyclic aromatic ring. Since little is known of the reactions of diborane with aromatic heterocycles, we decided to explore this area for the purpose of determining the scope of this reaction. This and subsequent papers contain the results of our examination of the reactions of diborane with a wide variety of aromatic heterocycles. In this article we describe results with heterocycles containing one or more six-membered rings with only one nitrogen atom per ring.

RESULTS AND DISCUSSION

Quinoline, isoquinoline and their N-methyl cations

The stable monoborane complexes of quinoline (**I**) and isoquinoline (**II**) have been known for a number of years.

I

II
The adducts may be prepared by the direct reaction of the bases with stoichiometric quantities of diborane[3] or by displacement of borane from weak base complexes like $Me_2S·BH_3$.[4]

In a recent paper Martin *et al.* reported that quinoline and isoquinoline react with quantities of $Me_2S·BH_3$ *in excess* of that required for adduct formation to give complex mixtures of high melting point which the authors postulate as resulting from hydroboration of the heterocyclic ring.[4]

In another recent publication Nose and Kudo reported the reduction of quinoline, isoquinoline, and a number of their C-methyl derivatives by treatment with *two* equivalents of $THF·BH_3$ followed by hydrolysis with hydrochloric acid.[5] The authors propose that ring reduction occurs during the hydrolysis step by the action of B–H-containing intermediates. Although this is evidently the case when immediate hydrolysis is involved, the studies of Martin *et al.*[4] and the results presented in this article demonstrate that hydroboration occurs before hydrolysis when the reaction time is sufficient.

We have obtained results similar to those of Martin *et al.* in reactions of quinoline and isoquinoline with $THF·BH_3$ in excess of that required for simple adduct formation. Protonolysis gave the tetrahydro derivatives of quinoline (**III**) and isoquinoline (**IV**) in 34 and 50% yield, respectively.

We have also observed that yields of **III** and **IV** improve if reactions are carried out using borane complexes of somewhat stronger bases. Thus, treat-

III   IV
ment of quinoline with $Me_2S \cdot BH_3$ or $py \cdot BH_3$ followed by protonolysis gave III in 53 and 73% yields, respectively.

Reaction of quinoline with excess $THF \cdot BH_3$ followed by deuteronolysis with 20% DCl/D_2O then 50% CH_3COOD/D_2O gave the trideutero compound V.

V
The presence of deuterium on the aromatic ring results from electrophilic aromatic substitution during workup. The position of the deuterium on the reduced ring reveals the site of the boron–carbon bond in the hydroborated intermediate.[6]

The first step in these reactions is undoubtedly coordination of BH_3 to the nitrogen lone pair. Once this site is blocked, the π-bonds in the heterocyclic ring are susceptible to attack by additional BH_3. In support of this hypothesis we studied the reactions of the N-methyl cation salts with diborane. The reactions in both cases were slower, taking *ca* 3 weeks at ambient temperature, but the usual workup gave the reduced products VI and VII in 34 and 51% yield, respectively.

VI   VII
Scheme 1 illustrates the proposed reaction sequence for the case of quinoline. After initial hydroboration, reduction of the isolated CN double bond would probably follow easily by hydride shift from coordinated BH_3 to give an aminoborane. The final structure shown is an oversimplification since the BH_2 group on the 3-position and possibly the BH_2 group attached to nitrogen can engage in further hydroborations to form complex crosslinked products. That this situation probably exists is supported by our boron-11 NMR studies of heterocycle–excess borane solutions. Spectra usually comprise only very broad featureless signals, and no resolved quartets or triplets characteristic of amine–boranes or aminoboranes are present.

As an extension of this work, the reactions of diborane with the 2-, 3-, and 4-haloquinolines VIII, IX, and X were examined. In all cases heterocyclic ring reduction with loss of halogen occurred. After protonolysis and workup, VIII, and IX afforded 1,2,3,4-tetrahydroquinoline III in 4 and 37% yield, respectively. The 7-chloro derivative of III was obtained from X in 19% yield.

VIII   IX

X
These results are consistent with the studies of Pasto and coworkers on haloborane eliminations in the hydroborations of halogen-substituted olefins.[7,8] Assuming boron–carbon bond formation at the 3-position, the situation with VIII and X would resemble that found by Pasto and Hickman in the hydroboration of 3-chlorocyclohexene.[7] In this system the principal hydroboration product was *trans*-2-
Scheme 1.
Scheme 2.

chlorocyclohexylborane from which BH_2Cl was readily eliminated in the presence of THF. The resulting cyclohexene subsequently underwent rapid hydroboration. This sequence is illustrated for the case of VIII in Scheme 2.

Again assuming boron addition at the 3-position, the hydroboration of IX would parallel the reaction found by Pasto and Snyder with 2-bromostyrene in which α-transfer rather than BH_2Br elimination occurred.[8] A possible sequence for IX is illustrated in Scheme 3. If BC bond formation occurred at the 4-position on IX, the situation would resemble Scheme 2.

8-Hydroxyquinoline and its sodium salt

Reaction with diborane is a two-stage process in which complexation and chelate formation are followed by a slower hydroboration. In the early stage of the reaction 8-hydroxyquinoline combines with one equivalent of BH_3 and rapidly evolves 1 mole of hydrogen. A boron-11 NMR spectrum of the reacting solution taken immediately after mixing shows a quartet and a triplet in addition to the signal of excess

diborane itself. During a period of 5 min at room temperature the triplet completely replaces the quartet, and hydrogen evolution ceases. Prompt hydrolysis yields only unaltered 8-hydroxyquinoline. These observations are consistent with the sequence shown in eqn (1). The borane complex XI gives rise to the

$$(1)$$

Scheme 3.
quartet in the boron-11 NMR spectrum. The complex then eliminates hydrogen, and we speculate that this step may be intramolecular giving the ring compound **XII**. Hydrolysis of **XII** would give unaltered 8-hydroxyquinoline.

The reaction of excess diborane with the salt sodium 8-hydroxyquinolinate proceeds in a similar manner. A boron-11 NMR spectrum run moments after initiation of the reaction shows the same triplet as that assigned to **XII** plus a relatively sharp singlet. The chemical shift of the latter depends directly on the quantity of excess diborane present and results from the rapid hydride ion exchange between B_2H_6 and $B_2H_7^-$.[9] These observations are consistent with the unsymmetrical cleavage reaction[10] (eqn 2) and the associated exchange reaction (eqns 3 and 4) shown.

Prompt hydrolysis again yields unaltered 8-hydroxyquinoline.

If these reactions are allowed to stand 24 hr before hydrolysis, no 8-hydroxyquinoline is recovered, and the triplet in the boron-11 NMR spectrum assigned to **XII** disappears and is replaced by a very broad featureless signal. Protonolysis affords small yields (7% with 8-hydroxyquinoline) of 1,2,3,4-tetra-hydro-8-hydroquinoline. Excess diborane is not necessary for the loss of **XII**, although it is consumed if present.

Phenanthridine and N-*methylphenanthridinium iodide*

Borane adds across the CN double bond in phenanthridine in THF at room temperature. Protonolysis gives 5,6-dihydrophenanthridine **XIII** in 53% yield. In the presence of excess diborane solid N-methylphenanthridinium iodide dissolves in a few hours in monoglyme, but requires several weeks in ethyl ether. Methanolysis of the resulting solution gives the tertiary amine **XIV** in 99% yield. A boron-11 NMR study of this reaction revealed that the hydroboration intermediate is the borane complex **XV**
XIII   XIV
XV

(quartet, $\delta = -7.7$ ppm, $J = 81$ Hz). This was proved by isolation of the intermediate and comparison of its IR and boron-11 NMR spectra with those of the actual borane complex prepared from the tertiary amine **XIV**. In addition to the quartet assigned to **XV**, the boron-11 NMR spectrum contained a singlet ($\delta = 17.8$ ppm) and a sharp doublet ($\delta = 27.3$ ppm, $J = 160$ Hz) suggestive of the presence of the tri- and dialkoxyboranes $B(OR)_3$ and $HB(OR)_2$, respectively.[11]

These observations are consistent with the addition of the elements of BH_4^- across the CN double bond (eqn 5). The presence of the alkoxyboranes can be explained by an ether cleavage by the iodoborane[12] followed by known disproportionation reactions (eqns 6 and 7).[13] Cleavage of monoglyme could give several products, but with ethyl ether only ethyl iodide and ethoxyboranes would form. The isolation of ethyl iodide established the occurrence of ether cleavage.

XII   (2)

$$BH_4^- + 1/2\ B_2H_6 \longrightarrow B_2H_7^- \qquad (3)$$

$$B_2H_7^- + B_2H_6 \rightleftharpoons B_2H_6 + B_2H_7^- \qquad (4)$$

(5)

$$BH_2I\cdot OR_2 \longrightarrow RI + BH_2OR \qquad (6)$$

$$BH_2OR \longrightarrow HB(OR)_2,\quad B(OR)_3,\quad BH_3 \qquad (7)$$
A similar addition of the elements of BH_4^- to an N-methyl iminium group has been reported by Yamada and Ikegami in the reaction of $THF \cdot BH_3$ with 1,2-dimethyl-3,4-dihydroisoquinolinium iodide XVI.[14] The product was found to be the tertiary amine–borane XVII, but no investigation of possible ether cleavage was undertaken.

XVI   XVII
1,8-Naphthyridine

Boron-11 NMR study reveals that at low temperature 1,8-naphthyridine forms a borane complex of as yet undetermined stoichiometry. Above 0° the quartet signal of the adduct loses intensity, and an irreversible hydroboration occurs which is complete within 4 hr at room temperature. Approximately 1.19 mol of diborane is consumed per mol of 1,8-naphthyridine. The IR spectrum of the hydroboration product shows both BH terminal and bridge stretching. Protonolysis gives the 1,2,3,4-tetrahydro-derivative XVIII in 44% yield. Similar workup using CH_3COOD gives a product with deuterium in both the 3 and 4 positions on the saturated ring.

XVIII
2,2′ and 4,4′-bipyridyl

Excess diborane reacts immediately with 2,2′-bipyridyl (bpy) in monoglyme to form an insoluble air-stable bis-borane complex $bpy \cdot 2BH_3$.[15] In an attempt to prepare and characterise the monoborane adduct $bpy \cdot BH_3$, we reacted bpy with one half mole of diborane in monoglyme. Surprisingly, the reaction proved to be more complex as evidenced by the precipitation of solid products over a 1–2-day period and the gradual coloring of the initially clear colorless solution to a deep orange–red. The IR spectrum of the insoluble material comprised all the absorptions of $bpy \cdot 2BH_3$ plus bands from an unidentified substance. The IR spectrum of the monoglyme-soluble products showed no BH stretching bands and was not that of bpy itself. Protonolysis of these products gave unaltered bpy and a mixture of partially reduced products (PMR and mass spectroscopic evidence). The further separation and characterisation of these materials was not pursued.

As with bpy, excess diborane reacts with 4,4′-bipyridyl in monoglyme to form an insoluble air-stable bisborane complex which regenerates 4,4′-bipyridyl on hydrolysis. Reaction of 4,4′-bipyridyl with one half mole of diborane gives no evidence for hydroboration, and hydrolysis regenerates unaltered 4,4′-bipyridyl in high yield.

In the case of the 2,2′-isomer it appears that $bpy \cdot BH_3$ may form initially, but a variety of more complex reactions including disproportionation and hydroboration subsequently occur. As pure speculation, we suggest that the difference in behavior of the 2,2′- and 4,4′-isomers toward one equivalent of BH_3 may hinge upon a chelate effect. Reduction of the 2,2′-isomer may be promoted by a hydride displacement from coordinated BH_3 assisted by a neighboring nitrogen lone pair (eqn 8).

further
hydroboration

(8)
1,10- and 1,7-phenanthroline

Both bases react rapidly with diborane in a complex manner giving colored intermediates and complex stoichiometry. The products give broad, unresolved boron-11 NMR spectra and IR spectra showing both terminal and bridge BH stretching absorptions. Protonolysis gives poor yields of mixed tetra- and octahydrophenthrolines (mass spectral evidence). The further separation and characterisation of these substances was not pursued.

Pyridine and 2-phenylpyridine

The borane adducts of many pyridine (py) derivatives are relatively stable, well characterized substances. Pyridine–borane itself $(py \cdot BH_3)$ is commonly used as a reducing agent and is available commercially. Although these substances can be handled safely at room temperature, $py \cdot BH_3$ is known to undergo a violent reaction when heated.[16,17] To determine whether this process might be a hydroboration, we examined the products formed by heating diglyme solutions of $py \cdot BH_3$ and 2-phenylpyridine-borane. We found that refluxing diglyme solutions of $py \cdot BH_3$ as dilute as 0.29 M underwent violent exothermic reaction, suddenly generating large amounts of colorless insoluble material after induction periods of 30–45 min. The decomposition of 2-phenylpyridine-borane was not violent. Protonolysis gave no product at all in the case of $py \cdot BH_3$ and only a small amount of starting material with 2-phenylpyridine-borane. Substantial quantities of intractable materials were formed in both workup procedures. The decomposition reactions may involve a Lewis-acid promoted ring-opening polymerization rather than a hydroboration.[18]

Note on protonolysis procedure

In the early stages of this work we found that the standard protonolysis procedure of adding propionic

or acetic acid to cleave boron–carbon bonds in organoboranes[19] often resulted in the isolation of N-propyl or N-ethyl derivatives of reduced heterocycles. These products probably arise through the reducing action of intermediate acyloxyboranes formed by the action of the carboxylic acid on residual or unreacted borane. Processes of this type have been proposed by Gribble et al. in studies of amine alkylations using sodium borohydride in carboxylic acid media.[20] The problem of unwanted N-alkylation was circumvented by carrying out the protonolysis step with 50% aqueous acetic or propionic acid. The effect of the added water is most likely the rapid destruction of residual boranes or acyloxyboranes before reduction can occur.

EXPERIMENTAL

Reagents. The following were purchased from the Aldrich Chemical Co.: quinoline, isoquinoline, 2-chloroquinoline, 3-bromoquinoline, 4,7-dichloroquinoline, 8-hydroxyquinoline, phenanthridine, 2,2'-bipyridyl, 4,4'-bipyridyl, 1,10-phenanthroline, pyridine–borane, 2-phenylpyridine, THF·BH$_3$, and Me$_2$S·BH$_3$. 1,7-Phenanthroline was obtained from the Pfaltz and Bauer Chemical Co. Purification, dehydration, or conversion from hydrochloride salts of some of the above bases was performed as needed by standard methods. N-methylquinolinium iodide, N-methylisoquinolinium iodide, and N-methylphenanthridinium iodide were prepared by treating the appropriate base with CH$_3$I followed by standard purification. Diborane,[21] acetic acid-d,[22] and 1,8-naphthyridine[23] were prepared by standard methods. The solvents ethyl ether, monoglyme (1,2-dimethoxyethane), diglyme (bis(2-methoxyethyl) ether), tetrahydrofuran (THF), and methanol were purchased commercially and were dried by standard methods. For use on the vacuum line the first four were stored in evacuated bulbs over LiAlH$_4$ and were vacuum transferred directly into reaction vessels when needed.

Spectra. Boron-11 NMR spectra were obtained using a Varian HA-100 spectrometer operating at 32.1 MHz. Chemical shifts are relative to Et$_2$O·BF$_3$, and downfield shifts are positive. NMR reactions were performed in a vessel of about 10 ml volume designed to fit into the probe of the spectrometer. Proton NMR spectra were obtained with a Varian T60 spectrometer. IR spectra were obtained with a Perkin–Elmer 337 spectrophotometer. Mass spectra were run on a Hewlet-Packard 5930A spectrometer operated by the University of Arizona Analytical Center.

Methods. Standard high vacuum and inert atmosphere techniques were used in all small quantitative experiments.[24] On a larger scale the basic methods described by Brown et al. were employed.[25] In most cases the workup of hydroboration products was generally the same and involved preliminary refluxing with 50% acetic or propionic acid (see above) followed by treatment with aqueous NaOH until basic, extraction with CHCl$_3$, drying with MgSO$_4$, evaporation, and recrystallization or distillation as appropriate.

Quinoline and diborane

A freshly dried and distilled sample of 5.0 g (39 mmol) of quinoline was added to 116 cm^3 of 1M BH$_3$ in THF in a nitrogen filled dry box and the mixture was allowed to stand at room temperature for 5 days. The resulting yellow solution was concentrated under vacuum and treated with 100 cm^3 of methanol to destroy residual active hydride. The solution was again concentrated and worked up as described above. Vacuum distillation of the dried CHCl$_3$ extract gave 1.7 g (34%) of 1,2,3,4-tetrahydroquinoline (III) (b.p. 88–90° at 1 torr; identification by IR and PMR).

In an experiment similar to the above, the hydroborated

quinoline was treated with D$_2$O, then 20% DCl/D$_2$O to destroy active hydride and was then refluxed with 50% CH$_3$COOD/D$_2$O. Workup gave 3,6,8-trideuterio-1,2,3,4-tetrahydroquinoline (V). IR (neat, ν CD) 2251, 2166 cm^{-1}; PMR (neat) 1.78 (m, 1H), 2.69 (d, 2H, J6.3 Hz), 3.08 (d, 2H, J5.4 Hz), 3.75 (s, 1H), 7.02 and 7.07 (s, 2H combined); MS, m/e 136 [P$^+$], base peak at low ionization energy.

Isoquinoline and diborane

An experiment paralleling the above with 19 g (148 mmol) of isoquinoline and 220 cm^3 of 0.45M BH$_3$ in THF gave 9.78 g (50%) of 1,2,3,4-tetrahydroisoquinoline (IV), identified by comparison of IR and PMR spectra with an authentic sample. In a vacuum line experiment, 2.78 g (21.6 mmol) of isoquinoline in diglyme consumed 27.6 mmol of B$_2$H$_6$ (1:1.28 ratio).

N-*Methylquinolinium iodide and diborane*

Treatment of 22.2 g (82 mmol) of N-methylquinolinium iodie in 50 cm^3 of THF with 164 ml 1M BH$_3$ in THF for 3 weeks gave, after workup, 4.1 g (34%) VI by vacuum distillation (85° at 1 torr). The product was identified by IR, PMR and mass spectrometry.

N-*Methylisoquinolinium iodide and diborane*

Treatment of 22.2 g (82 mmol) of N-methylisoquinolinium iodide in 50 cm^3 THF with 164 ml 1M BH$_3$ in THF for 3 weeks gave, after workup, 6.2 g (51%) of VII, m.p. methiodide, 189–190°, lit. 190°.[26]

2-*Chloro-, 3-bromo- and 4,7-dichloroquinoline and diborane*

Reactions were carried out in the usual way with the quantities of reactants listed below. After standard workup the crude products were chromatographed in alumina using hexane, hexane–isopropanol (9:1), and hexane–isopropanol (3:1) as successive eluants. Much tarry material was retained on the column in all cases. Product identification was by IR and PMR.

Treatment of 5.07 g (31.0 mmol) of 2-chloroquinoline in 50 cm^3 THF with 95 ml 1M BH$_3$ in THF for 1 week at 25° gave after workup 0.161 g (3.9%) III.

Reaction of 4.97 g (23.9 mmol) of 3-bromoquinoline in 50 cm^3 THF with 72 ml 1M BH$_3$ in THF for 1 week at 25° produced after workup 1.17 g (36.7%) III.

Treatment of 5.08 g (25.7 mmol) of 4,7-dichloroquinoline in 50 cm^3 THF with 80 ml 1M BH$_3$ in THF for 1 week at 25° gave after workup 0.81 g (18.8%) of the 7-chloroderivative of III.

8-*Hydroxyquinoline and diborane*

A freshly-combined mixture of 0.131 g (0.906 mmol) of 8-hydroxyquinoline, 1 cm^3 monoglyme, and 1.2 mmol of B$_2$H$_6$ was allowed to warm from the solvent melting point to −5° in the NMR probe. The boron-11 NMR spectrum initially consisted of three approximately equal signals: that of unreacted B$_2$H$_6$, a triplet at 5.1 ppm, J, 112 Hz (XII), and a quartet at −11.1 ppm, J, 93 Hz (XI). Within 15 min the quartet had disappeared leaving the diborane signal and a greatly enhanced triplet. The evolution of hydrogen, which had been steady since the start of the reaction, stopped at this point. Over a 20-hr period at room temperature the triplet and the diborane signals were replaced by very broad featureless absorptions.

In a larger scale reaction, a 1.016-g (7.01 mmol) sample of 8-hydroxyquinoline dissolved in 20 cm^3 of monoglyme was allowed to react with 7.74 mmol of B$_2$H$_6$ at 25°. Vigorous hydrogen evolution ceased within 30 min leaving a clear yellow solution. The vessel was opened after standing several days and 7.35 mmol of hydrogen was collected. Vacuum fractionation of volatile products gave 0.99 mmol of recovered B$_2$H$_6$ (6.75 mmol consumed). The usual workup of the yellow, oily residue gave a low yield (<10%) of 1,2,3,4-tetrahydro-8-hydroxyquinoline m.p. 119–121°, lit. 122.5°.[27] Mass spec. parent ion m/e 149.

A similar experiment in which workup was performed 3 hr after initiation of the reaction gave only unchanged 8-hydroxyquinoline (62% recovery).

Sodium 8-hydroxyquinolinate and diborane

An NMR reaction was carried out using 0.129 g (0.774 mmol) of sodium 8-hydroxyquinolinate and 1.02 mmol of B_2H_6 in 1 cm³ of monoglyme. The solid dissolved readily giving a clear yellow solution. No hydrogen was produced. The boron-11 NMR consisted of a strong triplet identical with that of XII and a singlet due to $B_2H_7^- - B_2H_6$ exchange[10] at −20.7 ppm. After 24 hr the triplet had disappeared, and the spectrum comprised the $B_2H_7^- - B_2H_6$ exchange singlet and a very broad featureless absorption at lower field.

Phenanthridine and diborane

A 1.55-g (9.99 mmol) sample of phenanthridine was allowed to react with 13.9 cm³ of $1M$ BH_3 in THF at room temperature for 2 weeks. Workup gave 0.96 g (53%) of 5,6-dihydrophenanthridine (XIII), m.p. 122.5–123°, lit. 123°.[28] In a separate quantitative vacuum line experiment 0.358 g (2.00 mmol) of phenanthridine consumed 2.72 mmol B_2H_6 (1:1.36 ratio).

N-Methylphenanthridinium iodide and diborane

A 0.587-g (1.83 mmol) sample of N-methylphenanthridinium iodide was sealed in an all-glass vessel with 10 cm³ Et_2O and 1.83 mmol B_2H_6. The solid gradually dissolved over a 6-week period giving a clear colorless solution. Vacuum line separation of volatile products gave 0.27 mmol of unreacted B_2H_6 and a small amount of C_2H_5I (gas IR). A mass spectrum of the colorless solid residue showed it to be 5,6-dihydro-5-methylphenanthridine-borane (XV) (parent ion m/e 209). IR νBH (in cm⁻¹): 2400s, 2350s, 2255m. Treatment of XV with anhydrous methanol followed by vacuum evaporation of the clear colorless solution gave 0.409 g (99.4%) of the 5,6-dihydro compound XIV, m.p. 49–51°, lit 46–48°.[29] Reaction of 0.215 g (1.10 mmol) of XIV with 1.51 mmol B_2H_6 in monoglyme followed by separation of volatiles (0.56 mmol B_2H_6 consumed) gave a solid with an IR spectrum superimposable upon that of XV.

In a separate NMR reaction, a 0.283 g (0.878 mmol) sample of N-methylphenanthridinium iodide dissolved in 1 cm³ of monoglyme in the presence of 1.13 mmol B_2H_6 in 24 hr. The boron-11 NMR spectrum is described above.

1,8-Naphthyridine and diborane

A 0.622-g (4.79 mmol) sample of 1,8-naphthyridine in 10 cm³ of monoglyme was allowed to react with 7.36 mmol of B_2H_6 at room temperature for 24 hr. Vacuum line separation of volatile materials indicated the consumption of 5.71 mmol of B_2H_6. The involatile solid residue was air-sensitive and showed BH and BHB IR stretching bands at 2400, 2390, 2310, 2000 and 1880 cm⁻¹. Treatment of this residue with 50% acetic acid followed by the usual recovery procedure gave 0.283 g (44%) of the tetrahydro compound XVIII, identified by PMR.[30]

In an NMR experiment a 1.62-mmol sample of B_2H_6 was condensed on to 0.142 g (1.09 mmol) of 1,8-naphthyridine and 1 cm³ of monoglyme at −196°. The vessel was warmed until the solvent melted and was placed in the NMR probe cooled to −40°. The boron-11 NMR spectrum at this temperature consisted of a B_2H_6 signal and a broad quartet at approx. 7 ppm, J, 80 Hz. Upon warming to room temperature the quartet rapidly disappeared and was replaced by a broad unresolved signal.

4,4′-Bipyridyl and diborane

A 1.86-mmol sample of B_2H_6 was condensed into a vessel containing a solution of 0.208 g (1.33 mmol) of 4,4′-bipyridyl in 10 cm³ of monoglyme. As the solvent melted, a colorless solid formed and persisted at room temperature. No further change was seen. After 24 hr, fractionation of volatiles showed 1.37 mmol of B_2H_6 had been consumed

(complex composition bpy·1.03 B_2H_6). The colorless solid bisborane adduct was air stable and showed IR BH stretching bands at 2350 s, br; 2275 m, sh. Solvolysis in acidified ethanol and treatment with base gave unchanged 4,4′-bipyridyl.

In a long term experiment 2.09 mmol of B_2H_6, 0.226 g (1.45 mmol) of 4,4′-bipyridyl, and 10 cm³ of monoglyme were left to stand in a sealed Pyrex tube at room temperature for 1 yr. Solvolysis as above gave unchanged starting material (80%).

A sample of 0.217 g (1.39 mmol) of 4,4′-bipyridyl in 10 cm³ of monoglyme was allowed to react with 0.691 mmol of B_2H_6 in a sealed Pyrex tube. The solid-free, light-yellow solution was allowed to stand at ambient temperature for 1 yr prior to standard workup. Only starting material was recovered (91%).

2,2′-Bipyridyl and 0.5 equivalent of diborane

A 2.275-g (14.6 mmol) sample of 2,2′-bipyridyl in 10 cm³ of monoglyme was treated with 7.22 mmol of diborane in a 100-cm³ reaction vessel. The originally clear colorless solution turned dark orange over several hours and a colorless solid, identified as bpy·2BH₃ by its IR spectrum,[15] formed over a period of 2 days. The usual workup gave a dark red liquid product. The PMR of this material showed it to be a mixture of starting material and nonaromatic products. A mass spectrum of the mixture showed parent peaks at m/e 156 (bpy) and m/e 166 (a decahydro product). No further separation or characterization of the products was attempted.

1,10-Phenanthroline and diborane

A 0.106 g (0.588 mmol) sample of 1,10-phenanthroline in 5 cm³ of monoglyme was treated with 1.43 mmol of B_2H_6. The initially colorless mixture rapidly turned dark purple as the vessel came to room temperature, then changed to dark green over 1 hr and finally lightened to yellow with the formation of a solid of the same color after 24 hr. No further changes occurred and no hydrogen was evolved. A sample of the air-sensitive yellow solid showed BH stretching absorptions at 2580, 2470, 2410, 2360, 2310, 2030 and 1940 cm⁻¹. Fractionation of volatiles showed that 1.49 mmol of B_2H_6 had been consumed per mmol of 1,10-phenanthroline. Standard workup gave an air-stable oil which was chromatographed on alumina using benzene–chloroform (80/20) as an eluant to give a light yellow oil which was a mixture of tetra- and octa-hydro-1,10-phenanthrolines (MS parent ions m/e 184, 188) in less than 10% yield. No further separation was attempted.

1,7-Phenanthroline and diborane

A 0.363-g (2.01 mmol) sample of 1,7-phenanthroline in 10 cm³ of monoglyme was treated with 3.87 mmol of diborane. Reaction was evidenced by the appearance of yellow–brown crystals on standing 24 hr. After 3 days, fractionation of volatiles showed 1.65 mmol B_2H_6 absorbed per mmol phenanthroline. Standard workup gave a red–orange oil which was a mixture of tetra- and octahydro-derivatives (MS parent ions m/e 184, 188). No further separation or characterization was attempted.

Decomposition of pyridine–borane

A 0.560-g (6.02 mmol) sample of pyridine–borane in 21 cm³ of diglyme (0.29 M solution) was heated to reflux in a nitrogen atmosphere. After 45 min, cream-colored solid began to separate from solution. Within 4 min the formation of this material became so vigorous and exothermic that much of the solution and solid bumped to the top of the reflux condenser. On cooling, the products were subjected to standard workup. Nothing was recovered.

2-Phenylpyridine and diborane

A diglyme solution of 2-phenylpyridine-borane, formed by treating 4.0 g (25.8 mmol) of 2-phenylpyridine in 20 cm³ diglyme with 28.2 mmol of B_2H_6 followed by vacuum evap-

oration of excess B_2H_6, was refluxed in a nitrogen atmosphere for 2 days. The usual workup followed by distillation gave 1.2 g (30%) of unchanged 2-phenylpyridine and *ca* 1.5 g of tarry residue in the distilling flask.

Abstract—With several chloro ruthenium phosphine complexes, allyldifluorophosphite, F₂POC₃H₅, displaces triphenylphosphine to form new compounds in which it acts as a phosphorus donor ligand. The new complexes [PPh₃]₂[F₂POC₃H₅]Ru[CO][Cl][H], I, and [(PPh₃)₂(F₂POC₃H₅)₂RuCl₂]ₙ, II, have been characterized by chemical, spectroscopic, and, in the case of I, crystallographic means. This behaviour of F₂POC₃H₅ contrasts to its reactions with several platinum and palladium chloro complexes where it undergoes Arbuzov-type rearrangements.

Both PF₃ and phosphite esters, P(OR)₃, are important ligands in organometallic and coordination chemistry. Consequently, it is somewhat surprising that the metal chemistry of the organofluorophosphites, $F_nP(OR)_{3-n}$, $n = 1$ or 2, has not received much attention. In previous studies a few complexes in which compounds of the type $F_nP(OR)_{3-n}$ serve as conventional phosphorus ligands have been isolated.[1,2] Of greater interest, however, is the ability of certain organodifluorophosphites to undergo reactions, formally related to the classic "Michaelis–Arbuzov" reaction, producing complexes of F₂PO⁻.[3–8] The F₂PO⁻ ion is isoelectronic with PF₃, and is known to serve both as a monodentate ligand bonding through phosphorus and a bridging ligand in which both phosphorus and oxygen are coordinated.[3–9]

The lack of simple synthetic routes to F₂PO⁻ or its complexes has, no doubt, prevented a systematic evaluation of its ligand properties. Thus, the possibility that reactions of F₂POR could provide a general route to its preparation is an interesting question to explore. Previously square planar platinum group halides have been shown to effect the transformation in several cases.[3–8] In this note we would like to report the reaction of F₂POCH₂CH=CH₂ with several ruthenium complexes. Allyldifluorophosphite, F₂POC₃H₅, was chosen for these studies since it is the organodifluorophosphite which is known to form most easily F₂PO⁻ complexes via a Michaelis–Arbuzov reaction.

EXPERIMENTAL

All manipulations were carried out under a dry nitrogen or argon atmosphere using standard techniques. Solvents were dried and deoxygenated by appropriate means and distilled immediately before use. Published procedures were used to prepare F₂POC₃H₅,[1] (Ph₃P)₃Ru(CO)(H)(Cl),[10] (Ph₃P)₃RuCl₂,[11] and (Ph₃P)₄RuCl₂.[11]

NMR spectra were recorded on CDCl₃ solutions using a Varian XL-100 spectrometer. Chemical shifts are referenced to internal Si(CH₃)₄ for ¹H, external CCl₃F for ¹⁹F, and external 85% H₃PO₄ for ³¹P. Chemical shifts are positive to high frequency. IR spectra were obtained on Nujol mulls, KBr pellets and solutions using a Perkin–Elmer IR 4260 spectrometer. Elemental analysis was performed by Mikroanalytisches Laboratorium Beller, Göttingen, West Germany.

Reaction of (Ph₃P)₃Ru(H)(CO)(Cl) with F₂POC₃H₅. The preparation of (Ph₃P)₂(F₂POC₃H₅)Ru(CO)(H)(Cl), I

A 0.24 g sample of (Ph₃P)₃Ru(H)(CO)(Cl) was dissolved in 10 cm³ of CH₂Cl₂. From a syringe 0.46 g (3.6 mmol, about 0.5 cm³) of F₂POC₃H₅ was added to the solution. After 1 hr stirring the volume was reduced to about 3 cm³ by evaporation under vacuum; the mixture was then placed in a freezer at −20° for about 18 hr. After this period white crystals had formed. They were removed, washed with two 10-cm³ portions of diethylether and dried under vacuum to yield 0.12 g of (Ph₃P)₂(F₂POC₃H₅)Ru(CO)(Cl)(H)·H₂CCl₂. Anal. for C₄₁H₃₈Cl₃F₂O₂P₃Ru. Calc. C, 55.7; H, 4.02; P, 11.68. Found: C, 56.69; H, 4.43; P, 11.66%. IR ν(CO), 1985 cm⁻¹ (s); ν(Ru–H), 1915 cm⁻¹ (w).

Reaction of (Ph₃P)₃RuCl₂ with F₂POC₃H₅. The preparation of (Ph₃P)₂(F₂POC₃H₅)₂RuCl₂, II

A 1.06 g sample of (Ph₃P)₃RuCl₂ was dissolved in 20 cm³ of benzene and 0.9 cm³ of F₂POC₃H₅ added. Over a 1/2 hr period the initially very deeply coloured solution faded to a light yellow color and a pale yellow solid began to precipitate. After 24 hr the solution was filtered, the precipitate washed with four 10 cm³ portions of diethylether and dried

under vacuum to give 0.56 g of $(Ph_3P)_2(F_2POC_3H_5)_2RuCl_2$. Anal. for $C_{42}H_{40}Cl_2F_4O_2P_4Ru$. Calc. C, 53.16; H, 4.22; Cl, 7.49; P, 13.08. Found: C, 53.63; H, 4.35; Cl, 7.56; P, 13.00%.

Using the same procedure, II, can be obtained by the reaction of $(Ph_3P)_4RuCl_2$ with $F_2POC_3H_5$. II can be recrystallized from CH_2Cl_2 or $CHCl_3$.

RESULTS AND DISCUSSION

The reaction of $(Ph_3P)_3Ru(H)(CO)(Cl)$ with an excess of $F_2POC_3H_5$ at ambient temperature produces $(Ph_3P)_2(F_2POC_3H_5)Ru(H)(CO)(Cl)$, I. This white complex has been characterized by the usual analytical and spectroscopic methods. NMR data, obtained on freshly prepared $CDCl_3$ solutions, are summarized in Table 1, and are consistent with the proposed empirical formula for I. The 27.7 Hz coupling of the phosphorus in $F_2POC_3H_5$ with two equivalent PPh_3 phosphorus nuclei is typical of couplings between *cis* phosphorus ligands in octahedral complexes,[12] and the 224 Hz J(PRuH) coupling observed between F_2POC$_3$H$_5$ and the Ru–H is in the characteristic range for a phosphite *trans* to a hydride.[13] In the IR spectrum, a strong band at 1983 ± 3 cm^{-1} can be assigned as $\nu(CO)$ while a weak absorption at 1918 ± 5 cm^{-1} arises from ν(Ru–H). Thus, $\nu(C \equiv O)$ is shifted to a higher frequency in I than in the starting material, where it appears at about 1920 cm^{-1}. Such shifts are typical when a PPh_3 group is substituted by a better π-accepting ligand, and have previously been seen with phosphite, $P(OR)_3$, derivatives, $(Ph_3P)_{3-n}(P(OR)_3)_nRu(H)(CO)(Cl)$.[13] The IR spectrum also contains peaks virtually identical to those of free $F_2POC_3H_5$ and indicates that extensive ligand rearrangement has not occurred during the formation of I.

These data suggest that I is an octahedral complex derived from $(Ph_3P)_3Ru(H)(CO)(Cl)$ by substitution of the Ph_3P group trans to the hydride ligand by

$F_2POC_3H_5$. This structure has been confirmed by single crystal X-ray diffraction[14] and the resulting structure is shown in Fig. 1. It is noteworthy that $F_2POC_3H_5$ is coordinated through the phosphorus atom and that no interaction occurs between the allyl fragment and any other portion of the molecule.[14]

Reaction of $F_2POC_3H_5$ with both $(Ph_3P)_4RuCl_2$ and $(Ph_3P)_3RuCl_2$ produces a pale yellow complex of empirical formula $(Ph_3P)_2(F_2POC_3H_5)_2RuCl_2$, II. Between 750 and 4000 cm^{-1} the IR spectrum of II is essentially a superposition of the spectra of Ph_3P and $F_2POC_3H_5$, and thus strongly implies that no rearrangements have occurred in these ligands upon their coordination to ruthenium. NMR data indicate that II is an octahedral complex with *trans* $F_2POC_3H_5$ ligands located *cis* to two *cis* Ph_3P groups. If ^1H couplings are ignored, ^{19}F and ^{31}P spectra obtained on freshly prepared samples of II in $DCCl_3$ represent a well-resolved $A_2A_2'MM'XX'$ spin system. While the spectra are not first order, they can be analyzed and computer simulated, yielding the parameters given in Table 1. The 889.9 Hz coupling between phosphorus atoms in two equivalent $F_2POC_3H_5$ ligands indicates[12] that they are *trans* while the 53.3 Hz coupling between $F_2POC_3H_5$ and PPh_3 phosphorus atoms is characteristic of *cis* ligand configurations. The following stereochemistry for II is thus indicated

$$F_2POC_3H_5$$
$$Ph_3P \diagdown \;\Big|\; \diagup Cl$$
$$Ru$$
$$Ph_3P \diagup \;\Big|\; \diagdown Cl$$
$$F_2POC_3H_5$$
Whether II is monomeric or possesses an oligomeric, chloride-bridged, ionic structure similar to those of
Fig. 1. Molecular structure of $(Ph_3P)_2(F_2POC_3H_5)Ru(H)(CO)(Cl)$.[14] A hydrogen atom (which was not located) is assumed to occupy the vacant position in the coordination sphere about ruthenium.

Table 1. NMR data[a]

[PPh$_3$]$_2$[F$_2$POC$_3$H$_5$]Ru[CO][Cl][H]:

Chemical Shifts:

^{19}F: -33.49 ppm (F$_2$P)

^{31}P: +130.10 ppm (F$_2$P)

  + 38.06 ppm (Ph$_3$P)

^{1}H:[b] -4.29 ppm (HRu)

Coupling Constants:

^{1}J(PF) = (-) 1286.8 Hz

^{3}J(PF) = 4.0 Hz

^{2}J(PhPRuPF) = 27.7 Hz

^{2}J(F$_2$PRuH) = 224 Hz

^{2}J(Ph$_3$PRuH) = 19.2 or 33.2 Hz[c]

^{3}J(F$_2$PRuH) = 33.2 or 19.2 Hz[c]

[(PPh$_3$)$_2$(F$_2$POC$_3$H$_5$)$_2$RuCl$_2$]$_n$

Chemical Shifts:

^{19}F: -37.09 ppm (F$_2$P)

^{1}H: see note (b)

^{31}P: +124.9 ppm (F$_2$P)

  + 22.7 ppm (Ph$_3$P)

Coupling Constants:[d]

^{1}J(PF) = -1258.6 Hz

^{3}J(F$_2$PRuPF) = 67.9 Hz

^{2}J(Ph$_3$PRuPF) = 53.3 Hz

^{2}J(F$_2$PRuPF) = 889.9 Hz

^{3}J(F$_2$PRuPPh) = ~6.1 Hz

[a]Spectra are second order. Chemical shifts and coupling constants have been obtained from theoretical spectra which have been matched to the experimental data by iterative calculations using a modified LAOCOON III program.

[b]The ^{1}H spectrum between 1–6 ppm was second order and qualitatively resembled the complex spectra expected for F$_2$POCH$_2$CH=CH$_2$. Between 7–9 ppm typical PPh$_3$ resonances occurred. No attempt was made to extract detailed spectral parameters, however.

[c]The Ru–*H* resonance appeared as a doublet of triplets. Since both *F*$_2$PRu*H* and (Ph$_3$P)$_2$Ru*H* couplings would generate triplet splittings, it was impossible to assign these couplings uniquely from the ^{1}H data. In order to enhance intensity, ^{31}P and ^{19}F spectra were obtained with [^{1}H] decoupling; consequently the assignment of these coupling constants is ambiguous.

[d]^{4}J(FF) and ^{2}J(Ph$_3$P Ru*P*Ph$_3$) were arbitrarily set to 10 Hz and 20 Hz, respectively; variations in these values did not affect the form of the spectrum at experimental resolution.

some other phosphine and phosphite ruthenium complexes[13,15] is not certain. However, after a few minutes the NMR spectra show changes and within 15–20 min the ^{19}F spectrum becomes a complex series of many weak resonances and the F$_2$POC$_3$H$_5$ resonances and couplings become unresolvable in the ^{31}P spectrum. This is not the result of decomposition of the F$_2$POC$_3$H$_5$ since **II** can be recrystallized from these solutions after concentration and cooling, or upon the addition of petroleum ether. Similar behavior has been noted in other mixed phosphine or mixed phosphine/phosphite ruthenium complexes and has been found to be the result of complex oligomerization and ligand interchange equilibria.[15] In all likelihood **II** enters into similar equilibria, but the exact details of these must await further study.

The formation of compounds **I** and **II** is noteworthy since they demonstrate that the F$_2$POC$_3$H$_5$ moiety can exist, coordinated to ruthenium, in media which undoubtedly contain Cl$^-$ and PPh$_3$. A Michaelis–Arbuzov reaction in which a nucleophile displaces an organo group from a coordinated organodifluorophosphite is consistent with the formation of F$_2$PO$^-$ in square planar platinum and palladium systems,[3,5] but obviously does not occur in the compounds studied here. Arbuzov-like rear-

rangements also occur in phosphite complexes. Recently these and some related intramolecular alkyl group exchanges have been shown to involve an oxidative alkyl migration to the metal.[16–18] The possibility that such a process could also be responsible for F$_2$PO$^-$ formation in F$_2$POR metal complexes, but is blocked in **I** and **II** by the unfavorable thermodynamics for the oxidation of Ru(II), is presently under investigation.

SYNTHESIS AND CHARACTERIZATION OF LAYERED TETRAVALENT METAL TERPHENYL MONO- AND *BIS*-PHOSPHONATES

MARTIN B. DINES✠ and PETER C. GRIFFITH

Occidental Research Corporation, Irvine, CA 92713, U.S.A.

Abstract—The syntheses of *p*-terphenylphosphonic acid and *p,p"*-terphenyl-*bis*-phosphonic acid have been developed, and the resulting products were used to prepare layered Th(IV) and Zr(IV) phosphonates. The monoacidic terphenyl species formed a bilayered structure while the diacid created a pillared geometry. Mixed component phases were also produced. Synthesis, characterization, X-ray and thermal properties of these materials are discussed.

INTRODUCTION

Several reports of the preparation and properties of the tetravalent metal phosphonates $-M(O_3PR)_2-$ which have a layered structure and therefore access to the bulky $-R$ groups via intercalation have now appeared.[1–5] The terminal functions of the appended organic group can thus interact with guest species in a variety of selective sorption, ion-exchange or catalytic reactions. Furthermore, since the coexistence of more than one group between the layers is possible[3,6] polyfunctional systems can be conceived, microporosity can be incorporated (using pillaring cross-linking groups) and groups larger than the limiting cross-sectional area per site (about 24 Å² for the zirconium salts) can be included by adding compensatory small groups.

The synthesis of these compounds usually involves simple precipitation of the phosphonic acid with the metal ion. However, in many cases some of the most desirable $-R$ groups are not readily available as phosphonic acids, either commercially or via the simple Arbuzov or related reactions.[7] We have chosen one of the more difficult, and most useful, of the class, the polyaromatic mono- and *bis*-phosphonic derivatives, to illustrate how the layered compounds can be prepared and characterized. We focus upon the thorium salts because they are found to be generally more crystalline (i.e. they yield sharper X-ray diffraction reflections). The polyphenyl-*bis*-phosphonic acids are particularly good pillars because they are rigid and oriented perpendicularly between the lamellae. They are potentially valuable, therefore, in the architecture of microporosity in the interlayer regions.

Figure 1 shows a simplified structure of the layered phosphonates.

EXPERIMENTAL

All reagents and starting materials were obtained from commercial suppliers and used as received. Powder patterns were run on a Philips diffractometer using Cu K$_\alpha$ radiation. The thermogravimetry was performed on a DuPont DTA/TGA instrument, using air, and a heating rate of 20°/min.

p-Bromoterphenyl and p,p"-*dibromoterphenyl*. These com-

pounds were prepared by methods described in the literature,[8] and were actually obtained in the same reaction. They can be separated into pure components by selective extraction with hot ethanol. Each had the proper melting point.

Diethyl-p-terphenylphosphonate. *p*-Bromoterphenyl, 4.0 g (0.0129 mol), was slurried in 50 cm³ of *m*-diisopropylbenzene, heated to 140°C, and 100 mg of palladium dichloride were added to the solution. Then, while the reaction mixture was maintained at 160°C, 2.55 cm³ (0.0148 mol) of triethylphosphite were added over a period of 1 hr. This slow addition is required to prevent deactivation of the catalyst. After 3 hr at 160°C, the reaction mixture was cooled and the product fractionally distilled using a Kugelrohr at 170°C/0.4 torr, leading to a residual dark solid (4.0 g) which proved to be a 1:1 mixture of starting material and product. This assessment was made on grounds of both NMR and elemental analysis. Since we planned subsequently to hydrolyze and precipitate the phosphonate, this mixture was used without further purification. This "shortcut" could not be used in the case of the *bis*-phosphonic acid (*vide infra*), since contaminants would also react in later steps, unlike the case with bromoterphenyl.

p,p"-Terphenyl(bis)diethylphosphonate. Using the same route as before, 5.00 g (0.0129 mol) of dibromoterphenyl were added to 50 cm³ *m*-diisopropylbenzene and heated to 150°C. To the slurry which resulted, 0.220 g of palladium dichloride was added and the mixture brought to 160°C, whence 4.86 cm³ (0.0283 mol) triethylphosphite were added

Zr(O₃PR)₂
Fig. 1. Depiction of the framework sheet structure of the tetravalent metal phosphonates.

dropwise over 3 hr. (The addition was timed so that no triethylphosphite reflux occurred) Vacuum distillation (120°C/1 torr) of the solvent and phosphite left a dark solid which still contained some bromoaromatic, so the procedure was repeated to yield finally 5.8 g (90%) of solid having the appropriate NMR, but containing residual palladium. (Calcd. for $C_{26}H_{32}O_6P_2$: C, 62.1%, H, 6.43, P, 12.3; Found: C, 59.6, H, 6.01, P, 11.3, Pd, 3.1.) The palladium was removed in the next step, the hydrolysis of the phosphonic ester to the acid. When chromatography was attempted to purify the ester, much was lost on the column, presumably due to its association with the palladium.

Hydrolysis of the phosphonate esters and precipitation with thorium(IV). In the case of both phosphonate esters, the mono- and *bis*-substituted terphenyls, suitable conditions were sought for hydrolysis and separation of contaminating palladium. Furthermore, in the case of the mono-phosphonate, the product has to be freed of bromoterphenyl which was present (*vide supra*). The best conditions for hydrolysis were found to be heating for 1 hr in 30 cm³ of 30% HBr in acetic acid, cooling, and filtering to remove palladium and the product phosphonic acid. The latter was extracted into hot dioxane to which was added a solution of thorium nitrate in 80% dioxane/water. The resulting precipitate after refluxing for 20 hr. was washed with hot ethanol, then ether, and dried at 105°C for several hours. The phosphonic acid should always be in excess over the metal ion in the precipitation. This procedure led to a satisfactory product in the case of the *bis*-phosphonic acid (Calcd. for $Th(O_3PC_{18}H_{12}PO_3)$: C, 34.9%, H, 1.96; Found: C, 32.5, H, 3.00—other data in Results and Discussion); however, for the monophosphonic acid it remained to remove the significant contamination by bromoterphenyl. Based on the observation of two distinct weight loss processes in the thermogravimetric curve at 280 and 520°C, the first of which is sublimation of the bromoterphenyl, the product of precipitation in dioxane/water was heated in flowing helium at 240°C until no more material sublimed, leaving the product (Calcd. for $Th(O_3PC_{18}H_{13})_2$: C, 50.9, H, 3.09, Found: C, 52.3, H, 3.33).

Corresponding zirconium products were prepared in analogous reactions, using zirconyl chloride. Mixed component phases described in the text were prepared by precipitating combined solutions of the phosphonic acids.

RESULTS AND DISCUSSION

The general strategy for the preparation of both the bilayered, singly-bound terphenyl derivative and the cross-linking (monolayered) analogue is outlined in Fig. 2. Starting with the monobromo- and *p,p"*-dibromoaromatic, which are both formed by bromination of terphenyl and are separable due to their solubility difference in ethanol, the phosphorylated products can be made by a modified Arbuzov reaction (aryl halides required a group 8 metal catalyst,[9] see eqns 1 and 2).

Arbuzov reaction:

$$R-X + P(OR')_3 \rightarrow [R\overset{+}{-}P(OR')_3X^-] \rightarrow RPO(OR)_2$$
$$+ R'-X \quad (1)$$

Modified:

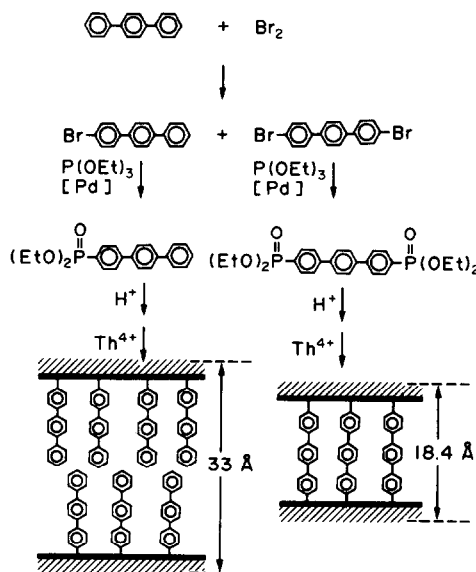
$$Ar-X + P(OR')_3 \xrightarrow{\text{Pd(II)}} [Ar-Pd-X] \rightarrow ArPO(OR')_2$$
$$+ R'-X. \quad (2)$$
After hydrolysis to the phosphonic acid, the precipitation with tetravalent metal ion is carried out in an appropriate solvent system, i.e. one in which reactants


Fig. 2. The strategy for the preparation of the terphenyl compounds.

are all soluble. Given the nature of the aryl substituent, this was not achievable in straight aqueous media, as are most of the preparations of the layered metal(IV) phosphonates.

The choice of conditions for the precipitation (and purification) of the final products is not the only complication in the synthesis; we found it necessary to modify the preceding steps as well, and this is spelled out in the Experimental.

In the next sections we shall discuss some of the characterization of the products, compare the results of zirconium use to thorium, and touch upon some mixed composition compounds containing the terphenyl substituent.

$Th(O_3P\text{-}terphenyl)_2$

This product was prepared under conditions in which contaminating bromoterphenyl had to be removed. The presence of the halide was apparent in the thermogravimetric curve of the product of the thorium precipitation, which clearly showed two weight loss processes, at 280 and 520°C. The first weight loss is attributed to evaporation of the aryl bromide from the solid, the second is the decomposition of the layered phosphonate. The organic component is not intercalated in the thorium compound, as evidenced by its X-ray diffraction pattern, which shows the *d*-spacing series at about 33 Å. Since this is approximately the value expected for a bi-layered terphenyl structure, no guest is included in the crystalline product. This does not preclude the possibility of an amorphous or very poorly crystalline intercalated phase coexisting with the simple terphenyl-phosphonate.

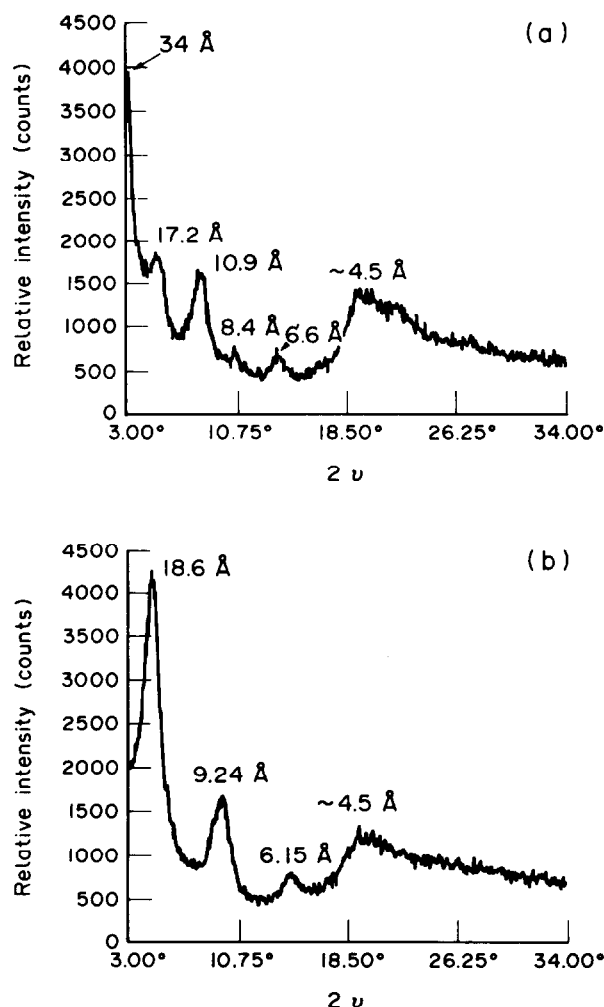
On heating the impure product to 240°C in flowing helium, about half of the weight is lost, and the clean product results. The TGA now exhibits a single process at 520°C, and the XRD still has the 001 series corresponding to an interlayer distance of 33 Å (Fig. 3). This value is exactly that predicted based on a structure of non-interleaving perpendicularly oriented


Fig. 3. X-ray diffraction powder patterns of the terphenyl compounds: A, Th(O₃P-terphenyl)₂; B, Th(O₃P-terphenyl-PO₃).

terphenyl groups appended from every site on the basal surface of a thorium-PO₃ sheet similar in structure to α-zirconium phosphate. The corresponding layer–layer spacings for mono- and diphenyl-substituted thorium phosphonates[6] are 15 and 24 Å, which make for a good linear relationship (Fig. 4). The slope, 9 Å/(2) phenyl groups, agrees with the value of 4.2 Å for -⬡- from CPK models.

Th(O₃P-*terphenyl*-PO₃)

The preparation and characterization of this product was actually more straightforward than the monophosphonate, because the starting material was purer. Although the thermogravimetric curve did not show any occluded organic as before, the decomposition process was not as sharp. Instead of a single narrow weight loss, there was a broadened continuous decomposition which occurred from 250 to 800°C, corresponding to the loss of the organic component (calcd loss for $C_{18}H_{12}$, 37%; found, 37.5%). The cause of this extended range may be the fact that the organic groups are doubly bound, and that deintercalation of the products of decomposition is inhibited, necessitating an edge-inwards process.

The XRD spacing found for the crosslinked terphenyl was 18.6 Å (see Fig. 3), which when compared with the diphenyl analogue[10] yields a slope of 4.1 Å per phenyl group, in good agreement with the model discussed for the monophosphonate. It is also interesting that the intercept, which implies a value for the thickness of the Th(O₃P-)₂ inorganic layer, is the same in both cases, 6.2 Å (Fig. 5). The corresponding value for the zirconium compounds is 5.4 Å, in close enough agreement (after correcting for the greater ionic radius of Th^{4+}) to suggest that both series have the α-zirconium phosphate sheet structure.

The value estimate for the pillar length of the terphenyl group (18.6–6.2 = 12.4 Å) suggests that this might be an attractive candidate for mixed component microporous products. Our only attempt at this, using the terphenyl-*bis*-phosphonate together with phenylphosphonic acid, led to a product whose X-ray powder pattern indicated that mostly a pure phase of the phenyl derivative had formed. This could occur if the rate of precipitation of the phenyl product is much faster than that of the *bis*-acid, a situation we have observed in other instances. In such situations mixed component products can often be formed by using excessive amounts of the slower
Fig. 4. Plot of the d-spacing (interlayer distance) for the series of thorium arylphosphonates.

Fig. 6. Representation of two alternative structures for the mixed component thorium phenyl/terphenyl phosphonate product. Top, ordered with the same group covering basal surfaces; bottom, ordered or disordered with variable basal content. In both cases, the interlayer distance corresponds to phenyl–terphenyl interactions dictating the interlayer distance.

Fig. 5. Plot of the d-spacings for the cross-linked thorium arylphosphonates.

precipitating species, but we did not explore this possibility in the case at hand.

Other terphenyl-containing products

Although the attempt at the preparation of a mixed-component cross-linked compound was not successful, it did prove possible to produce one containing a monophosphonate group, namely $Th(O_3PC_6H_5)(O_3PC_{18}H_{13})$. In this case, by co-precipitation of the corresponding phosphonic acids, a product having the correct analysis, and more significantly an X-ray powder pattern exhibiting predominantly the series of reflections for a d-spacing of 24.3 Å was afforded. This dimension is just what would be expected for a structure in which terphenyl groups oppose phenyl groups across the interlayer (i.e. $1/2(15 \text{ Å} + 33 \text{ Å})$. Two alternative ways this could be arranged are: (a) either one entire face contains one group and the other the opposite group (an ordered array), or (b) a random structure in which somehow terphenyls are fitted efficiently with phenyls (Fig. 6). We cannot differentiate experimentally between these alternatives, although one might expect that there would be density differences between the two structures.

The analogous zirconium compounds were prepared for most of the cases under discussion and true to our past experience, they were generally found to be of inferior crystallinity as implied by their poor XRD patterns.

PREPARATION AND CHARACTERIZATION OF DICHLOROBIS(N-ALKYL-SUBSTITUTED SALICYLIDENEAMINATO)MANGANESE(IV) COMPLEXES

TAKAYUKI MATSUSHITA* and TOSHIYUKI SHONO
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565, Japan

Abstract—A series of dichlorobis(N-alkyl-substituted salicylideneaminato)manganese(IV) complexes, $Mn(N-R-Xsal)_2Cl_2$, was prepared by the reaction of $Mn(N-R-Xsal)_2Cl$ complexes with hydrogen chloride, where R can be $n\text{-}C_8H_{17}$ (Oct), $n\text{-}C_{12}H_{25}$ (Dod), $n\text{-}C_{18}H_{37}$ (Octd), and $CH_2C_6H_5$ (Bz) and X can be 5-bromo, 5-nitro, and 5,6-benzo groups. These complexes were characterized by the magnetic susceptibilities, IR and electronic spectra, and cyclic voltammograms.

Manganese(III) and -(IV) complexes are of interest in relation to the biological redox systems catalyzed by manganese ions, which include the disproportionation of superoxide ion (O_2^-) by the manganese-containing superoxide dismutases and the photosynthetic oxygen evolution by water oxidation in green plants.[1,2] Although a number of manganese(III) complexes with various ligands have been investigated, very few manganese(IV) complexes have been isolated and characterized so far. The reason seems to be that manganese(IV) ion is a strong oxidizing agent and its complexes are unstable toward moisture.[3,4]

Previously we have found that a series of chloromanganese(III) complexes with the bidentate and tetradentate Schiff base ligands reacts with hydrogen chloride to give the corresponding dichloromanganese(IV) complexes as deep green crystals.[5] These complexes, however, are not stable toward water even in the solid state and decompose gradually to their reduced manganese(III) complexes. In an earlier paper we have shown that the dichloromanganese(IV) complexes with the bidenatae Schiff bases which were derived from salicylaldehyde and long-chain aliphatic monoamines such as $n\text{-}C_{12}H_{25}NH_2$ and $n\text{-}C_{18}H_{37}NH_2$ are more stable toward water than those derived from $n\text{-}C_3H_7NH_2$ and $n\text{-}C_4H_9NH_2$.[6]

Present paper describes the preparation and characterization of new dichloromanganese(IV) complexes as shown in Fig. 1.

EXPERIMENTAL

Preparation of Mn(III) Schiff Base Complexes, Mn(N-R-Xsal)$_2$Cl. Chlorobis(N - dodecyl - 5 - bromosalicylideneaminato)manganese(III), Mn(N - Dod - 5 - Brsal)$_2$Cl. N - Dodecyl - 5 - bromosalicylideneamine (N - Dod - 5 - BrsalH) was prepared by the condensation of 5-bromosalicylaldehyde and equimolar dodecylamine in tetrahydrofuran. This was recrystallized from ether. The other bidentate Schiff bases were prepared in a similar manner. Their melting points and analytical data are listed in Table 1.

To an ethanol solution (100 cm³) of N-Dod-5-BrsalH (7.37 g, 0.02 mol), Mn(III) $(CH_3CO_2)_3 \cdot 2H_2O$ (2.68 g, 0.01 mol) and LiCl (0.84 g, 0.02 mol) were added. The mixture was warmed at 60°C for 1 hr with stirring and then

evaporated to remove the solvent under reduced pressure. The resulting brown solids were collected on a glass filter, washed with small amounts of ethanol, and dried *in vacuo*. They were extracted with dichloromethane (150 cm³), and the solution was evaporated to give brown solids. They were recrystallized from acetonitrile.

The other manganese(III) complexes were prepared in a similar manner. The solvents employed for recrystallization were acetonitrile for Mn(N-Oct-5-Brsal)$_2$Cl, Mn(N-Oct-5,6-Benzosal)$_2$Cl, Mn(N-Dod-5,6-Benzosal)$_2$Cl, Mn(N-Oct-5-NO$_2$sal)$_2$Cl, and Mn(N-Dod-5-NO$_2$sal)$_2$Cl, acetone for Mn(N-Octd-5-Brsal)$_2$Cl and Mn(N-Octd-5,6-Benzosal)$_2$Cl, dichloromethane for Mn(N-Bz-5Brsal)$_2$Cl and Mn(N-Octd-5-NO$_2$sal)$_2$Cl, methanol for Mn(N-Bz-5-Brsal)$_2$Cl, and N,N-dimethylformamide for Mn(N-Bz-5-NO$_2$sal)$_2$OH. These complexes are soluble in dichloromethane, methanol, and acetonitrile, slightly soluble in ether, and insoluble in water. The analytical data for these complexes are given in Table 2.

Preparation of Mn(IV) Schiff Base Complexes, Mn(N-R-Xsal)$_2$Cl$_2$. Dichlorobis(N - dodecyl - 5 - bromosalicylideneaminato)manganese(IV), Mn(N-Dod-5-Brsal)$_2$Cl$_2$. To a 2-propanol (70 cm³) containing Mn(N-Dod-5-Brsal)$_2$Cl (1.0 g) was added a 2-propanol solution of hydrogen chloride (1.5 molar folds over the complex) at room temperature. The mixture was stirred for 1 hr to give deep green precipitates. They were collected on a glass filter, washed with 2-propanol, and dried *in vacuo*. They were recrystallized from benzene to give deep green crystals. The yield was *ca.* 0.2 g. This complex is soluble in dichloromethane, benzene, and acetone to give deep green colour. These solutions show no measurable change in colour allowing to stand for 1 hr in an aerial atmosphere. This complex

also is soluble in pyridine and methanol but these solutions change in colour from green to brown gradually.

The other dichloromanganese(IV) Schiff base complexes were prepared in a similar manner. The analytical data for the manganese(IV) complexes are given in Table 3.

Measurements. The melting points were determined by means of a Yanagimoto MP-1 melting point apparatus and uncorrected. The UV and VIS spectra were obtained by a Hitachi 340 spectrophotometer. The IR spectra were recorded on a Hitachi EPI-215 grating spectrophotometer in the 650–4000 cm^{-1} regions and on a Hitachi EPI-L grating spectrophotometer in the 200–700 cm^{-1} regions. The magnetic susceptibilities were measured by the Gouy method at room temperature. The cyclic voltammetry was performed with a Yanagimoto P-8 polarograph connected with a Yanagimoto P8-PT potentiostat. The working electrode was a platinum-inlay electrode, while the auxiliary electrode was a platinum wire. The reference electrode was a saturated calomel electrode which was inserted in an aqueous solution of 1 M KCl in a 100 cm^3 beaker connected with a conventional brown H-Type cell by means of a 4% agar-saturated KCl gel bridge. Tetrabutylammonium perchlorate, Bu$_4$NClO$_4$, was used as the supporting electrolyte (0.1 M). The dissolved oxygen was removed by passing N$_2$ gas through a sample solution for 20 min. The cyclic voltammograms were recorded under the following conditions: concentration of the complexes was 5×10^{-4} M, the scan rate was 0.06 V/s, and temperature was kept at 25°C.

Materials. All reagents were of reagent grade. The solvents were purified by a usual manner. Acetonitrile was distilled twice over diphosphorus pentaoxide prior to use. Benzene was distilled over sodium.

RESULTS AND DISCUSSION

Preparation. We reported previously the preparation and characterization of dichlorobis (N-butyl-substituted salicylideneaminato)manganese(IV) complexes, Mn(N-Bu-Xsal)$_2$Cl$_2$, where X can be H, 5-Br, 5-NO$_2$, and 5,6-Benzo groups.[5] These complexes were decomposed gradually to the reduced manganese(III) complexes by moisture allowing to stand in an aerial condition even in the solid state. Thus in order to obtain pure manganese (IV) complexes much care should be taken to remove trace amounts of water in the solvents used. In an earlier paper[6] we have reported that the manganese(IV) complexes incorporating long-chain alkyl groups such as n-C$_{12}$H$_{25}$ and n-C$_{18}$H$_{37}$ can be protected from attack of water. These

findings led us to prepare a series of dichloromanganese(IV) Schiff base complexes having long-chain alkyl groups. All the manganese(III) complexes which were prepared have a composition of $Mn(N-R-Xsal)_2Cl$, with the exception of $Mn(N-Bz-5-NO_2sal)_2OH$ (Table 2). All the manganese(IV) complexes which were obtained have a composition of $Mn(N-R-Xsal)_2Cl_2$ (Table 3). The properties for the

manganese(III) and manganese(IV) complexes are summarized in Tables 4 and 5, respectively.

Melting points. The manganese(III) complexes having the long-chain alkyl groups showed low melting points without decomposition. As seen in Table 4, the longer the alkyl groups the lower melting points are obtained in the order of Bz > Oct > Dod > Octd. As to the substituents on the aromatic ring the melting

points are lowered in the order of 5-NO₂ > H > 5-Br > 5,6-Benzo groups. The melting points for Mn(N-R-sal)₂Cl which were prepared in a preceding work are 154-155, 129-130, 119.5-120, and 205-206°C for R = Oct, Dod, Octd and Bz, respectively. On the other hand, the melting points of the manganese(IV) complexes are lower than those of the corresponding manganese(III) complexes, and they decompose at near melting points, showing colour changes from green to brown (Table 5). As to the alkyl groups the melting points are lowered in the same order as that for the manganese(III) complexes, and as to the substituents on the aromatic ring they are lowered in the order of 5-NO₂ > 5-Br > H > 5,6-Benzo groups, with the exception of Mn(N-Bzsal)₂Cl₂. The melting points of Mn(N-R-sal)₂Cl₂ which were prepared in a preceding work are 106-107, 97.5-98.5, 94-95, and 112-113°C for R = Oct, Dod, Octd and Bz, respectively.

Magnetic properties. The magnetic moments for the manganese(III) complexes fall within the range of 4.82-4.95 BM, with the exception of Mn(N-Bz-5,6-Benzosal)₂Cl and all the 5-nitro derivatives (Table 4). These values are consistent with the spin-only value expected for a complex having a d^4 high-spin electron configuration. The lower values observed for the above complexes may be caused by antiferromagnetic interaction between manganese atoms due to a binuclear structure in which they are bridged by two phenolic oxygen atoms. No further investigation on magnetic properties for these complexes has been made.

The magnetic moments for the manganese(IV) complexes fall within the range of 3.87-4.10 BM

(Table 5). These values are consistent with the spin-only value expected for a complex having a d^3 electron configuration.

Electronic spectra. The electronic spectra of the manganese(III) complexes measured in dichloromethane show the absorption bands (log ε = 2.7) around 15000 cm⁻¹. These complexes may have a five-coordinate configuration around the central manganese atom in such a noncoordinating solvent.[7] Therefore, these bands can be assigned to a ligand field transition due to $d_{xy} \rightarrow d_{x^2-y^2}$. The absorption maxima are affected by the aromatic ring substituents and are shifted to higher energies in the order of 5-NO₂ > H > 5,6-Benzo > 5-Br groups (Table 4). The alkyl groups attached to the nitrogen atoms have little effect on the absorption maxima. On the other hand, the electronic spectra of the manganese(IV) complexes in dichloromethane show the more intense absorption bands (log ε = 3.7) in the range of 14700-17100 cm⁻¹ compared with those for the manganese(III) complexes. These bands can be assigned to a charge-transfer transition due to $Cl(p\pi) \rightarrow Mn(d\pi)$ from their intensities as discussed in the previous papers.[5,6] These absorption maxima are also affected by the aromatic ring substituents and are shifted to higher energies in the order of 5-NO₂ > H > 5-Br > 5,6-Benzo groups (Table 5). The alkyl groups have little effect on the absorption maxima as well as the manganese(III) complexes.

IR spectra. The IR spectra of the manganese(IV) complexes show almost the same pattern as those of the manganese(III) complexes in the region from 500 to 4000 cm⁻¹, but both spectra are significantly different in the region from 200 to 500 cm⁻¹. In this

region the absorption bands due to Mn–Cl stretching vibrations should be observed.[8] Both manganese(III) and manganese(IV) complexes showed one absorption band assignable to ν(Mn–Cl) (Tables 4 and 5). The frequencies for the manganese(IV) complexes are observed in higher energies compared with those for the corresponding manganese(III) complexes. This may be caused by the change in the oxidation state of the central manganese atom from Mn(III) to Mn(IV). The results that one absorption band due to ν(Mn–Cl) is observed for the manganese(IV) complexes imply that two chlorine atoms coordinate to the manganese atom as a *trans*-configuration. Thus we propose a *trans*-octahedral configuration for the manganese(IV) complexes investigated here as shown above.

Electrochemical properties. The cyclic voltammograms of the manganese(III) and manganese(IV) complexes were measured in acetonitrile. Some of the manganese(IV) complexes were measured in a mixture of acetonitrile and dichloromethane (1:1) owing to their poor solubility in acetonitrile. The current-potential curves for the manganese(III) complexes showed the one cathodic wave around 0.0 V (vs SCE) in the +1.2 to −0.8 V range. This can be assigned to the one-electron reduction from Mn(III) to Mn(II).[9] On the other hand, the current-potential curves for the manganese(IV) complexes showed the two-step cathodic waves around +0.9 and 0.0 V with similar wave heights. These waves can be assigned to the one-electron reductions from Mn(IV) to Mn(III) and from Mn(III) to Mn(II), respectively. The separations of the peak potentials between the cathodic wave and the corresponding anodic wave for both redox waves are larger than the 57 mV expected for a reversible

one-electron redox wave, so these electrode reactions may be irreversible. Thus the half-peak potentials ($E_{p/2}$) of the cathodic waves for the manganese(III) and manganese(IV) complexes are summarized in Tables 4 and 5, respectively. The reduction potentials for the manganese(III) complexes are affected by the aromatic ring substituents and are shifted to more positive potentials in the order of 5-NO_2 > 5-Br > 5,6-Benzo groups. And they are little affected by the alkyl groups. On the other hand, the reduction potentials for the manganese(IV) complexes are significantly affected by the aromatic ring substituents and are shifted to more positive potentials in the order of 5-NO_2 > 5-Br > 5,6-Benzo groups. These potential shifts can be explained by the electron-withdrawing ability of the substituent groups. And also the alkyl groups have little effect on the reduction potentials. These results are not inconsistent with those obtained in the electronic and IR spectra.

THE REACTION OF LITHIUM ALUMINIUM HYDRIDE WITH CARBON DIOXIDE OR SODIUM BICARBONATE

B. T. THOMPSON, T. N. GALLAHER* and T. C. DeVORE

James Madison University, Department of Chemistry, Harrisonburg, VA 22807, U.S.A.

Abstract—The reaction of $LiAlH_4$ with CO_2 or $NaHCO_3$ at elevated temperatures has been investigated. Methane and ethylene are the primary products of each reaction. These molecules are probably the "explosive" reaction products formed when CO_2 fire extinguishers are used on $LiAlH_4$ fires.

Recently several letters have appeared in the literature discussing the hazards of lithium aluminium hydride (LiAlH₄ or LAH) fires.[1-3] It was reported that burning LAH pellets could not be quenched in a nitrogen atmosphere and an intert gas such as argon was required to extinguish the fire safely. It was also noted that the use of a sodium bicarbonate or carbon dioxide (CO_2) fire extinguisher to extinguish a LAH fire formed "explosive" reaction products.[2-4] LAH is a common reducing reagent for both organic and inorganic reactions.[5,6] In addition, there has been a considerable amount of interest generated in C_1 chemistry.[7-10] The reaction of CO and CO_2 with H_2 in the presence of metal reducing catalysts can produce a variety of organic molecules ranging from methane to gasoline hydrocarbons.[7] Since LAH is such a good reducing agent and there are hazards in trying to extinguish a LAH fire, an investigation of the reaction of LAH with CO_2 and with $NaHCO_3$ was undertaken. This paper presents the results of this investigation.

EXPERIMENTAL

The apparatus used to investigate the LAH reactions has been described in detail previously.[11,12] Briefly, the reactions were carried out in a quartz tube attached to an MDC Manufacturing Company stainless steel 4-way cross vacuum flange. Two opposing sides of the flange were equipped with KBr windows to make an infrared gas cell. The entire system was maintained under vacuum by a liquid nitrogen trap, 2 in. oil diffusion pump and a rotary vacuum pump. An uncalibrated thermocouple gauge was used to monitor the pressure in the system. This cell was placed in the sample compartment of a Nicolet MX-1 Fourier Transform IR Spectrometer (FTIR). The spectra were taken using 1 min scans at 1 cm⁻¹ resolution as the reaction progressed. After completion of the reactions, the trapped gases were either allowed to flow back into the cell so spectra could be retaken or they were collected in a mass spectrometer sampling bulb. In most cases the IR spectrum was sufficient to identify the reaction products, however, mass spectra, taken on a Varian

EM-600, were occasionally used to confirm the product assignments.

All of the experiments were performed in essentially the same way. LAH or mixtures of LAH and various reactants were placed in the quartz tube and the system was evacuated to 0.1 Pa pressure. The tube was resistively heated with a nichrome wire. Sufficient CO_2 was added to the reaction mixture to produce a combined total pressure of 10^2 Pa and the spectrum was taken as the reaction proceeded.

RESULTS AND DISCUSSION

From the reaction of $LiAlH_4$ with CO_2, the following products were identified from the IR absorption bands (cm⁻¹) cited: CH_4 (3016, 1305); C_2H_4 (3100, 949); CO (2144). At approximately 400 K, small amounts of methane (CH_4) were formed. When the quartz tube was heated to 600 K, CH_4 and ethylene (C_2H_4) were rapidly formed. After prolonged heating which partially depleted the LAH, carbon monoxide bands also appeared in the spectrum. Reactions involving CO_2 and CO in solution with LAH have been investigated previously.[13-16] Apparently, the reaction products from solution are very different from the gas/solid reaction products found here. Cox *et al.*[16] reported that methane and carbon monoxide were not present as reduction products of the solution reaction. However, while carrying out methanolysis reactions using CO and LAH in solution, Martin *et al.* determined that methane was one of the reaction products.[14] The lower reaction temperatures ($\sim$ 373 K) of these solution reactions, solvent effects, stirring, etc. apparently can combine to yield a variety of different products. In the gas/solid reactions performed here, only CO, CH_4 and C_2H_2 have been observed as the reaction products.

The second experiment performed was the reaction between sodium bicarbonate and LAH. In this experiment the LAH and $NaHCO_3$ were mxied ($\sim$ 50/50, v/v) and placed in the quartz tube. This mixture was heated and the spectra were taken. As the mixture was warmed to 325 K, bands for H_2O (1600 cm⁻¹) and CO_2 (2350, 667 cm⁻¹) could be observed. As the temperature was increased, the bands

---

*Author to whom correspondence should be addressed.

for water decreased and bands for methane ($3016, 1305 \text{ cm}^{-1}$) and ethylene ($3100, 949 \text{ cm}^{-1}$) appeared in a manner similar to the CO_2/LAH experiments. $NaHCO_3$ is known to decompose at ~ 325 K to form H_2O and CO_2[17] which readily explains the observation of these bands in the spectra at these temperatures. The other products resulted from the reaction of CO_2 and LAH.

Differential Thermal Analysis (DTA) indicates that LAH decomposes through several steps.[18] The first of these occurs at 421–431 K where part of the hydrogen is evolved. As the LAH is heated to higher temperatures (~ 500–555 K) significant amounts of H_2 are evolved as the compound decomposes. Since no CH_4 was observed at temperatures lower than ~ 400 K, it was assumed that the reactions of LAH with CO_2 and $NaHCO_3$ must first proceed with the partial decomposition of the LAH to form finely divided Al metal. This Al would then react with CO_2 to form CO and aluminium oxide. The CO must then further react to form a CH_2 radical. This radical could either react with H_2 to form CH_4 or with additional CH_2 to form C_2H_4. To test this hypothesis another experiment was performed. In this experiment CO_2 and H_2 were passed over finely divided aluminium powder placed in the quartz tube. The tube was heated and the spectrum taken. No reaction was observed until the tube was heated to 650–800 K. At these temperatures the bands for CO_2 slowly disappeared and bands for CH_4, C_2H_4, CO and H_2O grew into the spectrum. It is interesting that H_2O was produced in this experiment since it was not observed in the LAH reactions with CO_2. One possible explanation of this observation is that any H_2O produced in the previous experiments rapidly reacted with LAH and thus was not observed. The Al formed from the thermal decomposition of LAH is expected to be more finely divided and hence more reactive than the Al powder used in these experiments. These results suggest that Al metal takes part in the reaction mechanism. Since H_2O was observed in this set of reactions, it is not certain if Al functions as a reactant or a catalyst. In either case, the first step of the reaction probably is

$$Al + CO_2 \rightarrow \text{``AlO''} + CO.$$
This is not unlike the mechanism proposed by Fontijn *et al.* for the reaction of Al atoms and CO_2.[19] This "AlO" may then react with hydrogen to reform the Al and H_2O or it may further react with CO_2 to form Al_2O_3. The failure to observe clearly Al_2O_3 suggests that the former may have occurred. However, since the total amount of Al_2O_3 formed is expected to be small, this cannot be taken as definite proof that Al is acting as a catalyst. The role of H_2 gas in the mechanism is also not known with certainty. It is likely that some of the hydrogenations occur on the Al surface. The reaction of hydrogen in the gas phase may also occur for some steps in the mechanism. The steps where each is the case could not be clearly established.

Bellama and MacDiarmid investigated the solid phase reactions of SiO_2, GeO_2, P_2O_5, As_2O_3 and Sb_2O_3, with LAH.[20] They found that these reactions produced the various hydrides of these elements. In addition, they reported that some of their samples of

LAH were contaminated with small quantities of diethylether and ethylene since they also observed these molecules in their system. Based on the results of the experiments performed here, it appears reasonable to suggest that they may have actually observed products from the reaction of the LAH with residual CO_2 in the reaction vessel. To test this hypothesis, one of their experiments was repeated using this apparatus. In this experiment SiO_2 and LAH were mixed ($\sim 50/50$, v/v), placed in the quartz tube, and heated. In addition to the expected silane (SiH_4) bands at 2188 and 909 cm^{-1}, bands for methane and ethylene were clearly visible in the spectrum even though no CO_2 was passed over this reaction mixture. No bands were observed which could be assigned to diethyl ether. It does, however, appear that Bellama and MacDiarmid may also have observed the reaction of LAH with residual CO_2 in their reaction vessel. Methane probably was not observed in their experiments because of a failure to trap it. Any methane produced may have been pumped out of their system with the evolved hydrogen.

CONCLUSION

Based on the results of these experiments, a reaction scheme may be written for the gas/solid reaction of CO_2 and LAH.

(1) $LiAlH_4 \xrightarrow{\sim 500 \text{ K}} Al + LiH + 3H_2$.

(2) $2Al + 3CO_2 \xrightarrow{\sim 500 \text{ K}} Al_2O_3 + 3CO$.

(3) $2Al + 3H_2 + 3CO \rightarrow Al_2O_3 + 3CH_2$.

(4) $CH_2 + H_2 \rightarrow CH_4$.

(5) $CH_2 + CH_2 \rightarrow C_2H_4$.

The formulas shown are meant to indicate only the overall stoichiometry of the reaction. As stated previously, it is not certain that Al_2O_3 forms directly from the reaction of Al and CO_2. It is possible that it could be produced by the sequence

(a) $Al + CO_2 \rightarrow \text{``AlO''} + CO$.

(b) $\text{``AlO''} + H_2 \rightarrow H_2O + Al$.

(c) $4H_2O + LiAlH_4 \rightarrow LiOH + Al(OH)_3 + 4H_2$.

(d) $2Al(OH)_3 \xrightarrow{\Delta} Al_2O_3 + 3H_2O$.

Since no H_2O was observed in the LAH reaction and the final products are largely the same, the simpler overall scheme (not involving H_2O) is proposed as the actual reaction sequence. Sapienza *et al.* have proposed a mechanism for the formation of methanol from the reaction of CO_2 and H_2 on metal oxide surfaces.[21] They propose that CO_2 is dissociated to CO and O which are chemisorbed on to the surface of the metal oxide. In the presence of H_2 the CO is reduced to methanol. No bands for methanol were observed in the spectra from these epxeriments. Whether the absence of methanol bands indicates that no Al_2O_3 is formed or that the H_2 is largely depleted by the time it forms cannot be determined from these experiments. CH_2 radical also was not observed. Its presence is inferred from the observation of only ethylene and methane as the reaction products. Additionally, the decomposition products of LAH have not been well characterized. Thus, while the proposed reaction scheme accounts for all of the products, many details of the mechanism still have not been established.

Based on these experiments, it appears that the

"explosive" reaction products reported for the burning LAH/CO₂ reaction are methane and ethylene. Both molecules would react explosively with oxygen in the air if ignited. A CH_4/C_2H_4/Air mixture could easily be ignited by the heat from the burning LAH. Additionally, when NaHCO₃ is used to put out a LAH fire, H_2O is formed. Normally this would be desirable for a fire extinguisher. In this case, however, it would only serve to aggravate the situation since LAH and H_2O react violently.

VIBRATIONAL AND LUMINESCENCE SPECTRA OF A NEW BINUCLEAR URANYL COMPLEX [(C₂H₅)₄N]₂[UO₂F(NO₃)₂]₂

COLIN D. FLINT* and PETER A. TANNER

Department of Chemistry, Birkbeck College, University of London, London WC1E 7HX, England

Abstract—The preparation, vibrational and luminescence spectra of the title compound are described. The complex has bidentate nitrate groups and bridging fluoride ions. The spectra are assigned in detail and interpreted as showing couplings between the uranyl antisymmetric stretching modes and between the nitrate modes within the dimer, the coupling energy being $17 \, \text{cm}^{-1}$ in the former case. There is no clear evidence for electronic coupling involving the uranyl groups.

INTRODUCTION

During recent synthetic and spectroscopic studies of the coordination chemistry of the uranyl ion[1,2] we prepared a new uranyl complex of stoichiometry $[(C_2H_5)_4N]UO_2F(NO_3)_2$. A preliminary X-ray investigation[3] indicated that the compound is binuclear, fluorine-bridged with bidentate nitrate groups completing an in-plane six-fold coordination of the uranyl group. By contrast to the other fluorine-bridged uranyl complexes we have studied, the low-temperature luminescence spectrum is well resolved and free from traps. This permits a clear comparison of the uranyl vibrations and the nitrate vibrations observed in the luminescence spectra with those observed in the infrared and Raman Spectra.

EXPERIMENTAL

$[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]_2$ was prepared as well-formed lime green crystals by the following method. A solution of 5 g uranyl nitrate in 20 cm³ of water was added to a solution prepared from tetraethylammonium hydroxide (2 cm³ of 25% aqueous solution) and hydrofluoric acid (0.5 cm³ of 40% aqueous solution) in 20 cm³ water and the mixture allowed to stand at room temperature. The initial lemon-yellow precipitate was discarded and the solution deposited crystals of the product after several days. Analysis: Calcd. for $[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]_2$: C, 17.7; H, 3.7; N, 7.7; F, 3.5; U, 43.8%. Found: C, 17.5; H, 3.6; N, 7.6; F, 3.5; U, 43.9%.

Spectroscopic measurements

These were made as previously described.[4]

STRUCTURAL DATA

A preliminary X-ray study[3] shows that the compound $[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]_2$ crystallises in the $P2_1/c - C_{2h}^5$ space group with two centrosymmetric binuclear units in the Bravais cell. The crystallographic site symmetry of the uranyl ion is therefore C_1 but nearly C_{2v}. The space group and number of formula units per Bravais cell are the same[5] as

those of the binuclear fluorine-bridged complex $Cs_4(UO_2)_2F_8 \cdot 2H_2O$.

RESULTS

The high-energy region of the 15 K luminescence spectrum is shown in Fig. 1. The relative intensities of features were observed to be independent of the exciting line, and the decay of emission from a 4 cm⁻¹ band width is exponential with a (e^{-1}) lifetime of 2.5 ms. The $\Pi_g \rightarrow \Sigma_g^+$ electronic origin of the uranyl ion is intense and the excited state is split into two components at $20\,547$, $20\,555$ cm⁻¹ due to the low site symmetry. These origins are only 200 cm⁻¹ to low energy of their positions in $(C_2H_5)_4N[UO_2(NO_3)_3]$ where the uranyl groups have an in-plane coordination of six oxygen atoms,[6] but more than 700 cm⁻¹ to high energy of the origins in $Cs_4(UO_2)_2F_8 \cdot 2H_2O$ where the uranyl groups have an in-plane coordination of five fluorine atoms. Between the origins and $20,250$ cm⁻¹ there is a complex group of incompletely resolved vibronic bands. The most intense features occur near 145, 200 and 250 cm⁻¹ from the origin. The first of these is almost coincident with a strong Raman shift (155 cm⁻¹) and by comparison with the Raman and luminescence spectra of $CsUO_2(NO_3)_3$ these probably correspond to one or more ligand bending modes. The remaining two strong bands shift some 15 cm⁻¹ to low vibrational wavenumber in the absorption spectrum and are therefore assigned as the uranyl rocking and bending modes. These bending and rocking modes are also observed in both the IR and Raman spectra. As usual the rock is stronger in the Raman and the bend in the IR spectrum. Other weaker bands in this region show smaller shifts in the absorption spectrum and are therefore attributed to uranyl-ligand stretching modes coupled to the rock and bend.

During our recent studies of bi-[1] and polynuclear[2] uranyl fluoride complexes, we correlated modes of vibration with those of the $UO_2F_5^{3-}$ monomer, neglecting specific assignments for U–F (bridge) modes. These vibrations are more conveniently studied in $[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]_2$ due to the absence of U–F (terminal) bonds. The two bands at 405, 365 cm⁻¹ in the luminescence spectrum of

---
Fig. 1. The high energy part of the 457 nm-excited 15 K luminescence spectrum of $[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]_2$.

$[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]$ clearly involve motion of the bridging fluorides. The higher wavenumber band is strong in the IR spectrum whereas the other is barely detected; both bands are weak in the Raman spectrum. The 405 cm^{-1} mode is therefore assigned as the in-phase fluoride motion along the U–U axis and the 365 cm^{-1} mode as the corresponding anti-phase motion. The assignment of the two other motions with substantial uranium–fluoride stretch character is less certain. A mode at 315 cm^{-1} appears with moderate strength in the luminescence spectrum but weakly in the 120 K Raman spectrum. This is nearly but not exactly coincident with a strong 300 K IR band at 308 cm^{-1}. It is not certain whether these features are one or both of the expected modes. If the former is the case, the differences in wavenumber can be attributed to the different temperatures of measurement and selection rules. The remaining U–F mode may then lie in the complex vibronic structure below 300 cm^{-1}.

The O–U–O stretching vibrations in $[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]$ are readily accounted for under a dimer model contrasting with our results from other binuclear uranyl systems.[1] For the O–U–O symmetric stretch (v_1), a centrosymmetric dimer model predicts the occurrence of one IR and one Raman band. This mode is observed at 854 cm^{-1} as the strongest band in the Raman spectrum but weakly in the IR spectrum (852 cm^{-1}). In luminescence, progressions in v_1 on the electronic origin

and all the vibronic features may be followed to at least six members, the modes with one quantum of v_1 being the most intense. The $\Pi_g \to \Sigma_g^+ + nv_1$ bands $(n = 2–6)$ exhibit the same splitting $(7.5 \pm 1.5$ cm$^{-1})$ as the electronic origin. However, for $n = 3$ these bands are accompanied by a third component at 5 cm^{-1} to high vibrational energy which moves further away and loses intensity in successive members (Fig. 2). The behaviour of the antisymmetric O–U–O stretch (v_3) is more complex. From studies of other binuclear uranyl complexes we expect the coupling between uranyl groups to be largest for this mode. In the 300 K IR spectrum v_3 occurs as a single band at 934 cm^{-1} but at 85 K a shoulder near 920 cm^{-1} becomes resolved. The luminescence spectrum in the region of the v_3 vibronic origin is rather different, consisting of a weaker, sharp feature at 921 cm^{-1} and a broader band at 938 cm^{-1} from the lower energy origin. We attribute these two bands to the in-phase (938 cm^{-1}) and antiphase components of the O–U–O antisymmetric stretch. It is curious, however, that the origin splitting is not resolved in the 921 cm^{-1} feature. The behaviour of successive members of the v_1 progression based on the v_3 vibronic origin raises further problems. For the $n = 1$ member of the $\Pi_g \to \Sigma_g^+ + nv_1 + v_3$ progression, three bands are resolved between 1775 and 1792 cm^{-1}, the separation of the lower energy components being 4 cm^{-1} (Fig. 2). For the $n = 2–5$ members the highest vibrational energy component of v_3 moves away from and loses
Fig. 2. The 15 K luminescence spectrum of $[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]_2$ in the region of the $\Pi_g \to \Sigma_g^+ + nv_1$ and $\Pi_g \to \Sigma_g^+ + v_2 + (n-1)v_1$ transitions for $n = 1–6$. (The wavenumbers are measured from the lower energy electronic origin, 20,547 cm^{-1}. Note the scale discontinuities.)

intensity relative to the other component. The splitting of $6.7 \pm 1.5\,\text{cm}^{-1}$ observed for the latter is the same as that of the electronic origin within experimental error. For the $\Pi_g \to \Sigma_g^+ + \nu_1 + \nu_3$ and $\Pi_g \to \Sigma_g^+ + 3\nu_1$ bands, the most reasonable assignment of the additional component in each case is to a Fermi resonance with nitrate modes.

All of the internal modes of the coordinated nitrate ions may be observed in either the IR or Raman spectra and also in the luminescence spectrum (Table). In most cases all four components expected for a centrosymmetric dimer may be resolved, together with additional features which may be due to Fermi resonances or unit cell group couplings. As expected the coupling between *cis* nitrate groups (as reflected by the separation of the two IR- or two Raman-active components) is larger than the *trans*-coupling across the bridge.

DISCUSSION

The most interesting feature of the spectroscopic behaviour of $[(C_2H_5)_4N]_2[(UO_2)F(NO_3)_2]_2$ is the coupling between the $UO_2F(NO_3)_2$ entities. We consider first the evidence for an electronic coupling between the uranyl groups. If significant this would produce a splitting of the electronic origin and of the progressions in ν_1 proportional to the square of the dipole strength of the individual lines, but no appreciable splitting of the vibronic origins. The constant splitting of the $\Pi_g \to \Sigma_g^+ + n\nu_1$ and $\Pi_g \to \Sigma_g^+ + \nu_3 + n\nu_1 (n \geqslant 2)$ transitions (which is equal to the origin splitting) is not consistent with this. This splitting must then be attributed to a site symmetry

splitting of the degenerate excited electronic state, although we are unable to give a convincing explanation for the absence of this splitting for several vibronic features, notably $\Pi_g \to \Sigma_g^+ + \nu_3$. A similar observation may be made[1] from the luminescence spectrum of $Cs_4(UO_2)_2F_8 \cdot 2H_2O$.

By contrast, the splitting of about $17\,\text{cm}^{-1}$ in $\nu_3[\nu_{as}(O-U-O)]$ in both the IR and luminescence spectra of $[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]_2$ is attributed to a vibrational coupling within the dimer. This is consistent with our previous assignment[1] of the two *strong* IR ν_3 bands (split by $15\,\text{cm}^{-1}$) in $Cs_4(UO_2)_2F_8 \cdot 2H_2O$ to α_u, $\beta_u(C_{2h})$ unit cell group modes. The similar intensity of these two components cannot be explained under a centrosymmetric dimer model since the $\beta_{2g}(D_{2h})$, $\alpha_g(C_i)$ antiphase ν_3 dimer mode is IR-inactive, but this vibration gives rise to one IR-active and one IR-inactive mode under C_{2h} unit cell group rules, (the irreducible representation corresponding to the IR-active mode depends upon the location of the C_{2h} symmetry elements). The intensity of the antiphase intradimer ν_3 mode in $Cs_4(UO_2)_2F_8 \cdot 2H_2O$ thus arises from the interdimer coupling dipole. The same splitting of ν_3 in the IR spectra $(16 \pm 1\,\text{cm}^{-1})$ of $Cs_4(UO_2)_2F_8 \cdot 2H_2O$ and $[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]$, but the very different intensity ratios of the two components are both consistent with structural data[3,5] since although the U–U intradimer distances are similar, the interdimer coupling in the latter compound is reduced due to shielding by the large organic cations.

The ν_3 antiphase mode is more intense (relative to the in-phase mode) in luminescence, rather than

in the IR absorption spectrum of $[(C_2H_5)_4N]_2 \cdot [UO_2F(NO_3)_2]_2$ since for the former process the selection rules are relaxed at the C_{2v} uranyl site. As in the luminescence spectrum of $Cs_4(UO_2)_2F_8 \cdot 2H_2O$, progressions are observed in the v_3 mode. The agreement between the IR and luminescence frequencies for the v_3 modes in $[(C_2H_5)_4N]_2[UO_2F(NO_3)_2]_2$ illustrates the small dispersion of these local dimer modes, by contrast to the $v_{as}(O–U–O)$ vibrations in other luminescence spectra.[1,2,7]

STUDY OF THE COMPLEXES OF Np(V) WITH ORGANIC LIGANDS BY SOLVENT EXTRACTION WITH TTA AND 1, 10-PHENANTHROLINE

YASUSHI INOUE* and OSAMU TOCHIYAMA

Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki-aza-aoba, Sendai 980, Japan

Abstract—Complex formation constants of Np(V) with 22 organic ligands, 7 hydroxycarboxylic acids, 4 dicarboxylic acids, 4 aminocarboxylic acids, 3 pyridinecarboxylic acids, 8-hydroxyquinoline-5-sulfonic acid, IDA, NTA and EDTA, have been determined in 1M NaClO$_4$ at 25°C by using the solvent extraction method with TTA and 1, 10-phenanthroline. The factors influencing the stabilities of Np(V) complexes are discussed in connection with the linear structure of NpO$_2^+$.

The aqueous solution chemistry of actinides, particularly of U, Np, Pu and Am, offers us an enormous task because of its complicated features connected with redox, disproportionation, hydrolysis and complex formation reactions. Among the actinide ions, penta- and hexavalent actinides assume the form of dioxo ions called "yl" ions which are a special type of cations as regards complex chemistry. Although a vast amount of data exists on complex formation of actinides in solution, pentavalent actinides have not been so extensively studied because of their reduced reactivity with various ligands as a result of their low ionic potential.

Since the valence stability of Np(V) in aqueous solution makes neptunium a useful representative element for studying the aqueous complex chemistry of pentavalent actinides, we decided to study the complex formation of Np(V) with different organic ligands by using a solvent extraction technique. Recently, we succeeded in extracting Np(V) by the combined use of either thenoyltrifluoroacetone (TTA) and quaternary alkylammonium salts[1] or TTA and 1,10-phenanthroline (phen).[2] The former system has been successfully applied to the determination of stability constants of the complexes of Np(V) with several hydroxycarboxylic acids.[3] This system, however, has limited applicability because it does not allow the presence of large, hydrophobic anions such as perchlorate, or dissociated anions of organic acids because of their interaction with the quaternary alkylammonium cation. Although the synergistic enhancement of TTA extraction of Np(V) is somewhat smaller with phen than with quaternary alkylammonium salts, the TTA-phen system permits us to study the aqueous chemistry of Np(V) with fewer restrictions. By using this extraction system in the presence of 1M NaClO$_4$, we have obtained complex formation constants of Np(V) with 22 organic ligands including hydroxycarboxylic acids, dicarboxylic acids, aminocarboxylic acids and some other widely-known chelating reagents.

EXPERIMENTAL

Reagents. ^{239}Np tracer was prepared by milking from ^{243}Am (obtained from the Commissariat a l'Energie Atomique) by the method of Sill[4] and adjusted to the pentavalent state by evapora-

tion to dryness and dissolution in water.[5] TTA and 2-(N-Morpholino)ethanesulphonic acid monohydrate (MES) were obtained from Dojindo Laboratories (Kumamoto, Japan) and used as received. All the other reagents were of A.R. grade and used without further purification. The solutions of these chemicals were freshly prepared just prior to use.

Procedures. An aqueous solution (4 cm³) containing ^{239}Np, 1M sodium perchlorate, buffer reagents (a proper mixture of 0.05 M of MES and 0.05 M of THAM [Tris(hydroxymethyl)aminomethane] and a variable concentration of complex forming reagent was mixed in a glass tube with the same volume of organic solution containing the desired concentration of TTA and phen, and the tube was shaken mechanically for 15 min (140 times/min) at 25±1°C. The phases were separated and a 1-cm³ portion of each phase was pipetted into a counting tube and the γ-activity of each phase was measured in a well-type NaI(Tl) scintillation counter (Fuji Denki Model⁸ NHS2). The remaining part of the aqueous phase was used for pH measurement with a pH meter (Tōa Dempa HM-5BS) equipped with a glass electrode. Conditions adopted in the experiments are listed in Table 1.

Calculation of stability constants. The distribution ratio of neptunium in the absence of complexing agents, D$_0$, can be represented by[2]:

$$D_0 = K_{ex}[HT]_O[phen]_O{}^m/[H^+], \qquad (1)$$

where HT and phen denote the neutral form of TTA and phen, K$_{ex}$ the extraction constant, m number of molecules of phen in the extracted species, and O refers to the organic phase. From the published data of distribution constants of TTA and phen between water and organic solvents[6], [HT]$_O$ and [phen]$_O$ were assumed to be equal to the total added concentrations C$_{TTA}$ and C$_{phen}$ in the conditions adopted in the experiment. Contributions from the formation of water-soluble complexes of Np(V) with TTA anion to the log β (stability constant) values were estimated to be less than 0.02, using the reported value of the stability of Np(V)–TTA complexes[7], and were neglected under all conditions shown in Table 1. The distribution ratio D of Np(V) in the presence of a complexing agent (L) can be expressed by:

$$D = D_0/(1 + \sum_n \beta_n[L]^n), \qquad (2)$$

where the values of β_n are the overall formation constants of Np(V) complexes with ligand L (charges of ions are omitted for simplicity). [L] was evaluated from the total added concentration of ligand acid, C$_L$, by using the dissociation constants[8] listed in Table 2. In the calculation, the concentration of neutral acid in the organic phase was assumed to be negligibly small. Equation

   ix: ion exchange[12] at 25°C, $\mu = 0.1$.

(2) is equivalent to a linear function,

$$y = f(x), \tag{3}$$

where

$$y = 1/D,$$

$$f(x) = 1/D_0 + \sum_n (\beta_n/D_0)x^n$$

and

$$x = [L].$$

About twenty sets of data (x_i, y_i) were analyzed by the least-squares method to give β_n values. Since the counting-time of γ-activities was set to make the relative statistical errors of the total counts approximately constant, residuals of observed ratios, *y*, are expected to be proportional to the value of $1/D$ from error propagation rules. Although the observed value of $1/D$ is not error-free, this value gives a good basis for the estimate of the weight of the observation. Therefore least-squares fitting was carried out to minimize the following sum of the weighted squares of the residuals:

$$S = \sum_i \{y_i - f(x_i)\}^2/y_i^2. \tag{4}$$

When a polybasic acid is used as the complexing agent, there is the possibility of forming different types of complex; that is, the ligands in different stages of dissociation can react with Np(V). In this case, the proper form of complex is taken to be that which gives self-consistent values of stability constants when series of experiments are conducted at different values of pH.

RESULTS AND DISCUSSION

The results are listed in Table 2 together with literature values. The maximum concentration of the ligand adop-

ted in each series of experiment is shown in the last column of Table 2. Standard deviations, shown in parentheses, indicate that each series of experiment is of fairly high precision. However, comparison between the values obtained under different conditions (diluent, pH, concentration of extractants) reveals that the accuracy of the value is somewhat poorer than that expected from standard deviations. As a whole, the total error in log β_n remains less than 0.1, and therefore the present values agree well with literature values within the limits of the experimental error. Our two-solvent extraction systems, TTA plus alkylammonium salts and TTA plus phen, gave very similar values, although the former were a little smaller than the latter in almost every case. This may be attributed to the difficulty of correcting the effect of the formation of water-soluble complexes of Np(V) with TTA anion in the former system. The fact that the present values also agree well with those obtained by completely different techniques such as spectrophotometry or potentiometry, supports the validity of this extraction technique.

The results in Table 2 can be used to elucidate the factors influencing the stabilities of complexes—those common to chelates in general and those characteristic only of chelates involving dioxo ions.

The effect of the size of the chelate ring can be seen by comparing the stabilities of the chelates of hydroxycarboxylates, dicarboxylates and pyridinecarboxylates. The orders of stability are:

α-hydroxycarboxylate > β-hydroxycarboxylate,
oxalate > malonate > succinate ~ glutarate,

and

picolinate > nicotinate.
Fig. 1. Correlation between 1:1 chelate stability constants of UO_2^{2+} and NpO_2^+. Numbers correspond to the compounds listed in Table 2.
Fig. 2. Correlation between 1:1 chelate stability constants of Zn^{2+} and NpO_2^+. Numbers correspond to the compounds listed in Table 2. For 22, Zn^{2+} forms ML, while NpO_2^+ forms MHL. Dipicolinic acid (18) shows a large deviation from the line (log $\beta = 6.35$, 11.88 for Zn^{2+}).

These orders are consistent with the general rule that chelates with a five-membered ring are most stable. For these chelates with a five-membered ring, the nature of the donor atoms affects the stability sequence as follows:

sulfoxine(phenolic O^-, N)>dicarboxylate(O^-, O^-)$\geq$ aminocarboxylate(O^-, N)>hydroxycarboxylate(O^-, O).
It is interesting to note the effect of the number of available coordination sites of the chelating agent. All the tri- or tetradentate ligands investigated give more stable chelates than bidentate ligands. However, these ligands give only 1:1 complexes suggesting that a steric effect opposes the formation of higher complexes. This steric hindrance can be considered to result from the fact that the pentavalent neptunium exists as very stable "yl" ions NpO_2^+ with two short covalent metal–oxygen bonds and can accommodate ligands only in the plane equatorial to "yl" bond.

Another point of interest is the comparison of the results for Np(V) with those for other metal ions. For this purpose, it is desirable to compare with other actinides, but we have little comparable data because the pentavalent state of other actinides is very unstable (except in the case of protactinium which behaves differently from other members of this group of elements). Instead, the stabilities of Np(V) complexes were compared with those of UO_2^{2+} and Zn^{2+} complexes because UO_2^{2+} is also a dioxo cation of similar type and complexes of Zn^{2+} have stability constants comparable to those of Np(V). Figures 1 and 2 clearly indicate that both UO_2^{2+} and Zn^{2+} give a good correlation of stabilities with Np(V). One reason is that all these complexes are considered to be formed by the interaction of a hard

acid and a hard base. Another reason is that we are comparing the values of log β_1, which are not affected by the steric factors. As a proof, stability constants of Np(V) with IDA, NTA and EDTA correlate better with those of UO_2^{2+} than those of Zn^{2+}. Moreover, UO_2^{2+} gives only 1:1 complexes with the above ligands, while Zn^{2+} gives higher complexes as well. Slopes in Figs. 1 and 2 indicate that NpO_2^+ in its complex-forming behaviour resembles cations with a charge between +1 and +2.

A POTENTIOMETRIC STUDY ON COMPLEX FORMATION OF CADMIUM(II) ION WITH 2-MERCAPTOACETIC AND 2-MERCAPTOPROPIONIC ACIDS

HARUO MATSUI*

Government Industrial Research Institute, Nagoya, Hirate-cho, Kita-ku, Nagoya 462, Japan

and

HITOSHI OHTAKI

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227, Japan

Abstract—Complex equilibria between cadmium ions and 2-mercaptoacetic acid (H_2maa) or 2-mercaptopropionic acid (H_2mpa) have been studied in aqueous solutions containing 3 mol dm^{-3} LiClO$_4$ as a constant ionic medium at 25°C by potentiometric titration. Formation constants of mono-η and bis-2-mercaptoalkanoato)cadmium complexes were found to ge log K_{11} = 4.34 and log K_{12} = 2.15 for the cadmium-H_2maa complexes, and log K_{11} = 5.66 and log K_{12} = 2.85 for the cadmium-H_2mpa complexes, respectively. The protonated complexes, CdHmaa$^+$ and CdHmpa$^+$, and a mixed ligand complex, Cd(maa)(mpa)$^{2-}$, were also detected.

In a previous investigation on the complex formation between cadmium ions and glycine and α-alanine,[1] we found that the glycine complex is more stable than the α-alanine complex, in spite of the smaller basicity (or the larger dissociation constant) of the former ligand than the latter. Such a reverse trend of the formation constants of glycinate and α-alaninate complexes to the basicity of the ligands has also been observed for complexes with other divalent metal ions.[2] In the paper[1] we interpreted the result in terms of ligand–ligand interactions through the central metal ion, in which electron back-donation was assumed from the cadmium ion to oxygen and nitrogen atoms within the complexes. In the present work we have studied complex equilibria between cadmium ions and 2-mercaptoacetic acid {H_2maa, maa = (SCH$_2$COO)$^{2-}$} or 2-mercaptopropionic acid {H_2mpa, mpa = (CH$_3$CHSCOO)$^{2-}$}. These ligands have a sulphur atom which acts as a stronger electron-donor, as well as a stronger π-electron acceptor, than an oxygen or a nitrogen atom and can be regarded as SH-substituted compounds of glycine and α-alanine. The formation constant of the mixed ligand complex, Cd(maa)(mpa)$^{2-}$ has also been determined. In this study we detected protonated complexes CdHmaa$^+$ and CdHmpa$^+$, the CdHL-type complex having not been found in the previous cases with glycine and α-alanine.

EXPERIMENTAL

Cadmium perchlorate was prepared by dissolving CdO (99.99%, Mitsuwa Pure Chemicals Co., Osaka) in a 1:1 HClO$_4$ (reagent grade) solution. The purity of the cadmium oxide was checked by emission spectroscopy. The cadmium perchlorate was recrystallized twice from water. Lithium perchlorate was prepared according to the method of Biedermann and Ciavatta.[3] Lithium hydroxide was prepared by electrolysis of a 3 mol dm^{-3} LiClO$_4$ solution and used within 2 weeks after preparation. 2-Mercaptoacetic acid (88% in water) and 2-mercaptopropionic acid (99.8) were

obtained from Katayama Chemicals Co., Osaka, and concentrations of each reagent were determined by both pH titration and total organic carbon analysis by using a TOC analyzer, Model-GCT-12N, Sumitomo Chemicals Ind., Tokyo. An Orion Digital pH Meter Model 801 was used for pH-metric titrations of test solutions in combination with a Beckman glass electrode No. 40495 and a silver–silver chloride electrode. The method of the measurements was essentially the same as that described in previous papers.[1,4] The ratio of the total concentration of the ligand (or ligands) to that of cadmium ions was 5 in all the cases. During the pH-metric titrations the total concentration of perchlorate ions was kept constant at 3 mol dm^{-3} by using lithium perchlorate.

All the measurements were carried out under a nitrogen atmosphere at 25.00 ± 0.02°C in a liquid paraffin bath set in a room thermostated at 25.0 ± 1.5°C.

RESULTS AND DISCUSSION

The complex formation of 2-mercaptoacetic acid with metal ions has been investigated by Leussing[5] for manganese(II), cobalt(II), nickel(II), and zinc(II) in 1958. He found the formation of the M(maa) and M(mae)$_2^{2-}$ complexes, but did not examine reactions between cadmium ions and the ligand. In 1962, Cabrera and West[6] reported the formation of the polynuclear Cd$_2$(maa)$_3^{2-}$ complex in an ammoniacal aqueous solution at pH 10, but they did not report the formation of the 1:1 and 1:2 complexes in the solution. In the present work we found the 1:1 and 1:2 complexes, together with a protonated MHL-type complex, in solutions of pH 5–9 in the cadmium-H_2maa system. In the cadmium-H_2mpa system the same types of the complexes were found.

Typical results of titration curves of solutions of H_2mpa and cadmium–H_2mpa mixtures are shown in Fig. 1, in which the degree of neutralization X of H_2mpa in the solutions was plotted vs $-$ log [H$^+$] (X = $-$ H/C$_L$; H stands for the analytical excess of hydrogen ion and C$_L$ is the total concentration of the ligand). Similar results were obtained for the cadmium–H_2maa system.

The formation constants (K$_{11}$, K$_{12}$, and β_{pqrs}) of the

Fig. 1. Titration curves of 2-mercaptopropionic acid and cadmium(II)-2-mercaptopropionic acid solutions. Curve (1) C_{Cd}(mmol dm^{-3}) = 0.0, C_L(mmol dm^{-3}) = 41.05; (2) 3.130, 16.00; (3) 3.441, 17.76; (4) 4.168, 21.51; (5) 4.304, 22.21.

where H_2L and H_2L' denote 2-mercaptoacetic and 2-mercaptopropionic acids, respectively.

Calculations were carried out by using the SCOGS program[7] with an electronic computer FACOM M-160S. The results obtained are summarized in Table 1. The solid lines in Fig. 1 were calculated curves using the estimated constants.

The formation constants (K_{11}) of the cadmium complexes with H$_2$maa and H$_2$mpa are larger than those with glycine (Hgly) and α-alanine (Hala), respectively (see Table 1b). This indicates that a cadmium ion combines more strongly with a mercapto group than an amino group due to a stronger electron-donating ability of the former than the latter to the central cadmium ion. However, the electrostatic interactions between cadmium ions and the ligands must be considered. The large values of the formation constants (K_{11} and K_{12}) of the cadmium–H$_2$mpa complexes compared with those of the cadmium–H$_2$maa complexes may be caused by the stronger electron-donating ability of a sulphur atom in the former ligand than in the latter, due to the inductive effect of a methyl group introduced. In this case we did not see a reverse trend of the formation constants of the complexes to the dissociation constants of the ligands, which has been observed in the systems of glycine and α-alamine, and a usual relationship between the formation constants and the pK values of the ligands was found. The result may be explained as follows: since electron donation from the sulphur atom within

complexes are defined by the following equations:

$$\left.\begin{array}{l} Cd^{2+} + L^{2-} = CdL \\ K_{11} = [CdL]/([Cd^{2+}][L^{2-}]) \end{array}\right\} \quad (1)$$

$$\left.\begin{array}{l} CdL + L^{2-} = CdL_2^{2-} \\ K_{12} = [CdL_2^{2-}]/([CdL][L^{2-}]) \end{array}\right\} \quad (2)$$

$$\left.\begin{array}{l} p\,Cd^{2+} + q\,H^+ + r\,L^{2-} + s\,L'^{2-} = Cd_pH_qL_rL_s'^{(2p+q-2r-2s)+} \\ \beta_{pqrs} = [Cd_pH_qL_rL_s'^{(2p+q-2r-2s)+}]/([Cd^{2+}]^p[H^+]^q[L^{2-}]^r[L'^{2-}]^s) \end{array}\right\} \quad (3)$$
Table 1. Formation constant, $\beta_{pqrs} = [Cd_pH_qL_rL_s'^{(2p+q-2r-2s)+}]/([Cd^{2+}]^p[H^+]^q[L^{2-}]^r[L'^{2-}]^r)$, of cadmium complexes with 2-mercaptoacetic and 2-mercaptopropionic acids in 3 mol dm^{-3} LiClO$_4$ at 25°C*[1]

2-mercaptopropionic acid is stronger than that from the ligand sulphur within 2-mercaptoacetic acid, the π-electron acceptability of the former may be relatively smaller than the latter. The effect of the electron donation may be more pronounced in this case than the electron-accepting effect, because of a strong electron-donating ability of sulphur atoms. The formation constants of H_2maa complexes with other divalent metal ions are also larger than those with Hgly.[5]

However, the second stepwise formation constants (K_{12}) of the complexes with cadmium and H_2maa or H_2mpa are smaller than those with the metal and glycine or α-alanine, respectively. This may be explained in terms of a smaller electrostatic interaction between the neutral 1:1 complex of the Cd(maa) or Cd(mpa) and a second entering ligand anion (maa^{2-} or mpa^{2-}) than that between a positively charged Cd(gly)$^+$ or Cd(ala)$^+$ and the relevant ligand.

The protonated complexes Cd(Hmaa)$^+$ and Cd(Hmpa)$^+$ were found in the both solutions of cadmium–H_2maa and –H_2mpa. The dissociation equilibria of the ligands can be described as follows:

wise formation constant of the mixed ligand complex from that of the corresponding parent complex is explained in terms of the so-called "entropy effect", and the increment is 0.6 in an ideal case.

The value of $\log K_{12} = 3.59$ observed for the reaction, Cd(maa) + mpa^{2-} = Cd(maa)(mpa)$^{2-}$, was considerably larger than the second stepwise formation constant of the Cd(mpa)$_2^{2-}$ ($\log K_{12} = 2.85$). The increment was much larger than the statistical value of 0.6. The increased constant at the second step of the formation of the Cd(maa)(mpa)$^{2-}$ complex from Cd(maa) and mpa^{2-} may be explained as follows: since maa^{2-} has a weaker electron-donating ability than mpa^{2-}, the charge density of the cadmium ion within the Cd(maa) complex is still low compared with that within the Cd(mpa) complex. Thus, the entering ligand mpa^{2-} can combine with the Cd(maa) complex more strongly than with Cd(mpa) to form the more stable complex of Cd(maa)(mpa)$^{2-}$ than Cd(mpa)$_2^{2-}$.

When the Cd(mpa) complex is formed at the first stage, the charge density at the cadmium ion within the complex is increased by a strong electron-

$$HSCH_2COOH \rightleftharpoons HSCH_2COO^- + H^+ \rightleftharpoons {}^-SCH_2COO^- + 2H^+$$

$$\underset{\underset{CH_3CHCOOH}{|}}{SH} \rightleftharpoons \underset{\underset{CH_3CHCOO^-}{|}}{SH} + H^+ \rightleftharpoons \underset{\underset{CH_3CHCOO^-}{|}}{S^-} + 2H^+$$

As is seen from Fig. 1, the complex formation between cadmium ions and H_2mpa is not observed until the hydrogen ion of the carboxyl group is almost fully dissociated. Therefore, we assumed that protons within the protonated complexes, Cd·(Hmaa)$^+$ and Cd(Hmpa)$^+$, were combined with the sulphur atom of the mercapto group. No polynuclear complex was found in the solution.

The formation constant of the mixed ligand complex Cd(maa)(mpa)$^{2-}$ was also determined. The formation constant of the mixed ligand complex lies between the values of the two parent complexes, thus, $\beta_{1002} > \beta_{1011} > \beta_{1002}$, although the relationship $\beta_{1011}^2 > \beta_{1020} \cdot \beta_{1002}$ still holds for the complex.

The second stepwise formation constant was evaluated to be $\log K_{12} = 3.59$ for the reaction, Cd(maa) + mpa^{2-} = Cd(maa)(mpa)$^{2-}$ and 2.27 for Cd(mpa) + maa^{2-} = Cd(maa)(mpa)$^{2-}$. The second stepwise formation of a mixed ligand complex is usually larger than that of the corresponding parent complex. The values of $\log K_{12}$ of the parent complexes are 2.15 and 2.85 for Cd(maa)$_2^{2-}$ and Cd(mpa)$_2^{2-}$, respectively. The increment of the step-

donation from mpa^{2-}, and therefore, the electron acceptability of the cadmium ion for the second entering ligand of maa^{2-} is decreased, which is a weaker ligand than mpa^{2-}. Therefore, the second stepwise formation constant of the Cd(maa)(mpa)$^{2-}$ complex from Cd(mpa) and maa^{2-} is smaller than that of the Cd(mpa)$_2^{2-}$, although the former value is still larger by 0.12 log unit than the second stepwise formation constant of the Cd(maa)$_2^{2-}$ complex ($\log K_{12} = 2.15$) due to the entropy effect.

ORGANOTIN COMPLEXES OF
5-ARYLAZO-8-QUINOLINOLS

T. S. BASU BAUL, T. K. CHATTOPADHYAY and B. MAJEE*
Department of Chemistry, University of North Bengal, Darjeeling—734430, India

Abstract—5-Phenylazo-8-quinolinol (LH) forms di/tri-organotin complexes similar to the well-known organotin oxinates, but 5-(2'-carboxyphenylazo)-8-quinolinol (L'HH') forms three classes, viz., the carboxylate derivatives of the type $R_3SnL'H$, the quinolinolates of the type $R_2Sn(L'SnR_3')_2$ and $R_3SnL'SnR_3'$. The carboxylates, $R_3SnL'H$, are 5-coordinate complexes similar to other triorganotin arylazobenzoates and the quinolinolates, R_2Sn (L'H')$_2$, closely resemble the corresponding organotin oxinates. Unlike the oxinates, $R_2Sn(L'H')_2$ type complexes can, be made water soluble by treatment with aqueous $NaHCO_3$ whereby $R_2Sn(L'Na)_2$ type complexes are formed. The binuclear complexes of the type $R_2Sn(L'SnR_3')_2$ contain 5- and 6-coordinate organotin groups in the same ligand.

Although known for a long time as analytical reagents for qualitative detection of metal ions,[1–3] the extant literature contains no report of isolation and characterisation of metal or organometallic complexes of 5-arylazo-8-quinolinols (I). More recent studies on this group of compounds concern mainly the azo-hydrazone tautomeric equilibria[4–6] and bacteriocidal properties[7,8] although some of these compounds, particularly, 5-(2'-carboxyphenylazo)-8-quinolinol, appear to be suitable ligands for the preparation of a variety of a rare type of complex in which the two coordination sites (2'—COOH and 8–OH groups) are bonded to two different ions/groups. In this paper we report the preparation and electronic spectra of organotin complexes of 5-arylazo-8-quinolinols (I). Of particular interest is the diorganotin-5-(2'-carboxyphenyl azo)-8-quino-linolates which can be made water soluble through conversion into their sodium-salts by reaction with $NaHCO_3$. The corresponding triorganotin compounds are likely to find wide application as water soluble organotin biocides and attempts are therefore being made to prepare these compounds.

EXPERIMENTAL

(a) *Preparation of 5-arylazo-8-quinolinols* (I) *and their methyl derivatives.* The ligands LH and L'HH' were synthesised according to methods given in Ref. 2.

5-(2'-carbomethoxyphenyl)azo-8-quinolinol, L'MeH, was prepared by the method reported by Sawicki.[6]

Preparation of 5-(2'-carbomethoxyphenyl)azo-8-methoxyquinoline, L'Me₂. L'HH' was methylated by refluxing in MeOH and conc. H_2SO_4 as described by Vogel.[9] The product was purified by repeated crystallisation from ether. m.p. 112°C; PMR(δ), 3.78(COOCH₃), 4.03(Aryl–OCH₃); IR ν_{as}(OCO) 1730 cm⁻¹; ms *m/e* (M⁺), 321.

5-(2'-carboxyphenyl)azo-8-methoxyquinoline, L'MeH' was prepared by saponification of L'Me₂ using standard procedures.[10]

(b) *Preparation of organotin derivatives of 5-arylazo-8-quinolinols* (I). A few preparative details are given below:

(i) Ph₂SnL₂: A mixture of diphenyltin oxide (0.85 g) and LH (0.75 g) in 100 cm³ dry benzene was refluxed for 20 hr, cooled and filtered. The filtrate was concentrated and petroleum ether (60–80) added when the crude product separated out. This was purified by repeated crystallisation from benzene and petroleum ether (60–80). The pure product was obtained as orange crystals; m.p. 202°C; yield 80–82%.

(ii) Ph₃SnL'H: A mixture of Ph₃SnCl(2.03 g) and the Ag–salt of L'HH'(2.1 g) was refluxed in 250 cm³ dry benzene for 25 hr, cooled and filtered. Addition of petroleum ether to the concentrated filtrate yielded the crude product which was filtered and washed with hot petroleum ether, 2% NaHCO₃ and then with water. The product was crystallised from benzene and petroleum ether (60–80); m.p. > 300°C; yield 70–75%.

(iii) Ph₂Sn(L'H')₂: ¹HH' (2.5 g) was Soxhlet-extracted in 300 cm³ THF. To the solution was added 1.46 g. Ph₂SnCl₂ and few drops of pyridine. The reaction mixture was stirred at room temperature for 10 hr. THF was then distilled off, the solid washed with hot petroleum ether and extracted with cold benzene. Addition of petroleum ether (60–80) to the concentrated solution afforded the orange-red product which was again recrystallised from benzene and petroleum ether; d.p. 259°C; yield 40–45%.

(iv) Ph₂Sn(L'Me)₂: L'MeH(1.3 g) and Ph₂SnCl₂(0.73 g) were taken in 150 cm³ dry benzene containing a few drops of pyridine. The mixture was refluxed for 10 hr, cooled and filtered. Addition of petroleum ether to the concentrated filtrate yielded the crude product which was filtered, washed with hot petroleum ether, 2% NaHCO₃ and finally with water. The brown coloured compound was purified by repeated crystallisation from benzene and petroleum ether (60–80); m.p. 178°C; yield 50–55%.

(v) $Ph_2Sn(L'SnPh_3)_2$: A mixture of $Ph_2Sn(L'H')_2(1.0 g)$ and $(Ph_3Sn)_2O(0.83 g)$ in 200 cm³ dry benzene was refluxed for 15 hr, cooled and filtered. Addition of petroleum ether to the concentrated filtrate yielded the crude product which was filtered, washed with hot petroleum ether, 2% $NaHCO_3$ and finally with water. The solid was purified by repeated crystallisation from benzene and petroleum ether (60–80); m.p. > 300°C; yield 60–65%.

RESULTS AND DISCUSSION

(a) *Method of preparation of the organotin derivatives*

While the monobasic ligand LH, forms only one type of organotin complexes, viz. the organotin quinolinolates, the dibasic ligand L'HH' can form three types, viz. the organotin carboxylate, organotin quinolinolate and the binuclear di/triorganotin (triorganotincarboxyphenyl)azo-quinolinolates.

The organotin carboxylates are conveniently prepared by reactions (1) and (2):

$$R_3SnCl + L'HAg \longrightarrow R_3SnL'H + AgCl \qquad (1)$$

$$R_3SnOCOCH_3 + L'HH' \longrightarrow R_3SnL'H + CH_3COOH \qquad (2)$$
The quinolinolates were prepared by using reactions (3)–(6):

$$(Ph_3Sn)_2O + 2LH \longrightarrow 2Ph_3SnL + H_2O \qquad (3)$$

$$R_2SnX_2 + 2LH \longrightarrow R_2SnL_2 + 2HX \qquad (4)$$

$$R_2SnX_2 + 2L'HH' \longrightarrow R_2Sn(L'H')_2 + 2HX \qquad (5)$$

$$R_2SnX_2 + 2L'MeH \longrightarrow R_2Sn(L'Me)_2 + 2HX \qquad (6)$$
Addition of a small amount of pyridine to the reaction mixture to neutralise the acid formed in reactions (2) and (4)–(6) improves the yield. The binuclear di/tri-organotin (triorganotincarboxyphenyl)azoquinolinolates were prepared in 20–70% yield by reactions (7) and (8) which take place on refluxing the reactants in dry benzene.

$$(R_3'Sn)_2O + R_2Sn(L'H')_2 \rightarrow R_2Sn(L'SnR_3')_2 + H_2O \qquad (7)$$

$$(Ph_3Sn)_2O + L'HH' \rightarrow Ph_3SnL'SnPh_3 + H_2O \qquad (8)$$
Reaction (9) and (10), were also tried for the preparation of the binuclear complexes:

$$2R_3'SnL'H + R_2SnCl_2 \longrightarrow R_2Sn(L'SnR_3')_2 + 2HCl \qquad (9)$$

$$R_2Sn(L'Ag)_2 + 2R_3'SnCl \longrightarrow R_2Sn(L'SnR_3')_2 + 2AgCl \qquad (10)$$
However, the yield in reaction (9) is not good although the reaction time is short. The reverse holds good for reaction (10).

The diorganotin quinolinolates of the type $R_2Sn(L'H')_2$ can be easily converted into the corresponding Na-salts, $R_2Sn(L'Na)_2$ which are water soluble, by treatment with aqueous $NaHCO_3$. The Na-salts can also be crystallised from methanol.

(b) Electronic absorption spectra

Ligands and their organotin complexes in which the 8–OH group is present show two absorption bands in the visible region at ~ 400 nm and ~ 460–480 nm (Table 2) due to azo-hydrazone tautomerism, well-known in such systems.[5,6] The lower wavelength band must be assigned to the π–π^* transition of the azo form since all compounds in which the –OH group is methylated or complexed with organotin group and, thus, exist only in the azo form, show a single intense absorption at ~ 400 nm. The ~ 460–480 nm band must, therefore, be attributed to the hydrazone form in agreement with the earlier observations that the hydrazone form generally absorbs at a longer wavelength.[10] The solvent dependence of the relative intensities of the two bands are also consistent with the known trends in similar molecules.[6]

The relative intensities of the ~ 400 and ~ 460 nm bands show that the azo-hydrazone equilibrium in the carboxylate derivatives of the type $R_3SnL'H$ is considerably shifted towards the azo form compared to that in the corresponding methyl ester, $L'MeH$. In the latter, the hydrazone form is stabilised by the formation of a 6-membered ring due to intramolecular H-bonding (II).[6]

(II)
In the organotin complexes (III), the presence of N→Sn coordinate bond prevents the formation of any such intramolecular H-bond in the hydrazone form. The hydrazone form is, therefore, less favoured in the organotin complexes.
The large bathochromic shift of the π–π^* transition in the azo form in $R_3SnL'H$ type complexes (λ_{max}, ~ 420 nm) compared to that in the corresponding methyl ester $L'MeH$ (λ_{max}, 385 nm) is also consistent with the presence of N→Sn coordination.

Though the possibility of azo-hydrazone tautomerism is eliminated in the organotin quinolinolates of the type $R_2Sn(L'H')_2$, their electronic spectra (Table 2) are strongly influenced by the nature of solvent due to solute–solvent interaction through the carboxylic H-atom as shown by the following observations.

5 - (2' - carbomethoxyphenyl)azo - 8 - methoxyquinoline (IV), a model for the azo form, shows a single absorption maximum at 380 nm in polar as well as nonpolar solvents.

(IV)
The corresponding organotin derivatives, $R_2Sn(L'Me)_2$, absorb at considerably longer wavelength (λ_{max}, 420 nm). The organotin complexes are, thus, structurally quite similar to the organotin oxinates[11–15] and should be formulated as shown in (V). On the other hand, complexes of the type $R_2Sn(L'H')_2$ in which the carboxyl group is free, absorb predominantly at 415–420 nm in donor solvents (acetone, methanol, DMSO, etc.) and at 480 nm

(VIA)

(VIB)
in nonpolar solvents. Since all compounds of this series in which the carboxylic proton has been replaced, e.g. $R_2Sn(L'Me)_2$, $R_3SnL'H$, $R_2Sn(L'SnR_3')_2$ have a single intense absorption at ~ 410 nm in all the solvents, the ~ 420 nm absorption in $R_2Sn(L'H')_2$ should be attributed to the structure (VIA) which is expected to exist in donor solvents (S) due to intermolecular H-bonding involving the carboxylic proton and the donor atom of the solvent. Since the H-atom is not directly involved in the π-system, such interaction will have little influence on the $\pi-\pi^*$ transition and consequently the absorption spectra closely resemble those of the corresponding carbomethoxy compounds in donor solvents (λ_{max}, $Ph_2Sn(L'H')_2 = 415$ nm; $Ph_2Sn(L'Me)_2$, 420 nm).

On the other hand, formation of an intermolecular H-bond involving the azo N-atom (VIB) would certainly result in a large bathochromic shift of the $\pi-\pi^*$ transition.[16,17] The 480 nm absorption should, therefore, be attributed to the species (VIB), the two forms (VIA) and (VIB) being in equilibrium. Clearly, the intramolecular H-bonded form (VIB) will be the main species in nonpolar solvents while donor solvents will tend to form solvent-solute or intermolecular hydrogen bond, thereby shifting the equilibrium towards the form (VIA).

In the binuclear derivatives of the type $R_2Sn(L'SnR_3')_2$ and $(R_3Sn)_2L'$, the possibility of azohydrazone tautomerism as well as intra-or intermolecular H-bonding involving the carboxyl group is eliminated. Consequently, the visible spectra shows a single absorption at 410 nm in both types of solvents. The bathochromic shift of the absorption maximum compared to that in the corresponding methyl derivative, $L'Me_2$ (λ_{max}, 380 nm) indicates the formation of $N \rightarrow Sn$ bond.

(c) *IR spectra*

Both in the organotin carboxylates $R_3SnL'H$ and the binuclear derivatives $(R_3Sn)_2L'$ and $R_2Sn(L'SnR_3')_2$, the asymmetric carboxyl stretch occurs at 1630–1650 cm^{-1} which is typical of 5-coordinate organotin arylazocarboxylates.[18,19] The binuclear derivatives $R_2Sn(L'SnR_3')_2$ which should be formulated as in (VII), therefore, constitute probably the first examples of mixed organotin complexes of polyfunctional ligands.

Interestingly, $\nu_{as}(OCO)$ occurs at 1730 cm^{-1} both in $R_2Sn(L'H')_2$ and $R_2Sn(L'Me)_2$ type compounds indicating the absence of intramolecular H-bonding

(VII)
involving the –COOH group in the former in solid phase. This is somewhat surprising since the electronic spectra indicate presence of intramolecular H-bond in the solution phase. Presumably, the intermolecular interactions are more important in the solid phase so that intramolecular H-bonds are broken as in the polar solvents (VIA).

CYANO- AND THIOCYANATO-DERIVATIVES OF TETRAHALOPHOSPHONIUM IONS

KEITH B. DILLON* and ANDREW W. G. PLATT

Chemistry Department, University of Durham, South Road, Durham DH1 3LE, England

Abstract—Several cyano- and thiocyanato-derivatives of the ions PBr_4^+ and PCl_4^+, including some mixed species, have been obtained in solution by using liquid halogens as solvents, and identified by means of ^{31}P NMR spectroscopy. The method of pairwise interactions has proved very valuable for assigning structures to the various species.

INTRODUCTION

During the course of our recent investigations into pseudohalogeno-derivatives of simple phosphorus(V) species[1–6] we were naturally interested in preparing derivatives of the tetrahalophosphonium ions PBr_4^+ and PCl_4^+. The tetra-azidophosphonium ion $P(N_3)_4^{+7}$ and the series $PCl_{4-n}(N_3)_n^{+3}$ are the only known examples of pseudohalogeno-species derived from PCl_4^+, while no derivatives of PBr_4^+ have been reported. We describe here the identification by means of ^{31}P NMR spectroscopy of several cyano- and thiocyanato-species, including some mixed ions $PCl_xBr_yX_z^+$ ($x + y + z = 4$; $X = CN$ or NCS), derived from PBr_4^+ or PCl_4^+ and prepared in liquid halogens as solvents. The use of the pairwise additivity of chemical shifts[8–10] over a wide range of tetrahedrally-coordinated phosphorus(V) species has proved invaluable as an aid to structural assignment.

EXPERIMENTAL

All manipulations including NMR sample preparation were carried out either *in vacuo* or under an atmosphere of dry nitrogen. Chemicals of the best available commercial grade were used, in general without further purification, except as described below. Bromine and chlorine were dried over P_2O_5 before use. Zinc cyanide was dried by heating to 373K *in vacuo* for 5 hr. $P(CN)_3$ and cyanogen were prepared as described in a previous paper.[5] Anhydrous LiNCS was prepared by the method of Lee.[11] PBr_4BBr_4 was obtained by the action of BBr_3 on PBr_5 in a suitable inert solvent, and the salts PCl_4BCl_4 and PCl_4SbCl_6 were prepared by standard methods.[12] Reactions involving Cl_2 were carried out in thick-walled silica tubes which were sealed under vacuum. The $P(CN)_3/(CN)_2$ system was prepared in a similar manner.

^{31}P NMR spectra were recorded at 307.2K on the Fourier transform spectrometer as described previously.[3] Chemical shifts were measured relative to external H_3PO_4, with the downfield direction taken as positive. Where an entire series of compounds was observed, e.g. $PCl_{4-n}Br_n^+$ or $PBr_{4-n}(CN)_n^+$, the pairwise additivity parameters were refined by a least squares method and these "best fit" values were used in the calculation of chemical shifts.

RESULTS AND DISCUSSION

The formation of $P(N_3)_4^+$ by direct substitution is very dependent on the choice of solvent,[3,7] and $MeNO_2$ was found to be the only common solvent which promotes the reaction.[3] It is thus not surprising that the reactions of PBr_4^+ and PCl_4^+ with other pseudohalides depend greatly on the choice of solvent. Normal organic solvents were found not to

favour simple substitution reactions; some examples of the types of reaction we have observed therein are outlined in eqns (1)–(6).

$$PCl_4SbCl_6 + AgCN \xrightarrow[PhNO_2]{MeCN} PCl_3(CN)_3^- \quad (1)$$

or

$$PCl_4BCl_4 + AgCN \xrightarrow{PhNO_2} PCl_3 + ClCN \quad (2)$$

$$PCl_4SbCl_6 + AgNCS \xrightarrow[slow]{PhNO_2} SPCl_{3-n}(NCS)_n \quad (3)$$

$$PCl_4SbCl_6 + AgNCS \xrightarrow[rapid]{MeCN} SPCl_{3-n}(NCS)_n \quad (4)$$

$$PCl_4SbCl_6 + LiNCS \xrightarrow{MeNO_2} SPCl_{3-n}(NCS)_n \quad (5)$$

$$PCl_4BCl_4 + LiNCS \xrightarrow{MeNO_2} SPCl_{3-n}(NCS)_n + PCl_3 \quad (6)$$
The phosphorus-containing products were identified by means of their characteristic ^{31}P NMR shifts,[5,13] and ClCN (eqn 2) by its gas phase IR spectrum. The usual reactions were either reduction to PCl_3 and/or (for thiocyanates) the formation of thiophosphoryl compounds, although PCl_4SbCl_6 reacted with AgCN in either MeCN or $PhNO_2$ to give the ion $PCl_3(CN)_3^{-5}$. The salts containing the PBr_4^+ ion were either insoluble (PBr_4PF_6), or decomposed readily to $PBr_3(PBr_5$ or PBr_4BBr_4) in normal organic solvents.

In liquid bromine, however, PBr_5 dissolves to give the PBr_4^+ cation (δ ^{31}P − 76.5 ppm), there being no possibility of reduction to phosphorus(III) species in such an oxidising medium. Since some of the reactions above led to reduction of phosphorus(V), the use of liquid halogens as solvent systems seemed feasible. Although side reactions of the metal pseudohalide with the solvent were sometimes apparent they were not always rapid, and reaction with the phosphonium ions often seemed to occur at a faster rate.

Cyano-derivatives of PBr_4^+ *and* PCl_4^+. The reaction of PBr_5 with $Zn(CN)_2$ in liquid bromine gave rise to four new resonances in the ^{31}P NMR spectrum (Table 1). Assignment of the signals is not straightforward as the shift of $P(CN)_4^+$ is to higher field of those of $PBr_2(CN)_2^+$ and $PBr(CN)_3^+$. The $P(CN)_4^+$ assignment was confirmed by measurements on a $P(CN)_3/(CN)_2$ system,[14] where in addition to resonances assigned to $P(CN)_3(\delta$ − 130.6 ppm)[15] and

0	-76.2	-76.5	-76.2	-76.5
1	-32.6	-32.9	-51.7	-49.3
2	8.5	8.5	-37.8	-40.3
3	47.2	47.1	-34.5	-33.3
4	83.2	83.2	-41.8	-41.9

$P(CN)_5(\delta - 98.4\,ppm)$, a higher frequency signal was observed at $\delta - 43.6\,ppm$, agreeing well with the value of $-41.9\,ppm$ in Br_2.

From these observations, and a series of measurements on the $PCl_5/ZnBr_2/Br_2$ system to obtain the shifts of the $PCl_{4-n}Br_n^{+}$[16,17] cations in Br_2 (Table 1), the pairwise additivity parameters Cl : Cl, Cl : Br, Br : Br, Br : CN and CN : CN can be evaluated. Thus to calculate the shifts for the series of cations $PBr_xCl_y(CN)_z^+$ $(x + y + z = 4)$ only the Cl : CN term needs to be found. This was evaluated from the shift of $PCl_3(CN)^+$ (δ 44 ppm), which was observed in the spectra from the reaction between PCl_4SbCl_6 and $Zn(CN)_2$ in Cl_2. All the phosphorus-containing species were insoluble in Cl_2 at room temperature, but the reaction proceeded slowly in the solid state, and the separate resonances due to solid state signals were resolvable because of the large chemical shift differences. $PCl_2(CN)_2^+$ was also observed at δ 11 ppm. PCl_5 also reacted with $Zn(CN)_2$ in Cl_2 to form $PCl_3(CN)^+$ (δ 44 ppm), but no further substitution occurred in this instance.

The reaction of $Zn(CN)_2$ with PCl_5 in Br_2 gave rise to a complex series of spectra. The main reaction observed was the formation of $PCl_{4-n}Br_n^+$ ions (from reaction of $Zn(CN)_2$ with the solvent), and these were the most intense peaks in the ^{31} NMR spectrum, but several resonances were apparent which could be ascribed to cyano-containing derivatives. The observed shifts and assignments are shown in Table 2. The $PCl_2(CN)_2^+$ resonance is likely to be masked by the strong peak due to $PCl_2Br_2^+$, but the failure to detect any signal from $PClBr(CN)_2^+$ must be due to low concentration as no other strong resonances are expected in the region of $-12.5\,ppm$, which is the calculated shift for this species.

Thiocyanato-derivatives. The reactions between both PBr_5 and PCl_5 with AgNCS in Br_2 as solvent were exothermic, and the ^{31}P NMR spectra of the resulting solutions showed several new species to be present, in addition to (for PCl_5) the series $PCl_{3-n}Br_n^+$. The formation of both thiophosphoryl compounds and cyano-substituted species as well as thiocyanato-derivatives was apparent, leading to complex spectra. Possible assignments are shown in Table 3, following calculation of the shifts by the pairwise interaction method, as outlined below.

As pairwise additivity parameters have been shown to be independent of charge and only influenced by the geometry of the compound[4,9,10] the known shifts of $POCl_{3-n}(NCS)_n$ and $POBr_{3-n}(NCS)_n$[18] can be utilised to obtain some of these parameters. (Al-

though the shifts of these compounds have not been quoted for Br_2 as solvent the values seem relatively independent of the solvent in this case, as shown by the checks described subsequently.) The calculation of the pairwise parameters is as follows:

$$
\begin{aligned}
Cl : Cl &= 13.9\,ppm \text{ (from } \delta\ PCl_4^+) \\
O : Cl &= -12.9\,ppm \text{ (from } \delta\ POCl_3) \\
Cl : NCS &= 3.6\,ppm \text{ (from } \delta\ PCl_3(NCS)^+) \\
\delta\ POCl_2(NCS) &= -21.0\,ppm \\
&= 2O:Cl + O:NCS + 2Cl:NCS \\
&\quad + Cl:Cl \\
\therefore O : NCS &= -16.5\,ppm \\
\delta\ POCl(NCS)_2 &= -41.5\,ppm \\
&= O:Cl + 2O:NCS + 2Cl:NCS \\
&\quad + NCS:NCS \\
\therefore NCS : NCS &= -16.5\,ppm.
\end{aligned}
$$

Thus all the data required for the calculation of δ $PCl_{4-n}(NCS)_n^+$ are available. A simple check that the above approach is reasonable is to calculate δ $PO(NCS)_3 = -58.2\,ppm$, which agrees well with the

* observed shift used to calculate Cl:NCS parameter

observed value of -61.9 ppm.[13,18] The shift parameters required for the brominated derivatives were evaluated in a similar way. Thus

$$\delta\ PSBr_3 = -111.8\ \text{ppm gives S : Br as } -24.6\ \text{ppm}$$

$$\delta\ PS(NCS)_3 = -9.3\ \text{ppm gives S : NCS as } -0.2\ \text{ppm}$$

$$\delta\ PSBr_2(NCS) = -62.8\ \text{ppm}^{19}\ \text{gives Br : NCS as } -0.2\ \text{ppm}.$$

The values were checked by calculating δ for $PSBr(NCS)_2$ as -27.5 ppm, which compares well with the experimental value of -28.4 ppm.[19] Although there is ambiguity in a few of the assignments (Table 3), the majority of the observed peaks could be satisfactorily assigned.

Although the isolation of the species observed in these reactions is not feasible because of the complexity of the systems, the low concentration of some of the species and the likely instability of the compounds in the absence of oxidising media ($P(CN)_5$, for example, was observed to dissociate rapidly to $P(CN)_3$ and (presumably) $(CN)_2$ in CH_2Cl_2), they can be readily identified by solution ^{31}P NMR spectroscopy. This, combined with the use of the pairwise additivity method, allows the elucidation of the somewhat complex chemistry of these systems, giving an insight which would be difficult if not impossible to achieve by any other means. It is noteworthy that the parameters for the $PBr_{4-n}(CN)_n^+$ system correctly predict a maximum in the shift values for $n = 3$; a similar maximum (on the present sign convention) has been both observed and calculated previously for the six-coordinate species $PCl_{6-n}(N_3)_n^-$.[2,3]

Abstract—The extraction of nickel chelates with β-diketones containing either alkyl or phenyl groups was examined in the absence and in the presence of ammonia in the aqueous solution, in order to define the effect of substituents and the coordinating effect of ammonia on the extraction.

In the extraction of nickel chelates in the presence of ammonia, the extracted species were identified to be [NiA$_2$(NH$_3$)$_2$] (A: β-diketone anion) and ammonia acts both as adduct-forming in the organic phase and as a masking reagent in the aqueous phase.

INTRODUCTION

The β-diketone derivatives which are represented by acetyl–acetone are commonly used as extractants in the solvent extraction of many metals. The distribution coefficients of nickel chelates with the β-diketones are known to be much smaller than those of other divalent metals with the corresponding reagents and the low extractability is attributable to hydrous nickel chelate in an organic phase.[1]

Yosida *et al.*[2] had reported that nickel chelates with di-propyonylmethane, di-*n*-butyrylmethane, di-iso-butyrylmethane, di-iso-valerylmethane and di-*n*-caproylmethane were in a dimeric octahedral structure, and these dimeric chelates were stable in the solid state. However, they appeared to be dimeric monohydrates and monomeric dihydrates in non-coordinating solvents according to spectroscopic studies. It was also known that nickel acetyl–acetonate combined with base adducts such as pyridine[3].

In the previous studies,[4] it was proved that the logarithmic values of the distribution coefficients for the alkyl-substituted β-diketones and their copper or iron chelates were a linear function of the number of additional carbon atoms in the molecule of common water immiscible solvents.

In this paper, the extraction of the nickel chelate with β-diketones containing either alkyl or phenyl groups was investigated both in the absence and in the presence of ammonia in an aqueous phase, in order to define the effect of substituents and the effect of ammonia on the extraction.

EXPERIMENTAL

Materials. Benzoylacetylacetone (BAA), di-benzoylmethane (DBM) and acetylacetone were obtained from Dojindo Co., Ltd. Alkyl-substituted β-diketones, dipropyonylmethane (DPrM), di-*n*-butyrylmethane (DNBM), di-*n*-valerylmethane (DNVM), di-*n*-caproyl-methane (DNCM), di-iso-butyrylmethane (DIBM), di-iso-

valerylmethane (DIVM), dipivaloylmethane (DPM) and pivaloylacetylmethane (PAM) were synthesized by a procedure similar to that of Adams *et al.*[5] and their compositions were confirmed by elementary analysis.

Stock solution of 10^{-4}M NiClO$_4$ was prepared by careful evaporation of the initial chloride solution with perchloric acid. The aqueous pH was controlled with borate buffer in the absence of ammonia, while an ammonium chloride solution was used in the presence of ammonia and perchloric acid or sodium hydroxide was used for pH adjustment.

Benzene of chemical grade was used as the diluent with no further purification. All the other reagents were reagent-grade and were used without further purification.

The ionic strength was kept at 0.10 with sodium perchlorate, which was not added, however, at the concentration of ammonium salt in excess of 0.1 M.

Procedure. An aqueous phase initially containing 10^{-4} M nickel was shaken with an equal volume of 0.10 M β-diketone in benzene. After contrifugation, the concentration of nickel in an aliquot of the organic phase was measured as an oxinate with spectrophotometry. The pH value of the aqueous phase was measured with a pH meter. The equilibrium of extraction was reached slowly in the absence and rapidly in the presence of ammonium salt, then the time of shaking was 2 days for the former and 5 hr for the latter. All experiments were carried out at 20°C.

Apparatus. Most of the apparatus used were essentially the same as that described previously.[4] A Toadempa HM 9A pH meter was used for the measurement of pH. Absorbances were measured with Yuniongiken SM 401 spectrophotometer.

RESULT AND DISCUSSION

The formation of nickel chelates in the aqueous solution is expressed as

$$\text{Ni}^{2+} + nA^- \rightleftharpoons \text{Ni}An^{(2-n)}$$

$$\beta_A = \frac{[\text{Ni}An]}{[\text{Ni}^{2+}][A^-]^n} \tag{1}$$
where A^- denotes the β-diketon anion and β_A is the stability constant. The distribution coefficient of the neutral chelate, P_M, between the two phases is defined

---

by:

$$P_M = \frac{[\text{Ni}An]\text{org}}{[\text{Ni}An]\text{aq}} \qquad (2)$$

where subscripts org and aq refer to the organic and aqueous phases respectively, which may be omitted, if not necessary. In a case where the organic phase contains only the $[\text{Ni}A_2]$ species, and the aqueous phase contains a series of metal chelates, the distribution ratio D is described as:

$$D = \frac{[\text{Ni}A_2]\text{org}}{[\text{Ni}^{2+}]\{1 + \Sigma\beta n[A^-]^n\}}. \qquad (3)$$

By introducing eqns (1) and (2), eqn (3) can be rewritten as:

$$D = \frac{P_M\beta_2[A^-]^2}{\{1 + \Sigma\beta n[A^-]^n\}}. \qquad (4)$$

When the concentration of the nickel chelates is sufficiently low as compared with that of the free nickel ions in the aqueous phase, the overall extraction equilibrium can be written as:

$$[\text{Ni}^{2+}] + 2[HA]\text{org} \rightleftharpoons [\text{Ni}A_2]\text{org} + 2[\text{H}^+]$$

$$\text{Kex}^{(1)} = \frac{[\text{Ni}A_2]\text{org}[\text{H}^+]^2}{[\text{Ni}^{2+}][HA]^2\text{org}} = D_1\frac{[\text{H}^+]^2}{[HA]^2\text{org}}. \qquad (5)$$
The distribution ratio can be described as:

$$D_1 = \frac{[\text{Ni}A_2]\text{org}}{[\text{Ni}^{2+}]} = \text{Kex}^{(1)}\frac{[HA]^2_{\text{org}}}{[\text{H}^+]^2}. \qquad (6)$$

Thus, when no aqueous chelate complex is formed, the distribution ratio is proportional to the square of the concentration of the chelating extractant in the
Fig. 2. Distribution ratios of nickel as a function of pH. Organic phase: DNBM, PAM 0.1 M benzene. Aqueous phase: blank dot 0.1 M NaClO$_4$; solid dot 1.0 M NH$_4$Cl.

organic phase and is inversely proportional to the square of the hydrogen ion concentration in the aqueous phase. However, when the distribution ratio is given by eqn (4), it can be described as:

$$D_1 = \text{Kex}^{(1)}\frac{[HA]^2_{\text{org}}[\text{H}^+]^{-2}}{\{1 + \Sigma\beta n[A^-]^n\}}. \qquad (7)$$

In addition, when the formation of metal hydrolysis products in the aqueous phase is not negligible over the pH range under consideration, eqn (7) can also be
Fig. 1. Distribution ratios of nickel as a function of pH. Organic phase: DNVM, DIBM 0.1 M benzene. Aqueous phase: blank dot 0.1 M NaClO$_4$; solid dot 1.0 M NH$_4$Cl.
Fig. 3. Distribution ratios of nickel as a function of pH. Organic phase: DNCM, DPM 0.1 M benzene. Aqueous phase: blank dot 0.1 M NaClO$_4$; solid dot 1.0 M NH$_4$Cl.

defined as:

$$D_1 = \text{Kex}^{(1)} \frac{[HA]^2_{org}[H^+]^{-2}}{1 + \Sigma\beta n[A^-]^n + \Sigma\beta_j[OH]^j} \quad (8)$$

where β_j is the overall formation constants for nickel hydroxocomplexes.

In order to identify the distributed species, the distribution ratio was measured at different hydrogen ion concentrations for each of β-diketones. The experimental data were plotted for the values of log D vs pH. Figures 1–3 show several typical examples with a blank dot for the absence and a solid dot for the presence of ammonia in the aqueous phase.

At the absence of ammonia, the distribution ratio increased with the pH value over a weak alkaline region, approached to a maximum value at about pH 9.5, and then decreased rapidly for higher pH region. This probably ascribed the formation of nickel hydroxocomplexes and/or of intermediate complexes with the reagent in the aqueous phase. However, the extraction curves as straight lines of a slope $+2$ were obtained only in the lower region of the distribution ratio for each of β-diketones except for the AA and DPrM, indicating that the simple 1:2 chelate [NiA$_2$] was present in the organic phase.

On the basis of the distribution data, the values for the extraction constants were calculated, which are given in Table 1 together with the aqueous pH values needed for 50% extraction, the distribution coefficients and the acid dissociation constants for each of β-diketones used here. The values of Kex$^{(1)}$ for the AA and DPrM systems could not be calculated due to the poor extractability of the nickel chelates. The values of Kex$^{(1)}$ for the DIBM, PAM and DPM were also in good agreement with those in the previous paper.[6]

It has been attempted to calculate the values of the formation constants of nickel hydrolysis with the aid of eqn (8) and using the values of D, pH and Kex$^{(1)}$ for the DNBM system, as a series of nickel chelates in the aqueous phase were negligibly small. The mean values of the formation constants were therefore

obtained as $10^{4.6}$ for $\beta_{j(OH)}$ and $10^{9.2}$ for $\beta_{j(OH)_2}$, respectively.

The chelates extracted with the DIBM, DPM and PAM into the organic phase appeared pink, which was distinctive other β-diketones. Fackler and Cotton[7] referring to the above fact, had indicated that the *bis*-DIBM and the *bis*-DPM nickel chelates were anhydrous in non-coordination solvents by means of the spectroscopic studies. Accordingly, in the case with the DIBM, DPM and PAM, either all or only part of the extracted species was probably existed as an anhydrous form in the organic phase.

At the presence of ammonia in the aqueous phase, the distribution ratios of nickel chelates increased within the high pH region as shown in Figs. 1–3. Figure 4 shows the visible absorption spectra of the DNBM system as an example of the extracted nickel chelates in the organic phase both at the presence and absence of ammonia in the aqueous phase, in which the absorption peaks of these chelates were shown at 610 nm for the presence and 650 nm for the absence of ammonia. The spectral change which is observed when ammonia gas was bubbled through the organic solution containing the extracted chelate at the absence of ammonia was also quite similar to that of the DNBM chelate described above.

In order to examine the contribution of ammonia on the extraction, the distribution ratios of the DIVM system as an example of the nickel chelates were measured at different concentrations of ammonium chloride at a pH value and the results are shown in Fig. 5. The distribution ratios increased slightly with the increase in the molar concentration of ammonia and decreased rapidly as the further increase in the concentration of one.

The concentration of free ammonia after equilibrium was reached was calculated according to eqn (9):

$$[NH_3] = \frac{[NH_4^+] \text{ in}}{\left\{1 + \dfrac{[H^+]}{Ka}\right\}} \quad (9)$$

where Ka is the apparent association constant $(= 10^{-9.37})^8$ of ammonium ion and $[NH_4^+]_{in}$ denotes the initial concentration of ammonium salt.

Figure 6 also gives the concentration of ammonia in the organic phase at varying concentration of the nickel ions equilibrated with a 1.0 M NH_4Cl aqueous solution. Obviously, the concentration of ammonia increases in proportion to the nickel concentration with a slope 1.9. The fact that the ammonia dependence is 1.9 means that two mole of the ammonia are coordinated in one mole of the nickel β-diketone.

On the other hand, it was known that the equilibrium of the extraction for the system AA, BAM or DBM alone was reached slowly after being shaken for few days,[9] it was however observed in the presence
Fig. 5. Distribution ratios of nickel as a function of the concentrations of the ammonia in the aqueous phase. Organic phase, DIVM 0.1 M benzene. Aqueous phase, pH 9.37.

of ammonia, the equilibrium in the extraction was reached within less than 1 hr. Consequently, it may be considered that the nickel chelate was not extracted by the ligand exchange between the β-diketone anion and the coordinated ammonia in the ammine nickel complex, but was extracted by the ligand exchange between the β-diketone anion and the coordinated water in the nickel aquo complex, because the ligand exchange was easily formed with an activated water molecule when 1 and/or 2 mole of the ammonia molecules were coordinated to the nickel aquo complex. The stepwise extraction equilibrium in the presence of ammonia can be written as:

$$[Ni(NH_3)^{2+}] + 2[HA]_{org} \rightleftharpoons [NiA_2(NH_3)]_{org} + 2[H^+]$$

$$[Ni(NH_3)_2^{2+}] + 2[HA]_{org} \rightleftharpoons [NiA_{2A2}(NH_3)_2]_{org}$$
$$+ 2[H^+] \rightarrow [NiA_2(NH_3)_2]_{org} + 2[H^+]$$
and thus

$$Kex^{(2)} = \frac{[NiA_2(NH_3)]_{org}[H^+]^2}{[Ni(NH_3)^{2+}][HA]_{org}^2}. \quad (10)$$

$$Kex^{(3)} = \frac{[NiA_2(NH_3)_2]_{org}[H^+]^2}{[Ni(NH_3)_2^{2+}][HA]_g^2}. \quad (11)$$

The distribution ratios in the presence of ammonia may be defined as:

$$D = \frac{[NiA_2]_{org} + [NiA_2(NH_3)]_{org} + [NiA_2(NH_3)_2]_{org}}{[Ni^{2+}] + [Ni(NH_3)^{2+}] + \cdots\cdots + [Ni(NH_3)_6^{2+}]}. \quad (12)$$

From eqns (6), (10) and (11), eqn (12) can then be rewritten as:

$$D = \frac{[HA]_{org}^2}{[H^+]^2} \cdot$$

$$\left[\frac{Kex^{(1)} + Kex^{(2)}\beta_1[NH_3] + Kex^{(3)}\beta_2[NH_3]^2}{1 + \Sigma\beta_n(NH_3)^n}\right]. \quad (13)$$
Fig. 7. Distribution ratios of nickel as a function of pH. Organic phase, reagent 0.1 M benzene. Aqueous phase, NH$_4$Cl 1.0 M. —, Calcd value; O, found value.
Fig. 8. Distribution ratios of nickel as a function of pH. Organic phase, reagent 0.1 M benzene. Aqueous phase, NH$_4$Cl 1.0 M. —, Calcd value; O, found value.

If the concentration of ammonia was comparatively high, eqn (13) may be reduced as:

$$D = \text{Kex}^{(3)} \cdot \frac{[HA]_{org}^2}{[H^+]^2} \cdot \frac{\beta_2 [NH_3]^2}{\{1 - \Sigma \beta_n (NH_3)^n\}} \qquad (14)$$

where β_n is the overall formation constants for ammine nickel complexes.

The distribution ratios of nickel chelates are then obtained as a function of the ammonia concentration. Equation (13) also suggests that the ammonia acts both as a masking reagents and simultaneously as an adduct forming ligands.

The values of Kex$^{(3)}$ for each of β-diketones were calculated from eqn (14) by employing the observed values of the pH, the distribution ratio, the ammonia concentration and the formation constants for ammin nickel complexes which had been known in the literature.[8] These results are given in Table 1. The results from the present study are shown in Figs. 7 and 8 in order to for the comparison of the behaviour of the distribution ratios for each of β-diketones with a rather wide pH region. The distribution curves show an almost similar tendency for each of β-diketones and a displacement is observed in the pH range of 9–10.

It may be considered that slight positive deviations from the curve for the DIBM system at low pH region are due to the formation of the adduct-comples [NiA_2(NH$_3$)] in the organic phase. Providing that the distribution ratios were compared with a fixed pH, it seems that the values of log D increases as the values of log Ka of corresponding β-diketones lower except for the DBM system. In addition, the synergistic effect with ammonia which is expressed as Kex$^{(3)}$/Kex$^{(1)}$ is approximately the same for β-diketones used here.

CHEMISTRY IN FUMING NITRIC ACIDS—I. NMR SPECTROSCOPIC STUDY OF PF₅, HPO₂F₂ AND P₄O₁₀ IN THE SOLVENT SYSTEM 44 wt.% N₂O₄ IN 100% HNO₃

C. CLIFFORD ADDISON, JOHN W. BAILEY, SIMON H. BRUCE, MICHAEL F. A.
DOVE, RICHARD C. HIBBERT and NORMAN LOGAN*

Nottingham NG7 2RD, England

Abstract—^{31}P and ^{19}F NMR spectroscopy has been used to elucidate the nature of the interaction of PF$_5$, HPO$_2$F$_2$ and P$_4$O$_{10}$ with the solvent system 44 wt.% N$_2$O$_4$ in 100% HNO$_3$ ("High Density Acid", HDA). PF$_5$ generates the species PF$_6^-$, HPO$_2$F$_2$ and HF (with some H$_2$PO$_3$F present as a minor product). HPO$_2$F$_2$ gives rise to H$_2$PO$_3$F and HF (with smaller amounts of PF$_6^-$ also present). The ^{31}P NMR spectrum of P$_4$O$_{10}$ in HDA exhibits four resonances assigned to P(OH)$_4^+$, H$_4$P$_2$O$_7$, (HPO$_3$)$_4$ and a mixture of cyclic and branched phosphoric acids, respectively.

Fuming nitric acids have found widespread use over the last 40 yr as oxidiser components of liquid rocket propellants.[1] They possess a number of advantages in this role, namely, a high specific gravity (1.5 or greater), a convenient liquid range ($-40°C$, or lower, to $+80°C$), hypergolicity (spontaneous ignition) with a number of fuels and they are relatively cheap to manufacture. They have, however, several disadvantages, particularly their highly corrosive nature. 100% nitric acid undergoes the auto-ionisation (1)

$$2HNO_3 \rightleftharpoons NO_2^+ + NO_3^- + H_2O. \qquad (1)$$

The presence of NO$_2^+$, NO$_3^-$ and molecular H$_2$O in 100% HNO$_3$ was established by Raman spectroscopy.[2,3] ^{1}H NMR studies have shown that a rapid exchange takes place between the chemical species present.[4,5] Due to the presence of molecular H$_2$O the terms "pure" or "anhydrous" nitric acid are misleading; the term "analytically 100% nitric acid" is preferred and, if not specified, should be understood whenever HNO$_3$ or nitric acid is referred to in this paper. This acid is termed white fuming nitric acid (WFNA). WFNA is, however, unstable and undergoes thermal or photolytic decomposition (eqn 2).

$$2HNO_3 \xrightarrow{\Delta \text{ or } h\nu} N_2O_4 + H_2O + \tfrac{1}{2}O_2. \qquad (2)$$
*Author to whom correspondence should be addressed.

This limits the suitability of WFNA as a propellant due to possible pressure build-up in tanks and uncertainty in the oxidising power. The addition of N$_2$O$_4$ improves the stability and storability of the oxidiser. Of particular interest is the mixture 44 wt.% N$_2$O$_4$ in 100% HNO$_3$. This composition gives the maximum density of any N$_2$O$_4$–100% HNO$_3$ mixture and is thus referred to as High Density Acid (HDA). N$_2$O$_4$–100% HNO$_3$ mixtures are highly corrosive towards the series 300 stainless steels and aluminium alloys used as containment materials for the oxidiser and thus small quantities (*ca.* 0.5 wt%) of a third component are added to inhibit corrosion. HF and PF$_5$ are found to be the most highly successful inhibitors thus far tried[6] but P$_4$O$_{10}$ and HPO$_2$F$_2$ are potential alternatives.

The purpose of the present study was to investigate the interaction of the solutes PF$_5$, HPO$_2$F$_2$ and P$_4$O$_{10}$ with the system 44 wt.% N$_2$O$_4$ in 100% HNO$_3$ (HDA), by means of ^{19}F and ^{31}P NMR spectroscopy. The chemical nature of the HDA medium is of considerable interest. N$_2$O$_4$ is known to undergo essentially complete ionic self-dissociation (eqn 3) at concentrations up to 1M ($\sim$9 wt.%) in 100% HNO$_3$[7]

$$N_2O_4 \rightleftharpoons NO^+ + NO_3^-. \qquad (3)$$

The proportions of the various species at higher concentrations of N$_2$O$_4$ are not precisely known, although a recent investigation by Raman spectroscopy in our laboratories[8] has confirmed the presence of the molecular species NO$^+$, NO$_3^-$,

HNO$_3$ and N$_2$O$_4$ in HDA, which is also known to contain small concentrations of NO$_2$ (as indicated by its orange colour) and H$_2$O (characteristic absorption in the near IR at 7117 cm^{-1}). The chemistry of HDA has been reviewed.[9] The present study enables the reactivity of this complex medium to be further elucidated.

EXPERIMENTAL

Materials

PF$_5$ was prepared by the controlled fluorination of red phosphorus. Any POF$_3$ impurity formed in the reaction was removed by holding the reaction vessel at $-78°C$ during the transfer of PF$_5$ to a steel storage vessel. Pure HPO$_2$F$_2$ was obtained from the commercial material (Koch–Light) by the method of DesMarteau et al.[10] The purity of samples prepared in this way was confirmed by ^{19}F NMR spectroscopy,

$$(\delta_{CFCl_3} = -87.3 \text{ ppm}, \quad J_{F-P} = 982 \text{ Hz}).$$

Commercial P$_4$O$_{10}$ (Albright and Wilson) was used without further purification.

HDA is prepared on a routine basis in our laboratories by mixing 100% HNO$_3$ and liquid N$_2$O$_4$. 100% HNO$_3$ was obtained by distillation under reduced pressure (10^{-2} Torr) of a 3:1 (v:v) mixture of concentrated sulphuric acid and 95% nitric acid. The product was collected and stored at low temperature (ca. $-20°C$). Commercial N$_2$O$_4$ (Air Products Ltd.) was purified by drying the liquid over P$_4$O$_{10}$ (1 day) followed by distillation in a slow oxygen stream through a P$_4$O$_{10}$ drying column. The purified N$_2$O$_4$ was collected as a colourless solid at $-78°C$. HDA, as prepared in our laboratories, was found to contain ca. 0.23 wt.% H$_2$O.[8]

Preparation of NMR samples

The samples were made up by weight in 6 mm o.d. fluorinated ethylene propylene (FEP) polymer tubes. These tubes were coupled to Kel–F vacuum valves so that samples could be degassed and volatile components added from a calibrated fluorocarbon polymer vacuum manifold. Finally, the FEP tubes containing the prepared solutions were heat sealed.

NMR spectra

All NMR spectra were obtained using a Bruker WM250 pulse Fourier transform spectrometer (^{19}F studies at 235.35 MHz and ^{31}P at 101.27 MHz). The FEP tubes were placed inside 10 mm dia. glass NMR tubes containing CDCl$_3$ (to provide a deuterium lock) in the outer annulus. Samples for ^{19}F

NMR investigations also contained CFCl$_3$ (as external standard) in the glass tube. All ^{31}P spectra were externally referenced to 85% H$_3$PO$_4$ by sample replacement. Relative concentrations of species were determined from measured peak integrals. The spectra were accumulated until a satisfactory signal-to-noise ratio was attained. For low concentrations of solutes (0.7 wt.% PF$_5$ and 1 wt.% P$_4$O$_{10}$) approx. 100,000 pulses (ca. 15 hr accumulation time) were required for the production of a high quality spectrum.

RESULTS AND DISCUSSION

(a) The PF$_5$–HDA system

The PF$_5$–HDA system was studied at PF$_5$ concentrations of 6 and 0.7 wt.% (PF$_5$ is used as an inhibitor in HDA at concentrations between 0.5 and 0.7 wt.%). The 6 wt.% mixture contained a white solid (although this did not interfere with the running of NMR spectra). This solid was identified on the basis of its IR spectrum and X-ray powder pattern as predominantly NO$^+$PF$_6^-$. The precipitation of NO$^+$PF$_6^-$ rather than NO$_2^+$PF$_6^-$ is to be expected since the self-dissociation of N$_2$O$_4$ supresses the self-dissociation of HNO$_3$ to the extent that the NO$_2^+$ concentration becomes very small in HDA. The 0.7 wt.% mixture was completely homogeneous.

The ^{19}F chemical shifts and coupling constants for the observed species (HF, H$_2$PO$_3$F, HPO$_2$F$_2$ and PF$_6^-$) are collected in Table 1. ^{31}P NMR spectroscopy demonstrated the absence of any other phosphorus-containing species in either mixture. The formation of the observed products may be rationalised using the following series of equations

$$2PF_5 + HNO_3 \rightarrow POF_3 + NO_2^+ + PF_6^- + HF \quad (4)$$

$$POF_3 + HNO_3 \rightarrow HPO_2F_2 + NO_2^+ + F^-. \quad (5)$$

$$HPO_2F_2 + HNO_3 \rightleftharpoons H_2PO_3F + NO_2^+ + F^-. \quad (6)$$

$$HPO_2F_2 + 4F^- + 2NO_2^+ \rightleftharpoons PF_6^- + NO_3^- \\ + HNO_3. \quad (7)$$
Neither POF$_3$ nor PF$_5$ was detected in the solution phase by NMR spectroscopy, presumably because they are very rapidly solvolysed in HDA. However, POF$_3$ has been observed (by NMR spectroscopy) in solution in other strongly acidic media (e.g. fluorosulphuric acid[12]) and we have observed it in the vapour phase above a 5 wt.% solution of PF$_5$ in HNO$_3$ (although it was not detected in the solution phase by NMR). A de-

tailed NMR investigation of the PF$_5$–HNO$_3$ system has not yet been conducted but preliminary results indicate that the interaction of PF$_5$ with HNO$_3$ is similar to that with HDA except that, at PF$_5$ concentrations in excess of ca. 5 wt%, NO$_2^+$PF$_6^-$, rather than NO$^+$PF$_6^-$, is precipitated from solution. The variation with time of the concentrations of the observed species in the 0.7 wt.% mixture is displayed in Fig. 1. HF concentrations determined by direct integration were unreliable due to interference from a very broad signal (centred at

Fig. 1. Variation with time of species detected by ^{19}F NMR in a solution of 0.7 wt.% PF$_5$ in HDA. ○, HF (calculated)/2; ●, HPO$_2$F$_2$; △, PF$_6^-$; ▲, H$_2$PO$_3$F.

ca. −122 ppm) produced by the fluoroplastic NMR tube (see Fig. 2). The HF concentrations shown in Fig. 1 were therefore determined using the measured concentrations of H$_2$PO$_3$F, HPO$_2$F$_2$ and PF$_6^-$ and by assuming that the P:F ratio in the sealed system remained constant at 1:5.

Results from the 6 wt.% mixture indicate that the hydrolysis of HPO$_2$F$_2$ (as indicated by the rate of formation of H$_2$PO$_3$F) is concurrent with that of PF$_6^-$ (as indicated by the rate of formation of HPO$_2$F$_2$) although it is less rapid. In the 0.7 wt.% system (Fig. 1) the HPO$_2$F$_2$ and HF concentrations increase in a regular manner as the PF$_6^-$ concentration diminishes, whereas the H$_2$PO$_3$F concentration remains relatively small but slowly increases. Figure 1 also indicates that a stable (equilibrium) situation would eventually be reached in the 0.7 wt.% mixture.

(b) The HPO$_2$F$_2$–HDA system

The HPO$_2$F$_2$–HDA system was studied at initial HPO$_2$F$_2$ concentrations of 2.7, 4.1, 9.7 and 22.8 wt.% (all mixtures were homogeneous). At all concentrations the only observed species were HF, H$_2$PO$_3$F, HPO$_2$F$_2$ and PF$_6^-$. The ^{19}F NMR parameters of these species were similar to those observed in the PF$_5$–HDA system and were virtually independent of concentration. Typical ^{31}P NMR parameters are presented in Table 2. The major fluorophosphate species observed were HPO$_2$F$_2$ and H$_2$PO$_3$F (as opposed to PF$_6^-$ and HPO$_2$F$_2$ in the PF$_5$–HDA system). H$_2$PO$_3$F is formed by solvolysis of HPO$_2$F$_2$ (eqn 6) and the fluoride thus generated subsequently attacks HPO$_2$F$_2$ to form PF$_6^-$ (eqn 7). The observed PF$_6^-$ concentrations were never more than 11% of the corresponding H$_2$PO$_3$F concentration.

In HPO$_2$F$_2$–HDA mixtures and PF$_5$–HDA mixtures the chemical shift of the resonance ascribed to HF is in the region which corresponds to
Fig. 2. ^{19}F NMR spectrum of 0.7 wt.% PF$_5$ in HDA after 83 days.

hydrogen-bonded HF molecules, rather than to HF$_2^-$ or F^{-13} (Table 1). The change in chemical shifts of the fluorophosphoric acids (Tables 1 and 2) in HDA with respect to the pure compounds, can be ascribed to solvation effects rather than protonation. Protonation of the phosphoryl oxygen of H$_2$PO$_3$F or HPO$_2$F$_2$ in 1:1 fluorosulphuric acid–antimony pentafluoride ("Magic Acid") substantially increases the coupling constants (^{1}J$_{F-P}$) for these species,[14] however, no such increase was observed in HDA. A solution of HPO$_2$F$_2$ (19 wt.%) in HNO$_3$ (at $-20°$C to inhibit the thermal decomposition of nitric acid) was also examined. In addition to the species observed in HDA, a weak peak at $+2.1$ ppm, assignable to protonated orthophosphoric acid,[15] was observed. The coupling constants of HPO$_2$F$_2$ (994 Hz) and H$_2$PO$_3$F (965 Hz) were higher than in HDA and are indicative of some degree of protonation of these species also.

(c) *The P$_4$O$_{10}$–HDA system*

Solutions at initial P$_4$O$_{10}$ concentrations of 4.2, 2.9 and 1 wt.% in HDA were examined. A solution

of P$_4$O$_{10}$ (4.3 wt.%) in 100% HNO$_3$ was also prepared for comparison purposes. The tubes containing ca. 4.2 wt.% P$_4$O$_{10}$ were stored at $-20°$C (freezer) between ^{31}P NMR measurements. This enabled a comparison of the two systems to be made (it being necessary to store the tube containing HNO$_3$ at $-20°$C to prevent thermal decomposition of the acid).

The results are summarised in Tables 3 and 4. Generally speaking, four ^{31}P resonances were observed for each solution (see Fig. 3). The low field peak at 2.0 ± 0.3 ppm has been assigned to protonated orthophosphoric acid (P(OH)$_4^+$).[15] A down-field shift is observed when protonation of the doubly bound oxygen takes place.[15] (This assignment is, however, made with some reservation because HPO$_2$F$_2$ and H$_2$PO$_3$F also show a ^{31}P downfield shift in HDA but no increase in coupling constant; see Section (a)). The peak at -11.75 ± 0.25 ppm can be assigned to diphosphoric acid, H$_4$P$_2$O$_7$. An aqueous solution of this acid has a shift of -10.6 ppm[16] and a solid sample rotating at the "magic angle" of 54°44′ resonates at -12 ppm.[17]

The position of the third peak is very close to that reported for tetrametaphosphoric acid $(-24.0$ ppm)[18] and this assignment is supported by the observation that under controlled conditions this acid is the principal hydrolysis product of P$_4$O$_{10}$. The position $(-26.7 \pm 0.6$ ppm) of the fourth peak is intermediate between that expected for cyclic (ca. -20 to -24 ppm) and branched (ca. -30 ppm) phosphate.[15] This peak (which is quite broad; ca. 230 Hz) is therefore tentatively assigned to a mixture of cyclic and branched phosphoric acids in fairly rapidly reversible equilibrium giving a single averaged signal. The variation with time of the proportions of the various

products (expressed as % of total phosphorus present) is summarised in Table 4. A number of conclusions can be drawn from these results. Provided the initial concentration of P_4O_{10} in HDA is small (around 1 wt.%), complete conversion to protonated orthophosphoric acid $(P(OH)_4^+)$ would eventually be observed, whereas at higher initial P_4O_{10} concentrations an equilibrium mixture of phosphoric acids would ultimately be obtained. The attainment of this equilibrium position (or of complete hydrolysis of P_4O_{10}) appears to require a considerable length of time. This is probably due

to the resistance to hydrolysis of some of the cyclic and branched phosphoric acids present in the system. The hydrolysis of P_4O_{10} in 100% HNO_3 is more extensive and rapid than in HDA, although similar species are observed in both media.

SUMMARY

In the solvent system 44 wt.% N_2O_4 in 100% HNO_3 (HDA) the solutes PF_5, HPO_2F_2 and P_4O_{10} undergo what may be termed "hydrolysis" reactions. The hydrolysis of all three solutes is incomplete (except at low concentrations) equilibrium mixtures of fluorophosphate species (PF_5 and HPO_2F_2) or phosphoric acids (P_4O_{10}) being ultimately obtained. Reactions in HDA therefore more closely resemble those in aqueous solution,[19,20] than in strongly acidic media.[12,13,15]

Abstract—³¹P and ¹⁹⁵Pt NMR measurements on compounds of the type [Pt(PPh₃)₂ (μ-η²-C₂H₄₋ₙXₙ)] (n = 0 ...4; X = CN, COOMe) are reported and discussed.

The study of platinum complexes with unsaturated organic molecules has received attention for several years and there is still much activity in trying to distinguish and understand the resulting electronic and steric effects on varying the olefin and/or coordinated ligands. The complexes [Pt(PR₃)₂(μ-η²-ol)] (ol = olefin) have an approximately planar arrangement with a small dihedral angle between the PtC₁C₂ and PtP₁P₂ planes.[1–7]

The most widely accepted description of metal–olefin bonding was proposed by Dewar, Chatt and Duncanson. This model has been a stimulus to much synthetic, structural and mechanistic work. A metallacyclopropane model is also reported, sometimes in contrast with the former. In terms of resulting electronic structure within the M.O. approach the two models are equivalent and complexes with different olefins imply only different amounts of orbital mixing[8] but often the metallacyclopropane model is used as being synonymous with a strong metal–carbon interaction. Recently considerable theoretical effort has been devoted to obtaining detailed theoretical descriptions of the electronic structure of transition metal–olefin complexes.

NMR parameters of single compounds have been taken into consideration to get some insight into the electronic structure of the coordinated olefin. $^2J_{H,H}$ observed in [Pt(PPh₃)₂(C₂H₄)] is much nearer to the value found in cylcopropane than in free ethylene. On the other hand, $^1J_{Pt,C}$ is noticeably lower than one should expect for a σPt–C bond[9], but in this respect it should be noticed that the variation of $^1J_{Pt,C}$ in the series cis-[Pt(PPh₃)₂Et₂] (700 Hz), (PPh₃)₂Pt–CH₂–CH₂–CH₂ (400 Hz), [Pt(PPh₃)₂(C₂H₄)] (200 Hz) [10] parallels the strong decrease in $^1J_{C,C}$ observed in ethane (∼37 Hz) and cyclopropane (∼10 Hz).

The fact that, through olefin substitution it is possible to modulate the complex properties without essential changes in geometry around the platinum atom and with only minor variations in bond distances should simplify the recognition of the main factors responsible for the variations of molecular properties and thus reveal details of the electronic structure in the platinum–olefin region.

Calorimetric measurements have shown that the platinum–olefin bond in [Pt(PPh₃)₂(C₂(CN)₄)] is 156 kJ mole⁻¹ more stable than in [Pt(PPh₃)₂(C₂H₄)][11], although there is little variation in Pt–C distance with the Pt–P distance being slightly longer in the C₂(CN)₄ complex (2.289 Å) than in the C₂H₄ complex (2.267 Å).

*Author to whom correspondence should be addressed.

ESCA measurements have been reported for [Pt(PPh₃)₂(olefin)] (olefin = ethylene, tetrachloroethylene, tetrafluoroethylene, tetracyanoethylene) and for [Ni(PPh₃)₂(olefin)] (olefin = ethylene, acrylonitrile, methylacrylate).[12]

In order further to investigate the effect of olefin substitution in this type of compound we now report ³¹P and ¹⁹⁵Pt NMR measurements on the complexes [Pt(PPh₃)₂(C₂H₄₋ₙXₙ)], (n = 0 ... 4; X = CN and COOMe); ¹H NMR spectra of these complexes have already been reported.[13]

RESULTS AND DISCUSSION

The ³¹P and ¹⁹⁵Pt chemical shifts, together with the values obtained for $^1J_{Pt,P}$, for the cyano and carbomethoxy derivatives are shown in Tables 1 and 2, respectively.

Platinum–phosphorus coupling constants

Various reports have appeared on the ³¹P NMR of [Pt(PPh₃)₂(C₂H₄)] and the reported values of $^1J_{Pt,P}$ range from 3425 to 3694 Hz.[9,4-17] The reason for this rather large variation in $^1J_{Pt,P}$ is not obvious but the value is clearly much higher than is normally found (⩽2000 Hz) for cis-[Pt(PPh₃)₂R₂] (R = alkyl) [18]. Similar high values of $^1J_{Pt,P}$ have been found for phosphorus trans to carbon, which is part of a $\overline{Pt–C–X}$ three-membered ring, X = S,[19,20] X = C,[6,9,16] X = P,[21-23] and high values are also found in related alkyne complexes.[24]

Phosphorus ligands trans to 3-membered rings are thus associated with high values of $^1J_{Pt,P}$. The reason is however still obscure since, although Ph₃PPtPPh₃ bond angles trans to 3-membered rings are usually in the region of 110° giving rise

to values of $^1J_{Pt,P}$ *ca* 3400–3600 Hz, the complex [Pt(Ph$_2$PN(CHMePh)PPh$_2$)(C$_2$(CF$_3$)$_2$)], which has an extremely small value for PPtP angle (71.3°), still has a high value of $^1J_{Pt,P}$ (2929 Hz).[25]

Similar problems are associated with providing a plausible explanation for the small variation in $^1J_{Pt,P}$ on going from the ethylene to di- and tetra-substituted cyano and carbomethoxy derivatives since it has previously been found that there is a significant decrease in the value of $^1J_{Pt,P}$ *trans* to CH$_2$X in [Pt(PPh$_2$(CH$_2$)$_n$PPh$_2$)(CH$_2$X)Cl] ($n = 2$ and 3; X = H and CN) on going from the methyl to cyanomethyl derivative with a corresponding increase in the value of $^1J_{Pt,P}$ *cis* to CH$_2$X.[26] A bigger variation in $^1J_{Pt,P}$ is found in our unsymmetrically substituted derivatives, [Pt(PPh$_3$)$_2$(C$_2$H$_{4-n}$X$_n$)] ($n = 1$ and 3; X = CN and COOMe), but it is not possible to make an unambiguous assignment, although these results are similar to those found in the acyclic CH$_2$X derivatives. The apparent insensitivity of $^1J_{Pt,P}$ to cyanide or carbomethoxy substitution contrasts with the variations

observed in substituted alkyne derivatives[24,27] and with the strong *trans*-influence on the $^1J_{Pt,P}$ observed in [Pt(dppe)MeX]$^{n+}$ where X = neutral ($n = 1$) or anionic ($n = 0$) ligands.[28] We presently have no explanation for this difference in behaviour between alkyne and olefin complexes containing the Pt(PPh$_3$)$_2$ moiety.

Platinum chemical shifts.

In the CN substituted compounds the platinum is monotonically deshielded by increasing the number of substituents whilst the dependence is less marked and non monotonic in the case of the COOMe substitution. Analogous behaviour is found for CN and COOMe substituted acetylene complexes.[24]

The electronic charge on the metal is expected to decrease monotonically increasing the number of electron withdrawing substituents on the olefin. If the main factor responsible for the ^{195}Pt chemical shift variations within a series of complexes is the
Fig. 1. $\delta(^{195}$Pt) values for Pt(PPH$_3$)$_2$(C$_2$H$_{4-n}$X$_n$) complexes. ●, CN or ▲, COOMe.

charge on the metal it would be difficult to explain the difference in trends observed for CN and COOMe in olefin and acetylene[24] derivatives.

According to the Ramsey formulae the paramagnetic contribution to the nuclear screening constant is connected with the existence of nonvanishing angular momentum mixed matrix elements from low lying monoelectronic states and depends on the value of these matrix elements and on $(\Delta E)^{-1}$.

Some relevant features of the electronic structure of [PtL$_2$(olefin)] compounds have been described by interacting the M.O.s of the L$_2$Pt fragment[8,29] with the suitable π and π^* olefin orbitals.

These descriptions show the existence of a low-lying empty M.O. built up from the b_2 orbital of PtL$_2$ fragment (mainly Ptd_x with some p_x character) and the olefin in antibonding combination. A relevant local paramagnetic contribution to the platinum screening constant can be ascribed to the above situation as the matrix element between this M.O., which has significant metal character, and some of the filled mainly d M.O.s can be rather large and ΔE is small.

Substitution of alkene hydrogens with CN groups decreases the π^* energy in the free olefin[7,8,30,31] and, assuming a constant geometry for the Pt(PPh$_3$)$_2$ fragment,[8] should mainly imply a lowering of the low-lying empty M.O. Thus, like in the alkyne complexes,[24] the experimental trend of platinum chemical shifts in the CN substituted olefins can be explained through a decrease in the relevant ΔE as the number of substituents increases. However, according to this explanation the platinum in the ethylene complex should resonate at higher fields than observed. Perhaps this discrepancy could be ascribed to the neglect of the $P_1\widehat{Pt}P_2$ angles variation.[1-3] An increase of this angle should cause[8] a decrease in energy and p_x character of the b_2 M.O. of the PtL$_2$ fragment and therefore a weakening of the interaction with the olefin π^* M.O. So, due to the particularly high value of $P_1\widehat{Pt}P_2$ angle the ethylene complex can have a low-lying empty M.O. with energy very close to that of the acrylonitrile complex despite the difference of the π^* energies in the two uncoordinated olefins.

Thus olefin substitution affects the energy of the relevant empty M.O. both through a variation of the free alkene empty level and through variation of the $P_1\widehat{Pt}P_2$ angle, the two effects being opposite in the cyano substituted compounds and the former being predominant from acrylonitrile to tetracyanoethylene. Carbomethoxy substitution is expected to cause small variations on the olefin π^* energies. No structural data on the $P_1\widehat{Pt}P_2$ angles are reported but it is possible that the two effects are almost in balance in this series of compounds and this could explain the observed ^{195}Pt shifts trend.

Phosphorus chemical shifts

Acceptable conclusions about phosphorus chemical shifts in metal complexes are usually difficult to establish due to the variety of factors which can play a determinant role.[18] This is even more so for the complexes reported in this paper as more structural parameters are needed to determine meaningful correlations. Nevertheless the increase of phosphorus shielding on increasing the number of olefin substituents observed both for CN and for COOMe and the similarity both in
Fig. 2. P_1PtP_2 angle in complexes $Pt(PPh_3)_2(C_2H_{4-n}X_n)$.

trend and in magnitude with the phosphorus chemical shifts of [Pt(PPh$_3$)$_2$(acetylenes)] complexes revealed by inspection of the data reported in Ref. 24 are remarkable. If this behaviour is connected primarily with the local contributions to the screening constant of phosphorus, it should reflect a decrease in paramagnetic contribution as the lone pair electronic charge moves further from phosphorus atom. However, the previously mentioned variation of P$_1$P̂tP$_2$ angles suggests the possibility that the observed trends for phosphorus chemical shifts are linked with changes in geometrical factors and recent reports on platinum chemical shift anisotropy[32] in Pt(II) and Pt(IV) complexes indicate that the magnetic anisotropy of the platinum electron cloud has to be taken into consideration in an explanation of the above trends.

As expected ^{31}P NMR spectra of [Pt(PPh$_3$)$_2$ (olefin)] complexes with asymmetrically substituted olefins confirm that the alkene C–C axis does not lie in a plane perpendicular to the P$_1$PtP$_2$ plane and that no olefin rotation occurs with a speed significant in the NMR time scale.

EXPERIMENTAL

The complexes Pt(PPh$_3$)$_4$ and Pt(PPh$_3$)$_2$(C$_2$H$_4$) were prepared by literature methods.[33] Slightly modified literature methods were used for olefin synthesis,[34] except for commericially available products. All preparations were performed under an atmosphere of nitrogen or argon; work up was done in the air. All solvents were dried and degassed before use.

^{195}Pt and ^{31}P NMR spectra were recorded as described previously.[35,36]

COMPLEXATION OF THE LANTHANIDES BY PYRAZINECARBOXYLATE

Gyu Shik Kim, Young Inn Kim[+], and Sock Sung Yun[*]

Department of Chemistry, Chungnam National University
Daejeon 300-31, Korea

(Received 2 March 1983)

ABSTRACT

The stability constants of the lanthanide pyrazinecarboxylate
complexes in aqueous solution have been determined in the ionic
medium of 1.0 M $NaClO_4$ at 25°C. The stability of the lanthanide
pyrazinecarboxylates is relatively larger than those of the
monodentate ligands, indicating that the heterocyclic 1-nitrogen
atom of the ligand is involved in the chelate formation.

INTRODUCTION

Relatively little attention has been given to the lanthanide
complexation with the heterocyclic carboxylic acids. The complexation
reactions in aqueous solution of trivalent lanthanide cations by
furoate[1], α-picolinate[2-4], α-picolinate N-oxides[2], and dipicolinate[5]
have been studied. The results[1-4] have shown that the heterocyclic
nitrogen atom of α-picolinate is involved in the chelate ring
structure whereas the heterocyclic ring oxygen of furoate does not.

To study the influence of the heterocyclic ring of the ligands
on the complexation, we have determined the stability constants for
the lanthanide pyrazinecarboxylate complexes in aqueous solution.
The potentiometric titration technique was employed in this study.

EXPERIMENTAL

<u>Chemicals</u>. Stock solutions of the lanthanide perchlorates were
prepared by dissolving the lanthanide oxides (Merck Co) in concentr-
ated $HClO_4$. Standardization of the stock solutions was accomplished
by EDTA titration with xylenol orange indicator in the acetate buffer.
The total ionic strength of the working solution was adjusted to 1.0 M
with $NaClO_4$. The stock solution of pyrazinecarboxylic acid (Aldrich
Chemical Co.) was prepared and standardized using the Acid-Base
titration method. The sodium pyrazinecarboxylate buffer solutions
were prepared in the buffer ratio of 0.4 with the standard NaOH
solution. Deionized water was used for the preparation of all
solutions.

. The electrode potential was measured using Fisher
Accumet 520 Digital pH/Ion meter and Fluke 8000-A Digital Multimeter
with the quinhydrone-Pt electrode and the salt bridge. About 200 mg
of quinhydrone (Merck Co) were added for every 15.0 ml of the solution
titrated. The pure platinum wire was cleaned occationally by immersion
in the chromic acid-conc. H_2SO_4 solution.

Procedure. The experimental procedure is essentially same as that
described by Choppin[6]. The measured e.m.f. values were used to
calculate the hydrogen ion concentrations. The titration was performed
in the conditions of $\mu = 1.0$ M $NaClO_4$ and t = $25^\circ C$.

Assuming that only mononuclear complexes are formed, the average
number of the ligands bound per cation, $\bar{n}$, is related to the stability
products, β_n, in the equation[6],

$$\bar{n} = \frac{\sum\limits_{n=1}^{N} n \cdot \beta_n [L]^n}{1 + \sum\limits_{n=1}^{N} \beta_n [L]^n}$$

where $[L]$ is the free ligand concentration. The initial values of β_n
were estimated by the graphical method of Bjerrum[7]. These initial
values of β_n along with $\bar{n}$ and $[L]$ were used for the iterative least
square analysis of above equation to obtain the final values of the
stability products, β_n. The calculations were performed on the IBM
370/1482 computer. All error limits are expressed in 95 % confidence
level.

RESULTS AND DISCUSSION

The dissociation constant of pyrazinecarboxylic acid, $pK_a = 2.76 \pm 0.05$,
was obtained by the titration with the base for the acid solution of 1.0 M
ionic strength at $25^\circ C$.

Figure 1 is the plot of the complex formation functions $\bar{n} = f(p[L])$,
where $p[L] = -\log[L]$, for some typical titrations. The curves approach
to around $\bar{n} = 3$, indicating the possible formation of the fourth complex,
ML_4^-. To check the possibility of the polynuclear complex formation,
the titrations for Sm^{3+} system were made at two different metal ion
concentrations, one at $C_M = 7.808$ mM and the other at $C_M = 3.904$ mM.
Figure 1 shows that these two curves are overlapped and thus no
measurable amount of the polynuclear complexes is formed.

Table 1 lists the values of the log of the stability products
for the some lanthanide(III) pyrazinecarboxylates. The variation in
the stability constants for the lanthanide pyrazinecarboxylates with
increasing atomic number of the cations is similar to those[2] for the
α-picolinate and α-picolinate N-oxide systems. This similarity would
suggest that the pyrazinecarboxylate ligand forms too the chelate
complexes with lanthanide ions.

Figure 1.   Complex formation curves, $\bar{n} = f(p[L])$, for the lanthanide pyrazinecarboxylates; Nd^{3+} ($\blacktriangle$), $Sm^{3+}(1C_m)$ ($\bigcirc$), Sm^{3+} ($\frac{1}{2}C_m$) ($\bullet$), Gd^{3+} ($\times$), Eu^{3+} ($\triangle$).
Choppin[4,8] has shown the linear relationship between the stability constants β_1 and the acid constants pK_a of the ligands for a number of lanthanide complexes in aqueous solution. Similarly, we have plotted the value of log β_1 against pK_a of the ligand for some Sm(III) complexes with monocarboxylate ligands in Figure 2. All the values[8,9,10] were

Table 1. Stability products of the lanthanide(III) pyrazine-
          carboxylates, $\mu = 1.0$ M (NaClO$_4$), t = 25.0°C.

M^{3+} ions	Log β_1	Log β_2	Log β_3
La	2.30 ± 0.03	4.09 ± 0.06	5.26 ± 0.08
Nd	2.77 ± 0.08	4.78 ± 0.13	6.27 ± 0.20
Sm	2.85 ± 0.09	5.22 ± 0.15	7.07 ± 0.20
Eu	2.82 ± 0.06	5.14 ± 0.10	6.86 ± 0.11
Gd	2.50 ± 0.06	4.58 ± 0.08	6.08 ± 0.10
Tb	2.77 ± 0.08	4.83 ± 0.14	6.82 ± 0.17
Ho	2.91 ± 0.09	4.91 ± 0.23	6.83 ± 0.26
Er	2.84 ± 0.03	4.95 ± 0.07	6.66 ± 0.11
Lu	2.98 ± 0.05	5.13 ± 0.10	7.07 ± 0.16

measured in 0.10 M NaClO$_4$ ionic medium beside those for the ligands
with the heterocyclic ring, in 1.0 M NaClO$_4$ for the pyrazinecarboxylate,
and 2.0 M NaClO$_4$ for the α-picolinate[2], α-picolinate N-oxide[2], and
furoate[1]. For the α-picolinate, two other values measured in 0.1 M[3]
and 0.5 M[4] NaClO$_4$ are also given.

However, the qualitative comparison of the values plotted in Figure
2 could be made since the stability constant of the complex is generally
increased with decreasing the ionic strength of the solution. It is
expected that the stability constants of the complexes for the hetero-
cyclic ligand systems would be somewhat larger at 0.1 M ionic strength
than the present data. The data for the pyrazinecarboxylate,
-picolinate, and α-picolinate N-oxide deviate above from the linear
correlation of log β_1 vs. pK$_a$ for the monodentate ligand systems,
whereas the furoate data fit the correlation well. This would mean
that these ligands beside the furoate form the chelate complexes with
the lanthanide cations. It has been reported[1] that the ring oxygen of
the furoate is not involved in formation of a chelate ring. Even though
the basicities of 1-nitrogen atom of the heterocyclic ring and 2-
carboxylate of the pyrazinecarboxylate ligand are greatly reduced by
the electron withdrawing effect of 4-nitrogen atom, it seems like that
the pyrazinecarboxylate ligand forms quite stable chelate complexes with
the lanthanide ions as the α-picolinate does. To obtain detailed
information on the complexation of the pyrazinecarboxylate in aqueous
solution, we are conducting a thermodynamic investigation on the
lanthanide pyrazinecarboxylates.

Figure 2. Relationship of log β_1 and pK_a of SmL^{2+} complexes where L = propionate (1), acetate (2), benzoate (3), thioacetate (4), methoxyacetate (5), chloroacetate (6), furoate (7), α-picolinate (μ = 0.1 M (8), 0.5 M (9), and 2.0 M (10)), α-picolinate N-oxide (11), and pyrazinecarboxylate (12).

NOTES

Polarographic study of mixed ligand complex stability constants and kinetic parameters of reduction of zinc(II)-tartrate—Thiocyanate system

Km. KRISHNA and S. K. JHA*
Department of Chemistry, Agra College, Agra, India

Abstract—The Zn-tartrate-thiocyanate system has been investigated polarographically and the composition and stability constants of mixed complexes formed have been determined.

Simple Zn-thiocyanate complexes have been reported[1,2] and Matsuda and Ayabe[3] studied the Zn-tartrate system polarographically and have reported the formation of four successive complexes. Since Zn is hexacoordinated when tartrate acts as a bidentate ligand, the maximum possible number of successive complexes can be three and not four as reported by Matsuda and Ayabe. From the survey of literature it is evident that so far no attempt has been made to determine the stability constants and kinetic parameters of reduction of simple Zn-tartrate and mixed Zn-tartrate-thiocyanate complexes. With this aim in view the present study has been undertaken.

EXPERIMENTAL

The studies were done at pH8, constant ionic strength $\mu = 2$ and a temperature of $25 \pm 0.1°C$. The d.m.e had the following characteristics: $m = 4.67$ mg/sec, $t = 2.4$ sec, $m^{2/3}t^{1/6} = 3.176$ mg$^{2/3}$ sec$^{-1/2}$, (in 0.1 M NaNO$_3$, open circuit) and $h_{corr} = 61.8$ cm. Rest of the experimental procedure was the same as reported earlier.[4,5]

RESULTS AND DISCUSSION

The stability constants of simple complexes of Zn-thiocyanate[1] and Zn-tartrate were determined prior to the study of mixed ligand system. Identical conditions were maintained in both the simple and mixed ligand systems. Since results of simple Zn-thiocyanate system have already been reported by the authors these are not being incorporated in the present paper.

1. Zn-*tartrate system*

A series of polarograms were obtained with increasing concentrations of tartrate (0–0.6 M). In each case a well-defined and diffusion-controlled wave was obtained. The slope values indicated that quasi-reversible reduction of Zn(II) becomes irreversible in the presence of ligand. The reversible half-wave potential ($E'_{1/2}$) was calculated by Gellings'[6] method.

The plot of $E'_{1/2}$ vs log [Tart^{2-}] is a smooth curve thereby showing the formation of successive complexes. Deford and Hume's method[7] modified by Irving[8] has been applied for determination of composition and stability constants of the complexes. The plots of $F_j[x]$ vs [x] (Fig. 1) clearly indicates that only three successive complexes are formed. If four complexes were possible $F_3[x]$ should not have been a straight line. Our results are also in accordance with well established fact that a hexacoordinated metal ion can form only three complexes with a bidentate ligand. A 1:4 complex as claimed by Matsuda and Ayabe will require the coordination number of Zn to be eight which is improbable. Three complexes are [Zn(Tart)], [Zn(Tart)$_2$]$^{2-}$ and [Zn(Tart)$_3$]$^{4-}$ with stability constants log $\beta_1 = 2.0$, log $\beta_2 = 3.0$ and log $\beta_3 = 4.3$. The percentage distribution of Zn(II) in its various forms as a function of [Tart^{2-}] is presented in Fig. 2.

Fig. 2. Percentage distribution of Zn(II) in its various forms as a function of Tart^{2-}. M% ▲; MX$_1$% △; MX$_2$% ●; MX$_3$% ○.

2. Zn-*tartrate-thiocyanate system*

The concentration of tartrate has been varied from 0 to 0.6 M keeping concentration of thiocyanate constant at 0.1 M in one set and at 0.2 M in another. These two sets are referred as series I and Series II respectively in the Table 1. A perusal of slope values shows that the reduction of the mixed complexes are irreversible. Having calculated $E'_{1/2}$ by Gellings' method, the method of Schaap and McMasters[9] has been used to determine the composition and stability constants of the mixed complexes.

F_{ij} vs [Tart^{2-}] plots required to calculate the stability constants are presented in Fig. 3. Two mixed complexes viz. [Zn(Tart)(SCN)$_2$]$^{2-}$ and [Zn(Tart)$_2$(SCN)$_2$]$^{4-}$ with stability constants log $\beta_{12} = 3.65$ and log $\beta_{22} = 6.07$ are formed. The values are reproducible to $\pm 0.5\%$. The negative values[10] of β_{11} and β_{12} rule out the possibility of [Zn(Tart)(SCN)]$^{1-}$ and [Zn(Tart)$_2$(SCN)]$^{3-}$ species.

Assuming that Zn is hexacoordinated and tartrate is acting as a bidentate ligand and aforesaid two species are

0.50	6.80	1.110	1.080	0.630	6.07	1.090	1.080	0.52	4.92	1.115	1.110	0.62
0.60	6.64	1.130	1.100	0.590	5.80	1.100	1.090	0.68	4.75	1.125	1.120	0.59

ruled out, then the two mixed complexes existing in solution have the equilibria shown in Table 2. The equilibrium constants (log values) are given for each equilibrium. From these values of equilibrium constants (β) the tendency of a ligand to add to a complex and to substitute another ligand may be compared. The relative tendencies to substitute SCN^- and $Tart^{2-}$ can be compared (equilibria 6, 7 and 8). It shows that $Tart^{2-}$ has greater complexation tendency than SCN^-. From log values it is evident that formation of $[Zn(Tart)_2(SCN)_2]^{4-}$ (as per equilibria 7) is favoured over other mixed complexes being formed through equilibrium Nos. 3, 4, 5, 6, 8 and 9.

The stability of the mixed complexes, follows the order:

$$[Zn(Tart)(SCN)_2]^{2-} < [Zn(Tart)_2(SCN)_2]^{4-}.$$
The mixing constants[11] for the reactions:

$$[Zn(Tart)] + [Zn(SCN)_2] \rightleftharpoons [Zn(Tart)(SCN)_2]^{2-} + Zn^{2+} \quad (1)$$

$$\tfrac{1}{2}[Zn(Tart)_2]^{2-} + [Zn(SCN)_2] \rightleftharpoons [ZN(Tart)(SCN)_2]^{2-} + \tfrac{1}{2}Zn^{2+} \quad (2)$$

$$[Zn(Tart)_2]^{2-} + [Zn(SCN)_2] \rightleftharpoons [Zn(Tart)_2(SCN)_2]^{4-} + Zn^{2+} \quad (3)$$
can be given by the relations:

$$K_M(1) = \beta_{12}/(\beta_{10}\ \beta_{02})$$

$$K_M(2) = \beta_{12}/(\beta_{20}^{1/2}\ \beta_{02})$$

$$K_M(3) = \beta_{22}/(\beta_{20}\ \beta_{02}).$$

The $\log K_M$ values for the reactions 1, 2 and 3 work out to be 1.05, 1.55 and 2.47 respectively. The positive values of mixing constants show that the mixed complexes $[Zn(Tart)(SCN)_2]^{2-}$ and $[Zn(Tart)_2(SCN)_2]^{4-}$ are more stable than simple mono and bis complexes.

αn_a values

"n" the total number of electrons involved in the electrode process as determined by the method of DeVries and Kroon[12] gives value close to 2 for both Zn-tartrate and mixed Zn-tart-SCN systems. This is in conformity with the earlier study of Matsuda and Ayabe.[3] When n is two the n_a the number of electrons involved in activation step can either be one or two. However, Meites[13] is of the opinion that only a single electron can be transferred at a time and a value exceeding 1 should merely mean that the successive steps are too nearly simultaneous to be distinguished on the time scale implicit in the polarographic measurement. The values of αn_a (Table 2) are decreasing in indiscrete manner and no two consecutive values have ratio of 2. Thus it can safely be concluded that it is α which is undergoing the change and not n_a.

αn_a values for simple Zn-tartrate system show a regular decrease while values for Zn-tart-SCN do not follow any order. According to Crow[14] in most of the systems studied polarographically a mobile equilibria exists between the various complexes and aquo–metal ion and different number of complexes are present at varying ligand concentration.

$$[Zn(Tart)_0]^{2+} + 2e \rightleftharpoons Zn$$
prevails while $[Tart^{2-}] \leq 0.1$ M, whereas at $[Tart^{2-}] > 0.1$ M the equilibrium, $[Zn(Tart)_2]^{2-} + 2e \rightleftharpoons Zn + 2Tart^{2-}$ operates and, therefore, at concentrations reported (Table 1), sequential decrease in αn_a values or in other words decrease in α with increasing ligand concentration signifying that reduction becomes more and more difficult is quite obvious. In case of mixed Zn-tart-

Synthesis and studies on dichloro iodo triphenylphosphine oxide nickel(III)

K. P. SARMA and RAJ K. PODDAR*

Department of Chemistry, North-Eastern Hill University, Bijni House, Shillong 793 003, India

Abstract—A new compound of nickel(III), [Ni(OPPh$_3$)Cl$_2$I] has been prepared by the action of nitrosyl chloride or chlorine gas on [Ni(PPh$_3$)$_2$I$_2$]. Various physical studies of the compound are reported.

During the investigation on the reactions of [Ni(PPh$_3$)$_2$X$_2$] (X = Cl, Br, I, NCS and NO$_3$) with nitrosyl chloride, it was found that the nickel(II) complexes gave dimeric species, viz. [Ni(PPh$_3$)XCl]$_2$ (X = Cl, Br, NCS, NO$_3$) and the oxidation of the liberated triphenylphosphine molecule to triphenylphosphine oxide.[1] However, reaction of [Ni(PPh$_3$)$_2$I$_2$] with nitrosyl chloride resulted in the oxidation of nickel(II) to nickel(III) with formation of [Ni(OPPh$_3$)Cl$_2$I]. In this work, the synthesis and studies of the complex [Ni(OPPh$_3$)Cl$_2$I] are reported.

EXPERIMENTAL

Diiodo bistriphenylphosphine nickel(II) was prepared according to the method of Venanzi.[2]

Preparation of dichloro iodo triphenylphosphine oxide nickel(III)

A suspension of powdered [Ni(PPh$_3$)$_2$I$_2$] (1 g) was taken in dry cyclohexane (50 cm^3) and nitrosyl chloride was bubbled slowly through the suspension for about 20 min while stirring the mixture. Slowly the suspended material went into solution. After discontinuing the bubbling of the gas, the mixture was stirred at room temperature for about 8 hr, when yellow compound (m.p. 100–105°d) separated out. During the reaction, colour of the solution changed from dark reddish brown to light red through green. The compound was filtered out and washed several times with dry diethyl ether and dried under vacuum. It was analysed for [Ni(OPPh$_3$)ICl$_2$]: Found: Ni, 10.95; Cl, 13.57; I, 24.12; P, 5.80; C, 40.68; H, 3.12; [N: (OPPh$_3$)ICl$_2$] requires: Ni, 10.97; Cl, 13.27; I, 23.74; P, 5.79; C, 40.37; H, 2.80%. The same compound was also obtained by using chlorine gas instead of nitrosyl chloride.

The mother liquor, after the separation of the compound, on concentration yielded triphenylphosphine oxide, characterised by m.p. (157°C) and IR spectrum ($v_{P=O}$ at 1185 cm^{-1}).

The total halide content in the compound was obtained by decomposing the compound with KNO$_3$, KOH mixture, acidifying with dil. nitric acid to make the solution just acidic and then precipitating as silver halide using silver nitrate. Chloride estimation was done by decomposing the compound with dilute nitric acid and heating for about 30 min to oxidise iodide to iodine and get liberated and then precipitating silver halide by silver nitrate. Iodide content was obtained by subtracting chloride content from the total halide content. For phosphorus estimation, the compound was decomposed with a mixture of sugar, KNO$_3$ and Na$_2$O$_2$ in a Parr–Bomb, extracted with water, acidified with slight excess of dilute sulphuric acid, heated to dryness, extracted again with water, filtered and estimated it as phosphate using ammonium molybdate.

IR spectra were recorded on Perkin–Elmer 297 in the range 4000–600 cm^{-1} and on Polytec FIR 30 spectrophotometer in the range 600–100 cm^{-1}. The UV-visible spectral studies were carried out on Beckman 26 spec-

trophotometer. The ESR spectrum was recorded at liquid nitrogen temperature using Varian E 104 spectrophotometer. The magnetic measurements were made by the Gouy method. Conductivity measurements in nitrobenzene was made on an Elico type CM 82 conductivity bridge. The oxidation state of nickel in the compound was determined iodometrically by the reduction of a known amount of the compound with aqueous potassium iodide solution, followed by titration of the liberated iodine with standard sodium thiosulphate solution.

RESULTS AND DISCUSSION

The compound was characterised by the elemental analyses and the physical studies mentioned above. The compound has the empirical formula [Ni(OPPh$_3$)Cl$_2$I]. The magnetic moment of the complex at room temperature was found to be 1.68 B.M., characteristic of nickel(III) having one unpaired electron. The conductivity measurements in acetonitrile and nitrobenzene solvents did not show any conductance, confirming that all the anions are coordinated to the metal ion.

The presence of triphenylphosphine oxide was confirmed by the infrared studies. A strong band at 1180 cm^{-1} could be assigned to $v_{P=O}$ of the triphenylphosphine oxide molecule[3] coordinated with the metal. After decomposing the complex with water, the liberated ligand was isolated and characterised as triphenylphosphine oxide (m.p. and IR spectrum). The IR spectrum in the region 600–100 cm^{-1} showed the presence of bands at 548, 520, 452, 365, 308 and 225 cm^{-1}. The bands at 548 and 520 cm^{-1} are due to triphenylphosphine oxide. The band at 452 cm^{-1} could be assigned to v_{Ni-O}, at 365 and 308 cm^{-1} to v_{Ni-Cl} (terminal) and at 225 cm^{-1} to v_{Ni-I} (terminal). These assignments are made in accordance with that of isotopically labelled nickel complexes, viz. [Ni(PPh$_3$)$_2$X$_2$] (X = Cl, Br, I).[4]

The ESR spectrum of a powdered sample at liquid nitrogen temperature showed two absorption lines from which the g-values calculated are, $g_\perp = 2.085$ and $g_\parallel = 2.430$. If we choose the z coordinate such that it bisects the ClNiCl angle and x and y coordinates perpendicular to the above, then a possible configuration is $(d_{x^2-y^2})^2 (d_{z^2})^2 (d_{xz})^2 (d_{yz})^\pm$. Following the detailed treatment of d^7 system with the above configuration,[5,6] we can predict $g_{zz} > g_{yy}$, which is observed experimentally too. Due to the lack of the availability of all the d–d-transitions, it is not possible to interpret the ESR data quantitatively, at present. On the basis of the observed g-values, we can make a tentative assignment of 25,000 cm^{-1} ($\epsilon = 70$) band to $d_{x^2-y^2} \rightarrow d_{yz}$ and 16,000 cm^{-1} ($\epsilon = 13$) band to $d_{z^2} \rightarrow d_{yz}$ transitions. Thus, the compound has a tetrahedral geometry with tetragonal distortions.

The complex, on treatment with triphenylphosphine in acetic acid resulted a dark brown crystalline compound with probable composition [Ni(PPh$_3$)$_2$ClI], with nickel in +2 oxidation state. The nickel(III) complex acts as a catalyst in the oxidation of triphenylphosphine to triphenylphosphine oxide. The catalytic oxidation reaction using the complex and triphenylphosphine in varying

---

proportions (up to 1:25) in cyclohexane or nitrobenzene gave quantitative yield of the oxide. The method of reaction and characterization is similar to the one reported earlier.[7] The complex is found to oxidise cyclohexanol to cyclohenanone in pyridine solvent. More studies concerning the oxidising property of the complex are being carried out.

On the nature of the peroxoborate ion in solution

CHRISTOPHER J. ADAMS* and IAN E. CLARK
Unilever Research Laboratory, Port Sunlight, Bebington, Wirral, Merseyside, L63 3JW, England

Abstract—The Raman spectra of alkaline lithium metaborate solutions containing H_2O_2 reveal lines attributable to a peroxoborate anion, $B(OH)_3OOH^-$, in equilibrium with $B(OH)_4^-$ and H_2O_2. There is no evidence for the formation of peroxoboric acids at low pH.

Sodium perborate is in widespread use as a bleaching agent in fabric washing products, but the chemistry of perborates has not been much investigated. There has recently been a determination of the crystal structure of the commercial material "sodium perborate tetrahydrate", showing that it contains dinuclear anions with double peroxo bridges (I),[1] and is therefore better formulated as $Na_2[B_2(O_2)_2(OH)_4].6H_2O$.

(I)

However, the nature of peroxoborate species in solution has remained elusive. Potentiometric titrations[2] and polarographic studies[3] suggest that alkaline perborate solutions display an equilibrium involving a hydroperoxotrihydroxoborate anion (II).

$$B(OH)_4^- + H_2O_2 \rightleftharpoons B(OH)_3(OOH)^- + H_2O$$

(II)

giving $K = \dfrac{[B(OH)_3(OOH)^-]}{[B(OH)_4^-][H_2O_2]}$

as ca. $25 \, mol^{-1} \, dm^3$ at 25°C. Other potentiometric investigations have been interpreted in terms of the formation of higher perborates in alkaline solution containing two or more peroxide groups for each boron atom[4]. In acid solu-

tions, the formation of peroxoboric acids has been postulated to explain the drop in pH when hydrogen peroxide is added to boric acid solutions[2].

We set out to use Raman spectroscopy to identify and characterise the peroxoboron species in aqueous solution and to monitor changes in the position of equilibrium with changes in solution composition. It soon became clear that solution concentrations of about 1 mol dm^{-3} were needed to facilitate the observation of spectra, and so the lithium borate/H_2O_2 system was chosen for investigation.

EXPERIMENTAL

Preparation of materials

Lithium metaborate, $LiB(OH)_4.6H_2O$, and sodium perborate tetrahydrate, $Na_2[B_2(O_2)_2(OH)_4].6H_2O$ were prepared from AnalaR reagents. Hydrogen peroxide, Na_2H_2EDTA, boric acid, and hydrochloric acid (all AR Grade) and lithium hydroxide (GPR) were used without further purification.

Preparation of solutions

The solutions were made up by dissolving lithium metaborate in the required concentration of hydrogen peroxide, and adding HCl or LiOH to adjust the pH. All the solutions contained EDTA (1×10^{-4} mol dm^{-3}) to inhibit the metal-catalysed decomposition of H_2O_2. The pH and H_2O_2 content were checked before and after measurement of spectra.

Raman spectra

The filtered solutions were contained in a quartz cell which had been cleaned with aqua regia. Sodium perborate was finely ground and packed into a glass capillary. The spectra were excited at 5145 Å by an Ar^+ laser and were recorded at room temperature (23 ± 1°C) using a Spex Ramalog 5M spectrometer.

RESULTS AND DISCUSSION

a. Reported as Raman shift in cm^{-1} (Relative Intensity).

spectra are shown in Fig. 1. Our Raman shifts for Na$_2$[B$_2$(O$_2$)$_2$(OH$_4$)].6H$_2$O agree well with an earlier report[5], and so are not given in full detail.

Alkaline solutions

The first set of experiments to be discussed used solutions A–F with lithium metaborate concentrations 1.0 mol dm^{-3} and various pH and [H$_2$O$_2$] values. The Raman spectra show two broad features, at *ca.* 880 and 740 cm^{-1}, but the peak positions and the line shapes change as the solution composition changes. The spectra can be interpreted in terms of the known Raman lines of B(OH)$_4^-$, H$_2$O$_2$, B(OH)$_3$ and OOH$^-$, together with a set of lines (at 1250, 950, 890, 735 and 715 cm^{-1}) which cannot be attributed to any known polyborate[6]. The intensities of the new lines all respond in the same way to changes in solution composition, suggesting that they can all be attributed to a single peroxoborate anion present in the solutions.

Increasing the ratio of peroxide:borate much above 1 : 1 gives only the new set of Raman lines together with H$_2$O$_2$ and we are thus justified in formulating the anion as a monoperoxoborate. The spectrum of the anion in solution, however, is different from that of the solid sodium perborate tetrahydrate and so the centrosymmetric binuclear species (I) cannot be the anion in solution. (The most telling evidence is the absence of a strong polarised line at 960 cm^{-1}, associated in the solid with the *gerade* combination of the B(OH)$_2$ antisymmetric stretches.) By default, then, the spectra must be assigned to the B(OH)$_3$OOH$^-$ anion proposed by potentiometric titration.

The Raman line at 890 cm^{-1} is clearly a fundamental of the O–O stretching mode; the value of 890 cm^{-1} compares with that found for XOOH groups (e.g. 886 cm^{-1} for H$_2$SO$_5$)[7] rather than XOO$^-$ groups (849 cm^{-1} in OOH$^-$). The lines at 735 cm^{-1} and 950 cm^{-1} are respectively the symmetric and antisymmetric stretches of the B(OH)$_3$ unit, while the B–OOH stretch occurs at 715 cm^{-1} (close to the B–F stretch in [B(OH)$_3$F]$^-$)[6]. Finally the weak feature at 1250 cm^{-1} is assignable to the BOOH deformation mode.

The spectra show that peroxoborate formation reaches a maximum at pH *ca.* 10.2 but significant amounts are present between pH 8.5 and 11.1. At higher pH, hydrogen peroxide is removed as OOH$^-$ (solution D), and at lower pH the tetrahydroxoborate anion is converted into boric acid. In all
Fig. 1. Raman spectra of alkaline perborate solutions.

cases the proportion of peroxoborate falls as the concentration falls. A quantitative estimate of the equilibrium constant is impossible because of the overlap of the Raman lines, but the observations are consistent with a value of 20 mol^{-1} dm^3 as suggested by potentiometric titration.

Acid solutions

Solutions of boric acid with H$_2$O$_2$ (both 1 mol dm^{-3}) show only one intense Raman line at 875 cm^{-1}. This sharp line must include contributions from the symmetric BO$_3$ stretch of B(OH)$_3$ and the O–O stretch of H$_2$O$_2$, which

coincide at this frequency. There is thus no evidence for the formation of peroxoboric acids, and some other explanation must be found for the large pH changes noted by Edwards.[2]

SUMMARY

The Raman spectra of lithium metaborate–hydrogen peroxide solutions are consistent with the equilibrium $B(OH)_4^- + H_2O \rightleftharpoons B(OH)_3OOH^- + H_2O$ $(K \simeq 20\,mol^{-1}\,dm^3)$. There is no evidence for the formation of peroxoboric acids at low pH.

Taft substituent constants for arene chromium dicarbonyl phosphine and arsine derivatives

THOMAS E. BITTERWOLF
Department of Chemistry, U.S. Naval Academy, Annapolis, MD 21402, U.S.A.

Abstract—A series of biphenyl, meta- and para-fluorobiphenyl complexes of chromiumtricarbonyl, chromiumdicarbonyltriphenylphosphine and chromiumdicarbonyltriphenylarsine have been prepared and their spectral and physical properties recorded. Taft substituent constants have been calculated for the coordinated arenes and the consequences of substituting a Group V ligand for a carbonyl are discussed.

For organometallic complexes, a comparison of the substituent constants of free and coordinated organic groups provides a quantitative measure of the electronic changes which occur upon complexation. For example, substituent constants for the arenechromiumtricarbonyl group have been measured by several groups using a variety of techniques.[1–6] The values of these substituent constants generally support the interpretation that complexation of a chromiumtricarbonyl to a phenyl group results in a significant increase in the inductive electron withdrawal by the coordinated phenyl and reduction of the resonance electron donation to a fraction of that of an uncoordinated phenyl.

As a consequence of our recent synthesis of a series of biphenylbis(chromiumdicarbonyl)-μ-diphosphine dimers, we have become interested in the changes in electronic character which occur when a carbonyl is removed and replaced by a Group V ligand. In order to determine these effects, we have measured the Taft substituent constants of arenechromiumdicarbonyl derivatives of triphenylphosphine and triphenylarsine.

RESULTS AND DISCUSSION

A set of nine compounds were prepared and examined in the present work. Biphenylchromiumtricarbonyl and its *m*- and *p*-fluorobiphenyl derivatives were prepared by the method of Top and Jaouen[7] and had properties consistent with the physical and spectral properties reported in the literature. Triphenylphosphine and triphenylarsine were introduced to the chromium by UV photolysis in benzene.[8] After recrystallization from petroleum ether, the compounds were examined for purity by HPLC using petroleum ether:tetrahydrofuran (3:2) as an elutant on a silica gel column. Elemental analyses and/or melting points of the compounds are presented in Table 1. UV-visible and IR spectra were recorded for all compounds and the major spectral features are summarized in Table 2. ^1H, ^{19}F and ^{31}P NMR results are also included in Table 2.

σ_I and σ_R^0 constants were calculated from the ^{19}F chemical shifts of *m*- and *p*-fluorobiphenyl derivatives relative to internal fluorobenzene using the equations presented by Taft *et al.*[9] These substituent constants are summarized in Table 3 for both benzene and chloroform as solvents.

Comparison of the UV-visible and IR spectra for compounds 1–3 indicates that for these compounds the electronic and vibrational changes brought about by the phosphine and arsine ligands are very similar. Introduction of a fluorine onto the uncoordinated ring of a biphenyl has little effect on either the electronic or vibrational spectra. ^{31}P NMR of the biphenyl and fluorobiphenylchromiumdicarbonyltriphenylphosphine compounds show only a small shift of the phosphorus resonance with introduction of the fluorine.

Gubin *et al.*[4] obtained Taft substituent constants for the phenylchromiumtricarbonyl group. These workers used a slightly modified form of the Taft equations, but obtained substituent constants in close agreement with those found in the present work. These constants show that coordination of a phenyl ring by a chromiumtricarbonyl enhances the electron withdrawing ability of the phenyl ring and sharply reduces the resonance contribution of the phenyl. The

coincide at this frequency. There is thus no evidence for the formation of peroxoboric acids, and some other explanation must be found for the large pH changes noted by Edwards.[2]

SUMMARY

The Raman spectra of lithium metaborate–hydrogen peroxide solutions are consistent with the equilibrium $B(OH)_4^- + H_2O \rightleftharpoons B(OH)_3OOH^- + H_2O$ $(K \simeq 20 \, mol^{-1} \, dm^3)$. There is no evidence for the formation of peroxoboric acids at low pH.

Taft substituent constants for arene chromium dicarbonyl phosphine and arsine derivatives

THOMAS E. BITTERWOLF
Department of Chemistry, U.S. Naval Academy, Annapolis, MD 21402, U.S.A.

Abstract—A series of biphenyl, meta- and para-fluorobiphenyl complexes of chromiumtricarbonyl, chromiumdicarbonyltriphenylphosphine and chromiumdicarbonyltriphenylarsine have been prepared and their spectral and physical properties recorded. Taft substituent constants have been calculated for the coordinated arenes and the consequences of substituting a Group V ligand for a carbonyl are discussed.

For organometallic complexes, a comparison of the substituent constants of free and coordinated organic groups provides a quantitative measure of the electronic changes which occur upon complexation. For example, substituent constants for the arenechromiumtricarbonyl group have been measured by several groups using a variety of techniques.[1–6] The values of these substituent constants generally support the interpretation that complexation of a chromiumtricarbonyl to a phenyl group results in a significant increase in the inductive electron withdrawal by the coordinated phenyl and reduction of the resonance electron donation to a fraction of that of an uncoordinated phenyl.

As a consequence of our recent synthesis of a series of biphenylbis(chromiumdicarbonyl)-μ-diphosphine dimers, we have become interested in the changes in electronic character which occur when a carbonyl is removed and replaced by a Group V ligand. In order to determine these effects, we have measured the Taft substituent constants of arenechromiumdicarbonyl derivatives of triphenylphosphine and triphenylarsine.

RESULTS AND DISCUSSION

A set of nine compounds were prepared and examined in the present work. Biphenylchromiumtricarbonyl and its *m*- and *p*-fluorobiphenyl derivatives were prepared by the method of Top and Jaouen[7] and had properties consistent with the physical and spectral properties reported in the literature. Triphenylphosphine and triphenylarsine were introduced to the chromium by UV photolysis in benzene.[8] After recrystallization from petroleum ether, the com-

pounds were examined for purity by HPLC using petroleum ether:tetrahydrofuran (3:2) as an elutant on a silica gel column. Elemental analyses and/or melting points of the compounds are presented in Table 1. UV-visible and IR spectra were recorded for all compounds and the major spectral features are summarized in Table 2. ^{1}H, ^{19}F and ^{31}P NMR results are also included in Table 2.

σ_I and σ_R^0 constants were calculated from the ^{19}F chemical shifts of *m*- and *p*-fluorobiphenyl derivatives relative to internal fluorobenzene using the equations presented by Taft *et al.*[9] These substituent constants are summarized in Table 3 for both benzene and chloroform as solvents.

Comparison of the UV-visible and IR spectra for compounds 1–3 indicates that for these compounds the electronic and vibrational changes brought about by the phosphine and arsine ligands are very similar. Introduction of a fluorine onto the uncoordinated ring of a biphenyl has little effect on either the electronic or vibrational spectra. ^{31}P NMR of the biphenyl and fluorobiphenylchromiumdicarbonyltriphenylphosphine compounds show only a small shift of the phosphorus resonance with introduction of the fluorine.

Gubin *et al.*[4] obtained Taft substituent constants for the phenylchromiumtricarbonyl group. These workers used a slightly modified form of the Taft equations, but obtained substituent constants in close agreement with those found in the present work. These constants show that coordination of a phenyl ring by a chromiumtricarbonyl enhances the electron withdrawing ability of the phenyl ring and sharply reduces the resonance contribution of the phenyl. present work demonstrates that substitution of either a triphenylphosphine or triphenylarsine for a carbonyl reverses both the inductive and resonance changes brought about by coordination. The inductive electron donating abilities of the phosphine and arsine substituted compounds are actually greater than that of the uncoordinated phenyl ring, and the resonance contribution of these compounds is intermediate between that of the chromiumtricarbonyl compound and the free arene.

Substituent constants calculated for the chromium compounds in both benzene and chloroform are presented in Table 3. Resonance constants for the two solvents were identical within experimental error, but the inductive electron withdrawal is increased in chloroform relative to its value in benzene. We suggest that the increased electron withdrawal in chloroform results from interaction of the strongly polar solvent with the electron rich chromium center.

Kursanov et al.[10] have recently reported on the reactivity of coordinated diarenes towards electrophilic hydrogen exchange. They found that the hydrogen exchange rate of biphenylchromiumtricarbonyl was an order of magnitude slower than that of biphenyl, but that biphenylchromiumdicarbonyltriphenylphosphine was an order of magnitude faster than that of the uncoordinated biphenyl. For the case of biphenylchromiumtricarbonyl, it

is inferred from the data that most of the hydrogen exchange occurs on the uncoordinated ring, while the data clearly show that hydrogen exchange occurs equally on the two rings of the triphenylphosphine substituted compound. The increased reactivity of the coordinated biphenyl to electrophilic hydrogen exchange when carbonyl is replaced by triphenylphosphine is entirely consistent with the changes in the substituent constant found in the present work.

EXPERIMENTAL

UV-visible spectra were recorded on a Cary 15 Spectrometer. IR spectra were recorded on a Perkin–Elmer 467 Grating Spectrometer. NMR spectra were recorded on a Varian FT-80 NMR Spectrometer. Analyses were conducted by Micro-Analysis, Inc. of Wilmington, DE.

COMMUNICATION

On the mechanism of the chromium(III)-periodate reaction

YOUSIF SULFAB

Department of Chemistry, University of Kuwait, Kuwait

We have previously reported an unusual second-order dependence on the concentration of aqua chromium(III) ion in its reaction with periodate in aqueous acidic solution.[1] The activated complex is believed to contain two chromium(III) species and one periodate ion. Simultaneous two one-electron transfer from the two chromium(III) species to iodine(VII), which is rate determining, is attained. The mechanism of this reaction was described by eqns (1)-(6)

$$H_4IO_6^- + H^+ \rightleftharpoons H_5IO_6 \quad (K_1) \quad (1)$$

$$Cr^{3+} + H_2O \rightleftharpoons CrOH^{2+} + H^+ \quad (K_h) \quad (2)$$

$$CrOH^{2+} + H_4IO_6^- \rightleftharpoons [Cr-(OH)-IO_5H_2]^+ + H_2O \quad (K_2) \quad (3)$$

$$[Cr-(OH)-IO_5H_2]^+ Cr^{3+} \rightleftharpoons$$
$$[Cr-(OH)-IO_4H-(OH)-Cr]^{4+} + H_2O \quad (K_3) \quad (4)$$

$$[Cr-(OH)-IO_4H-(OH)-Cr]^{4+} \rightarrow 2Cr(IV) + IO_3^- \quad \text{(slow)} \quad (5)$$

$$Cr(IV) + I(VII) \rightarrow Cr(VI) + IO_3^- \quad \text{(fast)}. \quad (6)$$
An alternative mechanism which also accounts for the second-order dependence on chromium(III) ion concentration was suggested.[2] This mechanism is described by eqns (7)-(9).

$$Cr(III) + I(VII) \rightleftharpoons Cr(V) + I(V) \quad k_1, k_{-1} \quad (7)$$

$$Cr(III) + Cr(V) \rightarrow 2Cr(IV) \quad k_2 \quad \text{(slow)} \quad (8)$$

$$Cr(IV) + I(VII) \rightarrow Cr(VI) + IO_3^- \quad \text{(fast)}. \quad (9)$$
Applying the steady state approximation for Cr(V) the rate law given in eqn (10) is obtained.

$$-d[Cr(III)]/dt = \frac{k_1 k_2 [Cr(III)]^2 [I(VII)]}{k_2 [Cr(III)] + k_{-1} [IO_3^-]}. \quad (10)$$

In this mechanism step (7) is postulated as a reversible reaction with the equilibrium lying on the left side. Step (8) is considered the rate-determining reaction with step (9) following rapidly.

Table 1. Effect of addition of iodate on the chromium(III)-periodate reaction[†]

$10^2[IO_3^-]$M	k_2M^{-1}s^{-1}	$10^{-2}k_3$, M^{-2}s^{-1}
0.50	2.56 ± 0.02	2.56 ± 0.02
1.00	2.36 ± 0.02	2.36 ± 0.02
1.50	2.42 ± 0.03	2.42 ± 0.03
3.50	2.63 ± 0.04	2.63 ± 0.04

[†][IO_3^-] = 1.0×10^{-2} M, [Cr(III)] = 4.43×10^{-4} M, pH = 2.05 ± 0.01, Ionic strength $I = 0.50$ M and $T = 25.0 \pm 0.1°C$.

If $k_{-1}[IO_3^-] \gg k_2[Cr(III)]$ eqn (10) reduces to the form of eqn (11) which predicts retardation of the reaction rate by the deliberate addition of IO_3^-.

$$-d[Cr(III)]/dt = \frac{k_1 k_2 [Cr(III)]^2 [I(VII)]}{k_{-1}[IO_3^-]}. \quad (11)$$

The effect of addition of iodate on the reaction rate was investigated over the iodate concentration range $(0.50-3.5) \times 10^{-2}$ M at fixed reaction conditions. The results in Table 1 show that the initial addition of varying concentrations of iodate did not lead to any retardation of the reaction rate as indicated by the constancy of k_3. These results clearly indicate that iodate does not supress the rate of oxidation of aqua chromium(III) by periodate, and the alternative mechanism does not seem to operate. The mechanism in which two one-electron transfer, from two chromium(III) species, in a single activated state, seems to operate.

METAL–METAL BONDS AND METAL–CARBON BONDS IN THE CHEMISTRY OF MOLYBDENUM AND TUNGSTEN ALKOXIDES

MALCOLM H. CHISHOLM
Department of Chemistry, Indiana University, Bloomington, IN 47405, U.S.A.

CONTENTS

I. INTRODUCTION

Simple binary alkoxides of formula $M(OR)_n$ are known for most electro-positive metals and the majority of the transition elements and lanthanides. Mixed metal alkoxides are known for a variety of metals and some of these have quite remarkable properties. For example, the lanthanide elements and aluminum form an extensive series of isopropoxides of formula $MAl_3(OPr^i)_{12}$ which are volatile solids or liquids.

A characteristic feature of an alkoxy ligand is its ability to readily form bridges between two or even three metal atoms. Such oligomerization proceeds in order to satisfy the metal atom's desire to attain a preferred coordination geometry. Oligomerization may be suppressed by the use of sterically bulky alkoxy ligands and, in this way, unusual coordination numbers and geometries may be imposed. Many examples could be used to illustrate these simple concepts. I shall mention but a few.

(1) Alkoxides of niobium and tantalum in the +5 oxidation state exist as dimers when the alkoxy group is not too sterically demanding, e.g. MeO and EtO, as shown in **I** below. However, with bulky alkoxides, such as Bu^tO, monomeric five coordination is imposed.

(2) The ethoxides and methoxides of titanium (+4) adopt a tetrameric structure in the solid state, **II**, whereby each metal atom achieves an octahedral environment. In benzene solution, the titanium ethoxide dissociates to trimers, while with the bulky Bu^tO ligand, a monomeric $Ti(OBu^t)_4$ is found.

I

II

X = OMe, OEt
(3) Aluminium-tert-butoxide is a dimer, **III**, while the isopropoxide is a trimer when freshly distilled and a tetramer in the solid state, and when aged in solution, **IV**. Chromium(III), which is a similar size to aluminium(III), has a greater propensity for forming octahedral complexes because of the crystal field stabilization energy arising from the t_{2g}^3 orbital configuration in an O_h field. Cr(III) forms a non-volatile, non-hydrocarbon soluble isopropoxide $[Cr(OPr^i)_3]_n$ and based upon electronic spectral and magnetic properties, it is formulated as having a polymeric $Cr(3+)O_6$ lattice structure.

III

IV

X = OPr^i
It should also be emphasized that alkoxide ligands may act as π-donor ligands, RO⇒M. This capability will have maximum effect for terminal alkoxy ligands and for transition metals in high oxidation states with vacant d orbitals of appropriate symmetry to receive π-electrons.

Metal alkoxides are in general a highly reactive group of complexes. The metal atoms are commonly susceptible to nucleophilic attack and the oxygen atoms are susceptible to electrophilic attack. Common reactions involving substrates with acidic hydrogens include hydrolysis with water, alcohol exchange with other alcohols or silanols, substitution reactions with organic acids or acid anhydrides, acyl halides, β-diketones, β-keto-esters, β-ketoamines and Schiff bases. Insertion reactions may also occur with unsaturated molecules such as CO_2, CS_2 and ArNCO.

The preparations, physico–chemical properties and chemical reactions of metal alkoxides have been extensively reviewed within the past few years.[1,2] The scope of this report is confined to the alkoxide chemistry of molybdenum and tungsten. Except in the oxidation state +6, where the metal atoms have no valence d electrons, the alkoxide chemistry of these elements is markedly different from that anticipated by Bradley's early theories for metal alkoxide polymers.[3,4] In all the lower oxidation states, the d^n valence electrons on the metal atoms are used to form metal–metal bonds which may be localized single or multiple bonds or delocalized into cluster bonding molecular orbitals. The formation of metal–metal bonds may modify or totally change the structural ground state of a molecule from that anticipated for a d^0 metal complex. Furthermore, metal–metal bonds provide a reservoir for electrons which may be "tapped" for oxidative-addition reactions or "filled" in reductive–elimination reactions.

One other area of chemistry that is emphasized concerns the use of alkoxy ligands in organometallic chemistry. Alkoxy ligands, which are strong π-donors and may readily interchange bonding modes between terminal and bridging (μ_2 and μ_3), are clearly very different from the now "classical" ligands in organometallic chemistry, such as tertiary phosphines, carbonyl, cyclopentadienes and olefins, all of which are soft and π-acceptors. We see a new facet of organometallic chemistry emerging in the area of early transition metal organoalkoxide chemistry.

II. CLASSES OF COMPOUNDS

1. d^3–d^3 dimers with M–M triple bonds

The addition of alcohols to hydrocarbon solutions of $Mo_2(NMe_2)_6$[5] leads to an extensive series of dinuclear alkoxides $Mo_2(OR)_6$, where $R = Bu^t$, Pr^i, CH_2Bu^t, $CH(Me)Ph$, $SiMe_3$ and SiE_3.[6] Polymeric compounds $[Mo(OR)_3]_n$ are obtained for sterically unencumbered alkoxy ligands such as OEt and OMe, but little is yet known about these compounds. The dinuclear alkoxides, $Mo_2(OR)_6$ are yellow–orange, hydrocarbon soluble, crystalline compounds. They sublime *in vacuo* in the temperature range 70–120°C at 10^{-4} Torr. In the mass spectrometer, they yield strong molecular ions, together with an extensive series of Mo_2-containing ions. They are diamagnetic and show only one type of alkoxy or trialkylsiloxy group in their ^1H and ^{13}C NMR spectra, independent of temperature. Only one compound, the neopentoxide, has been fully characterized by a single crystal X-ray study and its molecular structure is shown in Fig. 1. There is an unbridged Mo–Mo triple bond of distance 2.22 Å and the central Mo_2O_6 skeleton has virtual D_{3d} symmetry. There can be little, if any, doubt that the other alkoxides of formula $Mo_2(OR)_6$ adopt similar structures and, as such, are members of an extensive series of compounds containing M–M triple bonds (M = Mo, W) between tri-ligated metal atoms.[7]

Rather interestingly, alcoholysis reactions involving $W_2(NMe_2)_6$[8] do not lead to an extensive series of compounds of formula $W_2(OR)_6$.[9] Only $W_2(OBu^t)_6$ has been isolated, though amine adducts $W_2(OR)_6(HNMe_2)_2$ have been obtained for $R = Pr^i$ and CH_2Bu^t.[10] Tungsten appears to differ from molybdenum in three important respects with regard to the formation and stability of $M_2(OR)_6$ compounds. (1) Tungsten binds Lewis bases more tightly for a given alkoxy group, e.g. as in the isolation of $W_2(OR)_6(HNMe_2)_2$ noted above. (2) Tungsten is more readily oxidized to W(4+) alkoxides. Both of these points will be elaborated upon further in this article. (3) Whereas $Mo_2(OR)_6$ compounds readily sublime when heated *in vacuo*, $W_2(OBu^t)_6$ and the amine adducts $W_2(OR)_6(HNMe_2)_2$, where $R = SiMe_3$, Pr^i and CH_2Bu^t, decompose when heated *in vacuo* above 80°C.[9] In the mass spectrometer, however, $W_2(OR)_6{}^+$ ions are observed.[9]

Some mixed amido– or alkyl–alkoxy compounds containing M≡M bonds have been prepared. For example, treatment of $1,2$-$Mo_2X_2Y_4$ (M≡M), where X = Br and Y = CH_2SiMe_3 or X = Cl and Y = NMe_2, with LiOR (2 equivalents) yields compounds of formula $1,2$-$Mo_2(OR)_2Y_4$ where $R = Bu^t$ and Pr^i. The molecular structure of $1,2$-$Mo_2(OBu^t)_2(CH_2SiMe_3)_4$ deduced from a single crystal X-ray study reveals the *anti*-conformation[11] (see Fig. 2). Rather interestingly, the $1,1$-isomer, $(Bu^tO)_2(Me_3SiCH_2)Mo≡Mo(CH_2SiMe_3)_3$, is obtained from the addition of Bu^tOH to $1,1$-$Mo_2(NMe_2)_2(CH_2SiMe_3)_4$.[11]

Alcoholysis reactions involving $1,2$-$Mo_2R_2(NMe_2)_4$ proceed *via* elimination of $HNMe_2$ to give $1,2$-$Mo_2R_2(OR')_4$ compounds [R = Me, R' = Bu^t; R = CH_2SiMe_3, CH_2CMe_3 and R' = Bu^t, Pr^i, CH_2CMe_3 and Et], but when R contains β-hydrogens, elimination of one equivalent of alkane results in $Mo_2R(OR')_5$ compounds [R = Et and Pr; R' = Bu^t and Pr^i]. The mechanistic aspects of these reactions are discussed later.
Fig. 1. An ORTEP view of the centrosymmetric $Mo_2(OCH_2Bu^t)_6$ molecule. Pertinent distances (Å) and angles (°) are: Mo–Mo = 2.222(2); Mo–O(1), –O(2), –O(3) = 1.905(6), 1.867(6), 1.855(6); Mo′–Mo–O(1), –O(2), –O(3) = 98.3(2), 105.5(2), 105.4(2).
Fig. 2. An ORTEP view of the centrosymmetric $1,2\text{-}Mo_2(OBu^t)_2(CH_2SiMe_3)_4$ molecule. Pertinent distances (Å) and angles (°) are: Mo(1)–Mo(1)′ = 2.209(2); Mo(1)–O(2), –C(7), –C(12) = 1.865(8), 2.13(1), 2.14(1); Mo(1)′–Mo(1)–O(2), –C(7), –C(12) = 110.7(2), 100.0(3), 100.2(4).

The most striking feature of the aforementioned compounds of formula $M_2(OR)_6$ and $M_2X_n(OR)_{6-n}$ is the presence of the M–M triple bond, unsupported by bridging alkoxide ligands. Evidently the bridged $Al_2(OR)_6$ structure, **III**, is considerably higher in energy since compounds of formula $X_2YM\equiv MY_3$ and $XY_2M\equiv MXY_2$ do not readily isomerize in hydrocarbon solvents, even at $+100°C$.[11]

From calorimetric studies, it has been estimated that the formation of a pair of bridging OR ligands from two terminal OR ligands, $2Mo–OR\rightarrow Mo_2(\mu–OR)_2$, is favoured by $10–15\,kcal\,mol^{-1}$.[12] That bridges are not seen in these compounds, and that isomerizations which would be possible if bridged intermediates were energetically accessible, imply that the energy difference between $(RO)_3Mo\equiv Mo(OR)_3$ and $(RO)_2Mo(\mu–OR)_2Mo(OR)_2$ must be quite large and at least greater than $ca.\ 30\,kcal\,mol^{-1}$. This in turn must reflect upon the relative strengths of Mo–Mo bonds in the bridged and non-bridged structures.

The strength of $D(Mo\equiv Mo)$ in $Mo_2(OPr^i)_6$ has been estimated to be $90\,kcal\,mol^{-1}$ from calorimetric studies wherein the heat of formation of $Mo_2(OPr^i)_6$ is determined.[12] However, it is impossible to separate $D(Mo–OR)$ and $D(Mo\equiv Mo)$ in such calculations and thus an error in the assumption of $D(Mo–OR)$ is magnified six-fold in $D(Mo\equiv Mo)$. Since $D(Mo–OR)$ can be determined for a large number of mononuclear compounds, a reasonable estimate of $D(Mo–OR)$ in $Mo_2(OR)_6$ compounds can be obtained to $\pm 5\,kcal\,mol^{-1}$. The strength of the $Mo\equiv Mo$ bond may therefore be determined to lie within the range $60–120\,kcal\,mol^{-1}$, and so a value of $90–100\,kcal\,mol^{-1}$ seems most plausible.

A simple bonding picture for $M_2(OR)_6$ compounds can be constructed as follows. Letting the z axis be coincident with the M–M axis, the metal atomic d_{z^2} orbitals may interact to form σ and σ^* M–M molecular orbitals and d_{xz} and d_{yz} may form π and π^* orbitals. In oxidation state $+3$, each metal has the d^3 configuration and thus a M–M triple bond of configuration $\sigma^2\pi^4$ can be formed. Each metal may use s, p_x and p_y atomic orbitals to form three σ bonds with the OR ligands, and metal d_{xy}, $d_{x^2-y^2}$ and p_z atomic orbitals have the appropriate symmetry to form π-bonds with oxygen filled p atomic orbitals. It is clear from considerations of the short Mo–OR bond distances that there is considerable multiple bond character. (See also Part 7, this section).

This qualitative bonding scheme finds support from detailed calculations employing the SCF X_α–SW technique on $Mo_2(OH)_6$.[13] The orbital energies so calculated correlate well with the data obtained from He(I) and He(II) photoelectron spectroscopic studies. For $Mo_2(OCH_2Bu^t)_6$, the first ionization occurs at $ca.\ 7.2\,eV$ and the second at $8.0\,eV$, corresponding to ionizations from M–M π and σ bonding orbitals, respectively.

The electronic absorption spectra of $M_2(OR)_6$ compounds have recently been examined[14]. There are no absorption maxima in the visible region of the spectra: the colours (yellow or orange) are derived from higher energy absorptions tailing into the visible. The first absorption maximum, v_1, occurs at $360\,nm$ ($\epsilon\ ca.\ 1400$) for $Mo_2(POr^i)_6$ and can be assigned to a M–M π-to-M–Lπ^* transition (M–M π-to-M–M δ). The second absorption maximum, v_2, occurs at $210.5\,nm$ ($\epsilon\ ca.\ 22,400$) and is assigned to the M–M π-to-π^* transition. The spectrum of $W_2(OBu^t)_6$ is very similar with v_1 at $380\,nm$ ($\epsilon\ ca.\ 1600$) and v_2 at $210\,nm$ ($\epsilon\ ca.\ 13,000$). The spectrum of $W_2(OBu^t)_6$ also shows quite pronounced shoulders to low energy of these absorption maxima which can be assigned to the spin forbidden transitions to triplet states: $v_1' = 460\,nm$ ($\epsilon\ ca.\ 500$) and $v_2' = 250\,nm$ ($\epsilon\ ca.\ 6800$). The electronic absorption spectra of $Mo_2(OPr^i)_6$ and $W_2(OBu^t)_6$ are compared in Fig. 3.

2. d^2–d^2 dimers with M–M double bonds

The addition of alcohols to $Mo(NMe_2)_4$ leads to an extensive series of compounds of formula $[Mo(OR)_4]_n$.[15] The bulky tert-butoxide appears to be monomeric in benzene, but its structure is not known in the solid state. It is weakly paramagnetic, which contrasts with the diamagnetic monomeric four-coordinate compounds, MoX_4, where $X = NMe_2$[16] and SBu^t.[17] $Mo(OBu^t)_4$ is clearly a molecule worthy of further attention. The isopropoxide is dimeric and diamagnetic in hydrocarbon solutions, but in the presence of pyridine, a paramagnetic species, believed to be $Mo(OPr^i)_4(py)_2$ akin to $Mo(OSiMe_3)_4(HNMe_2)_2$,[15] is formed. In the solid state, an interesting dimeric structure is found.[18] Each molybdenum atom is in a distorted trigonal bipyramidal geometry. The two halves of the molecule share a common axial equatorial edge through the agency of alkoxy bridges as shown schematically in **V** below.

An ORTEP view of this molecule is shown in Fig. 4. The Mo–O distances show the expected

V

O = OPr^i
Fig. 3. Comparison of the electronic absorption spectra of Mo$_2$(OPr^i)$_6$ and W$_2$(OBu^t)$_6$ in hexane solutions.
Fig. 4. An ORTEP view of the centrosymmetric Mo$_2$(OPr^i)$_8$ molecule. Pertinent distances are given in comparison with the Mo$_2$(OPr^i)$_6$(NO)$_2$ molecule in Fig. 18.

and general trend that terminal M–O distances are shorter than bridging ones, but we also find that the axial bonds are longer than the equatorial bonds within each set of terminal and bridging ligands. This also turns out to be a general trend in what is now quite an extensive series of dimeric molybdenum compounds whose structures are based on fused trigonal bipyramids.

The diamagnetism and the shortness of the Mo–Mo distance, 2.523(1) Å, are readily rationalized by the presence of an Mo–Mo double bond. This may be formulated in the following manner. Let the z axis be coincident with the axial O–Mo–O groups of each metal. Then the formation of five σ bonds to oxygen may use s, p_x, p_y, p_z and d_{z^2} atomic orbitals. This leaves two doubly degenerate d orbitals (d_{xz}, d_{yz}) and ($d_{x^2-y^2}$, d_{xy}) with the former lying lower in energy in a simple trigonal bipyramidal field. If we then choose the y axis to be coincident with the Mo–O (equatorial) bridging ligands, then the d_{yz} atomic orbitals can form M–M σ and σ^* orbitals; the d_{xz}–d_{xz} interaction will yield π and π^* orbitals. This simple picture predicts a M–M bonding configuration $\sigma^2\pi^2$ for a d^2–d^2 dimer. Note the degeneracy of the M–M π bonds, which is present in $X_3M\equiv MX_3$ compounds, is removed for a dimer of type V.

The M–M distances in the molecules $Mo_2(OPr^i)_8$ and $Mo_2(OPr^i)_6(NO)_2$ make an interesting comparison. The latter compound adopts a structure similar to that shown in V in which two axial OR groups are replaced by linear Mo–N–O groups.[19] If for the purposes of electron counting we use the formalism that a linear M–N–O group is equivalent to $M^-\leftarrow(NO^+)$, then the formal oxidation state of molybdenum is $+2$ in $Mo_2(OPr^i)_6(NO)_2$, resulting in a d^4–d^4 dimer. In terms of M–M bonding, this would lead to a totally non-bonding configuration $\sigma^2\pi^2\pi^{2*}\sigma^{*2}$ and the Mo-to-Mo distance, 3.335(2) Å, precludes an M–M bond. In fact, the d^4 electrons on each molybdenum reside in the (d_{xz}, d_{yz}) orbitals and are extensively used in backbonding to the NO π^* orbitals, as evidenced by the low $v(N-O)$ value, 1640 cm^{-1}.

Other alkoxides of Mo(4+) derived from alcoholysis reactions involving $Mo(NMe_2)_4$ are less well characterized. With decreasing size of the alkoxide ligand, there is a tendency to associate further in solution. For example, a cryoscopic molecular determination on the ethoxide gave a value close to that expected for a trimer, $[Mo(OEt)_4]_3$. In view of the tetranuclear structure of the tungsten analogue (discussed later), further studies of these $[Mo(OR)_4]_n$ compounds should be undertaken.

Dinuclear tungsten(IV) alkoxides of formula $W_2(OR)_8$ are presently not known. However, it seems that routes to such compounds should be forthcoming, even though $W(NMe_2)_4$ is not a known compound. For example, oxidative-addition reactions involving RO–OR and $W_2(OR)_6$ compounds might prove effective. The only simple d^2–d^2 dinuclear tungsten alkoxides are the green compounds of formula $W_2Cl_4(OR)_4(HOR)_2$.[20] These were first prepared by Wentworth and Clark from the reactions of $[Bu_4N]_3W_2Cl_9$ with alcohols and were incorrectly formulated as tungsten(III) compounds. $W_2Cl_4(OR)_2(HOR)_4$.[21] Later work, however, showed that these compounds could be prepared by a variety of routes including alcoholysis of WCl_4 and that they were in fact tungsten(IV) dimers.[22] The structure of $W_2Cl_4(OEt)_4(HOEt)_2$ was determined by a single crystal study and revealed the edge-shared octahedral geometry shown in VI.[20]

VI
The fusing of two octahedral units along a common edge allows the metal t_{2g} atomic orbitals to interact to form one σ, one π and one δ bonding and anti-bonding set of molecular orbitals. The d^2–d^2 dimer thus provides a double bond of configuration $\sigma^2\pi^2$, which is compatible with the W–W distance of 2.479(1) Å.

There are a number of other dinuclear alkoxides of molybdenum and tungsten which are formed by addition reactions involving $M_2(OR)_6$ compounds that can be considered to have M–M double bonds. These are discussed later.

3. d^1–d^1 dimers with M–M single bonds

The only homoleptic M(5+) compound that is known for molybdenum and tungsten is $W(OPh)_5$, formed by the reduction of $W(OPh)_6$ with molecular hydrogen and Raney nickel.[23] In solution, a molecular weight determination yielded a value greater than a monomer, but less than a dimer. In view of the structural characterization of $M_2Cl_4(OR)_6$ compounds, it is possible that the phenoxide has an edge-shared W_2O_{10} moiety.

There are a number of reports in the early literature concerning compounds of empirical formula $WCl_2(OR)_3$ formed from reactions of WCl_6 with alcohols and under electrolysis. It is not clear that the early workers were correct in their formulations since various colours and magnetic properties were attributed to these compounds. However, more recently Cotton and Walton[24] have prepared an extensive series of $W_2Cl_4(OR)_6$ compounds by the oxidation of $W_2Cl_4(OR)_4(HOR)_2$ compounds using molecular oxygen or Ag^+ as oxidants.[24] Addition of halogens to $Mo_2(OPr^i)_6$ leads to $Mo_2X_4(OPr^i)_6$ compounds, where X = Cl, Br and I.[25] All of these compounds are orange crystalline solids. They are diamagnetic and show two types of OR ligands, consistent with the maintenance in solution of the structure found in the solid state, depicted by VII, for $Mo_2(OPr^i)_6X_4$ where X = Cl and Br[25] and for $W_2(OEt)_6Cl_4$.[24]
In all of the structurally characterized compounds of formula $M_2Cl_4(OR)_6$, the M–M distance is close to 2.71 Å, which is roughly 0.8 Å less than that of a M–M non-bonding distance found for the d^0–d^0 compound $[Nb(OMe)_5]_2$.[26]

A compilation of bond distances and assigned bond orders for a number of simple dinuclear alkoxides and their adducts or derivatives is given in Table 1. A fairly consistent picture emerges. Triple bonds of configuration $\sigma^2\pi^4$ have distances in the range 2.2–2.3 Å; double bonds, $\sigma^2\pi^2$, are all close to 2.5 Å; single bonds, σ^2, are close to 2.7 Å, while non-bonding distances for $M_2(\mu\text{–}OR)_2$-containing compounds are all greater than 3 Å, typically in the range 3.3–3.5 Å.

4. Trinuclear alkoxides

Since some of the alkoxides of molybdenum(IV) appear trimeric in solution, it is interesting to speculate that triangulo Mo_3 structures might be found for certain $[Mo(OR)_4]_n$ compounds. The six metal valence electrons not used in M–OR bonding could be used to form M–M bonds: $a^2 + e^4$. This situation is seen for $Mo_3O(OR)_{10}$ compounds, where R = Pr^i and CH_2Bu^t.[27] An ORTEP view of the central skeleton of the $Mo_3O(OCH_2Bu^t)_{10}$ molecule is shown in Fig. 5. The structure is closely related to a large group of triangulo Mo_3- and W_3-containing complexes with capping (μ_3-) oxo, sulphido and carbyne ligands.[28] In solution, the ^1H NMR spectra indicate that the solid state structure is maintained. Four types of alkoxy ligands are seen in the integral ratio 3:3:3:1, indicating that the molecule is not fluxional on the NMR time-scale.

5. Tetranuclear alkoxides

Addition of ethanol or methanol to hydrocarbon solutions of $W_2(NMe_2)_6$ yields the tetranuclear alkoxides $W_4(OR)_{16}$.[29,30] The structure of the ethoxide has been determined by an X-ray study and is shown in Fig. 6. The structure is of type II which is found for $[Ti(OR)_4]_4$ compounds where R = Me and Et,[31] but the W——W distances are all shorter than the analogous Ti——Ti

Table 1. Metal–metal distances and metal–metal bond orders in representative dinuclear alkoxides of molybdenum and tungsten

Compound	Bridging Ligands	M–M Distance ($\mathring{A}$)	Bond Order	Ref

^{a}A.J. Nielson and J.M. Waters, Polyhedron 1982, 1, 561.

distances. Evidently in $W_4(OEt)_{16}$, the eight tungsten valence electrons are used to form delocalized M–M bonds.

The central centrosymmetric M_4X_{16} unit formed by four fused octahedral units appears quite common in coordination compounds and in ternary metal oxides. A mixed oxo-alkoxy–pyridine compound, $Mo_4(\mu_3$-$O)_2(\mu_2$-$O)_2(O)_4(\mu_2$-$OPr^i)_2(OPr^i)_2(py)_4$, has been structurally characterized.[30] $Ag_8W_4O_{16}$[32] and $Ba_{1.14}Mo_8O_{16}$[33] also have M_4O_{16} subunits. The molybdenum oxide contains two types of M_4 units differing most significantly in the M–M distances. This difference can be correlated with the number of bonding cluster electrons: 8 vs 10. The M_4X_{16} framework has been found to accommodate 0, 4, 8 and 10 cluster bonding electrons. The changes in M–M distances as a function of the number of cluster electrons are summarized in Table 2. It is clear that molybdenum and tungsten use their d^n electrons to form M–M bonds. The nature of the M–M bonding in the 8 and 10 electron clusters has recently been the subject of a Fenske–Hall calculation by Cotton and Fang.[34] They rationalized the elongation of two M——M distances, which accompanies the change from the 10 electron to the 8 electron cluster, in terms of a second order Jahn–Teller distortion.

Aside from the solid state structural parameters, the presence of M–M cluster bonding electrons drastically alters the solution behaviour of $M_4(OR)_{16}$ compounds. Whereas $[Ti(OEt)_4]_4$ dissociates in benzene solution to trimers, the tungsten compound retains its tetranuclear nature as evidenced
Fig. 5. An ORTEP view of the central $Mo_3O(OC)_{10}$ skeleton of the $Mo_3O(OCH_2Bu^t)_{10}$ molecule. All atoms are assigned arbitrary thermal parameters. Each molybdenum atom is in a distorted octahedral environment with respect to six directly bonded oxygen atoms. Pertinent bond distances in Å (averaged) are: Mo–Mo = 2.529(9), Mo–μ_3O(oxo) = 2.03(3), Mo–μ_3OR = 2.21(3), Mo–μ_2OR = 2.02(3), Mo–OR (terminal) *trans* to O(4) = 1.94(2), Mo–OR (terminal) *trans* to μ_3OR = 1.85(3).
Fig. 6. An ORTEP view of the centrosymmetric $W_4(OEt)_{16}$ molecule emphasizing the local WO_6 octahedral geometry for each tungsten atom. Pertinent W–W and W–O distances are given in Tables 2 and 3, respectively.

Table 2. M–M distances (Å) found in compounds which are structurally related to $W_4(OEt)_{16}$[a]

Compound	M(2)–M(1)'	M(1)–M(2)	M(1)–M(1)'	Number of M_4 Cluster Electrons	Ref.
$[Ti(OEt)_4]_4$	3.34	3.50	3.42	0	31
$Ag_8W_4O_{16}$	3.32	3.23	3.49	0	32
$Mo_4O_8(OPr^i)_4(py)_4$	3.47	2.60	3.22	4	30
$Mo_4Cl_4O_6(OPr^n)_6$	3.43	2.67	not given	4	b
$W_4(OEt)_{16}$	2.65	2.94	2.76	8	30
$Ba_{1.14}Mo_8O_{16}$	2.54	2.84	2.56	8	33
$Ba_{1.14}Mo_8O_{16}$	2.61	2.57	2.58	10	33

(a) Distances are quoted to ±0.01 Å; the labelling scheme for M(1), M(2) and M(1)' is shown below and is such that M(1) and M(2) have, respectively, two and three terminal groups. (b) S.A. Koch and S. Lincoln, *Inorg. Chem.* 1982, **21**, 2904.
by cryoscopic molecular weight determinations. Also, the ^{1}H NMR spectrum of $W_4(OMe)_{16}$ shows eight sharp resonances of equal intensity, which is exactly what is predicted by a consideration of the centrosymmetric solid state structure of $W_4(OEt)_{16}$.

From reactions between $W_2(NMe_2)_6$ and Pr^iOH, a most intriguing hydrido–alkoxide, $W_4(\mu-H)_2(OPr^i)_{14}$, has been isolated and characterized.[35] The central $W_4(\mu-H)_2O_{14}$ skeleton of this molecule is shown in Fig. 7. The molecule is centrosymmetric and the eight electrons available
Fig. 7. An ORTEP view of the central skeleton of the centrosymmetric $W_4(\mu-H)_2(OPr^i)_{14}$ molecule. Some pertinent distances (Å) and angles (°) are: W(1)——W(1)' = 3.407(1), W(1)–W(2) = 2.446(1) and W(2)–W(1)–W(1)' = 142. The W–OR distances are within the range reported in Table 3 for terminal and μ_2–OR ligands.

for M–M bonding are evidently used to form two localized M–M double bonds: W(1)–W(2) = W(1)′–W(2)′ = 2.446(1) Å. The central distance, W(1)——W(1)′ = 3.407(1) Å, is typical of a non-bonding distance in $M_2(\mu_2\text{–OR})_2$-containing compounds (see Table 1). The molecule may thus be viewed as a dimer of dinuclear compounds: $[W_2(\mu\text{–H})(OPr^i)_7]_2$. It is interesting to speculate why $W_4(\mu\text{–H})_2(OPr^i)_{14}$ adopts a chain structure rather than a cluster based on the $W_4(OEt)_{16}$ structure in which a pair of μ_2 or μ_3 OEt ligands are replaced by hydrides.

A cryoscopic molecular weight determination in benzene indicates that a tetranuclear structure is maintained in solution. However, in contrast to the rigid (NMR timescale) structure of $W_4(OR)_{16}$ compounds (R = Me and Et), $W_4(\mu\text{–H})_2(OPr^i)_{14}$ is highly fluxional. In the ^1H NMR spectrum, only one type of OPr^i ligand is observed in the temperature range $-60°$ to $+80°C$. Evidently some fluxional process rapidly scrambles all the OPr^i ligands. This process also exchanges the two types of tungsten atoms, which are in formal oxidation states $+4\frac{1}{2}$ and $+3\frac{1}{2}$, since the hydride resonance at $\delta = 7.87$ ppm shows only one coupling to ^{183}W, $I = \frac{1}{2}$, 14.5 natural abundance. From the relative intensities of the satellites to the central hydride resonance, it is evident that the hydride ligand bridges two equivalent tungsten atoms; the hydride ligands are not scrambled over all four tungsten atoms. One can readily accommodate these observations by a fluxional process in which the molecule essentially "turns itself inside-out". A cleavage of one of the central W(1)–μ–OR bridges could be followed by a succession of bridge$\rightleftharpoons$terminal OPr^i exchanges to give an intermediate of the type shown in **VIII** below. From such an intermediate, a return to the chain structure could occur with exchange of W(1) and W(2). It is, however, still quite remarkable that $W_4(\mu\text{–H})_2(OPr^i)_{14}$ is so labile to OPr^i scrambling.
Three further types of tetranuclear alkoxides have recently been found for compounds of formula $Mo_4X_4(OR)_8$, where X = F, Cl and Br. These are described later since they are formed in X-for-OR exchange reactions involving $Mo_2(OR)_6$ compounds. It should be noted, however, that each of these structures is possible for a compound of formula $Mo_4(OR)_{12}$ and, since the $Mo_2(OR)_6$ (M≡M) structure is only realized with bulky R groups, the structures of the polymeric compounds $[Mo(OEt)_3]_n$ and $[Mo(OMe)_3]_n$ are clearly worthy of investigation.

6. Hexanuclear alkoxides

In methanol as solvent, molybdenum(II) halides react with NaOMe to give $Na_2Mo_6X_8(OMe)_6$ compounds, where X = Cl and Br.[36] Based on spectroscopic data, these compounds can reasonably be formulated as $Mo_6(\mu_3\text{–X})_8^{4+}$-containing clusters in which six OMe ligands are terminally bonded to each molybdenum atom and radiate from the centre of an idealized Mo_6-octahedral unit. Under more forcing conditions (150°C, NaOMe melt), a yellow–brown crystalline compound of formula $Na_2Mo_6(OMe)_{14}$ is obtained.[36] This compound is pyrophoric in air and shows two types of OMe ligands in the ^1H NMR spectrum in the integral ratio 3:4, which is consistent with a cube–octahedral relationship for a $Mo_6(\mu_3\text{–OMe})_8^{4+}$ moiety with six terminal OMe ligands. A full structural study seems warranted for this 24-electron Mo_6 cluster compound.

7. Physical evidence for RO-to-M π-bonding

Direct evidence for RO-to-M multiple bonding can be seen in a large number of structural studies. For terminal alkoxy ligands, the C_{sp^3}–O distances average 1.44(2) Å. Given that this is a

single bond distance and that the radius of C_{sp^3} is 0.77 Å, then the covalent radius of oxygen (single bond) is placed at 0.67 Å. The covalent radius of molybdenum or tungsten may be reasonably estimated from M–C_{sp^3} distances. For example, in compounds of formula 1,2-$M_2R_2(NMe_2)_4$[37] or 1,2-$Mo_2(OBu^t)_2(CH_2SiMe_3)_4$,[38] where the M–$C_{sp^3}$ distances are 2.17(2) Å, the single bond covalent radius for M is determined to be 1.40 Å. This then sets $d_{(Mo-O)} = r_M + r_0 = 2.06$ Å. This value is in fact typical of M–μ–OR distances, but considerably longer than any seen for terminal M–OR groups which fall in the range 1.80–1.96 Å. In $Mo_2(OCH_2Bu^t)_6$, the average Mo–O distance is 1.88(2) Å.[6] In this molecule, it is the metal δ-type orbitals, d_{xy} and $d_{x^2-y^2}$, which are primarily involved in π-bonding and an average Mo–O bond order of 1.66 is thus expected to correlate with this distance. Upon addition of another ligand, one of the in-plane orbitals becomes used in σ-bonding. Typically in $M_2(OR)_6L_2$ compounds, the M–O distances are in the range 1.90–1.96 Å, consistent with a net decrease in π-bonding. On the other hand, in 1,2-$Mo_2(OBu^t)_2(CH_2SiMe_3)_4$, where each alkoxy group may be fully involved in π-bonding, the Mo–O distance is shorter. A listing of terminal and bridging M–OR bond distances is given in Table 3.

Table 3. Representative M–O distances (Å) in molybdenum and tungsten alkoxides[a]

Compound	M–O (terminal)	Mo–O (μ_2)	Mo–O (μ_3)	Ref

[a]Averaged where appropriate.

[b]A.J. Nielson and J.M. Waters, Polyhedron 1981, 1, 561.

Of course, many factors may influence an individual M–O distance, particularly the oxidation state of the metal, the *trans*-ligand and steric and electronic properties of adjacent ligands.[39] It is, however, safe to say terminal RO-to-Mo or -W distances are always shorter than would be expected from considerations of single bond radii.

The influence of RO-to-M π-bonding may be shown in the spectroscopic properties of adjacent ligands. (1) In $Mo(OBu^t)_2(py)_2(CO)_2$,[40] the low values of $v(CO)$, 1906 and 1776 cm^{-1}, arise because π-donor ligands enhance t_{2g}^4 backbonding to carbonyl π^* orbitals. (2) In $MoO_2(OPr^i)_2(bpy)$,[41] which contains the *cis*-Mo(6+)O$_2$ moiety and a pair of mutually *trans* OPr^i ligands, the oxo and OPr^i ligands compete to fill (π-donate with) the vacant Mo t_{2g} orbitals. There is an abundance of π-electrons to do this job. An oxo group may be a six electron donor and usually a *cis*-Mo(6+)O$_2$ group will contain two Mo–O groups of bond order 2.5. It has been noted that Mo–O bond distance, Mo–O bond order and ^{17}O chemical shifts correlate linearly for terminal Mo–O groups.[42] In $MoO_2(OPr^i)_2(bpy)$, the Mo–O (oxo) distances, 1.71(1) Å (averaged), and the ^{17}O chemical shift value of 878 ppm are longer and lower, respectively, than the values anticipated for a *cis*-Mo(6+)O$_2$ function in octahedral complexes. The maximum Mo–O π bond order of 1.5 is evidently not attained because some RO-to-Mo π-bonding occurs. The latter, however, is relatively small as evidenced by the rather long Mo–OPr^i distances, 1.93(1) Å (averaged).[41]

III. CHEMICAL REACTIONS

By far the most extensively studied group of alkoxides of molybdenum and tungsten are the dinuclear compounds of formula $M_2(OR)_6$ (M≡M). Their reactions are discussed in detail and, where appropriate, related reactions involving other alkoxides are noted.

1. *Lewis base association reactions*

In hydrocarbon solutions, $M_2(OR)_6$ compounds (M≡M) react with N and P donor ligands, L, according to the equilibrium reaction (1) shown below.[6,9,10,43,44]

$$M_2(OR)_6 + 2L \rightleftharpoons M_2(OR)_6L_2; \text{ K.} \tag{1}$$

The position of equilibrium is very sensitive to the nature of R and L and for related compounds $K_W > K_{Mo}$. Also, tungsten prefers to coordinate P donors relative to N donors, provided steric factors permit coordination. Several adducts have now been structurally characterized. All structures are based on conformations of **IX**.
Each metal atom is coordinated to four atoms which lie roughly in a plane; the two metal atoms are united by a triple bond and the two halves of the molecule adopt a conformation which is determined by ligand–ligand interactions across the M–M bond. In general, steric repulsive interactions favour staggered conformations, but for $W_2(OPr^i)_6(HNMe_2)_2$, a near eclipsed geometry is found. In the latter case, N–H——OR hydrogen bonding occurs across the M–M bond similar to that found in $W_2Cl_4(OR)_4(HOR)_2$ compounds.[20] Some pertinent structural data for these Lewis base adducts are given in Table 4.

The equilibrium (1) may be monitored by NMR spectroscopy as a function of temperature. At room temperature in toluene-d_8, $Mo_2(OPr^i)_6$ and pyridine react rapidly and reversibly to give $Mo_2(OPr^i)_6(py)_2$. On lowering the temperature, the equilibrium position shifts in favour of the adduct and pyridine dissociation–association becomes slow on the NMR time-scale. The spectrum of the adduct at *ca.* −25°C, 220 MHz, indicates two types of OPr^i ligands in the integral ratio 2:1, consistent with *cis* and *trans* Pr^{i}O–W–*py* groups. At this temperature, rotation about the M–M

$Mo_2(OCH_2Bu^t)_6(DMEDA)$	2.218(1)	2.31	91.1	51.3	1.92	101.6	1.96	102	43

[a]Abbreviations are as follows: py = pyridine; pyMe-4 = 4-methylpyridine; DMEDA = $Me_2NCH_2CH_2NMe_2$; O^t = oxygen trans to L; O^c = oxygens cis to L. [b]M.J. Chetcuti, M.H. Chisholm and J.C. Huffman, results to be published. [c]M.H. Chisholm, F.A. Cotton, M.W. Extine and W.W. Reichert, J. Am. Chem. Soc. 1978, 100, 153.

bond is rapid, but at lower temperatures and at higher magnetic field strengths (below $-50°C$, 360 MHz), three OPr^i ligands are seen in the integral ratio $1:1:1$. The spectrum is thus consistent with the adoption of a structure having C_2 symmetry akin to that found in the solid state.[43] For some compounds, e.g. $Mo_2(OCH_2Bu')_6(py)_2$, low temperature spectra have been obtained indicative of freezing out two conformations, each having C_2 symmetry for the $M_2O_6N_2$ skeleton; furthermore, restricted rotations about Mo–L bonds are observed.[43]

For P donor ligands (PMe_3, PMe_2Ph, PPh_3, $Me_2PCH_2CH_2PMe_2$ and $Ph_2PCH_2CH_2PPh_2$), the equilibrium (1) may also be monitored by ^{31}P NMR spectroscopy. For specific combinations of alkoxide and P donor ligands, it is possible to observe high temperature limiting spectra corresponding to free phosphine and low temperature spectra corresponding to the adducts. This is because the favourable enthalpy of binding in (1) may be offset at higher temperatures by the negative entropy of binding. The ^{31}P chemical shifts of free and coordinated phosphines differ by ca. 25 ppm. At intermediate temperatures, a single broadened resonance is observed. The position of this resonance is dependent upon the relative concentrations of coordinated and free phosphine and the line shape is influenced by the rate of exchange. The ^{31}P NMR spectra of the ditungsten adducts show interesting satellite features due to couplings (one and two bond) to ^{183}W, $I = \frac{1}{2}$, 15% natural abundances (see Fig. 8).
Fig. 8. ^{31}P NMR spectrum (40.5 MHz, 25°C, toluene-d_8 solvent) of $W_2(OCH_2Bu')_6(PMe_3)_2$. Chemical shift $\delta = 1.5$ ppm relative to external H_3PO_4 (85% aq); $^1J_{183W-31P} = 240$ Hz, $^2J_{183W-31P} = 20$ Hz and $^3H_{31P-31P} = 5.4$ Hz.

The equilibrium (1) may also be monitored by UV-visible spectroscopy. All the adducts of formula $M_2(OR)_6L_2$ are more intensely coloured than the parent $M_2(OR)_6$ compounds. On adduct formation, the lowest energy transition of the $M_2(OR)_6$ compounds, v_1, which corresponds to M–M π-to-M–L π^*, $(d_{xy}, d_{x^2-y^2})$ splits into two bands. One band moves to higher energy and the other to lower energy: it is the latter which is responsible for absorption in the visible region.

One other intriguing aspect to emerge from studies of (1) is the finding that $M_2(OR)_6L$ species are unstable with respect to disproportionation to $M_2(OR)_6$ and $M_2(OR)_6L_2$. This leads to a cooperative phenomenon. For the sequence depicted by (2), where M_2 represents $M_2(OR)_6$ and M_2L_2 represents $M_2(OR)_6L_2$, both of which are in equilibrium, the second addition of L occurs more rapidly than the first, $k_2 > k_1$. Similarly in the dissociation reaction, the second loss of L is more rapid than the first, $k_{-1} > k_{-2}$.

$$M_2 + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} M_2L$$

$$M_2L + L \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} M_2L_2. \tag{2}$$

This observation is quite contrary to what would be expected from simple considerations of both steric factors and Lewis acid–Lewis base concepts. The origin of the relative instability of $M_2(OR)_6L$ compounds must be electronic, but at present it is not clearly understood.

In contrast to Lewis base association reactions involving $M_2(OR)_6$ compounds which retain the $M{\equiv}M$ bond, $Mo_2(OPr^i)_8$ (M=M) reacts with Lewis bases to give $Mo(OPr^i)_4L_2$ compounds. The latter are paramagnetic and are most likely related to the $Mo(OSiMe_3)_4(HNMe_2)_2$ molecule which has a central MoO_4N_4 skeleton of octahedral geometry in the solid state[15] as is shown in Fig. 9.

2. M–OR bond insertion reactions

$M_2(OR)_6$ compounds react rapidly and reversibly with CO_2, both in hydrocarbon solutions and in the solid state, to give mixed alkoxide–alkylcarbonato compounds according to eqn (3)[45,46]

$$M_2(OR)_6 + 2CO_2 \rightleftharpoons M_2(OR)_4(O_2COR)_2. \tag{3}$$

The mechanism of CO_2 insertion in (3) involves a direct pathway: it does not require a catalyst such as ROH.[46] The alkylcarbonato compounds, $M_2(OR)_4(O_2COR)_2$ are quite stable at room
Fig. 9. An ORTEP view of the centrosymmetric $Mo(OSiMe_3)_4(HNMe_2)_2$ molecule showing the *trans* octahedral geometry of the MoO_4N_2 skeleton. Pertinent distances (Å) and angles (°) are: Mo–O(1), –O(2), –N(1) = 1.950(4), 1.951(4), 2.219(4); O(1)–Mo–O(1)′, –O(2), –O(2)′, –N(1), –N(1)′ = 180.0(3), 89.2(1), 90.8(1), 94.6(1), 85.4(1); Mo–O(1)–Si(1) = 170.8(2); Mo–O(2)–Si(2) = 174.2(2).

temperature, but readily and reversibly lose CO_2 when heated to 60–80°C. In solution, however, the alkylcarbonato compounds readily lose CO_2 according to (3) and must be maintained under an atmosphere of CO_2 (25°C) if the equilibrium is to favour the insertion product.

The solid state molecular structure of $Mo_2(OBu^i)_4(O_2COBu^i)_2$ was determined by an X-ray study and revealed the *cis*-bridged geometry depicted by **X**. The presence of a pair of bridging O_2CX groups imposes a near-eclipsed conformation as is shown in Fig. 10.
The ^1H NMR spectra of $M_2(OR)_4(O_2COR)_2$ compounds (R = $CHMe_2$ and CH_2CMe_3) are consistent with the presence of a *cis*-bridged O_2COR structure in solution. Specifically, for the Mo–OR ligands, the methyl groups are diastereotopic for the isopropoxy compound, giving rise to a pair of doublets, and the methylene protons are diastereotopic for the neopentoxide, which gives rise to an AB quartet.
Fig. 10. An ORTEP view of the central skeleton of the $Mo_2(OBu^i)_4(O_2COBu^i)_2$ molecule viewed down the Mo–Mo bond showing the near eclipsed geometry caused by the presence of the *cis*-bridging O_2COR ligands. Some pertinent distances (Å) are: Mo–Mo = 2.241(1); Mo–OBu^i = 1.88(2), Mo–O–(alkylcarbonate) = 2.12(2).

$M_2(OR)_6$ compounds have also been found to react with alkyl- and aryl-cyanates, $R'NCO$, to give insertion products $M_2(OR)_4\{OC(OR)NR'\}_2$. This insertion reaction is irreversible and the products are quite stable in solution. The ^1H NMR spectra are generally consistent with the *cis*-bridged, head-to-tail structure found for $Mo_2(O_2CH_2CMe_3)_4(OC(OCH_2CMe_3)NPh)_2$ in the solid state,[47] which is represented by **XI** below.
3. *Ligand exchange reactions*

A number of closely related compounds to those depicted by **X** and **XI** have been obtained from protolysis reactions in which a bidentate ligand is substituted for an OR group. For example, the reactions between 1,3-diaryltriazines and $Mo_2(OR)_6$ compounds give $Mo_2(OR)_4(ArN_3Ar)_2$ compounds and related reactions involving 2-hydroxypyridine yield $Mo_2(OR)_4(O-N)_2$ where O–N is the dianion derived from deprotonation of 2-hydroxypyridine.[48] The structural characterization of $Mo_2(OPr^i)_4(O-N)_2$ revealed the *cis*-bridged, head-to-tail geometry depicted by **XI** in the solid state and ^1H NMR studies are consistent with this structure being maintained in solution.

Bidentate ligands generally bridge the Mo≡Mo bond when formation of a five-membered ring is achieved, e.g. as is found for $RCOO^-$, $ArNNNAr^-$ and $R'NC(OR)O^-$ ligands. However, reactions between $M_2(OR)_6$ compounds and 2,4-pentanedione, acacH, proceed to give $M_2(OR)_4(acac)_2$ derivatives in which the acac ligands are bidentate, but are chelated to each metal. The structure of $Mo_2(OCH_2CMe_3)_4(acac)_2$ found in the solid state is shown in Fig. 11. Presumably
Fig. 11. An ORTEP view of the $Mo_2(OCH_2Bu^t)_4(acac)_2$ molecule looking down the Mo–Mo bond showing the staggered conformation. Some pertinent distances (Å) are Mo–Mo = 2.237(1), Mo–OR = 1.89(1) (averaged) and Mo–O–(acac) = 2.08(2) (averaged). The Mo–Mo–O angles fall in the range 97–104°.

the formation of the six-membered ring is favoured relative to the seven-membered ring which would be required if acac⁻ were to span the Mo≡Mo bond. Using unsymmetrically substituted acac⁻ ligands which form A–B-type chelates, three geometric isomers are possible, each having an enantiomer. However, in solution we have only been able to observe two isomers, probably because extremely facile rotation about the Mo≡Mo bond rapidly interconverts two isomers on the ^{1}H NMR time-scale.

4. *Halide-for-alkoxide exchange*

From the reaction between $Mo_2(OBu^t)_6$ and PF_3 in hydrocarbon solvents, a black crystalline product of empirical formula $MoF(OBu^t)_2$ was isolated.[49] During one such preparation, crystals suitable for an X-ray study were obtained and, when this was undertaken, the unit cell was found to contain a mixture of molecules $Mo_4F_4(OBu^t)_8$ and $Mo_4F_3(OBu^t)_8(NMe_2)$ in the ratio 1:2. The presence of the NMe_2 group, which was not anticipated, can reasonably be traced to incomplete alcoholysis in the preparation of $Mo_2(OBu^t)_6$ from $Mo_2(NMe_2)_6$. The structure of the $Mo_4F_4(OBu^t)_8$ molecule is shown in Fig. 12. The central Mo_4 unit is a bisphenoid with two short Mo–Mo distances, 2.24 Å, and four long Mo–Mo distances, ca 3.75 Å. The molecule may be viewed as two Mo≡Mo units brought together through the agency of fluoride bridges. Each $Mo_2(OBu^t)_4(\mu\text{-F})_2$ unit (M≡M) has a geometry very similar to that found in $Mo_2(OBu^t)_4(O_2COBu^t)_2$.[46] The $Mo_4F_3(OBu^t)_8(NMe_2)$ molecule has one $\mu\text{-NMe}_2$ group in place of a μ–F group, but this produces a negligible effect on the M–M distances in the Mo_4 moiety.

In search of a more general route to mixed halide–alkoxide compounds, we have initiated studies of the reactions between $Mo_2(OPr^i)_6$ and acetyl halides.[50] In hexane, $Mo_2(OPr^i)_6$ and CH_3COX (X = Cl and Br) produce black crystalline compounds of empirical formula $Mo_4X_3(OPr^i)_9$. These compounds are only very sparingly soluble in hexane, but are appreciably soluble in toluene. ^{1}H NMR spectra recorded in toluene-d_8 and benzene-d_6 are consistent with that
Fig. 12. An ORTEP view of the central skeleton of the $Mo_4(OBu^t)_8(\mu_2\text{-F})_4$ molecule. Pertinent distances (Å) are: Mo(1′)–Mo(2′) = 2.262(2), Mo(3′)–Mo(4′) = 2.263(2), Mo(1′)–Mo(3′) = 3.743(2), Mo(1′)–Mo(4′) = 3.730(2), Mo(2′)–Mo(3′) = 3.713(2), Mo(2′)–Mo(4′) = 3.700(2), Mo–μ–F = 2.10(2) (averaged) and Mo–O = 1.94(2) (averaged).

expected for a $Mo_4(\mu_2\text{-}X)_3(\mu_2\text{-}OPr^i)(OPr^i)_8$ structure akin to that described above for $Mo_4F_3(NMe_2)(OBu^t)_8$.

A further reaction between $Mo_4X_3(OPr^i)_9$ and CH_3COX or a direct reaction between $Mo_2(OPr^i)_6$ and CH_3COX (2 equiv) in toluene yield black crystalline compounds of empirical formula $MoX(OPr^i)_2$. These compounds are only very sparingly soluble in toluene and little is known about their solution properties. The solid state molecular structures are fascinating, however. For the chloride,[50] there is a square of molybdenum atoms with eight bridging (μ_2)OPr^i ligands, four lying above and four lying below thĕ Mo_4 plane. The Mo–Cl bonds are terminal and radiate from the centre of the Mo_4-square (see Fig. 13). The central $Mo_4O_8Cl_4$ unit has virtual D_{4h} symmetry. The Mo–Mo distance of 2.37 Å implies strong Mo–Mo bonding. The compound is diamagnetic and, in a formal sense, may be viewed as an inorganic analogue of cyclobutadiene formed by the coupling of two Mo≡Mo units.

Quite remarkably, the structure of the bromide, $Mo_4Br_4(OPr^i)_8$, is different from that of the chloride just discussed. The bromide contains a butterfly or opened-tetrahedron of molybdenum atoms with five relatively short Mo–Mo distances, ca. 2.5 Å, and one long distance, 3.1 Å.[50] The Mo–Br groups are all terminal, but the Mo–OPr^i groups are terminal (2) and doubly (4) and triply (2) bridging as shown in Fig. 14.

The $Mo_4X_4(OPr^i)_8$ structures, where X = Cl and Br, may be viewed as subunits of the well known $Mo_6(\mu_3\text{-}X)_8^{4+}$ unit.[51-53] In both of the alkoxide structures, the oxygen atoms lie roughly at the corners of an idealized O_8 cube. The four molybdenum atoms occupy positions at four faces of the cube such that two opposite faces are vacant (X = Cl) or two adjacent faces are vacant (M = Br) relative to the $Mo_6(\mu_3\text{-}X)_8^{4+}$ geometry.
Fig. 13. An ORTEP view of the $Mo_4Cl_4(OPr^i)_8$ molecule. The molecule has a crystallographically imposed C_2 axis, which contains Cl(3)–Mo(1)–Mo(1D)–Cl(3D), and a mirror plane, which contains Cl(4C)–Mo(2C)–Mo(2A)–Cl(4A) and relates atoms O(5) and O(5D), O(5A) and O(5E), etc. Pertinent bond distances (Å) and angles are: Mo(1)–Mo(2C) = 2.378(2), Mo(1)–Cl(3) = 2.442(5), Mo(1)–O(5) = 1.981(4), Mo(2C)–O(5) = 2.078(4); Mo(2C)–Mo(1)–Mo(1D) = 91.4(1); Mo(1)–Mo(2C)–Mo(1D) = 88.5(1); Cl(3)–Mo(1)–O(5) = 93.3(1).
Fig. 14. An ORTEP view of the $Mo_4Br_4(OPr^i)_8$ molecule which has C_{2v} symmetry. Some pertinent distances (Å) and angles (°) are: $Mo(1)-Mo(2) = 2.513(1)$, $Mo(2)-Mo(1)' = 2.516(1)$; $Mo(2)-Mo(2)' = 2.481(1)$; $Mo(1)-Br(3) = 2.596(1)$; $Mo(2)-Br(4) = 2.568(1)$; $Mo-OR = 1.84(1)$ (terminal), $2.02(1)$ (μ_2) and $2.15(1)$ (μ_3) (averaged); $Mo(1)-Mo(2)-Mo(1)' = 81.6(1)$; $Mo(1)-Mo(2)-Mo(2)' = 60.5(1)$.

It seems likely that the $Mo_4X_4(OPr^i)_8$ molecules will be reactive toward further association reactions: $M_2 + M_4 \rightarrow M_6$, etc. It may ultimately be possible to systematically interconvert M_2 (multiple bond), M_4 (cluster) and M_6 (octahedral) complexes. It should also be noted that McCarley et al.[54] have coupled two $Mo\equiv Mo$ bonds to form a rectangular Mo_4^{8+} containing compound: $2Mo_2Cl_4(PR_3)_2(HOMe)_2 \rightarrow Mo_4Cl_4(\mu_2-Cl)_4(PR_3)_4 + 4MeOH$. The M–M distances are alternating long and short, indicative of single and triple bonds, respectively, in a simple valence bond description.

At this point, it is worth noting the variety of M_4-alkoxide structures that have been found for molybdenum and tungsten: $Mo_4F_4(OBu^i)_8$,[49] $Mo_4Cl_4(OPr^i)_8$,[50] $Mo_4Br_4(OPr^i)_8$,[50] $W_4(OEt)_{16}$[30] and $W_4(\mu-H)_2(OPr^i)_{14}$.[35] In each structure, M–M bonding is clearly important, but it is not clear what factors are responsible for the adoption of one geometry relative to another. Why do the $Mo_4X_4(OR)_8$ structures differ for X = F, Cl and Br, and why are two localized W=W bonds found in $W_4(\mu-H)_2(OPr^i)_{14}$, rather than an 8-electron W_4 cluster of the type seen in $W_4(OEt)_{16}$? These questions provide the stimulus for further studies in the area.

5. Oxidative-addition reactions

Compounds with M–M multiple bonds have a source of electrons which may be tapped for oxidative processes. A number of simple stepwise M–M bond order transformations have been observed.[55] Oxidative-addition reactions involving $Mo_2(OPr^i)_6$ ($M\equiv M$) have been noted to give $(Mo=Mo)^{8+}$-containing compounds as shown in eqn (4).

$$Mo_2(OPr^i)_6 + X_2 \rightarrow Mo_2(OPr^i)_6X_2 \qquad (4)$$
where $X = Pr^iO^{11}$ or $PhCOO$.[41,56]

The structure and bonding in $Mo_2(OPr^i)_8$ has already been discussed. The structure of $Mo_2(OPr^i)_6(O_2CPh)_2$ has not been determined by a single crystal study, but NMR characterization suggests the edge-shared octahedral geometry shown in XII.

XII

O = OR

$\overset{\frown}{O \quad O}$ = $PhCO_2$
The direct addition of halogens X_2, where $X = Cl$, Br and I, to hydrocarbon solutions of $Mo_2(OPr^i)_6$ gives edge-shared octahedral complexes with Mo–Mo single bonds, $Mo_2(OPr^i)_6X_4$, VII.[25] Attempts to prepare $Mo_2(OPr^i)_6X_2$ (M=M) compounds by the careful addition of one equivalent of the halogen were unsuccessful and there is evidence that such compounds are unstable with respect to disproportionation to $Mo_2(OR)_6$ and $Mo_2(OPr^i)_6X_4$ compounds. However, from the reaction between $Mo_2(OR)_6$ and $PhCHBr_2$ in hexane/pyridine solvent mixtures, compounds of formula $Mo_2(OR)_6Br(py)$ have been isolated.[57] The neopentoxide has been shown to have an interesting confacial bioctahedral geometry involving two μ_2-OR and one μ-Br ligand (see Fig. 15). The Mo–Mo distance, 2.534(1) Å, is consistent with the presence of a $(Mo=Mo)^{8+}$ unit. However, in a formal sense, the oxidation states of the two molybdenum atoms differ, $Mo(4\frac{1}{2}+)$ and $Mo(3\frac{1}{2}+)$. The ^1H NMR spectra in toluene-d_8 are consistent with the maintenance of this structure in solution.

A number of other substrates react with $M_2(OR)_6$ compounds to give adducts which may be viewed as products of redox reactions. For example, orthoquinone ligands can behave as neutral, -1 (semiquinones) or -2 (catecholate) ligands.[58] The adducts with $M_2(OR)_6$ compounds, either 1:1 or 2:1, are often highly coloured, presumably due to low energy charge transfer, either MLCT or LMCT. Tetrachloroorthoquinone, which is known to be a good oxidizing agent $(C_6Cl_4O_2 + 2e^- = C_6Cl_4O_2^{2-}, -0.78$ V$)$ has been found to react with $Mo_2(OR)_6$ compounds to give
Fig. 15. An ORTEP view of the $Mo_2(OCH_2Bu^t)_6Br_2(py)$ molecule showing the confacial bioctahedral geometry. Some pertinent distances (Å) are: Mo–Mo = 2.534(1), Mo–Br (terminal) = 2.584(1), Mo–Br (μ_2) = 2.73(1) (averaged), Mo–N = 2.257(6). The Mo–O distances are all within the range commonly found for terminal and μ_2 ligands as shown in Table 3.
Fig. 16. An ORTEP view of the $Mo_2(OPr^i)_6(O_2C_6Cl_4)_2$ molecule emphasizing the edge-shared octahedral geometry. The Mo–Mo distance is 2.754(2) Å and the Mo–O distances (averaged) are 1.83(1) (terminal OR), 2.01(1) $-\mu$–OR) and 2.02(1) Å $(O_2C_6Cl_4)$.

2:1 adducts $Mo_2(OR)_6(O_2C_6Cl_4)_2$, which may best be viewed as d^1–d^1 dimers. The structure of the isopropoxide is shown in Fig. 16. From a consideration of the Mo–Mo, Mo–O and C–O (quinine) distances, this is clearly a Mo_2^{10+}-containing compound.

$W_2(OPr^i)_6(py)_2$ also reacts with benzil and 2,3-butanedione to give 2:1 adducts of formula $W_2(OR)_6(R_2'C_2O_2)_2$. The structures of the compounds where R = Pr^i and R' = p-tolyl and methyl have been determined in the solid state.[60] The structure of the 2,3-butanedione derivative is shown in Fig. 17. Once again, the W–W, W–O and C–C distances (2,3-butanedione ligand) are indicative of a d^1–d^1, W_2^{10+}-containing molecule. Most notably, the C–C double bond is evidenced by the 1.33(1) Å bond distance which demonstrates the importance of the resonance form **XIIIb** relative to **XIIIa**.
XIIIa   **XIIIb**

In these reactions which oxidize the $(M{\equiv}M)^{6+}$ unit, it is interesting to note that oxidation occurs more readily for tungsten than molybdenum. This is seen, for example, in the alcoholysis reactions of $M_2(NMe_2)_6$ compounds. Whereas molybdenum forms an extensive series of $Mo_2(OR)_6$ compounds, tungsten is readily oxidized to the +4 oxidation state as in the formation of $W_4(\mu-H)_2(OPr^i)_{14}$[35] and $W_4(OEt)_{16}$.[30] The oxidation of the $(W{\equiv}W)^{6+}$ unit may be blocked by strongly coordinating ligands such as pyridine, $MeN(H)CH_2CH_2N(H)Me$ and PMe_3 which give adducts $W_2(OR)_6L_2$ or $W_2(OR)_6(L-L)$ when alcoholysis of $W_2(NMe_2)_6$ is carried out in their presence.[10] The oxidative-addition step presumably proceeds through an unsaturated and reactive intermediate of the form $W_2(OR)_6(HOR)$. This type of oxidative-addition finds a parallel in the recent work of Brown and Nubel.[61] $1,2-Re_2(CO)_8(X-H)_2 \rightarrow Re_2(CO)_8(X-H) \rightarrow Re_2(CO)_8(\mu-H)(\mu-X)$ where X–H = H_2O and C_6H_5N (pyridine).

A number of other reactions with unsaturated organic molecules (π-acceptors such as CO, $RC{\equiv}CR$) lead to adducts which may be viewed as oxidative-addition products. These are discussed later.
Fig. 17. An ORTEP view of the $W_2(OPr^i)_6(O_2C_2Me_2)_2$ molecule. The W–W distance is 2.754(1) Å and the distances (Å) associated with the $W-O_2C_2Me_2$ moiety are: (averaged) W–O = 1.94(4), C–O = 1.34(2); C–C (central) = 1.35(1).

6. M–M cleavage reactions

$M_2(OR)_6$ compounds react with NO (2 equiv) in hydrocarbon solvents to cleave the M≡M bond. In a formal sense, the M–M σ and π bonds are broken to form two M–N σ bonds and four M–N π bonds (Md-to-NO π^*) as shown in eqn (5).

$$M≡M + 2X \longrightarrow 2M≡X. \tag{5}$$

The molecular structure of $[Mo(OPr^i)_3NO]_2$ deduced from an X-ray study[19] is shown in Fig. 18. Each molybdenum atom is in a distorted trigonal bipyramidal geometry. The molecule is

(a)

(b)

$Mo_2(O-i-Pr)_6(NO)_2$
Skeleton
Fig. 18. Comparison of some structural parameters for the centrosymmetric molecules $Mo_2(OPr^i)_8$ and $Mo_2(OPr^i)_6(NO)_2$.

centrosymmetric with linear terminal Mo–N–O groups which occupy axial positions. The two halves of the molecule are joined along a common equatorial axial edge by a pair of μ–OPr^i ligands. The Mo-to-Mo distance is 3.335 Å, typical of a non-bonding M——M distance spanned by a pair of μ–OR ligands (see Table 1). The lack of any M–M bond in $M_2(OR)_6(NO)_2$ compounds can also be seen in their reactions with donor ligands such as pyridine, which leads to $M(OR)_3(NO)(py)$ compounds.[62] The structure of the $W(OBu^i)_3(NO)(py)$[63] molecule is shown in Fig. 19. Again, the local trigonal bipyramidal geometry is seen and extensive $W(d_{xz}, d_{yz})^4$-to-NO π^* bonding is evident from the extremely short W–NO distance and the low value of $v(NO)$, 1555 cm^{-1}. For a series of related $M_2(OR)_6(NO)_2$ compounds, the $v(NO)$ values fall ca. 1720 (M=Cr), 1640 (M = Mo) and 1550 (M = W), which reflects the relative ability of the group 6 metals to backbond to the π-acceptor NO ligand in their oxidation state 3+ (or 2+ if we count $M^-\leftarrow(NO^+)$ for a linear M–N–O group).

Another cleavage of the M≡M bond has recently been reported by Schrock et al.[64] in the reaction between $W_2(OBu^i)_6$ and alkynes as shown in eqn (6)

$$W_2(OBu^i)_6 + RC{\equiv}CR \rightarrow 2(Bu^iO)_3W{\equiv}CR \tag{6}$$
where R = Me, Et, Pr.

The reaction appears to be specific to $W_2(OBu^i)_6$: other alkoxides of W_2^{6+} and related dimolybdenum compounds give different products as will be discussed later. Also, the cleavage of the W≡W bond in (6) is not observed in reactions with ethyne. Closely related to (6) is the cleavage of the W≡W bond in reactions involving nitriles, eqn (7).[64]

$$W_2(OBu^i)_6 + RC{\equiv}N \rightarrow (Bu^iO)_3W{\equiv}N + (Bu^iO)_3W{\equiv}CR \tag{7}$$
where R = Me, Ph and PhCH$_2$.

If the alkylidyne ligand is counted as a 3-ligand like nitride N^{3-}, then reactions (6) and (7) may be viewed as oxidative-cleavages of the M≡M bond.

Other $W_2(OR)_6$ compounds will react with nitriles to give nitrides, i.e. the reaction is not specific to the Bu^iO ligand, but we have not been able to use (7) to prepare other $(RO)_3W{\equiv}CR'$ compounds. It appears that the alkylidynes may themselves react with nitriles to give nitrides and alkynes. $Mo_2(OR)_6$ compounds do not react with nitriles to give nitrides. Once again the greater reactivity of the W≡W bond, relative to Mo≡Mo, is seen with respect to oxidation.

The molecular structures of the $(Bu^iO)_3W{\equiv}X$ compounds, where X = CMe and N, have been determined in the solid state and are shown in Figs. 20 and 21, respectively.[65] A comparison with
Fig. 19. An ORTEP view of the $W(OBu^i)_3(NO)(py)$ molecule. Some pertinent distances (Å) and angles (°) are W–NO = 1.732(8), W–N(py) = 2.323(7), W–O = 1.88(1) (averaged); W–N–O = 179.2(8), N–W–N = 177.0(3), O–W–N(NO) = 100(1) (averaged).
Fig. 20. An ORTEP view of the centrosymmetric [(Bu'O)₃W≡CMe]₂ molecule. Pertinent bond distances (Å) and angles (°) are: W(1)–O(4), –O(9), –O(14), –C(2) = 1.886(4), 1.897(4), 1.934(4) and 1.759(6); W(1)'–O(14) = 2.484(4); C(2)–W(1), –O(4), –O(9), –O(14) = 102.3(2), 101.2(2) and 102.8(2); W(1)–C(2)–C(3) = 179.8(6).

the structures of [Mo(OPr')₃NO]₂ and W(OBu')₃(NO)(py), shown in Figs. 18 and 19, is most interesting. (Bu'O)₃W≡N crystallizes in the hexagonal space group $P6_3cm$ yielding a beautiful view down the C axis, as shown in Fig. 22.

Closely related to (6) and (7) is the cleavage of a M≡M bond by reaction with O₂ to give two M=O bonds, eqn (8).[27,41]

$$Mo_2(OPr')_8 + O_2 \rightarrow 2MoO(OPr')_4. \tag{8}$$
Reaction (8) is extremely rapid and quantitative. However, addition of molecular oxygen to
Fig. 21. An ORTEP view of the repeating unit along the C axis in the [(Bu'O)₃WN]ₓ polymer. Pertinent distances (Å) and angles (°) are: W(1)–N(2) = 1.740(15); W(1)–O(3) = 1.872(7); W(1)–N(2)' = 2.661(15); N(2)–W(1)–O(3) = 101.6(2); W(1)–O(3)–C(4) = 136.6(8).
Fig. 22. View of the [W(OBu^t)$_3$N]$_x$ polymer viewed down the C axis from a point at $x = 1/3$, $y = 2/3$. Five cells along the C axis are shown. Hydrogen atoms have been omitted. In the space group $P6_3cm$, there is a hexagonal network of tungsten atoms perpendicular to the C axis.

$M_2(OR)_6$ compounds leads to a variety of products, depending on the metal and the steric properties of the alkoxy ligands.

For molybdenum, the overall reaction proceeds according to (9), but many intermediates may be detected or isolated where $R = Pr^i$ and CH_2CMe_3.[66,41]

$$Mo_2(OR)_6 + 2O_2 \rightarrow 2MoO_2(OR)_2 + 2RO \qquad (9)$$
$R = Bu^t$, Pr^i and CH_2CMe_3.

The compound $MoO_2(OBu^t)_2$ is monomeric; the related isopropoxy and neopentoxy compounds are oligomers $[MoO_2(OR)_2]_n$ of, as yet, unknown structures. A clean synthesis of the latter compounds involves the addition of excess of ROH ($R = Pr^i$, CH_2CMe_3) to $MoO_2(OBu^t)_2$. Addition of pyridine or 2,2'-bipyridine to $[MoO_2(OR)_2]_n$ compounds yields monomeric octahedral complexes. The molecular structure of $MoO_2(OPr^i)_2(bpy)$ in the solid state reveals the cis-MoO_2 group with mutually trans OPr^i ligands as shown in Fig. 23.[41]

The addition of molecular oxygen to $Mo_2(OR)_6$ compounds, where $R = Pr^i$ and CH_2CMe_3, leads initially to green solutions containing the triangulo $Mo_3O(OR)_{10}$ compounds (see Fig. 5). A clean, direct synthesis of these compounds is by the addition of $MoO(OR)_4$ to $Mo_2(OR)_6$ compounds, eqn (10). This simple redox reaction redistributes the six electrons available for metal–metal bonding from $\sigma^2\pi^4$ in M≡M to $a^2 + e^4$ in the triangulo Mo_3^{12+} unit.

$$Mo_2(OR)_6 + MoO(OR)_4 \rightarrow Mo_3O(OR)_{10} \qquad (10)$$

$R = Pr^i$ and CH_2CMe_3.

Further reaction of $Mo_3O(OR)_{10}$ with O_2 leads to cleavage of the Mo_3 unit and elimination of RO˙ which abstracts H from solvent. A hexanuclear chain compound $Mo_6O_{10}(OPr^i)_{12}$ has been isolated and structurally characterized.[67] A view of this fascinating molecule is shown in Fig. 24. The average oxidation state of molybdenum is +5.33. Four electrons are available for metal–metal bonding and these are used to form two localized Mo–Mo single bonds, as is evidenced by the two short Mo–Mo distances, 2.585(1) Å, compared to the four long distances, 3.3 Å. These electrons are reactive toward further oxidation by molecular oxygen: $Mo_6O_{10}(OPr^i)_{12} + O_2 \rightarrow 6MoO_2(OPr^i)_2$.
Fig. 23. An ORTEP view of the $MoO_2(OPr^i)_2(bpy)$ molecule. Some pertinent bond distances (Å) and angles (°) are: Mo(1)–O(14), –O(15), –O(16), –O(20), –N(2), –N(13) = 1.69(1), 1.72(1), 1.91(1), 1.94(1), 2.37(1) and 2.35(1); O(14)–Mo(1)–O(15) = 108.0(3), O(14)–Mo(1)–O(16) = 96.6(3), O(14)–Mo(1)–O(20) = 96.7(3), O(16)–Mo(1)–O(20) = 160.9(3), N(2)–Mo(1)–N(13) = 69.2(3).

For tungsten, the story is much simpler, but quite different from molybdenum as is shown in eqn (11).[41]

$$W_2(OR)_6 + 3/2O_2 \rightarrow W_2O_3(OR)_6 \tag{11}$$
R = Bu^t, Pr^i and CH_2CMe_3.

The structures of $W_2O_3(OR)_6$ compounds are not known and, in solution, only one OR group is seen in the NMR spectra. A cryoscopic molecular weight determination in benzene indicated that $W_2O_3(OBu^t)_6$ is extensively (60%) dissociated, presumably to $WO_2(OBu^t)_2$ and $WO(OBu^t)_4$. The mass spectra of $W_2O_3(OR)_6$ compounds show only mononuclear ions and may be viewed as a superimposition of fragments derived from $WO(OR)_4$ and $WO_2(OR)_2$. A plausible structure for $W_2O_3(OR)_6$ compounds can be based on a confacial bioctahedral unit with two bridging OR ligands and one bridging oxo group.

IV. METAL–CARBON BONDS

1. Reactions with carbon monoxide

Carbon monoxide reacts rapidly with hydrocarbon solutions of $M_2(OR)_6$ compounds at 1 atm, 25°C. In some cases, the reactions produce $M(CO)_6$ compounds and oxidized metal containing species, i.e. CO induces disproportionation. The detailed course of the reaction depends upon the metal, Mo vs W, and on the steric properties of the alkoxy ligand. In the case of $Mo_2(OBu^t)_6$, the stoichiometric reaction (12) has been established and has been shown to proceed via an initial reversible reaction (13).[68]

$$2Mo_2(OBu^t)_6 + 6CO \rightarrow Mo(CO)_6 + 3Mo(OBu^t)_4 \tag{12}$$

$$Mo_2(OBu^t)_6 + CO \rightleftharpoons Mo_2(OBu^t)_6(\mu\text{-}CO). \tag{13}$$
The dark purple crystalline compound $Mo_2(OBu^t)_6(\mu\text{-}CO)$ adopts a structure in which each molybdenum atom is in a square based pyramidal geometry. The two halves of the molecule are joined by a μ_2–CO ligand which occupies the apical position and a pair of μ_2–OBu^t ligands which
Fig. 24. An ORTEP view of the centrosymmetric molecule $Mo_6O_{10}(OPr^i)_{12}$. Some pertinent bond distances (Å) and bond angles (°) are: $Mo(1)-Mo(2) = Mo(1)'-Mo(2)' = 2.585(1)$; $Mo(1)-Mo(1)' = 3.353(1)$, $Mo(2)-Mo(3) = Mo(2)'-Mo(3)' = 3.285(1)$, $Mo(1)'-Mo(1)-Mo(2) = 146.5(1)$, $Mo(1)-Mo(2)-Mo(3) = 134.3(1)$; Mo–oxo (terminal) = 1.68 (averaged); Mo–oxo $(\mu_2) = 1.93$ (averaged); Mo–OR (terminal) = 1.86 (averaged), Mo–OR $(\mu_2) = 2.05$–2.19.

are basal with respect to the fused square based pyramids. The central skeleton of this beautiful molecule is shown in Fig. 25.

Since the bridging carbonyl ligand can be counted as a one-electron donor to each metal, the addition of CO transforms a d^3–d^3 dimer to a d^2–d^2 dimer and thus a M–M triple to a double bond. The Mo–Mo distance, 2.498(1) Å is consistent with this assignment. The C–O triple bond is also reduced to a C–O double bond: $(M{\equiv}M)^{6+} + CO{\rightarrow}(M{=}M)^{8+}(\mu-CO^{2-})$.

In the presence of donor ligands, such as pyridine, it is possible to isolate an extensive series of compounds of formula $M_2(OR)_6L_2(\mu-CO)$ from reactions between $M_2(OR)_6$ compounds and CO.[69] These compounds are closely related to $Mo_2(OBu^t)_6(\mu-CO)$, having a donor ligand *trans* to the M–C bond of the bridging CO ligand. In solution, the donor ligands are labile to reversible dissociation and, on the NMR time-scale, bridge $\rightleftharpoons$ terminal OR group exchange is rapid. However, at low temperature and high magnetic field strengths, low temperature limiting spectra are obtained which are consistent with the structures observed in the solid state. The donor ligands serve the important role of suppressing the kinetically facile disproportionation reactions which occur in the presence of excess CO. Also, CO dissociation from $Mo_2(OR)_6(\mu-CO)$ is blocked when the dimer is ligated.

These μ_2–CO compounds show anomalous spectroscopic properties (see Table 5). The values of $v(CO)$ are unprecedentedly low for μ_2–CO ligands in neutral molecules. Also, the ^{13}C carbonyl chemical shifts appear below 300 ppm, which is out of the range of bridging carbonyl ligands in organometallic compounds. From simple symmetry considerations, it can be seen that the M–M
Fig. 25. Central skeleton of the $Mo_2(OBu^i)_6(\mu\text{–CO})$ molecule showing some of the pertinent distances.

π bond can interact strongly with the C=O π^* orbital. These molecules are inorganic analogues of cyclopropenones and show a significant contribution of the resonance shown in **XIV**.
The resonance form **XIV** is equivalent to an oxycarbyne ligand bridging two metal atoms and suggests that the μ–CO ligand might behave as a good Lewis base. This has actually been demonstrated in the isolation of a molecule of formula $W_4(OPr^i)_{12}(py)_2(CO)_2$ formed in the reaction between CO and $W_2(OPr^i)_6(py)_2$.[70] This intriguing complex may be viewed as a dimer of dimers

Table 5. Some characterization data for the $M_2(OPr^i)_6(py)_2(\mu\text{–CO})$ compounds[a]

	M = Mo	M = W
$\nu(CO)$ cm^{-1}	1655	1555
$\nu(^{13}CO)$ cm^{-1}	1637	1532
$\delta(^{13}CO)$ ppm	325.7	310.4 $J_{183W-13C}$ = 170 MHz
d(C–O) Å	1.19(1)	1.22(2)
d(M–CO) Å	2.06(1)	2.04(2)
d(M–M) Å	2.486(2)	2.490(3)

[a]All data taken from ref. 69.
Fig. 26. An ORTEP view of the central $W_4O_{12}(CO)_2N_2$ skeleton of the centrosymmetric $W_4(OPr^i)_{12}(py)_2(CO)_2$ molecule. Some key bond distances are: $W(1)-W(2) = 2.654(1)$, $W(1)-C(1) = 2.00(3)$, $W(2)-C(1) = 1.91(3)$, $C(1)-O(1)' = 1.33(3)$ and $W(2)-O(1) = 2.01(1)$ Å.

formed by the loss of one pyridine from $W_2(OPr^i)_6(py)_2(CO)$: $2W_2(OPr^i)_6(py)_2(CO) \rightarrow$ $W_4(OPr^i)_{12}(py)_2(CO)_2 + 2py$. Figure 26 shows the essential details of this molecule.[70]

Four points should be noted. (1) The W–W distance of 2.654(1) Å is close to that of a single bond distance found in edge-shared octahedral complexes of $W(5+)$, e.g. 2.715(1) Å in $W_2(OEt)_6Cl_4$ and certainly longer than the $W{=}W$ bond in $W_2(OEt)_4(HOEt)_2Cl_4$[24] and $W_2(OPr^i)_6(py)_2(CO)$. (2) The W–O (carbonyl) distance of 2.02 Å is much shorter than would be expected for a simple donor $O{\rightarrow}W$ distance. The W–O distance is approaching a W–OR terminal distance. (3) The C–O bond distance of 1.32 Å is close to that expected for a $C_{(sp^2)}$–O single bond distance. (4) The W–C (carbonyl) distance is shorter by *ca.* 0.1 Å than it is in the $W_2(OPr^i)_6(py)_2(\mu{-}CO)$ molecule. All four points are indicative of the importance of the resonance forms **XVa** and **XVb**.
XV a   **XV b**

Thus, in a simple sequence, the $W{\equiv}W$ and $C{\equiv}O$ bonds are transformed to single bonds, W–W and C–O, respectively. In a further reaction with $W_2(OPr^i)_6$, it appears that an additional two-electron reduction of the CO ligand occurs to give carbido and oxotungsten clusters. It is not yet clear how this proceeds: the stoichiometry of the reaction is not known. The structural characterization of $W_4(OPr^i)_{12}(NMe)(C)$, a molecule derived from the degradation of $W_2(OPr^i)_6(HNMe_2)_2$, reveals[71] the butterfly W_4C unit shown in Fig. 27 and bears a striking resemblance to the "iron-butterfly", $Fe_4(C)(CO)_{13}$.[72]

In the presence of excess CO, two other carbonyl compounds have been isolated and structurally characterized. $Mo(OBu^i)_2(py)_2(CO)_2$ is formed in the reaction between $Mo_2(OBu^i)_6$ and CO, in the presence of pyridine, and has a distorted octahedral geometry based on **XVI**.[40]

This molecule is characterized by unusually low $v(CO)$ values, 1906 and 1776 cm^{-1}, for *cis* dicarbonyl $Mo(2+)$ containing compounds. In part, this may be understood in terms of the RO

BuO

BuO

XVI
π-donating ability of the RO ligands. The C–Mo–C angle is also unusually small, 72°, and this presumably influences the magnitude of the CO coupling which is exceedingly large, $\Delta = 140 \text{ cm}^{-1}$.

Cotton and Schwotzer[70] have isolated a compound of formula $W_2(OPr^i)_6(CO)_4$ from the reaction between $W_2(OPr^i)_6(py)_2$ and CO. This molecule has the edge-shared octahedral geometry shown in **XVII**.

XVII
The W–W distance is greater than 3 Å, too long to indicate any W–W bonding. Also, the W–O distances associated with the $W_2(\mu_2\text{-}OPr^i)_2$ group are asymmetric, averaging 1.92 and 2.10 Å to W(1) and W(2), respectively. The compound may be viewed as a W(6+)–W(O) dimer in which a pair of alkoxy groups act as neutral ligands to a $W(CO)_4$ group. It is easy to see how $W(CO)_6$ and $W(OPr^i)_6$ could be derived by the further reaction with two equivalents of CO. In the reaction between CO and $Mo_2(OPr^i)_8$, an adduct, $Mo_2(OPr^i)_8(CO_2)_2$, was isolated[40] and was proposed to have the similar structure shown in **XVIII** based on the appearance of two CO bands at 1940 and 1820 cm^{-1}.
Fig. 27. ORTEP view of the central $W_4(C)(N)O_{12}$ skeleton of $W_4(\mu_4\text{-}C)$–$(\mu_2\text{-}NMe)(OPr^i)_{12}$. Some pertinent bond distances (Å) are: W(1)–W(3) = 2.799(2), W(1)–W(4) = 2.814(2), W(2)–W(3) = 2.822(1), W(2)–W(4) = 2.747(2), W(3)–W(4) = 2.795(2), W(1)–C = 1.91(1), W(2)–C = 1.96(1), W(3)–C = 2.25(1), W(4)–C = 2.24(1), W–O (terminal OR) = 1.90 (averaged), W–μ_2O (bridging OR) = 2.05 (averaged), W–μ–N = 1.94 (averaged).

XVIII
If for the sake of electron counting we split the bridge asymmetrically, this may be viewed as a Mo(6+)——Mo(2+) dimer. $Mo_2(OPr^i)_8(CO)_2$ would then be related to $Mo(OBu^t)_2(py)_2(CO)_2$, **XVI**.

2. *Addition of alkynes*

Hydrocarbon solutions of $Mo_2(OR)_6$ compounds (R = Bu^t, Pr^i and CH$_2$Bu^t) react rapidly with the sterically unencumbered alkynes, CH≡CH, MeC≡CH and MeC≡CMe. Ethyne produces an insoluble polymer of grey–black metallic appearance; propyne yields a yellow powdery material and but-2-yne gives a rubbery material. The detailed nature of these polymers are not known at present. The polymerization processes are very rapid at room temperature and, in an attempt to moderate these reactions and investigate the mechanism of polymerization, we carried out alkyne additions in the presence of donor ligands such as pyridine. This approach yielded a number of interesting compounds containing alkyne or alkyne fragments. For the isopropoxy ligand, compounds of formula $Mo_2(OPr^i)_6(py)_2(\mu-C_2RR')$ were isolated (R = R' = H, Me and R = Me, R' = H). The structure of $Mo_2(OPr^i)_6(py)_2(\mu-C_2H_2)$ is shown in Fig. 28, wherein a close resemblance can be seen to the $Mo_2(OPr^i)_6(py)_2(CO)$ molecule. In solution, these molecules are fluxional and show rapid reversible dissociation of pyridine on the NMR time scale.

With the less sterically demanding neopentoxy ligand, flyover compounds are formed and a view of the structurally characterized compound $Mo_2(OCH_2Bu^t)_6(py)(\mu-C_4H_4)$ is shown in Fig. 29. A number of interesting points emerge from a consideration of this structure. Whereas it is possible to view the $Mo_2(OPr^i)_6(py)_2(\mu-C_2H_2)$ molecule as a d^3-d^3 dimer with the bridging alkyne acting as a four-electron donor, in the $\mu-C_4H_4$ compound, the dimolybdenum center has clearly been oxidized. The Mo–Mo distance, 2.69(1) Å, is approaching that of a single bond distance. If the $\mu-C_4H_4$ ligand is counted as a 2-ligand with respect to Mo(1) and merely a η^4-diene to Mo(2), then the formal oxidation state of Mo(1) is $+4\frac{1}{2}$ and that of Mo(2) is $+3\frac{1}{2}$. The Mo(1)–μ–O distance, 2.06(2) Å, is notably shorter than the Mo(2)–μ–O distance, 2.17(2) Å, and the Mo(1)–N(pyridine)
Fig. 28. An ORTEP view of the central $Mo_2O_6N_2(\mu-C_2H_2)$ skeleton of the $Mo_2(OPr^i)_6(py)_2(\mu-C_2H_2)$ molecule. Some bond distances (Å) (averaged where appropriate) are: Mo–Mo = 2.554(1), Mo–O (terminal) = 1.94(2), Mo–O(μ_2) = 2.15(1), Mo–N = 2.31(1), Mo–C = 2.09(1) and C–C ($\mu-C_2H_2$) = 1.368(6).
Fig. 29. An ORTEP view of the $Mo_2(OCH_2Bu^t)_6(\mu\text{-}C_4H_4)(py)$ molecule. Some pertinent bond distances (Å) (averaged where appropriate) are: Mo–Mo = 2.69(1), Mo–O = 1.92(2), Mo–O (μ_2) = 2.15(2), Mo–N = 2.15(1), Mo–C (σ) = 2.12(2), Mo–C (π) = 2.37(2); C–C $(\mu\text{-}C_4H_4)$ = 1.45(2).

distance, 2.15(3) Å, is significantly shorter than those in $Mo_2(OPr^i)_6(py)_2(\mu\text{-}C_2H_2)$ which average 2.31(1) Å. In solution (toluene-d_8), the molecule is not fluxional on the NMR time scale and the pyridine ligand does not exchange with free pyridine. Only at +90°C do these processes become sufficiently rapid to cause line broadening.

The nature of the formation of the $\mu\text{-}C_4H_4$ ligand is evidently a simple coupling process since the ^1H NMR spectrum of the $\mu\text{-}C_4H_2D_2$ ligand formed from the addition of C_2H_2 to $Mo_2(OCH_2Bu^t)_6(py)_2(\mu\text{-}C_2H_2)$, is an AX spectrum whereas that of the protio ligand $\mu\text{-}C_4H_4$ is an AA'XX' spectrum at 220 MHz.

The possible role of these compounds in alkyne polymerization was investigated by a variety of labelling studies which showed that they were only involved in alkyne trimerization to give benzenes, e.g. as in eqns (14) and (15).[73]

$$Mo_2(OPr^i)_6(py)_2(MeC_2H) + 3HC{\equiv}CH \rightarrow Mo_2(OPr^i)_6(py)_2(HC_2H) + C_6H_5Me \qquad (14)$$

$$Mo_2(OCH_2Bu^t)_6(py)(\mu\text{-}C_4H_4) + 3DC{\equiv}CD \rightarrow Mo_2(OCH_2Bu^t)_6(py)(\mu\text{-}C_4D_4) + C_6H_4D_2. \qquad (15)$$
The catalytically active species in the polymerization process, which is kinetically more rapid than cyclotrimerization, is not yet known. It could conceivably be a carbene, vinylidene or carbyne function,[74] all of which could be derived from an alkyne.

Analogous reactions involving $W_2(OR)_6L_2$ compounds with C_2H_2 have led to the isolation of simple adducts $W_2(OR)_6(py)_2(\mu\text{-}C_2H_2)$ where R = Bu^t and Pr^i.[43] The isopropoxide is isostructural with its molybdenum analogue and shows similar solution behaviour. However, its reactivity is somewhat different. Addition of more ethyne leads to $W_2(OPr^i)_6(\mu\text{-}C_4H_4)(C_2H_2)$ presumably via an intermediate $W_2(OPr^i)_6(py)(\mu\text{-}C_4H_4)$ analogous to $Mo_2(OCH_2Bu^t)_6(py)(\mu_2\text{-}C_4H_4)$. Similarly, addition of 2-butyne to $W_2(OPr^i)_6(py)_2$ proceeds ultimately to give $W_2(OPr^i))_6(\mu\text{-}C_4Me_4)(C_2Me_2)$. The solid state structures of the compounds $W_2(OPr^i)_6(\mu\text{-}C_4R_4)(C_2R_2)$ where R = H and Me have been determined by X-ray studies and their dynamic solution behaviour investigated by variable temperature NMR studies. An ORTEP view of the $W_2(OPr^i)_{16}(\mu\text{-}C_4H_4)(C_2H_2)$ compound is given in Fig. 30 which provides the basis for a comparison with the $Mo_2(OCH_2Bu^t)_6(py)(\mu\text{-}C_4H_4)$ molecule. The W–W distance is 2.877(1) Å, indicative of a relatively weak M–M bond. This distance is ca. 0.2 Å longer than that in $Mo_2(OCH_2Bu^t)_6(py)(\mu\text{-}C_4H_4)$, consistent with the view that metal d electrons are effectively tied up in backbonding to the π-acceptor ligands. Tungsten, relative to molybdenum, is more easily oxidized and, in this instance, is reluctant to eliminate a benzene molecule.
Fig. 30. An ORTEP view of the $W_2(OPr^i)_6(\mu-C_4H_4)(C_2H_2)$ molecule. Some pertinent bond distances (Å), averaged where appropriate, are: W(1)–W(2) = 2.877(1), W(2)–C(3), –C(6) = 2.11(1), 2.14(1); W(1)–C(3), –C(4), –C(5), –C(6) = 2.42(1), 2.42(1), 2.40(1), 2.37(1); W(2)–C(7), –C(8) = 2.09(1), 2.06(1). The W–O distances fall within the range of W–OR terminal and μ_2 reported in Table 3.

As noted earlier, $W_2(OBu^t)_6$ reacts with 2-butyne to give $(Bu^tO)_3W{\equiv}CMe$.[64] Cotton and Schwotzer[70] have characterized $[(Bu^tO)_2W(\mu-CPh)]_2$ and $W_2(OBu^t)_4(\mu-C_2Ph_2)_2$ compounds from reactions involving $W_2(OBu^t)_6$ and $PhC{\equiv}CPh$. The structure of the former compound is similar to that observed for $[(Me_3SiCH_2)_2W(\mu-CSiMe_3)]_2$,[76] while the latter contains a planar W_2O_4 moiety with terminal OBu^t ligands with two skewed bridging μ–acetylene ligands. It is evident that a wide variety of products are derived from reactions involving alkynes and $M_2(OR)_6$ compounds and that steric and electronic factors and reaction conditions are critical in controlling the course of the reaction.

3. Alkyl–alkoxides of dimolybdenum $(M{\equiv}M)$

Two approaches to the synthesis of mixed alkyl–alkoxides of dimolybdenum $(M{\equiv}M)$ have been taken. One involves metathetic reactions wherein an alkyl ligand or an alkoxy ligand is introduced to the dimetal center, e.g. as in (16)[11] and (17).[77]

$$1,2\text{-}Mo_2Br_2R_4 + 2LiOR' \rightarrow 1,2\text{-}Mo_2(OR')_2R_4 + 2LiCl \tag{16}$$

where $R = CH_2SiMe_3$, $R' = Bu^t$ or Pr^i.

$$Mo_2(OBu^t)_6 + 2ZnMe_2 \rightarrow 1,2\text{-}Mo_2Me_2(OBu^t)_4 + \tfrac{1}{2}[Zn(Me)OBu^t]_4. \tag{17}$$

The other approach involves the alcoholysis of $1,2\text{-}Mo_2R_2(NMe_2)_4$ compounds. The latter reaction yield products dependent on the nature of the alkyl ligand as is shown in (18) and (19).[78]

$$1,2\text{-}Mo_2R_2(NMe_2)_4 + R'OH \rightarrow 1,2\text{-}Mo_2R_2(OR')_4 + 4HNMe_2 \tag{18}$$
where $R = Me$, $R' = Bu^t$; $R = CH_2CMe_3$, CH_2SiMe_3 and $R' = Bu^t$, Pr^i, CH_2CMe_3 and Et.

$$1,2\text{-}Mo_2R_2(NMe_2)_4 + R'OH \rightarrow Mo_2R(OR')_5 + RH + 4NMe_2 \tag{19}$$

where $R = Et$ and Pr; $R' = Bu^t$ and Pr^i.

The rate of alcoholysis is dependent on the steric factors of R and R', being much slower for bulky combinations. Alcoholysis is faster for $Mo-NMe_2$ groups than for Mo–R groups, but the thermodynamically favoured products in (18) and (19) are $Mo_2(OR')_6$ compounds, and these are

ultimately formed under prolonged alcoholysis. For example, while $Mo_2Me_2(NMe_2)_4$ reacts rapidly with $Bu'OH$ to give $Mo_2Me_2(OBu')_4$, further reaction to give $Mo_2Me(OBu')_5$ and $Mo_2(OBu')_6$ occurs more slowly.

The failure to isolate or even detect $Mo_2R_2(OR')_4$ compounds, where $R = Et$ and Pr and $R' = Bu'$ and Pr^i, suggested a β-hydrogen elimination pathway was involved. This was confirmed and delineated in the following reactions.[78] (1) When $Mo_2(CH_2CD_3)_2(NMe_2)_4$ and $Mo_2\{CH(CD_3)_2\}_2(NMe_2)_4$ were allowed to react with $Bu'OH$, the eliminated alkanes were CH_2DCD_3 and CD_3CHDCD_3, respectively. (2) When $Mo_2(CH_2CH_3)_2(NMe_2)_4$ was allowed to react with $Bu'OD$, the resulting ethyl complex was $Mo_2(CH_2CH_2D)(OBu')_5$. Evidently the elimination of alkane involves the transference of a β-hydrogen (or deuterium) from one alkyl group to the α-carbon of the other, and the resultant ethyl ligand is formed from the hydrogen atom (deuterium) of the hydroxyl group of the alcohol and a coordinated alkene. A reductive–elimination and oxidative–addition sequence of the type schematically represented by (20a, b and c) is implicated.

$$Et–Mo\equiv Mo–Et \rightarrow Mo\equiv Mo + C_2H_6 + C_2H_4 \qquad (20a)$$

$$Mo\equiv Mo + ROH \rightarrow RO–Mo\equiv Mo–H \qquad (20b)$$

$$RO–Mo\equiv Mo–H + C_2H_4 \rightarrow RO–Mo\equiv Mo–Et. \qquad (20c)$$
Each step has precedence in the dinuclear chemistry of molybdenum and tungsten. (1) Reductive elimination by alkyl group disproportionation has been observed in the reactions between $Mo_2Et_2(NMe_2)_4$ and CO_2, reaction (21).[79]

$$Mo_2(CH_2CD_3)_2(NMe_2)_4 + CO_2 \rightarrow Mo_2(O_2CNMe_2)_4 + CH_2{=}CD_2 + CH_2DCD_3. \qquad (21)$$

(2) Oxidative-addition of ROH to a $W–W$ triple bond is seen in the formation of $W_4(\mu–H)_2(OPr^i)_{14}$.[35] (3) Insertion of alkenes into metal hydrides is, of course, well documented in organometallic chemistry and $W_2(\mu–H)_2(OPr^i)_{14}$ reacts reversibly with ethylene.[35]

Further evidence for the sequence in (20) is seen in the observation that $Mo_2Bu_2^i(NMe_2)_4$ reacts with Pr^i OH to give an intense blue solution which by ^1H NMR can be seen to contain a Mo_2-hydride ($\delta = 6.7$ ppm). This probably is a confacial bioctahedral compound: $Mo_2(OPr^i)_3(\mu–H)(\mu–OPr^i)_2(HNMe_2)_3$. Addition of ethylene gives $Mo_2Et(OPr^i)_5$.

One other interesting feature of (19) concerns the insertion step forming the alkyl. In reactions involving $Mo_2R_2(NMe_2)_4$ with $Bu'OH$, where $R = Pr^i$, Pr^n and Bu^i, the products are $Mo_2Pr^i(OBu')_5$ and $Mo_2Bu^i(OBu')_5$. In the reaction between $Mo_2Pr_2^n(NMe_2)_4$ and Pr^iOH, the initially formed compound is $Mo_2Pr^i(OPr^i)_5$ which, in the absence of donor ligands such as $HNMe_2$, is quite stable. However, upon addition of donor ligands, $HNMe_2$ or py, isomerization to $Mo_2Pr^n(OPr^i)_5$ is observed. It is apparent that (1) the insertion of the alkene ligand occurs with kinetic control and (2) that isomerization of the alkyl ligand by a β-hydrogen elimination process does not readily occur for $Mo_2R(OR')_5$ compounds, but that this may be promoted by a Lewis base association reaction.

It is possible to rationalize these observations in the following way. (1) The metal–hydride insertion step occurs across the M–M bond and thus the conformational preference for alkene coordination with its alkyl substituent(s) distal to the M–M bond will generate, upon hydride insertion, the most highly substituted carbon being σ-bonded to molybdenum. (2) The strongly π-donating RO ligands will effectively tie up empty molybdenum atomic orbitals which would otherwise be available for M----H–C interactions leading to M–H and alkene. This stabilization of β-hydrogen containing alkyls has been discussed in detail in connection with $M_2R_2(NMe_2)_4$ compounds.[37] (3) In the presence of donor ligands, the coordination of a ligand to one metal activates the other toward β-hydrogen abstraction. This may be viewed as another aspect of the cooperative binding of $M_2(OR)_6$ compounds, reaction (2), discussed previously.

A common intermediate of the type shown in **XIX** can be envisaged.

When $X = R$ (alkyl), elimination of alkane occurs. When $X = OR$, insertion will lead to $Mo_2\{CH(CH_3)R'\}(OR)_5$, where $R' = H$ or Me. A subsequent isomerization of the alkyl ligand may occur in the presence of L providing the alkene can ultimately gain access to a position with the alkyl group(s) over the M–M bond. Alternatively, if the Lewis base coordinates to the $Mo(OR)_3$

R'
CH₃ ════ H
        OR   X
    Mo ════ Mo   **XIX**
L'   │   RO' │
    RO   RO
end of the molecule, β-hydrogen abstraction followed by an insertion to give the isomerized alkyl may occur at the other metal. Clearly more work is required to delineate the intricacies of these reactions.

4. Olefin– and acetylene–metathesis reactions

One of the most fascinating reactions to capture the minds of organic and organometallic chemists within recent years is the olefin metathesis reaction.[80,81] There is now a large body of evidence to support the intimate mechanism originally proposed by Chauvin[82] which is depicted by (22).

$$M{=}CHR + R'CH{=}CH_2 \rightarrow M \underset{\underset{R'}{\overset{|}{CH}}}{\overset{\overset{R}{\overset{|}{CH}}}{<}} CH_2 \rightarrow M{=}CHR' + RCH{=}CH_2 \qquad (22)$$
Schrock et al.[83] have shown that niobuim and tantalum alkylidene complexes can indeed promote olefin metathesis. One of the terminating steps and breakdown in the catalytic cycle involves a β-hydrogen elimination step either from the metallacycle or from the alkylidene complex as shown in (23) and (24).

$$M \underset{CH_2}{\overset{CH_2}{<}} CH_2 \rightarrow M + \underset{CH_2}{\overset{CH_3}{>}} CH \qquad (23)$$

$$M{=}C \overset{H}{\underset{CH_2R}{<}} \rightarrow M + CH_2{=}CHR. \qquad (24)$$
In both (23) and (24), β-hydrogen abstraction is followed by reductive elimination of alkene by C–H bond formation. The net effect is a 1,2-H atom shift. Schrock et al. have shown that these competing β-hydrogen abstraction reactions can be greatly suppressed by replacing Cl by RO ligands.[84] Tungsten(VI) oxo, imido and alkoxy alkylidene complexes are amongst the best homogeneous olefin metathesis catalysts known.[83] The role of the ancillary π-donor ligands in the olefin metatesis reaction has recently been the subject of a theoretical study: the so-called spectator group effect.[85]

The alkoxy–alkylidyne complexes $(Bu^tO)_3W{\equiv}CR$ are efficient alkyne metathesis catalysts. There is good evidence to support the view that alkyne metathesis proceeds via the intermediacy of the tungstenacyclobutadiene as shown in eqn (25).

$$M \equiv CR + R'C \equiv CR' \longrightarrow \quad \text{[structure]} \quad \longrightarrow M \equiv CR' + R'C \equiv CR \qquad (25)$$
When chloride ligands are on tungsten, a tungstencyclobutadiene complex, **XX**, has been isolated and structurally characterized[86] and found to have a trigonal bipyramidal geometry with one W–Cl and two W–C bonds in the equatorial plane.

XX
Further reaction with another molecule of dimethylacetylene gives $(\eta^5\text{-}C_5Me_4R)WCl_3$: tungsten is reduced from $+6$ to $+4$. However, when alkoxy ligands are present, the alkylidyne complex is stabilized relative to the metallacyclobutadiene and the ultimate formation of the π-cyclopentadiene $W(4+)$ complex is not observed. Interestingly, one Bu^{t}O ligand can be introduced into the equatorial site replacing Cl in **XX**, but a further Bu^{t}O for Cl substitution reforms the alkylidyne complex, eqn (26).

$$\text{[structure]} \quad \xrightarrow{\text{LiOBu}^t} \quad (Bu^tO)_3W \equiv CR \qquad (26)$$
where $R = Bu^t$ or Me

The Bu^{t}O ligands favour the alkylidyne ligand, relative to the metallacyclobutadiene; they suppress β-hydrogen elimination and favour the oxidation state $+6$ for tungsten.

V. CONCLUDING REMARKS

Metal–metal bonds are pervasive in the chemistry of molybdenum and tungsten alkoxides. They may modify structures found for d^0 metal alkoxides as is seen for $W_4(OEt)_{16}$ or may provide for totally new geometries as is seen for the $M_2(OR)_6$ compounds. Metal–metal bonds provide a reservoir of electrons for redox chemistry: the reservoir may be tapped in oxidative-addition reactions and may be filled in reductive–elimination processes. Alkoxide ligands may act as four- or two-electron donors and may readily change between terminal and bridging positions. This allows for the facile interconversion of saturated and unsaturated metal centers. As π-donor ligands, they can enhance backbonding to π-acid ligands on the same metal; they can tie up vacant metal d orbitals and suppress metal–hydride abstraction from coordinated alkyl ligands and they stabilize metals in high oxidation states. A variety of steric control may be engineered by suitable choice of alkyl group and this may greatly influence structure, M–M bonding and the reactivity

of coordinated ligands. This is well illustrated in the reactions of $MeC{\equiv}CMe$ with $W_2(OBu^t)_6$ and $W_2(OPr^i)_6$ which lead to $(Bu^tO)_3W{\equiv}CMe$ and $W_2(OPr^i)_6(\mu-C_4Me_4)(MeC_2Me)$. It is now clear that an extensive organometallic chemistry can be supported in the absence of ligands commonly employed in organometallic chemistry.

ADDENDUM

Since the submission of this Report, two particulary significant findings have been made which warrant mention here.

(1) From the reaction between $Mo_2(Bu^i)_2(NMe_2)_4$ and Pr^iOH in hexane/pyridine solvent, the crystalline compound $Mo_2(OPr^i)_4(py)_4$ has been isolated and structurally characterized.[87] This compound is the first M–M quadruple bond supported by RO ligands[88] and its isolation in the reaction between $Mo_2(Bu^i)_2(NMe_2)_4$ and Pr^iOH supports

the proposed reductive–elimination sequence **20a**. The molecular structure of $Mo_2(OPr^i)_4(py)_4$ is depicted in **XXI** below and is typical in conformation to that seen for many other $Mo_2X_4L_4(M \equiv M)$ compounds.[88]
XXI

Of particular note, however, are the Mo–Mo distances, 2.195(1)Å, and the Mo–O distances, 2.030(3) Å (averaged). The Mo–Mo distance is the longest thus far seen for a Mo–Mo quadruple bond[88] and the Mo–O distances are the longest known for Mo–OR (terminal) bonds (see Table 3). The lengthening of these bonds can be understood in terms of the mutual influence of alkoxy-π-donor ligands and the Mo–Mo quadruple bond. The metal d orbitals are used to form M–M bonds, $d_{z^2}(\sigma)$, d_{xz}, $d_{yz}(\pi)$ and $d_{xy}(\delta)$, and metal ligand bonds, $d_{x^2-y^2}$, along with s and p_x and p_y. The Mo–OR σ-bonds are thus not supplemented by RO-to-Mo π bonds: the observed Mo–OR distances are close to the value 2.06 Å predicted for d(Mo–O) as a single bond in $Mo_2R_2(OR)_4$ compounds (see section entitled *Physical Evidence for RO-to-M π-Bonding*). To the extent that RO-to-Mo π-bonding does occur in $Mo_2(OPr^i)_4(py)_4$, this will weaken and lengthen the Mo–Mo bond, since it will destabilize the M–M π and δ bonds.

(2) Though $W_2(OPr^i)_6(py)_2(\mu\text{-}C_2H_2)$ is isostructural with its molybdenum analogue (Fig. 28), the compound believed to be $W_2(OBu^i)_6(py)_2\text{-}(\mu\text{-}C_2H_2)$ has now been shown to be $W_2(OBu^i)_6(py)(\mu\text{-}C_2H_2)$ with a solvent molecule of pyridine in the unit cell.[89] Each tungsten atom is in a distorted trigonal bipyramidal geometry. There is a perpendicular acetylene bridge (perpendicular to the M–M bond) which occupies a common equatorial bridging position and a bridging OBu^t ligand which provides a common axial site as shown schematically in **XXII** below.
XXII

Of further interest are the W–W distance, 2.667(1) Å, and the C–C (acetylene) distance, 1.441(14) Å, both of which are longer than those in $W_2(OPr^i)_6(py)_2(\mu\text{-}C_2H_2)$. It is, of course, not clear whether this has any relevance to the fact that $W_2(OBu^t)_6$ and $MeC \equiv CMe$ react to give two equivalents of $(Bu^tO)_3W \equiv CMe$, eqn (6). However, we have found that, whereas $W_2(OBu^t)_6$ and $MeC \equiv N$ react to give methylcarbyne and nitrido tungsten compounds, eqn (7), the addition of $MeC \equiv N$ to $W_2(OR)_6(\mu\text{-}C_2R_2)$ compounds yields $W_2(OR)_6(\mu\text{-}NC_4R_2Me_2N)$ compounds containing a ligand derived from coupling one $C \equiv C$ and two $C \equiv N$ bonds.[90] For example, $MeC \equiv CMe$ and $MeC \equiv N$ give the ligand which may be viewed as the deprotonated 4-anion of **XXIII** below.

COMPLEXES OF ZINC, CADMIUM AND MERCURY(II) WITH THE ZWITTER-IONIC FORM OF NN'-ETHYLENEBIS (SALICYLIDENEIMINE)

H. A. TAJMIR-RIAHI*

Department of Chemistry, University of Aburayhan-Birouni, Tehran P.O. Box 2719, Iran

Abstract—The Schiff base NN'-ethylenebis(salicylideneimine), H_2 salen reacts with hydrous and anhydrous Zinc, Cadmium and Mercury(II) salts to give complexes $M(H_2$ salen$)X_2 \cdot nH_2O$ (M = Zn, Cd, Hg; X=Cl, Br, I, NO_3; M=Zn, X_2=SO_4; n = 0-2). Spectroscopic and other evidence indicated that; (i) halide and sulphate are coordinated to the metal ion, whereas the nitrate group is ionic in mercury nitrate compound and covalently bonded in zinc and cadmium nitrato complexes, (ii) the Schiff base is coordinated through the negatively charged phenolic oxygen atoms and not the nitrogen atoms, which carry the protons transferred from phenolic groups on coordination, (iii) therefore the coordination numbers suggested are 4-, in mercury and 4- or 6- in zinc and cadmium Schiff base complexes.

Schiff bases derived from salicylaldehyde, such as NN'-ethylenebis (salicylideneimine), H_2 salen are well known as poly-dentate ligands[1,2] coordinating in two ways.

In the first (and better understood), the ligand is ionised by removal of the phenolic protons giving complexes such as Zn(salen).[3] In the second the Schiff base is apparently either un-ionised[4,5] or partly ionised.[6] In this case the metal ion has class A character: lanthanides,[4,5] actinides,[7] Ti(IV),[8] Zr(IV),[9] Sn(IV),[10,11] Co(II)[12] and Fe(III).[13] Typical examples are TiCl$_4$(H$_2$ salen),[8] UCl$_4$(H$_2$ salen)thf[7] (thf = tetrahydrofuran) and LaCl$_3$(H$_2$ salen)$_2$.[4] There has been no report on un-ionised Schiff base complexes of the class B metal cations such as Zn,[11] Cd[11] and Hg.[11] Although many examples (Bullock and Tajmir-Riahi references therein)[4] of the second type are known, until very recently the structures of this type of complex were unknown. Some authors[14] have supposed that the Schiff base is coordinated through the phenolic oxygen since an enol-imine(I) to ketoenamine(II) tautometric conversion is possible; evidence for this came from IR and UV spectroscopy. From essentially identical IR results, other workers[4,7-11] suggest that the Schiff base is coordinated only through the azomethine nitrogen atoms, with the ligand remaining in the enol-imine form in the complexes.

Recently we have reported[15] the structure of Ca(H$_2$L)(NO$_3$)$_2$, H$_2$L=NN' - propane - 1.3 - diylbis (salicylideneimine), (H$_2$sal-1,3pd), in which the Schiff base is best described by the third tautomer(III), namely, the charge-separated (zwitter-ionic) form. Coordination takes place through the negatively charged oxygen atoms only (not the nitrogen atoms, which carry the proton transferred from the phenolic groups on coordination) and bi-dentate nitrate groups.

The changes observed on comparing the IR spectra of this compound and the free Schiff base in the C=N stretching region are the same for the complexes discussed in this work as for the other compounds.[4,5,7-11]

(III)
RESULTS AND DISCUSSION

The thirteen new complexes (M=Zn, Cd, Hg) with H$_2$salen which have been prepared are shown with analytical data and millimolar conductance in Table 1. The low molar conductivities[16] of 1×10^{-3}M solutions of the halide and sulphate complexes in dimethylformamide, dimethylsulphoxide and butanol (in the range 5–30 Ω^{-1} cm^2) indicate non-electrolytic behaviour, while the nitrate complexes show considerable dissociation in these solvents (Λ_M = 83–155 Ω^{-1} cm^2), this is due to some ligand exchange between the strong donors DMF, DMSO and the weakly bonded nitrate group in the coordination sphere of these metal ions in these solvents.[17]

IR spectroscopy

(a) 4000–2000 cm^{-1}. In this region, the free Schiff base shows a strong intramolecular hydrogen bonding (O–H . . . . N)[4] which gives rise to a broad absorption near 2700 cm^{-1}; this band shifts to 3000 cm^{-1} in the spectra of metal complexes as the hydrogen bonding arrangements change (O . . . . H$^+$—N).[15]

On examining the IR spectra of the complexes with fully ionised Schiff base, there is neither absorption near 2700 or at 3000 cm^{-1}; in these complexes only the aliphatic and aromatic C–H vibrations are observed. For the hydrated complexes an additional broad band near 3400 cm^{-1} was assigned to water molecules.

[a]Calc. analyses in parentheses; [b]millimolar conductance values in c DMF, d butanol, e DMSO.

(b) 2000–600 cm^{-1}. The main features of this region relevant to the present discussion for the ligand and the complexes are listed in Table 2. A strong absorption band at 1630 cm^{-1} was assigned to C=N stretching frequency in the free ligand which shifts to a higher frequency at about 1650 cm^{-1} in metal complexes ($\Delta \bar{\nu}$ 8–35 cm^{-1}). It has been found[18] that C=N$^+$ groups have in general higher frequencies than the parent C=N groups, thus the results are consistent with the presence of charge-separated forms and these and the other complexes[4,5,7–11,14,15] are likely to be structurally related in that the coordination takes place through the nega-

tively charged phenolic oxygen atoms rather than the positively-charged nitrogen atoms of the azomethine groups. A sharp absorption at 1280 cm^{-1} assignable to C–O stretching vibration in the free base changes little on complex formation ($\Delta \bar{\nu} - 10$ to $+17$ cm^{-1}). The C–O stretching vibration must include considerable contributions from the skeletal vibrations of the aromatic ring and because the vibration changed little in the complexes it was suggested[15] that the bonding arrangements of the oxygen atoms were the same in the free Schiff base and the metal complexes.

On comparing the IR spectra of these complexes with

Table 2. Selected IR bands (cm^{-1}) for the ligand and metal complexes

Ligand	Complexes	C=N	C-O	M-O (ligand)	Other bands

	Hg(H_2salen)I_2	1640 s	1290 s	480 m	---		
	Hg(H_2salen)(NO_3)$_2$·$2H_2O$	1640 s	1290 m	505 m	---		
	Hg(salen)	1610 vs	1275 s	520 m	550	s	Hg-N

s, strong; b, broad; v, very; m, medium.

the fully ionised Schiff base compounds one can see that the C=N stretching vibration of the free ligand has fallen on complex formation and the C–O stretching vibration increased to a higher frequency (Table 2). Therefore the results are consistent with those of the structurally known ionised complexes such as U(salen)Cl$_2$·2thf[7,19] where the coordination took place via the phenolic oxygen atoms and the nitrogen atoms of the azomethine groups.

Nitrate complexes

The IR spectra of Hg(H$_2$ salen)(NO$_3$)$_2$·2H$_2$O showed a broad and strong absorption band centered at 1370 cm^{-1} which was related to the presence of the ionic nitrate[20] in this compound, whereas the absence of the said absorption in the spectra of the Zn(H$_2$ salen)(NO$_3$)$_2$·2H$_2$O and Cd(H$_2$ salen)(NO$_3$)$_2$·2H$_2$O with the presence of the strong absorption from ν_1 (1480–1500 cm^{-1}), ν_2(1020–1030 cm^{-1}), ν_4(1280–1300 cm^{-1}) and ν_6(820 cm^{-1}) was indicative of the coordinated nitrate group in C$_{2v}$ symmetry[21,22] in these two nitrato complexes. The weak fundamentals ν_4 (720 cm^{-1}) of the ionic nitrate and ν_3 and ν_5 of bonded nitrato group were masked by the strong ligand absorption (700–800 cm^{-1}).

Sulphate complex

On comparing the spectra of the free ligand and the halide complexes with the sulphate compound, the sulphate spectra were dominated by the strong absorption from ν_3(1190, 1155 and 1120 cm^{-1}), ν_1(998 cm^{-1}), ν_2(450 cm^{-1}) and ν_4(610, 640 cm^{-1}) of the sulphate group in C$_{2v}$ symmetry.[23,24] Therefore the sulphate group must act as a chelated ligand in this compound.

(c) 600–200 cm^{-1}. A broad band in the spectra of the halide complexes around 200–300 cm^{-1} may be associated with metal–halide stretching vibrations[25,26] (Table 2). However conclusive evidence regarding the bonding of M–O[25] of the ligand has been provided by the occurrence of the strong absorption band at about 500 cm^{-1} in the spectra of the metal complexes (Table 2). The metal-oxygen[25] stretching vibrations of the coordinated anions (nitrato and sulphato) were found near 250–350 cm^{-1} in the spectra of zinc and cadmium complexes. A sharp, strong absorption around 550–600 cm^{-1} in the spectra of the fully ionised Schiff base complexes, M(salen), is attributed to M–N stretching.[27]

CONCLUSION

On the basis of the properties of the complexes studied here, some features can be emphasized: (a) the ligand is coordinated through the phenolic oxygen atoms only, (b) the halides and sulphate are bonded to the metal ions, (c) the nitrate group has shown ionic character in the mercury nitrate compound but covalently bonded in the corresponding zinc and cadmium Schiff base complexes, (d) therefore the mercury ion would be 4-coordinated in these series of Schiff base complexes whereas the zinc and cadmium ions could have 4-coordination in halo and sulphato and 6-coordination in nitrato (except for Hg(II)nitrate) complexes with possible tetrahedral or octahedral geometry around these metal cations.

EXPERIMENTAL

Materials

All the chemicals were reagent grade. The ligand was prepared by routine method.[3]

Preparation of the complexes

Most of the complexes were prepared by the addition of the stoichiometric amount of the hydrous or anhydrous metal ion salt in absolute ethanol or methanol (containing 1% water) to a hot solution of the ligand in absolute ethanol. A yellow precipitate formed almost immediately. This was filtered off and washed with hot ethanol and ether several times and dried (CaCl$_2$). The complexes are not soluble in common organic solvents, only dissolve in dimethylformamide, dimethylsulphoxide and slightly hot alcohol. Many unsuccessful attempts were made to prepare the Schiff base complexes of cadmium and mercury sulphate due to the insolubility of CdSO$_4$ and HgSO$_4$ in alcohol.

Analysis of the complexes

The metal ions were determined complexometrically,[28] halides as silver halide and sulphate ion as BaSO$_4$, nitrate was analyzed by precipitation with nitron[28] and nitrogen was estimated by Kejeldahl's method.[28]

Vibrational spectra

IR spectra were obtained on Perkin–Elmer 598 (4000–200 cm^{-1}) using Nujol and Hexachlorobutadien mulls technique with KBr and polyethylene disks.

Conductance measurements

Conductivity measurements were made in 10^{-3} M dimethylformamide, dimethylsulphoxide and butanol solutions at 25°C with a CDM2e conductivity meter (Radiometer, Copenhagen).

A RADIOCHEMICAL INVESTIGATION OF YbCl$_3$–(AlCl$_3$)$_n$ COMPLEXES IN THE GAS PHASE

G. STEIDL, F. DIENSTBACH and K. BÄCHMANN*

Fachbereich Anorganische Chemie und Kernchemie, Technische Hochschule Darmstadt, 6100 Darmstadt, Federal
Republic of Germany

Abstract—The vapour densities of complex species in the YbCl$_3$/AlCl$_3$ system were investigated by using tracer ^{169}Yb. The results obtained allowed a description of the equilibria in the vapour phase in the temperature range from 500 to 1000 K. The equilibrium constants according to YbCl$_{3(s)}$ + n*Al$_2$Cl$_{6(g)}$⇌YbAl$_{2n}$Cl$_{6n+3(g)}$ were fitted to expressions of the form log K_p = A + (B/T) and the thermodynamic values of ΔH and ΔS were calculated.

$$YbCl_{3(s)} + 0.5\ Al_2Cl_{6(g)} \rightleftharpoons YbAlCl_{6(g)} \qquad \Delta H_{298} = 149.9(\pm 13)kJ/mol$$
$$\Delta S_{298} = 124.4(\pm 13)J/mol\ K$$

$$YbCl_{3(s)} + 1.0\ Al_2Cl_{6(g)} \rightleftharpoons YbAl_2Cl_{9(g)} \qquad \Delta H_{298} = 87.5(\pm 13)kJ/mol$$
$$\Delta S_{298} = 47.7(\pm 13)J/mol\ K$$

$$YbCl_{3(s)} + 1.5\ Al_2Cl_{6(g)} \rightleftharpoons YbAl_3Cl_{12(g)} \qquad \Delta H_{298} = 27.6(\pm 4)kJ/mol$$
$$\Delta S_{298} = -11.5(\pm 8)J/mol\ K$$

$$YbCl_{3(s)} + 2.0\ Al_2Cl_{6(g)} \rightleftharpoons YbAl_4Cl_{15(g)} \qquad \Delta H_{298} = 0(\pm 4)kJ/mol$$
$$\Delta S_{298} = -65.9(\pm 10)J/mol\ K.$$
The formation of gaseous complexes has gained in significance in the preparative chemistry and in industrial problems. Slightly volatile halides can be transported chemically through temperature gradients and the combination of this chemical transport together with other reactions leads to new synthetic routes.[1–3] The halides of the lanthanides are important in the development of high pressure discharge tubes. The halides are decomposed in the plasma and reformed near the wall. To increase the saturation of the halides the addition of complex formers is necessary, e.g. CeI$_3$ + NaI + CsI.[4–6]

A further field of application of gaseous complexes is the separation of lanthanides and actinides by gas chromatography of the aluminium chloride complexes.[7–9] Like many other complexes[1] the aluminium chloride–lanthanide chloride system presents a special problem containing several complexes.[10–16] The general methods used to investigate these aluminium chloride–lanthanide chloride systems and to determine the thermodynamic values are UV-Vis spectrometry[10,11,17] and entrainment, quenching and chemical transport experiments[14] and mass spectrometric investigations.[16] The applications of these methods are limited. At temperatures above 850 K spectrometric methods are not useful because the AlCl$_3$ attacks the cell. At temperatures lower than 650 K it is difficult to investigate the complex systems because of the small absorbances measured. Mass spectrometric investigations allow pressures up to 10^{-1} atm only.[18,19] The entrainment experiments are limited to low pressures, too.

To get further information on the equilibrium and on the thermodynamic data of the lanthanide chloride–aluminium chloride system we have applied a new method suggested by Peterson *et al.*[12] The basic idea is to use a heated quartz tube and to measure the radioactivity of ^{169}YbCl in the vapour as a function of the temperature, knowing the amount of solid YbCl$_3$, ^{169}YbCl$_3$ and AlCl$_3$ at the start of the experiments. The γ-counting rate of ^{169}Yb is related to the vapour density of the complexes in the gas. The vapour pressure of pure YbCl$_3$ is negligible in the temperature range measured. The advantages of this measuring system are:

(a) The method is useful for volatile inorganic species, which are not accessible to spectrometric techniques.

(b) The method allows investigation of the system at low temperatures and at low complex concentrations by adding elevated amounts of tracer ^{169}Yb (important for the determination of the vapour density of the large YbAl$_4$Cl$_{15}$-complex).

(c) The method allows measurement of the vapour densities of the complexes at elevated temperatures (1000 K) and pressures (5 atm).

In the present study we have investigated the YbCl$_3$–AlCl$_3$-system in the temperature range from 500 to 1000 K. Like the other lanthanide chloride–aluminium chloride complexes YbCl$_3$ can be expected to react with AlCl$_3$ according to the general equation

$$YbCl_{3(s)} + n^*Al_2Cl_{6(g)} \rightleftharpoons YbAl_{2n}Cl_{6n+3(g)}. \qquad (1)$$

The occurrence of the gaseous complex is responsible for increased concentrations of the lanthanide in the gas phase.

EXPERIMENTAL

AlCl$_3$ was prepared by passing chlorine over analytical grade aluminium metal at temperatures of 600 K. The chlorine was dried by passage through sulphuric acid and phosphorus pentoxide. The aluminium chloride was sublimed under a chlorine atmosphere into a quartz tube and flushed with dry helium (99.999%, passed through a cold trap at −190°C).

furnace

Fig. 1. Schematic diagram of the experimental section.

In order to prepare $YbCl_3$, dry Yb_2O_3 was transferred to a quartz tube containing a great excess of $AlCl_3$ (Fig. 1). The tube was flushed with helium, evacuated and sealed, then placed in a furnace and slowly heated to 600 K. Yb_2O_3 reacted with $AlCl_3$ according to equation

$$Yb_2O_{3(s)} + Al_2Cl_{6(g)} \longrightarrow Al_2O_{3(s)} + 2YbCl_{3(s)}. \qquad (2)$$
This method was worked out and reported by Papatheodorou *et al.*[11] for preparing some lanthanide chlorides and $ThCl_4/AlCl_3$ by reaction of the corresponding oxide with $AlCl_3$. Under a helium atmosphere known amounts of $YbCl_3$, irradiated $^{169}YbCl$, and $AlCl_3$ were transferred to a helium flushed cylindrical quartz tube. The quartz tube was evacuated and sealed, then placed into a furnace surrounded by a shield of lead bricks except for a detection slot (Fig. 2). (Size of the quartz tube: $\emptyset_i = 6.5$ cm, $1 = 30$ cm, volume = 40 cm³.)

The furnace consists of three resistance-heated, 1 mm thick Kantal wires around a ceramic tube (26 mm I. D., 35 mm O. D.). The furnace is insulated with a 40 mm thick "ceramic fibre felt", which guarantees a sufficient uniform temperature distribution inside the ceramic tube. Thermocouples are used for temperature measurement and control. The three parts of the oven have separate temperature controls allowing as well isothermal as temperature-programmed operation with constant heating and cooling rates.[20] The temperature gradient along the furnace was adjusted so that the temperature of the detection point was 3–4°C higher than that of the sample containing the end of the tube. The non-volatilized portion of the $YbCl_3$, thus, remained outside of the detection volume. Reported temperatures were those of the cooler end of the tube, because the equilibrium between Al_2Cl_6 and $YbCl_3$ was established over the condensed phase.[12] In the temperature range measured the vapour pressure of pure $YbCl_3$ did not contribute to the γ-ray measuring.[21]
Fig. 2. Schematic diagram of the experimental set-up.

For the detection of the radioactive compound a Ge–Li-detector was used, placed outside the furnace at the opposite side of the cool end of the quartz tube. It was surrounded by lead bricks so that only the γ-rays of a small section were detected and the background counting rate was less than 1% of the maximum counting rate obtained when all the $YbCl_3$ was in the vapour phase.

The γ-rays of $^{169}YbCl_3$ were measured several times for ascending and descending temperatures. To calculate the concentration of ytterbium chloride in the vapour phase the average values of the γ-countings of every measuring point were used.

The experiments were evaluated for temperatures between 500 and 1000 K only. At temperatures below the triple point of $AlCl_3$ (T ~ 460 K) a solid vapour interface can exist.[12] The solids which are present can be $AlCl_3$, $LnCl_3$ (Ln = lanthanides) and/or a solid solution of the two.[15] At temperatures between 460 and 500 K a region of liquid–vapour equilibrium exists.[11–13] A break in the plot of the complexed metal ion quantity vs the temperature curve indicates the physical change of the condensed phase from solid to liquid.[12,13,22] The nature of these phases in the vicinity of the triple point are not well known.[12] The reaction of $AlCl_3$ with quartz was investigated by Schäfer *et al.*[23] Despite favourable thermodynamics the reaction does not occur to any significant extent below 1000 K.

In order to determine the vapour complex density and thermodynamics of the $AlCl_3/YbCl_3$-system the following experiments were performed: Five different $YbCl_3$ and $AlCl_3$ weight-ins the γ-peak contents of ^{169}Yb in dependence of the corresponding temperatures are recorded in 5 K intervals from 500 to 1000 K. To maintain equilibrium, ascend and descend rates of 0.4 K/min are sufficient for high reactant concentrations, for lower $AlCl_3$ weight-ins, ascend rates lower than 0.1 K/min are necessary. The γ-peaks are evaluated automatically by an "ND-66 Multichannel Analyzer System" and recorded by a PDP-11 system processor. The partial pressure of aluminium chloride is calculated from the known amounts of $AlCl_3$, corrected for the $AlCl_3$, which combines with ytterbium chloride and that part which forms the dimerisation according to

$$2 AlCl_{3(g)} \rightleftharpoons Al_2Cl_{6(g)}$$
using literature data[13] for the equilibrium constant of the dissociation. Some aluminium chloride vapour pressures and corresponding temperatures of the experiments are given in Table 1.

The weight-in of $AlCl_3$ and $YbCl_3$ is chosen in such a manner that at temperatures of about 1000 K all the $YbCl_3$ is in the vapour phase. Thus, the maximum number of the γ-counting rate is proportional to the weight-in. Assuming a linear function between the γ-counting rate and the $YbCl_3$ present in the vapour phase it is possible to determine the partial pressure of the complexed ions.

3. RESULTS AND DISCUSSION

Assuming that only monolanthanide complexes were formed in the AlCl$_3$/LnCl$_3$-system, the LnAl$_3$Cl$_{12}$-complex was established to be the main complex in the temperature range from 500 to 1000 K.[13,14] Thus, the predominant vapour complex in the AlCl$_3$/YbCl$_3$-system was assumed to

$$(YbCl_3)_m * 1.5 \, Al_2Cl_6 \quad (m = 1).$$

The assumption ($m = 1$) as well has been used for the transition metal chloroaluminate complexes supported by mass spectrometric studies,[16,18] as for the investigation of NdCl$_3$,[13] SmCl$_3$,[11] GdCl$_3$,[14] and EuCl$_3$[10] AlCl$_3$-systems. For higher temperatures and low AlCl$_3$ pressures the formation of gas complexes with lower molecular weight (LnAl$_2$Cl$_9$, LnAlCl$_6$) became prevalent; at low temperatures, however, a complex according to

$$YbCl_3 + 2Al_2Cl_6 \rightleftharpoons YbAl_4Cl_{15} \qquad (3)$$

was supposed to exist in detectable quantities beside the 1.5-complex. The thermodynamics of the equivalent NdAl$_4$Cl$_{15}$-complex were determined by Øye and Gruen.[13]

In the temperature range from 500 to 1000 K the equilibrium of the vapour phase could best be rationalized by considering that two or more different YbCl$_3$/AlCl$_3$ complexes should coexist.[1] In agreement with these considerations the experimentally determination of the stoichiometric factor n according to

$$YbCl_3 + n*Al_2Cl_6 \rightleftharpoons YbAl_{2n}Cl_{6n+3} \qquad (1)$$

decreased from 1.8 to 0.95 with increasing temperature. Since $P_c \ll P\,Al_2Cl_6$ (P_c = pressure of the complexed vapour phase), the equilibrium constant of reaction (1) is

$$K_n = P_c/(P_{Al_2Cl_6})^n.$$

Between 670 and 770 K the stoichiometric factor n was nearly constant indicating the dominance of the YbAl$_3$Cl$_{12}$ complex. Assuming that only very small amounts of complexes other than YbAl$_3$Cl$_{12}$ were present in this temperature range, plots of the logarithm of the equilibrium constant $K_{1.5}$ vs $1/T$ according to

$$YbCl_{3(g)} + 1.5 \, Al_2Cl_{6(s)} \rightleftharpoons YbAl_3Cl_{12(g)} \qquad (4)$$
should as well be a linear function of $1/T$ as coincidence for different AlCl$_3$/YbCl$_3$ weight-ins. These conditions are sufficiently fulfilled in a first convergence and the equilibrium constant of the reaction (4) was fitted to an expression (Temp = 680–750 K) of the form

$$\lg K_{1.5} = A_{1.5} + (B_{1.5/T}) \qquad (5)$$

with

$$K_{1.5} = \frac{P_{YbAl_3Cl_{12}}}{(P_{Al_2Cl_6})^{1.5}} \qquad (6)$$

and

$$P_{YbAl_3Cl_{12}} = Pctot$$

(Pctot = sum of the partial pressures of the complexes)

Requiring $\lg K$ to be a linear function of $1/T$ with eqns (5) and (6) the partial pressure of the YbAl$_3$Cl$_{12}$-complex is given by eqn (7):

$$P_{YbAl_3Cl_{12}} = 10 \exp\,[A_{1.5} + (B_{1.5}/T)] * (P_{Al_2Cl_6})^{1.5}. \qquad (7)$$

The assumption that YbAl$_3$Cl$_{12}$ was the only complex present in the temperature range from 670 to 770 K was not exactly fulfilled. The larger complex—YbAl$_4$Cl$_{15}$—was present in small amounts, too. We tried to eliminate this interference. Knowing the approximate partial pressure of

Table 1. AlCl$_3$ and Al$_2$Cl$_6$ partial pressures at the start and the end of the experiments

Exp.	$P_{Al_2Cl_6}^{523}$ [atm]	$P_{AlCl_3}^{523}$ [atm]	$P_{Al_2Cl_6}^{873}$ [atm]	$P_{AlCl_3}^{873}$ [atm]
1	1.91	0.0054	2.02	2.94
2	1.46	0.0047	1.44	2.48
3	1.04	0.0040	0.91	1.99
4	0.51	0.0028	0.34	1.21
5	2.86	0.0067	——	——

the 1.5-complex from eqn (7) and assuming that the complexes with lower molecular weights did not contribute to the partial pressure Pctot at temperatures lower than 750 K

$$P_{YbAl_4Cl_{15}} = Pctot - P_{YbAl_3Cl_{12}} \qquad (8)$$

and the equilibrium constant of the YbAl$_4$Cl$_{15}$-complex according to reaction (3) in the temperature range from 550 to 600 K is

$$K_{2.0} = (Pctot - P_{YbAl_3Cl_{12}}/(P_{Al_2Cl_6})^{2.0} \qquad (9)$$

$$= P_{YbAl_4Cl_{15}}/(P_{Al_2Cl_6})^{2.0}$$

and

$$lg\, K_{2.0} = A_{2.0} + (B_{2.0}/T). \qquad (10)$$
Fig. 3. Gaseous equilibrium of $YbCl_{3(s)} + nAl_2Cl_{6(g)} \rightleftharpoons YbAl_{2n}Cl_{6n+3(g)}$ lg Kn in dependence of 1/T (for different weight-ins).
Fig. 4. Complexed YbCl$_3$ for different weight-ins in dependence of the temperature T.

The partial pressure $P_{YbAl_3Cl_{12}}$ is calculated from eqn (7). The values of $A_{2.0}$ and $B_{2.0}$ were determined from the plot of lg $K_{2.0}$ vs $1/T$. Knowing the values of $A_{2.0}$ and $B_{2.0}$ new values of $A_{1.5}$ and $B_{1.5}$ were determined with

$$P_{YbAl_3Cl_{12}} = Pctot - P_{YbAl_4Cl_{15}} \qquad (ii)$$

and eqns (5) and (6).

The partial pressure $P_{YbAl_4Cl_{15}}$ is calculated from eqn (7b)

$$P_{YbAl_4Cl_{15}} = 10 \exp[(A_{2.0} + \left(\int \Delta C_p \, d \ln T/R * \ln 10\right))$$
$$+ (B_{2.0}/T + \left(\int \Delta C_p \, dT/R * \ln 10 * T\right))] * (P_{Al_2Cl_6})^{2.0} \qquad (7b)$$

with $\Delta Cp = 3$ cal/K for reaction (3). This iteration method was repeated till the values of $A_{2.0}$, $B_{2.0}$, $A_{1.5}$ and $B_{1.5}$ became constant. For temperatures below 750 K the vapour pressures then could be represented by:

$$A_{1.5} = -0.60 \quad B_{1.5} = -1442$$

$$A_{2.0} = -3.35 \quad B_{2.0} = -30.$$

Using

$$\lg K = \frac{\Delta S}{R * \ln 10} - \frac{\Delta H}{R * T * \ln 10} \qquad (12)$$

the thermodynamic data were calculated and listed in Table 2 with

$$\Delta C_p = 0 \text{ cal/K} \quad \text{for reaction (4)}$$

and

$$\Delta C_p = +3 \text{ cal/K} \quad \text{for reaction (3).}$$

The complexes with lower molecular weights did coexist at higher temperatures, each in significant amounts. The approximation method used for the determination of the larger complexes (YbAl$_4$Cl$_{15}$ and YbAl$_3$Cl$_{12}$) is not practicable for the smaller complexes.

To determine the thermodynamic values of the complexes YbAlCl$_6$ and YbAl$_2$Cl$_8$ we set:

$$PC21 = P_{YbAlCl_6} + P_{YbAl_2Cl_9}$$
$$= Pctot - P_{YbAl_3Cl_{12}} - P_{YbAl_4Cl_{15}} \qquad (13)$$

and

$$PC21 = K_{1.0} * (P_{Al_2Cl_6})^{1.0} + K_{0.5} * (P_{Al_2Cl_6})^{0.5} \qquad (14)$$

with

$$\lg K_{1.0} = A_{1.0} + (B_{1.0}/T)$$

and

$$\lg K_{0.5} = A_{0.5} + (B_{0.5}/T)$$

$P_{YbAl_3Cl_{12}}$ is calculated from eqn (7), $P_{YbAl_4Cl_{15}}$ is calculated from eqn (7b).

Knowing the partial pressures PC21 from eqn (13) as a function of temperature, the constants $A_{1.0}$, $B_{1.0}$, $A_{0.5}$ and $B_{0.5}$ were varied and computer processed. With

$$10 \exp(A_{1.0} + B_{1.0}/T) * (P_{Al_2Cl_6})^{1.0}$$
$$+ 10 \exp(A_{0.5} + B_{0.5}/T) * (P_{Al_2Cl_6})^{0.5} = PC21t \qquad (15)$$

the partial pressures PC21t were determined theoretically for every measuring point.

The best fit would be when the difference (D) between the sum of the measured partial pressures (PC21) and the sum of the theoretically determined partial pressures (PC21t) became zero:

$$\sum(PC21 - PC21t) = \sum|D| = 0. \qquad (16)$$

Table 2. Thermodynamic functions for the reaction LnCl$_{3(s)}$ + n*Al$_2$Cl$_{6(g)}$ $\rightleftharpoons$ LnAl$_{2n}$Cl$_{6n+3}$(y) at 298 K

COMPLEXES	ΔH_{298} [kJ/mol]	ΔS_{298} [J/mol K]	LIT.
LnCl$_3$ * 0.5 Al$_2$Cl$_6$	204.7	136.9	theoret.
YbCl$_3$ * 0.5 Al$_2$Cl$_6$	149.9 ± 13	124.4 ± 13	this work
NdCl$_3$ * 0.5 Al$_2$Cl$_6$	157.0 ± 13	110.3 ± 13	[16]
LnCl$_3$ * 1.0 Al$_2$Cl$_6$	100.9	45 ± 5	theoret.
YbCl$_3$ * 1.0 Al$_2$Cl$_6$	87.5 ± 13	47.7 ± 13	this work
YbCl$_3$ * 1.5 Al$_2$Cl$_6$	27.6 ± 4	−11.5 ± 8	this work
GdCl$_3$ * 1.5 Al$_2$Cl$_6$	35.8 ± 8	11.0 ± 11	[14]
SmCl$_3$ * 1.5 Al$_2$Cl$_6$	28.1 ± 1	− 4.2 ± 1	[11]
NdCl$_3$ * 1.5 Al$_2$Cl$_6$	45.2 ± 1	8.4 ± 1	[13]
YbCl$_3$ * 2.0 Al$_2$Cl$_6$	0 ± 4	−65.9 ± 10	this work
NdCl$_3$ * 2.0 Al$_2$Cl$_6$	0 ± 1	−67 ± 2	[13]

Equation (16) is fulfilled with

$A_{1.0} = 2.0$ $B_{1.0} = -4300$ $(\Delta C_p = -4\text{cal/K})^*$ [16]

$A_{0.5} = 5.5$ $B_{0.5} = -7300$ $(\Delta C_p = -2\text{cal/K})^*$ *estimated.

The thermodynamic values were calculated from eqn (19) shown in Table 2.

Figure 5 shows the amounts of complexed $YbCl_3$ in dependence of the corresponding temperature for experiment 1. The values of ΔH and ΔS for some lanthanide complexes are compared in Table 2. To estimate the thermodynamic values of the formation of the complexes a method is used suggested by Schäfer.[1] For

$$0.5\, Yb_2Cl_{6(g)} + 0.5\, Al_2Cl_{6(g)} \rightleftharpoons YbAlCl_{6(g)} \quad (19)$$
we set according to experience $\Delta H° \cong 0$ $\Delta S° \cong 0$ and $\Delta C_p \cong 0$.[1]

From the combination of the dimerisation[1] and the sublimation of $YbCl_3$ (eqn 20, 21) follows eqn (18).

$YbCl_{3(g)} \rightleftharpoons 0.5\, Yb_2Cl_{6(g)}$ $\Delta H_{(298)} = -24.8\,\text{kcal/mol}$
$\qquad\qquad\qquad\qquad\qquad \Delta S_{(298)} = -17.3\,\text{cal/mol K}$ (20)
$YbCl_{3(f)} \rightleftharpoons YbCl_{3(g)}$ $\Delta H_{(298)} = 73.7\,\text{kcal/mol}$
$\qquad\qquad\qquad\qquad\qquad \Delta S_{(298)} = 50\,\text{cal/mol K}$ (21)
$YbCl_{3(f)} + 0.5\, Al_2Cl_{6(g)} \rightleftharpoons YbAlCl_{6(g)}$
$\qquad\qquad\qquad\qquad\qquad \Delta H_{(298)} = 48.9\,\text{kcal/mol}$
$\qquad\qquad\qquad\qquad\qquad \Delta S_{(298)} = 32.7\,\text{cal/mol K}$ |(18)
$$\Delta C_p = -4\,\text{cal/K}. \quad [16]$$

From our experiment we determine for reaction (18)

$\Delta S_{950} = 25.12(\pm3)\text{cal/mol K} \triangleq 105.2(\pm13)\text{J/mol K}$
$\Delta H_{950} = 33.2(\pm3)\text{kcal/mol} \triangleq 139.0(\pm13)\text{kJ/mol}$
$\Delta S_{298} = 29.7(\pm3)\text{cal/mol K} \triangleq 124.4(\pm13)\text{J/mol K}$
$\Delta H_{298} = 35.8(\pm3)\text{kcal/mol} \triangleq 149.9(\pm13)\text{kJ/mol}.$

Schäfer *et al.*[16] determined the entropies and enthalpies of the equivalent $NdAlCl_6$-complex by mass spectroscopy (T = 1123 K) resulting:

$$\Delta S_{298} = 26.3(\pm3)\text{cal/K}$$

and

$$\Delta H_{298} = 37.5(\pm3)\text{kcal.}$$

These data give good correspondence with our experiments and the data calculated theoretically.
For the reaction

$$YbCl_{3(f)} + 1.0\, Al_2Cl_{6(g)} \rightleftharpoons YbAl_2Cl_{9(g)} \quad (12)$$
we estimate the entropy to be the same as the entropy of the divalent chloride compounds (ΔS 11 ± 1 cal/mol). With eqn (31) and

$$2YbCl_{3(g)} \rightleftharpoons 2*0.5\, Yb_2Cl_{6(g)}$$
the enthalpy of reaction (12) is

$$73.7 - 2*(-24.8\,\text{cal/mol}) \longrightarrow \Delta H_{298} = 24.1\,\text{kcal/mol.}$$

From our experiments follows the reaction (12)

$\Delta S_{950} = 9.1(\pm3)\,\text{cal/mol K}$ $38.2(\pm13)\text{J/mol K}$
$\Delta H_{950} = 19.6(\pm3)\text{kcal/mol}$ $82.1(\pm13)\text{kJ/mol}$
$\Delta S_{298} = 11.4(\pm3)\text{cal/mol K}$ $47.7(\pm13)\text{J/mol K}$
$\Delta H_{298} = 20.9(\pm3)\text{kcal/mol}$ $87.5(\pm13)\text{J/mol}$

with

$$\Delta C_p = -2\,\text{cal/mol (estimated).}$$

The experimental data are in good agreement with our calculated data; experimental data of other $LnAl_2Cl_9$ are not available.
For the reaction

$$LnCl_{3(s)} + 1.5\, Al_2Cl_{6(g)} \rightleftharpoons LnAl_3Cl_{12(g)} \quad (22)$$
we determined for Ln = Yb ($\Delta C_p = 0$)

$$\Delta S_{298} = -2.8(\pm2)\text{cal/mol K}$$
$$-11.5(\pm8)\text{J/mol K.}$$
$$\Delta H_{298} = +6.6(\pm1)\text{kcal/mol}$$
$$+27.6(\pm4)\text{kJ/mol.}$$

In Table 2 the thermodynamic values are listed.

weight-in :

1. experimental
2. calculated
3. YbCl₃ * 2.0 Al₂Cl₆
4. YbCl₃ * 1.5 Al₂Cl₆
5. YbCl₃ * 1.0 Al₂Cl₆
6. YbCl₃ * 0.5 Al₂Cl₆
Fig. 5. Amount of $YbCl_3$ in the vapour dependence of the temperature T.
Fig. 6. Partial pressures in the system YbCl₃*(AlCl₃)ₙ.

The entropies and enthalpies of the 1,5-complex appear very close to the data which Papatheodorou *et al.*[11] obtained. Compared with the thermodynamic values of the equivalent $NdAl_3Cl_{12}$[10] and $GdAl_3Cl_{12}$[14] a difference is observed. Papatheodorou *et al.*[11] consider this difference to be attributed to experimental uncertainties or bonding and structure differences of the vapour complexes.

From the changing of the stoichiometric factor and from the plot of the logarithm of the equilibrium constant (lgK_n) against the temperature ($1/T$) we conclude the existence of a large complex ($YbAl_4Cl_{15}$) according to eqn (3).

$$YbCl_{3(s)} + 2.0Al_2Cl_{6(g)} \rightleftharpoons YbAl_4Cl_{15(g)} \qquad (3)$$
In the temperature range from 520 to 600 K and with $\Delta C_p = +3$ cal/K we determined ΔH_{298} and ΔS_{298} of reaction (3)

$$\Delta S_{298} = -16.0(\pm 3)\text{cal/mol}$$
$$-65.9(\pm 10)\text{J/mol K}$$

$$\Delta H_{298} = 0(\pm 1)\text{kcal/mol}$$
$$0(\pm 4)\text{kJ/mol}$$

The thermodynamic data are compared in Table 1 with those of the equivalent $NdAl_4Cl_{15}$-complex, investigated by Øye and Gruen.[12] Our data are in accordance with the data Øye and Gruen obtained.

CONCLUSION

From our experiments follows the existence of four different ytterbium chloride–lanthanide chloride complexes ($YbAlCl_6$, $YbAl_2Cl_9$, $YbAl_3Cl_{12}$, $YbAl_4Cl_{15}$). We have determined the thermodynamic data of the complexes formed in the YbCl₃/AlCl₃-system in the temperature range from 500 to 1000 K. In accordance with former investigations of the LnCl₃/AlCl₃-systems the $YbAl_3Cl_{12}$ complex is found to be the main complex in the temperature range from 500 to 900 K (Figs. 5 and 6). The dominance of this complex leads to elevated statistical errors in the

determination of the thermodynamic values of the other vapour species; the existence of a large complex ($YbAl_4Cl_{15}$) at lower temperatures, however, and the appearance of $YbAlCl_6$ and $YbAl_2Cl_9$ at elevated temperatures is evident.

With ascending temperatures and low aluminium chloride pressures the existence of the $YbAlCl_6$-complex is favoured, probably that is the reason why Schäfer *et al.*[16] cannot find any fragments of the $NdAl_2Cl_9$ complex by mass spectrometric investigations in the NdCl₃/AlCl₃-system at temperatures of 1123 and 1150 K. With our data we determine theoretically the partial pressure of the $YbAl_2Cl_9$-complex to be less than 1% compared with the partial pressure of $YbAlCl_6$ under the experimental conditions Schäfer and Flörke[16] used.

Our experiments confirm the existence of a $YbAl_4Cl_{15}$-complex, equivalent to $NdAl_4Cl_{15}$ recorded by Øye and Gruen.[13]

The method is very useful for the investigations of volatile inorganic complex species, in particular it is possible to describe the equilibrium in the vapour phase within a great temperature range and with elevated AlCl₃/Al₂Cl₆-pressures, facilitating the determination of the thermodynamic data of the secondary complexes.

FORMATION AND THERMODYNAMIC PROPERTIES OF MIXED COMPLEXES OF Cd(II) WITH THIOUREA AND NITRITE OR THIOSULPHATE IONS AS LIGANDS

ATHOS BELLOMO, DOMENICO DE MARCO* and ALESSANDRO DE ROBERTIS
Istituto di Chimica Analitica, Universita di Messina, Via dei Verdi, 98100 Messina, Italy

Abstract—Formation and thermodynamic parameters of mononuclear mixed complexes $Cd(SCN_2H_4)_n(NO_2)_p^{2-p}$ and $Cd(SCN_2H_4)_n(S_2O_3)_p^{2(1-p)}$ in aqueous solution were investigated by potentiometric measurements at different temperatures and $\mu = 1$ for KNO_3.

NOTATION

Tu thiourea
Ts thiosulphate ion
Nt nitrite ion
X Nt or Ts
n index referred to Tu molecules coordinated
P index referred to Nt molecules coordinated
$\Delta G^*, \Delta H^*, \Delta S^*$ overall free energy, enthalpy and entropy changes (respectively in Kcal/mole, Kcal/mole and cal/mole/deg.)
$\Delta G^\circ, \Delta H^\circ, \Delta S^\circ$ free energy, enthalpy and entropy changes for the coordination of single Tu, Nt or Ts ligand (complex + Y = complexY, with Y = Tu, Nt, or Ts).

The equilibrium data on mixed complexes gives information about the thermodynamics of addition or displacement reactions. By means of the inter-

pretation of these quantities, changes in substrata structure (i.e. as produced by coordinated ligands) and solvent effects on the reactions can be deduced.

In aqueous solution, Cd(II) behaves like a "soft" or "class B" acid[1] and usually forms complexes of low thermodynamic stability.[2-6] Therefore, reactions of substrata complexes of this ion must depend considerably on coordination and solvation of various reaction terms.

On cadmium complexes with thiourea, nitrite or thiosulphate there are notes on equilibria with one ligand.[2-10] This paper refers to $Cd(II)–SCN_2H_4–NO_2^-$ and $Cd(II)–SCN_2H_4–S_2O_3^{2-}$ mixed complexes.

EXPERIMENTAL

Experimental parts and calculations are referred to in previous works[11-13] and will be summarized.

In every system the final ΔG^*, ΔH^* and ΔS^* data are based on 250–300 titrations (about 2500–3000 experimental points) covering four or five temperatures.

Function (1) (in tabulated form) in dependance on [Tu] and [X] was obtained by non-linear analytical extrapolation of values measured at finite $[Cd(II)]_{tot}$ by using the following

---

*Author to whom correspondence should be addressed.
Fig. 1. Relation between ln Φ_p and ln Tu at 20°C and $\mu = 1$ for the system Cd(II)–Tu–Nt.

potentiometric system (2).

$$\ln \alpha_0 = \lim_{[\text{Cd(II)}]_{\text{tot}} \to 0} \ln \left([\text{Cd(II)}]_{\text{tot}} / [\text{Cd(II)}]_{\text{free}} \right) \qquad (1)$$

$$\text{Cd/Cd(II)} /\!/ \text{KNO}_3 \text{sat} /\!/ \text{SCE}. \qquad (2)$$

Responses and reversibility of this cell were tested previously.[11] Electrode potentials were measured using an Amel mod. 333 potentiometer. The complexes identified by successive divided differences method[14] applied in two successive stages on linear transform eqn (1). Enthalpy and entropy changes were calculated by linear fitting of Gibbs–Helmoltz equation on the experimental data $\{\Delta G^\circ, T\}$.

All calculations were computerized by using our programs on HP 9825 desk computer.

Cd(II) and ligands concentration ranges are reported in the following scheme:

$$5 \times 10^{-3}\,\text{M} \le [\text{Cd(II)}]_{\text{tot}} \le 7 \times 10^{-2}\,\text{M}$$

$$0\,\text{M} \le [\text{SCN}_2\text{H}_4]_{\text{tot}} \le 0.5\,\text{M}$$

$$0\,\text{M} \le [\text{NO}_2^-]_{\text{tot}} \le 0.2\,\text{M}$$

$$0\,\text{M} \le [\text{S}_2\text{O}_3^{2-}]_{\text{tot}} \le 4.5 \times 10^{-2}\,\text{M}.$$

In order to have very meaningful $\ln \beta$ values, only solutions having $[\text{Cd(II)}]_{\text{tot}} < ([\text{Tu}]_{\text{tot}} + [\text{X}]_{\text{tot}})/4$ were considered. The cadmium solutions were as nitrate salt, nitrite as potassium salt and thiosulphate as sodium salt. Thiourea purified by recrystallization from ethanol was used for thiourea solutions. Ionic strength was kept constant ($\mu = 1$) by adding suitable amounts of KNO_3.

RESULTS AND DISCUSSION

Formation of mono and di-coordinated complexes with nitrite ion were found in the system $\text{Cd(II)}-\text{SCN}_2\text{H}_4-\text{NO}_2^-$. Figure 1 refers (on logarithmic diagram) to experimentally deduced dependence of conditional constants ($\phi_P = \sum_n \beta_{(n,p)}[\text{Tu}]^n$) and Tu concentration. Empty symbols are the values obtained by successive non-linear extrapolations, whereas filled ones correspond to the values obtained by non-linear least squares fitting. The sharp functional dependence of ϕ_p parameter on $[\text{SCN}_2\text{H}_4]$ is consistent with successive coordination of two thiourea molecules independently of substratum.

The number of simple cadmium complexes with thiourea (CdTu_n^{2+}, $n = 1-2$) is in apparent contrast with the one previously found[11] where a tetracoordinated cadmium–thiourea complex was found.[7-10] This suggests that the highest Cd–Tu complex may be tetracoordinate. Because of uncertainties in the measurements ($\simeq 5\%$)[12] and low thermodynamic stability of complexes, it is preferred to describe the function (1) by the least number of certainly identifiable terms. In any case, Fig. 1 clearly shows the first derivative of experimental dependence of $\ln \phi_p$ ($p = 0$) on $\ln [\text{Tu}]$ (as evaluated at the upper limit), is still increasing.

In the system $\text{Cd(II)}-\text{SCN}_2\text{H}_4-\text{S}_2\text{O}_3^{2-}$ dicoordinate complex with thiourea and a sharp dependence of $\phi_n = \sum \beta_{(m,p)}[\text{S}_2\text{O}_3^{2-}]^p$ on $[\text{S}_2\text{O}_3^{2-}]$ (Fig. 2) was found.

Table 1 refers to identified complexes and their formation parameters. Data in regular type are the most probable deduced from primitive experimental data; the ones starred are interpolated on $\{\Delta G^\circ, T\}$. By using the standard deviation of ΔH° and ΔS°, standard errors on ΔG° can be deduced.[14]

Binary diagrams of Figs. 3(a) and (b) refer to only mononuclear complexes. Although they are deduced from the most probable starred data, because of the experimental errors, the boundaries of different surfaces are shaded.

In the system $\text{Cd(II)}-\text{SCN}_2\text{H}_4-\text{NO}_2^-$, Cd(II) is mainly in hydrated form. The only mixed complex with analytical importance (because of its high percentage) is $\text{Cd(SCN}_2\text{H}_4)_2(\text{NO}_2)_2$.

In the system $\text{Cd(II)}-\text{SCN}_2\text{H}_4-\text{S}_2\text{O}_3^{2-}$ for $-2.9 \le p[\text{S}_2\text{O}_3^{2-}] \le -1.4$ and $-1.5 \le p[\text{SCN}_2\text{H}_4] \le -0.5$ there are the surfaces relative to the mixed complexes $\text{Cd(SCN}_2\text{H}_4)(\text{S}_2\text{O}_3)_2^{2-}$, $\text{Cd(SCN}_2\text{H}_4)_2(\text{S}_2\text{O}_3)$ and $\text{Cd(SCN}_2\text{H}_4)_2(\text{S}_2\text{O}_3)_2^{2-}$. Figure 4 refers to the changes of thermodynamic functions in some reactions of complexes as derived from the most probable values of Table 1. The successive coordination of a

single ligand is represented by an arrow while ligand displacement can be deduced along two opposite arrows.

The coordination of one thiourea or nitrite ligand causes nearly the same free energy losses ($\simeq$ 1–2 Kcal/mole). It seems the nature of coordinated groups does not have much influence on partial $\Delta G^{\ominus}$ values, which are dependent on coordination number of substratum reagent. In fact the $\Delta G^{\ominus}$ increases with the coordination number of substratum. In the coordination of thiosulphate ion the free energy losses are most evident ($\simeq$ 3–5 Kcal/mole) and are modified in a positive way by coordination number.

According to the experimental results, the coordination of Tu to complex substrata of Cd(II) shows the following stability sequence: $NO_2^- < SCN_2H_4 < S_2O_3^{2-}$.

Enthalpy changes for similar reactions show a different sequence. The coordination of $S_2O_3^{2-}$ has more positive $\Delta H^{\ominus}$ changes in respect to the values relative to the other two ligands. In the coordination of SCN_2H_4 or NO_2^- $\Delta H^{\ominus}$ is dependent on substrata and it is not possible to define an unequivocal sequence. Consequently, the higher stability of thiosulphate coordination comes from the entropy change.

At least, the direct relation between $\Delta S^{\ominus}$ and $\Delta H^{\ominus}$ ($\Delta S^{\circ} \gtrless 0 \Rightarrow \Delta H^{\ominus} \gtrless 0$) confirms the results of previous work.[11]

FORMATION AND PROPERTIES OF *n*-ALKYLAMMONIUM COMPLEXES WITH LAYERED TRI- AND TETRA-TITANATES

H. IZAWA†, S. KIKKAWA* and M. KOIZUMI
The Institute of Scientific and Industrial Research, Osaka University, Osaka 567, Japan

Abstract—The formation of *n*-alkylammonium complexes was studied using $Na_2Ti_3O_7$ and $K_2Ti_4O_9$ and the results for both compounds were compared. Alkylammonium complexes could be obtained from $H_2Ti_3O_7$ and $H_2Ti_4O_9 \cdot H_2O$, which were prepared by HCl treatment of $Na_2Ti_3O_7$ and $K_2Ti_4O_9$ respectively. The complexes were formed by exchange of H^+ with alkylammonium ions. Molecular intercalation of alkylamine was also possible with $H_2Ti_4O_9 \cdot H_2O$. However, alkylammonium complexes were not formed directly from $Na_2Ti_3O_7$ and from $K_2Ti_4O_9$. Orientations of alkylammonium ions in the interlayer are also discussed in relation to the structure of the titanate layers.

Organic intercalations have been thoroughly investigated for clay minerals and for transition metal dichalcogenides.[1-3] However, there have been few studies on synthetic layered oxides. Organic complexes were first investigated for $Na_2Ti_2O_5$, $K_4Nb_6O_{17}$ and $NaUO_2V_3O_9$.[4-6] They were obtained by direct exchange of the interlayered alkali metals with alkylammonium. These investigations did not pay attention to the structure of host layers. Most of the host materials have flat layers.

In recent years, we found that $HTiNbO_5$ could absorb alkylammonium into its interlayer;[7] $HTiNbO_5$ was prepared by the ion exchange of $KTiNbO_5$. The tilting angle of the alkyl chain to the basal plane was 71° in $HTiNbO_5$ complexes. It was much larger than 56° which is the value found for clay minerals and transition metal dichalcogenides.[2,3] The tilting angle might be different because the $TiNbO_5$ layer is uneven. It was not clear whether the organic complex was produced by the exchange of H^+ with alkylammonium cations or by the intercalation of alkylamine which then formed alkylammonium with the interlayered proton taken into the interlayer at an earlier stage.

There is a series of alkali titanates having general formula $A_2Ti_nO_{2n+1}$ where A is an alkali metal and $1 \leq n \leq 8$. $K_2Ti_4O_9$ and $Na_2Ti_3O_7$ have layers which are basically built up from four or three units of TiO_6 octahedra as depicted in Fig. 1. Their structures belong to the monoclinic system. All Ti_3O_7 layers stacking in the *a*-direction are constructed by exactly the same arrangement of three TiO_6 blocks in $Na_2Ti_3O_7$. Sodium ions are distributed equally in every Ti_3O_7 block. In $K_2Ti_4O_9$, every two Ti_4O_9 layers have the same configuration of Ti_4O_9 units. The convex and concave arrays are opposite in neighbouring layers. Potassium ions are accommodated in a widely opened space in the interlayer. Ion exchange and dehydration of these compounds have been studied.[8] All sodium ion were substituted with proton in trititanate. In tetratitanate, half of the potassium ions

were exchanged with proton but the other half were substituted with H_3O^+ probably for structural reasons. The difference in structure between $Na_2Ti_3O_7$ and $K_2Ti_4O_9$ and the presence of water in the latter may affect the formation of alkylammonium complexes.

This paper deals with the formation of alkylammonium complexes of trititanate and of tetratitanate from the viewpoint of reaction mechanism and of structure. The reaction was firstly investigated with $Na_2Ti_3O_7$, $K_2Ti_4O_9$ and their HCl-treated products using *n*-propylamine or *n*-propylammonium as intercalants. The rate of reactions and the properties of products were then examined with various alkylammonium ions having different lengths of alkyl chain.

EXPERIMENTAL

$Na_2Ti_3O_7$ was prepared by heating a mixture of Na_2CO_3 and TiO_2 in the molar ratio 1:3 at 800°C for 20 hr and for another 20 hr after grinding. $K_2Ti_4O_9$ was obtained by the reaction of K_2CO_3 and TiO_2 in the ratio 1:3.5, using the same heat treatment as in the case of $Na_2Ti_3O_7$. The hydrolyses of $Na_2Ti_3O_7$ (ca. 0.75 g) and $K_2Ti_4O_9$ (ca. 1 g) were performed in 200 cm³ of 0.5 M HCl at 60°C for 3 days. The acid solution was changed every day in order to remove alkali completely from the compounds. The products were washed with distilled water and dried in vacuum at 30°C. Hereafter we denote $Na_2Ti_3O_7$, $K_2Ti_4O_9$ and their acid-treated products as Na–, K–, NaH– and KH–types, respectively.

These materials (*ca.* 50 mg) were respectively sealed in glass tubes with 50% aqueous solution of *n*-propylamine (*ca.* 2 ml). *n*-Propylamine (>98% pure) was supplied by Nakarai Chemical Co. Ltd. *n*-Propylamine has a large dissociation constant of $pK_a = 10.53$, so that most would be ionized as *n*-propylammonium in the presence of water.[9] Durations of reaction were about a month at 60°C. The glass tubes were shaken well during the reaction to keep the reaction homogeneous. We also investigated whether NaH– and KH–type compounds can intercalate *n*-propylamine molecules with or without addition of water. Exchange of the interlayered H^+ or H_3O^+ was also investigated in 50% aqueous solutions of *n*-alkylammonium salts having various lengths of alkyl chain.

Excess alkylammonium ions were removed when the reactions were completed. The products were washed with

acetone and dried in air. The products were characterized by X-ray powder diffraction. C, H and N contents were determined by conventional chemical analysis.

RESULTS AND DISCUSSION

Formation of alkylammonium-titanate complexes

Exchange of interlayered cation with n-propylammonium was investigated with Na-, K-, NaH- and KH-type compounds. The amounts of n-propylammonium in the complexes were determined by C, H, N chemical analysis on the products from NaH- and KH-compounds. They were plotted against run duration as shown in Fig. 2, and reached a maximum within a week. The lattice parameter, a, which can be related to basal spacing, expanded from 8.08 to 16.63 Å on the formation of the n-propylammonium complex of NaH-compound, and from 18.77 to 34.15 Å in the case of the KH-compound. The expansions suggest that n-propylammonium is accommodated in the interlayer regions. The reaction did not proceed homogeneously. Both the original and the final a-parameters were observed in X-ray diffraction photographs of the compounds during the exchange reactions. On the other hand, there were no changes in the X-ray diffraction patterns of Na- and K-type compounds even after three weeks. The aqueous solution of n-propylamine is basic, while NaH- and KH-type compounds behave as Lewis acids. Acid-base interaction might enhance the exchange reactions with n-propylammonium cations.

Experiments were carried out to determine whether the reactions of NaH- or KH-compounds with n-propylamine proceed by exchange of interlayered H^+ with n-propylammonium or by intercalation of n-propylamine which then forms propylammonium within the interlayer. The NaH-compound did not react with n-propylamine without the presence of water, as shown in Fig. 3. However, the propylammonium complex was formed when water was added to the reaction system. These results suggest that the complex could be obtained by the exchange of H^+ with n-propylammonium. On the other hand, the propylammonium complex could be easily prepared from the KH-compound even if water was not added to the reaction system.

The n-alkylammonium complexes were formed more rapidly from the KH-compound than from the NaH-compound. The amount of interlayered propylammonium for the KH-compound reached its maximum value within a day, as shown in Fig. 3. In

the case of the NaH-compound, it still continued to increase after one day, and the reaction was completed in a week. The rate of reaction was much affected by the length of the alkyl chain, because alkylammonium ions had to diffuse through the interlayer space: the rate decreases with increase in length of alkyl chains. It took one month to obtain the maximum amount of n-$C_6H_{13}NH_3^+$ in the interlayer region of NaH-compound. However, the reaction with the KH-compound finished within a week.

The KH-compound has a composition of $H_2Ti_4O_9 \cdot H_2O$, which can be rewritten as (H^+, H_3O^+)Ti_4O_9. Hydroxonium ions, H_3O^+, are probably located in the wide interlayer space of tetratitanate as is K^+ in $K_2Ti_4O_9$. The parts of the Ti_4O_9 layers which do not accommodate interlayered ions face very closely to each other. Absorption of alkylammonium increases the interlayer distance and decreases the repulsive force between neighbouring $Ti_4O_9^{2-}$ layers. The interlayered water in the KH-compound may also keep the interlayer space open, so that it is easy for tetratitanate to be intercalated by alkylamine, forming alkylammonium with the interlayered proton. It is already known that prior intercalation of a smaller molecule makes additional intercalation of a larger species possible.[10] This ion exchange is obviously possible in the case of the KH-compound as shown in Fig. 3. In conclusion, the KH-alkylammonium complex can probably be obtained through both mechanisms, ion exchange and molecular intercalation.

Structure of the complexes

The C, H and N percentages and the chemical formulae for tri- and for tetratitanate are listed in Tables 1 and 2 respectively. The ratios of C/N in the products are almost the same as the values for corresponding alkylammoniums. These results lead
Fig. 4. Interlayer distances of alkylammonium-titanate complexes as a function of carbon number in the alkyl chain.

hexylammonium	24.91	3.76	9.21	100.0	50.59	3.78	11.54	104.0

Parameters, a, b, c, were initially calculated using reflections 100, 020 and 002. The value of β was estimated using the parameters of a, b and c and reflections 101, 10$\bar{1}$ and/or 20$\bar{1}$ of trititanate complexes. Lattice parameters of tetratitanate complexes were similarly calculated using reflections of 200, 020, 003, 101 and 301. The values were then refined by the least squares method for all diffraction lines. Accuracy might be not so good for the longer alkylammonium complexes as for ethylammonium because they showed only a few X-ray diffraction lines.

to the conclusion that alkylammonium ions were absorbed in the titanates without decomposition during the reactions. Chemical formulae presented in Table 1 suggest that less than half of the interlayered protons were substituted by alkylammonium in $H_2Ti_3O_7$. X-Ray powder diffractions of all the products could be indexed as monoclinic, having almost the same lattice parameters as those of $H_2Ti_3O_7$ except for a. The parameters are summarized in Table 3. The unit cell in the basal plane has a dimension of $b \cdot c = 3.8 \times 9.2 \, \text{Å}^2$ for trititanate. Two alkyl chains standing perpendicularly to the Ti_3O_7 layer can be accommodated in one Ti_3O_7 unit of the basal plane because the van der Waals radius of an alkyl group is about 2 Å. However, judging from the results given in Tables 1 and 3, it is reasonable to estimate that half of the protons were substituted for alkylammonium, forming double layers in the interlayer region. Alkylammonium and proton stand alternately within the same layer. In the case of $H_2Ti_4O_9 \cdot H_2O$, Table 2 suggests that only the proton was exchanged with alkylammonium, leaving H_3O^+ as it was in the interlayer. Alkylammonium and hydroxonium stand alternately in the same interlayer, forming a double layer of these ions. Such an arrangement is also acceptable judging from the unit cell size of $b \cdot c = 3.8 \times 12 \, \text{Å}^2$.

Interlayer distances of the alkylammonium complexes are plotted against the numbers of carbons in alkylammonium chains, as presented in Fig. 4. They were roughly estimated as $a \sin \beta$ in trititanate and $a/2 \sin \beta$ in tetratitanate. They increase almost linearly with the number of carbon atoms, having a gradient of 2.1 Å/carbon number. The alkyl chains grow by 1.27 Å per added carbon. The gradient therefore suggests that the interlayered alkylammonium ions form double layers with their terminal NH_3^+ groups pointing to the host $(Ti_3O_7)^{2-}$ and $(Ti_4O_9)^{-2}$ layers. The inclination angle of the alkyl chain to the basal plane is $\sin^{-1}(2.1/1.27 \times 2) \approx 57°$. This value is about the same as those observed for intercalation compounds prepared using materials with flat layers such as clay minerals. The structure of the host $(Ti_3O_7)^{2-}$ and $(Ti_4O_9)^{2-}$ layers does not seem to affect greatly the tilting of alkyl chains in the interlayer. The interlayer distance of the methylammonium-tetratitanate complex was well off the line presented in Fig. 4, and was not very different from the value for the ammonium complex.

The ammonium ion is spherical having an ionic radius of 1.5 Å; methylammonium has a length of about 5 Å because the van der Waals radius of an alkyl group is 2 Å and the covalent bond distance between C–N is 1.5 Å. The dimensions of the unit cell are $b \cdot c = 3.8 \times 12 \, \text{Å}$ in the basal plane of tetratitanate. Methylammonium ions can lie horizontally in the basal plane. Ethylammonium cannot have the same configuration as methylammonium because its length of 6.5 Å is greater than half the c-parameter. In the case of trititanate, the unit cell is not large enough to accommodate even methylammonium when keeping its alkyl chain horizontal. Thus all the alkylamonium ion, $C_mH_{2m+1}NH_3^+$, have the same orientations in the series $m = 0$–6.

In summary, alkylammonium complexes were obtained from $H_2Ti_3O_7$ and $H_2Ti_4O_9 \cdot H_2O$. The interlayered proton was exchanged with alkylammonium. Molecular intercalation was also possible with tetratitanate. Slopes of alkyl chains in the complexes were not much different from those of flat layered materials, in spite of the convex and concave features of uneven host layers in the titanates.

HALOMETALLATES OF 1-METHYL-4,4-DIMERCAPTO-PIPERIDINIUM. EVIDENCE OF STRONG HYDROGEN BONDS WITH PARTICIPATING THIOL GROUPS

H. BARRERA and F. TEIXIDOR*

Departament de Química Inorgànica, Universitat Autònoma de Barcelona, Bellaterra, Barcelona, Spain

Abstract—Chlorometallates of transition and B subgroup elements are readily prepared and precipitated by reaction of the corresponding metallic salts with 1-methyl-4,4-dimercaptopiperidinium chloride. These chlorometallates investigated were $[ZnCl_4]^{2-}$, $[CdCl_3]^-$, $[CoCl_4]^{2-}$, $[CuCl_5]^{3-}$ and $[FeCl_4]^{2-}$. Strong S–H . . . Cl interactions, but not N–H . . . Cl, have been evidenced by IR spectroscopy in the zinc, cadmium and cobalt complexes. The S–H and N–H absorptions are observed at $\simeq 2480\,cm^{-1}$ and $3060\,cm^{-1}$, respectively. Partial deuteration of the $[ZnCl_4]^{2-}$ complex with d_1-methanol, shifted these IR signals to 1800 and $2260\,cm^{-1}$, clearly evidencing a X-hydrogen type of bond. The S–H . . . Cl interaction is smaller in the $[FeCl_4]^{2-}$ complex, and practically nonexistent in the $[CuCl_5]^{3-}$ complex.

Ambidentate ligands which may, in principle, coordinate through nitrogen or sulfur have received considerable interest. A great deal of work has been done with β-mercaptoamines[2] and recently with 1-methyl-4-mercaptopiperidine.[2,3] However, amino-*gem*-dithiols, i.e. ligands with two thiol groups on the same carbon and an amine group in the molecule, have not been studied.

We report in this communication the syntheses of halocomplexes of the first transition series and I-B and II-B subgroups, which are crystallized as salts of 1-methyl-4,4-dimercaptopiperidinium, an amino-*gem*-dithiol cation. These compounds (the copper compound excepted), display strong S–H . . . Cl interactions. In addition, the N–H bond is very little externally perturbed if at all. The complexing ability of the 1-methyl-4,4-dimercaptopiperidine ligand will be the object of a following communication.

EXPERIMENTAL

General

IR spectra were determined on a Beckman IR-20A as KBr pellets. The IR spectral data are listed in Table 1. The UV-visible spectra were recorded on a Beckman, Acta III. The 1-methyl-4-piperidone (Fluka) was distilled before use. The *gem*-dithiol 1-methyl-4,4-dimercaptopiperidine

was prepared according to a reported method.[4] Hydriodic acid (Merck) was purified by the hypophosphorous acid method.[5] Unless specifically mentioned all other reagents and solvents were commercial grade and were used without further purification. Elemental analyses were performed in our laboratories. All melting points are uncorrected.

$[C_6H_{14}NS_2]X$ (X = Cl, Br, I)

Bromide (**II**) and iodide(**III**) salts of $[C_6H_{14}NS_2]$ have been prepared following the procedure used for chloride(**I**).[4] Hydriodic acid (57%) and hydrobromic acid (48%) have been utilized instead of hydrogen halides.

$[C_6H_{14}NS_2]_2[ZnCl_4]$ (IV)

A solution containing 2 g (14.6 mmol) of $ZnCl_2$ finely divided in ethanol and 1.5 cm³ of hydrochloric acid (36%) was slowly poured into a stirred solution of 2 g of $[C_6H_{14}NS_2]Cl$ (10 mmol) in ethanol previously filtered. A white, crystalline solid separated, m.p. 116.5°C (dec). Found: Zn, 12.2; Cl, 26.4; S, 23.3. Calc: Zn, 12.2; Cl, 26.5; S, 23.9%.

$[C_6H_{14}NS_2]CdCl_3.1.5H_2O$ (V)

A stream of hydrogen chloride was passed through a methanolic solution of 1 g (4.4 mmol) of $CdCl_2.2.5H_2O$, for 5–10 min. A methanolic solution of 1.3 g (6.5 mmol) of $[C_6H_{14}NS_2]Cl$ was

treated in the same way. Both solutions were mixed and, upon partial removal of the solvent at room temperature by means of a rotary evaporator, white crystals of (V) separated. After the first crystals were formed the vessel containing them was separated from the rotary evaporator and cooled with ice–water until no more precipitation was observed. The white crystals were filtered and washed with cold methanol containing hydrogen chloride. Found: Cd, 27.2; Cl, 26.3; S, 15.4. Calc: Cd, 27.4; Cl, 26.0; S, 15.6%.

$[C_6H_{14}NS_2]_2CoCl_4.H_2O$ (VI)

The method described for (V) was used with few variations (ethanol as solvent and $CoCl_2.6H_2O$ as the metallic salt) to synthesize (VI). The precipitation of blue crystals takes several days unless

ether is added (m.p. = 117°C (dec)). Found: Co, 10.6; Cl, 25.8; S, 23.4. Calc: Co, 10.7; Cl, 25.9; S, 23.4%.

$[C_6H_{14}NS_2]_3CuCl_5.3H_2O$ (VII)

A stream of hydrogen chloride was passed through a ethanolic solution of 2 g (9.7 mmol) of $CuCl_2.4H_2O$ until a yellowish red coloration is obtained ($\simeq 20$ min). An ethanolic solution of 2 g (10 mmol) of $[C_6H_{14}NS_2]Cl$ was saturated with hydrogen chloride as before.

Upon mixing, a yellow precipitate separated. It was filtered, washed with ethanol containing some hydrogen chloride and dried under vacuum. The compound is yellow but becomes greenish unless kept in anhydrous atmosphere. Found: Cu, 8.03; Cl, 22.4. Calc: Cu, 8.05; Cl, 22.5%.

[C₆H₁₄NS₂]₂FeCl₄.H₂O (VIII)

A stream of hydrogen chloride was passed through a solution of 2 g (10 mmol) of [C₆H₁₄NS₂]Cl in degassed absolute ethanol. In another vessel were introduced 1 g (5 mmol) of FeCl₂.4H₂O, a small piece of pure metallic ion and enough degassed absolute ethanol to dissolve the metallic salt. Hydrogen chloride was passed during a 10-min period. By mixing both solutions a pale yellow solid immediately separated. The precipitation was complete in a 3–4 hr period. The solid was filtered and rinsed, first with cold degassed absolute ethanol containing some HCl, finally with dry ether. The solid was dried under vacuum. Found: Fe, 10.1; Cl, 25.9. Calc: Fe, 10.2; Cl, 26.0%.

Partial deuteration of [C₆H₁₄NS₂]₂ZnCl₄ (IX)

Compound (VII) was dissolved in d_1-methanol. After 2 hr the resulting solution was rotoevaporated down to dryness yielding a white solid.

RESULTS

Reaction of metallic salts of transition and B sub-groups elements: ZnCl₂; CdCl₂.2.5H₂O; CoCl₂.6H₂O; CuCl₂.4H₂O; FeCl₄.4H₂O with 1-methyl-4,4-dimercaptopiperidinium chloride yields, in alcohols and in presence of hydrogen chloride, halometallates of 1-methyl-4,4-dimercaptopiperidinium. In absence of hydrogen chloride metal complexation would take place *via* sulphur.

The identity of the species containing the anions [CoCl₄]²⁻, [ZnCl₄]²⁻ and [FeCl₄]²⁻ was definitively established by their elemental analysis and far IR spectroscopy (Table 1). Besides, the absorptions centered at $\simeq$ 685 nm, $\epsilon \simeq$ 700 in VI, are in good concordance with literature data for [CoCl₄]²⁻ complexes.[6] Unfortunately, not so much spectroscopic information is available regarding the structures of (V) and (VII). Discrete species [CuCl₅]³⁻ are known to exist in the series [M(NH₃)₆]CuCl₅. However, most of the compounds whose stoichiometry could indicate the presence of the anion [CuCl₅]³⁻ are actually made up of [CuCl₄]²⁻ and Cl⁻.[7] According to literature data, the most energetic absorptions due to [CuCl₄]²⁻ and [CuCl₅]³⁻ species happen to be between 280–305 and 256–280 cm⁻¹, respectively.[7] The corresponding absorption in (VII) is at 301, and the next one at 287 cm⁻¹ favouring, therefore, a [CuCl₄]²⁻/Cl⁻ species. The existence of Cd–Cl bonds in (V), is clearly proved by IR absorptions at 280 cm⁻¹. However, the IR information is not sufficient to choose among the different structural possibilities of the trichlorocadmiates.

DISCUSSION

Complexes having *gem*-dithiol ligands have not been described in the literature. The scarcity of *gem*-dithiols, and the sulfur atom tendency to form bridges between two metal atoms poses serious difficulty to use them as complexing ligands. We have evidenced this difficulty using the ligand 1-methyl-4,4-dimercaptopiperidine to complex VIIIB and IIB transition metal ions.[8] However, the N-methyl-4,4-dimercaptopiperidinium ion has been shown to be very efficient to precipitate halocomplexes of VIIIB, IB and IIB metal ions.

An interesting point about some of these salts is the formation of hydrogen bonds S–H . . . Cl, and the existence of non externally perturbed H–N bonds. We arrived to this conclusion upon observation of the IR spectra of these complexes in the 3500–2000 cm⁻¹ range. Strong absorptions at $\simeq$ 3060 and $\simeq$ 2480 cm⁻¹ stand out in the spectra of (IV), (V) and (VI). Deuteration of (IV) by means of d_1-methanol, and IR spectral analysis of the deuterated sample indicated that these absorptions were due to hydrogen participating bonds, where the hydrogen atom is easily replacable by deuterium. Two new bands at 2260 and 1800 cm⁻¹ were observed as a result of the deuteration. The ratios of frequencies between the corresponding former and new bands are 3060/2260 = 1.35 and 2480/1800 = 1.37 in good agreement with the expected ratios for N–H or S–H: 1.37 and 1.39, respectively. Accordingly, the absorptions at 3060 and 2480 cm⁻¹ in IV are due to bonds having labile hydrogens, i.e. in this case S–H or N–H. The IR spectrum of (IV) in the 3200–2200 cm⁻¹ range is depicted in Fig. 1. We have attributed the absorption at 3060 cm⁻¹ to the N–H bond, for the S–H bond absorbs at 2600–2570 cm⁻¹ when it is not externally perturbed. Moreover, the S–H absorption moves to lower wavenumbers when the proton
Fig. 1. IR spectrum of [C₆H₁₄NS₂]₂[ZnCl₄] in the range 3200–2200 cm⁻¹.

is participating in a hydrogen bond. According to Chenon and Sandorfy's prediction this absorption at 3060 cm^{-1} corresponds to a non-externally perturbed N–H bond.[9,10].

Absorptions near 2500 cm^{-1} are observed in the IR spectra of amine halohydrates (e.g. 2510 cm^{-1} in triethylammonium chloride)[9] and are attributed to hydrogen bonds N–H ... Cl. However, the N–H absorption at 3060 cm^{-1} in (IV), (V), (VI) suggests that N–H does not participate, at least strongly, in hydrogen bond formation and consequently, no N–H bonds would be expected around 2500 cm^{-1} for these compounds. Therefore, we assign the absorption at 2480 cm^{-1} to the S–H bond. The unusual strong intensity of the S–H absorption in these spectra is attributed to hydrogen bond formation. Supporting our assignation are the strong absorptions at 2400 and 2520 cm^{-1}, that are observed in 1,1-dimethyl-4-mercaptopiperidinium chloride and 1,1-dimethyl-4-mercaptopiperidinium trichloroestannate, respectively.[11] None of these compounds has a N–H bond that could give rise to these absorptions.

The assignation is further corroborated comparing the position of this absorption in $[C_6NSH_{14}]_2[CoCl_4]$ and $[C_6NS_2H_{14}]_2[CoCl_4]$. As may be seen in Fig. 2, the cations are identical except

(a)   (b)
Fig. 2. The cations 1-methyl-4,4-dimercaptopiperidinium (A), and 1-methyl-4-mercaptopiperidinium (B). Piperidine hydrogens have been omitted for clarity.

that one is a *gem*-dithiol, and the other is a monothiol. Because both salts have the same anion, any difference in the position of the S–H absorption must be due to the cation. It is generally accepted that the strength of the hydrogen bond is dependent on the acidity of the proton and the electronegativity of the two elements bonded by hydrogen. The pK_1 of 1-methyl-4-mercaptopiperidine is 9.5^{12} and the pK_1 of 1-methyl-4,4-dimercaptopiperidine, calculated from the former using Taft and Hammett's parameters is 7.5.[13] These pK values suggest that the strongest hydrogen bond should take place in $[C_6NS_2H_{14}]_2[CoCl_4]$. This compound should, therefore, display a SH absorption at lower frequency and with higher intensity than $[C_6NSH_{14}]_2[CoCl_4]$. The experimental results are $2530(m) \text{ cm}^{-1}$ for

$[C_6NSH_{14}]_2[CoCl_4]$[14] and $2480(s) \text{ cm}^{-1}$ for $[C_6NS_2H_{14}]_2[CoCl_4]$ in concordance with our interpretation. We believe, therefore, that in compounds (IV), (V) and (VI) there is a hydrogen bond *via* SH connecting the halocomplex and the cation.

The IR spectrum of $[C_6NS_2H_{14}]_3[CuCl_5]$ displays absorptions at $2680(s)$ and $2580(s) \text{ cm}^{-1}$ but none of both above discussed. These absorptions at 2680 and 2580 are in the typical range for ammine halohydrates and are indicative of a hydrogen bond via N–H. In $[C_6NS_2H_{14}]_2[FeCl_4]$ it is probable that both types of hydrogen bond via S–H and N–H coexist because the IR absorption at $3000(s, b)$ and $2500(s)$ suggest a S–H hydrogen bond type and the absorption at 2760 a bond of the N–H type.

As can be seen from the former discussion all halocomplexes described here, except $[CuCl_5]^{3-}$, manifest a tendency to form hydrogen bonds via SH. This trend is very clear in the $[CoCl_4]^{2-}$, $[ZnCl_4]^{2-}$ and $[CdCl_3]^{-}$ but not so much in $[FeCl_4]^{2-}$. On the contrary, $[CuCl_5]^{3-}$ does not show it since the hydrogen bond is formed via N–H. The reason may be that $[CuCl_5]^{3-}$ is actually made up of $[CuCl_4]^{2-}$ and Cl^{-}.

STRUCTURES AND REARRANGEMENTS OF
CLOSO-BORON HYDRIDES

DARRYL J. FULLER and DAVID L. KEPERT*

School of Chemistry, University of Western Australia, Nedlands, Western Australia,
Australia

Abstract—The bonding in *closo*-boron hydrides, $B_nH_n^{2-}$ (where $n = 5$–12), is considered to be the sum of all possible $n(n - 1)/2$ boron–boron interactions. The bonding energy u between any pair of boron atoms is taken to depend only upon the internuclear distance d, and to be given by $u = 1/d^2 - 1/d$. This scheme can be used to rationalize details of molecular geometry and also allows the relative importance of various intramolecular rearrangement pathways to be assessed. This method is compared with alternative approaches to treating the bonding in these molecules.

In a recent paper[1] we have proposed a new approach which may be used for the prediction of the structures and the intramolecular rearrangement pathways for the *closo*-boron hydrides, $B_nH_n^{2-}$. It is assumed that every boron atom is directly bonded to every other boron atom, the bonding depending only upon the interatomic distance. A convenient relation between the bonding energy u_{ij} and the interatomic distance d_{ij} between boron atoms i and j is of the form:

$$u_{ij} = \frac{1}{d_{ij}^x} - \frac{1}{d_{ij}^y}. \tag{1}$$

The total bonding energy of the molecule is then:

$$U = \sum_{ij} u_{ij}. \tag{2}$$

Fitting this function vs the known crystal structures of $[Zn(NH_3)_4][B_8H_8]^2$ and $Rb_2[B_9H_9]^3$ yields $x \sim 2$ and $y \sim 1$. A particular advantage of this approach is its extreme simplicity which allows structures to be calculated without imposing any symmetry on the molecule and allows a wide range of reaction coordinates to be examined for the intramolecular rearrangement of these compounds.

In this work we complete the analysis of the *closo*-boron hydrides and compare the results with those obtained from experiment and with those obtained from PRDDO calculations by Lipscomb *et al.*[4-7] and from MNDO calculations by Dewar and McKee.[8] Future work will extend this approach to *nido-*, *arachno-* and *hypho*-compounds.

RESULTS

$B_5H_5^{2-}$

The structure calculated for $B_5H_5^{2-}$ using a 2:1 potential is a trigonal bipyramid, the distances between the boron atoms and the polyhedral centre being $r_{eq} = 1.220$ and $r_{ax} = 1.445$ ($r_{eq}/r_{ax} = 0.844$). The bonding energy $U = -2.4692$. A trigonal bipyramidal D_{3h} symmetry was assumed for the PRDDO calculations,[5] the resulting structural parameters being $r_{eq} = 1.06$ Å, $r_{ax} = 1.19$ Å and $r_{eq}/r_{ax} = 0.89$. The $B_5H_5^{2-}$ anion is experimentally unknown.

$B_6H_6^{2-}$

The present calculations show that the regular octahedron is the stable geometry, $r = 1.352$, $U = -3.6928$. The octahedral structure is the experimentally observed structure for $(Me_4N)_2[B_6H_6]$,[9] $r = 1.20$ Å, and is also that found from PRDDO[4,5] calculations, $r = 1.20$ Å, and from MNDO[8] calculations, $r = 1.225$ Å.

Using the 2:1 potential the trigonal prism lies 0.0371 units higher in energy, $r = 1.381$, $U = -3.6557$, the angles the polyhedral centre-

boron atom vectors make with the three-fold axis being 50.6°. The PRDDO and MNDO calculations show the trigonal prism is 728 kJ mol^{-1} and 296 kJ mol^{-1} respectively less stable than the octahedron. A lower symmetry (C_s) transition state for the rearrangement of $B_6H_6^{2-}$ with an activation energy of 347 kJ mol^{-1} located from the PRDDO calculations could not be located using our model.

$B_7H_7^{2-}$

Using the 2:1 potential the pentagonal bipyramid was found to be the stable geometry for $B_7H_7^{2-}$ with $r_{eq} = 1.489$, $r_{ax} = 1.229$, $r_{eq}/r_{ax} = 1.212$. A pentagonal bipyramidal structure was assumed for the PRDDO calculations[5] yielding $r_{eq} = 1.35$ Å, $r_{ax} = 1.13$ Å, $r_{eq}/r_{ax} = 1.20$. The pentagonal bipyramid was also found from MNDO calculations,[8] $r_{eq} = 1.399$ Å, $r_{ax} = 1.190$ Å, $r_{eq}/r_{ax} = 1.176$. These three sets of results are in approximate agreement but in contrast to early EHT calculations[10,11] which assumed pentagonal bipyramidal stereochemistry with $B_{eq} - B_{eq} = 1.80$ Å, the stable structure being found at $r_{eq}/r_{ax} = 0.92$. The structure of $B_7H_7^{2-}$ is experimentally unknown although ^{11}B NMR spectra are consistent with a pentagonal bipyramidal structure.[10]

Using the 2:1 potential, the capped octahedron and the capped trigonal prism lie 0.0085 and 0.0087 energy units above the pentagonal bipyramid (Tables 1 and 2). The capped trigonal prism lies 106 (or 148)[12] kJ mol^{-1} above the pentagonal bipyramid from the MNDO calculations.

$B_8H_8^{2-}$

The D_{2d} dodecahedron is the most stable structure calculated using $x = 2$, $y = 1$. The calculated stereochemical parameters, $r_A = 1.563$, $r_B = 1.351$, $r_A/r_B = 1.157$, $\phi_A = 35.6°$, $\phi_B = 107.4°$ are in agreement with the known crystal structure of $[Zn(NH_3)_4][B_8H_8]^2$: $r_A = 1.51$ Å, $r_B = 1.31$ Å, $r_A/r_B = 1.15$, $\phi_A = 31.1°$, $\phi_B = 105.7°$. The dodecahedral structure is similarly found to be the most stable stereochemistry from PRDDO[7] and MNDO[8] calculations, the structural parameters again being reasonable ($r_A = 1.476$ Å, $r_B = 1.257$ Å, $r_A/r_B = 1.17$, $\phi_A = 31.6°$, $\phi_B = 103.1°$ and $r_A = 1.495$ Å, $r_B = 1.388$ Å, $r_A/r_B = 1.078$, $\phi_A = 33.9°$, $\phi_B = 102.5°$ respectively).

The 2:1 potential shows the bicapped trigonal prism to be the next most stable stereochemistry at 0.0013 energy units above the dodecahedron.[1] The bicapped trigonal prism was also found to be

polyhedron	U	$U-U$(pentagonal bipyramid)
pentagonal bipyramid	-5.1048	0.0000
capped octahedron	-5.0962	0.0085
capped trigonal prism	-5.0961	0.0087

the next most stable stereochemistry from the PRDDO and MNDO calculations, at 15 and 8 kJ mol^{-1} respectively above the dodecahedron.

$B_9H_9{}^{2-}$

The results using the $x = 2$, $y = 1$ potential for $B_9H_9{}^{2-}$ have also been reported previously.[1] The tricapped trigonal prism is the most stable structure, with $r_{cap} = 1.633$, $r_{prism} = 1.423$, $r_{cap}/r_{prism} = 1.148$ and $\phi = 46.6°$. The tricapped trigonal prismatic structure was assumed for the PRDDO calculations,[5] which yielded $r_{cap} = 1.57$ Å, $r_{prism} = 1.42$ Å, $r_{cap}/r_{prism} = 1.11$, $\phi = 51.2°$. In contrast, the MNDO calculations[8] yield the capped square antiprism as the most stable structure, with the tricapped trigonal prism being less stable by 98 kJ mol^{-1}. The 2:1 potential calculations show that the capped square antiprism is less stable than the tricapped trigonal prism by 0.0021 energy units.[1]

The experimentally observed structure in $Rb_2[B_9H_9]$[3] is a tricapped trigonal prism, $r_{cap} = 1.630$ Å, $r_{prism} = 1.434$ Å, $r_{cap}/r_{prism} = 1.14$, $\phi = 50.1°$. In $[B_9H_7(SMe_2)_2]$[13] one sulphur atom is attached to a prism boron atom and the other

sulphur atom to the *trans*-capping atom. For all nine boron atoms, $r_{cap} = 1.63$ Å, $r_{prism} = 1.44$ Å, $r_{cap}/r_{prism} = 1.13$, $\phi = 52°$. If only the seven BH groups are considered, $r_{cap} = 1.63$ Å, $r_{prism} = 1.46$ Å, $r_{cap}/r_{prism} = 1.11$, $\phi = 52°$ and if only the two $BSMe_2$ groups are considered, $r_{cap} = 1.63$ Å, $r_{prism} = 1.33$ Å, $r_{cap}/r_{prism} = 1.23$, $\phi = 52°$.

$B_{10}H_{10}{}^{2-}$

With the imposition of no symmetry elements, the $x = 2$, $y = 1$ potential yields the bicapped square antiprism as the stable structure for $B_{10}H_{10}{}^{2-}$. The calculated structural parameters, $r_{cap} = 1.729$, $r_{antiprism} = 1.480$, $r_{cap}/r_{antiprism} = 1.17$, $\phi = 63.0°$, may be compared with $r_{cap} = 1.84$ Å, $r_{antiprism} = 1.51$ Å, $r_{cap}/r_{antiprism} = 1.22$, $\phi = 60°$, observed for a variety of bicapped square antiprismatic molecules (Table 3). A bicapped square antiprism was the assumed structure for the PRDDO calculations,[5] which yielded $r_{cap} = 1.75$ Å, $r_{antiprism} = 1.46$ Å, $r_{cap}/r_{antiprism} = 1.20$, $\phi = 60.3°$. A bicapped square antiprism was similarly obtained from MNDO calculations,[8] $r_{cap} = 1.822$ Å, $r_{antiprism} = 1.540$ Å, $r_{cap}/r_{antiprism} = 1.18$, $\phi = 60.7°$.

A number of approaches were used to consider

Table 3. Structural parameters (degrees and Å) for bicapped square antiprismatic molecules

	r_{cap}	$r_{antiprism}$	$\dfrac{r_{cap}}{r_{antiprism}}$	ϕ	cap-centre-cap	Ref

[a]   Two bicapped square antiprisms are linked through BHB bridges to antiprism atoms. Neglecting these atoms, $r_{cap}/r_{antiprism} = 1.83/1.49 = 1.23$, $\phi = 60.2°$/

[b]   The nitrosyl group links two bicapped square antiprisms through capping atoms. Neglecting these atoms, $r_{cap}/r_{antiprism} = 1.87/1.53 = 1.23$, $\phi = 60.2°$.

[c]   One chlorine atom is attached to a capping atom and two chlorine atoms to antiprism atoms. For the BCl groups, $r_{cap}/r_{antiprism} = 1.86/1.46 = 1.27$, $\phi = 60.2°$. For the BH groups, $r_{cap}/r_{antiprism} = 1.78/1.54 = 1.16$, $\phi = 61.0°$.

[d]   Each copper atom asymmetrically bridges a capping site and an antiprism site, $Cu-H_{cap} = 1.86$Å, $Cu-H_{antiprism} = 2.07_5$Å. For these four chemically similar boron atoms, $r_{cap}/r_{antiprism} = 1.82/1.46 = 1.25$, $\phi = 59.3°$.

[e]   The SMe_2 group is attached to one capping atom, and one of the antiprism boron atoms is bonded to the other half of the dimer. For all other BH groups, $r_{cap}/r_{antiprism} = 1.89/1.51 = 1.25$, $\phi = 60.8°$.

possible intermediates for the intramolecular rear-rangement of $B_{10}H_{10}^{2-}$, including those based on classical geometrical polyhedra and those based on fragments of close packing.

There are no regular polyhedra available for a cluster of ten atoms in which all vertices are identical, all edges are identical, and all faces are identical. There are two semiregular polyhedra in which all vertices are identical, that is, all boron atoms are the same. These are the pentagonal prism with regular pentagonal and square faces and the pentagonal antiprism with regular pentagonal and equilateral triangular faces (Fig. 1).

Five non-uniform convex polyhedra can be constructed with regular polygons as faces (Fig. 2). These have more than one type of vertex, that is, there are boron atoms in different environments. The bicapped square antiprism has 16 triangular faces, the sphenocorona has two square and 12 triangular faces, the bicapped cube has four square and eight triangular faces, the bidiminished icosahedron has two pentagonal and ten triangular faces, and the capped tridiminished icosahedron has three pentagonal and seven triangular faces. The detailed shapes of these polyhedra change using the $x = 2$, $y = 1$ potential, the structural parameters being listed in Table 4. The bidiminished icosahedron does not exist as a minimum under the constraints of C_{2v} symmetry with the two mirror planes containing four atoms and two atoms respectively, but turns into a sphenocorona with substantial creasing of the two pentagonal faces ABDIC and ABEJF (Fig. 2b).

A capped tridiminished icosahedron (Fig. 2e) is a particular case of a general series of structures with C_{3v} symmetry and can be considered as a $1:3:3:\bar{3}$ stack (Fig. 3a). A "tetracapped trigonal prism" (Fig. 3b) is closely related, being a $1:3:\bar{3}:3$ stack; this polyhedron is not convex if constructed from equilateral triangles. Both of these polyhedra grossly distort using a $2:1$ potential to form the "trirhombohedron" containing three rhomboidal and ten triangular faces (Fig. 3c and Table 4). For a "hard sphere model" trirhombohedron, that is, one in which all edge lengths are identical, the dimensions of each rhomboidal face is given by $ABE = 72.0°$, $BAC = 108.0°$, and the ratio of the
Fig. 2. (a) Bicapped square antiprism. (b) Spheno-corona. (c) Bicapped cube. (d) Bidiminished ico-sahedron. (e) Capped tridiminished icosahedron.

long diagonal to an edge is $BC/AB = (\sqrt{5} + 1)/2$. This ubiquitous "golden ratio" is also found in other rhombic polyhedra. For example the rhombic triacontahedron consists of 30 equal rhomboids in which the ratio of the *long diagonals* to the *short diagonals* is $(\sqrt{5} + 1)/2$. It may be noted that a trirhombohedron can be considered as half a regular icosahedron fused to half a rhombohedron (Fig. 4). Alternatively, a trirhombohedron can be formed if one face of a regular icosahedron is coalesced to a point. The trirhombohedron created using the $x = 2$, $y = 1$ bireciprocal potential is slightly distorted with a small creasing of each rhomboid along a long diagonal, the dihedral

[a]Values in parenthesis are enforced by symmetry or by choice of axes.

angle between ABC and BCE (Fig. 3c) being 176.7°.

Rhomboidal semiregular polyhedra formed from rhomboids and regular polygons are not usually considered in classical accounts of polyhedra but are nevertheless encountered in chemistry. For example a central gold atom is surrounded by a trirhombohedral arrangement of gold atoms in [Au{Au(ligand)}$_{10}$].[20] The simplest examples of rhomboidal semiregular polyhedra are those formed by the face-sharing of polyhedra which have been chosen so that the dihedral angle between adjacent equilateral triangular faces is 180.0°. Two simple examples are shown in Fig. 5, the face-sharing of an octahedron and a tetrahedron to form a "capped octahedron" with

Fig. 6. (a) Regular pentagon. (b) Scarab.

four triangular and three rhomboidal faces, and the face-sharing of a cuboctahedron and a square pyramid to form a "capped cuboctahedron" with four triangular, five square and four rhomboidal faces. Other polyhedra composed of rhomboids and regular polygons may be formed by contraction of parallelohedra as discussed by Coxeter.[21]

Two additional stereochemistries can be generated by removal of some of the applied symmetry elements from the pentagonal prism and the pentagonal antiprism respectively. It is generally observed that removal of five-fold axes from polyhedra with pentagonal faces results in linkage across the 1,3-positions to form a "scarab" (Fig. 6). Removal of the five-fold axis from the pentagonal prism so that the symmetry is reduced from D_{5h} to C_{2v} results in the formation of the more stable scarab prism (Fig. 7a and Table 4). This polyhedron is very slightly concave, the dihedral angle between the trapezoidal CFJG face and the triangular ACF face being 180.8°. A similar process generates the C_{2h} scarab antiprism from the D_{5d} pentagonal antiprism (Fig. 7b and Table 4). This again results in creasing of the scarab faces, the dihedral angle between ADHI and AEI now being 169.2° for a 2:1 potential.

Other stereochemistries for ten atom clusters can

be generated by taking fragments of close packing, by the linking of octahedra, or by the capping of octahedra. The edge-shared bioctahedron (Fig. 8a and Table 4) is formed from two octahedra, ACDHGI and BEFGHJ, sharing the GH edge. Alternatively it can be considered as a tetracapped octahedron (ABGHIJ as the octahedron, CDEF as the capping atoms). The structure can be considered as a fragment of close packing, the close packed layers being ABCGF and DHEIJ. The layers are slightly buckled, the dihedral angle between ABG and ACG being 172.8°. This arrangement of metal atoms is observed in $V_{10}O_{28}^{6-}$.[22]

The most symmetrical ten-atom cluster is the large tetrahedron (Fig. 8b and Table 4). It can also be considered as a tetracapped octahedron (ADEFGJ as the octahedron, BCHI as the capping atoms), or as a fragment of cubic close packing (layers being B, ADG and CEHJIF). For a 2:1 potential the large triangular faces are slightly convex, the dihedral angle between ABD and ADE being 176.6°.

The last plausible intermediate to consider for the rearrangement of a bicapped square antiprism is that formed when two adjacent triangular faces flatten out and distort to form a square as in a "diamond-square-diamond" (dsd) transition

(a)   (b)
Fig. 7. (a) Scarab prism. (b) Scarab antiprism.

state.[23] If only a single square face is enforced, the resulting *dsd* transition state is shown in Fig. 9. The dihedral angle between the triangular faces BEG and EGI (and the symmetry related DFH and FHJ) is 176.1° so that the structure approaches a polyhedron formed from one square face, two rhomboidal faces and ten triangular faces.

(a)

(b)
Fig. 8. (a) Edge-shared bioctahedron. (b) Large tetrahedron.

The bonding energies of these ten-atom polyhedra calculated using a 2:1 potential are given in Table 5. The most stable polyhedron is the bicapped square antiprism containing only triangular faces. The calculated transition states for the rearrangement of the bicapped square antiprism is the trirhombohedron with three rhomboidal faces, which is preferred to the sphenocorona with two square faces. All other polyhedra are much less stable. The relation between the two possible transition states is shown in Fig. 10; sliding the top edge of the sphenocorona as indicated by the arrows transforms the square faces into two of the rhomboidal faces of the trirhombohedron. Experiments which will distinguish between these two transition states are not easy to envisage, for example rearrangement of the bisubstituted bicapped square antiprismatic $[B_{10}H_8(\text{ligand})_2]$ will lead to the same mixture of isomers through either intermediate.

$B_{11}H_{11}^{2-}$

With no applied symmetry, the structure calculated for $B_{11}H_{11}^{2-}$ using the 2:1 energy potential is the octadecahedron of C_{2v} symmetry (Fig. 11). This polyhedron can be considered to be formed from an icosahedron by coalescing one edge to form a vertex, atom B in Fig. 11. This boron atom has six close boron neighbours. The changes in bonding energy arising from moving this atom are extremely small and a detailed consideration of the stereochemical parameters is not warranted. The structural parameters quoted in Table 6 are those obtained from calculations in which only a single mirror plane was assumed. The structure of

the rearrangement of the octadecahedron of C_{2v} symmetry. The MNDO calculations[8] also show the C_{2v} structure to be the most stable, with the C_s structure 2 kJ mol^{-1} higher in energy. Within the precision of the PRDDO calculations[6] both of these structures were found to be within approximately 10 kJ mol^{-1} of each other.

$B_{12}H_{12}^{2-}$

The $x = 2$, $y = 1$ potential function leads to the expected icosahedral structure for $B_{12}H_{12}^{2-}$ with $r = 1.586$.[1] The icosahedral structure was also found from MNDO calculations, with $r = 1.728$ Å.[8] Icosahedral symmetry was assumed for the PRDDO calculations[5] which yielded $r = 1.65$ Å. Icosahedral structures are observed for $K_2[B_{12}H_{12}]$[25] and $(Et_3NH)_2[B_{12}H_{12}]$,[26] with $r = 1.688$ and 1.694 Å respectively. Examination of a large number of possible pathways for the intramolecular rearrangement of $B_{12}H_{12}^{2-}$ reveals that face rotation with the formation of a C_{3h} icosahedron as intermediate is preferred, with an activation energy of 0.0587 energy units.[1] A similar but not identical intermediate was found from MNDO calculations with an activation energy of 376 kJ mol^{-1}.

$B_{11}H_{11}^{2-}$ is not known, although this octadecahedral structure is observed in $(Et_4N)_2[B_{11}H_9Se_3]$[24] in which the Se_3 ring links atoms D and G (Fig. 11).

The stereochemical parameters of other eleven-atom polyhedra are given in Table 6. The pentacapped trigonal prism, capped pentagonal prism and capped pentagonal antiprism are obviously related to classic geometric polyhedra. Lowering of symmetry of the capped pentagonal antiprism so that only one mirror plane is retained results in the pentagonal face forming a *scarab*, EACDB in Fig. 12, with the formation of a *scarab*-heptadecahedron or capped sphenocorona.

Table 7 shows that the *scarab* heptadecahedron of C_s symmetry is the favoured transition state for

DISCUSSION

Theoretical calculations on boron hydrides which allow geometrical optimisation of a particular structure are presently restricted to the empirical $x = 2$, $y = 1$ potential used in this work and the semi-empirical MNDO and PRDDO methods.

The MNDO calculations yield the incorrect structure for $B_9H_9^{2-}$. The PRDDO calculations using full geometrical optimisation appear to have been carried out only for $B_6H_6^{2-}$, $B_8H_8^{2-}$, and $B_{11}H_{11}^{2-}$. The very simple 2:1 potential has allowed structures to be calculated with no implied symmetry

and has allowed a great diversity of rearrangement pathways to be examined. In some instances reaction intermediates have been located which have not been considered by previous workers, namely the capped octahedron for the rearrangement of $B_7H_7^{2-}$, the trirhombohedron for the rearrangement of $B_{10}H_{10}^{2-}$, and the C_{3h} icosahedron for the rearrangement of $B_{12}H_{12}^{2-}$.

The activation energies for the intramolecular rearrangement of $B_nH_n^{2-}$, in arbitrary units, are shown in Table 8. Experimental data is in general, but not exact, agreement with this qualitative order. There appears to be no experimental information on $B_6H_6^{2-}$ or substituted compounds. The ^{11}B NMR spectrum of $B_7H_7^{2-}$ in water shows a 5:2 pattern of boron atoms consistent with a rigid pentagonal bipyramidal structure at room temperatures.[10] The ^{11}B NMR spectrum of $Na_2[B_8H_8]$ in 1,2-dimethoxyethane at $-32°C$ shows a 2:4:2 pattern consistent with a bicapped trigonal prism but not a dodecahedron. The spectrum collapses above $46°C$ as expected for a stereochemically non-rigid molecule, the detailed behaviour depending both on choice of solvent and cation.[27] The ^{11}B NMR spectrum of $(Me_3S)_2[B_9H_9]$ in water is reported to show boron atoms in the ratio 3:6 indicating a tricapped trigonal prismatic structure.[28] However, the ^1H NMR spectrum of $[B_9H_7(SMe_2)_2]$ shows rapid rearrangement at room temperature with two distinct dimethylsulphide groups at low temperature.[13] The halide complexes $B_9X_9^{2-}$ also show two types of boron atoms,[29] whereas the oxidised B_9Br_9 shows only a ^{11}B NMR singlet.[30] Disubstituted derivatives of $B_{10}H_{10}^{2-}$ have been extensively studied, the compounds only rearranging above $200°C$.[31,32] The most extensive data is for

$[B_{10}H_8(NMe_2)_2]$;[31] equilibrium between all possible bicapped square antiprismatic isomers is established in the melt after 30 min at $300°C$. For the single pathway $2,3-[B_{10}H_8(MNe_3)_2] \rightarrow 1,6-[B_{10}H_8(NMe_3)_2]$ at $230°C$, $\Delta H^{\neq} \sim 150\,kJ\,mol^{-1}$. The ^{11}B NMR spectrum of $(Et_4N)_2[B_{11}H_{11}]$ in dimethylformamide/acetone/methanol mixtures from -70 to $30°C$ shows only a single boron atom indicating rapid rearrangement.[33] Since all boron atoms in an icosahedron are identical, information can only be obtained from substituted derivatives of $B_{12}H_{12}^{2-}$. They are exceptionally resistant to rearrangement, for example $1,7-[B_{12}H_{10}(NMe_3)_2]$ remains mostly unchanged after five minutes in the melt at $400°C$.[31]

SYNTHESIS AND SPECTRAL STUDIES OF
MIXED COPPER(II) DIPEPTIDE COMPLEXES
OF IMIDAZOLE AND RELATED NITROGEN DONORS

S. V. DESHPANDE and T. S. SRIVASTAVA*

Department of Chemistry, Indian Institute of Technology Powai, Bombay 400 076, India

Abstract—Eight mixed copper(II) complexes of the type [Cu(II)(D)(HL)], where D = anion of glycylglycine, glycyl-L-tyrosine or glycyl-L-phenylalanine, and HL = imidazole, 1-methylimidazole, 2-methylimidazole or benzimidazole have been prepared and characterised. The visible and EPR spectral studies of these complexes indicate that they are monomeric having five coordinate square pyramidal geometry (possibly distorted) about Cu(II). The dipeptide behaves as terdentate ligand in these complexes with amino, ionised amide nitrogen and carboxylate oxygen donor atoms approximately tetragonally disposed about Cu(II). The magnetic and bonding parameters obtained by detailed EPR spectral analysis coupled with electronic absorption spectral data suggest that imidazole, 1-methylimidazole, 2-methylimidazole or benzimidazole occupies the fourth position in the tetragonal plane and water molecule occupies an axial position about Cu(II) in solid state and in solution.

Current interest in the study of Cu(II) complexes with imidazole ligand has emphasised the importance of the bond between copper and imidazole from histidine residues of blue copper proteins and nonblue proteins.[1-3] The X-ray structural studies of poplar plastocyanine[4] and *pseudomonas aeruginosa azurin*[5] have revealed that imidazoles from histidine residues of these proteins are involved in the bonding of Cu(II) at the active site. It is also known that the imidazole acts as a bridging ligand at the active site of the bovine erythrocyte superoxide dismutase which catalyses the conversion of superoxide to peroxide.[6,7] The study of a series of model Cu(II) complexes has suggested a distorted square pyramidal configuration at the copper site in galactose oxidase, in oxyhemocyanine and in magnetically coupled ion pairs believed to constitute type **III** copper.[8] Recently, many low molecular weight complexes of Cu(II) containing imidazole ligand(s) have been proposed as models of active site of copper proteins.[9-11] In view of the importance of Cu(II)-imidazole complexes as models for copper proteins, we report here the synthesis and spectral properties of several mixed monomeric Cu(II) dipeptide complexes of imidazole, 1-methylimidazole, 2-methylimidazole and benzimidazole.

EXPERIMENTAL

Materials

Glycylglycine (Gly.Gly), glycyl-L-tyrosine (Gly.Tyr) and glycyl-L-phenylalanine (Gly.Phe) were purchased from Sigma, U.S.A. Imidazole (imH), 2-methylimidazole (2-MeimH) and benzimidazole (BzimH) were bought from SISCO, India. 1-methylimidazole (1-Meim) was obtained from Aldrich, U.S.A. Other commercially available reagent grade chemicals were used without further purification.

Synthetic procedures

Cu(Gly.Gly).3H$_2$O (**Ia**). This complex was prepared by the method described earlier.[12] The product was recrystallised from water.

Cu(Gly.Tyr).4H$_2$O (**IIa**). This was prepared by the method of Dehand *et al.*, and recrystallised from water.[13]

Cu(Gly.Gly)(imH).2H$_2$O (**Ib**) *and* Cu(Gly.Gly)(1-Meim).H$_2$O (**Ic**). These complexes were pre-

---

pared by the methods of Driver and Walker[14] and recrystallised from 50% methanol.

Cu(Gly.Gly)(2-MeimH).2H$_2$O (Id). The blue copper hydroxide was prepared by adding excess of 6N NaOH to a solution of 0.170 g of copper chloride in 15 cm^3 of water. This precipitate was filtered and washed with distilled water to get it free from chloride ions. The precipitate was suspended in 20 cm^3 of water to which 2-methylimidazole (0.083 g) and glycylglycine (0.132 g) were added. The solution was stirred for 1 hr and then filtered. The deep blue filtrate was concentrated to a small volume and kept in a refrigerator for 1 day. The deep blue needle crystals obtained were filtered, washed with cold water and dried in a vacuum desiccator over anhydrous calcium chloride. Found: C, 30.9; H, 5.1; N, 17.2. Calc. for [C$_8$H$_{12}$N$_4$O$_3$Cu].2H$_2$O: C, 30.82; H, 5.13; N, 17.98%.

Cu(Gly.Gly)(BzimH).H$_2$O (Ie). A solution of 0.118 g of benzimidazole in 20 cm^3 of methanol was added to a solution of 0.248 g of (Ia). The resulting solution was incubated at room temperature for 1 day. The sky blue fibre-like crystals obtained were filtered and washed with ice cold water. The product was recrystallized from 50% methanol. The crystals were filtered, washed with cold ethanol and dried in air. Found: C, 41.0; H, 4.1; N, 16.7. Calc. for [C$_{11}$H$_{12}$N$_4$O$_3$Cu].H$_2$O: C, 40.06; H, 4.25; N, 16.99%.

Cu(Gly.Tyr)(imH).H$_2$O (IIb). Glycyl-L-tyrosine (0.238 g, 10^{-3} M) and imidazole (0.68 g, 10^{-3} M) were added to a freshly prepared copper hydroxide (10^{-3} M) suspended in 30 cm^3 of water. This mixture was stirred for 30 min at 60°C and then boiled for 2 min. The mixed solution was filtered to remove unreacted copper hydroxide. The deep blue filtrate was concentrated to 15 cm^3, on a water bath. The resulting solution was kept at room temperature for 2 hr. The sky-blue crystals obtained were filtered. This product was recrystallized from water. The crystals obtained were filtered, washed with cold water, methanol and then diethyl ether. They were finally dried in air. Found: C, 43.9; H, 4.5; N, 14.4. Calc. for [C$_{14}$H$_{16}$N$_4$O$_4$Cu].H$_2$O: C, 43.58; H, 4.66; N, 14.53%.

Cu(Gly.Tyr)(2-MeimH).H$_2$O (IIc). This complex was prepared by the addition of glycyl-L-tyrosine (0.238 g, 10^{-3} M) and 2-methylimidazole (0.083 g, 10^{-3} M) to a freshly prepared copper hydroxide (10^{-3} M) suspended in 25 cm^3 of 50% aqueous methanol. This mixture was stirred for 2 hr and then filtered. The deep blue solution was concentrated to a small volume and kept frozen for 12 hr. The deep blue needle crystals obtained were

filtered, washed with cold water, methanol and finally with diethyl ether. The crystals were finally dried in air. Found: C, 44.8; H, 4.8; N, 13.8. Calc. for [C$_{15}$H$_{18}$N$_4$O$_4$Cu].H$_2$O: C, 45.06; H, 5.01; N, 14.02%.

Cu(Gly.Tyr)(BzimH).3.5H$_2$O (IId). Glycyl-L-tyrosine (0.238 g, 10^{-3} M) and benzimidazole (0.118 g, 10^{-3} M) were added to a suspension of 10^{-3} M copper hydroxide in methanol–water mixture (2:1) (v/v). The mixture was heated on a water bath for 30 min with occasional stirring and then filtered. When this filtrate was cooled, shining sky blue crystals were obtained. They were filtered, washed with cold water, methanol and diethyl ether. The product was recrystallized from 70% methanol. The crystals obtained were dried in air. Found: C, 45.2; H, 5.3; N, 11.0. Calc. for [C$_{18}$H$_{18}$N$_4$O$_4$Cu]3.5H$_2$O: C, 44.95; H, 5.20; N, 11.66%.

Cu(Gly.Phe)(imH).H$_2$O (IIIa). The complex was prepared by the same method as described for (Ib). This was recrystallised from 50% aqueous ethanol solution when dark blue crystals were obtained. Found: C, 45.9; H, 4.5; N, 14.9. Calc. for [C$_{14}$H$_{16}$N$_4$O$_3$Cu].H$_2$O: C, 45.47; H, 4.88; N, 15.16%.

Physical measurements

The electronic absorption spectra of the Cu(II) complexes were recorded using Perkin–Elmer (model 402) spectrophotometer. The matched quartz cells of 10 mm pathlength were used. The complexes were dispersed in Nujol and their IR spectra were recorded on Perkin–Elmer (model-577) IR spectrophotometer in the range of 4000–600 cm^{-1}. This instrument was calibrated using polystyrene film.

The magnetic susceptibility measurements at room temperature were performed on a Gouy balance following the procedure described elsewhere.[15] The electron paramagnetic resonance (EPR) spectra of the Cu(II) complexes in solution at room temperature and at low temperature (77 K) were recorded on Varian E-112 ESR spectrometer (X-band) by using TCNE (g = 2.00277) as g marker. The EPR spectra of all complexes except (IIc) and (IId) were measured by dissolving them in a mixture of ethyleneglycol and water in the ratios of 1:1 and 2:1 (v/v). The room temperature solution spectra of the Cu(II) complexes were measured using Varian aqueous solution cell, E-248. The EPR spectra of (IIc) and (IId) were taken in dimethyl sulphoxide (DMSO). The pH of aqueous solutions was adjusted using dilute NaOH solution.

RESULTS AND DISCUSSION

Eight Cu(II) dipeptide complexes such as (**Ib**, **Ic**, **Id**, **Ie**, **IIb**, **IIc**, **IId** and **IIIa**, with imidazole, 1-methyl-imidazole, 2-methylimidazole and benzimidazole) have been prepared and characterised by elemental analysis, and by IR, visible and EPR spectroscopy. The IR spectra of these complexes show a strong band between 1575 and 1591 cm^{-1}. This can be assigned to peptide carbonyl stretching band with ionisation of peptide N–H hydrogen.[16] The N–H bending vibrations were observed between 1597 and 1633 cm^{-1}. The N–H stretching vibrations of NH_2 group, imidazole, 2-methylimidazole and benzimidazole were observed between 3066 and 3466 cm^{-1}. The O–H stretching vibration of phenol group in complexes containing Gly.Tyr was observed between 3552–3628.[17] The effective magnetic moments (μ_{eff}) of Cu(II) complexes at room temperature are given in Table 1. The magnetic moments are in the range of 1.80–2.00 B.M. These values indicate that they are magnetically dilute systems.[18]

The electronic absorption spectra of the Cu(II) complexes were taken in different solvents in the range of 400–850 nm. The absorption maxima with their extinction coefficients (ϵ) are given in Table 1. All the complexes show only one broad band in the visible region, which is assigned to d–d transition of the Cu(II) complexes.[18] The fairly high extinction coefficient observed for this transition is indicative of presence of square pyramidal geometry about Cu(II). The d–d transitions of adducts of

imidazole, 1-methylimidazole and 2-methylimidazole and benzimidazole with (**Ia**) and (**IIa**) occur at higher energies than of (**Ia**) and (**IIa**) respectively. This may be attributed to stronger ligand fields of imidazole and related nitrogen donors than of water.[19] The slightly higher position of absorption bands of (**Ic**) and (**Id**) as compared to the Cu(Gly.Gly) adduct of imidazole (**Ib**) is probably due to increase of steric hindrance, which may result in longer Cu–N bonds and thus relatively lowering the 10 Dq values.[20]

The absorption spectra of Cu(II) complexes also show some absorption at 850 nm. The percentage ratio of ϵ_{850} and ϵ_{max} is also measured and they are given in Table 1. This percentage varies between 2 and 9 in Cu(II) dipeptide adducts of imidazole and related nitrogen donors. These lower values suggest that these nitrogen bases are substituting for an equatorial water in Cu(II) dipeptide complexes with dipeptides still behaving terdentate ligands.[21] However, the 1:1 complex of $CuCl_2$ and Gly.Gly shows a λ_{max} at 770 nm with the percentage ratio of ϵ_{850} and ϵ_{max} as 75. In this complex, the Gly.Gly binds Cu(II) quite differently[22,23] and supports the terdentate binding of dipeptide to Cu(II) in Cu(II) dipeptide adducts of imidazole and related nitrogen donors.

The EPR spectra of Cu(II) complexes at room temperature are isotropic due to tumbling motion of the molecules. The isotropic g value, g_0, is calculated at the centre of the spectrum of the four lines. The isotropic nuclear hyperfine constant, A_0,

^{a}The pH of the solution was between 6.7 to 7.1

is expressed in cm^{-1} and is calculated between two adjacent lines of the spectrum.[24] The EPR spectra of the complexes in glassy state at 77 K show three well resolved peaks of low intensity in the low field region and intense unresolved peaks are obtained in the high field region. The $g_\parallel$ and $A_\parallel$ values were accurately calculated from this spectrum while $g_\perp$ and $A_\perp$ values were evaluated using the following equations.[25] The EPR parameters thus

$$g_1 = \frac{3g_0 - g_\parallel}{2} \quad \text{and} \quad A_1 = \frac{3A_0 - A_\parallel}{2}$$

obtained are given in Table 2.

The X-ray structural studies of (Ia, Ib and IIa) reveal that they have distorted square pyramidal geometry about Cu(II).[9,13,19] Similar structures are expected for other Cu(II) complexes. The $g_\parallel$ values of these complexes are also greater than corresponding $g_\perp$ values,[18,26] and therefore, they have an unpaired electron in $d_{x^2-y^2}$ molecular orbital. Considering an approximate D_{4h} symmetry in these complexes, the metal ligand σ-bonding parameter α^2, was calculated by using the following relationship[27]

$$\alpha^2 = \frac{1}{8}[-14(A_\parallel + K)/P + 11(g_\parallel - g_e) + 9(g_0 - g_e)]$$

where P = dipole coefficient = $0.036\,cm^{-1}$ for free Cu^{2+} ion. K represents the Fermi contact term

which is calculated by using the relationship

$$K = -A_0 + P(g_0 - g_e).$$

The out-of-plane σ-bond strength, α'^2, was calculated by using the relationship

$$\alpha^2 + \alpha'^2 - 2\alpha\alpha'S = 1$$

where S is the overlap integral which is taken as 0.093.[28] The bonding parameters, β'^2 and β^2, which represent in-plane and out-of-plane π-bond strengths respectively, were calculated by Kevilson and Neiman method.[28] The charge density in the 4s orbital or the 4s contribution to the ground state can be represented by ϵ'^2 and is calculated by the method of Rockenbauer.[27] The values of α^2, $\alpha'^2 \cdot \beta_1^2$, β^2 and ϵ'^2 are given in Table 3.

The metal ligand in-plane σ-bonding, α^2, is completely ionic if $\alpha^2 = 1$ and it is completely covalent if $\alpha^2 = 0.5$. The α^2 values of these Cu(II) complexes fall in the range of 0.71–0.82. These values are indicative of appreciable in-plane covalence. The substitution of a water molecule by imidazole in (Ia) lowers its α^2 value and thus introduces more in-plane covalency. The trend can be explained in terms of imidazole substituting for equatorial water in (Ia).[28] Similar changes were observed in Cu(II) dipeptide adducts of other nitrogen bases. The values of in-plane π-bonding, β_1^2, for the Cu(II) complexes vary in the range of 0.79–0.90. The trend of β_1^2 values is opposite to that observed for α^2 values, which is indicative of competitive mechanism of in-plane σ- and π-bonding in these Cu(II) complexes. The values of out-of-plane π-bonding, β^2, vary in the range of

0.83–0.93 showing little to appreciable out-of-plane π-bonding.

The $g_\parallel$ values of Cu(II) dipeptide adducts of the imidazole and related nitrogen donors decrease as compared to the $g_\parallel$ values of the corresponding Cu(II) dipeptides (see Table 2). This variation is also explained in terms of imidazole, 1-methylimidazole, 2-methylimidazole or benzimidazole substituting for an equitorial water in (Ia) or (IIa).[29] This is also supported by the conclusion obtained above by trends of α^2 values as well as X-ray structural studies of (Ib).[26] The isotropic spectra of these nitrogen base adducts at room temperature shows even superhyperfine lines at the highest field of Cu hyperfines with ^{14}N hyperfine constant of about 11 gauss. This supports the presence of three nitrogen donors in the equitorial plane of Cu(II) ions in these complexes. These conclusions are further supported in solution also by the change of electronic absorption maximum of (Ia) from 640 to 610 nm in its imidazole adduct (Ib). If the imidazole binds at apical position by displacing an apical water molecule from (Ia), the absorption maximum may shift to longer wavelength due to the pentammine effect.[30] The blue shifts on adduct formation by other nitrogen donors have also been observed (see Table 1). These observations are in contrast with the suggestion of Hartzell et al.[31] that the imidazole occupies an apical position in (Ib).

The theoretical straight line plot of ϵ'^2 the $4s$ contribution to the ground state, against α^2 for these Cu(II) complexes, assuming approximate D_{4h} symmetry, was obtained by using empirical equation

$$\epsilon'^2 = 1.06\ \alpha^2 - 0.567$$

suggested by Rochenbauer.[27] This plot is given in Fig. 1. If ϵ'^2 values are obtained using eqn (15) from the Rockenbauer's paper,[27] the points fall near, above and below the theoretical straight line (see Fig. 1). Actually, the above analysis was applied to Cu(II) complexes having tetragonal ligand field (square planar). If ϵ'^2 values calculated from eqn (15) are plotted vs corresponding α^2 values, the points divert upward in rhombic distortion and downward in tetrahedral distortion. If a similar plot is made of Cu(II) complexes having square pyramidal geometry, by analogy, the points divert upward in rhombic distorted square pyramidal configuration and downwards in tetrahedral distorted square pyramidal configuration[32] or distortion towards configuration intermediate between square pyramidal and trigonal bipyramidal. The rhombic distortion seems to be present in (Ib, Ic, Id and IIb), but distortion towards tetrahedron or intermediate configuration is present in (IIc) and (IId). This may be because of steric crowding due to bulky substituents on dipeptide and imidazole.

The Cu(II) dipeptide complexes with imidazole and other nitrogen donors have distorted square pyramidal geometry about Cu(II) in these complexes. The dipeptide occupies three coordination positions and imidazole (or other nitrogen donor) occupies fourth position in the tetragonal plane, and the apical position is occupied by water.

THE FORMATION OF FLUORIDE
COMPLEXES OF TITANIUM(IV)

LIBERATO CIAVATTA* and ADRIANA PIROZZI
Istituto di Chimica dell'Università, Via Mezzocannone 4, 80134 Napoli, Italy

Abstract—The complex formation equilibria between titanium(IV) and fluoride ions have been studied at 25°C in 3 M(Na)Cl ionic medium by measuring, with an ion selective electrode for F^-, the free HF concentration in acid Ti(IV) solutions. The $[H^+]$ was kept within 0.25 and 1 M where the predominant form of uncomplexed metal is the dihydroxotitanium(IV) ion, $Ti(OH)_2^{2+}$. The potentiometric data have been explained by assuming $Ti(OH)_2F^+$, TiF_4 and $HTiF_6^-$, with equilibrium constants given in Table 3. Within the accuracy of the present e.m.f. study, ± 0.2 mV, no evidence for intermediate complexes bearing 2, 3 and 5 F^- was found.

From a special series of measurements, carried out by replacing a large part of the Cl^- with ClO_4^-, it is concluded that no appreciable amount of Ti(IV)–Cl complexes is formed at the 3 M level employed as ionic medium.

NOTATION

a concentration of HF
A total fluoride concentration
B total titanium concentration
f_i activity coefficient of the i species
$F_{i,n}$ activity coefficient quotient, eqn (5)
h concentration of H^+
H analytical concentration excess of H^+, $= [Cl^-] - [Na^+] - 2B$
K_n formation constant for all species containing n F^-, eqn (9)
Z average number of fluoride ions bound per titanium atom, $= (A - a - [F^-] - [HF_2^-])/B$
$\beta_{i,n}$ formation constant for $Ti(OH)_iF_n^{4-i-n}$, eqn (4)

When not stated, concentrations and equilibrium constants are expressed on the molar scale.

Previous measurements[1] with the redox Ti(IV)/Ti(III) couple in chloride solution have shown the predominance of the hydroxotitanium(IV) ion, $Ti(OH)_2^{2+}$, in the acidity range from 0.25 to 2 M. This result is the starting point of the present investigation aiming at the elucidation of the complex formation equilibria between $Ti(OH)_2^{2+}$ and HF.

METHOD

This work describes the determination of [HF] a, using an ion specific electrode for fluoride, in a series of acid titanium(IV) chloride solutions of various A and B values. The acidity levels, H, were chosen between 0.25 and 1 M. From the primary data the function $Z(\log a)_{B,H}$, which forms the basis of the following treatment, was calculated.

In the attempt to minimize the activity coefficient variation of the reacting species the chloride concentration was maintained at the 3 M level by introducing sodium chloride. Thus the test solution (TS) had the general composition: B M Ti(IV), A M F^-, H M H^+, $(3 - 2B - H)$ M Na^+, 3 M $Cl^- = TS$. As the reference state 3 M NaCl is taken and the activity coefficient of a reacting species is defined to tend to

unity as the composition of TS approaches this pure salt solution. We recall at this stage that no certain conclusions on the number of Cl^- bound to Ti(IV) species can be drawn from data obtained in a constant Cl^- medium. To gain an idea of the extent to which Ti(IV) associates with Cl^- a special series of measurements was performed by replacing 2.7 M of Cl^- with ClO_4^-.

The a values in TS were measured with cell(I)

$$- EF/TS, Q.QH_2(s)/Pt + \qquad (I)$$
where EF indicates the ion specific electrode for F^- and $Q.QH_2$ stands for quinhydrone.

The e.m.f. of cell(I) may be written, in V, at 25°C

$$E = E_0' + 0.05916 \log(af_{HF}) + E_q \qquad (1)$$

in which E_0' is a constant, and E_q is a small correction term accounting for the basicity of p-benzoquinone[2] and for f_Q and f_{QH_2}. In each experiment H was kept constant while Z was successively varied. Since $B < 0.1H$, the composition of TS changed only slightly. Consequently, for H constant we may neglect the variation of f_{HF} and of E_q and calculate $\log a$ by the simplified form of (1), eqn (2), where E_0 includes the f_{HF} and E_q terms,

$$E = E_0 + 0.05916 \log a. \qquad (2)$$

The measurements were carried out as potentiometric titrations. First, E_0 was determined in the absence of titanium. Since in the chosen experimental conditions practically all the fluoride is present in form of HF[3], E_0 was calculated by putting $a = A$ in eqn (2). In any case E_0 proved to be constant within ± 0.1 mV in the A range from 10^{-3} to 0.1 M. Then the complex formation was followed (i) by increasing the A/B ratio while B was kept constant, or (ii) by decreasing the A/B values. The coincidence of data obtained with these different procedures served as a criterion for true equilibrium. With the known E_0 and using (2) a could be calculated for each point. Finally, Z was obtained from $(A - a)/B$ being the concentration of F^- and HF_2^- negligible in our solutions.

EXPERIMENTAL

Materials and analysis

Titanium(IV) chloride solutions were made from $TiCl_4$ p.a. quality furnished by C. Erba. This product was found to contain trace amounts of Fe(III), less than 0.05%, which may be considered unimportant for our purposes.

A series of 0.8 M stock solutions was prepared by adding $TiCl_4$ to ice cold 6 M HCl and was stored in a refrigerator at 4°C. Storage at low temperature proved convenient due to the appreciable HCl vapour tension at room temperature. Periodical controls of the acid concentration indicated HCl losses of less than 0.3% in 6 months.

The [Ti(IV)] in the stock solutions was determined gravimetrically (a) as TiO_2 by precipitating titanium hydroxide with gaseous ammonia and then igniting it at 800°C or (b) as oxinate according to Berg and Teitelbaum.[4] Accurate results can be attained with the last procedure provided the oxinate is protected by moisture during cooling and weighing. The results of analyses agreed to within 0.1%.

The total chloride concentration of the stock solutions was obtained gravimetrically as AgCl and by Volhard's method. The results coincided within 0.1%.

The analytical concentration excess of H^+ was found from $H = [Cl^-] - 2[Ti(IV)]$.

Solutions of *hydrochloric acid* were prepared by diluting the p.a. product Merck and were standardized against $KHCO_3$ using methyl red as visual indicator. The results agreed better than 0.1%.

Sodium fluoride was obtained as described previously.[3]

Sodium chloride Merck p.a. was ignited in a platinum vessel at 360°C in an electric oven.

Sodium perchlorate and *perchloric acid* solutions were prepared and analysed as described in a previous work.[5]

The *quinhydrone* Merck p.a. was recrystallised from water and was dried over H_2SO_4. No Fe(III) and Cl^- ions could be detected in the final product.

Details of the e.m.f. measurements

All the e.m.f. measurements were performed in a paraffin oil thermostat kept at $25 \pm 0.02°C$.

The fluoride electrode used, Metrohm, consisted of a membrane of LaF_3 doped with europium(II) ions. The electrode, 5 min after the addition of reagents, acquired a potential which remained constant within ± 0.2 mV for 12 hr. To check the Nernstian response to the HF concentration, the e.m.f. of cell (I) was measured in acid solutions, $H > 0.25$ M, as a function of a in the interval from 10^{-3} and 0.1 M. In any case E_0 values constant to ± 0.1 mV were found.

The titration vessel was a gold cup which assured chemical inertia against TS and furthermore a rapid thermal equilibrium. Cell arrangements made of plastic material achieved the bath temperature in more than 1 hr. A Teflon-coated magnetic bar served for stirring. The burette tips and other parts which might come into contact with fluoride solutions were constructed by Teflon or Plexiglas. Fluoride solutions were added with a polythene weighing burette.

The e.m.f. values of cell(I) were measured, with a precision of 0.01 mV, with a Dynamco Ltd. 2022 digital voltmeter.

DATA AND CALCULATIONS

The $Z(\log a)_{B,H}$ data, which form the basis of the calculations, are collected in Table 1. In Fig. 1 are represented the measurements for $H = 0.5$ M.

At each of the studied H levels the Z values were found to tend to 6 as a increases. Furthermore data of different B fell practically on the same curve. These features of the $Z(\log a)$ functions suggest mononuclear complexes with 6 maximum coordination. However, as the plot of Fig. 1 shows, the formation function is accomplished within less than $2 \log a$
Fig. 1. Z, the average number of fluoride ions bound per titanium atom, as a function of $\log a$ in solutions of $H = 0.5$ M. The curve has been calculated by assuming $B = 0.01$ M and the constants of Table 3.

units, indicating the limited range of existence for intermediate complexes.

The calculations of the number of OH^- and F^- ions in the predominating complexes and the corresponding equilibrium constants were performed in three steps. First, data of constant H were treated separately. By this approach the number of F^- in the complexes and the conditional constants K_n were computed. Then the OH^- groups and preliminary values of $\beta_{t,n}$ were estimated by examining the variation of K_n with H. Finally, the equilibrium constants were refined with numerical procedures based on the principle of the least-squares.

Treatment of data of constant H

In this section the $Z(\log a)_H$ data are considered separately.

In the presence of only mononuclear complexes Z may be expressed by

$$Z = \frac{\sum n\beta_{t,n}F_{t,n}h^{-p}a^n}{1 + \sum \beta_{t,n}F_{t,n}h^{-p}a^n} \quad (3)$$

in which n, t and $p = (n + t - 2)$ are integers, $\beta_{t,n}$ is the equilibrium constant for

$$Ti(OH)_2^{2+} + n\,HF \rightleftarrows Ti(OH)_tF_n^{4-n-t} + p\,H^+ \quad (4)$$

and $F_{t,n}$ is the activity coefficient quotient

$$F_{t,n} = \frac{f_{HF}^n f_{Ti(OH)_2^{2+}}}{f_{t,n}f_{H^+}^p}. \quad (5)$$

At constant H we may use the approximation $F_{t,n} = $ constant without introducing any appreciable error.

In order to find n of the main complexes the experimental data were confronted with normalised

model functions representing different hypotheses. For the calculations some assumptions had to be made about the dependence of h upon B and Z. Since $B < 0.1H$, h must be close to H and therefore it is sufficient to estimate only a lower and a higher limit for h. We have postulated the validity of the inequalities

$$H < h \le H + BZ \qquad (6)$$

in which the upper limit comes from the hypothesis that $p = n$ in (4). The results of the next section show that in our solutions h never exceeds $H + BZ$.

On the basis of (3) and (6) two types of functions, $G(a)$ and $\Phi(w)$, were constructed

$$\log G(a) = \log\left(\sum nK_n a^{n-6}\right) > \log Z +$$
$$0.434 \int_0^a (Z/a)\,da - 6\log a \qquad (7)$$

$$\log \Phi(w) = \log\left(\sum nK_n w^{n-6}\right) \le \log Z +$$
$$0.434 \int_0^w (Z/w)\,dw - 6\log w \qquad (8)$$

where K_n, the conditional constant, is defined by

$$K_n = \sum \beta_{i,n} H^{-p} F_{i,n} \qquad (9)$$

and

$$w = a(1 + BZ/H)^{-1}. \qquad (10)$$

The integrals $\int_{a_0}^{a} (Z/a)\,da$ as well as $\int_{w_0}^{w} (Z/w)\,dw$, where a_0 and w_0 denote the lowest measured values, were evaluated by the trapezoidal rule, thus no smoothing was involved. To obtain $\int_0^{a_0} (Z/a)\,da$ and $\int_0^{w_0} (Z/w)\,dw$ the parabola fitting the lowest three $(Z/a) = f(a)$ and $(Z/w) = f(w)$ points was assumed to represent the experimental points at values where no data are available.

In any case the same n values were obtained if either $G(a)$ or $\Phi(w)$ was employed to approximate the data. In order to save space only the functions originating from (7) are given. At each acidity studied a satisfactory agreement, within the limits of experimental error, could be found between the $\log G(a)(\log a)$ data and the normalised functions $Y(\log v)_L$ in which

$$Y = \log G - \log K_6 = \log (6 + 4Lv^{-2} + v^{-5}) \quad (11)$$

$$\log v = \log a + (1/5)\log K_6 - (1/5)\log K_1 \quad (12)$$

$$L = K_4(K_6^3 K_1^2)^{-(1/5)}. \qquad (13)$$

On the other hand large systematic trends were observed with any other model representing the presence of only three complexes. We may thus conclude that the data of present accuracy are explained with the formation of $Ti(OH)_t F^{3-t}$, $Ti(OH)_p$, F_4^{-t} and $Ti(OH)_t F_6^{-t-2}$.

The conditional constants given in Table 2 were computed, using (11)–(13), from the differences $\log G - Y$, $\log v - \log a$ and L read off in position of best fit. Practically coincident results for K_1 and K_4 were obtained with either (7) or (8), whereas $\log K_6$ values higher than 0.3 units were found when (7) was replaced by (8). The discrepancy however introduces no uncertainty in the evaluation of n of the main species.

The most probable number of OH$^-$ *in* $Ti(OH)_t f_n^{4-t-n}$

To evaluate t in the reaction products the dependence on H of the apparent constants was examined according to (9). Clearly, correct conclusions on t and $\beta_{t,n}$ may be reached only if we are able to estimate the activity coefficient changes caused by the replacement of a large part of the medium ion Na$^+$ with H$^+$. However, since from structural considerations p is expected to be a small integer, the determination of t of the predominating species should be only slightly influenced putting $F_{t,n} = 1$ in (9). On the other hand, activity coefficient variations cannot be neglected if the evaluation of t for minor complexes and if more accurate $\beta_{t,n}$ are required. The calculations presented in this section assume $F_{t,n} = 1$. Medium effects are taken into account in the next section as it was impossible to consider them simultaneously with the evaluation of t.

The plots of $\log K_1$ and $\log K_4$ against $\log H$ could be well described by straight lines of slope 1 and 2, respectively, thus indicating the presence of $Ti(OH)_2F^+$ and TiF_4. The constants $\beta_{2,1}$ and $\beta_{0,4}$ of Table 3 were calculated as the average of $\log K_1 + \log H$ and $\log K_4 + 2 \log H$.

Analysis of the $K_6(H)$ function led to different conclusions. The quantity $\log K_6 + 3 \log H$, evaluated using approximation (8) was found to be constant indicating the formation of $HTiF_6^-$ with a constant $\beta_{-1,6}$ given in Table 3. On the contrary $K_6 H^{-3}$ values obtained using (7) showed a systematic trend with H which might be due to either medium effects or additional species. Most probably, as it will result from the treatment of the next section, the trend stems from the approximation $F_{-1,6} = $ constant.

Refinement of the equilibrium constants

The calculations of the previous sections were based on equations of limited validity and moreover on the assumption that no significant activity coefficient changes occur when Na$^+$ is exchanged with H$^+$. It was therefore desirable to prove the

formation of minor species and to refine the constants with more exact procedures.

The experimental data were treated with Sillén's powerful least-squares method Letagrop.[6] The computation consisted in the minimization of the sum

$$U = \sum (Z_c - Z)^2 \qquad (14)$$

where Z_c designates values of Z calculated with a certain set of assumed constants.

As a first run we tested the hypothesis involving the formation of $Ti(OH)_2F^+$, TiF_4 and $HTiF_6^-$. Then we took account for medium changes according the specific interaction theory (SIT).[7,8] The molal activity coefficient γ_i of the species i, defined so that $\gamma_i \to 1$ as the molality of i, m_i, tends to zero in the solvent salt 3.2 m NaCl, may be expressed in NaCl–HCl mixtures of constant chloride molality by

$$\log \gamma_i = (b(i, H^+) - b(i, Na^+)) m_{H^+} \qquad (15)$$

in which b is the symbol of the interaction coefficient. According to the theory $b = 0$ for positively charged i. As a consequence the formation equilibria of $Ti(OH)_2F^+$ and TiF_4 should not be sensibly affected by the substitution of Na^+ with H^+ since, as supported by the estimates of the next section, reagents and products are neutral or positively charged. On the contrary the equilibrium leading to $HTiF_6^-$ should be influenced to the extent to which $b(HTiF_6^-, H^+)$ differs from $b(HTiF_6^-, Na^+)$. In other words the medium effects are accounted for by

$$\log F_{-1,6} = \xi H \qquad (16)$$

where ξ includes interaction coefficients as well as conversion terms from molality to molarity. Being not able to guess the probable ξ value, we considered it as an unknown parameter to be determined simultaneously with $\beta_{-1,6}$. When ξ was adjusted to vary together with the constants $\beta_{2,1}$, $\beta_{0,4}$ and $\beta_{-1,6}$ U decreased by more than 50%. The minimum was found with $\xi = 0.17$ and the constants listed in Table 3. These are seen to agree well with the graphical evaluation. The uncertainty of the Letagrop constants is 3 times the standard deviation and is lower of the maximum error estimated by curve-fitting.

As the most important measure of the fit between experimental data and the proposed model let us consider Fig. 2, where $(Z_c - Z)/Z$ is plotted as a function of Z. From a total 67 points 33 are found to show positive and 34 negative deviations. The average positive deviation amounts to 3.7%, the average negative to 2.9%. The magnitude and the sign of the deviations do not exhibit appreciable trend with H and Z.

Calculations were carried out also by assuming, besides $Ti(OH)_2F^+$, TiF_4 and $HTiF_6^-$, other conceivable species like $Ti(OH)F^{2+}$, $Ti(OH)_2F_2^{2+}$, TiF_5^-. However no significant lower minima were afforded to make plausible the presence of detectable amounts of such minor species in the concentration range investigated.

The influence of the Cl^- ions on the complex formation

The probable number of Cl^- ions bound to $Ti(OH)_2^{2+}$ and to the fluoride complexes can be
Fig. 2. Illustration of the fit between experimental data and the model represented by the equilibrium constants of the second row of Table 3 and $\xi = 0.17$ (eqn 16). Points for 3 M Cl^-: $(Z_c/Z - 1) \times 100$ as a function of Z.

estimated from the differences between equilibrium constants determined in solutions where Cl^- is replaced by ClO_4^-. If we neglect as first approximation changes of the activity coefficients and postulate that $Ti(OH)_2^{2+}$ and the $Ti(OH)_iF_n^{4-i-n}$ species do not form complexes with ClO_4^-, then we may conclude from the small difference between the constants valid in 3 M NaCl and those found from the special measurements in 2.7 M ClO_4^-, 0.3 M Cl^- medium, given in Table 3, that titanium chloride complexes are hardly detectable in 3 M NaCl.

In order to explain quantitatively the magnitude of the $\beta_{i,n}(ClO_4^-) - \beta_{i,n}(Cl^-)$ differences, the variation of the activity coefficients when Cl^- is replaced by ClO_4^- was evaluated with the SIT.[7,8] By assimilating $Ti(OH)_2^{2+}$ and $Ti(OH)_2F^+$ to Mg^{2+} and Li^+, respectively, and setting equal to zero the interaction coefficients of neutral species, the constants

$$\log \beta_{2,1} = 2.5_1 \pm 0.10$$

$$\log \beta_{0,4} = 8.7_4 \pm 0.10$$

$$\log \beta_{-1,6} = 11.7_6 \pm 0.10$$

were estimated to hold in 3 M $NaClO_4$. For the calculations the interaction coefficients listed in Ref. 8 were employed. The coincidence of experimentally determined with predicted constants corroborates the hypothesis that chloride complexes are formed in negligible extent in 3 M NaCl solutions.

Comparison with the results of previous work

The fluoride complex formation has been the subject of a number of investigations.

In 1952, Kleiner[9] determined spectrophotometrically, in 0.1 M HNO_3, temperature not stated, the equilibrium constant for $[TiO(H_2O_2)]^{2+} + F^- \rightleftarrows TiOF^+ + H_2O_2$ which, combined with the constant of $TiO^{2+} + H_2O_2 \rightleftarrows [TiO(H_2O_2)]^{2+}$, yielded $\log ([TiOF^+] [TiO^{2+}]^{-1}[F^-]^{-1}) = 6.44$.

In 1960, one of the present authors, in cooperation with Caglioti and Liberti,[10] measured, at 25°C in 3 M $NaClO_4$, using a quinhydrone half-cell, the competition of F^- for H^+ and Ti(IV) in the acidity range from 0.05 to 0.2 M. By assuming that no protons were involved in the reaction of TiO^{2+} with F^- the data were explained with $TiOF_n^{2-n}$, $n = 1, 2, \ldots 4$.

The results of the present work prove, however, the inadequacy of that assumption and led the present authors to undertake a recalculation of the earlier (B, H^*, A, h) data. Here H^* stands for the H^+ analytical concentration excess counting H_2O, Ti^{4+} and F^- as zero level. The function

$$R = \frac{A + h - (H^* + 2B)}{B}$$

$$= \frac{\sum P[Ti(OH)_t F_n^{4-t-n}]}{[Ti(OH)_2^{2+}] + \sum [Ti(OH)_t F_n^{4-t-n}]} \quad (17)$$

was first constructed. Then the various hypotheses were tested by minimizing the error sum $\sum (R_c - R)^2$ in which R_c is a value calculated with a set of assumed constants. For $R > 2$ the constants of the third row of Table 3 gave ($R_c - R$) values of the expected order of magnitude, e.g. a few percent, whilst deviations as large as 20% were observed for lower R. In consideration of the inferior acidity the deviations were ascribed to additional species. As a matter of fact, $Ti(OH)_2F_2$ and TiF_6^{2-}, with equilibrium constants, respectively, of $10^{4.5}$ M^0 and $10^{10.9}$ M^{-2}, improved considerably the fit. A practically coincident minimum was, however, obtained by replacing $Ti(OH)_2F_2$ with $Ti(OH)_3F$ and probably a better agreement would involve other conceivable species. In conclusion these results are in substantial concordance with those of the present work, although the limited accuracy of the earlier measurements does not allow an independent and unequivocal interpretation. Nabivanets[11] as well as Parpiev and Maslennikov[12] have studied the distribution equilibria between titanium chloride solutions and ion exchange resins. Nabivanets explained his data in 0.2 M HCl in terms of $TiOF_n^{2-n}$, $n = 1, \ldots 4$, while Parpiev and Maslennikov estimated from measurements in 0.5 M HCl a constant of about 6.3×10^3 for $TiF_5^- + F^- \rightleftarrows TiF_6^{2-}$. A satisfactory explanation of the distribution data is made difficult by the lack of experimental details.

DISCUSSION

Most often the titanyl ion, formulated here as $Ti(OH)_2^{2+}$, has been assumed to describe the ti-

tanium(IV) solution chemistry. The results of the present work show, on the contrary, how the central group loses its identity through the removal of OH^- by F^-. As a consequence a quantitative explanation of the successive complexation equilibria can be achieved only using approaches suitable for the investigation of a ternary system $(Ti(IV) - H^+ - F^-)$, i.e. the knowledge of two variables, h and a, in as wide a range as possible.

It is intended to extend the study to acidities enclosing the limits from 0.05 to 10 M. At $h < 0.25$ M, in addition to hydrolytic species, the complexes $Ti(OH)_2F_2$ and $Ti(OH)_2F_3^-$ are favoured. On the other hand, measurements obtained in the $h > 1$ M range should contain information on TiF_n^{4-n} with $n < 4$. In a new attack of the system one should provide e.m.f. data more accurate than 0.2 mV. The detection of TiF_5^-, whose limited range of existence has to be connected with structural changes from TiF_4 to $HTiF_6^-$, is committed to the improvement of the potentiometric measurements.

COMPLEXES OF VITAMIN B₆—XV†
QUATERNARY COMPLEXES INVOLVING PYRIDOXAMINE, GLYCINE AND ETHYLENEDIAMINE WITH Co(II), Ni(II), Cu(II) and Zn

HAYAT M. MARAFIE, MOHAMMED S. EL-EZABY* and AHMAD S. SHAWALI‡
Department of Chemistry, Faculty of Science, University of Kuwait, Kuwait

Abstract—The formation constants of quaternary Co(II), Ni(II), Cu(II) and Zn complexes comprising pyridoxamine as a first, glycine as a second and ethylenediamine as a third ligand were determined by pH-metric titration at I = 0.5 M NaNO₃ and 30°. The complexes are generally protonated in which the ligands may act as bidentate as well as monodentate. The formation of the quaternary species is discussed in relation to pertinent binary and ternary species. The validity of the Van Panthaleon van Eck equation was also tested.

Pyridoxamine (Pm), glycine (Gly) and ethylenediamine (en) are of considerable interest in biological studies, since they are present in significant amounts in all cells. Pyridoxamine, a vitamin B₆ compound, may act as a coenzyme for reactions of carbonyl compounds.[1] Glycine is one of the amino acids constituting proteins and has been of considerable interest as models for metal-proteins reactions.[2] Ethylenediamine and other polyamines were found to be involved in catalytic reactions and act in the transfer of metal ions in peptide complexes.[3] These ligands were proved to form stable binary complexes with some divalent metal ions.[4,5] They have been involved in some ternary complex formation with Co(II), Ni(II), Cu(II), Zn and Cd ions.[4,5] However, quaternary complexes comprising the three ligands were not studied. These complex equilibria may act as a model for the cluster of ligands around a trace metal ion in biological systems. They may describe the functions of some vitamin B₆-dependent enzymes. In addition, they may give a clue for their role in humans if the complexes are introduced as chemotherapeutic agents.

supplied. Ethylenediamine (en) was purified by distillation under reduced pressure. The concentration of the stock solutions of the ligands (0.1 M) were checked potentiometrically. Only en (0.1 M) was acidified with HNO₃ (0.2 M). The concentration of the stock solutions of Co(II), Ni(II), Cu(II) and Zn nitrates were checked complexometrically, by using potentiometric methods, utilizing a Radiometer Cupric Selective Electrode.[6]

Equipment

A Radiometer pH-meter model 63, equipped with Radiometer combination electrode type GK 2301C was used to follow the pH during the titration of sample solutions of ligands in the absence or presence of metal ions. A Radiometer autoburette model ABU 12 was used to deliver the titrant (0.1 M carbonate-free NaOH).

Methods

Titrations were carried out as previously described.[7] The concentration of the ligands never exceeded twice that of the metal ions. Titration data were taken at 30°C and at an ionic strength of 0.5 M NaNO₃. Purified nitrogen was surged in the solutions of Co(II) system during titration. The direct pH-meter readings were used in the calculations. The pK$_w$ value was taken as 13.75 at I = 0.5 and T = 30°C[8].

The MINIQUAD-75 program was used to assess the titration data.[9] The procedures for selecting the correct equilibrium model were described in previous report.[7] All equilibrium constants were calculated from at least six titration curves of different concentration ratios of metal ions and ligands.
Fig. 1. Typical titration curve of the quaternary systems involving Pm, Gly and en with various metal ions. A, ligands only; B, Zn; C, Co(II); D, Ni(II); and E, Cu(II).

RESULTS AND DISCUSSION

Figure 1 shows typical titration curves for Co(II), Ni(II), Cu(II) and Zn in the presence of equivalent amounts of Pm, Gly and en. Precipitation occurs above pH 8.0 only in Zn system when the composition ratio is $1:1:1:1$, (Pm : Gly : en : Zn). The quaternary complex formation may be represented by the following reaction,

$$l \, Pm^- + p \, Gly^- + q \, en + r \, M^{2+} + s \, H^+ \rightleftharpoons$$

$$(M_r Pm_l Gly_p en_q H_s)^Z \quad (1)$$
where l, p, q, r and s are the stoichiometric coefficients and $Z = (2r + s) - (l + p)$.

In order to determine the formation constants of the equilibria represented by reaction (1) using program MINIQUAD-75, the relevant constants of the binary and ternary complexes should be known together with the protonation constants of the ligands. However, not all these constants were determined.[4,5] The only systems which were not investigated were those of M-Gly-en. Table 1 depicts the values of the ternary complex formation constants for Co(II), Ni(II), Cu(II) and Zn with Gly and en determined under the experimental conditions of this work. Some of the values were estimated assuming that the difference in the formation constants between e.g. 01110 and 01111 is independent of the metal type Cu(II) is excepted) and that log β's for different metal ternary complexes is linear function of the sum of the log

of the 1st protonation constants of their ligands (Fig. 2).

The values of formation constants of the quaternary systems expressed for the equilibrium reaction (1) are recorded in Table 2. At least 20 sets of complexes for each system were examined using MINIQUAD-75. The criteria of model choice were as previously reported.[7] Table 2 shows that most of the quaternary complexes are protonated even at higher pH's than in ternary and binary species indicating that the protons may be located on the Pm moiety as in $1:1:1:1:1$ and $1:1:1:1:2$ and
Fig. 2. The formation constants of the ternary species in the log forms in their dependence on the sum of log forms of the 1st protonation constants of the ligands.

on Gly or en or both as in 1 : 1 : 1 : 1 : 3 and 1 : 1 : 1 : 1 : 4. Moreover, the existence of quaternary species with two ligand molecules of the same kind could not be proved.

A good linear relationship is found between log formation constants of the quaternary complexes (log β_{1Q}) and the second ionization potential (I_2) of the metal ions under consideration (Zn is excepted) which prove the validity of Van panthaleon van Eck equation[10] (Fig. 3).

$$\log \beta_{1Q} = A(I_2 - B) \qquad (2)$$

where A and B are constants depending on the ligand and the experimental conditions but independent of metal ions; A depends on the number of donor atoms and the polarizability of ligands, while B is characteristic of the donor atoms. The values of A decreases as the number of protons increases in the complex. They are 3.14, 2.56 and 0.8 for 1 : 1 : 1 : 1 : 1, 1 : 1 : 1 : 1 : 2 and

1 : 1 : 1 : 1 : 4, respectively. This observation indicates a decrease in the number of the ligating atoms, as the number of protons increases in the complex. This linear relationship of log β_{1Q} on I_2 made it possible to predict values of log β_{1Q} of Cu(II) system for 1 : 1 : 1 : 1 : 0 and 1 : 1 : 1 : 1 : 3, species (Table 2). The difficulty in obtaining an equilibrium model including the latter two species for Cu(II) system may be due to structural factors. In case of the 1 : 1 : 1 : 1 : 0 species an octahedral structure should be expected which is not as stable as in the Ni(II) and Co(II) systems. On the other hand, steric hindrance may be excercised more in the Cu(II) square planar complex of 1 : 1 : 1 : 1 : 3 species. It is unfortunate that log β_{1Q} for Zn complexes cannot be fitted in the above linear relationship invalidating eqn (2).

The affinity of the ternary complexes M Pm Gly H_s, M Pm en H_s and M Gly en H_s to the ligands en, Gly⁻ and Pm⁻, respectively, to form the quaternary complex species, 1 : 1 : 1 : 1 : sH may be

visualized if one considers the following equilibria:
$$M\ Pm\ Gly\ H_s + en \rightleftarrows M\ Pm\ Gly\ en\ H_s;$$

$$K^I = \beta_{1Q}/\beta_{MPmGlyH_s} \qquad (3)$$

$$M\ Pm\ en\ H_s + Gly^- \rightleftarrows M\ Pm\ Gly\ en\ H_s;$$

$$K^{II} = \beta_{1Q}/\beta_{M\ Pm\ en\ H_s} \qquad (4)$$
$$M\ Gly\ en\ H_s + Pm^- \rightleftarrows M\ Pm\ Gly\ en\ H_s;$$

$$K^{III} = \beta_{1Q}/\beta_{M\ Gly\ en\ H_s} \qquad (5)$$

where $\beta_{M\ Pm\ Gly\ H_s}$, $\beta_{M\ Pm\ en\ H_s}$ and $\beta_{M\ Gly\ en\ H_s}$ are the formation constants of the ternary complexes.[4,5] Table 3 lists the log values of K^I, K^{II} and K^{III} whenever their calculation is permissible. It appears that reactions (3) and (5) are more favorable than reaction (4).

The formation of quaternary complex may also arise from the interaction of three different binary complexes or one binary species with one ternary species or even from the combination of two different ternary complexes.

Different combination of binary complexes may lead to the formation of the 1 : 1 : 1 : 1 : sH quaternary complex. However, a detailed description

of these equilibria depends on the availability of different species. The forthcoming analysis will deal only with symmetric combination of binary complexes. The proton will be assumed to be located on the Pm since most of the binary complexes of Gly and en are unprotonated;

$$MLH_s + ML' + ML'' \rightleftarrows MLL'L''H_s + 2M$$

$$K^{IV} = \beta_{1Q}/\beta_{1ML'}\beta_{1ML''}\beta_{1MLH_s} \qquad (6)$$

$$M(LH_s)_2 + M(L')_2 + M(L'')_2 \rightleftarrows MLL'L''H_s + LH_s + ML' + ML''$$
$$K^{V}_{(a)} = \beta_{1Q}\beta_{1ML'}\beta_{1ML''}/\beta_{2MLH_s}\beta_{2ML'2ML''} \qquad (7a)$$

or

$$\rightleftarrows MLL'L''H_s + ML' + MLH_s + L''$$

$$K^{V(b)} = \beta_{1Q}\beta_{1ML'}\beta_{1MLH_s}/\beta_{2MLH_s}\beta_{2ML'}\beta_{2ML''} \qquad (7b)$$

or

$$\rightleftarrows MLL'L''H_s + MLH_s + ML'' + L'$$

$$K^{V(c)} = \beta_{1Q}\beta_{1MLH_s}\beta_{1ML''}/\beta_{2MLH_s}\beta_{2ML'}\beta_{2ML''} \qquad (7c)$$

where LH_s, L' and L'' stand for PmH_s, Gly and en, and β_{1ML}, $\beta_{1ML''}$ and β_{1MLH_s} are the formation constants of the monobility species and β_{2ML}, $\beta_{2ML''}$ and β_{2MLH_s} are the formation constants of the dibinary species. The values of log K^{IV} and K^{V} are depicted in Table 3. It seems that quaternary complex formation are not enhanced via the interaction of

binary species since most of the values of log K^{IV} and log K^{V} are negative. However, it has been proved that ternary complexes of systems involving Pm, Gly and en with Co(II), Ni(II), Cu(II) and Zn can generally coexist with binary species involved in these systems[4, 5]. So it may be reasonable to discuss the formation of $1:1:1:1:sH$ quaternary complexes from the point of the interaction of the $1:1:1:1:sH$ ternary species. This may be viewed from the following equilibria,

$$MLL'H_n + MLL''H_m \rightleftarrows MLL'L''H_s + MLH_t$$
$$K^{VI} = \beta_{1Q}\beta_{1MLH_t}/\beta_{1MLL'H_n}\beta_{1MLL''H_m} \qquad (6)$$

$$MLL'H_n + ML'L''H_m \rightleftarrows MLL'L''H_s + ML'H_t$$
$$K^{VII} = \beta_{1Q}\beta_{1ML'H_t}/\beta_{1MLL'H_n}\beta_{1ML'L''H_m} \qquad (7)$$

$$MLL''H_n + ML'L''H_m \rightleftarrows MLL'L''H_s + ML''H_t$$
$$K^{VIII} = \beta_{1Q}\beta_{1ML''H_t}/\beta_{1MLL''H_n}\beta_{1ML'L''H_m} \qquad (8)$$

where $\beta_{1MLL'H_m}$, $\beta_{1MLL''H_m}$, $\beta_{1ML'L''H_M}$ and $\beta_{1MLLL''H_n}$ are the formation constants for the ternary species mentioned in the above equilibria and $n + m = s + t$ (the number of hydrogen atoms). The values of log K's are recorded in Table 3. Although, other ternary species than $1:1:1:sH$ may be also involved in quaternary complex formation, yet they are of minor importance due to their lower relative concentrations.[4,5]

Since some binary species may exist with some ternary species, their interactions are unavoidable.
Fig. 4. Distribution diagrams of the quaternary system as function of pH. (a) Co-Pm-Gly-en, (b) Ni-Pm-Gly-en, (c) Cu-Pm-Gly-en, (d) Zn-Pm-Gly-en.

The following possibilities are only representative and probably the most important;

$$MLH_n + ML'L''H_m \rightleftarrows MLL'L''H_s + M,$$

$$K^{IX} = \beta_{1Q}/\beta_{1MLH_n}\beta_{1MLL'L''H_m} \qquad (9)$$

$$ML' + MLL''H_s \rightleftarrows MLL'L''H_s + M,$$

$$K^{X} = \beta_{1Q}/\beta_{1ML'}\beta_{1MLL''H_s} \qquad (10)$$

$$ML'' + MLL'H_s \rightleftarrows MLL'L''H_s + M,$$
$$K^{XI} = \beta_{1Q}/\beta_{1ML''}\beta_{1MLL'H_s} \qquad (11)$$

$$M(LH_n)_2 + ML'L''H_m \rightleftarrows MLL'L''H_s + MLH_n$$
$$K^{XII} = \beta_{1Q}\beta_{1MLH_n}/\beta_{2MLH_n}\beta_{1ML'L''H_m} \qquad (12)$$

$$ML'_2 + MLL''H_s \rightleftarrows MLL'L''H_s + ML$$
$$K^{XIII} = \beta_{1Q}\beta_{1ML}/\beta_{1MLL''H_s}\beta_{2ML'} \qquad (13)$$

$$ML''_2 + MLL'H_s \rightleftarrows MLL'L''H_s + ML''$$
$$K^{XIV} = \beta_{1Q}\beta_{1ML''}/\beta_{2ML''}\beta_{1MLL'H_s}, \qquad (14)$$

The values of $\log K^{IX-XIV}$ are shown in Table 3. There is a certain degree of enhancement of quaternary complex formation through some of the above equilibria specially for $1:1:1:1:2$ species.

If we assume that chemical and electrical attraction between the metal ion and the ligand are independent of ligands already attached, then the magnitude of the stepwise formation constants are determined by statistical considerations. The ratio of the three constants for a bidentate ligand in an octahedral complex is $K_1:K_2:K_3 = 12/1 : 5/2 : 4/15.^{11}$

The ratio which interests us is that between the stepwise formation constant of a tris-complex and that of a bis-complex. This amounts to $8/75$ ($= -0.97$ in log form). Upon consulting Table 3, the values of $\log K^{I-III}$ and most of $\log K^{VI-XIV}$ are greater than -0.97 which indicate various degrees of enhancement of quaternary complex formulation. Only those of $\log K^{IV-V}$ are much less than the statistical value indicating dehancement of quaternary complex formation. The conclusion which may be extracted from these results is that quaternary complexes cannot be simply formed from the interaction of only binary complexes and that ternary complexes should exist for their effective formation. A general conclusion, however, cannot be drawn to rationalize the negative values occurred less than -0.97 among those of $\log K^{VI-XIV}$. The interesting result which is observed for Zn system is that about 95% of the $\log K^{VI-XIV}$ values obtained are highly positive, which means that crystal field stabilization energy is not the only

governing factor in the enhancement of quaternary complex formation.

Figures 4(a–d) show the distribution curves of the binary, ternary and quaternary complexes involving Pm, Gly and en with the metal ions under consideration as function of pH. As it has been mentioned previously,[5] these curves are dependent on the initial concentration of the reactants. In equal concentration of M : Pm : Gly : en a mixture of binary, ternary and quaternary complexes may exist in various ratios. Of course, highly protonated quaternary species (containing 2 protons or more) are present in acidic media and the less protonated (containing 2 protons or less) are in neutral or basic solutions. The predominance of quaternary species may be arranged according to the type of metal ions in their systems as Zn > Co(II) > Ni(II) > Cu(II). In other words, the distribution of Cu(II) among different complexes in Cu(II)-system is more or less identical and there is no preference to quaternary species opposite to what is in Zn system. This may be explained as due to the fact that Zn with a filled d-shell and no ligand field stabilization energy may accommodate the distorted geometry (which may also be acquired by Co, Ni and Cu) without destabilization.

It is worth mentioning that most of the quaternary complexes are positively charged which make them susceptible for easier transportation in biological fluids.

FOURIER TRANSFORM HETERONUCLEAR MAGNETIC TRIPLE RESONANCE IN COMPLEX SPIN SYSTEMS—III†

SYMMETRICAL DITERTIARY PHOSPHINE COMPLEXES OF GROUP VI METAL CARBONYLS

GEOFFREY T. ANDREWS, IAN J. COLQUHOUN and WILLIAM McFARLANE*
Chemistry Department, City of London Polytechnic, Jewry Street, London EC3N 2EY, England

Abstract—Magnetic multiple resonance experiments of the types $^{13}C-\{^{31}P, {}^{1}H\}$, $^{13}C-\{^{1}H\}$ and $^{31}P-\{^{183}W, {}^{1}H\}$ have been used to determine the magnitudes and signs of P–C and P–P coupling constants in the symmetrical complexes $LM(CO)_4$ ($L = Ph_2P(CH_2)_nPPh_2$, $Ph_2PN(H)PPh_2$, $(Ph_2P)_2C=CH_2$, *cis*-$Ph_2PCH=CHPPh_2$; M = Cr, Mo, W; $n = 1$–4). A knowledge of the signs of the couplings shows that they display a systematic pattern of behaviour according to metal atom and ring size and this may have diagnostic value. ^{13}C, ^{31}P and ^{183}W chemical shifts are also reported.

INTRODUCTION

Proton and more recently ^{13}C and ^{31}P NMR spectroscopy has played an important part in the development of the chemistry of phosphine complexes of metal carbonyls. Not only can the technique be used to establish molecular structure and stereochemistry, it can also in principle be used to probe intimate details of electronic distribution and the factors which determine this. For this latter purpose ^{13}C and ^{31}P are probably more valuable than proton NMR, since the shieldings and coupling constants for these two nuclei are more directly affected by the metal atom and are also less subject to external influences such as changes of solvent. However, ordinary proton-decoupled spectra seldom yield all the information necessary for a proper assessment of the relationship between the NMR parameters and electronic structure, and in this paper we describe the results of multiple resonance experiments upon a series of chelating tertiary biphosphine complexes of group VI metal carbonyls which resolve this difficulty. In particular, the magnitudes of the two-bond coupling constants between ^{31}P and the ^{13}C nuclei of the carbonyl groups show a complex pattern of variation[1–4] whose dependence upon the metal and upon the stereochemical relationships can be understood only if the *signs* of the couplings are also known. Additionally, the important homonuclear phosphorus–phosphorus couplings are not normally available directly from simple ^{31}P spectra when the ligands are chemically symmetrical. In order to get the signs of the $^{31}P-^{13}C$ coupling constants it is necessary to perform $^{31}P-\{^{13}C\}$ or $^{13}C-\{^{31}P\}$ selective multiple resonance experiments,[5] the latter being generally the more convenient,[6] but neither type of experiment has been usual in previous work. For the $^{31}P-^{31}P$ couplings considerable effort[7,8] in the past has gone into making complexes with unsymmetrical ligands such as $R_2P(CH_2)_nPR_2'$ where

R and R′ are sufficiently different (e.g. Et and Ph) for there to be a substantial chemical shift difference between the two kinds of phosphorus so as to allow $^2J(PP)$ to be read off directly from the essentially first-order spectra. This method is synthetically demanding and does not give the sign of $J(PP)$. The multiple resonance approach used here is easier synthetically and gives the sign of $J(PP)$ in complexes of symmetrical ligands of possibly greater fundamental importance; it is based upon using spin-tickling experiments[9] for the indirect detection of weak transitions in the spectra from species which are chemically but not magnetically symmetric.[5,6] All of the complexes studied are of the type *cis*-$LM(CO)_4$ with M = Cr, Mo, or W, and L = $(Ph_2P)_2CH_2$ (*dppm*), $(Ph_2P)_2C=CH_2$ (*gem-pp*), $(Ph_2P)_2NH$ (*dpnp*), $Ph_2P(CH_2)_2PPh_2$ (*dppe*), *cis*-$Ph_2PCH=CHPPh_2$ (*cis-vpp*), $Ph_2P(CH_2)_3PPh_2$ (*dppp*), or $Ph_2P(CH_2)_4PPh_2$ (*dppb*). They have octahedral co-ordination at the metal and thus contain two types of CO group—axial and equatorial as in (I). With the exception of [4] and the three *dpnp* derivatives all have been previously reported.[10–13]

(I)
EXPERIMENTAL

All solutions of ligands and their complexes were prepared and manipulated under an atomsphere of gaseous dry dinitrogen. The ligands were made as described elsewhere[6] and were purified by recrystallization; the complexes[10–13] were made by refluxing together stoichiometric amounts of ligand and the appropriate metal hexacarbonyl in diglyme for 12 hr, followed by removal of the diglyme *in vacuo* and recrystallization from $CHCl_3/MeOH$ (1:1). New complexes were: *gem-pp*$Cr(CO)_4$ [4]: Found: C 64.1; H 3.9; $C_{30}H_{22}CrO_4P_2$ requires: C 64.3; H 3.9%. m.p. 197–198°. *dpnp*

†For Part II see Ref. 6.
*Author to whom correspondence should be addressed.

$Cr(CO)_4$ [7]: Found: C 61.1; H 3.8; $C_{28}H_{21}CrO_4P_2$ requires: C 61.2; H 3.8%. m.p. 194°. *dpnp* $Mo(CO)_4$ [8]: Found: C 56.5; H 3.6; $C_{28}H_{21}MoO_4P_2$ requires: C 56.7; H 3.5%. m.p. 216°. *dpnp* $W(CO)_4$ [9]: Found: C 49.1; H 3.1; $C_{28}H_{21}WO_4P_2$ requires: C 49.4; H 3.1%. m.p. 205°. The others had properties identical to those previously reported.

The NMR measurements were performed at 22°C upon concentrated solutions in dichloromethane containing ca. 10% C_6D_6 to provide a locking signal for the spectrometer. This was a JEOL FX-60 Fourier transform instrument operating at measuring frequencies of 59.8, 15.0 and 24.2 MHz for ^1H, ^{13}C and ^{31}P respectively. The probes of the spectrometer were modified[5] to permit ^1H-$\{^{31}P\}$, ^{13}C-$\{^{31}P, ^1H\}$ and ^{31}P-$\{^{183}W, ^1H\}$ multiple resonance experiments, the additional radio frequency being provided by a GenRad model 1061 frequency synthesizer which was locked to the master oscillator of the spectrometer. $Cr(acac)_3$ was added to the solutions to facilitate observations of the ^{13}CO signals. Samples were examined in 10 mm o.d. tubes, and prior to Fourier transformation the f.i.d. was weighted so as to maximise the signal-to-noise ratio while retaining sufficient resolution for the purpose in hand.

METHODS AND RESULTS

The proton-decoupled ^{31}P NMR spectra of the complexes (I) consist of a single line due to an A_2 spin system from which it is not possible to derive a value of $J(PP)$ when the two phosphorus atoms are *chemically* equivalent, as is the case with all the molecules studied here. However, the presence of ^{13}C ($I = \frac{1}{2}$, natural abundance 1.1%) at a particular site can lower the *magnetic* symmetry so that the relevant spin system becomes AA'X (A, A' = ^{31}P, X = ^{13}C) and more information is available.[14] It is convenient to distinguish three general cases.

(i) J(*PP*) *is zero or very small*. The main ^{31}P peak (from molecules containing ^{12}C) is flanked by ^{13}C satellites whose positions give the magnitudes of the two ^{31}P-^{13}C coupling constants, and the ^{13}C spectrum is a doublet of doublets. Neither spectrum gives the relative signs of the two ^{31}P-^{13}C coupling constants.

(ii) J(*PP*) *is of moderate size*. The magnitude of $J(PP)$ can be obtained from the positions of the ^{13}C satellites in the ^{31}P spectrum, and their intensity pattern normally makes it possible to get the relative signs of the two ^{31}P-^{13}C coupling constants. The ^{13}C spectrum is a symmetrical five-line pattern having half its intensity in two lines separated by N, the algebraic sum of the two ^{31}P-^{13}C coupling constants, and the remainder in a central ine and two weaker outer lines whose positions depend upon $J(PP)$ and the ^{31}P-^{13}C couplings. Analysis of this pattern can also give a good indication of the magnitude of $J(PP)$.

(iii) J(*PP*) *is large*. The ^{13}C satellites in the ^{31}P spectrum are again in positions which give the values of the various coupling constants, but four of them are too weak to be detected and the other four are close to the central main peak and may be obscured by its wings. The ^{13}C spectrum is a triplet with almost a 1:2:1 intensity distribution, the small amount of intensity missing from the central line being in two outer lines at approx. $\pm J(PP)$, but which are too weak to be detected by normal observation.

The transition between cases (ii) and (iii) depends upon the relative values of the three coupling constants involved, and also upon the capabilities of the spectrometer, but as a very rough guide $|J(PP)| = 50$ Hz usually represents the maximum value that can be measured from a normal spectrum.

For case (ii) it is possible to use straightforward selective heteronuclear double resonance experiments[15] (under conditions of complete proton decoupling) to compare the sign of $J(PP)$ with that of either of the two ^{31}P-^{13}C couplings. Either ^{31}P-$\{^{13}C, ^1H_{noise}\}$ or ^{13}C-$\{^{31}P, H_{noise}\}$ experiments can be used, but the latter are generally more convenient since they avoid the severe dynamic range problems associated with detecting the weak ^{13}C satellites in the presence of a strong ^{31}P signal from molecules containing no ^{13}C. An important feature of this approach is that it can also be applied to case (iii) and used to determine the positions of *all* of the lines including the very weak ones even though only the strong ones are detected directly. This is because no matter how weak a particular line is, it is possible to increase the amplitude of the heteronuclear irradiating field to such a level that tickling effects will be transferred to a strong observed line, and a systematic search over a suitable range of trial frequencies will than give the position of the normally unobservable weak line.[5]

In the complexes studied in the present work the sites where the presence of ^{13}C can lead to the above kind of magnetic inequivalence are the equatorial CO groups, any of the positions in the phenyl groups, and certain of the backbone carbons of the bidentate phosphine ligands. However, a ^{13}C in an axial CO group or a symmetric central position in the backbone (i.e. in *dppm*, *gem-pp*, or *dppp*) leads to an A_2X spin system from which it is not possible to determine either $J(AA)[= J(PP)]$ or the sign of $J(AX)[= J(PC)]$. However, this latter parameter can often be inferred by comparison with another similar coupling.

The experiments involving the aromatic carbons are particularly valuable because they permit almost all of the signs of the coupling constants to be put onto an absolute basis. In practice, the signals from the non-protonated carbons bound to phosphorus were too weak (owing to the long relaxation times and absence of any n.O.e.) to be used conveniently in this way, whilst the couplings to the *para*-carbons were too small. However, in the case of the *ortho*-carbons the determination of $J(PP)$ also gave its sign relative to $N(PC)[= ^2J(PC) + ^4J(PC)]$. Since $^4J(PC) \ll ^2J(PC)$ the sign of $N(PC)$ is also that of $^2J(PC)$ which was found to be positive by comparison with $^3J(PH)$ [itself known[16] to be positive] in a selective ^{13}C-$\{^1H\}$ decoupling experiment. Similar considerations apply to the *meta*-carbons with the added security that $^5J(PC)$ is even smaller. The signs of the various other ^{31}P-^{13}C couplings were then related to that of $J(PP)$ in each complex. At high power levels the ^{31}P irradiation gives complete decoupling in the ^{13}C spectra, and the simplification achieved in this way can be a valuable aid to assignment in certain cases, although this was not really necessary in the present work.

The peaks of the ^{31}P spectra of the tungsten complexes are flanked by satellites arising from coupling to ^{183}W ($I = \frac{1}{2}$, natural abundance = 14%); ^{31}P-$\{^{183}W, ^1H_{noise}\}$ experiments gave the tungsten resonance frequency and hence $\delta(^{183}W)$. The sign of $^1J(PW)$ can be reliably taken as positive in this type

of compound.[17] Tables 1–4 list the NMR parameters of these complexes.

DISCUSSION

(a) Coupling constants

The main factors which are known to affect nuclear spin-coupling constants involving phosphorus are the effective nuclear charge and hybridization of phosphorus and of the other nucleus, and the geometry of the coupling path.[18] With the possible exception of the three derivatives [7–9] of *dpnp* all of the complexes examined here must have very comparable effective nuclear charges at phosphorus since in each case the phosphorus is bound to the metal atom, to two

phenyl groups, and to a carbon atom which may be either sp^3 or sp^2 hybridized. The phosphorus hybridization will be between p^3 and sp^3 in all of the compounds, and although it will be affected by changes in the interbond angles at phosphorus brought about by different ring sizes, this effect is likely to be relatively unimportant. Support for this contention is provided by the narrow range of variation for any particular metal atom of the coupling $^2J(P-CO_{ax})$ for which the relevant PMC interbond angle is 90° and should be little affected by alterations in the size of the chelate ring. It thus seems reasonable to attribute the major trends in the phosphorus-phosphorus and phosphorus-carbonyl couplings to

geometrical and electronic changes in the through-bond coupling path(s).

(i) $^2J(PP)$. This coupling can be regarded as being the sum of through-metal and "backbone" contributions as suggested by Grim et al.[7] For the complexes of dppb the backbone contribution will be over five sigma bonds and can probably be ignored, so that the observed coupling is a good measure of the through-metal component. Furthermore, for these complexes and those of dppp there is likely to be little or no distortion of the interbond angle at the metal atom due to the constraints of the chelate ring. The uniform difference in $^2J(PP)$ between the three complexes of dppb and the corresponding ones of

dppp, which is essentially independent of the metal atom, may thus be ascribed to a backbone contribution of -6.8 ± 0.3 Hz in the latter complexes. This may be compared with a value of ± 1.0 Hz in the free ligand dppp itself[6] where there is no special rigid stereochemical relationship between the two phosphorus atoms. In cis-$(Me_3P)_2M(CO)_4$ where the PMP interbond angles are likely to be close to 90° and there can be no backbone contribution $J(PP)$ has values of -36, -29.7 and -25.0 Hz for M = Cr, Mo and W respectively.[19]

By contrast, a comparison of the complexes having a five-membered chelate ring with those of dppb does show a significant dependence upon the metal atom,

Notes: (a) In Hz, ± 0.2 Hz.   Signs are given only when definitely known.

(b) For meanings of abbreviations see text.

(c) When there is only one entry it refers to $\underline{N}(PC)$, the algebraic sum of the two coupling·constants.

(d) Strictly $\underline{N}(PC)$, but it is reasonable to assume $^6\underline{J}(PC)$ = 0.

the changes of *dppb* → *dppe* being + 16.2, + 17.5 and + 20.5 Hz for Cr, Mo, and W respectively, while for *dppb* → *cis-vpp* the corresponding changes are + 27.0, + 30.2 and + 34.8 Hz. This is certainly consistent with there being significant (different) backbone contributions in the complexes of *dppe* and *cis-vpp*, but it should also be noted that the presence of two sp^2 hybridized carbon atoms in the chelate ring formed by *cis-vpp* will seriously affect the conformational mobility of its complexes and hence will produce greater constraints upon the PMP interbond angle than in the case of *dppe*. For the complexes with a four-membered ring the differences are even greater, the chromium complex being the most discrepant, as is to be expected if through-metal interactions are beginning to play a major role.

Although it can hardly be doubted that there are two separate paths available for the coupling mechanism, a problem with this type of analysis is that changes in the geometry of the ring are likely to affect both paths. Thus the smaller size of chromium compared with molybdenum and tungsten will affect the conformation of the chelate ring and hence of the ligand backbone—values of *J*(PP) are known to be very sensitive to such conformational effects. Nonetheless, it does emerge clearly from this study that in the sequence chromium, molybdenum, tungsten there is a progressive positive increment in $^2J(PP)$ for all types of complex studied. In view of the diversity of types of backbone involved it seems reasonable to attribute the major part of this change to the through-metal contribution. For the four-membered chelate rings the difference between $^2J(PP)$ for the chromium and molybdenum complexes is much greater than for the molybdenum and tungsten: this is reasonable since in these complexes the PMP interbond angle is constrained to be substantially less (typically it is 70°) than its "normal" value of 90° and

is very sensitive to the PM bond lengths which are quite similar for molybdenum and tungsten.[20] It is of course well-known that $^2J(PP)$ is strongly dependent upon the hybridization of an intermediate carbon atom, and on theoretical grounds it is believed that differences in the energies of the various metal electronic excitations will affect this coupling and may cause it to change sign. It is also clear from our results that it is essential to determine the sign of $^2J(PP)$ *experimentally*. Previously, it has been usual[3] simply to rely upon the expected algebraic increase in the sequence Cr, Mo, W, to estimate the signs, but evidently this would not necessarily have predicted the negative sign in compound [1].

(ii) $^2J(^{31}P-^{13}CO)$. The symmetry of the complexes is such that it was possible to obtain only the magnitude of $^2J(P-CO_{ax})$ and not its sign. However, comparison with the other similar *cis* couplings $^2J(P-CO_{eq})$ of known sign in these complexes makes it obvious that in all cases the sign is actually negative. Indeed, the magnitudes of the two kinds of *cis* P–CO coupling run so closely parallel that it is feasible to use the value of $^2J(P-CO_{ax})$ to estimate $^2J(P-CO_{eq})$ in those complexes where it was possible to measure only the sum of the *cis* and *trans* P–CO$_{eq}$ couplings and hence to obtain a good estimate of the *trans* $^2J(P-CO_{eq})$. For the six complexes to which this applies the calculated values are: [4], -4.9; [5], $+24.9$; [6], $+23.4$; [7], -5.2; [19], -4.4; [20], $+24.9$ Hz; all probably correct to within 1 Hz.

Our results demonstrate that for all the chromium complexes the *cis*- and *trans* P–CO couplings are negative, while for the molybdenum and tungsten complexes the *cis*-couplings are still negative but the *trans* are positive. This could constitute a useful assignment aid. It had been previously observed that in *cis*-(PH$_3$)$_2$Cr(CO)$_4$ the *cis* and *trans* P–CO couplings are of opposite sign although their absolute signs were unknown.[2] It is perhaps worth noting that for the complexes with a four-membered chelate ring two paths are in principle available for the P–CO coupling: the two-bond P–M–C one, and the four-bond P–C–P–M–C route which is not necessarily negligible, especially when there is a fixed geometry. However, the relative insensitivity of the P–CO coupling to chelate ring size suggests that in fact the four-bond route is unimportant. The most striking feature of the behaviour of $J(P–CO)$ is that in the sequence Cr, Mo, W there are algebraic increases of *ca.* 4 and 2 Hz respectively for the *cis* relationship, whereas the changes are *ca.* $+30$ and -2 Hz for the *trans*. These changes are much more consistent throughout the series of complexes than the changes in $J(PP)$, suggesting that the previously observed correlation between the two types of coupling may not be of very great generality.[3] It has been proposed elsewhere[21] that geminal coupling constants can be represented by an expression which for our complexes will take the form

$$^2J(P-M-C) = S \cdot {}^1J(PM) \cdot {}^1J(MC) \qquad (1)$$

where S depends upon the hybridization and electronic excitations of the intermediary atom M. In the tungsten complexes there is a rough correlation between the *trans* $^2J(P-CO_{eq})$ coupling and $^1J(PW)$ which is in agreement with eqn (1), but not for the *cis*

$^2J(P-CO)$ couplings. Thus it is probably reasonable to apply the mean electronic excitation energy approximation to the *trans* couplings, which are relatively large and positive, but not to the *cis*, which are smaller and negative. In this context it would be very interesting to know the signs and magnitudes of the geminal $^{13}C-^{13}C$ couplings between the carbonyl groups.

(iii) $^1J(^{183}W-^{31}P)$. This coupling increases with increasing size of the chelate ring, i.e. with increasing PWP interbond angle, and as pointed out above is broadly paralleled by *trans* $^2J(^{31}P-CO)$.

(iv) $J(^{31}P-^{13}C)_{backbone}$. The most striking feature of the one-bond couplings is that the differences between the tungsten and molybdenum complexes are greater than those between the molybdenum and chromium ones. For sp^3 hybridized phosphorus one-bond P–C couplings are normally positive and fairly large, while for p^3 they are negative and fairly small. Thus $^1J(PC)$ can be regarded as indicative of phosphorus hydribization, and shows it to be intermediate between p^3 and sp^3 in these complexes as expected. However, it is surprising that the phosphorus hybridizations in the molybdenum and tungsten complexes differ sufficiently to produce the observed differences in $^1J(PC)$. In this connection it must be realized that particularly for the complexes with smaller rings the nominally one-bond P–C couplings will in fact be made up of contributions from the true one-bond pathway and also from a route *via* the metal atom. This latter contribution will depend upon the electronic excitations involving the metal atom which may well differ significantly for molybdenum and tungsten.

The longer-range P–C$_{backbone}$ couplings will depend upon the above factors and also upon the stereochemical constraints of the ring; further discussion is not warranted at present. In principle the P–C couplings of the phenyl groups can also provide a guide to phosphorus hybridization and again provide evidence for significant differences between the phosphorus hybridizations in the molybdenum and tungsten (and also the chromium complexes).

(b) *Chemical shifts*

As has been discussed elsewhere[11] the tungsten chemical shifts in these complexes are sensitive to the size of the chelate ring, but the precise nature of the relationship is complex. Thus a four-membered ring experiences a large shift to high frequency, and a five-membered ring a large shift to low frequency, compared with an unstrained ring or no ring at all. This feature may be of diagnostic value, since it should be possible to use $\delta(^{183}W)$ to distinguish between small-ring monomers and large-ring dimers which might otherwise have very similar NMR parameters. The newly reported phosphorus coordination shifts, $\Delta\delta(^{31}P)$, also show the same marked dependence upon ring size and metal atom that was previously noted by Grim for *dppm*, *dppe* and *dppp* complexes.[10]

For any particular metal atom the ^{13}C chemical shifts of the axial carbonyl groups are quite insensitive to the size of the chelate ring, whilst those of the equatorial carbonyls do show some effect. This is reasonable, since for an axial CO group the P–M–C interbond angle will always be very close to 90° and

hence any through-space shielding effect will be essentially constant, whilst for an equatorial CO group this interbond angle and the concomitant shielding effect will be much more variable, according to the size of the chelate ring.

SELF-REDUCTION OF CHLOROHEMIN IN PYRIDINE: COMPARISON WITH THE PHOTOREDUCTION PROCESS

P. ZANELLO

Istituto di Chimica Generale dell'Universita' di Siena, Siena, Italy

Abstract—The self-reduction of chlorohemin in pure pyridine has been investigated by voltammetric techniques. The results obtained indicate that the self-reduction follows a first-order kinetic rate law. The reduction is strongly inhibited by the presence of chloride ions suggesting that the monopyridine protoporphyrin iron(III) $[Fe(III)(PP)(py)]^+$ axial complex is the species undergoing self-reduction. In oxygenated solution the process is strongly retarded since the oxidation of the $Fe(II)PP$ intermediate strongly competes with the formation of a stable $Fe(II)(PP)(py)_2$ complex. The results are discussed in the light of those obtained in a previous investigation on the photochemistry of chlorohemin under similar conditions.

It is well known that, in a number of biological systems, cytochromes, heme-containing iron-proteins, play a fundamental role in electron transfer processes. However, the means by which these proteins carry out their redox catalyst function is not clear and to date has been the subject of many investigations.[1-4]

The study of the iron porphyrin complex redox behaviour appears to be very useful in view of the construction of model systems capable of mimicking the features of biological redox processes. In a recent paper Bartocci *et al.*[5] have reported on the photoreduction process of chlorohemin [Fe(III)Protoporphyrin(IX) chloride, Fe(III) solvent, the authors attempted to simulate the solvent, the authors attempted, to simulate the aprotic environment of the heme-containing protein socket. In that paper it was observed that Fe(III)(PP)Cl underwent photoreduction yielding a dipyridine Fe(II)protoporphyrin(IX) complex as the final product. A slow thermal reduction, giving rise to the same final product obtained in the photochemical process, occurred when chlorohemin was dissolved in pyridine. This process has previously been observed by several authors,[6-8] during their investigations on Fe(III)porphyrin

complexes in pyridine solution. However, different explanations have been given and the possibility that impurities were responsible for this reduction were not ruled out.

In order to contribute to clarifying this unexplained self-reduction process, a re-investigation of this phenomenon was carried out.

EXPERIMENTAL

Materials

The supporting tetraethylammonium perchlorate† and tetraethylammonium chloride (Carlo Erba) electrolytes were dried in a vacuum oven and used without further purification. Chlorohemin, iron(III) protoporphyrin(IX) chloride [Fe(III)(PP)Cl] was recrystallized following the reported[9] glacial acid method. Imidazole (BDH) and phenyl-*tert*-butyl nitrone (PBN)(Aldrich) were used without further purification. Spectroscopic grade pyridine (Merck) was dried with calcium hydride, twice distilled and used within 24 hr after purification. Nitrogen (99.99%) was employed to remove oxygen from the tested solutions. When necessary, ultrapure oxygen was bubbled through the solutions.

Apparatus

In all the voltammetric experiments, a P.A.R. Model 170 Electrochemistry System was used as a polarizing unit. A water-jacketed cell maintained

at a selected temperature ($\pm$ 0.1C) by a Haake FE water thermostat was employed. Cyclic voltammetric tests were performed with a platinum microelectrode surrounded by a platinum spiral counter electrode. The potential of the working microelectrode was probed by a Luggin capillary reference electrode compartment. An electrode with periodical renewal of the diffusion layer was obtained by moving the solid electrode with a time-controlled knocker. All potential values refer to a saturated aqueous calomel electrode.

Electron spin resonance measurements were performed using a Bruker 220 SE spectrometer, equipped with accessory for variable temperatures.

Irradiation equipment and procedures were as previously reported.[5]

RESULTS AND DISCUSSION

In the potential range of the iron(III)–iron(II) couple, the cyclic voltammetric response of a de-aerated pyridine solution just after the addition of chlorohemin shows a cathodic peak to which an anodic peak is directly associated. As previously pointed out,[6] the charge-transfer involves a simple one-electron quasi-reversible step ($E_{1/2}$ = + 0.06 V, ΔE_p = 110 mV at 0.2 V/sec, i_{pa}/i_{pc} = 1.0).

The occurrence of a de-aerated hemin solution self-reduction reaction in time has been investigated by d.c. voltammetry using a platinum electrode with periodical renewal of the diffusion layer. As an example, the voltammetric responses obtained at 25°C at two different times are reported in Fig. 1. (Timing starts after the addition of hemin to pre-deaerated pyridine solutions.) Plots of the Fe(II)/Fe(III) ratio as a function of time at different temperatures are represented in Fig. 2. These ratios were calculated using cathodic and anodic limiting currents. Thus one can see that the self-reduction of chlorohemin in de-aerated pyridine is highly dependent on temperature.

In the concentration range of chlorohemin from 1.10×10^{-4} to 2.0×10^{-3} mol dm^{-3} the same trends hold. This datum, together with those reported in previous investigations,[8] indicates that a first-order reaction is involved in the self-reduction. A rate constant of 1.3×10^{-5} sec^{-1} was computed at 25°C, a value which is very close to that previously obtained (1.1×10^{-5} sec^{-1}) by spectrophotometric techniques.[8]

The influence of di-oxygen on the reduction rate of chlorohemin has been tested by bubbling ultra-pure oxygen (P_{O_2} = 1 atm) in the voltammetric cell. The results can be seen in Fig. 3. When the oxygenated solution was successively de-aerated, the self-reduction occurred again at the same rate as in the case of chlorohemin added to de-aerated pyridine.

Since the addition of chloride ions noticeably prevents the self-reduction of chlorohemin, the process was carried out in the presence of tet-
Fig. 1. D.c. voltammetric curves recorded for a pyridine solution containing chlorohemin (1.20×10^{-3} mol dm^{-3}) and [NEt$_4$][ClO$_4$] (0.1 mol dm^{-3}). (a) After 1 hr. (b) After 23 hr. Platinum working microelectrode, t = 25°C.
Fig. 2. Rate of reduction of chlorohemin in de-aerated pyridine solution at different temperatures. Chlorohemin concentrations are: curve a, 1.35×10^{-3} mol dm^{-3}; curve b, 1.20×10^{-3} mol dm^{-3}; curve c, 1.29×10^{-3} mol dm^{-3}. Supporting electrolyte, [NEt]$_4$[ClO$_4$] (0.1 mol dm^{-3}).

Fig. 3. Comparison between the rate of reduction of chlorohemin in de-aerated pyridine solution (curve a) and in pyridine saturated with dioxygen ($P_{O_2} = 1$ atm). Chlorohemin concentrations are: curva a, 1.00×10^{-3} mol dm^{-3}; curve b, 9.7×10^{-4} mol dm^{-3}, $t = 25°C$.

Scheme 1.

raethylammonium chloride (0.1 mol dm^{-3}) as supporting electrolyte. The data at 25°C indicate that under these experimental conditions the reduction of chlorohemin occurs to a degree quite similar to that reported in Fig. 3 for the influence of dioxygen. It must be noted that in the presence of an excess of chloride the reduction wave of chlorohemin shifts to more negative potentials ($E_{1/2} = -0.07$ V), indicating that chloride ions stabilize chlorohemin with respect to the reduction. An explanation for this result can be given by taking into consideration the fact that chloride influences the equilibria when chlorohemin is dissolved in pyridine, as reported by Bartocci et al.[5] (Scheme 1). It is evident from this scheme that an excess of chloride ions shifts the equilibria towards chloride complexes 2 and 3. The drastic lowering of the reduction rate observed under these conditions is clear evidence that the pyridine complex (1) undergo self-reduction more easily than the chlo-

ride complexes (2 and 3). The low self-reducibility of these species is an indication that Fe(III)-porphyrin chloride complexes are more stable than the corresponding Fe(II) complexes. Accordingly, by assuming the concentration of chloro-complexes to be negligible in the absence of free chloride ions, the shift of $E_{1/2}$ observed in the presence of excess [Cl$^-$] suggests that the stability constant of iron(III) chloride complexes is roughly 10^2 greater than that of the corresponding iron(II) complexes.

It is well known[6,7] that the reduction of chlorohemin in pyridine is strongly inhibited by the presence of an excess of imidazole, due to the formation of a bis-imidazole Fe(III)porphyrin

complex. D.c. voltammetric experiments carried out using pyridine chlorohemin solutions containing 0.1 mol dm^{-3} imidazole indicated that no iron(II) was formed within 7 hr. The shift of half-wave potential ($E_{1/2} = -0.56$ V), indicating that the stability constant of the imidazole iron(III) complex is 10^{10} greater than that of the corresponding imidazole iron(II) complex, accounts for the great stability of chlorohemin solutions in the presence of imidazole.

In order to detect the formation of radical intermediates during the self-reduction process, freshly prepared pyridine solutions of chlorohemin containing 5×10^{-2} M phenyl-*tert*-butyl nitrone (PBN) as a spin trap,[10] have been kept in an ESR cavity. No ESR signals indicating the formation of PBN radical adducts were observed at room temperature even after eight hours. This behaviour appears to be quite different from that observed by Bartocci *et al.* in the photoreduction investigation[5] where clear evidence of formation of pyridyl radicals was obtained by ESR trapping experiments. Identical results were obtained at 40°C, under conditions where the self-reduction rate was observed to be about three times faster than at room temperature (Fig. 2). In order to verify that the lack of detection of radical species is due to the PBN adduct instability, solutions of Fe(III)(PP)Cl in pyridine were irradiated both at room temperature (25°C) and at 40°C. In both cases ESR signals characteristic of pyridyl radical adducts with PBN appeared after a few minutes. No appreciable decrease in the signal intensity, which would indicate the decomposition of the adduct, was observed within 3 hr. The above results suggest that no appreciable amount of radical species are trapped by PBN during self-reduction. The observed discrepancy between photochemical and thermal reduction could simply be accounted for by assuming that an impurity reduces Fe(III) to Fe(II). However, this hypothesis may be ruled out since the reaction can go to completion, and in the wide range tested, it is not dependent on the chlorohemin concentration. Another, more plau-

sible, explanation should be that, although the final reduction products are identical, the photochemical and thermal systems do not follow exactly the same reaction coordinate. In a previous paper,[5] the primary photochemical process was identified as an intramolecular electron transfer from the axial pyridine to iron. Since the two electrons of the nitrogen of the coordinated pyridine are held in a strong σ bond, it is very likely that a π electron of the aromatic ring is involved in the electron transfer to central iron. As a consequence, the radical species formed in the primary photochemical act should be a π-type radical cation, which, by reacting with pyridine solvent, gives rise to the formation of a pyridyl radical, which is intercepted by the powerful radical scavenger, PBN. Unlike the photochemical reduction, the primary process in the self-reduction of chlorohemin should be an intermolecular electron transfer from pyridine solvent to iron. In this case the transfer of an electron of the *lone pair* of the pyridine nitrogen to metal appears to be the most probable event, and a pyridine N-radical cation should be the species formed in the primary act. The lack of formation of PBN paramagnetic adducts observed in the self-reduction process can then be explained in terms of a different fate of the N-radical cation in comparison with the π radical cation, i.e. the first could give rise to a different, very fast process, before giving radical species capable of being trapped by PBN. As a matter of fact, it is reported[11] that a pyridine N-radical cation can react very rapidly with pyridine to give bipyridine species rather than pyridyl radicals.

The pronounced effect of oxygen in slowing the reduction reaction (see results) can be explained in terms of an oxidation of the Fe(II)(PP)py complex, which is formed in the primary event (Scheme 2) in competition with pyridine axial coordination. This conclusion is substantiated by the finding that the final product Fe(II)(PP)(py)$_2$ oxidation cannot be responsible for the observed lowering of the reduction reaction because oxygen very slowly oxidizes this complex.[12]

$$\text{Fe (III) (PP) (py)}^+ + \text{py} \longrightarrow \text{Fe (II)(PP)(py)} + \text{py}^+$$

$$\text{py}^+ + \text{py} \xrightarrow{\text{very fast}} \text{products}$$

$$\text{Fe (II)(PP)(py)} + \text{py} \longrightarrow \text{Fe (II) (PP)(py)}_2$$

$$\text{Fe (II)(PP)(py)} + \text{O}_2 \longrightarrow \text{Fe (III)(PP)(py)}^+ + \text{O}_2^-$$
Scheme 2.

Abstract—Direct reduction of WCl_6 with PMe_3 in toluene at 120°C in a sealed tube affords the complexes $[WCl_4(PMe_3)_x]$ ($x = 2, 3$). $[WCl_4(PMe_3)_3]$ abstracts oxygen from equimolar amounts of water in wet acetone or tetrahydrofuran to give $[WOCl_2(PMe_3)_3]$ in very high yields. This procedure has been successfully applied to the high yield synthesis of other known oxotungsten(IV) complexes, $[WOCl_2(PR_3)_3]$ ($PR_3 = PMe_2Ph$ and $PMePh_2$). Metathesis reactions of $[WOCl_2(PMe_3)_3]$ with NaX give $[WOX_2(PMe_3)_3]$ (X = NCO, NCS) and $[WOX_2(PMe_3)]$ (X = Me_2NCS_2). The synthesis of the trimethylphosphite analogue, $[WOCl_2(P(OMe)_3)_3]$, is also described and the structures of the new complexes assigned on the basis of IR and ^1H and ^{31}P NMR spectroscopy.

In recent years we have been interested in the preparation and properties of trimethylphosphine complexes of Group VI metals, particularly molybdenum. This work has resulted in the synthesis of dinitrogen, ethylene, acyl and related complexes,[1,2] with the metal in oxidation states 0 or +2. Adequate starting reagents for these preparations are the chlorophosphine complexes $[MoCl_3(PMe_3)_3]$ and $[MoCl_2(PMe_3)_4]$. A natural extension of this work was the preparation of the tungsten analogues. However, at the time our work started little was known on the chemistry of trimethylphosphine derivatives of tungsten chlorides. In our search for a suitable starting material we have found that the tungsten(IV) complexes $[WCl_4(PMe_3)_x]$ ($x = 2, 3$) can be prepared in high yields by the PMe_3 reduction of WCl_6 in toluene, at 120°C in a sealed Carius tube. While our work was in progress Sharp and Schrock[3a] reported the preparation of these and other related complexes, including the metal–metal bonded dimer $[W_2Cl_4(PMe_3)_4]$. In this paper we wish to report our synthesis for the W(IV) complexes, $[WCl_4(PMe_3)_x]$ ($x = 2, 3$), and their facile conversion into the oxo species $[WOCl_2(PMe_3)_3]$ by oxygen abstraction from water in wet acetone or tetrahydrofuran (THF). The preparations and properties

of the oxo-trimethylphosphite analogue, $[WOCl_2(P(OMe)_3)_3]$, and other related complexes are also reported. We finally show the generality of the oxygen abstraction process for the conversion of $[WCl_4(PR_3)_2]$ complexes into the corresponding oxo-derivatives $[WOCl_2(PR_3)_3]$, by applying it to the synthesis of the known compounds $[WOCl_2(PR_3)_3]$ ($PR_3 = PMe_2Ph$, $PMePh_2$), previously prepared in rather low yields.[4] The reactions leading to these complexes are summarized in the Scheme.

RESULTS AND DISCUSSION

(1) *Tetrachlorobis- and tris-(trimethylphosphine) tungsten(IV)*

Although previous attempts to prepare $[WCl_4(PR_3)_2]$ complexes, directly from WCl_6 without reducing agents other than the phosphine in either cold or boiling THF yielded only oily materials,[4] it was later shown[5] that these complexes can be obtained in good yields by carrying out the reaction in boiling benzene (eqn 1)

$$WCl_6 + 3PR_3 \xrightarrow[\text{reflux}]{C_6H_6} [WCl_4(PR_3)_2] + R_3PCl_2 \quad (1)$$
($PR_3 = PMe_2Ph$, $PMePh_2$).

We have successfully applied this procedure to the synthesis of the trimethylphosphine analogue,

Scheme. (i) PMe₃ (less than 3 equiv), toluene, 120°C, 12–18 hr; (ii) as in (i), excess PMe₃; (iii) PMe₃, THF or toluene; (iv) reflux in toluene; (v) H₂O, PMe₃, THF or acetone, 40–50°C, 3 hr; (vi) KNCO or KNCS, THF, 3–4 hr; (vii) anhydrous NaS₂CNMe₂, THF, 3 hr.

[WCl₄(PMe₃)₂]. The reaction is best carried out in a sealed tube to avoid loss of volatile PMe₃. Thus, when WCl₆ and PMe₃ (*ca.* 1:2.5 molar ratio) are reacted in toluene at 120°C in a Carius tube, [WCl₄(PMe₃)₂] is formed in high yields. Using more than 3 equiv of PMe₃ a mixture of red [WCl₄(PMe₃)₂] and red–purple [WCl₄(PMe₃)₃] is obtained. These complexes can be easily converted into one another, addition of PMe₃ to solutions of the former causing precipitation of the latter, while moderate heating of solutions of [WCl₄(PMe₃)₃] produces loss of PMe₃ and formation of [WCl₄(PMe₃)₂]. Both complexes are moderately stable to air in the solid state but decompose quickly in solution. [WCl₄(PMe₃)₂] is monomeric in solution (cryoscopically in benzene) and paramagnetic with $\mu_{eff} = 1.87$ M.B. (Evans's method[6]), in the range expected for this type of complex [7]. Despite its paramagnetism it shows a relatively sharp NMR signal at $\delta - 25.2$ ppm. [WCl₄(PMe₃)₃] gives also a sharp NMR signal ($\delta - 8.2$ ppm) but its low solubility has precluded solution molecular weight and magnetic moment determinations. As mentioned above these two complexes have been independently prepared[3a] from WCl₄ and PMe₃. The crystal structure of [WCl₄(PMe₃)₃] has been determined.[3b]

(2) Oxotungsten(IV) complexes

Complexes of composition [WOCl₂(PR₃)₃] are known[4] for several monotertiary phosphines (PR₃ = PMe₂Ph, PMePh₂, PEt₂Ph) and were prepared in rather poor yields (*ca.* 30%) by reaction of WCl₆ with the phosphine in ethanol for PR₃ = PMe₂Ph, and in the presence of zinc in the case of the less reducing phosphines PMePh₂ and PEt₂Ph. We have now prepared the trimethylphosphine analogue [WOCl₂(PMe₃)₃] in 80% yield by an oxygen–atom abstraction reaction between [WCl₄(PMe₃)ₓ] (x = 2, 3) and stoicheiometric amounts of water, in the presence of an excess of PMe₃ to accept the generated hydrogen chloride, (eqn 2)

$$[\text{WCl}_4(\text{PMe}_3)_2] + \text{H}_2\text{O} + 3\text{PMe}_3$$

$$\rightarrow [\text{WOCl}_2(\text{PMe}_3)_3] + 2\text{HCl·PMe}_3. \quad (2)$$
Stirring a solution of [WCl₄(PMe₃)₂], or a suspension of [WCl₄(PMe₃)₃], in wet acetone or THF, at 40–50°C in the presence of PMe₃, produces a change in colour to dark-blue and precipitation of a white microcrystalline solid, identified as [HPMe₃]⁺Cl⁻ by comparison of its IR and NMR spectra with those of an authentic sample. When the reaction is complete and after work up, moderately air-stable dark blue crystals of [WOCl₂(PMe₃)₃] can be collected. This compound has been prepared independently by Wilkinson *et al.*[8] The IR spectrum of the complex shows absorptions characteristic of the PMe₃ ligands but no band due to $\nu(\text{W}=\text{O})$ can be observed. This is very likely due to overlapping with the strong, broad absorption centred at 940 cm⁻¹, characteristic of coordinated trimethylphosphine.[9] As in other related complexes[4] [WOCl₂(PMe₃)₃] is monomeric in benzene solution and diamagnetic. The ¹H NMR spectrum in CH₂Cl₂ shows a triplet at δ 1.57 and a doublet at 1.60 ppm (intensity ratio 2:1). This spectrum may be interpreted in terms of a *meridional* arrangement of the phosphine ligands and this along with the fact that the IR spectra of the complexes [WOX₂(PMe₃)₃] X = NCO, NCS) show two bands due to $\nu(\text{C–N})$ of the X ligands (see later) suggest stereochemistry as in I.

(1)
The procedure described above for the preparation of [WOCl₂(PMe₃)₃] is of general use and can be applied to the high yield synthesis of other known oxotungsten(IV) complexes. Thus, [WOCl₂(PMe₂Ph)₃], initially prepared in 25% yield by reaction of WCl₆ with PMe₂Ph in ethanol,[4] is obtained in *ca.* 75% yield by interaction of [WCl₄(PMe₂Ph)₂] with equimolecular amounts of water, in the presence of PMe₂Ph (see Experimental Section). Similarly, [WOCl₂(PMePh₂)₃] can be prepared by this same procedure in *ca.* 70%

yield, (eqn 3)

$$[WCl_4(PR_3)_2] + H_2O + 3PR_3$$

$$\rightarrow [WOCl_2(PR_3)_3] + 2HCl \cdot PR_3 \qquad (3)$$
($PR_3 = PMe_2Ph$, 75%; $PR_3 = PMePh_2$, 70%).

The trimethylphosphite derivative, $[WOCl_2\{P(OMe)_3\}_3]$, can be isolated in *ca.* 80% yield, as purple crystals, by the sodium amalgam reduction of $WOCl_4$ in the presence of $P(OMe)_3$. The IR spectrum has $\nu(W=O)$ at 955 cm^{-1}, and the ^1H NMR shows a multiplet at δ 3.82, that provides no information with regard to the stereochemistry of the complex. The $^{31}P\{^1H\}$ NMR spectrum consists of a triplet at δ 134.88 [$^2J(P-P) = 23.5$ Hz; $^1J(W-P) = 316.9$ Hz] and a doublet at 128.08 ($^1J(W-P) = 257.0$ Hz]. This is consistent with either a *facial* or a *meridional* distribution of the phosphite ligands.

Metathesis reactions of the chlorotrimethylphosphine complex $[WOCl_2(PMe_3)_3]$ with the appropriate potassium pseudohalide, yield $[WO(NCO)_2(PMe_3)_3]$ and $[WO(NCS)_2(PMe_3)_3]$ as dark blue crystalline materials. The Nujol-mull IR spectra show two strong bands at 2230 and 2190 cm^{-1} (cyanate complex) and 2060 and 2040 cm^{-1} (thyocyanate complex) attributed to $\nu(C-N)$ of the NCO and NCS ligands respectively. This and the appearance of the ^1H methyl resonances for these complexes as a triplet and a doublet (intensity ratio 2:1) strongly support structure of the type **I**.

The ease of the metathetical replacement of the chlorine atoms in $[WOCl_2(PMe_3)_3]$, provided an opportunity to synthesize the related oxodithiocarbamatetungsten(IV) complexes $[WO(S_2CNR_2)_2(PMe_3)]$ by similar procedures. Compounds of this type are to our knowledge unknown, although for both Mo and W a series of complexes of composition $[MO(S_2CNR_2)_2(R^1C_2R^2)]$ has been reported.[10,11] While for M = Mo these complexes are usually prepared by reaction of the known $[MoO(S_2CNR_2)_2]$ with the appropriate ligands,[10] for tungsten the corresponding $[WO(S_2CNR_2)_2]$ are still unknown, and the acetylene complexes $[WO(S_2CNR_2)_2(R^1C_2R^2)]$ have been obtained by the intermetal oxygen–atom transfer reaction[11] depicted in eqn (4),

$$[W(S_2CNR_2)_2(CO)(R^1C \equiv CR^2)]$$

$$+ [Mo_2O_3\{S_2P(OEt)_2\}_4] \rightarrow [WO(S_2CNR_2)_2(R^1C$$

$$\equiv CR^2)] + 2[MoO(S_2P(OEt)_2)_2] + CO. \qquad (4)$$
The complex oxodichlorotris(trimethylphosphine)tungsten(IV), $[WOCl_2(PMe_3)_3]$, reacts with anhydrous NaS_2CNMe_2, in THF, at room temperature to afford dark red crystals of $[WO(S_2CNMe_2)_2(PMe_3)]$ in *ca.* 70% yield. In addition to absorptions due to the PMe_3 ligand, the IR spectrum of this moderately air-stable solid is characterized by a strong band at 930 cm^{-1} due to the W=O stretch and two absorptions at 1540 and 1515 cm^{-1} which are assigned to the C=N stretch of the coordinated dithiocarbamate ligands. While the $^{31}P\{^1H\}$ NMR spectrum is a singlet at temperatures between 25° and $-80°C$ (δ -19.8 ppm, $^1J(W-P) = 210.9$ Hz) the ^1H NMR spectrum shows temperature dependence. At 35°C (CD_2Cl_2) the spectrum consist of three methyl signals at δ 3.81, 3.66 and 3.34 ppm (intensity ratio 1:1:2) for the dithiocarbamate groups and a doublet at 1.44 ppm ($^2J(P-H) = 9.2$ Hz) for the PMe_3 protons. Upon lowering the temperature, the singlet at 3.34 broadens, and at 20°C gives rise to an unresolved doublet. On further cooling this signal becomes a sharp doublet of resonances, no additional changes being observed down to $-80°C$. At this temperature four distinct ^1H methyl resonances at 3.81, 3.66, 3.37 and 3.30 ppm are observed for the $Me_2NCS_2^-$ ligands. This spectrum is consistent with structure type **II**.

(II)
Although a more detailed NMR study is required before any definite conclusion can be reached, it is tempting to assume that the averaging of the two low temperature methyl signals at 3.37 and 3.30 ppm, to give a singlet at 3.34 ppm in the 35°C spectrum, is due to fast exchange of the two methyl groups of the monodentate dithiocarbamate ligand in the short-lived 5-coordinate intermediate, $[WO(S_2CNMe_2)(SC(=S)NMe_2)(PMe_3)]$, formed by rupture of the W–S bond trans to oxygen. This assumption is supported by the high *trans*-influence of the oxo ligand which is well documented in this type of complex.[11,12]

EXPERIMENTAL

surements. Magnetic susceptibilities were obtained in solution by the Evans method.

All preparations and other operations were carried out under oxygen-free nitrogen following conventional Schlenk techniques. Solvents were dried and degassed before use.

The light petroleum used had b.p. 40–60°C. PMe₃ was prepared according to the literature method.[13] The complexes [WCl₄(PR₃)₂] (PR₃ = PMe₂Ph, PMePh₂) were prepared by a slight modification of the method of Galyer and Wilkinson.[5] Details of the preparations are given below. NaS₂CNMe₂ was dried by heating at 90°C under vacuum for 6–7 days.

Tetrachlorobis(trimethylphosphine)tungsten(IV)

A thick-walled 250 cm³ Carius tube, provided with a stirring-bar, was charged with WCl₆ (19.8 g, *ca.* 50 mmol). Toluene (100 cm³) and PMe₃ (14.0 cm³, *ca.* 140 mmol) were successively added via syringe, the resulting mixture frozen at liquid nitrogen temperature and the tube sealed under *vacuo*. The mixture was allowed to reach room temperature and then heated at 120°C for 12–18 hr, with occasional shaking to facilitate the reaction. The resulting dark red solution was transferred while hot (boiling water external bath) and the remaining solid extracted with several portions of hot toluene until no more [WCl₄(PMe₃)₂] was left (*ca.* 4 × 75 cm³). The solution was reduced in volume (to *ca.* 100 cm³) and cooled at −30°C overnight. 14 g of well formed red crystals impurified by relatively small amounts of a yellow powder (Cl₂PMe₃)[14] were obtained. Another crop (4 g) of less pure product was recovered from the mother liquor. The total yield of crude, but pure enough for most synthetic purposes, [WCl₄(PMe₃)₂] was *ca.* 75%. The compound can be purified by recrystallisation from hot toluene. [Found C, 15.4 (15.1); H, 3.9 (3.8); Cl, 29.4 (29.7)% *M*, 462 (444).]

IR (KBr) bands at: 2980, 2940, 1410, 1290, 1275, 1250, 1095, 1010, 935, 835, 785, 720, 650 cm⁻¹. NMR data ¹H(C₆H₆): −25.2 bs. $\mu_{eff} = 1.86 \, \mu_B$.

Tetrachlorotris(trimethylphosphine)tungsten(IV)

To a magnetically stirred solution of [WCl₄(PMe₃)₂] (0.95 g, *ca.* 2 mmol) in THF an excess of PMe₃ (0.3 cm³, *ca.* 3 mmol) was slowly added. Dark red–purple microcrystals of the title compound immediately formed. The mixture was kept overnight at −30°C to complete crystallisation, the resulting solid filtered off, washed with petroleum or Et₂O and vacuum dried. The yield was *ca.* 90%. Recrystallisation can be achieved from hot toluene in a closed flask to avoid loss of PMe₃. [Found C, 19.5 (19.5); H, 5.0 (4.9); Cl, 25.6 (25.6)%.]

IR (KBr) bands at: 2980, 2950, 1420, 1295, 1230, 1100, 950, 850, 800, 780, 730, 665 cm⁻¹. NMR data ¹H(C₆H₆): −8.2 bs.

Oxodichlorotris(trimethylphosphine)tungsten(IV)

To a stirred solution of [WCl₄(PMe₃)₂] (0.95 g, *ca.* 2 mmol) in THF or acetone (40 cm³), PMe₃ (0.7 cm³, *ca.* 7 mmol) was added. Immediate formation of red purple microcrystals of [WCl₄(PMe₃)₃] was observed. To the resulting suspension were added a few drops of deoxygenated water and the mixture stirred at 45°C. the reaction was followed by the disappearance of insoluble [WCl₄(PMe₃)₃] and more water added if required. A large excess of water should be avoided since considerable decomposition takes place. The stirring was continued at this temperature until all the initial [WCl₄(PMe₃)₃] had been taken into solution (*ca.* 2 hr) and then for another hour. The mixture was evaporated to dryness and the residue extracted with Et₂O (40 cm³). Filtration and cooling at −30°C afforded the title compound as dark-blue crystals in *ca.* 80% yield. [Found C, 21.5 (21.5); H, 5.5 (5.4)%. *M*, 490 (499).]

IR (Nujol mull) bands at: 1375, 1300, 1280, 1260, 950, 850, 800, 720, 660 cm⁻¹.

NMR. ¹H (C₆H₆): 1.57t (18), *J*(P-H)ap = 4 Hz; 1.60d (9), *J*(P-H) = 10 Hz.

Oxodichlorotris(dimethylphenylphosphine)tungsten (IV)

The complex [WOCl₂(PMe₂Ph)₃] was prepared in *ca.* 75% yield as dark blue crystals (from hot ethanol) following a procedure identical to that described above for [WOCl₂(PMe₃)₃]. The parent complex, [WCl₄(PMe₂Ph)₂] was prepared as follows:

To a suspension of WCl₆ (4.8 g, *ca.* 12 mmol) in benzene (100 cm³) were added 4 cm³ of PMe₂Ph (*ca.* 30 mmol). A grey oil formed in the bottom of the flask making stirring difficult. The mixture was refluxed for 12–18 hr when a red solution and a brown solid were obtained. The solid was decanted, the solution filtered while still hot and then evaporated until precipitation took place. Complete precipitation was achieved by addition of Et₂O (*ca.* 20 cm³) and cooling at −30°C overnight. Yield 60%.

The complex [WCl₄(PMePh₂)₂] was similarly prepared and reacted with water under the conditions mentioned above, to give mauve crystals (from Et₂O–THF) of [WOCl₂(PMePh₂)₃] in 80% yield. Both oxocomplexes were identified by comparison of their IR and ¹H NMR spectra with those of authentic samples.[4]

Oxochlorotris(trimethylphosphite)tungsten(IV)

Freshly prepared WOCl₄ (3.62 g, *ca.* 5.63 mmol)

was loaded into a 500 cm³-pressure bottle with four equivalents of Na–Hg amalgam (1.5 cm³ of a *ca.* 1% in Na). The contents were pumped on for *ca.* 1 hr. The pressure vessel was cooled to −78°C and degassed THF (150 cm³) and P(OMe)₃ (5.3 cm³, *ca.* 45 mmol) were added. The bottle was pressurized to 40 psi with hydrogen. The reaction vessel was allowed to warm slowly to room temperature and stirred for 12 hr. The volatile materials were removed under vacuum leaving a purple oil. This was extracted into Et₂O (50 cm³), filtered, evaporated to *ca.* 25 cm³ and cooled at −20°C. Purple crystals of [WOCl₂(P(OMe)₃)₃] were collected and dried under vacuum. Yield: 80%. [Found C, 17.0 (16.8); H, 4.2 (4.2); Cl, 10.9 (11.0); P, 14.4 (14.4)%.]

IR (Nujol mull) bands at: 2855, 1371, 1309, 1267, 1188, 1021, 955, 669 cm⁻¹.

NMR: ¹H (C₆D₆): 3.82 mult. ³¹P{¹H} (C₆D₆): 134.88t, ²J(P–P) = 23.5 Hz, ¹J(W–P) = 316.9 Hz; 128.08d, ¹J(W–P) = 257.0 Hz.

Oxobis (cyanate) tris (trimethylphosphine) tungsten (IV)

[WOCl₂(PMe₃)₃] (0.5 g, *ca.* 1 mmol) and dried (100°C, 24 hr) KCNO (0.2 g, excess) were stirred at room temperature in THF (40 cm³) over a period of 3–4 hr. The solvent was then stripped *in vacuo* and the residue extracted with 50 cm³ of Et₂O. The resulting suspension was centrifuged and small dark blue needles of [WO(NCO)₂(PMe₃)₃] were collected in *ca.* 80% yield by cooling at 0°C overnight. [Found C, 25.7 (25.8); H, 5.3 (5.3)%].

IR (Nujol mull) bands at: 2230, 2190, 1375, 1350, 1335, 1300, 1285, 950, 725, 665, 620 cm⁻¹.

RMN: ¹H (CH₂Cl₂): 1.60t (18), J(P–H)ₐₚ = 4 Hz; 1.70d (9), J(P–H) = 8 Hz.

Metathesis with KSCN was accomplished in a similar way to give small blue crystals of [WO(NCS)₂(PMe₃)₃] (from Et₂O–THF) in *ca.* 80% yield. [Found C, 24.4 (24.3); H, 5.0 (5.0)%.]

IR (Nujol mull) bands at: 2060, 2040, 1380, 1305, 1290, 1260, 965, 945, 835, 720, 665 cm⁻¹.

RMN: ¹H (CH₂Cl₂): 1.80t (18), J(P–H)ₐₚ = 4 Hz; 1.88d (9), J(P–H) = 8 Hz.

Oxobis(N,N - dimethyldithiocarbamate)trimethyl - phosphinetungsten(IV)

30 cm³ of THF were syringed into a mixture of [WOCl₂(PMe₃)₃] (0.5 g, *ca.* 1 mmol) and anhydrous NaS₂CNMe₂ (0.5 g, excess). The dark blue crystals of the tungsten compound dissolved immediately giving a dark red solution. The mixture was stirred for *ca.* 3 hr at room temperature and the solvent was

removed *in vacuo*. Extraction with 30 cm³ of a 1:1 mixture of Et₂O:CH₂Cl₂ and centrifugation afforded a dark red solution from which dark red crystals of [WO(S₂CNMe₂)₂(PMe₃)] were collected in *ca.* 70% yield after partial removal of the solvent and cooling at −30°C. [Found C, 22.2 (20.9); H, 4.4 (4.1); N, 5.7 (5.4)%.]

IR (Nujol mull) bands at: 1545, 1520, 1400, 1390, 1280, 1275, 1240, 1150, 1140, 1050, 1040, 950, 935, 930, 895, 850, 830, 730, 720, 660 cm⁻¹.

¹NMR: ¹H (CD₂Cl₂, −80°C): 3.81s (3); 3.66s (3); 3.37s (3); 3.30s (3); 1.44d (9), J(P–H) = 9.2 Hz. ³¹P{¹H} (CD₂Cl₂, −80°C): −19.8; J(W–P) = 210.9 Hz.

Abstract—The reduction of $WCl_4(PMe_3)_3$ by sodium amalgam in presence of phenylacetylene gives $W(PMe_3)(PhC\equiv CH)_3$ (*A*). Reduction in presence of methylisocyanide gives $W(PMe_3)_2(MeNC)_4$ (*B*), while in presence of excess PMe_3 in tetrahydrofuran under hydrogen, $WH_2Cl_2(PMe_3)_4$ (*C*) is formed. The reaction of $WCl_2(PMe_3)_4$ with methanol in tetrahydrofuran gives mixtures of $WH_2Cl_2(PMe_3)_4$ and $WOCl_2(PMe_3)_3$ (*D*).
The structures of A, B, and D have been determined by X-ray diffraction.

RESULTS AND DISCUSSION

1. *Reductions of tris(trimethylphosphine)tetrachlorotungsten*

(a) *Phenylacetylene.* The interaction of WCl_4 $(PMe_3)_3$,[1] and excess phenyl acetylene with sodium amalgam in tetrahydrofuran gives a pale yellow complex, $W(PMe_3)(PhC\equiv H)_3$ (*A*). Other compounds of the type $WX(RC\equiv CR')$, $X = CO$, MeCN or PMe_2Ph have been obtained from $W(CO)_3(MeCN)_3$.[2,3] The new complex is slightly soluble in petroleum but very soluble in benzene and toluene. The solid is moderately stable in air but solutions are sensitive. No $C\equiv C$ stretching frequency could be identified in the IR spectrum although for similar W or Mo compounds bands are reported around $1750\,cm^{-1}$.[2,4] The ^1H, ^{31}P and ^{13}C NMR spectra are in agreement with those expected for the structure (Fig. 1) as determined by X-ray diffraction. The $^{13}C\{^1H\}$ spectrum shows a doublet at $\delta\,201.4\,ppm$ $(^2J_{C-P} = 5\,Hz$; $^1J_{C-W} = 41\,Hz)$ assigned to $PhC\equiv CH$; a doublet at

$\delta\,164.2\,ppm$ $(^2J_{C-P} = 16\,Hz$; $^1J_{C-W} = 32.8\,Hz)$ assigned to $PhC\equiv CH$; singlets at $\delta\,142$, 130.2, 127.8 and 127.5 ppm corresponding to the 1, 2, 3 and 4 carbons of the phenyl ring; a doublet at $\delta\,17.5\,ppm$ $(^1J_{C-P} = 14.7\,Hz)$ due to PMe_3. These assignments are confirmed by the off-resonance ^{13}C spectrum where the peaks at $\delta\,201.4$ and 142 ppm remain as singlets while the peak at $\delta\,164.2\,ppm$ is a doublet of doublets and can be assigned to $PhC\equiv CH$.

A diagram of the molecular structure of *A* is given in Fig. 1, whilst selected geometry parameters are given in Table 1. The complex has an approximate three-fold axis of symmetry coincident with the W–P axis, and the acetylenic groups are aligned in such a way that the three WC_2 planes are approximately parallel to this axis (making angles of 2, 0 and 2°). The acetylenic carbon atoms are bonded almost symmetrically to the tungsten atom with all six W–C bonds equal within the limits of experimental error. The geometry of the phenylacetylenes are modified in the expected manner, with the formal $C\equiv C$ bonds lengthened to $\sim 1.30\,\text{Å}$ and the Ph groups bent away to give a $C\equiv C-C$ angle of $\sim 138°$. The structure and molec-

ular geometry parameters are closely analogous to those of the complex $(OC)W(HC\equiv CPh)_3$.[3b] The electronic structure of complexes of this type has been discussed previously by Tate *et al.*[3a] who suggested that the complex could be regarded as an eighteen electron system if two of the acetylenes were acting as 4-electron donors (i.e. donating both pairs of π electrons). The structural, and presumably electronic equivalence of all three acetylenes suggests that the unused pair is delocalised into a non-bonding MO (actually of a'_2 symmetry.[3a]

(b) *Methylisocyanide*. Reduction of WCl_4 $(PMe_3)_3$ in presence of MeNC gives an orange, air sensitive complex *trans*-$W(PMe_3)_2(MeNC)_4$ (B), which is very soluble in hydrocarbons.

This complex was shown by X-ray structure analysis to have an octahedral *trans*-phosphine structure. The crystal structure contains two independent centrosymmetric molecules which differ only in the crystallographic orientation of the equatorial $W(CNMe)_4$ groups. A diagram of the unit cell contents are given in Fig. 2, whilst selected molecular geometry parameters are given in Table 2. In view of the low precision of this structure

determination (see Experimental) it is not possible to discuss these parameters in any detail.

In solution both ^1H and $^{31}P\{^1H\}$ NMR spectra indicate that there is a mixture of *cis* and *trans* isomers in a ratio 1:3 at 25°C; the ^1H spectrum is essentially unchanged from -80 to $+75$°C. The ^1H NMR assigned to the *trans* isomer has a triplet at δ 1.8 $(^2J_{P-H} + {}^4J_{P-H} = 5.2\,Hz)$ for the PMe_3 groups and a multiplet at δ 2.84 for *Me*NC. The *cis* isomer has a doublet at δ 1.54 $(^2J_{P-H} + {}^4J_{P-H} = 5.2\,Hz)$ for PMe_3 and two multiplets at δ 2.85 and 2.83 for *Me*NC.

The $^{31}P\{^1H\}$ spectrum has two singlets at δ -25.5 ppm $(^1J_{P-W} = 286\,Hz)$ for the *trans* and δ -34.0 ppm $(^1J_{P-W} = 220\,Hz)$ for the *cis* isomer.

Orange red products are also obtained using Bu^{t}NC but we have been unable to isolate pure compounds. No other phosphine isocyanides appear to exist but a variety of carbonyl compounds $W(CO)_n(PR_3)_m$, $n + m = 6$ are known.[5]

(c) *Trimethylphosphine under hydrogen*. The reduction of $WCl_4(PMe_3)_3$ under hydrogen in presence of excess PMe$_3$ produces the air sensitive pale yellow $WH_2Cl_2(PMe_3)_4$ (C), whose analogue, $WH_2Cl_2(PMe_2Ph)_4$, has recently been reported.[6]
Fig. 2. Unit cell diagram of *trans*-$W(PMe_3)_2(MeNC)_4$.

*For the numbering of atoms in the isocyanides, X = 1, 2 for molecules

1, 2 respectively.

The compound is also obtained by the reaction of WCl$_2$(PMe$_3$)$_4$ with methanol (see below). The compound is very soluble in aromatic hydrocarbons and crystallises well from diethylether. The spectroscopic data is consistent with the structure (1) which is confirmed by preliminary X-ray crystallographic data. Thus, the IR has peaks at 1985 and 1936 cm^{-1} for W–H while the ^{1}H NMR spectrum shows a multiplet at δ 1.44 for PMe$_3$ groups and a triplet of doublets of doublets at δ -3.44 ($^2J_{P-H} = 37.7$ Hz, 42.1 Hz and 60.6 Hz) with an AA'B$_2$X$_2$ spin system for W–H. The ^{31}P{^{1}H} spectrum shows two triplets with an A$_2$B$_2$ spin system at δ -17.06 ppm ($^2J_{P-P} = 16$ Hz, $^1J_{P-W} = 174.4$ Hz) and δ -23.65 ($^2J_{P-P} = 16$ Hz, $^1J_{P-W} = 194$ Hz).

2. Oxodichlorotris(trimethylphosphine)tungsten(IV)

The complex trans-WCl$_2$(PMe$_3$)$_4$[1] is quite unreactive and can be recovered unchanged after treatment with methyllithium or Grignard reagents in ether although it does react with tri-

methylaluminium to give an alkylidyne.[7] However, it reacts readily with methanol alone or in tetrahydrofuran on refluxing to give mixtures of WH$_2$Cl$_2$(PMe$_3$)$_4$ and the purple air-stable WOCl$_2$(PMe$_3$)$_3$ (D).[8] Similar complexes, MOCl$_2$ (PR$_3$)$_3$, M = Mo, W, have long been known for different phosphines.[9,10]

This oxo complex is found to have a *meridional* arrangement of the three phosphines with one of the two chlorines *trans* to the oxo-function. The unit cell contains two independent molecules (a diagram of one of which is given in Fig. 3) whose geometries (Table 3) are essentially equal, within the limits of experimental error. All geometry parameters are close to expected values. The *trans*-influence of the oxo-function on the opposing W–Cl bond and the other chlorine on the opposing W–P bond are noticeable but are not very large. The spectroscopic data for the oxo complex is consistent with the structure determined by X-ray diffraction. The reaction presumably involves an initial oxidative addition of methanol followed by
(1)

further reactions of the intermediate methoxide which we have been able to detect spectroscopically but have been unable to isolate. The oxidative addition of methanol to the tungsten(II) species $WH_2(PMe_3)_5$ leading to $WH_3(OMe)(PMe_3)_4$ has previously been established.[11]

EXPERIMENTAL

Microanalysis were by Pascher (Bonn).

Spectrometers. NMR. Perkin–Elmer R32 (^1H), Bruker WM 250 (^1H 250 MHz, ^{31}P 101.2 MHz, ^{13}C 62.9 MHz, 28°C). ^1H data referenced to Me_4Si, $^{31}P\{^1H\}$ to external 85% H_3PO_4 in ppm.

IR. Perkin–Elmer 627; data in cm^{-1}.

All operations were performed under oxygen-free nitrogen or argon or *in vacuo*, and all solvents except methanol were dried over sodium and distilled from sodium benzophenone under nitrogen immediately before use. Methanol was dried over magnesium methoxide and distilled under nitrogen. Petroleum had b.p. 40–60°C. Melting points were determined in sealed tubes under nitrogen (uncorrected).

$WCl_2(PMe_3)_4$ and $WCl_4(PMe_3)_3$ were prepared according to the literature[1].

Trimethylphosphine   tris(phenylacetylene)   tungsten(O) (A)

To $WCl_4(PMe_3)_3$ (1.31 g, 2.36 mmol) suspended in thf (100 cm^3) was added excess phenylacetylene (1.2 cm^3, 10.9 mmol), and the mixture was added to thf (50 cm^3) containing sodium amalgam (1.0 g, 10 cm^3 Hg). The mixture was stirred overnight at room temperature, when the solution was filtered, and evaporated under vacuum. The residue was extracted into petroleum (2 × 40 cm)^3), the solution filtered, concentrated to *ca.* 60 cm^3 and cooled to − 10°C to give pale yellow crystals. Yield: 0.6 g, 50%; m.p., 148–9°C. [Found: C 57.4 (57.2), H 4.8 (4.8), Cl < 0.2 (0), P 5.9 (5.5)%. *M* 550 (566)].

Tetrakis(methylisocyanide) trans *bis(trimethylphosphine) tungsten(O)* (B)

To $WCl_4(PMe_3)_3$ (0.5 g, 0.9 mmol) suspended in thf (50 cm^3) was added excess MeNC (0.5 cm^3, 5.0 mmol), and sodium amalgam (0.5 g Na, 6 cm^3 Hg) in thf (50 cm^3). The mixture was stirred overnight at room temperature. After filtration the solution was evaporated under vacuum, the residue extracted into petroleum (40 cm^3), and the solution filtered, concentrated to *ca.* 10 cm^3 and cooled to − 20°C to give orange crystals. Yield, 0.36 g, 80%; m.p., 110°C. [Found: C33.2 (33.6), N

10.7 (11.4), H 6.0 (6.0), P 11.6 (12.4)%. *M* 480 (500)].

IR. 2118w, 1970sbr, 1830vsbr, 1406w, 1390m, 1380m, 1290m, 1270m, 955s, 938s, 750w, 662m.

NMR. See text.

Tetrakis(trimethylphosphine)   *dichlorodihydridotungsten(IV)* (C)

To a suspension of $WCl_4(PMe_3)_3$ (0.8 g, 1.44 mmol) in thf (20 cm^3) was added excess trimethylphosphine (0.5 cm^3, 5 mmol) and the slurry transferred to a pressure bottle containing sodium amalgam (0.5 g in 2 cm^3 Hg) at − 78°C. After pressurisation with hydrogen (9 atm) the suspension was allowed to warm slowly, and then stirred for 2 hr at room temperature. The resulting green solution was filtered, evaporated under reduced pressure and the residue extracted with diethyl ether (50 cm^3), the solution filtered, concentrated and cooled slowly to − 20°C to give yellow crystals. Yield: 0.36 g (*ca.* 51%); m.p. (decomp.) *ca.*

180°C. [Found: C 25.7 (25.7), H 6.77 (6.77), Cl 12.7 (12.6), P 21.8 (22.1)%. M 550 (561)].

IR. 1985w, 1936s, 1475m, 1432s, 1420s, 1400m, 1300m, 1280m, 1270m, 1100m, 1030w, 940vsbr, 860m, 850m, 820w, 800w, 720s, 665m.

NMR. See text.

4, 5, 6-*Tris*(*trimethylphosphine*)-2, 3-*cis*-*dichloro*-1 -*oxo* *tungsten*(*IV*) (D)

Dried methanol (20 cm³) was added to *trans*-WCl$_2$(PMe$_3$)$_4$ (1.5 g, 2.68 mmol) in thf (50 cm³) at room temperature. The solution was stirred *ca.* 16 hr when the solvent was removed and the residue extracted into toluene (2 × 30 cm³). The orange red extract was filtered, evaporated and the residue extracted into diethylether (2 × 40 cm³). This ether solution was filtered, concentrated to *ca.* 30 cm³ and cooled to − 10°C to give purple crystals of WOCl$_2$(PMe$_3$)$_3$, which were collected. The

filtrate was further concentrated and cooled to − 20°C to give pale yellow crystals, WH$_2$Cl$_2$ (PMe$_3$)$_4$, identical to that prepared as above. (Yield: 0.5 g, 35%).

For WOCl$_2$(Me$_3$)$_3$, Yield: 0.4 g, 30%, m.p., 134–5°C. [Found: C 21.6 (21.7), H 5.5 (5.4), Cl 13.7 (14.2), P. 19.1 (18.6), O 3.0 (3.2)%. M 470 (499)].

IR. 1475w, 1420m, 1300m, 1285m, 1210w, 950vsbr (W = O), 855m, 730s, 715msh, 667m.

NMR. ^{1}H (C$_6$D$_6$): δ 1.44 m.

^{31}P{^{1}H}(C$_6$H$_6$ + 10% C$_6$D$_6$): δ − 24.0 d (2), $^1J_{W-P}$ = 343 Hz, $^2J_{P-P}$ = 4.2 Hz; δ − 30.1 t (1), $^1J_{W-P}$ = 446 Hz, $^2J_{P-P}$ = 4.2 Hz.

Crystallographic studies

Crystals of all three compounds were sealed under argon in Lindemann capillaries. All crystallographic measurements were made using a CAD4 diffractometer, operating in the $\omega/2\theta$ scan

*Unit weights used

mode, with monochromated Mo–$K\alpha$ radiation ($\lambda = 0.71069$ Å) in a manner previously described in detail.[12] All data were corrected for absorption empirically.[13] The structures were determined using standard heavy atom procedures and refined by full matrix least-squares methods. Computers, programs and sources of scattering factor data were also as given in Ref. 12.

For compound A all non-hydrogen atoms were refined with anisotropic thermal parameters but the phenyl rings were refined as rigid bodies with hexagonal geometry, and the hydrogen atoms included in idealised positions (C–H = 1.08Å) and assigned a common, overall U_{iso} parameter (= 0.15Å^2). Unfortunately the acetylenic protons could not be located and were not included. For compound B, the refinement was difficult due to excessive pseudo-symmetry and some disorder in the orientation of the PMe_3 groups. The unit cell contains two independent, centrosymmetric molecules, centred at 0, 0, 0 and $\frac{1}{2}$, $\frac{1}{2}$, 0, and in addition to the heavy atom pseudo-centring, the linear P–W–P units are also approximately parallel. However, the set of equatorial $CNMe$ groups have different orientations in the two molecules and this allowed the pseudo symmetry to be broken, albeit weakly. Stable refinement could only be achieved by retaining isotropic thermal parameters for all but the metal atoms, and by constraining the P–C bonds to standard values (1.84 ± 0.02Å). As a result the structure has not been determined with high precision.

For compound D, high thermal motion and/or disorder in the PMe_3 groups also caused some problems in refinement and for this structure the P–C distances were also constrained during refinement, for which two blocks were used (one molecule per block).

Details of the crystal data, intensity measurement and refinement procedures are given in Table 4. Computer programs and sources of scattering factor data are as given previously.[13]

Tables of atomic coordinates, thermal parameters, bond lengths and angles and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Base.

ISOELECTRONIC REAGENTS. II. STANDARD FORMATION
ENTHALPIES OF PHENYL AND pFLUOROPHENYL IODINE DICHLORIDES

M. CARTWRIGHT and A.A. WOOLF*

School of Chemistry, University of Bath,
Bath BA2 7AY, UK

Abstract – The formation heats $\Delta H_f^o PhICl_2(c)$
= 21.7 kJ mol^{-1} and $\Delta H_f^o pFC_6H_4ICl_2(c)$ = −173.0 kJ mol^{-1}
were determined by reaction of iodides with excess
chlorine in methyl cyanide. These heats are used to
show:

(i)   that thermal or photo-decompositions of aryl
       iodine dichlorides are kinetically controlled,

(ii)   the greater halogenating ability of aryl
       iodine dichlorides than Ph_3ACl_2 (A = P, As,
       Sb) compounds, and

(iii) the weakening of halogenating ability with
       phenylation.

INTRODUCTION

In Part I[1] previously unrelated fluorinating reagents
such as $PhIF_2$, Ph_3PF_2 and XeF_2 were shown to be period-
ically related as isoelectronic molecules E_3AF_2, where
E represents a bonded or non-bonded electron pair and A
a main group element. They were arranged in order of
fluorinating ability by estimating the magnitude of
reduction couples as approximated by enthalpy
differences $\Delta H_f^o(E_3AF_2) - \Delta H_f^o(E_3A)$.

In this paper we start a quantitative study on the
halogenating ability of the corresponding series of di-
chlorides by measuring heats of formation of the well
known aryl iodine dichlorides.[2] This will enable
kinetic effects to be distinguished from equilibrium
control when these reagents are used.

EXPERIMENTAL

Materials

Phenyl and p-fluorophenyl iodine dichlorides were
made in high yields (>95%) by passing dichlorine into
ice-cold solutions of iodides in methylene chloride.
The precipitates were vacuum dried (1-2 hrs at
1.33 Nm^{-2}) and analysed iodometrically after adding

aqueous KI to solutions of the dichloride in CCl_4. At
room temperatures the loss of oxidising power per day
was 0.5% for $PhICl_2$ over a week, and 0.04% for
$pFC_6H_4ICl_2$ over a 40 day period. Hence samples were
used soon after preparation or were stored at $-10^\circ C$
before use.

Calorimetry

A glass isoperibol calorimeter was used at $25^\circ C$ with
solids or liquids held in PTFE screw-capped glass
cylinders closed with polythene foils. For heats of
gas absorption a 'bell' fitment, described previously,
held the gas prior to solution.[3]

Two strategies were adopted for determining heats of
formation of the iodine dichlorides; direct formation
from iodide and chlorine, and interaction of the
iodine dichloride with reductants. In the direct
formation the heats of chlorine dissolution in con-
ventionally purified methyl cyanide were inconsistent.
The presence of chlorine-consuming impurities left
after distillation had also been noted when $MeNO_2$ was
used as solvent.[4] Consistent heats of solution,
approaching values expected from Raoult's Law, were
only obtained after prechlorination, which consisted of
saturating the conventionally purified MeCN with
chlorine and leaving for 2 days before refractionating.
Approximately one fifth of the mid-fraction was again
saturated with chlorine and then added to the remainder
of this fraction. The heat of solution of chlorine in
an ideal solvent should approach the latent heat of
evaporation of chlorine (20.4 kJ mol^{-1}) or the heat
derived from the Clapeyron-Clausius equation over the
range $5-30^\circ C$ (20.0 kJ mol^{-1}). The value obtained in
MeCN of 23.1 kJ mol^{-1} compares with 17.8 kJ mol^{-1} in
CCl_4,[5] which is regarded as an 'ideal' solvent.

Even when solvent chlorination effects had been
eliminated, the heats of addition of chlorine to excess
of PhI were inconsistent. The heats of successive
additions decreased from values greater than, to values
less than, the heat of the inverse reaction in MeCN
(i.e. PhI into excess of Cl_2). This effect was caused
by slow chlorination of excess PhI with the generated
$PhICl_2$ as demonstrated by the gradual loss in the
ability of mixed $PhICl_2$-PhI solutions in MeCN to
liberate I_2 from KI.

Addition of aliquots of PhI to 20% saturated solutions
of Cl_2 in MeCN gave consistent heats, but at higher
concentrations values were unreliable because of
appreciable degassing of solutions.

The alternative technique, in which the redox couple $ArICl_2/ArI$ is combined with another couple, requires rapid quantitative reactions at $25°C$ and well defined accessible starting materials and products. The $SnCl_2/SnCl_4$ and I^-/I_2 or I_2/I^+ couples would normally meet the requirements, and indeed both $SnCl_2$ and KI are readily oxidised by $ArICl_2$. The data collected in Table 2 leads to heats inconsistent with those derived by direct chlorination.

Another reductant tried was sodium sulphite. This reaction, carried out in a mixed solvent ($MeCN-H_2O$) to maintain solution homogeneity, proceeded smoothly and reproducibly. Direct measurement of the heat of solution of Na_2SO_3 in the mixed solvent, which is liable to errors because of oxidation by dissolved oxygen, was avoided by using iodine as oxidant. The equation (3), used to calculate the heat of formation of the aryl iodine dichloride, was the difference between the redox reactions (1) and (2), with all components in solution apart from the added solid phases indicated (c).

$$pFC_6H_4ICl_2(c) + Na_2SO_3 + H_2O \rightarrow pFC_6H_4I + Na_2SO_4 + 2HCl \qquad (1)$$

$$Na_2SO_3 + I_2(c) + H_2O \rightarrow Na_2SO_4 + 2HI \qquad (2)$$

$$pFC_6H_4ICl_2(c) + 2HI \rightarrow pFC_6H_4I + 2HCl + I_2(c) \qquad (3)$$
The enthalpies obtained differed considerably from those determined by direct chlorination, and this was finally traced to the participation of the iodosulphite ion SO_2I^- in reaction (2). These results and the occurrence of iodosulphites in other reactions will be discussed in detail elsewhere.

Decomposition of phenyl iodine dichlorides

Compacted samples sealed in tubes appended to evacuated boro-silicate bulbs were decomposed in the dark at constant temperature ($\pm1°$) in a stirred-air oven of large thermal capacity. The size of bulb was chosen to keep the final pressure below 2 atmos., assuming 1 mole of HCl was formed per mole of polyhalide. Other specimens were irradiated under a mercury u.v. lamp in sealed silica tubes at $20°C$ until the sample had completely liquefied. Hydrogen chloride was removed in vacuo at $-30°C$, and the residual liquids were weighed by difference after washing out the removed tube-appendix with petroleum ether ($60-80°C$ range). Free iodine was extracted and estimated with excess aqueous thiosulphate or sulphurous acid solutions. The organic phase was separated through phase separating paper, dried with molecular seive (Linde 3A) and the

components separated on a Carbowax (15% chromosorb
W-AW-DCMS) column at 125°. Products were identified by
peak enhancement, retention times and i.r. spectra
where appropriate. The concentrations of the com-
ponents relative to iodobenzene were assessed by
comparison with synthetic mixtures. Results are
summarized in Table 3. At the higher temperatures
some solid product had sublimed onto the upper part of
the bulbs. It was not identified but probably
consisted of chlorinated di- and poly-phenyls. This
was supported by the iodine balance obtained at the
highest temperature. The iodine displaced as a % of
that originally present in the polyhalide was greater
than the measured % of non-iodinated products.
Analogous products were isolated from the $p\text{-}FC_6H_4ICl_2$
thermal and catalysed ($SnCl_4$) decompositions and were
identified by mass spectrometry.

RESULTS AND DISCUSSION

The standard heats of formation were calculated as
$\Delta H_f^o PhICl_2(c) = 21.7$ kJ mol^{-1} and $\Delta H_f^o pFC_6H_4ICl_2(c)$
$= -173.0$ kJ mol^{-1} using the data from oxidative
addition of dichlorine in Table 1 and the auxiliary
heats $\Delta H_f^o PhI(l) = 114.5$ kJ mol^{-1} and $\Delta H_f^o pFC_6H_4I(l)$
$= 81.7$ kJ mol^{-1}.[6] The latter has not been reported but
can be estimated by group-additivity methods, or more
simply by averaging the values for $\Delta H_f^o pFC_6H_4F(l)$ and
$\Delta H_f^o pIC_6H_4I(l)$. Some estimates of heats of melting and
vapourization are required also. Thus the heat of
fusion of pIC_6H_4I was taken as 1.17 times that of
the ortho-compound[7] from which $\Delta H_f^o pIC_6H_4I(l)$ was
estimated as 177.3 kJ mol^{-1}. The heat of vapouriz-
ation of pFC_6H_4I was estimated as 45.6 kJ mol^{-1} using a
Trouton constant of 100 kJ mol^{-1} K^{-1}. For the group
additivity method we accept Benson's C_B-H additivity
increment of 13.8 kJ,[8] but use C_B-F, C_B-I and C_B-Cl
values of -183 ± 2, 92.5 ± 0.6, -17.1 ± 0.6 kJ, about
4 kJ less than Benson's value since they are derived
from the mono- and di-halobenzenes heats rather than
from a more extended range of compounds. This leads to
$\Delta H_f^o pFC_6H_4I(l) = -80.9$ kJ mol^{-1}, compared to a value of
-82.4 kJ mol^{-1} by averaging dihalide values. Hence a
mean value of -81.7 kJ mol^{-1} is probably correct to
± 1 kJ. [These estimates can be cross-checked using the
iso-electronic heat method[9] in which heats of OH and F
compounds are equated, i.e.

$\Delta H_f^o pIC_6H_4OH(c) = -95.4$ kJ mol^{-1} $\pm 5.4 \approx \Delta H_f^o pIC_6H_4F(c)$
and a heat of fusion estimate of 17 kJ mol^{-1}.]

In reductions with stannous chloride or iodine, reactions additional to the expected simple reactions must occur (see Table 2).

$$ArICl_2 + SnCl_2 \rightarrow ArI + SnCl_4;$$
$$ArICl_2 + I_2 \rightarrow ArI + 2ICl; \text{ or}$$
$$3ArICl_2 + I_2 \rightarrow 3ArI + 2ICl_3.$$
It is probable that the stannic chloride formed reacts with $ArICl_2$ to produce a reactive salt such as $ArICl^+SnCl_5MeCN^-$, which can ring chlorinate the former to some extent as well as the aryl iodide. It is significant that in experiments with $Ar = pFC_6H_4$ the results neatly divide into groups above and below the ratio $ArICl_2/SnCl_2 = 2$, the limiting ratio required to completely form the salt. The reality of substitution reactions in this system was confirmed by gas chromatographic examination of products which were the same as those formed by thermal or photo-decomposition of $ArICl_2$. Salt formation was indicated by the large heat of mixing and increase in electrical conductivity when solutions of $pFC_6H_4ICl_2$ and $SnCl_4$ in MeCN were mixed. Even more complications could arise with the iodine oxidation, since as well as salt formation and substitution reactions, equilibration of I_2 with ICl and Cl^- could produce mixtures of ions such as I_3^-, I_2Cl^- and ICl_2^-, dependent on the iodine and chloride ion concentrations.

The decomposition of phenyl iodine dichloride can now be considered from a thermodynamic viewpoint. The decomposition products of thermal and photochemical decompositions can result from simple dissociation, A, the reverse of the formation reaction, from aromatic substitution, B, and from halogen displacement, C. The product distribution classified as A, B or C products is shown in Table 4. The enthalpies of these reaction types have been evaluated in Table 5.

The free energies for A and B can be approximated by adding a $T\Delta S^o$ term of about 66 kJ mol^{-1} to the enthalpy values due to the release of a mole of gas. The large endo-ergic value for A means that the PhI content in the decomposition reactions is far from equilibrium. Higher temperatures and longer periods of heating move the reactions closer to equilibrium with increasing participation of the most exo-ergic displacements, C, as shown in the last column of Table 5. Substitution reactions predominate under mild irradiation conditions and would be expected to be susceptible to catalysis as was illustrated in the thermochemical measurements with stannic chloride formed in situ.

Keefer and Andrews[4] claimed to have measured dissociation constants for reaction A in various solvents. They obtained a K value of 4.2×10^{-4} at 298 K for $PhICl_2$ in $MeNO_2$. The equivalent ΔG^o value of 19.3 kJ mol^{-1} is quite incompatible with our thermochemical measurements for reaction A. However, it is very much closer to the ΔG^o value for reaction B and we suggest that they were actually observing the substitution reaction rather than the dissociation. The experimental technique they used does not preclude this possibility. They measured the original oxidising power of the solution iodometrically to obtain iodobenzene dichloride concentrations and then observed the disappearance of the $PhICl_2$ absorption at 380 nm ($\varepsilon = 105$) at which wavelength PhI has an ε value of only 0.05. They did not consider any substitution products. These would also be unobserved, since the ε values for the ClC_6H_4I isomers are only 0.01 - 0.03. Perhaps the most revealing indication of substitution is the slight increase in the rate of equilibration by HCl and the tremendous effect of ICl. The last observation ties in with the inconsistencies we encountered in measuring heats of reaction of $PhICl_2$ with I_2 where the ICl formed caused substitution. Indeed, the interpretation of results in this and their subsequent series of papers can be questioned, if substitution reactions are involved to any appreciable extent.

The halogenating ability of E_3AX_2 compounds (X = halogen) has been placed in a sequence according to the central atom A:

P < Sb $\sim$ As $\sim$ Te < Se < S < I < Br < Cl $\sim$ Xe < Kr, mainly from qualitative observations.[1] It is therefore of interest to check part of this sequence with the new data. Chlorinating couples expressed in enthalpy values are collected in Table 6. (In making comparisons between isoelectronic reagents it is reasonable to assume that entropy changes will cancel approximately and that 'enthalpy couples' can be employed.)

The aryl iodine dichlorides are almost identical in reduction potentials and this was confirmed by showing that the equilibrium

$$C_6H_5ICl_2 + FC_6H_4I \rightleftharpoons C_6H_5I + FC_6H_4ICl_2$$
could be approached from either side as shown by in situ proton and fluorine magnetic resonance measurements. Phenyl iodine dichloride in methyl cyanide solutions is almost as powerful an oxidant as solid iodine trichloride.

The relative values of the other couples are also compatible with the known chemistry. Thus the weakest oxidant, Ph_3PCl_2, is unable to oxidise tetrachloroethene. Indeed, Ph_3PCl_2 is prepared quantitatively[10] by the reverse reaction: $Ph_3P + C_2Cl_6 \rightarrow Ph_3PCl_2 + C_2Cl_4$ or by using the more powerful oxidant $PhICl_2$ in MeCN.

Similarly, it is reported that Ph_3Sb is chlorinated with ferric chloride and Ph_3P by cupric chloride. This contrasts with the ability of $PhICl_2$ to dissolve iron or ferrous chloride, and copper or cuprous chloride. Sulphuryl chloride has been used in the preparation of Ph_3ACl_2 (A = As, Sb)[11] and we have shown that it can also chlorinate Ph_2S. (The SO_2Cl_2/SO_2 couple will be less negative than shown in Table 6 when in solutions such as methyl cyanide.) Heats of formation of E_3ACl_2 compounds in earlier groups can be determined using the greater chlorinating ability of the $PhICl_2/PhI$ couple.

Phenyl iodine dichloride is often referred to as an I(III) compound in the literature. This description violates the usual assignment rules for oxidation stated because it implies that the phenyl group is negatively charged with respect to iodine. Sanderson, using his electronegativity equalization method, has assigned charges to phenyl compounds of different elements and shown that phenyls are positive with respect to less electronegative elements.[12] Hence the oxidation state of iodine in $PhICl_2$ should be less than in ICl_3 and this is confirmed by the reduction potentials shown in Table 6. In general, phenylation of interhalogens and other E_3AX_2 compounds would be expected to moderate their reactivity, as the oxidation state on the central atom is lowered.

ABSTRACT – A bis(succinamato)copper(II) complex has been synthetized as well as several cyclic acid-amide ligand complexes. These compounds were characterized by elemental and thermogravimetric analyses, infrared and EPR spectroscopies. Analogous dicarboxylic acids give complexes of 1/1 stoichiometry which are thermally more stable than the acid-amide complexes. All the reported compounds show triplet state EPR spectra similar to cupric acetate. There is no evidence for a participation of the amide functions in cupric ion complexation.

INTRODUCTION

Metal salts of carboxylic acids are well known and several reviews have appeared on copper carboxylates,[1-3] magnetic and spectroscopic studies on copper dicarboxylates have also been reported.[4] We have been interested in carboxylic acid-amides difunctional ligands as sources of new metal complexes. Even though copper-biuret compounds have been known for a long time[5-7] and copper binding to deprotonated peptide-amide groups is well documented,[7] very few cupric salts of amides have been synthesized.[9,10]

We wish to report the first synthesis of a metal salt of succinamic acid and of several analogous cyclic dicarboxylic acid and carboxylic acid-amide salts of copper(II).

The dicarboxylic acids here examined and their abbreviations are respectively; cyclohexane 1,2 dicarboxylic acid (cyclohexane diA.); 4-cyclohexene 1,2 dicarboxylic acid (cyclohexene diA.); cyclopentane 1,1 diacetic acid (cyclopentane diA.). The carboxylic acid-amide are; succinamic acid (suc); cyclohexane 1-carboxylic acid 2-carboxamide (cyclohexane A.A.); and cyclopentane 1-acetic acid 1-acetamide (cyclopentane A.A.).

EXPERIMENTAL SECTION

Infrared spectra were recorded using a Perkin Elmer Model 577 spectrometer calibrated with a polystyrene film in the 4000–200 cm^{-1} range using KBr disks. The ESR spectra were obtained with a conventional X-band Bruker ER-200D spectrometer. Thermogravimetric analyses were carried out under nitrogen atmospheres with a Setaram electrobalance and a programmable furnace set at 3°C increase per minute.

[a] Present address : Laboratoire de Chimie Physique, Université de Genève, 30 quai Ernest-Ansermet, 1211 Genève 4, Suisse.

SYNTHESIS

1. Carboxylic acid-amide ligands

Dry ammonia is bubbled into a saturated 100 ml dimethoxypropane solution of the dicarboxylic anhydride (obtained commercially from Aldrich). A precipitate forms which is collected, washed with water and leached with boiling acetone to remove any dicarboxylic acid formed. Elemental analyses are in good agreement with the proposed formula for the resulting compounds.

2. Dicarboxylic acid complexes

The dicarboxylates were synthesized by adding aqueous cupric sulphate to potassium hydroxide neutralized solutions of the dicarboxylic acids. The resulting blue-green precipitates were filtered off and leached with boiling acetone to remove excess ligand.

3. Carboxylic acid-amide complexes

The carboxylic acid-amide complexes were obtained by reacting stoichiometric quantities of the ligand adjusted to pH 7 and cupric chloride. The desired precipitates were washed with water and then with acetone. All elemental analysis are in good agreement with the proposed formula listed in Table 1.

RESULTS AND DISCUSSION

The first result obtained from analytical data is that succinamic acid, like the other studied cyclic carboxylic acid-amide ligands, forms anhydrous bis-complexes with copper in analogy with acetic acid itself. This suggests that the amide functions are not implied in curpic salt formation. Indeed, acetamide is only known to form adducts with copper. Valeramide represents one example where it is claimed the deprotonated amide function forms a

copper acetate-like dimeric salt at basic pH.[11] It may be emphasized that biuret itself which is known to form the well-known violet complex with copper which is the prototype for the complexation of four deprotonated amide nitrogens (from two biuret ligands) only gives this type of reaction in strongly alkaline solutions.[5-7] In fact, biuret does not deprotonate at pH<11.5.

The infrared spectra are expected to give some more informations on the nature of the sites actually involved in bonding in the carboxylic acid-amide complexes. The strong band at 1660-1680 cm^{-1} has been interpreted as the amide I band and due to the C=O (amide) stretching modes. This band remains unaltered in position and intensity in the complexes excluding a coordination by the amidic carbonyl. This fact is supported by the presence in the spectra of the complexes as well as of the ligands of the two strong absorption bands at 3410-3200 cm^{-1} which are due to the asymmetric and symmetric N-H stretching vibrations of the amide groups, unaffected upon complexation. The assignments of the symmetric and asymmetric carboxylate stretching frequencies are at wave numbers very similar to those reported for dimeric Cu(II) carboxylates[12] i.e. at ca. 1600 and 1410 cm^{-1}, respectively. However, it has been difficult to ascertain the positioning of the ν_a vibration due to its overlapping with the amide II band of the amide group.

The cyclic dicarboxylates form hydrated monoligand complexes, where the water molecules appear to be coordinated to the cupric ions because they are lost in the temperature range 110-120°C. These complexes are insoluble in common solvents which suggest they are polymeric like the other known analogues.[4]

The thermogravimetric results show that the acid-amide complexes are less thermally-stable than the corresponding diacid complexes. This can be attributed in part to the lower decomposition temperature of the non-coordinated amide groups and also to the higher stability of the polymeric network in the dicarboxylate salts. The temperatures of maximum decomposition (see Table 1) reveal that the introduction of one double-bond in the cyclohexane ring for the dicarboxylate complexes lowers the thermal stability some 20°C. The cyclopentane dicarboxylate is partially degraded at even lower temperatures showing that stress in the ligand is responsible for the lower decomposition temperatures. The same observation is obtained by comparing cyclohexane and cyclopentane acid-amide complexes. The acid-amide complexes decompose in a multistep process, pointing to the alteration of the ligands followed by decomposition of the complexes formed with the intermediate carboxylic acid function. The final weight corresponds to the presence of a mixture of copper, copper oxide and traces of graphite.

The EPR results can be interpreted in a straightforward manner by attributing a dimeric copper-acetate like structure for the compounds. Thus, the main features of the EPR spectra yield the parameters of the paramagnetic triplet states obtained by coupling two doublet state cupric ions. Monomeric impurities are present in varying amounts, with the corresponding absorptions near 3000 gauss. The decrease in intensity and improved resolution at low temperature is compatible with a thermally accessible triplet state above the ground singlet state.

The EPR parameters are similar to those usually obtained for dimeric carboxylates and the results are presented in Table 2. The D values vary between .336 cm^{-1} and .357 cm^{-1}, with

E values quite small, the largest one, 77 gauss (.0072 cm^{-1}) being observed for the succinamate complex. This shows the copper ions are essentially in a square planar environment with little rhombic distortion. The observed hyperfine values are less than 70 gauss, which corresponds, as expected, to half the normal value, as obtained for the monomer impurity signals for example. There is a good agreement between the g values observed for the monomer impurities (Table 3) and the g values calculated from the spectra for the triplet state dimers (Table 2). Further data would be needed (structural information, magnetic susceptibilities), in order to find any trends in g or D values or to explain the lack of resolution in some cases.

Table 2. Electron paramagnetic resonance parameters derived from triplet spectra of dimer copper compounds

Compound	$g /\!/$	$g \perp$	$\overline{g}$	D, cm^{-1}	E', G	$A /\!/, G$
Cu(Suc)$_2$	2.348	2.062	2.157	.336	77	68.5
Cu(cyclohexane A.A.)$_2$	2.436	2.162	2.253	.357	-	-

Cu(cyclopentanediA).H$_2$O	2.392	2.096	2.195	.346	-	67

Table 3. Electron paramagnetic resonance parameters derived from monomer impurity signals

Compound	$g /\!/$	$g \perp$	$\overline{g}$	$A /\!/, G$
Cu(Suc)$_2$	2.334	2.077	2.164	140
Cu(cyclohexane A.A.)$_2$	2.358	2.077	2.171	150
Cu(cyclopentane A.A.)$_2$	2.352	2.076	2.168	130
Cu(cyclohexanediA).H$_2$O	2.388	2.081	2.183	-
Cu(cyclohexenediA).H$_2$O	2.357	2.066	2.163	145
Cu(cyclopentanediA).H$_2$O	-	-	2.166	-

In general, however, it may be stated the EPR spectra are characteristic of carboxylate salts of copper, with no direct influence of the amide functions. Perhaps, the amide groups occupy the axial coordination positions on copper, accounting for the minimal interdimer exchange resulting in well resolved dicopper hyperfine structure, as illustrated in the spectrum of the copper(II) succinamic acid complex (Fig. 1) compared to the copper(II) cyclohexene dicarboxylic complex (Fig. 2).
Fig. 1. EPR spectrum of the succinamic acid copper(II) complex recorded at 85 K.
Fig. 2. EPR spectrum of copper(II) cyclohexene dicarboxylate, recorded at 123 K.

CONCLUSION

The difunctional ligands used show no evidence for participation of the carboxamide group in complex or chelate formation. The formulae, infrared spectra as well as EPR spectra all point to a typically carboxylate-like behaviour for the ligands. The carboxylic acid-amide complexes are less thermally stable than the corresponding dicarboxylates. Further work is planned with metal ions with higher affinities for the carboxamide functions.

Reaction of 2,5-(Dibenzothiazolin-2-yl)thiophene with Some Metal Ions

A.S. Salameh and H.A. Tayim[*]

Department of Chemistry, American University of Beirut

Beirut, Lebanon

Abstract

2,5-(Dibenzothiazolin-2-yl)thiophene has been synthesized by the reaction of 2,5-thiophenedicarboxaldehyde and o-aminobenzenethiol. It reacts as a neutral ligand with Pd(II). However, it reacts as a dianion with Cu(II), Ag(I), Cd(II), Pb(II) and Zn(II), suggesting that the ligand is bonded as the conjugate base of the Schiff base 2,5-thiophenediylbis{N-(pheylen-2-thiol)aldimine}. Its behavior with Hg(II), Ru(III), Pt(II), Rh(III) and Ni(II) involves the opening of one of the thiazoline rings of the ligand.

Introduction

We have been investigating the coordination compounds of Schiff bases derived from the condensation of heterocyclic mono- and dialdehydes with o-aminobenzenethiol and o-aminophenol. The reaction of 2,5-thiophenedicarboxaldehyde with o-aminobenzenethiol did not afford the expected Schiff base (I)(SBH$_2$), but rather the poly-heterocyclic compound 2,5-(dibenzothiazolin-2-yl)-thiophene(II) (LH$_2$). The synthesis of this ligand and the results of its reactions with several metal salts are reported hereby.

Experimental

Preparation of 2,5-(dibenzothiazolin-2-yl)thiophene(II). A solution of thiophene-2,5-dicarboxaldehyde[1] (1.4 g, 0.01 mole) in ethanol (7 ml) was treated with a solution of o-aminobenzenethiol (3.13 g, 0.025 mole) in ethanol (6 ml). The mixture was refluxed with stirring for 30 min, then cooled. The pale yellow product obtained was filtered, washed with cold ethanol and dried. It melted at 115° forming a solid on the sides of the capillary tube, which melted at 200-250°. Yield: 3.2 g, 90%. The compound is insoluble in water, but soluble in ether, chloroform, hot methanol, hot ethanol and acetone. Found: C, 60.83; H, 3.90; N, 7.88; S, 26.97. Calcd. for C$_{18}$H$_{14}$N$_2$S$_3$: C, 60.98; H, 3.98; N, 7.90; S, 27.14%. ν_{NH} at 3350 cm^{-1}.

829

Reactions of the ligand with metal ions. The reactions of the ligand (II) with
several metal ions were attempted. Metal ions that afforded isolable complexes
are classified into three categories according to the method of synthesis of
their corresponding complexes.

(i) Metal ions whose compounds react with the ligand upon mixing: These
include $CuCl_2 \cdot 2H_2O$, $HgCl_2$, $AgClO_4$, $RuCl_3 \cdot 3H_2O$, $Pb(CH_3COO)_2$, $RhCl_3 \cdot 3H_2O$ and
$Pd(C_6H_5CN)_2Cl_2$. In a typical reaction of these salts with the ligand, a hot
(almost boiling) solution of the ligand in ethanol was added to a hot solution
of the metal salt in ethanol. The ligand-to-metal molar ratio was 2:1. Immediate
precipitation of the complex took place. The product was filtered, washed with
hot ethanol and dried in vacuo.

(ii) Metal ions which required refluxing: The reactions of $Cu(CH_3COO)_2 \cdot H_2O$
and $Ni(acetylacetonate)_2 \cdot H_2O$ with the ligand were carried out by refluxing the
solution of the ligand and the metal salt in ethanol for one hour. The precipi-
tates that formed were filtered off, washed with ethanol, then ether and dried
in vacuo over P_2O_5.

When the complex of Ag(I), obtained by the reaction of $AgClO_4$ with the
ligand immediately upon mixing of hot ethanolic solutions of the reactants, was
further refluxed for one hour, a different complex was obtained.

(iii) Metal ions which afforded complexes upon mixing hot ethanolic solutions
of the reactants, then cooling the reaction mixture. These include $Cd(CH_3OOO)_2 \cdot$
$2H_2O$, $FeCl_3 \cdot 6H_2O$ and $Zn(CH_3COO)_2 \cdot 2H_2O$. The reaction of aqueous K_2PtCl_4 with the
ethenolic solution of the ligand required stirring overnight at room temperature.

The complexes thus synthesized are listed in Table 1 along with their colors
and melting points. Table II lists the elemental analyses of these complexes.

Oxidation of 2,5-(dibenzothiazolin-2-yl)thiophene: Air was passed through a hot
ethanolic solution of 2,5-(dibenzothiazolin-2-yl)thiophene (1.00 g in 80 ml) with
stirring for 10 hours. In another procedure oxygen gas was passed through an
identical solution with stirring for 3 1/2 hours. The yellow solid formed was
filtered off and recrystallized from benzene to yeild 0.63 g (64%) of a compound
melting at 235-237° with decomposition. The IR spectrum did not show a v_{N-H} at
3350 cm^{-1}. Found: C, 61.90; H, 3.01; N, 7.86; S, 26.93. Calcd. for $C_{18}H_{12}N_2S_3$:
C, 61.68; H, 2.88; N, 7.99; S, 27.45%. The product was identified as 2,5-(di-
benzothiazol-2-yl)thiophene(III) (L).

Reaction of 2,5-(dibenzothiazol-2-yl)thiophene(III) with Pd(II): The oxidation
product of 2,5-(dibenzothiazolin-2-yl)thiophene(II) in hot benzene (0.140 g,
0.4 mole in 18 ml) was treated with a hot filtered solution of dichlorobis(ben-
zonitrile)palladium(II) (0.077 g, 0.2 mmole in 4 ml benzene). The precipitate
which formed immediately was filtered off, washed with hot benzene and ether
respectively; and dried in vacuo over P_2O_5. It melted with decomposition at

Results and Discussion

The condensation of 2,5-thiophenedicarboxaldehyde with o-aminobenzenethiol was attempted with the intention of preparing the corresponding Schiff base, 2,5-thiophenediylbis-{N-(pheylen-2-thiol)aldimine)(I)(SBH$_2$).
I (SBH$_2$)

However, the dithiazoline compound 2,5-(dibenzothiazolin-2-yl)thiophene(II) was obtained instead.
II (LH$_2$)

The identity of the dithiazoline(II), which has not hitherto been reported, is confirmed by its elemental analysis and by its IR spectrum. The spectrum contains a band at 3350 cm^{-1} characteristic of v_{NH}, and does not have a band at 2600 cm^{-1} suggesting the absence of SH bond and thus ruling out structure I. A similar behavior has been reported[2] for the condensation of 2,6-pyridinedicarboxaldehyde with o-aminobenzenethiol, except that the product isolated was the oxidized form, dithiazole. The formation of the dithiazoline was proposed as an intermediate. In the case of 2,5-thiophenedicaroxaldehyde, 2,5-(dibenzothiazol-2-yl)thiophene(III) could only be formed by the oxidation of the dithiazoline with air, oxygen or an oxidizing agent such as Fe^{+++}.
III (L)

The identity of the dithiazole(III) is confirmed by its elemental analysis and its IR spectrum. The v_{N-H} present in the spectrum of the dithiazoline at 3350 cm^{-1} disappeared upon oxidation, and instead, a band at 1590 cm^{-1} appeared, indicating the presence of a C=N bond.

The formation of the dithiazoline is most likely preceded by the formation of the Schiff base(I) which then rearranges to the dithiazoline. The rearrangement and interconversion of dithiazoline to dithiazole are influenced by the metal ions. The behavior of dithiazoline in its reactions with the metal ions investigated thus varied with the nature of the metal. Copper(II), Zinc(II), cadmium(II) and lead(II) afforded complexes of the form M(SB) where the ligand behaved as a tetradentate dithiolate Schiff base having structure(I) with the loss of the two acidic protons. This is suggested by the stoichiometry of the

complexes (ruling out structure(III) and the absence of v_{NH} in the IR spectra
of the complexes (thus ruling out structure(II)).

Ring-opening in the dithiazoline(II) was encountered with Hg(II), Ag(I),
Ru(III), Rh(III) and Ni(II) where the ligand adopted the anionic form(IV)(SBH).
The IR spectra of the complexes showed bands around 3350 cm^{-1} (v_{NH}) and 1590 cm^{-1}
($v_{C=N}$). Structure IV for the ligand in these complexes is substantiated by the
X-ray structure determination[3] of a Zn(II) complex with the 2,6-pyridine analogue
of our ligand.
IV (SBH)

The reaction of the dithiazoline(II) with Pd(II) afforded $Pd(LH_2)Cl_2 \cdot 2H_2O$
in which the ligand has not rearranged. The IR spectrum of the complex showed
a band at 3350 (v_{NH}), and no bands due to v_{SH} or $v_{C=N}$. Decomposition of the
complex with aqueous KCN followed by extraction with $CHCl_3$ afforded the di-
thiazoline(II). The oxidized form, the dithiazole(III) reacted with Pd(II) to
yield $Pd(L)Cl_2 \cdot 1/2 H_2O$. The decomposition of the complex with aqueous potassium
cyanide produced the dithiazole(III). The reaction of Pt(II) with the dithia-
zoline(II) afforded the complex $Pt(SBH)(LH_2)Cl \cdot 2H_2O$ in which one of the thiazoline
rings in one of the ligands must have opened to account for the divalence of
platinum.

The reaction of the dithiazoline with Fe(III) did not result in the forma-
tion of a complex, but the ligand was oxidized to the dithiazole(III) which was
isolated and identified by comparison with the authentic compound obtained from
the air-oxidation of the dithiazoline.

NOTES

REMARK ON PLUTONIUM DISPROPORTIONATION REACTIONS

G. L. Silver

Monsanto Research Corp., Mound Plant,* Miamisburg, Ohio 45342

Abstract - The course of a plutonium disproportionation reaction can be approximated by a succession of equilibrium valence state arrangements whose acidities are intermediate between the final solution acidity and the acidity for which the initial oxidation state configuration would have represented equilibrium.

In his interesting review of the kinetics of the lighter actinides, Newton[1] observes that the rate of a reaction such as

$$2Pu^{4+} + 2H_2O = Pu^{3+} + PuO_2^+ + 4H^+ \quad (K = K_1) \tag{1}$$
is slow, whereas the rate of the reaction

$$Pu^{4+} + PuO_2^+ = Pu^{3+} + PuO_2^{2+} \quad (K = K_2) \tag{2}$$

is relatively rapid, and under most circumstances a plutonium system will be near equilibrium with respect to it at all times. If this hypothesis is true, the expression

$$Q_2 = \frac{[Pu^{3+}][PuO_2^{2+}]}{[Pu^{4+}][PuO_2^+]} \approx K_2 \tag{3}$$

is a constraint upon the plutonium system whether or not the system is at equilibrium. Another constraint which always applies to plutonium systems is mass conservation

$$[Pu^{3+}] + [Pu^{4+}] + [PuO_2^+] + [PuO_2^{2+}] = T \tag{4}$$

where T is the total plutonium concentration, and may be taken as unity so that oxidation states in brackets may be conveniently interpreted as fractions of the total plutonium. Still another constraint which always applies to a plutonium system is charge conservation[2]

$$(6-N)[PuO_2^{2+}] + (5-N)[PuO_2^+] + (4-N)[Pu^{4+}] + (3-N)[Pu^{3+}] = 0 \tag{5}$$

in which N is the plutonium oxidation number. Equations (3), (4), and (5) constitute a system of three equations in the four unknowns $[Pu^{3+}]$, $[Pu^{4+}]$, $[PuO_2^+]$, and $[PuO_2^{2+}]$. If one further constraint upon the plutonium system were available, the system could be solved as a system of four equations in the four unknown fractions representing the various oxidation states.

If the composition of a nonequilibrium plutonium system is known at a certain time, and if the final, equilibrium composition is also known, it is ordinarily true that every species passed

from its initial value to its final value in a smooth, continuous manner. If the fraction of
a plutonium oxidation state likewise does not pass through a maximum or a minimum during
transit to equilibrium, then every intermediate value assumed by it between the initial and
final compositions corresponds to a unique arrangement of oxidation states. Since valence
state rearrangement reactions do not produce extrema in the fractions of all of the oxidation
states, it is possible to select arbitrary, unique, intermediate fractional values for at
least one of these oxidation states. Thus the fourth constraint upon the plutonium system
can be selected as

$$[Pu^{4+}] = \text{a unique value allowed by continuity} \qquad (6)$$

The continuity constraint is given in terms of $[Pu^{4+}]$ as an example; another oxidation state
could have been selected provided it passes from its initial to its final value in a contin-
uous, single-valued manner. Equation (6) states that if the initial fraction of $[Pu^{4+}]$ were
1.0 (pure tetravalent plutonium), and its final value 0.4 (after extensive disproportion-
ation), then there must have been an instant when its fraction was any chosen intermediate
value such as 0.65. Thus it is possible to approximate the courses of plutonium valence
rearrangement reactions by solving Equations (3)-(6) as a set of four equations in four
unknowns. (By "course" is meant the succession of oxidation state distributions correspond-
ing to the passage from initial state to the equilibrium state.) This method is considerably
easier than the conventional method of solving a pair of simultaneous differential equa-
tions[1]. The accuracy of the method is limited only by the accuracy of the approximation
$Q_2 \approx K_2$, where K_2 is the equilibrium constant for Equation (2), and Q_2 is the actual, non-
equilibrium concentration quotient for this reaction.

There is another, more interesting method of plotting the course of oxidation state rearrange-
ment reactions. It is to be observed that the solution acidity does not enter Equations (3)-
(6). The consequence of this is that the courses of rearrangement reactions are approximately
independent of the acidity, and that the error in this consequence is no greater than the
error in the hypothesis that $Q_2 = K_2$. Nowhere in the literature of plutonium chemistry does
this implication seem to have been noticed.

When calculating equilibrium oxidation state distributions, it is customary to use the solu-
tion acidity as one of the defining parameters[3]. Equations (3)-(5) are always satisfied in
this computation, and values for the fractions of oxidation states are the results of such
calculations. But the process may be turned around, so that Equations (3)-(5) are still
satisfied, and the fraction of one oxidation state, say $[Pu^{4+}]$, is given some value which it
must have momentarily assumed. The resulting nonequilibrium oxidation state distribution can
be made to fit the equation

$$K_1 = \frac{[Pu^{3+}][PuO_2^+][H^+]^4}{[Pu^{4+}]^2} \qquad (7)$$

so that a value of $[H^+]$ can be obtained. This value of $[H^+]$ (which is not the actual value
of the solution acidity) and the given value of N are sufficient to define an equilibrium
valence state distribution; this equilibrium distribution is identical to the distribution
known to be nonequilibrium for the actual solution acidity. In other words, the course of a

rearrangement reaction can be plotted by calculating the succession of equilibrium oxidation state distributions for acidities intermediate between the actual solution acidity and the acidity for which the initial nonequilibrium oxidation state distribution would have represented equilibrium. The observation that nonequilibrium distributions of plutonium valence states are a succession of equilibrium states for other (intermediate) acidities also seems to have been overlooked, but its value as an approximation is not worse than the approximation $Q_2 = K_2$ on which Newton comments favorably.

Many years ago, data were obtained on the passage to equilibrium of a solution initially containing about 50% each of pentavalent and hexavalent plutonium[4]. The oxidation number of this solution was therefore close to 5.5, and acidity is reported as $0.5\underline{M}$ HCl. From the data in the reference containing this information, it is possible to approximate $K_1 \approx (2.1)(10^{-4})$ and $K_2 \approx 8.5$ in this medium. The alpha coefficients[5,6] for the plutonium oxidation states may all be taken as unity, because their actual values (which are greater than unity) are reflected in the experimentally determined values of K_1 and K_2 in $0.5\underline{M}$ HCl. A solution which has the equilibrium composition of 50% each PuO_2^+ and PuO_2^{2+} has a very low acidity: for this purpose $[H^+] = 0.01\underline{M}$ is low enough to represent the initial acidity. Plotted in Figure 1 are equilibrium compositions for a succession of solutions whose equilibrium acidities are taken between $0.01\underline{M}$ and the final, actual solution acidity of $0.5\underline{M}$. The course predicted by this diagram may be compared to the experimentally determined course in $0.5\underline{M}$ HCl; it will be found that the agreement is striking[4]. This bears out as reasonable the hypothesis that generally $Q_2 \approx K_2$ and the consequence of this hypothesis that the course of a disproportionation reaction is well approximated by a succession of equilibrium states whose acidities are intermediate between the final, actual solution acidity, and the acidity for which the initial oxidation state distribution would have represented equilibrium.

SYNTHESIS OF NEW MIXED LIGAND COMPLEXES OF COPPER(II) DITHIOCARBAMATES

K.K.M. YUSUFF*, K. MUHAMMAD BASHEER and M. GOPALAN
Department of Chemistry, University of Calicut, Kerala, 673 635, India

Abstract: New mixed ligand complexes of copper(II) dithiocarbamates of the general formula, $[CuCl(R_2dtc)L]$ or $[CuCl(R'dtc)L]$ (R=CH_3 or C_2H_5, R' = $(CH_2)_5$, dtc =-NCSS⁻ and L = Pyridine, 3-picoline or 4-picoline), have been prepared by the reaction of bis(dithiocarbamato)di-μ-chloro-dicopper(II) complexes with pyridine or picolines. The complexes are found to be non-electrolytes in nitrobenzene. Magnetic susceptibilities, i.r. and electronic spectra of the complexes are reported. A psuedo-tetrahedral structure is suggested for these complexes.

INTRODUCTION

A series of bis(dithiocarbamato)di-μ-chloro-dicopper(II) (A) have been synthesized[1,2]. It was found that ligands like pyridine and picolines are able to break the chlorine bridges in these type of complexes to form some hitherto unknown mixed ligand complexes of copper(II). The preparation and some physico-chemical studies of the new complexes are presented here.
(A)

EXPERIMENTAL

Bis(dithiocarbamato)di-μ-chloro-dicopper(II) complexes were synthesized as described in the literature[1].

Physico-chemical measurements:

The molar conductances of the complexes (10^{-3}M solution) in pure dry nitrobenzene was determined at $30\pm2°C$ with a Toshniwal conductivity bridge using platinum electrodes.

Magnetic susceptibilities were determined at room temperature ($30\pm2°C$) by the Gouy Method using $Hg[Co(NCS)_4]$ as calibrant[3].

Electronic spectra of the complexes were recorded in the solid state by a mull technique following a procedure recommended by Venanzi[4] on a DMR-21 recording spectrophotometer.

---

*Author to whom all correspondence should be directed. Present address: Department of Applied Chemistry, University of Cochin, Cochin 682 002, Kerala, India.

The i.r. spectra in the region 400-4000 cm^{-1} were recorded on a Perkin-Elmer 257 infrared spectrophotometer. The far i.r. spectra (Nujol mull) in the region 200-600 cm^{-1} were recorded on a Beckman IR-12 infrared spectrophotometer.

Synthesis:

All the complexes were prepared by same general method given below. About 2 gms. of bis(dithiocarbamato)di-μ-chloro-dicopper(II) was dissolved in the minimum quantity of appropriate bases (pyridine, 3-picoline or 4-picoline) with vigorous stirring. The solution was filtered and kept for one hour. Diethyl ether was then added to precipitate the complex. The crystalline complex seperated was filtered, washed with ether and dried over anhydrous calcium chloride.

Analysis:

Copper, Chlorine and Nitrogen in the complexes were estimated using standard procedures[5].

Table 1

Py = Pyridine; 3-Pic. = 3-Picoline; 4-Pic. = 4-Picoline

RESULTS AND DISCUSSION

The analytical data of the complexes show that they have the general formula, $[CuCl(R_2dtc)L]$ or $[CuCl(R'dtc)L]$, where R = CH$_3$ or C$_2$H$_5$; R' = (CH$_2$)$_5$;

dtc = -NCSS⁻ and L = Pyridine, 3-picoline or 4-picoline. Our attempts to
prepare the mixed ligand complexes with 2-picoline met with failure. This
may be due to the steric strain caused by the methyl group in the 2-position,
which blocks the stable bond formation.

The complexes are moderately soluble in benzene, nitrobenzene, chloro-
form and carbon tetrachloride. They are almost insoluble in acetone,
diethyl ether and alcohol. All of them decompose on keeping, as indicated
by the tarnishing of colour and also by the poor analytical data given
by the older samples.

Conductance behaviour:

The molar conductance values of the complexes are around 4.5 $ohm^{-1}cm^2$
$mole^{-1}$, which indicate that the complexes are non-electrolytes in nitrobenzene.

Magnetic behaviour:

The magnetic moment (μeff.) values, tabulated in Table 1, indicate the
presence of one unpaired electron and the absence of metal-metal interaction.
The fairly high values suggest a psuedo-tetrahedral structure for these
complexes. In a completely undistorted tetrahedron, copper(II) should have
a room temperature magnetic moment of about 2.2 B.M.[6].

Electronic Spectra:

The electronic spectra of the complexes show bands around 23300 cm^{-1},
15900 cm^{-1} and 8300 cm^{-1}. The band around 23300 cm^{-1} is intense and is,
therefore, a charge transfer band. The small band around 8300 cm^{-1} may be
due to the psuedo-tetrahedral nature of the complexes[7,8].

I.R. Spectra:

Most of the bands in the spectrum of free pyridine or picolines are
almost reproduced with only minor shifts or splittings in the i.r. spectra
of the complexes[9]. The same is the case with the bands of dithiocarbamato
ligand. However, there is considerable amount of overlapping between the
bands of these two ligands.

The C-N stretching frequency usually occurs around 1500 cm^{-1} in metal
dithiocarbamato complexes[10]. In these mixed ligand complexes also, the
C-N stretching frequency appears around 1500 cm^{-1}. The region 950-1050 cm^{-1}
is associated with the C-S stretching frequency. According to Ugo and
Bonati[11], the presence of only one band in this region indicates a comple-
tely symmetric bidentate bonding by the dithiocarbamato ligand. In the
case of the present mixed ligand complexes, this region also contains vibra-
tions due to the bases. Therefore, more than one band in the 950-1050 cm^{-1}
region do not imply an unsymmetric bonding of the dithiocarbamato ligand in
these complexes. Instead, it would be more realistic to assume a symmetric
bidentate bonding in all these complexes.

The i.r. spectra in the region 200-400 cm^{-1} provide information regarding

the nature of metal ligand vibrations. All the complexes show a medium band around 360 cm^{-1} and a strong band around 300 cm^{-1} which can be assigned to Cu-S and Cu-Cl stretching vibrations respectively[12,13]. The band around 280 cm^{-1} in the pyridine derivatives and 260 cm^{-1} in the picoline derivatives may be attributed to Cu-N stretching vibration.

COMMUNICATIONS

A NOVEL DIMERIC ORGANOIMIDO TUNGSTEN(VI) COMPOUND.

X-RAY CRYSTAL AND MOLECULAR STRUCTURE OF

$[W(NBu\text{-}tert.)(\mu_2\text{-}NPh)Cl_2(tert.\text{-}BuNH_2)]_2$.

D.C. Bradley*, R.J. Errington, M.B. Hursthouse*,

A.J. Nielson and R.L. Short

Department of Chemistry, Queen Mary College,

Mile End Road, London E1 4NS

Abstract. The reaction of tetrachloro-phenylimido-tungsten(VI)
$[W(NPh)Cl_4]$ with tert.-butyltrimethylsilylamine $[tert.Bu(Me_3Si)NH]$ gave
the dimeric complex $[W(NBu\text{-}tert.)(\mu_2\text{-}NPh)Cl_2(tert.\text{-}BuNH_2)]_2$ which was
shown by X-ray crystallography to contain bridging phenylimido and non-
bridging (nearly linear) tertiary butylimido groups together with tertiary
butylamine ligands coodinated to octahedral tungsten. The tert.-butylamine
NH_2 protons were non-equivalent due to N-H....Cl bridging within the dimer.

*Authors to whom correspondence may be addressed.

A number of interesting organoimido complexes of molybdenum and tungsten have been synthesized and characterized in recent years.[1] Among the d^o W(VI) species are the monomeric tetrahedrally coordinated $W(NEt)_2(NEt_2)_2$ [2] and $W(NBu-tert.)_2(HNBu-tert.)_2$ [3], the dimeric 5-coordinated (TBP) $[W(NBu-tert.)(\mu_2-NBu-tert.)Me_2]_2$ [4] and the trimeric octahedrally coordinated $[W(NPh)(\mu_2-O)Me_2(PMe_3)_2]_3$ [5]. We have shown that $W(NPh)Cl_4$ (1) is a useful starting for synthesizing a range of W(VI), W(V) and W(IV) phenylimido complexes[5,6,7] and accordingly the ligand $tert.Bu(Me_3Si)NH$ (2) was selected as a means of re-placing two chlorines by a tert.-butylimido group in a reaction with (1) to produce a tungsten complex containing two different organoimido groups.

From the reaction involving (1) and (2) in 1:2 mole ratio the orange crystalline product $[W(NPh)(NBu-tert.)Cl_2(H_2NBu-tert.)]$ (3) was isolated. The ^1H nmr spectrum showed two distinguishable tert.-butyl groups as singlets ($\delta 1.28$ and 1.37) and two widely separated broad doublets ($\delta 3.38$ and 6.26; ^2J, 12Hz) which were assigned to two non-equivalent protons of the NH_2 groups. Moreover, the infrared spectrum showed two sharp bands in the ν_{NH} stretching region (3243 and 3142 cm^{-1}) confirming the non-equivalence of the NH protons. The structure of (3) was determined by a single crystal X-ray study.

Crystal Data: $W_2Cl_4N_6C_{28}H_{50}$, M = 980.26, monoclinic, space group $P2_1/c$, cell dimensions $\underline{a}$ = 10.063(3), $\underline{b}$ = 14.189(4), $\underline{c}$ = 13.287(3)Å, β = 97.40(2), V = 1881.4Å^3, Z = 2, D_c = 1.730 g cm^{-3}, λ(Mo-Kα) = 0.71073Å, μ(Mo-Kα) = 65.549 cm^{-1}, F(000) = 952.

The structure was solved by the heavy atom method, and refined by least square with anisotropic thermal parameters for all non-hydrogen atoms and iso-tropic for phenyl and amine hydrogen. Other hydrogens had fixed thermal para-

meters. The final R value is 0.031 (Unit weights). Tables of atomic positional

and thermal parameters and Fo/Fc values have been deposited as supplementary

data with the Editor, from whom copies are available on request.[†]

The structure (Figure) shows (3) to be dimeric with very unsymmetrical

phenylimido bridges [W-N, 1.895(3) and 2.324(3)$\overset{o}{A}$] and practically linear tert.-

butylimido groups [W-N, 1.729(4); $\overset{\frown}{\text{CNW}}$ 168.3(3)^o]. Of particular interest in

the structure is the present oc strong hydrogen bonding by one of the NH_2

protons to a chlorine on the neighbouring tungsten atom thus explaining the non-

equivalence noted in the nmr and infrared spectra. Another feature of interest

is the pronounced _trans_-influence of the tert.-butylimido groups acting as a

4-electron donor (N W) which allows the phenylimido nitrogen to π-donate only

where it is _cis_ to the tert.-butylimido nitrogen and thus produces the unsym-

metrical bridge. Interestingly a similar strong _trans_-influence was exerted

by the non-bridging phenylimido-nitrogen in the trimer [$W_3(NPh)_3(\mu_2-O)_3Me_6$

$(PMe_3)_3$] which led to very unsymmetrical WOW bridging.[5] It is clearly signifi-

cant that the unsymmetrical imido bridge (W-N, 1.842, 2.288$\overset{o}{A}$) in the dimer

[$W(NBu-tert.)(\mu_2-NBu-tert.)Me_2]_2$ involving 5-coordinated tungsten has the long

bond _trans_ to the linear non-bridging imido group (W-N, 1.736$\overset{o}{A}$)[4] whereas

symmetrical imido bridges are found in tetrahedral complexes such as

[$Ti(\mu_2-NBu-tert.)(NMe_2)_2]_2$ [1] where there is no possibility of a trans-influence

occurring.

A NOVEL TRINUCLEAR ORGANOIMIDO VANADIUM(V) COMPOUND.

CRYSTAL AND MOLECULAR STRUCTURE OF

$[V_3Cl_2(NBu\text{-}tert.)_3(\mu_2\text{-}NPh)_3(\mu_3\text{-}PhNCONHBu\text{-}tert.)]$

D.C. Bradley*, M.B. Hursthouse*, A.N. de M. Jelfs and R.L. Short

Department of Chemistry, Queen Mary College,

Mile End Road, London E1 4NS

Abstract. From the reaction involving $V(NPh)Cl_3$ and $tert.Bu(Me_3Si)NH$ the trinuclear complex $[V_3Cl_2(NBu\text{-}tert.)_3(\mu_2\text{-}NPh)_3(\mu_3\text{-}PhNCONHBu\text{-}tert.)]$ has been isolated and its structure determined by single-crystal X-ray diffraction. The molecule contains non-bridging (nearly linear) tert.-butyl imido groups, bridging phenylimido groups and a novel triple-bridging (through oxygen) PhNCONHBu-tert. ligand.

* Authors to whom correspondence may be addressed.

A recent review revealed that only a few authentic organoimido vanadium compounds have been characterized.[1,2,3] We have found that trichloro-phenyl-imidovanadium(V) (1) is readily prepared by the reaction of $VOCl_3$ with phenyl-isocyanate and that it is a useful starting material for synthesizing phenyl-imidovanadium compounds by replacement of the chlorine with other ligands. In attempting to prepare a vanadium complex containing two different organoimido ligands we have investigated the reaction of (1) with the unsymmetrical amine (tert.-Bu)(Me$_3$Si)NH which may be deprotonated and/or de-trimethylsilylated in reacting with V-Cl bonds. A crystalline product [V_3Cl_2(NBu-tert.)$_3$(μ_2-NPh)$_3$-(μ_3-PhNCONHBu-tert.)] was isolated and a single crystal X-ray structure deter-mination was carried out.

Crystal Data: $V_3OCl_2N_8C_{11}H_{56}$, M = 901.69, triclinic, a = 11.334(2), b = 11,420(2), c = 20.775(7)Å, α = 100.20(2), β = 75.55(2), γ = 111.21(1)$^\circ$, V = 2416.3Å^3, space group P$\bar{1}$, Z = 2, D_c = 1.24 g cm^{-3}, μ(Mo-Kα) = 7.38 cm^{-1}, (λMo-Kα = 0.71069Å), F(000) = 940.

The structure was solved by direct methods and refined by least-squares, with anisotropic thermal parameters for all non-hydrogen atoms and hydrogen positions calculated in idealised positions and assigned an overall, refined, isotropic thermal parameter. The final R and R_w values are 0.0495, 0.0475 with w = 1/[α^2(F) + 0.0005F^2]. Tables of atomic positional and thermal para-meters and Fo/Fc values have been deposited as supplementary data with the Editor, from whom copies are available.[†]

The structure (Figure) shows several interesting features. Thus the basic nucleus of the structure is a $(VN)_3$ ring in which the metal atoms are bridged by phenylimido groups [V-N = 1.853(9) - 1.912(8)A]. Each vanadium atoms is bonded to a nearly linear non-bridging tert.-butylimido group [V-N = 1.608(9), 1.611(8), 1.648(8)A] and two of the vanadiums, which are chemically equivalent, are each bonded to a chlorine [V-Cl = 2.254(4), 2.254(4)Å]. The third vanadium is bonded to the phenylamido nitrogen [V-N = 1.965(1)Å] of the unexpected ligand (tert.-BuNHCONPh)⁻, whose oxygen is triply bridging all three metal atoms [V-O = 2.252(7), 2.263(7), 2.287(6)Å]. The source of this ligand is a matter for conjecture but the structure suggests its formation _via_ insertion of PhNCO into a V-NHBu-tert. bond. The phenyl isocyanate may have been retained in the V(NPh)Cl₃ from its preparation and this aspect is the subject of continuing research.

Each vanadium is exhibiting a highly distorted trigonal bipyramidal configuration with the tert.-butylimido ligand and the oxygen of tert.-BuNHCONPh in the axial positions. The near-linear CNW groups show that the tert.-butylimido groups are acting as 4-electron donors with triple-bond character and bond lengths similar to that found in V(NR)(OSiMe₃)₃ (R = adamantyl, V-N = 1.614Å), in which the vanadium is 4-co-ordinated.[2] It is noteworthy that the bridging phenyl imido nitrogens are all _cis_ to the tert.-butylimido nitrogen which clearly exerts a powerful _trans_-influence on the triple-bridging ocygen.

Direct ¹H NMR assignment of [Co(III)(edta)]⁻

OLIVER W. HOWARTH

Department of Chemistry & Molecular Sciences, University of Warwick, Coventry,
CV4 7AL England

Abstract—Direct assignment of the ¹H NMR spectrum of the ethylenedinitrilo–NNN′N′-tetra-acetato-cobalt(III) anion [Co(III)(edta)]⁻, illustrates the value of n.O.e. difference and 2-D n.O.e. spectroscopy in coordination chemistry.

In 1971, Sudmeier *et al.*[1] assigned the ¹H NMR spectrum of aqueous [Co(III)(edta)]Cl on the basis of a theoretical argument concerning the relative rates of deuteriation of the glycinate protons. This assignment has been used as a starting point for many further papers on related compounds[2, 3]. We now confirm it directly *via* the nuclear Overhauser enhancement (n.O.e.) difference spectra[4] shown in the figure. Irradiation of resonance *b* gives not only the expected enhancement at *a* but also one at *c*, and similarly irradiation at *e* not only affects *f* but also *d*. The minor disturbances at other positions arise from imperfect subtraction, and do not integrate significantly. Unfortunately, the selectivity of n.O.e. difference spectroscopy is insufficient to penetrate the crowded region around δ 3.8. However, a 2D-n.O.e. experiment[5] confirms the absence of unreasonable dipolar interactions (such as *df*) as well as the presence of the above near-neighbour relationships. The two

methods clearly have considerable value in non-labile coordination chemistry.

ERRATUM

R. D. Gillard, M. F. Pilbrow, S. Leonard, M. C. Rendle, and C. F. H. Tipper: The reaction of carbon monoxide with platinum ylids. *Polyhedron* 1982, **1**, 689.

The reference numbers attached to types of compound in the Introduction (p. 689) are not all correct.

(**II**) is missing, and (**I**) appears twice.

To clarify this, the correct codes are:

[X₂PtCH₂CH₂(pyridine)₂]	(**I**) platina(IV)cyclobutane
[X₂Pt{CH(py)CH₂CH₃}(py)]	(**II**) platinum(II) ylid
[X₄Pt{CH(py)CH₂CH₃}(py)]	(**III**) platinum(IV) ylid
[Cl₂Pt{CH(py)CH₂CH₃}(CO)]	(**IV**) platinum carbonyl ylid.

The numbers appearing in Scheme 1 (p. 690) are correct.

HISTORICAL SKETCHES

NIKOLAĬ SEMENOVICH KURNAKOV, THE REACTION (1893) AND THE MAN (1860–1941) A NINETY-YEAR RETROSPECTIVE VIEW

GEORGE B. KAUFFMAN

Department of Chemistry, California State University, Fresno, CA 93740, U.S.A.

Abstract—Kurnakov's classic thiourea reaction, proposed ninety years ago and still used to differentiate *cis* from *trans* isomers of dipositive platinum and palladium, represents his best known contribution to coordination chemistry. The circumstances surrounding its discovery, its implications, and its relationship to Peyrone's and Jørgensen's reactions and Chernyaev's *trans* effect are discussed. A brief discussion of Kurnakov's other studies of coordination compounds, and a short biography are also provided.

[The] stability [of the platinum compounds of thiourea prepared by me] and their close relationships to other complex platinum salts permits a closer investigation into their nature and an important expansion of our conceptions of complex bases in general . . . in individual cases the ability to form salts of general formula PtX₂·2U·2A (in which A = NH₃) [and U = thiourea] serves as a characteristic indication for differentiating the isomeric salt[s] PtX₂·2A.[1]

These words, written in 1893, the same year that Alfred Werner's coordination theory[2] was published, occur in one of the first major systematic studies of the coordination compounds of platinum undertaken in Russia. Entitled *On Complex Metallic Bases*[3] and serving as his inaugural dissertation for the Professorship of Inorganic Chemistry at the St. Petersburg Mining Institute, this experimental and theoretical study by Nikolaĭ Semenovich Kurnakov (1860–1941) represents not only his first major work but also his most widely-known contribution to coordination chemistry. Published first in Russian and then in German translation,[1] it provided the nineteenth-century coordination chemist with a simple diagnostic test for differentiating *cis* from *trans* isomers of dipositive platinum or palladium—a test still used today for this purpose.[4]

THE REACTION

The first decade following Kurnakov's graduation as Mining Engineer from the Mining Institute in 1882 was devoted largely to research in halurgy (salt manufacture), metallurgy, and assaying, carried out both in the laboratory and in the plants and factories that he visited. His second research period (1891–1902), devoted to the structure and properties of coordination compounds, began with the complexes ("double compounds") of silver(I) nitrate and mercury(I) nitrate with thiourea, $CS(NH_2)_2$.[5] After a short study comparing the solubilities of the chlorides of the luteocobaltic ($CoCl_3 \cdot 6NH_3$; modern, $[Co(NH_3)_6]Cl_3$), purpureocobaltic ($CoCl_3 \cdot 5NH_3$; modern, $[Co(NH_3)_5Cl]Cl_2$), and roseopentamminecobaltic ($CoCl_3 \cdot 5NH_3 \cdot H_2O$; modern, $[Co(NH_3)_5H_2O]Cl_3$) series (1892),[6] he returned in 1893 to the ligand thiourea for the subject of his dissertation. Since platinum had been and still continues to be one of the most valuable of Russia's natural resources, it is not surprising that Kurnakov chose the complexes of platinum with thiourea for the main part of this experimental work. Throughout his long scientific career, he retained his interest in this noble metal; not only did he later become Director of the Institute for the Study of Platinum and Other Noble Metals following the death of its founder Lev Aleksandrovich Chugaev (1873–1922),[7] but also, because of his development of coordination theory and application of complexes to the refining of the platinum metals, he is regarded as one of the founders of the platinum industry of the U.S.S.R.[8]

In his first part of *On Complex Metallic Bases*[1] Kurnakov found that addition of excess aqueous potassium tetrachloroplatinate(II) ($PtCl_2 \cdot 2KCl$; modern, K_2PtCl_4) to aqueous thiourea (tu) caused precipitation of the compounds $PtCl_2 \cdot 2tu$ (reddish-yellow *trans*-$[Pt(tu)_2Cl_2]$, which he correctly recognized as analogous to the chloride of Reiset's second base, *trans*-$[Pt(NH_3)_2Cl_2]$):

Изъ химической лабораторіи Горнаго Института.

О сложныхъ металлическихъ основаніяхъ.

Н. Курнакова.

Глава I. Металлическія соединенія тіокарбамида.

Способность тіокарбамида или тіомочевины къ сочетаніямъ съ металлическими солями является весьма ясно выраженной. Уже Рейнольдсъ [1]), открывшій тіомочевину при изомерномъ превращеніи роданистаго аммонія, описалъ характерныя соединенія:

$$AuCl.2CSN_2H_4$$
$$PtCl_2.HCl.2CSN_2H_4,$$
образующіяся при дѣйствіи тіомочевины на растворы хлорныхъ солей золота и платины. Впослѣдствіи Клаусъ [2]), Мали [3]), Преторіусъ-Зейдлеръ [4]), Ратке [5]) и др. получили попутно при своихъ изслѣдованіяхъ надъ тіомочевиною и ея производными многочисленныя сочетанія съ солями свинца, кадмія, ртути, олова, висмута, серебра, таллія и мѣди. Всѣ эти соединенія заключаютъ тіомочевину въ видѣ цѣлыхъ частицъ и имѣютъ составъ, выражаемый слѣдующей общей формулой:

$$MX_m.nCSN_2H_4 \text{ или } MX_m.nu,$$
если обозначить для краткости $CSN_2H_4 = u$. Въ извѣстныхъ до настоящаго времени соляхъ коэффиціентъ n измѣняется въ предѣлахъ отъ 1 до 4 (на одинъ атомъ металла).

Особенно замѣчательны мѣдныя соединенія, изслѣдованныя Ратке. При взаимодѣйствіи съ солями окиси мѣди тіомочевина реагируетъ сначала, какъ возстановитель, по уравненію:

$$CSN_2H_4 + 2CuCl_2 = 2CuCl + (CSN_2H_4)_2Cl_2$$
Образующаяся CuCl вступаетъ затѣмъ въ сочетаніе съ новымъ количествомъ тіомочевины и даетъ сложную соль. Такимъ образомъ, смѣшивая на холоду разведенные растворы тіомочевины и хлорной

химич. общ. 36

Fig. 1. The first page of Kurnakov's classic paper "O Slozhnykh Metallicheskykh Osnovaniiakh" (On Complex Metallic Bases) J. Russ. Phys. Chem. Soc. 1893, 25, 565 (Ref. 1).

$$K_2\begin{bmatrix} Cl & & Cl \\ & Pt & \\ Cl & & Cl \end{bmatrix} + 2tu \rightarrow \begin{bmatrix} tu & & Cl \\ & Pt & \\ Cl & & tu \end{bmatrix}$$

+ 2KCl *(modern formulation)* (1)
and PtCl$_2$·tu (an orange–yellow water-insoluble substance, which was not obtained in a pure state and was not further investigated). Warming either of these compounds with excess thiourea transformed them into the soluble white compound PtCl$_2$·4tu([Pt(tu)$_4$]Cl$_2$), which Kurnakov correctly recognized as related to the chloride of Reiset's first base ([Pt(NH$_3$)$_4$]Cl$_2$). Kurnakov also prepared

the very stable PtCl$_2$·4tu directly by adding a warm, concentrated solution of K$_2$PtCl$_4$ to a warm, saturated solution of thiourea. He also prepared the bromide, sulphate, nitrate, hexachloroplatinate(IV) and tetrachloroplatinate(II) of the [Pt(tu)$_4$]$^{2+}$ ion as well as the palladium salt PdCl$_2$·4tu ([Pd(tu)$_4$]Cl$_2$). Substituted thioureas (methyl-, ethyl-, *sym*-diethyl- and triethylthiourea), thioacetamide (CH$_3$·CS·NH$_2$), and xanthogenamide (NH$_2$·CS·OC$_2$H$_5$) gave similar salts with 2 or 4 moles of base per mole of PtCl$_2$. Kurnakov correctly recognized that the thiourea was monodentate and bonded to the metal atom through the sulphur atom rather than through one

of the nitrogen atoms, a conclusion that has since been confirmed by studies of IR spectra.[9]

But it was Kurnakov's preparation of the $PtCl_2$ "salts of mixed bases" (those containing both thiourea and either ammonia or pyridine) that furnished the basis for what has since become known as Kurnakov's reaction or Kurnakov's test:

> The chloride salt of Reiset's second base (platosammine chloride) is especially interesting. . . . In the presence of thiourea β-$PtCl_2$·$2NH_3$ quickly dissolves on warming with formation of a colourless solution, from which snow-white needles of the mixed compound $PtCl_2$·$2NH_3$·$2CSN_2H_4$ separates on evaporation or treatment with hydrochloric acid. This compound apparently has the composition of the type of salt of Reiset's first base $PtCl_2$·$4NH_3$, in which 2 molecules of NH_3 are replaced by 2 molecules of CSN_2H_4. This formation is completely analogous to the formation of $PtCl_2$·$4NH_3$ from β-$PtCl_2$·$2NH_3$ and ammonia.[1]

In modern formulation,

$$\begin{bmatrix} H_3N & Cl \\ & Pt \\ Cl & NH_3 \end{bmatrix}_{trans} + 2tu \rightarrow \begin{bmatrix} H_3N & tu \\ & Pt \\ tu & NH_3 \end{bmatrix}_{trans} Cl_2$$

Kurnakov's Reaction   (2)

$$\begin{bmatrix} H_3N & Cl \\ & Pt \\ Cl & NH_3 \end{bmatrix}_{trans} + 2NH_3 \rightarrow \begin{bmatrix} H_3N & NH_3 \\ & Pt \\ H_3N & NH_3 \end{bmatrix} Cl_2$$

(3)
On the other hand, Kurnakov observed:

> It is noteworthy that the isomeric α-compounds, platosemidiammine chloride α-$PtCl_2$·$2NH_3$ of Peyrone and platosemidipyridine chloride α-$PtCl_2$·$2C_5H_5N$, apparently do not form mixed salts as do the β-compounds, at least not under the same conditions.

> Peyrone's salt and platosemidipyridine chloride dissolve easily on warming with thiourea. Ammonia or pyridine are here split off, and yellow solutions are formed, from which, on addition of hydrochloric acid, the salt $PtCl_2$·$4U$ is precipitated in yellow needles (recognizable by its behaviour with H_2SO_4 and Na_2PtCl_6). The same result is also obtained at room temperature.[1]

In modern formulation,

$$\begin{bmatrix} A & Cl \\ & Pt \\ A & Cl \end{bmatrix}_{cis} + 4tu \rightarrow \begin{bmatrix} tu & tu \\ & Pt \\ tu & tu \end{bmatrix} Cl_2 + 2A$$

Kurnakov's Reaction   (4)
($A = NH_3$ or pyridine).

Thus replacement by thiourea (or thioacetamide) occurs with all the ligands of the cis isomer but only with the acid radicals of the trans compound. Inasmuch as the isomers yield easily distinguishable, characteristically different products and by-products (eqns 2 and 4), reaction with thiourea or thioacetamide (Kurnakov's reaction) may be used to differentiate cis from trans isomers of Pt(II) and Pd(II).

Kurnakov's reaction, useful as it is, however, was not the first discovered example of directive influences in substitution reaction of coordination compounds. For example, the syntheses of two of the longest known platinum isomers, viz. platosemidiammine chloride or Peyrone's salt[10] (α- or cis-[Pt(NH_3)_2Cl_2]) and platosammine chloride or Reiset's second chloride[11] (β- or trans-[Pt(NH_3)_2Cl_2]), involve such influences. Their preparative reactions[12] were known as Peyrone's reaction[10] and Jørgensen's reaction,[13] respectively, and were said to exemplify Peyrone's rule (cis orientation) and Jørgensen's rule (trans orientation):

Peyrone's reaction

$$K_2 \begin{bmatrix} Cl & Cl \\ & Pt \\ Cl & Cl \end{bmatrix} + 2NH_3 \rightarrow$$

$$\begin{bmatrix} H_3N & Cl \\ & Pt \\ H_3N & Cl \end{bmatrix} + 2KCl \qquad (5)$$

cis

Jørgensen's reaction

$$\begin{bmatrix} H_3N & NH_3 \\ & Pt \\ H_3N & NH_3 \end{bmatrix} Cl_2 + 2HCl \rightarrow$$

$$\begin{bmatrix} H_3N & Cl \\ & Pt \\ Cl & NH_3 \end{bmatrix} + 2NH_4Cl \qquad (6)$$

trans
These reactions played crucial roles in Werner's proof of the square planar configuration for platinum(II)[2] and, along with Kurnakov's reaction, were valuable weapons in the inorganic stereochemist's arsenal. Kurnakov recognized that his synthesis of trans-[Pt(tu)$_2$Cl$_2$] by the action of thiourea on potassium tetrachloroplatinate(II) (eqn 1) constituted an exception to Peyrone's rule (eqn 5), which predicted formation of the cis isomer. Actually, the conflict is apparent rather than real, for Peyrone's reaction, Jørgensen's reaction, and Kurnakov's reaction are all specialized cases of a more general principle underlying the directive influence of coordinated ligands, which was not enunciated until well into the third decade of the twentieth century.

Although Werner[2] recognized the principle of "trans elimination" as early as 1893, it was not until 1926 that Il'ya Il'ich Chernyaev (1893–1966)[14] pointed out the general regularity of what he called the trans effect in order to describe the influence of a coordinated ligand on the practical ease of preparing compounds in which the group trans to it had been replaced.[15] Chernyaev theorized that a negative group coordinated to a metal atom labilizes the bond of any group trans to it, and thus he explained not only the empirically formulated Peyrone's, Jørgensen's, and Kurnakov's reactions but also many other features of the reactions of dipositive and tetrapositive platinum and palladium and of other metals as well. He postulated that electronegative ligands have a greater "trans influence" than neutral ligands, and his original trans-directing series has been extended to include a variety of ligands:

$$CN^- \sim CO \sim C_2H_4 \sim NO \sim H^- > CH_3$$
$$\sim SC(NH_2)_2 \sim SR_2 \sim PR_3 > SO_3H^-$$
$$> NO_2^- \sim I^- \sim SCN^- > Br^- > Cl^-$$
$$> C_5H_5N > RNH_2 \sim NH_3 > OH^-$$
$$> H_2O.[16]$$
Thus the formation of cis-diammines by reaction of ammonia or amines with tetraacidoplatinates(II) (eqn 5) is essentially due to the fact that the trans influence of ammonia or amines is less than the trans influence of the anions. Similarly, the course of Kurnakov's reaction is explained by the weak trans influence of ammonia and amines and the strong trans influence of thiourea, which, after displacement of the acid radicals in the cis-diammines (eqn 4) labilizes the ammonia or amine molecules so that they are also substituted by thiourea, while in trans-diammines

(eqn 2) the two ammonia or amine molecules are not labilized by thiourea and cannot be displaced by it.[17] Chernyaev's trans effect also explains not only the course of reaction (1) but also why Kurnakov's test fails with complexes containing ligands of strong trans effect. For example, the trans effect of thiourea is balanced by the trans effect of phosphorus-containing ligands, and cis-[Pt{(C$_2$H$_5$)$_3$P}$_2$Br$_2$] dissolves readily in cold aqueous thiourea to yield cis-[Pt(tu)$_2${(C$_2$H$_5$)$_3$P}$_2$]Br$_2$ rather than [Pt(tu)$_4$]Br$_2$ as predicted by eqn (4).[18]

At the time that Kurnakov was working on his dissertation, the Blomstrand–Jørgensen chain theory[19] was still the most widely accepted of the various theories of the structure of complexes,[20] and Werner's coordination theory was just being proposed. In his dissertation Kurnakov rejected Kekulé's outdated theory of molecular compounds[20] and critically reviewed the various theories that had been proposed to explain the structure of complexes. Like Werner, he noted the changes in chemical function of both metal and acid radicals in salts brought about by the combination of such salts with ammonia, water, or other bases, and he likewise noted the similarities between hydrated metal salts and metal–ammonia compounds. Nevertheless, in his opinion, none of the theories was completely satisfactory although each served to explain various facets of the problem.

Thus Kurnakov occupied an intermediate position between the old and new theories. While he did not find it possible to agree totally with the Blomstrand–Jørgensen chain theory, he likewise did not completely accept Werner's views. In each theory he found a sound core of ideas, which, nevertheless, in his opinion, could not explain all the known facts. According to the chain theory, in complex compounds the acid radicals were bonded to the metal through one or more (a chain) of neutral ligands. For example, the chloride of Reiset's second base was written

$$Pt \begin{matrix} NH_3-Cl \\ \\ NH_3-Cl \end{matrix} \quad .$$
According to Werner's coordination theory, the anions were directly bonded to only the metal, and the neutral ligands were similarly bonded:

$$\begin{matrix} Cl & & NH_3 \\ & Pt & \\ H_3N & & Cl \end{matrix} \quad .$$

trans
Kurnakov, however, thought that the anions were simultaneously bonded to both the metal atom and the neutral molecules:

$$\begin{array}{ccc} Cl & & NH_3 \\ & \diagdown Pt \diagup & \\ | & & | \\ H_3N & \diagup \diagdown & Cl \end{array}.$$
In support of this assumption he pointed to the fact that the chemical reactivities of halogens, hydroxide, and other acid substituents depend not only upon the metal to which they are bonded but upon the other groups to which the metal is bonded as well. He regarded complexes as intermediate between chemical compounds of fixed composition and phases of varying composition, a harbinger of his later "berthollide-daltonide" dichotomy (1914).[21]

Kurnakov did not limit himself to studying the synthesis and properties of coordination compounds, but he investigated physical properties of important theoretical significance such as colour, index of refraction (later useful in studies of dipole moment), crystal form, solubility, and acidic and basic properties (later developed more fully by A. A. Grinberg). For example, in 1898 he published an article on "The Relation Between the Colour and the Constitution of Haloid Double Salts", in which he investigated the change in colour caused by the introduction of water, ammonia, or other neutral ligands into inorganic salts.[22] In the following years he synthesized and studied hydrated lithium bromocuprite,[23] and he prepared new complexes of palladium(II) chloride[24] and nickel(II) chloride[25] with ethylenediamine. After a hiatus of three decades he returned to studies of coordination compounds of platinum. He studied derivatives of tetraammineplatinum(II) chloride,[26] the so-called "ice isotherms"[27] and the equilibrium[28] in the ternary system: $NaCl–PtCl_4–H_2O$, the latter two studies being examples of his technique of physicochemical analysis. He also drew a number of important inferences concerning the similarity between complex ions and simple metal ions, which was later confirmed by Chugaev's demonstration of the analogy between the $[Pt(NH_3)_5Cl]^{3+}$ ion and Ba^{2+} and Pb^{2+} ions.[29]

Nikolaĭ Semenovich Kurnakov is regarded as the founder of a new chemical discipline—physicochemical analysis—and it is his later works in this field that are immediately thought of when his name is mentioned. Yet, as Il'ya Il'ich Chernyaev has observed,

if Kurnakov had produced nothing but his early work on complex compounds, his name

would not be forgotten. . . . Kurnakov's work on complex compounds played an immense part in the development of the chemistry of complex compounds, both in its experimental and theoretical aspects.[4]

THE MAN

Nikolaĭ Semenovich Kurnakov was born in Nolinsk, Vyatka province, on 6 December (24 November, O.S.), 1860, but spent his childhood in the village of Zhedrin, Nizhegorodskaĭa province.[30] His father, an army officer, died in 1868, leaving him with his mother (Varvara Alekseevna Kurnakova, née Mezentseva) and brother. From 1871 to 1877 he received a high school education at the military gymnasium at Nizhni Novgorod (now Gorkiĭ). Distantly related to the great organic chemist Markovnikov, he made an early choice of a career, setting up a home laboratory at the age of fourteen. Immediately after graduation, he entered the St. Petersburg Mining Institute, where independent research under chemists Sushin and Lisenko and mineralogist Yeremyev resulted in his first publication, a crystallographic study of alum and Schlippe's salt $(Na_3SbS_4·9H_2O)$.[31] After graduation from the Factory Section in 1882 with the degree of Mining Engineer, he was retained by the chemical laboratory of the institute.

Kurnakov's interest in chemical industry would not permit him to remain exclusively a laboratory worker, and he now began the first of his many trips to plants and factories. In the summer of 1882, together with Prof. N. A. Iôssa, he investigated the smelting operations at the Altai (Siberia) refineries. The following year, during a trip abroad, he toured the laboratories of the Freiburg Akademie where he attended the lectures of Winkler and Richter. A detailed study of salt manufacturing in Prussia, Lorraine, Württemberg, Baden, Bavaria, and the Austrian Tyrol made during the summer of 1884 resulted the following year in his dissertation for the position of *Adiunkt* (Assistant) in metallurgy, halurgy, and assaying, a post which he held for eight years. This work, "Isparitel'nye Sistemy Solïanykh Varnits" (Evaporative Systems of Salt Boilers), containing the germs of Kurnakov's subsequent studies of salt equilibria, appeared long before van't Hoff's research on the Stassfurt salt beds. The eighties were years of great developments in physical chemistry; Kurnakov's work was in keeping with this trend.

Further scientifically fruitful summer travels included: a chemical study of therapeutic mineral muds in the Crimean salt lakes (1894), which resulted in Kurnakov's introduction of the coefficient of metamorphization, a new and im-

portant unit for the characterization of natural salt solutions; a study of firedamp (methane) in the Donets Basin anthracite mines (1895);[32] work as an expert at the All-Russian Industrial and Artistic Exhibition at Nizhni Novgorod (1896); a visit to Germany and France to study methods for the investigation of detonating (oxyhydrogen) gas (1898); a trip as a delegate to the International Congress of Chemical and Mining Industries and as a member of the Commission of Experts at the World's Fair, both in Paris (1900).

In 1893 Kurnakov was appointed Professor of Inorganic Chemistry following the successful defense of his dissertation "On Complex Metallic Bases",[3] discussed in detail above. In 1899 he was appointed a member of the Mining and Scientific Mining Institute, and he organized the teaching of physical chemistry at the Saint Petersburg Electrotechnical Institute. In 1902 he was appointed Professor of General Chemistry at the St. Petersburg Polytechnic Institute, which he had organized together with Mendeleev and Menschutkin; he held this post until 1930.

During the first decade of the twentieth century, Kurnakov was concerned with the solution of industrial problems such as platinum refining, metallic alloys, metallography, and salt manufacturing. In 1909 he was awarded the degree of Doctor of Chemical Sciences *honoris causa* by Moscow University, became a contributing editor of the *Zeitschrift für anorganische Chemie*, and was appointed a member of the Mining and Scientific Committee. In 1910 he directed studies of the Russian Council on Platinum Refining, and the following year he went abroad to study methods of transporting warm sulphur waters. In connection with his work on the Russian Commission for the Study of Toxic Properties of Commercial Ferrosilicon, he carried out chemical–metallographic studies of alloys of iron with aluminum, phosphorus and silicon.[33]

Official recognition abroad followed recognition at home. In 1912 Kurnakov was elected a council member of the Société chimique and became a member of the Russian Department of the Inter-national Commission on the Nomenclature of Inorganic Compounds. As a delegate of the Russian Physical-Chemical Society, he participated in the meetings of the International Association of Chemical Societies held at Berlin (1912) and Brussels (1913). In 1913 he was elected vice-president of the Russian Metallurgical Society and became Ordinary Academician in chemistry at the Russian Academy of Sciences. The laboratory of the academy had been inactive for a number of years, but it experienced a rebirth as a result of Kurnakov's extraordinary organizational talent.

World War I brought new tasks for Kurnakov. He was instrumental in the creation of a number of new institutes and commissions. In 1915, together with fellow academicians V. I. Vernadskiĭ and A. E. Fersman, he organized and became assistant chairman of Komissiĭa po Izucheniĭu Estestvenno Proizvodstvennykh Sil Rossii, KEPS (Commission for the Study of Russian Natural Productive Sources), at the Academy. At KEPS, he established a Salt Commission, and the study of salt solutions and related problems occupied much of his time for the next few years.

Upon mobilization, Kurnakov became chairman of the newly-created Artillery Commission for the Study of Asphyxiating Gases where he conducted research both in the field and laboratory on the physiological action of war gases. From 1916 to 1918 he participated in the work of the chemical plant of the Military Industrial Committee in Petrograd. During the Civil War following the October (1917) Revolution, a trying period of frost, famine, and other disasters, when all organized life was completely disrupted, research continued in Kurnakov's laboratories. He even organized an expedition to investigate the formation of Glauber's salt ($Na_2SO_4 \cdot 10H_2O$) at Kara–Bogaz–Gol Bay.[34]

In 1919 he organized and became director (a position held until 1927) of the Gosudarstvennyĭ Institut Prikladnoĭ Khimii, GIPKh (State Institute of Applied Chemistry) with facilities located at Vasil'yevskiĭ Island on the Neva at Petrograd, which had grown out of the first Russian labora-
Fig. 2. The N. S. Kurnakov Institute of General and Inorganic Chemistry, Leninskiĭ Prospect 31, Moscow (by courtesy of the late Academician Il'ya Il'ich Chernyaev).

tory founded by Mikhail Vasil'yevich Lomonosov (1711–1765). Here scientific workers from the provinces gathered, especially during the summers, to work under Kurnakov's guidance. In the fall they returned home with ideas and projects for the next few years. In this manner, Kurnakov disseminated his ideas and expanded his rapidly growing school.

In 1918 at KEPS Kurnakov founded and became director of the Institut Fiziko-Khimicheskogo Analiza (Institute of Physicochemical Analysis), and the following year he became editor of its *Izvestiia Instituta Fiziko-Khimicheskogo Analiza* (now *Izvestiia Sektora Fiziko-Khimicheskogo Analiza*); he held both positions until his death. The first volume of this journal contained a classic in halurgy, viz. Kurnakov and Zhemchuzhnyĭ's study of natural salt deposits of marine origin.[35] The year 1922 saw Kurnakov become director of the General Chemistry Laboratory of the Academy, director of the Platinum Institute at KEPS upon Chugaev's death, and a member of the Göttingen Akademie.

In 1934 the Institute of Physicochemical Analysis, the Platinum Institute, and the General Chemistry Laboratory of the Academy merged into the Institut Obshchei i Neorganicheskoĭ Khimii, IONKh (Institute of General and Inorganic Chemistry). with headquarters in Moscow and with Kurnakov as its director. IONKh rapidly became one of the leading scientific research institutes in the U.S.S.R. and a center for physicochemical investigations of metallurgy, halurgy, precious metals, organic substances, and other economically significant problems.[36] Following Kurnakov's death in 1941, it was renamed the N. S. Kurnakov Institute.

From 1920 to the end of his life there were few chemical or metallurgical conferences in which Kurnakov failed to participate as chairman, lecturer, or delegate. He was chairman of the Chemical Association of the Academy of Sciences of the U.S.S.R. (1930–1938) and vice-president of the D. I. Mendeleev All-Union Society. In addition to his industrial consulting, in which he gave technical advice to plants and factories throughout the U.S.S.R., he was extremely active in public affairs.

Kurnakov's contributions were recognized on numerous occasions by the Soviet government. He received the First Mendeleev Prize (1936), the Order of the Red Banner for Labor (1939), and the title of Meritorious Worker of Science of the Russian Soviet Federated Socialist Republic (1940), and the Stalin Prize, First Class, for the fourth edition of his book *Introduction to Physicochemical Analysis*,[37] dedicated to the memory

Fig. 3. President of the USSR, Mikhail Ivanovich Kalinin (1875–1946), right, presenting the medal of the Order of Lenin to Academician Nikolaĭ Semenovich Kurnakov (1860–1941) in 1940. Photograph by P. Troshkin, courtesy of the late Academician Chernyaev.

of his closest friend, his wife Anna Mikhailovna, who for more than half a century had accompanied him everywhere and supported him in all his endeavors. The Kurnakovs had two children—a son Dr. Nikolaĭ Nikolaevich Kurnakov (born in 1889), a chemist who worked at the Baikov Metallurgical Institute of the Academy of Sciences of the

Fig. 4. On 15 August 1951, Kurnakov's portrait appeared on a 40–kopek postage stamp, part of a commemorative issue honouring outstanding figures of Russian art and science. Legend reads "N. S. Kurnakov, outstanding Russian chemist, Founder of Physicochemical Analysis". Scott catalogue No. 1573.

U.S.S.R., and a daughter Vera Nikolaevna Kurnakova (born in 1898), who died at the age of 23 while still a student.

His wife's death in 1940 had serious effects on Kurnakov's health. Ignoring the cancer which was soon to claim his life, he continued his full work schedule almost to the very end, and when his colleagues inquired as to the state of his health, which was visibly deteriorating, he quickly shifted the conversation to scientific topics. At the beginning of March, 1941 he entered the sanitorium at Barvikha where he died on 19 March. His work is continued by an extensive school of scientists armed with new research methods, new apparatus, new theories, and new applications which he himself had created. The two-volume *Collection of the Selected Works of N. S. Kurnakov*[38] contains a complete list of his works published through 1939, and the three volumes of his *Selected Works*[39] appeared in 1960–1963. The majority of the works of one of Russia's most distinguished and versatile chemists, even those published almost a century ago, are still of great theoretical and practical interest today.

SYNTHESIS, CHARACTERISATION AND THERMAL PROPERTIES OF HYDRAZINIUM METAL OXALATE HYDRATES. CRYSTAL AND MOLECULAR STRUCTURE OF HYDRAZINIUM COPPER OXALATE MONOHYDRATE

D. GAJAPATHY, S. GOVINDARAJAN, K. C. PATIL and H. MANOHAR*

Department of Inorganic and Physical Chemistry, Indian Institute of Science,
Bangalore 560 012, India

Abstract—Complexes of the formula $(N_2H_5)_2M(C_2O_4)_2 \cdot nH_2O$ where M = Co, Ni, Cu and $n = 3, 2, 1$ respectively have been prepared and their spectral, magnetic and thermal properties investigated. The copper complex, $(N_2H_5)_2Cu(C_2O_4)_2 \cdot H_2O$ has a square planar geometry with no coordination of hydrazinium cations as confirmed by a single crystal X-ray study. Nickel and cobalt form octahedral complexes and X-ray powder patterns reveal that the complexes are not isomorphous.

Of the complexes containing positively charged ligands, those with the hydrazinium cation are of increasing interest.[1,2] Preparation and thermal study of metal double fluorides with hydrazinium cation have been reported.[3-12] A few chloride complexes of copper,[2] cadmium[13] and tin[14] with $N_2H_5^+$ cation have also been studied.

Another group of complexes containing $N_2H_5^+$ is the series of metal hydrazinium sulphates,[1,15-19] $M(N_2H_5)_2(SO_4)_2$ where M = Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd and Mg. Double sulphates of lighter rare earths (La–Sm) with $N_2H_5^+$ have been studied in this laboratory.[20] A few hydrazinium metal hydrazidocarbonate hydrates have also been mentioned in the literature.[21,22] However no complexes containing $N_2H_5^+$ with oxalate have been reported. We report in this paper the preparation, characterization, magnetic and thermal properties of hydrazinium metal oxalate hydrates $(N_2H_5)_2M(C_2O_4)_2 \cdot nH_2O$ where M = Co, Ni, Cu and $n = 3, 2, 1$ respectively, and the crystal structure of hydrazinium copper oxalate monohydrate.

EXPERIMENTAL

Preparation of the compounds

Aqueous solutions of hydrazinium oxalate $(N_2H_5)_2C_2O_4$ and the corresponding metal nitrate hydrates, in the ratio 4:1 are mixed at room temperature and the mixture cooled to 5°C when the crystals of the respective hydrazinium metal oxalate hydrates separate out. The rate of formation of the product is in the increasing order Co < Ni < Cu. The crystals are immediately washed with small quantity of ice cold water and air dried. Except for the cobalt compound these compounds are quite stable in air. Hydrazinium cobalt oxalate trihydrate slowly decomposes in air in the course of a few days. Efforts to prepare the corresponding Mn, Fe and Zn compounds using a similar procedure resulted only in the formation of simple metal oxalates.

Conventional chemical analysis of all the three samples was done. Hydrazine content was estimated by titrating against standard KIO_3 under Andrews condition.[23] Metal contents were determined by EDTA titrations. Oxalate in the compounds was precipitated as calcium oxalate which was dissolved in dilute H_2SO_4 and titrated against standard $KMnO_4$. Water content in the samples was obtained by the method of difference and was further confirmed by thermogravimetry.

Physical measurements

IR spectra (4000–200 cm^{-1}) of the complexes were recorded in Nujol mull using a Perkin–Elmer PE 599 spectrophotometer. Reflectance spectra were recorded on Shimadzu UV-210A double beam spectrophotometer using MgO as a reference material. Magnetic susceptibility values were measured at room temperature by the Gouy method and corrected with Pascal constants. ESR spec-

---

trum of the copper compound in the powder form was recorded on a Varian E 109 ESR spectrometer.

Differential thermal analysis (DTA) of the samples was recorded on an instrument described elsewhere[24] fitted with an omniscribe strip chart recorder. Thermogravimetric analysis (TG) was carried out on a Stanton Redcroft TG–750 thermobalance. Both the thermal experiments were done in air, with platinum cups as sample holders and a heating rate of $10°C\,min^{-1}$.

Crystallography of $(N_2H_5)_2Cu(C_2O_4)_2 \cdot H_2O$

Crystal data. $(N_2H_5)_2Cu(C_2O_4)_2 \cdot H_2O$, $M = 323.54$, monoclinic, $P2_1/n$, $a = 3.592(1)$, $b = 7.855(2)$, $c = 19.143(3)$ Å, $\beta = 94.3(3)°$, $Z = 2$, $D_c = 1.995\,g\,cm^{-3}$, $D_m = 1.99\,g\,cm^{-3}$, $F_{000} = 326$, $\mu(MoK\alpha) = 15.6\,cm^{-1}$.

X-Ray data collection and structure analysis

A crystal of dimensions $0.20 \times 0.25 \times 0.62$ mm was used for data collection. The unit cell dimensions and the intensities of all independent reflections with $\theta(MoK\alpha) < 32°$ were determined by standard experimental methods using an Enraf–Nonius CAD-4 diffractometer equipped with a graphite monochromator. Corrections were applied for Lorentz-polarisation and secondary extinction effects but not for absorption, since μ is small. 1550 independent reflections with $I \geqslant 3\sigma(I)$ were used in the subsequent analysis.

Copper positions were determined from a three-dimensional Patterson map and the remaining non-hydrogen atoms were located in subsequent Fourier maps. Atomic positions and thermal parameters were refined by full matrix least squares methods using the SHELX-76 program.[25] A difference Fourier synthesis at the end of the refinement gave peaks corresponding to all hydrogen atoms of the $N_2H_5^+$ group. Hydrogen atoms of disordered water could not be located. The final refinement including hydrogen atoms of $N_2H_5^+$ ion with an isotropic temperature factor $(5\,Å^2)$ converged at $R = 0.058$ and $R_w = 0.068$.

Atomic coordinates, thermal parameters and a table of Fo, Fc values have been deposited with the Editor as supplementary material. Atomic scattering factors and anomalous dispersion corrections were taken from Ref 26. The extinction coefficient g [(eqn 17.17) in Stout and Jensen[27]] was 5.8333×10^{-5}. The weighting function employed was $w = 0.5/(\sigma^2F + 0.023|F|^2)$.

Results and discussion

The results of chemical analysis (Table 1) of the samples agree well with the assigned composition of $(N_2H_5)_2M(C_2O_4)_2 \cdot nH_2O$ where M = Co, Ni, Cu and $n = 3, 2, 1$ respectively.

Infrared spectral data are tabulated (Table 2) and assigned on the basis of earlier work.[1,2,28–31] IR spectra of the complexes show absorptions corresponding to bidentate oxalate[28] at 1720–1650 cm^{-1}. The presence of hydrazine as a cation is revealed by the characteristic bands at 2650 cm^{-1} corresponding to the NH stretching of NH_3^{+} [29] and wagging vibrations of NH_3^+ at 1100 and 1085 cm^{-1}.[30] The N–N stretching frequency of $N_2H_5^+$ is known to occur $\sim 965\,cm^{-1}$ [31] and when hydrazinium ion is acting as a ligand ν_{N-N} invariably absorbs at 1005 cm^{-1}.[1,2]

Reflectance spectral data and the room temperature magnetic susceptibility values of the complexes are given in Table 3. These data furnish supporting evidence about the geometry of the complexes.

X-Ray powder patterns of the complexes indicate that they are not isomorphous. The d-spacings of the complexes are listed in Table 4.

Thermoanalytical curves of all the three complexes are shown in Figs. 1(a) and (b).

$(N_2H_5)_2[Cu(C_2O_4)_2]H_2O$

The IR spectrum of this complex does not offer conclusive evidence about the coordination of $N_2H_5^+$ to the metal. The spectrum exhibits two absorptions at 975 and 980 cm^{-1}. The assignment

	21,500		
	29,400	charge transfer	

of these absorptions is rather difficult since the observed frequency is too high for ionic $N_2H_5^+$ ($v_{N-N} = 965$ cm^{-1}) and too low for coordinated $N_2H_5^+$ ($v_{N-N} = 1005$ cm^{-1}).

Reflectance spectrum of the complex shows the $d-d$ transition at 15,100 cm^{-1} which favours square planar stereochemistry of Cu(II).[32]

The ESR spectrum of the complex is shown in Fig. 2. The lower g value ($g = 2.11$) is also in accordance with the square planar geometry around Cu(II).[33]

However the unequivocal proof about the coordination environment of the metal comes from a single crystal X-ray study of the complex. The crystal contains discrete $N_2H_5^+$ ions, $[Cu(C_2O_4)_2]^{2-}$ ions and water molecules. The copper atom lies on a centre of symmetry, with square planar coordination of oxygens from two bidentate oxalate groups (Fig. 3). The $N_2H_5^+$ ion is not coordinated to the copper. Selected interatomic bond distances and angles are listed in Table 5.

The Cu–O(1) distance (1.944 (2) Å) is slightly longer than Cu–O(2) distance (1.926 (2) Å). The bite angle of the bidentate ligand [O(1)–Cu–O(2)] is 85.5°. The oxalate group is planar and Cu(II) is out of this plane by 0.1 Å. As expected, coordi-

nated C–O distances (1.284 and 1.270 Å) are slightly longer than the free C–O distances (1.229 and 1.239 Å). The C–C–O bond angles (114.1–115.5°) are substantially smaller than the exterior angles (118.8–119.7°) due to the steric restrictions on the planar five-membered chelate ring. In the $N_2H_5^+$ ion, the NH_3 group is staggered with respect to the NH_2 group and its lone pair. The observed N(1)–N(2) bond distance of 1.429(4) Å is in agreement with the values reported for similar compounds, e.g. 1.427(3) Å in $N_2H_5LiSO_4$ and 1.435(9) Å in $N_2H_5[Sc(N_2H_3COO)_4] \cdot 3H_2O$.

In the crystal there is a network of hydrogen

bonds involving the $N_2H_5^+$ ion, lattice water and oxalate oxygens (Fig. 4). The hydrogen bond lengths are in the range 2.84 to 3.10 Å. The molecules are stacked one above the other along *a* axis with separation of 3.6 Å, the unit cell translation *a*.

The DTA curve of hydrazinium copper oxalate shows an endotherm at 119°C corresponding to dehydration; another endotherm at 198°C where the anhydrous compound melts sharply and an exotherm at 238°C in which the anhydrous hydrazinium copper oxalate decomposes to give copper oxalate which further decomposes exothermically at 305°C to give CuO.

The   decomposition   scheme   of
Fig. 4. Packing diagram of $(N_2H_5)_2Cu(C_2O_4)_2 \cdot H_2O$—view down *b*.

$(N_2H_5)_2Cu(C_2O_4)_2 \cdot H_2O$ in air can be represented as follows. The DTA peak temperatures for each step are indicated.

$$(N_2H_5)_2[Cu(C_2O_4)_2]H_2O \xrightarrow{119°C(endo)}$$

$$(N_2H_5)_2[Cu(C_2O_4)_2] + H_2O \quad (1)$$

$$(N_2H_5)_2[Cu(C_2O_4)_2] \xrightarrow{238°C(exo)}$$

$$CuC_2O_4 + 2NH_3 + N_2 + 2CO_2 + 2H_2O \quad (2)$$

$$CuC_2O_4 \xrightarrow{305(exo)} CuO + 2CO_2. \quad (3)$$
The percentage weight losses observed in TG for these steps are 5.5, 52.0 and 75 respectively. The calculated percentage weight losses of 5.6, 53.2 and 75.4 for these steps are in good agreement with the observed values.

$[(N_2H_5)_2Ni(C_2O_4)_2]2H_2O$

The IR spectrum of this complex shows ν_{N-N} at 1000, 1010 cm^{-1} proving the coordination of $N_2H_5^+$ to the metal unambiguously and suggesting an octahedral geometry. Supporting evidence for an octahedral environment around Ni(II) is furnished by the reflectance spectrum. The bands at 16,600 and 26,300 cm^{-1} can be assigned to $^3A_{2g} \rightarrow {^3T_{1g}}(F)$ and $^3A_{2g} \rightarrow {^3T_{1g}}(P)$ transitions respectively which are characteristic of octahedral geometry around Ni(II).[34] Magnetic susceptibility value ($\mu_{eff} = 3.1$ BM) is in accordance with that of a high spin complex of nickel. A single crystal X-ray study of the complex could not be carried out as the crystal showed twinning rendering the X-ray investigation difficult.

Thus based upon IR, UV spectra and magnetic susceptibility data, the proposed structure of hydrazinium nickel oxalate dihydrate is represented as follows:
The nickel complex decomposes in three steps. In the first step water is lost endothermically at 124°C. The anhydrous complex further decomposes to give nickel oxalate monohydrazinate. This is observed as an endotherm with peak temperature of 280°C. The final step corresponds to the decomposition of nickel oxalate monohydrazinate to nickel oxide (NiO). This decomposition is exothermic at 342°C.

$$[(N_2H_5)_2Ni(C_2O_4)_2]2H_2O \xrightarrow{124°C(endo)}$$

$$[(N_2H_5)_2Ni(C_2O_4)_2] + 2H_2O \quad (4)$$

$$[(N_2H_5)_2Ni(C_2O_4)_2] \xrightarrow{280°C(endo)} NiC_2O_4 \cdot N_2H_4$$

$$+ NH_3 + 1/2N_2 + 2CO_2 + 3/2H_2O \quad (5)$$

$$NiC_2O_4 \cdot N_2H_4 \xrightarrow{342°C(exo)}$$

$$NiO + 2CO_2 + NH_3 + 1/2N_2 + 1/2H_2O. \quad (6)$$
Thermogravimetric analysis data are in accordance with the DTA results. The TG curve shows three distinct steps with percentage weight losses of 10.5, 47 and 77 corresponding to the formation of the anhydrous compound, $NiC_2O_4 \cdot N_2H_4$ and NiO respectively. The calculated percentage weight losses for these steps are 10.7, 46.9 and 77.8 respectively.

$(N_2H_5)_2[Co(C_2O_4)_2]3H_2O$

The fact that hydrazinium cobalt oxalate trihydrate is not isomorphous either with the copper or nickel analogue suggests that the geometry around Co^{2+} is different from the other two. IR absorption of ν_{N-N} at 965 cm^{-1} clearly shows that $N_2H_5^+$ is outside the coordination sphere. Magnetic susceptibility value ($\mu_{eff} = 5.0$) shows that the complex is high spin and could have octahedral or tetrahedral geometry.

It has been shown previously[35] that orbital contributions in tetrahedral Co(II) complexes decrease as the ligand varies from I$^-$ towards CN$^-$ in the spectrochemical series I$^-$ < Br$^-$ < Cl$^-$ < OH$^-$ < NO$_3^-$ < C$_2$O$_4^{2-}$ < H$_2$O < NH$_3$ < CN$^-$. Hence tetracoordinated Co(II) complexes are given tetrahedral structures only if the values of magnetic moments are in the range 4.2–4.7 BM.[36] The observed magnetic moment of 5.00 BM in the present case of cobalt complex thus rules out the possibility of tetrahedral geometry.

Additional evidence against a tetrahedral structure comes from the visible absorption spectrum. All tetrahedral cobaltous complexes are known to exhibit a characteristic intense multicomponent band in the 13,300–16,600 cm^{-1} region associated

with $^4A_2 \rightarrow ^4T_1(P)$ transition in tetrahedral geometry, whereas no band is observed in this specified region in the reflectance spectrum of the cobalt complex. The electronic spectrum of hydrazinium cobalt oxalate trihydrate shows bands at 21,500 and 19,200 cm^{-1} assigned to $^4T_{1g}(F) \rightarrow ^4T_{1g}(P)$ which is usually split due to spin-orbit coupling in the $^4T_{1g}(P)$ state. The electronic spectrum is comparable with the spectrum of octahedral Co(II) complexes as reported by Ballhausen and Jorgensen[37] with a double band having centre of gravity ~20,000 cm^{-1}. The pink colour of the complex is also indicative of octahedrally coordinated Co(II).[38]

Cotton and Holm[39,40] have claimed that planar complexes of type [CoO$_4$] may also be of high spin and have μ_{eff} values in the range 4.8–5.2 BM. Based on energy level diagram for Co(II) in a ligand field of D$_{4h}$ symmetry, they have shown that planar spin-free complexes are possible if the four donor atoms provide a weak enough ligand field.

The foregoing evidence leads us to conclude that the cobalt complex reported herein might have planar Co(C$_2$O$_4$)$_2^{2-}$ anions which aggregate to form a chain structure with pairs of long Co–O bonds between anions making it octahedral. The structure could be represented as
Such a structure is known to exist in propylene diammonium bis(oxalato)cuprate (II).[41] Single crystal X-ray study of the Co complex could not be carried out to confirm the proposed structure as the compound is unstable.

Hydrazinium cobalt oxalate trihydrate decomposes in a manner similar to the nickel compound

$$(N_2H_5)_2[Co(C_2O_4)_2]3H_2O \xrightarrow{84°C(endo),\ 102°C(endo)}$$

$$(N_2H_5)_2[Co(C_2O_4)_2] + 3H_2O \quad (7)$$

$$(N_2H_5)_2[Co(C_2O_4)_2] \xrightarrow{210°C(endo),\ 254°C(endo)} CoC_2O_4$$

$$\cdot N_2H_4 + NH_3 + 1/2N_2 + 2CO_2 + 3/2H_2O \quad (8)$$

$$CoC_2O_4 \cdot N_2H_4 \xrightarrow{310-370°C(broad\ exo)}$$

$$Co_3O_4 + 3NH_3 + 3/2N_2 + 6CO_2 + 3/2H_2O. \quad (9)$$
This decomposition scheme is supported by the TG data; percentage weight losses observed being 16, 49 and 78 which tally with the calculated percentage weight losses for the above steps 15.2, 49.6 and 77.7 respectively.

SPECTROSCOPIC CHARACTERIZATION OF SUPERPARAMAGNETIC PARTICLES OF THERMOLYTIC PRODUCTS OF FERRIC SULPHATE HYDRATES

P. C. MORAIS and K. SKEFF NETO*

Grupo de Física Molecular e Magnetismo, Departamento de Física, Universidade de Brasília 70910-Brasília-DF, Brasil

Abstract—Superparamagnetic particles of chemically pure samples, in the system $Fe(OH)SO_4/Fe(OH)SO_4 \cdot (H_2O)$, are produced by thermal decomposition of ferric sulphate hydrates. The control of particle size distribution is achieved by successive hydration and dehydration processes monitored by X-ray diffraction, electron microscopy, Mössbauer and IR spectroscopy. The particle size modification is related for the particle growth and two mechanisms are suggested thereon.

Thermal treatments induces oxidation of Fe^{2+} ion to Fe^{3+} in sulphate hydrates. This well-known phenomenon has been reported by many workers.[1-9] The thermal decomposition of Fe^{2+} compounds can be probed by several techniques including Mössbauer spectroscopy, because of its high sensitivity to the valence state of the iron in solids. The oxidation mechanism is that Fe^{2+} is oxidized into Fe^{3+} by hydroxyl radicals which originate from the water of crystallization.[10] However, this mechanism does not specify the chemical formulae of the thermal decomposition products. The present report deals with an investigation of thermal decomposition products of ferrous sulphate monohydrate using Mössbauer, IR and X-ray diffraction. The main thermolytic product is a ferric specimen identified as $Fe(OH)SO_4$.

In an aqueous-vapour atmosphere this compound gives a hydrate $Fe(OH)SO_4(H_2O)_2$ which was confirmed by chemical and spectroscopic analysis. The process of hydration is monitored by X-ray diffraction, Mössbauer and IR spectroscopy. Heating of $Fe(OH)SO_4(H_2O)_2$ reconverts it to $Fe(OH)SO_4$ but the drying process induces a change in volume and alters significantly their magnetic properties. In the present paper we analyze the change on the particle size distribution based on electron microscopy patterns and magnetic measurements. The Mössbauer effect has proved to be a unique tool for the measurement of such magnetic preperties.

Another important reason for applying the Mössbauer technique is that no external field must be applied to the sample and the zero-field magnetization may be determined with great accuracy.

EXPERIMENTAL

Analytically pure $FeSO_4(H_2O)$ was used as the original material to obtain the $FeSO_4(H_2O)_4$. This compound is grown from aqueous solution of $FeSO_4(H_2O)_7$ at constant temperature within the range 54–64°C according to the literature.[11] $FeSO_4(H_2O)$ was obtained from the aqueous solution of $FeSO_4(H_2O)_7$ at constant temperature within the range 80–100°C in vacuum for a few days. On heating $FeSO_4(H_2O)$ in air up to 180°C a mixture of compounds was obtained.[12] However, the Mössbauer spectra at room temperature of $FeSO_4(H_2O)$ heated at 250°C for several days shows a pure well resolved doublet with I.S. (Fe) = 0.44 mm/s and Q.S. = 1.45 mm/s as depicted in Fig. 1, spectrum $AB(250)_0$.

This compound was called A (250) or $AB(250)_0$ and in the laboratory atmosphere the Mössbauer spectra changes slowly over a period of several months, but in an aqueous-vapour atmosphere (75%) the process of hydration is speeded up and at the end of 22 days we obtain another pure compound. This compound was called B(250) or $AB(250)_{22}$ and shows a pure well resolved doublet at room temperature as shown in Fig. 1. Compounds A (250) and B(250) show, at room temperature, essentially the same I.S. but a different quadrupole splitting. The Q.S. of B(250) is 0.97 mm/s.

The compounds A(250) and B(250) were

*Author to whom correspondence should be addressed.
Fig. 1. Mössbauer spectra of AB(250)$_d$, at room temperature, after $d = 0$, 4, 12, 18 and 22 days of hydration.

DISCUSSION

identified by chemical and spectroscopic measurements as $Fe(OH)SO_4$ and $Fe(OH)SO_4(H_2O)_2$ respectively.[13] The Mössbauer parameters were determined using computer fitting and are listed in Table 1. The process of hydration was monitored, at room temperature, by X-ray diffraction, Mössbauer and IR spectroscopy as shown in Figs. 1–3. During the process of hydration several samples of A(250) were collected after 0, 4, 12, 18 and 22 days of hydration. These samples were heated at 200°C, for several days until the total dehydration so that the final products were $Fe(OH)SO_4$. The Mössbauer spectra of such products at 77 K are depicted in Fig. 4. This process of hydration and subsequent dehydration was followed by electron microscopy and is shown in Figs. 5(a)–(c).

The presence of $FeSO_4(H_2O)$, in the vacuum treatment at room temperature of $FeSO_4(H_2O)_4$, can be confirmed by reported Mössbauer parameters.[6,7] A schematic sequence on the thermal and aqueous-vapour treatments is shown below. Here A(250) is the same

$$FeSO_4(H_2O)_7 \rightarrow FeSO_4(H_2O)_4 \rightarrow FeSO_4(H_2O)$$
$$\downarrow$$
$$BA(250)_d \leftarrow AB(250)_d \leftarrow A(250)$$
as $AB(250)_0$, $AB(250)_{22}$ is the same as B(250) and $BA(250)_d$ are chemically $Fe(OH)SO_4$. The subscript "d" that appears on $AB(250)_d$ may be referred as the days of hydration in an aqueous-vapour atmosphere (75%) at room temperature.

Fig. 3. IR spectra of $AB(250)_d$, at room temperature, after $d = 0$, 4, 12, 18 and 22 days of hydration.

Comparing the Mössbauer parameters of B(250) compound and those of Butlerite (Table 1) we can conclude that B(250) compound is the Butlerite

whose structure has been determined by Fanfani.[14]

In Fig. 1 we show the Mössbauer spectra sequence in the process of hydration at room temperature which convert $Fe(OH)SO_4$ into $Fe(OH)SO_4(H_2O)_2$. Here we represent the process of hydration by

$$Fe(OH)SO_4 \rightarrow x\ Fe(OH)SO_4,$$
$$(1 - x)Fe(OH)SO_4(H_2O)_2$$

where "x" is related to "d" parameter with $0 \le x \le 1$. The intermediate Mössbauer spectra, for which $0 < x < 1$, shows a superposition of $Fe(OH)SO_4$ and $Fe(OH)SO_4(H_2O)_2$. As shown in Table 1 the values of Q.S. for $AB(250)_0$ and $AB(250)_{22}$ samples is large for the high spin ferric compounds and it is characteristic for Fe–O–Fe bridge compounds.[15]

The X-ray diffraction pattern sequence in the process of hydration, taken at room temperature, is shown in Fig. 2. Here the observed diffraction pattern of $AB(250)_{22}$ sample agree exactly with those of Butlerite listed in the ASTM file. It is worth mentioning that the diffraction pattern of $AB(250)_0$ sample shown in Fig. 2, which we identified as pure $Fe(OH)SO_4$, have not been re-
Fig. 4. Mössbauer spectra of BA(250)$_d$, at 77 K, for $d = 0$, 4, 12, 18 and 22.

ported hitherto. The intermediate diffraction patterns shows a superposition of that Fe(OH)SO$_4$ and Fe(OH)SO$_4$(H$_2$O)$_2$. Besides the diffraction peaks of Fe(OH)SO$_4$(H$_2$O)$_2$ denoted by "b" in Fig. 2, there are other peaks which are denoted by "a" and related to Fe(OH)SO$_4$.

In order to gain more information about the process of hydration of Fe(OH)SO$_4$, the IR spectra sequence was obtained at room temperature and is shown in Fig. 3. Here the absorption in the region of 1100 cm^{-1} is indicative of the presence of SO$_4^{2-}$ ion in inorganic compounds.[16] The absorption about 1650 and 3450 cm^{-1} corresponds to HOH bending mode and OH stretching of water respectively. This characterizes the Fe(OH)SO$_4$(H$_2$O)$_2$ compound as the AB(250)$_{22}$ sample. The very little absorption near 1650 cm^{-1} and a sharp absorption at 4380 cm^{-1} characterize the Fe(OH)SO$_4$ compound as the AB(250)$_0$ sample. The intermediate IR spectra shows a superposition of AB(250)$_0$ and AB(250)$_{22}$ samples.

It is worth noting what would happen in the process of hydration and subsequent dehydration of Fe(OH)SO$_4$. Here the process of dehydration, by heating at 200°C for various days, may be represented by
$$AB(250)_d \rightarrow BA(250)_d.$$

The samples, namely BA(250)$_d$, collected during the process of hydration for $d = 0$, 4, 12, 18, 22 and heated as described above, show the same IR, Mössbauer and X-ray diffraction pattern at room temperature. These spectra show the same patterns as AB(250)$_0$ sample at room temperature. However, as we may expect, the Mössbauer spectra of BA(250)$_d$ samples depict different magnetic interactions at 77 K (see Fig. 4). The interesting fact about the foregoing result is that the process of hydration and dehydration induces a modification on the particle size distribution and change significantly their magnetic properties. In Fig. 4 the
Fig. 5. Electron microscopy patterns. (a) $AB(250)_0$ sample $(44.000x)$. (b) $AB(250)_4$ sample $(113.000x)$. (c) $BA(250)_4$ sample $(44.000x)$.

hfs lines broaden when the days of hydration (d) increase and the low resolution results in merging of the six hyperfine structure components into two lines. This variation of the Mössbauer spectra offers an evidence of superparamagnetic behavior of the $Fe(OH)SO_4$ particles.[17,18] Another behaviour clearly displayed in Fig. 4 is the increase of the internal field (H_0), as the days of hydration, to a maximum and subsequent decrease. This behaviour was associated with the growth of the $Fe(OH)SO_4$ particles as a function of "d" and the presence of a maximum in the value of the internal field (H_0) was associated with the existence of a critical diameter.[13]

The process of evolution in the particle size distribution may be suggested by the analysis of electron microscopy patterns shown in Fig. 5 and by the evolution of the X-ray diffraction sequence shown in Fig. 2. In Fig. 2 the narrowing of the X-ray lines during the process of hydration is an indication of a recrystalization process. In Fig. 5 we show the electron microscopy patterns of $AB(250)_0$, $AB(250)_4$ and $BA(250)_4$ which represents the process of hydration of $Fe(OH)SO_4$ for 4 days and subsequent heating at 200°C for various days until the total dehydration. In this process the diameter of particles has grown approx. 75%. Here the dimensional changes during drying process occur because the particles are brought into close

contact and porosity is reduced. The driving force is due to the decrease of total surface energies which comes about because of the particle contact and particle growth. The atoms in the small particles are transferred to the larger particles, and the pores are replaced by solid material.[19] The electron microscopy patterns, X-ray diffraction sequence and the magnetic nature of the samples suggest two distinct but concurrent mechanisms to this mass transfer in the process of the particle growth in accordance with Burke[20] and Mackenzie and Shuttleworth.[21] They are illustrated schematically in Fig. 6. Burke[20] analyzed the diffusion mechanism (Fig. 6a) which involves the movement of atoms and the countermovement of lattice vacancies. There is an accompanying shrinkage of bulk volume which maintains contact of the
Fig. 6. Schematic of mass transfer mechanisms. (a) Diffusion.[19] (b) Liquid phase.[20]

particle and brings the particle centers closer together. Mackenzie and Shuttleworth[21] studied the liquid phase sintering (Fig. 6b) which involves the removal of ions or atoms from surfaces of higher energy and depositing them on surfaces of lower energy. The highest-energy surfaces are those with small radii of convex curvature: the lowest-energy surfaces are those with small radii of concave curvature.

CONCLUSION

We have analyzed the process of production of chemically pure samples in form of small particles. By means of successive hydration and dehydration we can control adequately the particle size distribution. This is an important point because the magnetization in an amorphous material is very sensitive to the particle size distribution. In the present work we used the chemical system $Fe(OH)SO_4/Fe(OH)SO_4(H_2O)_2$ for two reasons; firstly the process of successive hydration and dehydration is chemically reversible and secondly the $Fe(OH)SO_4$ exhibit superparamagnetic properties.

The use of several techniques for monitoring the process of dimensional changes is very important because they ensure the reversible character in the chemical transformation. The Mössbauer spectroscopy shows the superparamagnetic behavior and the electron microscopy depict the particle size distribution. The particle size control in the process of growth was oriented by the mechanism suggested herein.

NICKEL(II) COMPLEXES OF PHTHALIC HYDRAZIDE OR ITS ANION, AND THEIR REACTION WITH OXYGEN AND NITROGEN-DONOR LIGANDS

M. ARSHAD ALI BEG* and S. ASHFAQ HUSAIN

PCSIR Laboratories, Karachi 39, Pakistan

Abstract—The reaction of phthalic hydrazide(H_2PH) with Ni(II) salts yields complexes of the type $[NiHPH)_2(H_2O)_2]2H_2O(I)$. Reaction of this complex with acetylacetone(acac) and ethylenediamine(en) gives mononuclear complexes of type $[NiHPH)(acac)_2(H_2O)]H_2O(II)$ and $[Ni(HPH)_2(en)_3(H_2O)]H_2O(IV)$ respectively and with monoethanolamine (MEA), aniline(An) and *p*-phenylenediamine(*p*-Phda) it gives trinuclear complexes of type $[Ni_3(PH)_7(MEA)_4 (H_2O)_3]3H_2O(III)$, $[Ni_3(HPH)_4(An)(H_2O)_7]H_2O(V)$ and $[Ni_3(HPH)_5(p-Phda)(H_2O)_7]H_2O(VI)$ respectively. The complexes have been characterized on the basis of infrared and electronic spectra and magnetic properties as containing octahedral Ni(II) and anionic hydrazide ligand.

Ligand field parameters have been calculated and compared with chromophores containing oxygen and nitrogen donor atoms. Analysis of electronic spectra, calculated Dq values and IR absorptions strongly indicate the presence of NiN_2O_4, $NiNO_5$, NiO_6 and NiN_3O_3 chromophores.

Coordination properties of acyclic hydrazides[1-10] towards metal ions have extensively been investigated. They act as neutral, anionic mono-, bi-, tri- or tetradentate ligands depending on the structure and reaction conditions. There are relatively few reports on the coordination compounds of cyclic hydrazides with metal ions. The *o*-aminophthalhydrazide and anthracene hydrazides[11-14] are some such ligands, the chemiluminescent reactions of which have been noted in the complex formation with some metal ions. *o*-Aminophthalhydrazide has been suggested to act as a bidentate ligand coordinating through carbonyl oxygen and amino nitrogen atoms to form a six membered chelate ring whereas anthracene hydrazide has been suggested to act as a monodentate ligand bonding possibly through carbonyl oxygen.[11]

In spite of the above studies very little information is available on the interaction of phthalic hydrazide with metal ions. Phthalic hydrazide is known to exist in the lactam-lactim form with 1-hydroxyphthalazine-4-one as its most stable tautomer[15] in the solid state and in neutral solutions.
In alkaline aqueous solutions it acts as a weak acid and exists in anionic form by liberating at least one proton. Accordingly the mono-metallic salts of Na^+ and Ag^+ ions of this ligand have been reported.[16] In an earlier study[17] Co(II) ion was reported to be chelated by anionic coordination in dilactim, i.e. 1,4-dihydroxyphthalazine form. The bidentate monoanionic and tetradentate bianionic coordination through oxygen and nitrogen of lactim group of the ligand has been suggested for the Co(II) complex containing metal/ligand ratios of 1:2 and 1:1 respectively.

The bis-phthalhydrazidato-diaquo-Co(II) complex of type $[Co(HPH)_2(H_2O)_2]$ like other diaquo metal chelates such as metal-quinolinates[18,19] and β-diketonates[20] has been found to form adducts with other nitrogenous bases, e.g. bipyridyl and ethylenediamine[17] by replacing the water molecules. These bases have been found to act as bidentate ligands.

The present paper is an extension of the previous studies and is concerned with the preparation and characterization of Ni(II) complex of phthalic hydrazide and its reaction with acetylacetone(acac), monoethanolamine(MEA), ethylenediamine(en), aniline(An) and *p*-phenylenediamine(*p*-Phda). Phthalic hydrazide, hereafter, is abbreviated as H_2PH and HPH to represent neutral and monoanionic form of the ligand respectively. The Lewis acidity of the parent complex towards the adducting ligands, their mode of bonding and the influence on stereochemistries of the complexes formed with different bases have been studied.

EXPERIMENTAL

Preparation of the ligand and complexes

Phthalic hydrazide (H_2PH) was prepared and purified by the methods reported in literature.[15,21]

Bis-phthalic hydrazidato-diaquo Ni(II) dihydrate $[Ni(HPH)_2(H_2O)_2]2H_2O(I)$ was obtained as a green solid using the method reported previously for bis-phthalic hydrazidato-diaquo Co(II) complex.[17] An aqueous solution of $NiCl_2 \cdot 6H_2O$ (10 mM) was mixed with one of

---

*Author to whom correspondence should be addressed.

phthalic hydrazide H_2PH (20 mM) in dilute aqueous ammonia at room temperature. The pH of the reaction medium was adjusted between 5.5 and 7.0. The resulting green precipitates were filtered, washed with water, ethanol and finally with ether and dried under vacuum over P_2O_5. Homogeneity of the product was ensured by correct maintenance of pH.

Complexes of $[Ni(HPH)_2(H_2O)_2]2H_2O$ (I) were obtained by refluxing the suspension of the latter (453 mg, 1 mM) for 1 hr in a methanolic solution of acetylacetone (10 mM) or of amine (2 mM) or in aqueous solution of ethylenediamine (2 mM). The resulting solution was filtered and its volume was reduced. Acetylacetone, aniline and p-phenylenediamine complexes were deposited immediately on cooling while the monoethanolamine and ethylenediamine complexes were precipitated on adding a methanol:ether mixture (1:5, v/v) to their cool solutions. The resulting solid produce was then washed with ethanol followed by an ethanol–ether mixture and finally with ether and dried under vacuum over P_2O_5. The acetylacetone(acac) and aniline(An) complexes of type $[Ni(HPH)(acac)_2(H_2O)]H_2O$ (II) and $[Ni_3(HPH)_4(An)(H_2O)_7]H_2O$ (V) were obtained as green solids while the monoethanolamine(MEA), ethylenediamine(en) and p-phenylenediamine(p-Phda) complexes of type $[Ni_3(HPH)_7(MEA)_4(H_2O)_3]3H_2O$ (III), $[Ni(HPH)_2(en)_3(H_2O)]H_2O$ (IV) and $[Ni_3(HPH)_5(p$-$Phda)(H_2O)_7]H_2O$ (VI) were obtained as violet, red and brown solids respectively.

Physical measurements

Electronic spectra were recorded with a Beckman DK-2 recording spectrophotometer. IR spectra of KBr pellets were recorded with a Perkin–Elmer spectrophotometer model 621 (4000–200 cm^{-1}) at the University of Western Ontario, London, Canada while one of the authors (MAAB) was on a CIDA–NRC Research Associateship. Room temperature magnetic susceptibility measurements were carried out by Gouy method using $HgCo(NCS)_4$ as calibrant. The diamagnetic corrections were made using the appropriate Pascal's constants. Elemental analyses were carried out by Chemalytics, Inc. Laboratories, U.S.A. Nickel in complexes was determined by colorimetric method[22] using dimethylglyoxime.

RESULTS AND DISCUSSIONS

Phthalic hydrazide (H_2PH) prepared by the method of Drew and Hatt[21] exhibits spectra similar to that reported in literature[15] for 1-hydroxyphthalazine-4-one.

The latter is the preferred tautomer as against the dilactim form, i.e. 1,4-dihydroxy-phthalazine mentioned previously.[17] Assignment of the IR spectral bands of metal complexes therefore has to take into account the metal bonded lactim group and the free C=O and NH vibrations.

Appearance of the bands due to NH and C=O groups in the complexes suggests that the lactim–lactam structure of the ligand does not change on complexation with Ni(II) ion and it is the lactim group which is involved in
coordination. The formation of this complex in the presence of ammonium hydroxide in the pH range 5.5–7.0 is apparently favourable to monobasic coordination through a lactim group. The mode of bonding seems analogous to the monobasic bidentate behaviour of 8-hydroxyquinoline,[23] possessing phenolic OH and C=N donor groups in its metal chelates which are formed at the same pH range and also in the presence of ammonium hydroxide.

Bonding through nitrogen of the lactim group with another metal ion may not be favoured in this pH range but may be expected at pH > 7.0 as it has been reported in the metal complexes of nucleic acid bases[24,25] such as uracil and thymine (dilactam). The reaction of the metal ion with phthalic hydrazide may preferentially adopt the following scheme.
Phthalic hydrazide, according to the above scheme, behaves as a monoanionic bidentate ligand in the formation of Ni(II) complex which is a green solid and according to analytical data can be formulated as $[Ni(HPH)_2(H_2O)_2]2H_2O$ (I). This complex like the Co(II) complex[17] and the diaquo Ni(II)-quinolinate[23] is precipitated in the pH range of 5.5–7.0 and likewise forms addition compounds with other oxygen and nitrogen donor ligands. Reaction products are obtained as solids having colours different from those of the parent complex(I). The reaction of the diaquo-Ni(II) complex(I) with acetylacetone and ethylenediamine yield the mononuclear complexes of type $[Ni(HPH)(acac)_2(H_2O]H_2O$ (II) and $[Ni(HPH)_2(en)_3(H_2O)]H_2O$ (IV) respectively while from the reactions with monoethanolamine, aniline and p-phenylenediamine trinuclear complexes of the type $[Ni_3(HPH)_7(MEA)_4(H_2O)_3]3H_2O$ (III), $[Ni_3(PH)_4(An)(H_2O)_7]H_2O$ (V) and $[Ni_3(PH)_5(p$-$Phda)(H_2O)_7](H_2O)$ (VI) respectively are obtained. The analytical results are reported in Table 1.

The complexes are stable under laboratory conditions and decompose above 350°C. They are slightly soluble in methanol, ethanol and water and are insoluble in other organic solvents. Poor solubility of these complexes does not permit the study of their NMR spectra.

Magnetism and electronic spectra

Magnetic moments of complexes (I–VI) are found in the range of 3.10–3.6 B.M. (Table 2) and these are consistent with octahedral Ni(II) complexes.[26] Support to this assignment is obtained from the electronic spectra and their assignment (Table 2). Appearance of spin-forbidden band due to $^3A_{2g} \rightarrow ^1E_g$ transition possibly suggests the presence of spin-orbit coupling[27] as is evident from the values of magnetic moment. Similarly since all the three spin-allowed bands are noted, the presence of weak octahedral field[27–29] around the metal ion can be suggested.

Parameters Dq, B' and β' have been calculated by numerical method[28] by fitting v_1 and sum of v_2 and v_3 bands from the observed data. A close agreement has been found between observed and calculated transition energies of v_2 and v_3.

The Dq value of [Ni(HPH)$_2$(H$_2$O)$_2$]2H$_2$O(I) is consistent with NiN$_2$O$_4$ chromophore[27,30–32] in literature, such as those of diaquo Ni(II) complexes of nicotinic and picolinic acid.[32] The trinuclear amine complexes (III, V and VI) of parent compound (I) shows the Dq values to be consistent with NiNO$_5$ chromophore[31,33] whereas the mononuclear amine complex (VI) and acetylacetone complex (II) agree with NiN$_3$NO$_3$[31,34] and NiO$_6$[27,30,31] chromophores respectively. These chromophores, hereafter have been confirmed by IR spectra.

The lower intensity of first d–d band (v_1) as compared with that of second (v_2) suggests a trans arrangement[34] for water molecules leaving the cis positions in octahedral structures of parent complex (I) and trinuclear amine complexes (V and VI), naturally for phthalic hydrazide. In complexes (II, III and IV) the intensities of these bands seem to be consistent with the trans occupation of phthalic hydrazide (HPH) and cis[34] position of water or adducting ligands.

IR spectra

The spectrum of phthalic hydrazide (H$_2$PH) is in accord with the published data[15] and corresponds with the monolactim form, i.e. 1-hydroxy phthalazine-4-one and analogous maleic hydrazide.[35]

Appearance of vNH, vC=O, vC=N and vC=O bands in all the complexes (I–IV) (Table 3) suggests the persistance of lactam-lactim structure of phthalic hydrazide. The strong vC=N and weak ring vibration bands of phthalic hydrazide (H$_2$PH), like those of nucleic acid bases,[36,37] are shifted to higher frequencies in the parent complex [Ni(HPH)$_2$(H$_2$O)$_2$]2H$_2$O(I) by exhibiting the bands at 1605, 842 and 560 cm^{-1} respectively. In acetylacetone and amine complexes (II–VI) these bands are shifted to lower frequencies as compared to parent complex (I). These results suggest the bonding through nitrogen C=N group of phthalic hydrazide (HPH) in parent complex (I) but in its complexes (II–VI) it may not be suggested.

The disappearance of strong OH band of free phthalic hydrazide at 1300 cm^{-1} and appearance of vM–O bands, like those of metal-β-diketonates,[38] in the 455–450 cm^{-1} region in all the complexes (I–VI) indicate coordination through enolic carbonyl oxygen of phthalic hydrazide which may behave as an anionic ligand, forming chelate ring in (I).

The vM–O band of parent complex (I) at 455 cm^{-1}, like those of metal-β-keto-enolates,[20,39,40] is shifted to lower frequency in its complex (II–VI) due to adduct formation.

The energies of vNH and vC=O bands of free phthalic hydrazide remain unchanged but those of δNH in- and out-of-plane modes are shifted to higher frequencies by 30 and 25 cm^{-1} respectively in parent complex (I). These results indicate that the above two groups are not donors in this complex. They remain hydrogen bonded (C=O ... HN) as is evidenced by the solid state spectrum of free ligand[41,42] and this supports the coordination through C=N and C–O groups, as concluded above. The higher shifts of δNH bands may possibly be the result of coupling with vC=O band as has been noted in metal complexes of nucleic acid bases such as those of thymine.[24]

In acetylacetone, monoethanolamine and ethylenediamine complexes (II, III and IV) the vNH and δNH bands of parent complex (I) are shifted to higher and lower frequencies respectively and vC=O band to higher frequency in (II) and lower frequencies in (III and IV). These results do not suggest coordination through NH and C=O groups; the hydrogen bonding of the type (C=O ... HN) in parent complex (I), may be broken possibly due to axial coordination of phthalic hydrazide (HPH) through the enolic carbonyl group, as concluded above. The shifting of vC=O band in (III and IV) to lower frequencies by 18–6 cm^{-1} may suggest the formation of hydrogen bonding possibly with hydrogen of coordinated water in monoethanolamine complex (III) and with hydrogen of free amino group[43–45] of ethylenediamine complex (IV) when water or ethyl-

s, strong; vs, very strong; m, medium; w, weak

enediamine is at one of the axial position along with the axially occupied phthalic hydrazide (HPH). Appearance of some new and broad νNH bands in the 3365–3332 and 3320–3280 cm⁻¹ regions in (IV) indicates the presence of hydrogen bonded and metal bonded NH2 groups due to monodentate[46] behaviour of ethylenediamine which seems to be consistent with above conclusion. CH2 twisting, CH2 rocking, NH2 rocking and νM–N bands appear as they do in ethylenediamine complexes of metal-β-diketonates[46,47] and of metal salts[48-49] at 1390, 1018, 980, 740 and 493 cm⁻¹ respectively which suggests the bonding of ethylenediamine with metal ion.

The trinuclear monoethanolamine complex (III) exhibits new bands due to νOH, νNH and νC–O modes at 3280–3260, 3214 and 1004 cm⁻¹ respectively which are at lower frequencies as compared with free mono-

thanolamine as has been noted in complexes of metal salts.[50,51] Coordination is apparently taking place through NH_2 and OH groups of monoethanolamine which may behave as a bridging ligand between the two metal ions.

The acetylacetonate complex (II) of (I), like the metal–acetylacetonates and their adducts[39,48] exhibits the bands at 1614, 1515 and 296 cm^{-1} due to $\nu C=O$, $\nu C-C-C$ and $\nu M-O$ modes respectively. This observation suggests a bidentate coordination of acetylacetonate anion with the metal ion.

In trinuclear aniline and p-phenylenediamine complexes (V and VI), the νNH and $\nu C-N$ bands of parent complex (I) are shifted to lower frequencies by 17–10 and 18–10 cm^{-1} respectively. It is therefore reasonable to suggest that coordination occurs through NH group of phthalic hydrazide (HPH) which may behave as a bridging ligand between the two metal ions through the enolic carbonyloxygen. The appearance of νNH and $\nu C-N$ bands, like the aromatic amine complexes of metal salts[52,53] in the 3278–3160 and 1214–1203 cm^{-1} regions respectively suggests the bonding of these amines with the metal ions. The new band due to free νNH_2 mode at 3404 cm^{-1} in (VI) indicates the monodentate behaviour of p-phenylenediamine.

The complexes (I–VI), like other aquo complexes[38,54,55] exhibit the νOH, $\rho w(H_2O)$, $\rho r(H_2O)$ and $\nu M-OH_2$ bands in the 3504–3500, 770–630, 822 and 376–375 cm^{-1} regions respectively thereby indicating the coordination of water molecules with the metal ion.

CONCLUSION

Phthalic hydrazide appears to behave as a monobasic ligand (HPH) in all the complexes (I–VI). It acts as a bidentate chelating ligand in parent compound (I) and bidentate bridging ligand in aniline and p-phenylenediamine complexes (V) and (VI) of (I) possibly occupying cis positions of the octahedral framework while aniline and p-phenylenediamine seem to act as monodentate ligands occupying $trans$ positions. In acetylacetone, monoethanolamine and ethylenediamine complexes (II, III and IV) of (I), these ligands seem to behave as a bidentate chelating, bidentate bridging and monodentate ligands respectively, possibly occupying cis, cis and $trans$ positions respectively while the phthalic hydrazide anion (HPH$^-$) acts as a monodentate ligand occupying the $trans$ position.

NUCLEAR MAGNETIC RESONANCE STUDY OF ALUMINUM CHLORIDE-n-BUTYLPYRIDINIUM CHLORIDE MELTS

FRANCIS TAULELLE and ALEXANDER I. POPOV*
Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

Abstract—High resolution proton and ^{13}C-NMR measurements were used to follow the variation of the n-butylpyridinium (BP^+) cation spectra in BP^+Cl^-–$AlCl_3$ molten mixtures. The mole fraction of $AlCl_3$ was varied between 0.45 and 0.60. It was found that chemical shifts and proton coupling constants are significantly affected by the BP^+–Cl^- and BP^+–$AlCl_4^-$ associations. Analysis of the NMR results shows that in the melts the ionic association into ion pairs is essentially quantitative. Lithium-7 NMR of $BPCl$–$AlCl_3$–$LiCl$ melt shows that when the mole-fraction of $AlCl_3$ is < 0.50 (basic melt) $LiCl_2^-$ ion is formed, while in the acidic melts the Li^+ ion probably interacts with two $AlCl_4^-$ ions to form $LiAl_2Cl_8^-$ ion.

The Lewis acid-base properties of molten mixtures of aluminum chloride and various chloride ion donors, such as alkali chlorides or alkylpyridinium chlorides, have been studied by several investigators.[1–10]

Various electrochemical techniques as well as electronic and vibrational spectroscopies, were used to characterize acid-base behavior of various solutes in these melts. The results of the above studies have been recently summarized by Mamantov and Osteryoung.[9]

Though acid-base properties are fairly well known for individual $AlCl_3$–MCl or $AlCl_3$–RCl mixtures, an absolute comparison of acid strengths of different mixtures is still very difficult and, in fact, an evaluation of cation–anion interactions is necessary to compare acid strengths of different MCl–$AlCl_3$ melts. For example, it has been shown[3,10] that the equilibria occurring in the above molten mixtures

$$2AlCl_4^- \rightleftarrows Al_2Cl_7^- + Cl^- \tag{1}$$

and

$$2Al_2Cl_7^- \rightleftarrows Al_2Cl_6 + 2AlCl_4^- \tag{2}$$
are strongly dependent on cation–anion associations,

$$M^+ + Cl^- \rightleftarrows M^+Cl^- \tag{3}$$

$$M^+ + AlCl_4^- \rightleftarrows M^+AlCl_4^- \tag{4}$$

$$M^+ + Al_2Cl_7^- \rightleftarrows M^+Al_2Cl_7^- \tag{5}$$
which, in turn, obviously depend on the nature of M^+. Therefore, equilibria (3)–(5), govern the acidity of the melt which is expressed as pCl^-. No quantitative and thermodynamically valid comparison of acid-base equilibria in aluminum chloride melts are possible without a knowledge of the equilibrium constants of reactions (3)–(5).

We and others have shown that multinuclear NMR is a powerful probe of the immediate chemical environment of ions and of organic ligands in aqueous and nonaqueous solutions.[11,12] It seemed reasonable to extend the use of this technique to studies of ionic associations in molten salt mixtures.

Osteryoung et al.[13] reported the variation in the room temperature proton and ^{13}C-NMR spectra of 1:1 and 1:2 butylpyridinium:aluminum chloride mixtures as they were progressively diluted with benzene. Since our interest is primarily focused on cation–anion interactions in $AlCl_3$–BP^+Cl^-–M^+Cl^- melts, it was of interest to us to determine precisely how the high resolution ^1H and ^{13}C spectra of the BP^+ cation vary with a change in the $AlCl_3/BP^+Cl^-$ ratio and, consequently, how the conformation of the organic cation is affected by the change in the acid-base characteristics of the melt. The use of a high field instrument under optimal resolution conditions was an indispensable prerequisite for such studies.

We also wish to report an initial investigation of alkali cation influence on the equilibria (1)–(5) in ternary melts. The ternary system studied was the $AlCl_3$–$BPCl$–$LiCl$ mixture. Lithium-7 NMR was used as a probe of the environment of the Li^+ ion.

EXPERIMENTAL

(1) Reagents

n-Butylpyridinium chloride was prepared by the method of Osteryoung et al.[14] The product was recrystallized twice from acetonitrile–ethylacetate mixture and dried under vacuum. After preparation the salt was kept in sealed ampules under inert atmosphere until used.

Aluminum chloride was sublimed in inert atmosphere in the presence of metallic aluminum as described previously;[15] CH_3NO_2-d_3 (Aldrich, gold label) was used as received. Lithium chloride (Alfa) was dried at 200°C for ~12 hr. All weighings, transfers and preparations of CH_3NO_2 solutions were carried out in a dry-box under nitrogen atmosphere. The concentrations of water and of oxygen in the dry-box atmosphere were less than 10 ppm.

(2) NMR measurements

Proton and ^{13}C NMR measurements were performed on a Bruker WM-250 spectrometer operating in the Fourier

---

*Author to whom correspondence should be addressed.

transform mode at a field strength of 58.7 kG and frequencies of 250.13 and 62.09 MHz respectively. Lithium-7 NMR spectra were obtained on a Bruker WH-180 F.T. spectrometer at a field strength of 42.28 kG and a frequency of 69.96 MHz. It was convenient to follow the probe temperature by monitoring temperature-sensitive ^{1}H chemical shifts of ethylene glycol as described by Bombi and Sachetto.[16] Ethylene glycol, in a 5-mm NMR tube, was placed concentrically in a 10-mm NMR tube containing D_2O as the lock. The rate of spinning and the heat flow were carefully adjusted and the proton spectrum of ethylene glycol was recorded when thermal equilibrium was attained. The sample temperature was calculated from the relationship given below which is corrected for field strength of our spectrometer.

$$\text{Temperature} = 466.40 - 0.402\Delta v \text{ K.} \qquad (6)$$

Equation (6) was checked at three different temperatures in the 25–100°C temperature range, with a copper-constantan thermocouple inside ethylene glycol (without spinning) and experimental differences were within ±0.5°C.

Resolution enhancement was performed on proton spectra by using Gaussian multiplication.[17] Bruker's LAOCOON program version has allowed coupling constant evaluation and comparison between experimental and theoretical spectra. Proton and ^{13}C chemical shifts were referenced to external TMS, except for one basic mixture (55% BPCl–45% AlCl₃) for which external and internal TMS peaks were measured. This difference was used to correct the shifts from external referencing.

Lithium-7 chemical shifts were referenced to an external aqueous 0.1 M LiCl solution. The chemical shifts were determined with an accuracy of 5×10^{-2} ppm.

RESULTS AND DISCUSSION

In order to obtain some detailed information on the behavior of the butylpyridinium cation in molten salt media, we obtained proton and ^{13}C NMR spectra in the BPCl–AlCl₃ melt as well as of BPCl in nitromethane solution. This solvent was selected since it has the best properties of the common organic solvents we tried, in terms of solubility and spectral resolution. The spectra of the CD_3NO_2 solution and of the BPCl–AlCl₃ 1:1 mixture are shown in Fig. 1. The latter spectrum is very similar to the one obtained by Osteryoung et al.[13]

In order to obtain highest possible resolution, we used a sweep width of 2500 Hz, aquisition of the F.I.D. in the quadrature mode, quadrature phase detection, memory size of 32 K, Gaussian filtering with zero filling up to 128 k. Under these conditions the mean line width was reduced from about 2.5 Hz shown in Fig. 1 to 0.25 Hz for the CD_3NO_2 solution and about 0.8 Hz for the molten salt.

PROTON NMR

The high resolution proton spectra are shown in Fig. 2. The results indicate that the resonances most sensitive to ionic association are those of protons on the carbons 2,6 (Fig. 2a), 3.5 (Fig. 2c) and α-CH_2 (Fig. 2d). Figure 2(a) shows that the 2,6 pattern is quite

^{1}H After Resolution Enhancement

Fig. 1. Proton and ^{13}C NMR spectra of BPCl solution in CD_3NO_2 at room temperature and of a 1:1 BPCl:AlCl₃ mixture at 40°C. A, ^{1}H of BPCl; B, ^{1}H of melt; C, ^{13}C of BPCl; D, ^{13}C of melt.

detailed in CD_3NO_2 solution and somewhat less so in the melt. It is seen that these protons mainly couple with the 3,5 and 4 protons. However, two small inner peaks were observed. They were well defined in CD_3NO_2 but seen as shoulders in the molten salt. Simulation experiments show that this splitting does not originate from a coupling between protons of the pyridine ring but rather from the coupling of the 2,6-protons with those of the α-CH_2 group.

On Fig. 2(c) the 3,5 pattern shows a quite marked difference between CD_3NO_2 solution and the molten salt. For the latter the pattern is better defined, indicating a simpler coupling system.

In the case of the α-CH_2 protons (Fig. 2d), the linewidth is much greater. This broadening could be due to the coupling with the 2,6-protons or to the relaxation of the ^{14}N nucleus.

In all cases a change in the BP^+ cation association from that with Cl^- to that with $AlCl_4^-$ anion (at higher $AlCl_3$ mole fractions), significantly affects not only the ^1H chemical shift but also, as shown in Table 2, the coupling constants, which differ in nitromethane solution and in the melt.

It should be noted that with the above described resolution enhancement it was possible to determine ^1H chemical shifts with a precision of 4×10^{-4} ppm in CD_3NO_2 solutions and 10^{-3} ppm in the melt.

^{13}C NMR

The ^{13}C decoupled spectra are rather simple (Fig. 1c and 1d) and the chemical shifts can be measured accurately without enhanced resolution. The precision of the chemical shift measurements was better than $\pm 10^{-2}$ ppm. The inversion of position 2 and 6 with 4 resonance, when compared to ^1H NMR has been previously explained[13] as the difference between paramagnetic and diamagnetic dominating effect respectively in ^{13}C and ^1H magnetic resonance experiments.

It is interesting to note that nitrogen couples more strongly with 2- and 6-carbons in the molten salt than in the CD_3NO_2 solution.

VARIATION OF ^1H AND ^{13}C SPECTRA WITH BPCl/AlCl₃ RATIO

Our main reason for seeking high resolution spectra of BPCl was to see how the resonance frequencies of

Table 2. Proton coupling constants of *n*-butylpyridinium chloride in nitromethane solution and in equimolar BPCl–AlCl₃ melt

Coupling	J_{H-H} (Hz) in CD_3NO_2	J_{H-H} (Hz) in Melt
J2.3 or J5.6	6.76	6.71
J2.4 or J4.6	1.28	1.44
J3.4 or J4.5	7.51	7.86
Jαβ	6.88	7.28
Jβγ	6.75	7.43
Jγδ	7.13	7.60

the cationic protons and carbons were affected as the melt changed from a basic to an acidic composition. Consequently, proton and ^{13}C measurements were carried out at 40°C in the $AlCl_3$ mole fraction range 0.45 to 0.60. Figures 3 and 4 show the variation of ^1H and ^{13}C chemical shifts with composition.

All ^1H and ^{13}C nuclei are sensitive to the composition of the melt, albeit to a different extent. The 2,6 and α-CH_2 protons and carbons show the highest sensitivity. The plots of chemical shift against concentration consist in most cases of two straight lines intersecting at the 1:1 BPCl/AlCl₃ mole ratio.

When we have a rapid exchange of NMR-active nuclei between several different sites, the observed chemical shift is given by the expression:

$$\delta_{obs} = \sum_i \delta_i X_i \tag{7}$$

where δ_i is the chemical shift of site i and X_i is the mole fraction of the species i. In the case of the BPCl–AlCl₃ system, when the mixture is basic (i.e. $AlCl_3 < 50$ mole %) only $PB^+AlCl_4^-$ and BP^+Cl^- species are present. On the acidic side we have $BP^+AlCl_4^-$ and $BP^+Al_2Cl_7^-$. Therefore, in the former case eqn (7) becomes

$$\delta_{obs} = \frac{N}{1-N}\delta_{BPAlCl_4} + \frac{1-2N}{1-N}\delta_{BPCl} \tag{8}$$

while on the acidic side we have,

Table 1. Proton and ^{13}C chemical shifts of *n*-butylpyridinium chloride in nitromethane solutions and in equimolar PBCl–AlCl₃ melt

| $^1H/^{13}C$ | ^1H Shifts | | ^{13}C Shifts | |
	CD_3NO_2	Melt	CD_3NO_2	Melt

^{1}H Shifts in BPCl—AlCl$_3$ Mixtures at 40°C
Fig. 3. Variation of ^{1}H chemical shifts of the BPCl:AlCl$_3$ mixture with composition at 40°C.

$$\delta_{obs} = \left(2\frac{N}{1-N}\right)\delta_{BPAlCl_4} + \frac{2N-1}{1-N}\delta_{BPAl_2Cl_7} \quad (9)$$

where N is AlCl$_3$ molar composition and can be expressed as:

$$N = \frac{n^0_{AlCl_3}}{n^0_{AlCl_3} + n^0_{BPCl}} \quad (10)$$

with $n^0_{AlCl_3}$ and n^0_{BPCl} representing the stoichiometric number of moles of AlCl$_3$ and butylpyridinium chloride respectively.

Since in the mixtures used in this investigation the fractions (N/1 − N), (1 − 2N/1 − N) and (2N − 1/1 − N) are essentially linear functions of N, it can be concluded that the ionic association into ion pairs is essentially quantitative. The ionic transport in these melts must involve migration of the BP$^+$ cation and/or the anions from one ion pair to another by a chain mechanism and not, as is usually assumed, by free ions.

LITHIUM-7 NMR MEASUREMENTS

Lithium chloride (mole fraction 10^{-2}) was introduced into a series of BPCl-AlCl$_3$ mixtures of variable composition. The NMR tubes were then sealed and allowed to stay overnight at 120°C so as to dissolve the LiCl. On cooling the tubes to room temperature, it was noted however, that only the melt with 45 mole % AlCl$_3$ and those above 50.5 mole % were completely homogeneous. The ^{7}Li signal was still observable in the 47 and 50% melts although not all the LiCl was dissolved, but not in the 48 or 49.5% melts.

The results shown in Fig. 5 clearly indicate that the Li$^+$ ion exists in very different environments on the acidic and the basic sides. The ^{7}Li chemical shifts in these two media differ by 2.4 ppm which is very large for this nucleus where the total chemical shift range is ~ 6 ppm.[18] Moreover, the lines are narrow on the acidic side (~ 1 Hz) and 3–4 times broader on the basic side, indicating a decrease in symmetry around the lithium nucleus.

Since on the basic side an excess of chloride ion is necessary to dissolve LiCl, the solubility is probably
Fig. 4. Variation of ^{13}C chemical shifts of the BPCl:AlCl$_3$ mixture with composition at 40°C.

due to the formation of a lithium chloride complex

$$LiCl + Cl^- \rightleftharpoons LiCl_2^-. \tag{11}$$
On the other nand, on the acidic side we probably have the equilibrium

Fig. 5. Variation of the ^{7}Li chemical shift with composition of the BPCl:AlCl$_3$ mixture at 25°C. Mole fraction of LiCl $= 10^{-2}$.

$$LiCl + Al_2Cl_7^- \rightleftharpoons Li^+ + 2AlCl_4^-. \tag{12}$$
Rytter *et al.* studied by Raman spectroscopy[19] MCl–AlCl$_3$ molten mixture containing 50–75 mole % AlCl$_3$. The authors found that in the case of a LiCl–AlCl$_3$ 50–50 mixture, the T$_d$ symmetry of AlCl$_4^-$ was distorted to C$_{2v}$; they proposed the structure
It seems equally likely that on the acidic side lithium can interact with two tetrachloroaluminates to give
If we assume that tetrahedral and octahedral environments are most probable for the lithium ion, an octahedral environment can be proposed for the acidic side leading to a higher symmetry and narrower NMR lines, while on the basic side Li$^+$ is in a tetrahedral environment which still gives a narrow resonance line but broader than the previous one. It follows from such an assumption that the only complex fulfilling these conditions in the basic range is

$LiCl_2AlCl_4^{2-}$, with the structure

$$III$$
since LiX_2^- species are known for the fluoride;[20] likewise a similar ion HCl_2^- has been identified in low temperature molten pyridinium chlorides.[21]

It can be seen from the above results that multinuclear NMR can indeed offer a novel view on equilibria in molten salt mixtures and can very efficiently complement studies of these systems by other physicochemical techniques. More detailed NMR studies of $MCl–BPCl–AlCl_3$ systems and others are underway at this time in our laboratory.

Abstract—^{31}P, ^{195}Pt and ^{199}Hg NMR spectra of complex $(PPh_3)_2Pt(HgGePh_3)(GePh_3)$ (I) have been studied. The spectra at temperatures below $-40°C$ prove that (I) is a *cis*-isomer with the square-planar coordination of the Pt atom. The reversibility of temperature dependences of spectra, insensitivity of line shape to the solvent, concentration and presence of free phosphine establish the fluxional behaviour of (I). The activation parameters of the intramolecular rearrangement which is realized, most probably, through a digonal twist, are: $\Delta G_{298}^{\neq} = 51.5 \pm 2.9$ kJ/mol, $\Delta H^{\neq} = 59.3 \pm 2.9$ kJ/mol, $\Delta S^{\neq} = 26.2 \pm 9.7$ J/mol · K.

Bivalent Pd and Pt can form with phosphine ligands square-planar complexes $MX_2(PR_3)_2$ whose *cis*- and *trans*-isomers in solution are able to transform into one another.[1-4] Isomerization rate greatly depends on the medium. The process is catalyzed by very small admixtures of free phosphine. For platinum complexes it proceeds according to the intermolecular mechanism with the rupture of the Pt–P bond which manifests itself in the disappearance of ^{195}Pt–^{31}P satellites in the NMR spectra at fast-exchange limit. Isomerization is most likely to proceed via a five-coordinated intermediate in the form of a square pyramid belonging to stereochemically nonrigid structure[5,6] or via an ion intermediate.[3] The *bis*-(triphenylphosphine)nickel (II) complex $(PPh_3)_2NiCl_2$ is paramagnetic and has a tetrahedral structure.[7,8] But a number of four-coordinated complexes of Ni(II)[9,10] exist in solution as equilibrium mixtures of diamagnetic planar and paramagnetic tetrahedral isomers. In dilute solutions of inert solvents there occurs interconversion between planar and tetrahedral forms via a digonal twist. So, in the process of ligand exchange *cis-trans*-isomerization may proceed according to the intramolecular mechanism with a low activation barrier. For square complexes of platinum there has been suggested[11] such a mechanism for photochemical isomerization but hitherto no intra-

molecular isomerization processes have been revealed under thermal conditions. Teplova *et al.*[12] who investigated ^{31}P NMR spectra of four-nuclear complex of *cis*-$(PPh_3)_2Pt(HgMPh_3')(M'Ph_3')$, M, M' = Ge, Sn; Ph = C_6H_5, Ph$' = C_6F_5$, which have the distorted planar-square structure, suggested that they are susceptible to isomerization in solution. The present work contains the results of ^{31}P, ^{195}Pt, ^{199}Hg NMR investigations of a previously obtained[13] complex $(PPh_3)_2Pt(HgGePh_3)(GePh_3)$ (I).

EXPERIMENTAL

Complex I[13] was dissolved in pure THF and toluene and the solutions placed in sample tubes (10 mm and 8 mm O.D.) under vacuum. The concentration of the solutions of THF (pure and with the addition of 4 vol% of $(CD_3)_2CO$) ranged within 0.003–0.03 M. The solutions in toluene were close to a saturation at room temperature. PPh₃ was commercial (CHEMAPOL) and used without further purification, $Pt(PPh_3)_3$ and $Pt(PPh_3)_4$ were synthesized using a literature method.[14]

Proton decoupled ^{31}P (40.32 MHz), ^{199}Hg (17.84 MHz) and ^{195}Pt (21.41 MHz) FT NMR spectra were recorded on a multi-nuclear spectrometer JEOL FX-100 using from 8 to 16 K real points and applying digital quadrature detection and internal ^{2}D-lock.

^{31}P NMR spectra were obtained with 60° flip angle (22 μs), 5500 Hz frequency range from 1.5 to 3s acquisition time and pulse delay is using from 1000 to 25,000 transitions. ^{199}Hg NMR spectra

---

were measured with 75° flip angle (24 μs), 20 KHz frequency range, *ca.* 0.4 s acquisition time, using from 60,000 to 190,000 transients. [195]Pt NMR spectra were taken with 75° flip angle (44 μs), 20 KHz frequency range, *ca.* 0.4 s acquisition time, using from 20,000 to 46,000 transients. Chemical shifts were measured from 80% H_3PO_4 (^{31}P NMR spectra), neat $(CH_3)_2Hg$ ([199]Hg NMR spectra) and saturated Na_2PtCl_6 solution in D_2O ([199]Pt NMR spectra) as external standards and are given on the δ-scale (the positive sign corresponds to a downfield shift) without corrections for bulk susceptibility. The temperature in the sample was controlled with an accuracy of ± 1°C.

RESULTS AND DISCUSSION

The parameters of ^{31}P, [199]Hg and [195]Pt NMR spectra are listed in Table 1. The proton decoupled ^{31}P and [199]Hg NMR spectra of complex I at temperatures below −40°C are given in Fig. 1(a) and 2(a). For isotopomers which do not contain magnetic metal isotopes ^{31}P atoms yield a spectrum of the AB type with a characteristic two-bond through metal coupling [2]J(P–P) unambiguously proving *cis*-configuration I with non-equivalent phosphorus atoms.[15] We failed to discover signals of the *trans*-isomer and if it is present in the solution its relative content cannot actually exceed 2–3%. In the ^{31}P NMR spectra one can distinctly see [195]Pt and [199]Hg satellites corresponding to the AB-parts of the ABM and ABMX systems from various isotopomers.† Of interest is the fact that

---

†In Fig. 1(a) the ABMX subspectrum is practically invisible, its observation calls for a more prolonged accumulation.

[199]Hg satellites are somewhat broadened ($\Delta v_{1/2} \approx 20$ Hz), so the two-bond P–P coupling in them is not resolved. When the temperature was lowered down to −80°C their line width slightly increased.

The broadening of the satellites may arise from relaxation of the [199]Hg via chemical shift anisotropy mechanism as it has been demonstrated for [195]Pt[16] and [205]Tl[17] and recently for [199]Hg.[18] The chemical shift anisotropy contribution to the [199]Hg spin-lattice relaxation in a linear mercury arrangement can be significant even at low magnetic field,[19] its effect becomes more substantial at low temperatures.

The [1]J(Pt–P) values of complex I (see Table 1) range within those typical of Pt(II) square complexes. These values imply that the $Hg(GePh_3)$ group has a smaller *trans*-influence than the $GePh_3$ group.[15] One should note a considerable difference of two [2]J(Hg–P) coupling, the *trans*-interaction manifests itself to a greater extent. The magnitude of this coupling constant may serve an independent indicator of mutual arrangement of mercury and phosphorus atoms. It has already been discovered that [2]J(Hg–P) *trans* and [2]J(Hg–P) *cis* in the iridium octahedral complex differ almost by 10 times.[20] This property is typical of other [2]J(M–P) and, in particular, of [2]J(P–P),[15] [2](Sn–P).[21,22] Two geminal couplings [2]J(Hg–P) in complex I which follows from the values of the averaged parameters of [199]Hg satellites spectra at fast-exchange limit, discussed below have opposite signs which is the case with [2]J(P–P)[15].

The [199]Hg-{^{1}H} NMR spectrum Fig. 2(a) and the [195]Pt-{^{1}H} NMR spectrum similar to it at low temperatures being a superposition of the M-parts of the ABM and ABMX systems provide addi-

tional information on the structure of complex I and the presence of the Pt–Hg bond. Besides splitting due to the interaction with the ^{31}P nuclei of two phosphine groups in them there are coupling $^1J(Hg-Pt)$ exceeding 8000 Hz. Up to now such

constants have not yet been measured. As was observed in ^{31}P NMR spectrum discussed above the ^{199}Hg satellites in the ^{195}Pt NMR spectrum are broadened at low temperatures as well.

Data of the ^{199}Hg and ^{195}Pt chemical shifts for the

compounds containing Pt–Hg bonds are unknown. The ^{199}Hg chemical shifts change in a wide range depending on the metal type at the mercury atom and the substituent at the metal.[23-26] For digermyl mercury derivatives ^{199}Hg shielding changes by more than 1200 ppm, from 500 ppm for $(Et_3Ge)_2Hg$[25] down to -700 ppm for $(Ph_3Ge)_2Hg$.[26] Since ^{199}Hg chemical shifts in first approximation are additive the data obtained for I illustrate Pt(II) effect on ^{199}Hg shielding. Complex I is noted for a somewhat larger ^{195}Pt shielding with respect to *cis*-$PtCl_2(PEt_3)_2$[27] which corresponds to an upfield shift of 255–275 ppm. It is noteworthy that the replacement of one halogen for GeH_2Cl group[27] or $SnCl_3^-$ group[21] in *cis*-$PtCl_2(PEt_3)_2$ causes a still stronger upfield shift.

The spectra of complex I have a reversible temperature dependence which reveals the fluxional behaviour of the molecule in the NMR timescale. A temperature rise results in typical of exchange process evolutions of the resonance line shapes corresponding to rearrangements AB⇌BA, ABM⇌BAM and ABMX⇌BAMX. At 60°C the ^{31}P NMR spectrum (Fig. 1b) displays a rather narrow signal from two phosphine groups of the isomer which contains no ^{199}Hg and ^{195}Pt magnetic isotopes. The satellites of these isotopes under such fast exchange conditions are also averaged, but they have an asymmetric broadening which is related to the difference of ^1J(Pt–P) and ^2J(Hg–P) couplings for two phosphine groups. At the further increase of the temperature the satellites' widths become equal (90°C, toluene). The parameters under fast exchange are close to arithmetic mean values obtained from the corresponding low temperature parameters (see Table 1). At room temperature the ^{199}Hg NMR spectrum (Fig. 2b) corresponds to intermediate exchange rates, and at 90°C (Fig. 2c) there occurs an averaged spectrum including platinum satellites. Similar changes are observed in the ^{195}Pt NMR spectra.

The temperature dependence of the spectra, and the observation of spin–spin couplings between magnetic isotopes of phosphorus, platinum and mercury at fast-exchange limit show that the dynamic process in I is intramolecular. It is taking place without a rupture of Pt–P and Pt–Hg bonds. Good evidence in favour of the latter conclusion is the similarity of the temperature dependence of the line shape in the ^{31}P NMR spectra of very diluted solutions of I in two very different solvents—THF and toluene. This is also proved by the study of the line shape at several temperatures for solutions of

---

†According to the ^{31}P spectra at -80°C the PPh_3 content cannot exceed 1%.

I in THF at concentrations of 0.003 and 0.03 M testifying to the absence of concentration dependence of the exchange rate.

Finally, the catalytic mechanism should be ruled out. It might be supposed that in the solutions there exist small admixtures of free phosphine† which is a dissociation product of $Pt(PPh_3)_4$[28] employed in the synthesis of I. There have been investigated solutions of I with equimolar $Pt(PPh_3)_4$ and $Pt(PPh_3)_3$ additions, as well as with greater PPh_3 quantities. The experiments have shown that these substances whose content exceeds by far the amounts necessary for catalysis did not perceptibly influence the character and kinetic of the process in question.

Thus, the phenomenon described is conditional by the fluxional nature of complex I. The fact that the ^{31}P and ^{195}Pt chemical shifts and the coupling ^1J(Pt–P) at fast-exchange limit are close to the averaged values of parameters of low temperature spectrum shows that no paramagnetic tetrahedral complex is taking part in the equilibrium. The degenerate rearrangement involved is of intramolecular character, its probable mechanism being a digonal twist with the transition state close to the tetrahedral structure. Thus, $(PPh_3)_2Pt(HgGePh_3)(GePh_3)$ is a stereochemically nonrigid molecule.

We can also note the temperature dependence of ^{199}Hg chemical shift of I, which is *ca.* -0.5 ppm/K. Very high sensitivity of ^{199}Hg shielding of mercury compounds to medium and temperature are well-known.[29-31] The temperature dependence of δHg is rather complicated. For example, according to our data, for solution $[(CF_3)_3Ge]_2Hg$ and $(CF_3)_2Hg$ in toluene it is *ca.* -0.1 ppm/K, for $(Et_3Si)_2Hg$ in THF it is *ca.* 0.8 ppm/K. The ^{199}Hg signal of Et_2Hg (as a pure liquid) moves upfield in the temperature range from -50 to $+25$°C $(-0.3$ ppm/K).

From the temperature dependence of the ^{31}P line shapes (sub-spectrum AB, THF, 0.013 M) the following activation parameters were obtained: $\Delta G_{298}^{\neq} = 51.5 \pm 2.9$ kJ/mol, $\Delta H^{\neq} = 59.3 \pm 2.9$ kJ/mol, $\Delta S^{\neq} = 26.2 \pm 9.7$ J/mol·K. The positive values of $\Delta S^{\neq}$ obtained for I is in good agreement with the data of La Mar and Sherman[9] which show that the tetrahedral-planar equilibrium for complex $[RP(Ph)_2]_2NiX_2$ is characterized by a larger values of entropy for the tetrahedral state.

NMR (^{195}Pt AND ^{13}C) CONTRIBUTION TO THE STUDY OF SOME Pt(II), Pt(IV) AND MIXED-VALENCE THIOAMIDO COMPLEXES

JEAN-MICHEL BRET, PAULE CASTAN,* GERARD COMMENGES and

Narbonne, 31400 Toulouse, France

Abstract—The ^{195}Pt and ^{13}C chemical shifts (δ_{Pt} and δ_C) are reported for platinum(II), platinum(IV) and class II mixed-valence complexes, with general formula [PtL$_4$]X$_2$, *cis*- and *trans*-PtL$_2$X$_2$, PtL$_2$X$_4$ and Pt$_2$L$_4$X$_6$ (where L may be thiourea, 2-imidazolidine-thione, tetrahydro 2-pyrimidinethione, thiocaprolactam, pyridine-2-thione and tetramethylthiourea, and X may be Cl or Br). The ^{195}Pt chemical shifts can be understood in view of ^{13}C data in terms of variations of electronegativities and σ-donor abilities of ligands attached to platinum.

Thiourea and its derivatives have played an important rôle in the early development of platinum chemistry. The thiourea complexes of platinum(II) first synthesized by Kurnakov at the end of the last century have afforded a large contribution to the knowledge of substitution reactions in square planar complexes with a particular reference to the *trans*-effect of these ligands.[1] In spite of their interest, these complexes have not yet been included in the numerous ^{195}Pt resonance works,[2,3] and little[4-6] has been done on magnetic shielding of platinum nuclei in compounds involving *s*-bonded ligands, these being almost limited to thiocyanates.

Recently, we have isolated some complexes involving coordination of thiourea and related ligands to platinum(II) and platinum(IV).[7] Furthermore, halogeno complexes of general formula PtL$_2$X$_3$ (where L = thioamido ligands, X = halogen) have been obtained.[8-10] They are reminiscent of the PtA$_n$X$_3$ complexes (A = monodentate or bidentate aminoligands, n = 2 or 1, X = halogen) which, according to physical measurements,[11-18] and particularly to X-ray determination,[19] are actually considered as "class II mixed-valence compounds" according to the classification of Robin and Day.[20]

In fact, direct proofs (XPS data) of the mixed-valence character of the thiomido complexes (PtL$_2$X$_3$)$_2$ have been reported in a previous paper,[8,9] however the precise structure of these complexes seems to be dependent on experimental conditions, at least when ethylene thiourea is involved as a ligand. Synthetic details, largely discussed in our last paper,[9] suggest that two isomeric mixed-valence complexes may be obtained: either [PtL$_4$][PtX$_6$] or [PtL$_2$X$_2$][PtL$_2$X$_4$]. Intermediate compounds, isolated during the course of the preparation, support this assumption. From the great sensitivity of the ^{195}Pt chemical shift, it may be inferred that NMR may provide indirect informations on the nature of these compounds, at least in solution.

Finally this work is devoted to the NMR behaviour (^{13}C and ^{195}Pt) of the single-valence complexes of platinum(II) and platinum(IV) and to the mixed-valence compounds obtained with the reactive –NH–C=S group in ligands such as thiourea (tu), 2-imidazolidine-thione (etu) (ethylenethiourea), tetrahydro 2-pyrimidinethione (tpt), thiocaprolactam (tcp), pyridine-2-thione (pyt) and tetramethylthiourea (tmt).

EXPERIMENTAL

NMR measurements

All NMR spectra were recorded on a WH250 Brucker spectrometer operating in the Fourier transform mode and equipped with wide band probe (23–103 MHz).

The complexes were dissoved in DMSO-d_6, the ^{2}H resonance of which provided the field/frequency locking signal. ^{1}H noise modulated decoupling ensured complete proton decoupling of the spectra.

^{13}C *spectra*. Typical parameters for ^{13}C spectra were: pulse width 20 μsec, impulse delay 1 sec; 2000–5000 accumulations were usually necessary to achieve a satisfactory signal to noise ratio. The ^{13}C shifts were measured relative to the solvent DMSO-d_6, however, δ values reported are quoted with respect to TMS.

^{195}Pt *spectra*. Typical parameters for ^{195}Pt spectra were: pulse width 20 μsec, impulse delay 1 sec; 500–3000 transients were collected. All the previous papers reporting ^{195}Pt chemical shifts mention use of different compounds as reference zero. We have adopted the convention suggested by Kerrisson,[21] which conforms to that of the IUPAC using ^{195}Pt of H$_2$PtCl$_6$ in D$_2$O solution as external zero reference at 53 770 768 MHz. The dependence of the chemical shift of the solvent was examined in the case of H$_2$PtCl$_6$ by use of solutions in DMSO-d_6.

Solutions for NMR spectra were nearly saturated and data were collected on freshly prepared samples. The data given were quite reproducible and there was no evidence of solvolysis or decomposition of the complexes during the course of the measurements.

The chemical shifts are given in Tables 1–3. A *positive* shift implies that the sample resonance occurs at a *higher frequency* and that the ^{195}Pt nucleus is less shielded than in reference.

Preparation of the complexes

The platinum complexes were prepared as previously described.[7-9] Their purities were checked by chemical analysis, IR, NMR and also XPS spectroscopy for the mixed-valence compounds.

RESULTS

Platinum(II) compounds. On the basis of IR and NMR data, it has been already inferred that, in the platinum(II) complexes, coordination of the thio-amido ligands occurs through the sulphur atom.[7,22-24] This bonding scheme has been definitively established by X-ray determination in the case of the (PtL$_4$)Cl$_2$ complexes (L = thiourea or dimethylthiourea).[25,26]

The data reported in Table 1 afford a new proof of the occurrence of a Pt–S bond in the PtL$_2$X$_2$ complexes as well as in the (PtL$_4$)Cl$_2$ ones since, in all cases, the C=S nucleus suffers an important high field shift with respect to the free ligand. Concerning the

configuration of the PtL$_2$X$_2$ complexes, very few data have been published. They are essentially deduced from far IR spectra. The presence of two ν(Pt–Cl) bands in the range of 300 cm^{-1}, split by 15–30 cm^{-1}, is taken as a proof for the *cis*-configuration.

Bearing in mind that interconversion between *cis* and *trans* isomers may occur quite readily in solution and that this study may not very easily be extended to the solid state, the ^{195}Pt resonance spectra for some of the PtL$_2$Cl$_2$ complexes herein investigated display two lines separated by *ca.* 290 ppm. These lines are attributed to the *cis* and *trans* isomers.

Considering the results already obtained for the

(R$_3$P)$_2$PtCl$_2$[27,28] and the low field shift (ca. 500 ppm observed between the *trans* complex and its *cis*-homologue, and those of Goodfellow et al.[29] for a series of trimethyl phosphine and related ligands complexes, we attribute the lines which appear at about 3700 and 3900 ppm to the *cis* isomers in the PtL$_2$Cl$_2$ and PtL$_2$Br$_2$ complexes, respectively.

While no significant changes in the platinum-ligand bond strength occur by replacement of a ligand by another, quite similar δ values are observed for all the *cis* (or *trans*) complexes except for the thio-caprolactam complexes. In this case, the only line observed strictly lies between the values expected for a *cis* and a *trans* isomer, respectively. Moreover the δ ^{195}Pt change (264 ppm) in going from this chloro complex to the *cis*-bromo complex is consistent neither with *cis* configuration ($\Delta\delta$ ^{195}Pt ca 180 ppm) nor *trans* configurations ($\Delta\delta^{195}$Pt ca. 315 ppm). This behaviour may be related to the steric hindrance of the thiocaprolactam ring which distorts the interbond angles from the idealized right-angle square planar geometry. Similar effects have been already observed for platinum in cycloalkanes derivatives[27] and for other heavier nuclei such as ^{207}Pb.[27]

Platinum(IV) compounds. We succeeded in preparing four complexes which have been identified by chemical analysis, IR spectroscopy and XPS measurements, as PtL$_2$X$_4$ species (X being Cl or Br and L = imidazolidine-2-thione and tetramethylthiourea).

Surprisingly, the ^{195}Pt resonance spectra of these species comprise two lines, indicating the occurrence of two types of platinum nuclei. In each case the shift of the low-field signal is identical with the shift of the corresponding [PtX$_6$]$^{2-}$ entity (+430 ppm for chloro and −1430 ppm for bromo complexes). It is very likely that when a PtL$_2$X$_4$ complex is in solution, a Pt(II)-catalysed Pt(IV) substitution reaction occurs, attended by the formation of a [PtX$_6$]$^{2-}$ [PtL$_4$X$_2$]$^{2+}$ species. This type of reaction has been recently de-

scribed by Scott.[30] Another possible explanation would be the formation of complexes in which one or more solvent molecules would have been introduced in the coordination sphere. Due to the fact that similar data have been obtained in two solvents (DMSO and DMF), we consider this possibility as unlikely. At first sight, one may consider that the chemical shift (ca. −3800 ppm) attributed to the platinum nucleus in the [PtL$_4$X$_2$]$^{2+}$ entity, is rather low for a platinum(IV). However, it is not unusual that the resonance of a platinum(IV) species occurs at a lower field than that of a platinum(II) analogue. The simplest example of such a behaviour refers to the couple [PtCl$_6$]$^{2-}$ (δ ^{195}Pt = 0 ppm in D$_2$O), [PtCl$_4$]$^{2-}$ (δ ^{195}Pt = −1620 ppm in D$_2$O).

The ^{13}C spectra show one signal only for the C=S nucleus which is strongly shielded with respect to the free ligand.

Mixed-valence compounds. As already reported, two types of compounds have been obtained. Their mixed-valence nature has been unambiguously established from XPS measurements.

In the case of the [PtL$_4$][PtX$_6$] complexes, the analysis of the NMR spectra is straightforward since these spectra are merely the sum of the spectra relating to the isolated entities [PtL$_4$]$^{2+}$ and [PtX$_6$]$^{2-}$.

The behaviour of the other type of mixed-valence compounds is more surprising at first sight. Instead of the two lines expected on the basis of a [L$_2$PtCl$_2$][L$_2$PtCl$_4$] formulation, three lines are observed in the ^{195}Pt spectra. However, one of them (δ = 3421 ppm) is unambiguously attributable to the platinum(II) moiety [L$_2$PtCl$_2$]. Accordingly, the remaining two lines (δ ^{195}Pt = + 430 and − 3844 ppm) would be due to the platinum(IV) moiety which would give rise in solution to a redistribution reaction analogous to the reaction mentioned for the Pt(IV) complexes (*vide supra*). This behaviour is not surprising since the specific character of mixed-valence complexes is known to disappear in solution where

their component entities recover their individuality. The two lines observed for $\delta_{C=S}$ in the ^{13}C spectra support this assumption.

DISCUSSION

Viewing the whole set of data relating to ^{195}Pt resonance (Tables 1–3), some general remarks can be made.

First of all, the two isomers, *cis*- and *trans*-PtL$_2$X$_2$ are easily distinguished, as their related Pt resonances are separated by *ca.* 280 ppm (X = Cl) and *ca.* 180 ppm (X = Br). On the basis of the correlation between the wavelength absorption and the ^{195}Pt chemical shifts of the PtL$_2$X$_2$ complexes, the Pt lines are expected to move towards higher field when going from the chloro to the bromo complexes. This trend is actually observed; however, the difference is less pronounced for the *cis*-PtL$_2$X$_2$ than for the *trans* isomers. A similar observation has already been made in the case of a number of PtL$_2$X$_2$ complexes (L = SR$_2$, PR$_3$, AsR$_3$).

Theoretically, the magnetic shielding in a nucleus may be ascribed in terms of local "paramagnetic" σ_p, and diamagnetic σ_d contributions.[31–33] For metals, the dominance of the σ_p is well acknowledged and an evaluation of this term has been performed by Dean and Green[34] through a modification of Ramsey's equation. σ_p depends on (i) the asymmetry of the electronic distribution with the 5d and 6p orbitals of the platinum atom, (ii) the mean inverse cube of the distance between these electrons and the nucleus, (iii) the magnitude of the energy of the ligand field transition (ΔE). Assuming that changes in (i) and (ii) are small, a correlation between metal shielding and ΔE is expected but interpretations of ^{195}Pt chemical shift variations on this basis have met very limited success.[27,6] A possible interpretation is that changes in ΔE do not necessarily dominate changes in the ^{195}Pt shielding. Moreover, attempts to include other contributions such as changes in $\langle r^{-3} \rangle$ due to the contraction of 5d orbitals turns out very modestly rewarded.

This stated, we will use a more empirical approach based on the joint consideration of ^{195}Pt and ^{13}C data. In this respect, it is noteworthy that satisfactory correlations of δ ^{13}C with substituent electronegativities have been found in many series of organic compounds. Substituent inductive effects may primarily affect the diamagnetic term (σ_d) but electronic withdrawal by a substituent on platinum may also modify the electronic imbalance among valence orbitals and cause a change in the paramagnetic contribution.[35]

In our analysis, we have first to consider the rôle of the oxidation state. It is generally assumed that the magnitude of related contributions for platinum complexes is a few tens of ppm at most and may therefore be neglected;[36] nevertheless, the trend usually observed for greater shielding in Pt(IV) complexes than in Pt(II) complexes is explained on the basis of a contraction of Pt(IV) 5d orbitals with respect to Pt(II) ones due to the greater charge on the metal. However, this explanation does not hold for the couple [PtI$_6$]$^{2-}$/[PtI$_4$]$^{2-}$. Considering the three couples [PtX$_6$]$^{2-}$/[PtX$_4$]$^{2-}$ (X = Cl, Br, I), we suggest that the

changes in the ^{195}Pt chemical shifts are better related to the inductive effects of six and four halogens, respectively. The chemical shift difference between Pt(IV) and Pt(II) decreases when Cl is replaced by Br in accordance with a lowering of the substituent electronegativity. When this electronegativity is further decreased—(PtI$_6$)$^{2-}$/(PtI$_4$)$^{2-}$—the order of the chemical shifts is even reversed (− 6300 and − 5420 ppm, respectively).

Thus, it seems that the deshielding of the platinum nucleus is first due to the electronegativity of the group attached to platinum as this will affect the electron density around the nucleus and/or the electronic imbalance among valence orbitals.

To apply this approach to our complexes, we must notice that the thiourea ligands are neutral π acid, since sulphur has vacant d orbitals which can accept electron density from filled metal orbitals to form a kind of π bonding that supplements the σ bonding arising from lone-pair donation. In the case of etu and tmtu complexes, the two entities [Pt^{II}L$_4$]$^{2+}$ and [Pt^{IV}L$_4$Cl$_2$]$^{2+}$ display almost the same ^{195}Pt chemical shift, i.e. − 3882 and − 3844 ppm respectively, while the corresponding C=S shifts are noticeably different. When going from the free ligand L to the [Pt^{II}L$_4$]$^{2+}$ complex, the thiocarbonyl carbon suffers a small shielding (*ca.* 4 ppm) which contrasts with the strong effect (*ca.* 27 ppm) related to the [Pt^{IV}L$_4$Cl$_2$]$^{2+}$ complex. These effects are consistent with a lowering of the C=S bond order, the change being small in the former case and more pronounced in the latter.

This decrease in the thiocarbonyl bond order may be related to two causes: either the possible backdonation of metal electrons towards ligands or the increase of the σ donor ability of sulphur towards platinum(IV) with respect to platinum(II). Backdonation would imply a high electron density on the metal atom which is not consistent with a high oxidation state. Thus, an increase of the σ donor ability of sulphur seems likely and it is suggested that this effect would balance the inductive influence of the two chlorine atoms yielding almost equal charge densities around platinum(II) and (IV). It is noteworthy that a very similar behaviour is observed in the case of platinum(II) and platinum(IV) cyano complexes for which the C≡N nucleus is more shielded in [Pt(CN)$_6$]$^{2-}$ (δ ^{13}C *ca.* 85 ppm) than in [Pt(CN)$_4$]$^{2-}$ (δ ^{13}C *ca.* 125 ppm),[37] in agreement with a greater donor ability towards Pt(IV) than towards Pt(II).

In a family of platinum(II) compounds, the same trend is observed. The shielding of the ^{195}Pt nucleus is increased in going from PtL$_2$Cl$_2$ to PtL$_2$Br$_2$ and [PtL$_4$]$^{2+}$. This effect is consistent with an increase of the charge on the metal dependent upon a decrease of the ligands electronegativity which causes the metal-ligand bond to become more covalent.

The data observed for the ^{13}C chemical shifts are quite in agreement with those noted for ^{195}Pt ones. When comparing the $\delta_{C=S}$ changes in the same ligand family we can observe that increasing the shielding of the platinum atom causes a subsequent low field shift in the corresponding thiocarbonyl carbon atoms. This implies a greater charge transfer from sulphur towards platinum for PtL$_2$Cl$_2$ than for the other compounds, observable either by ^{195}Pt or by ^{13}C NMR spectroscopy.

Techniques de Saint-Jéromé Laboratoire des Organometallique, 13397 Marseille Cedex 4,
France

Abstract—Thirty triorganotin(IV) derivatives of the type $R_3Sn(R'COCHCOCH_2COR'')$
and $[R_3Sn]_2$ ($R'COCHCOCHCOR''$) (where $R = CH_3$, C_2H_5, $n-C_3H_7$, $n-C_4H_9$, and C_6H_5
and $R' = R'' = CH_3$, C_6H_5 or $R' = C_6H_5$, $R'' = CH_3$) have been synthesised by the
interaction of R_3SnCl with mono- or disodium salt of 2, 4, 6-heptanetrione, 1-phenyl-1,
3, 5-hexanetrione and 1, 5-diphenyl-1, 3, 5-pentanetrione in 1:1 and 2:1 molar ratios,
respectively. The complexes have been examined by their molecular weight, IR, PMR and
elemental analyses and their tentative structures assigned. Both "Z" and "E" forms have
been identified in the 1:1 complexes in equilibrium with the enol form containing five
coordinate tin. The 2:1 derivatives contain one five- and other four coordinated tin(IV)
except the phenyl analogue where both the tins are five coordinated.

There has been an upsurge of interest in the
development of the chemistry of β,
δ-triketones,[1-15] their Schiff's bases[9,16] and
compartmental ligands.[17-19] These ligands
readily form homo- as well as hetero-bimetallic
complexes. However, no work appears to have
been done on the triorganotin(IV) derivatives of β,
δ-triketones. The work on diorganotin(IV) has
been recently completed in our laboratories.[20] In
the present communication we report the syntheses
and characterisation of thirty new derivatives of β,
δ-triketones.

EXPERIMENTAL

The syntheses of the ligands and their character-
isation are reported earlier.[21,22] All the reac-
tions were carried out under anhydrous conditions.
Carbon and hydrogen were analysed on a Col-

man Carbon–Hydrogen Analyser. IR spectra were
measured in Nujol mulls or neat between the range
of 4000–200 cm^{-1} using CsI optics on
Perkin–Elmer Model 577 spectrophotometer. The
PMR spectra were recorded on a Perkin–Elmer
R12B Spectrometer (60 MHz) in $CDCl_3$ or CCl_4
solutions using TMS as a reference.

Synthesis of trimethyltin -mono(2, 4, 6-*hepta-
netrionate*)

A benzene solution of trimethyltin chloride (0.01
mole) was added to the mono sodium salt of 2, 4,
6-heptanetrione (0.01 mole), prepared by the direct
interaction of the latter with sodium isopropoxide
(0.01 mole) in benzene. The mixture was refluxed
for 2 hr. The sodium chloride so formed was
filtered out and the solvent stripped off under
vacuum.

The complex is red viscous liquid which solidifies
on keeping. It is soluble in chloroform and other
polar and non-polar solvents. The compound de-
composes above 150°C. Found: Mol. Wt., 284; C,

*   Both the reactants were taken in 2:1 molar ratios and refluxed for four hours.

**   In boiling methanol, d for decomposed material.

39.02; H, 5.69; Sn, 38.38. Calc. for (CH₃)₃Sn(CH₃COCHCOCH₂COCH₃); Mol. Wt., 304; C, 39.39; H, 5.94; Sn, 38.92%.

Similarly the reactions of triethyltin-, tri-*n*-propyltin-tri-*n*-butyltin- and triphenyltin chlorides with 2, 4, 6-heptane-trione, 1-phenyl-1, 3, 5-hexanetrione and 1, 5-diphenyl-1, 3, 5-pentanetrione have been carried out. Their details of syntheses and identifications are given in Table 1.

Synthesis of bis[trimethyltin-mono(2,4,6-heptanetrionate)]

Trimethyltin chloride (0.02 mole) taken in 20 cm³ of benzene was added to the benzene suspension of disodium salt of 2, 4, 6-heptanetrione (0.01 mole) in isopropanol. The reaction mixture was allowed to reflux for 4–5 hr to complete the reaction. Sodium chloride formed during the reaction was removed by filteration. From the filtrate binary benzene-isopropanol azeotrope was fractionated out between the temperature range 68–80°C and the compound was isolated by removing the last traces of solvent under vacuum.

Bis(trimethyltin) -mono (2, 4, 6-heptanetrionate) was found to be soluble in methanol and other polar solvents but insoluble in non-polar solvents. It is monomeric in refluxing methanol and non-electrolyte in nitrobenzene. Found: Mol. Wt., 449; C, 33.12; H, 5.46; Sn, 50.30. Calc. for [(CH₃)₃Sn]₂(CH₃COCHCOCHCOCH₃); Mol. Wt., 467; C, 33.38; H, 5.60; Sn, 50.74%.

Likewise the reactions of triethyltin-, tri-*n*-propyltin tri-*n*-butyltin- and triphenyltin chlorides with disodium salt of 2, 4, 6-heptanetrione, 1-phenyl-1, 3, 5-hexanetrione and 1, 5-diphenyl-1, 3, 5-pentanetrione in 2:1 molar ratio have been carried out and their analytical results are given in Table 2.

RESULTS AND DISCUSSION

The triorganotin mono (β, δ-triketonates) and bis(triorganotin)-mono (β, δ-triketonates) are either yellow–brown coloured viscous liquids or crystalline solids, soluble in common organic polar and non-polar solvents, except the bis-derivatives of 2, 4, 6-heptanetrione. They decompose around 35–45°C. Both 1:1 and 2:1 products are monomeric in freezing benzene and non-electrolyte in nitrobenzene.

Infrared spectra of triorganotin-mono (β, δ-triketonates) show prominent bands in the region 3400–3200 and 1700–1500 cm⁻¹. The former has been assigned to the νOH. The strong intensity bands around 1680–1650 cm⁻¹ are assigned to the free carbonyl group. The band around 1600 cm⁻¹ has been assigned to the coordinated carbonyl groups.[7,23] The νC = O of the non-chelated carbonyl group is also slightly shifted in comparison to those of free ligands, presumably due to the shift in keto-enol equilibrium.

However in the IR spectra of bis-triorganotin)-mono (β, δ-triketonates) marked lowering in νC = O without splitting have been observed, indicating thereby coordination of all the carbonyl oxygens to the central tins.[23]

The presence of metal–oxygen[24] and metal–carbon is revealed by the presence of strong to medium intensity bands in the region 730–600 and 590–500 cm⁻¹, respectively. The presence of two bands in the latter region clearly reveals non-linear nature of -SnR₃ groups Tables 3 and 5.

The PMR spectra (Table 4) of triorganotin-mono (β, δ-triketonates) reveal the presence of tautomeric methine signal at δ, 7.15–7.3 ppm. This signal is a far more shifted downfield than the one due to free ligands. Such a situation has emerged because of the delocalisation of π-electrons (I),

implying coordination of both the terminal and central carbonyl groups to the central tin.

The CH_2 signals were found at δ, 5.8 and 5.4 ppm, respectively is implying that the vinylic proton is under two magnetically non-equivalent environments, the "Z" and "E" forms. These two forms are in equilibrium. In the "Z" form the vinylic proton is nearer to the alkyl group (II) because of the shielding effect of the alkyl group while the peak appearing in the downfield region is attributed to the vinylic proton of "E" form in which it is deshielded (III).

The PMR chemical shift data of some of the bis(triorganotin)-mono (β, δ-triketonates) are given in Table 6. The methylene signals appearing at δ, 3.5–4.3 ppm in the unchelated ligands,[25] altogether disappear in the chelates, implying involvement of all the three carbonyl groups in chelation. The methine signals shift towards lower magnetic field as compared to free ligand, implying delocalisation of π-electrons throughout the framework. Further appearance of two methine signals at δ, 7.15–7.5 and 5.75–6.0 ppm indicate two types of methine protons. In the former case

one of the trialkyl tin forms a part of the chelated ring, embracing two oxygens of the central and terminal carbonyl groups, stabilized through the π-electron delocalisation, imparting quasi-aromaticity.[26,27] In such a situation the methine proton is deshielded (IV), allowing the formation of penta-coordinated tin, while the second trialkyltin is attached to the oxygen of the terminal carbonyl group and it is four coordinated.

Further in the complexes (V) of triphenyltin there is only one CH proton signal, implying that each of the triphenylstannyl groups attached to the two of the three carbonyl groups forming homo bimetallic complex. The explanation of this strange situation can be advanced on the basis of the $-$ I effect of the phenyl group, resulting in the enhancement of the electron accepting property of tin(IV). As a result of this central oxygen becomes three-coordinated and on account of the ring current both the CH protons are rendered magnetically equivalent. The methine signal also merges into the those of the phenyl groups.

Abstract—Loading experiments in the extraction system $TOAH^+Cl^-$/benzene–$SnCl_2$–HCl and measurements of the IR spectra and the specific conductivities κ of the extracts revealed the occurrence of two Sn(II)complexes: $TOAH^+SnCl_3^-$ (1:1-complex) and $(TOAH\ldots Cl\ldots HTOA)^+SnCl_3^-$ (2:1-complex). The shift of the νNH frequencies of these complexes with N-deuteration, expressed by the ratio $\nu HN/\nu ND$, amounts to 1.33 and 1.28 respectively. This agrees very well with corresponding values of complexes with analogous or similar composition.

A few studies have been published on the extraction of Sn(II) with long-chain amine salts from halide solution[1-3] and only in one of those studies[3] supposed extractable Sn(II) containing species were mentioned in the form of general gross formulas. All investigations were performed without exclusion of oxygen. This doubtless caused the formation of considerable quantities of Sn(IV),[4] and therefore the results of these studies cannot reflect the true behaviour of pure Sn(II) compounds.

The present work deals with the occurrence and the composition of tri-*n*-octylammonium chlorocomplexes of Sn(II). By analogy with preceding studies[5-7] investigations were performed including loading experiments in the system $TOAH^+Cl^-$/C_6H_6–$SnCl_2$–HCl (TOA = tri-*n*-octylamine) as well as IR spectroscopic and conductivity measurements of the Sn(II) containing extracts.

EXPERIMENTAL

The reagents $SnCl_2 \cdot 2H_2O$, HCl and C_6H_6 were of analytical grade. Tri-*n*-octylamine (pract., $d_4^{20}0.82$;

n_D^{20} 1.4476) was supplied by Fluka AG (Switzerland), deuterobenzene (Benzol-D$_6$, b.p.$_{760}$80.1°C; 99.2 ± 0.1 at% D) by the Zentralinstitut für Isotopen- und Strahlenforschung Leipzig, deuterium chloride (20% DCl in D_2O; 99.9%) by VEB Berlin-Chemie, Berlin-Adlershof.

The loading experiments, the preparation of the extracts and the measurements of the IR spectra and specific conductivities were carried out as described earlier.[5-7] All operations with Sn(II) were performed with freshly prepared solutions under an atmosphere of pure argon. The distribution coefficients $D_{Sn(II)}$ were determined by iodometric titration of aliquot parts of the aqueous phase after equilibration. The chloride concentrations of the organic phase were determined by argentometric titration according to Volhard's method after a preceding back extraction shaking 5 cm³ of the organic phase twice with 10 cm³ 1M H_2SO_4/1 M $HClO_4$ for 5 min and then boiling 3 cm³ of the back extract with 6 cm³ conc. HNO_3. Anhydrous $SnCl_2$ was prepared by reaction of $SnCl_2 \cdot 2H_2O$ with acetic anhydride.[8]

LOADING EXPERIMENTS AND PREPARATION OF THE EXTRACTS

Solutions of 0.125–1.76 M $SnCl_2$ in 6 M HCl were extracted by solutions of 0.25 M $TOAH^+Cl^-$

in benzene (phase ratio $V_w/V_{org} = 1$; $t = 20$ min). The extraction isotherm is given in Fig. 1. It indicates the formation of a pure 1:1-complex at Sn(II) initial concentrations $\geqslant 0.5$ M under the extraction conditions used. This is confirmed by the molar ratio TOA: $Sn(II)_{(org)}$:$Cl_{(org)} = 0.98:1:2.79$, which approximates the theoretical ratio of the 1:1-complex 1:1:3 quite well. The corresponding molar ratio found at the Sn(II) initial concentration 0.125 M, 2.02:1:3.87, approximates the theoretical ratio of a 2:1-complex (2:1:4) indicating the formation of this complex at lower Sn(II) concentrations in the organic phase.

Using this knowledge of the extraction conditions extracts were prepared for the measurements of the IR spectra. The preparation conditions are given in Table 1. For measurements of the specific conductivity κ extracts No. 1 and No. 3 were also prepared with benzene as diluent and a Sn(II)

concentration of 0.1 M was set up by dilution with additional benzene (Table 1).

IR SPECTRA, CONDUCTIVITY MEASUREMENTS AND DISCUSSION

The IR spectra of the extracts were taken in the range 1800–3800 cm^{-1}. They are given in Fig. 2. The wave numbers of the νNH and νND absorptions are summarized in Table 2.

The IR spectra of the non-deuterated extract No. 1 with the stoichiometry TOA:Sn(II) = 1:1 exhibits a strong νNH band at 3030 cm^{-1} indicating only a weak cation–anion interaction by H-bond. The position of the band agrees very well with those of the 1:1-complexes of the trivalent ions of In, Ga and Fe, $TOAH^+MCl_4^-$[†], and is nearly identical with the νNH frequency of $TOAH^+CuCl_3^-$ (3015 cm^{-1}).[7] Furthermore there is complete agreement concerning the shift of this band with N-deuteration. The ratios νNH/νND for the 1:1-complexes of Sn(II), Cu(II) and Fe(III) are 1.33–1.34. Therefore the suggested structure of the 1:1-complex $TOAH^+SnCl_3^-$ is proved by the IR spectroscopic data as well as by the molar ratio of TOA, Sn(II) and Cl in the extract.

The stoichiometric data of the 2:1-extracts would permit complexes with the structures $(TOAH...Cl...HTOA)^+SnCl_3$ or $(TOAH^+)_2 SnCl_4^{2-}$. However, the peaks of the νNH vibration of the non-deuterated extract No. 3 at 2500, 2558 and 2613 cm^{-1} unambiguously confirm the structure $(TOAH ... Cl ... HTOA)^+SnCl_3^-$, because
Fig. 1. Extraction isotherms for SnCl$_2$, extracted from 6 M HCl with 0.25 M TOAH$^+$Cl$^-$/benzene. (- - - - Molar ratio TOA:Sn(II)$_{org}$).

[†]Complexes are here and subsequently written in monomeric form.

				(2280) vw$^{+)}$	

$^{+)}$ Due to small quantities of 1:1-complex

Table 3. Specific conductivity data κ. (Metal concentration: 0.1 M; diluent: benzene)

Complexes	$\kappa/\Omega^{-1}\text{cm}^{-1}$/ at 25 ± 0.02 °C	
1:1-Complexes		
TOAH$^+$FeCl$_4^-$	2.75 x 10^{-5}	/5/
TOAH$^+$SnCl$_3^-$	2.18 x 10^{-5}	(extract No. 1)
TOAH$^+$CuCl$_3^-$	1.84 x 10^{-5}	/7/
2:1-Complexes		
(TOAH...Cl...HTOA)$^+$FeCl$_4^-$	6.02 x 10^{-5}	/5/
(TOAH...Cl...HTOA)$^+$SnCl$_3^-$	7.18 x 10^{-5}	(extract No. 3)
(TOAH$^+$)$_2$CuCl$_4^-$	1.54 x 10^{-5}	/7/

of Fe(III); 3:1-complexes of Cu, Zn and Co) and with the 2:1-complexes of Cu, Zn and Co.[7]

The specific conductivity data κ of the Sn(II) bearing extracts are given in Table 3 together with the data of the corresponding Fe(III) and Cu(II) bearing extracts determined earlier [5–7]. They confirm the statements on the structure of Sn(II) complexes deduced by the IR spectra.

The 1:1-complex $TOAH^+SnCl_3^-$ exhibits a value between those of the equally composed complex $TOAH^+CuCl_3^-$ and the corresponding complex $TOAH^+FeCl_4^-$. The κ value of the 2:1-complex $(TOAH \ldots Cl \ldots HTOA)^+SnCl_3^-$ is near to that of the complex $(TOAH \ldots Cl \ldots HTOA)^+FeCl_4^-$ having the same cation, but is clearly distinguished from that of the 2:1-complex $(TOAH^+)_2CuCl_4^{2-}$ according to its different structure.

TETRAGONAL DISTORTIONS AND VIBRONIC COUPLING IN HEXAFLUORO NICKEL(II) AND COPPER (II) COMPLEXES

ROMAN BOČA*, PETER PELIKÁN, MARTIN BREZA and JÁN GAŽO

Departments of Inorganic Chemistry and Physical Chemistry, Slovak Technical University, CS-812 37 Bratislava, Czechoslovakia

Abstract—Two parameters, axial (R_a) and equatorial (R_e) metal–ligand distances, describe the tetragonal distortions of the NiF_6^{4-} and CuF_6^{4-} complexes under study. The experimental values of R_a plotted vs R_e exhibit a smooth curve type dependence valid for MF_6 chromophore of solid state compounds. In the model study it becomes explained by analyzing the shape of the adiabatic potential surface (APS) of the form of $E_T(R_a, R_e)$. Around the energy minima the map of numerical values (obtained by the quantum-chemical CNDO–UHF and INDO–UHF methods) was transformed to an analytic form from which the quantitative characteristics of APS were obtained in a new, simple way. The set of equatorial–axial parameters as well as the set of vibronic parameters were evaluated and discussed in more detail.

Fluoro complexes of M = Cr, Mn, Fe, Co, Ni, Cu and Zn belong to the transition metal complexes containing MX_6 chromophore in which the octahedral geometry is often disturbed so that tetragonal or orthorhombic distortions appear.[1–4] It was found that the mean axial (R_a) and the mean equatorial (R_e) metal ligand distances in these complexes are mutually dependent. In tetragonal bipyramids (the coordination number 4 + 2, 6 or 2 + 4), for a given chromophore, they show correlation along a smooth curve: the longer R_a, the shorter R_e, and vice versa.[5–8] Such a dependence R_a vs R_e also occurs in NiF_6^{4-} and CuF_6^{4-} coordination polyhedra in the solid state.[7,8] A more detailed understanding of particular factors operating in such distortion and dependences requires further re-solutions of several problems. Some of them form the subject of the present communication.

METHOD

Theoretical study of the stereochemistry of MF_6^{4-} type complexes poses the following problems.

(i) The shape of the adiabatic potential surface (APS) for the free MF_6^{4-} ion must be examined. It depends, in general, on fifteen degrees of freedom (internal coordinates). If only the tetragonal distortions within the symmetry point group of D_{4h} are considered, this number becomes reduced to

only two, so that APS will be considered as a simple function of the $E_T(R_a, R_e)$ type (E_T being the total molecular energy following from quantum-chemical calculations). For extreme distortions such as $R_a \to \infty$ the square-planar arrangement of the central atom, viz. MF_4^{2-} complex, is approached while for $R_e \to \infty$ the MF_2 molecule becomes linear. The numerical values of E_T were obtained by semiempirical CNDO/2 and INDO methods. The original CNDO/2 parametrization[9] extended to transition metals[10] for the Gouterman–Zerner basis set of valence atomic orbitals was used.[11] Additional Slater–Condon parameters[9,12] for the INDO method and some scaled radial integrals[13] were adapted in the program.[14] The self-consistent-field procedure for canonical molecular orbitals converges rapidly: *ca.* 13 cycles are required in order to obtain the electronic energy on the threshold of 10^{-4} eV.

(ii) The detailed form of APS depends on the electronic state of the system under study. For the non-degenerate state of A_{1g} a single energy minimum is exhibited in the octahedral geometry ($R_a^0 = R_e^0 = R_0$). For the doubly degenerate state of E_g a double energy minimum is found within the $E_T(R_a, R_e)$ picture. The first minimum corresponds to an elongated tetragonal bipyramid ($R_a^0 > R_e^0$) while the second minimum to its compressed form ($R_a^0 < R_e^0$).[3,5] The nature of this situation follows from the Jahn–Teller theorem or, more precisely, from the $E_g - e_g$ and $E_g - (a_{1g} + e_g)$ vibronic

Table 1. Mutual relationships between equatorial–axial parameters and vibronic parameters in square bipyramidal systems

Equatorial – axial parameters	Vibronic parameters
$R_a^0 = (de - 2bf)/(4cf - e^2)$	
$R_e^0 = (be - 2cd)/(4cf - e^2)$	
$R_e = R_0 + (\sqrt{2}\,Q_1 + Q_2)/\sqrt{12}$	$Q_1 = 2(2R_e + R_a)/\sqrt{6} - R_0\sqrt{6}$
$R_a = R_0 + (\sqrt{2}\,Q_1 - 2Q_2)/\sqrt{12}$	$Q_2 = 2(R_e - R_a)/\sqrt{3}$
	$Q_3 = 0$
$k_{aa} = (\partial^2 E_T/\partial R_a^2) = 2c$	$T_{11} = (\partial^2 E_T/\partial Q_1^2) = (k_{ee} + 2k_{ae} + k_{aa})/6$
$k_{ee} = (\partial^2 E_T/\partial R_e^2) = 2f$	$T_{22} = (\partial^2 E_T/\partial Q_2^2) = (k_{ee} - 4k_{ae} + 4k_{aa})/12$
$k_{ae} = (\partial^2 E_T/\partial R_a \partial R_e) = e$	$T_{12} = (\partial^2 E_T/\partial Q_1 \partial Q_2) = (k_{ee} - k_{ae} - 2k_{aa})/6\sqrt{2}$
$(d_a)_e = (k^{-1})_{ae}/(k^{-1})_{ee} = -k_{ae}/k_{aa}$	$K_a = T_{11}$
$(d_e)_a = (k^{-1})_{ea}/(k^{-1})_{aa} = -k_{ae}/k_{ee}$	$K_e = (T_{22}^{(1)} + T_{22}^{(2)})/2$
	$Y = -T_{11}Q_1^0 - T_{12}Q_2^0$
	$Z = sT_{12}$
	$A = s(T_{12}Q_1^0 + T_{22}Q_2^0)$ $s = -1$ for $E_T^{(1)}$
	$B = -s(T_{22} - K_e)/2$ $s = +1$ for $E_T^{(2)}$

coupling, respectively, as it will be discussed below.

(iii) The nearest region of the individual minima may be described by an analytic form of APS which in the harmonic approximation takes the form:

$$E_T(R_a, R_e) = a + bR_a + cR_a^2 + dR_e + eR_aR_e + fR_e^2 \tag{1}$$

Then the equilibrium coordinates, R_i^0, and the harmonic force constants, k_{ij}, may be evaluated (Table 1).

(iv) The ability of a coordination polyhedron to undergo tetragonal distortions (called here its plasticity[2]) may be expressed using the interaction displacement coordinates, $(d_i)_j$; their expressions are listed in Table 1. Applying the minimum energy coordinate approach,[15,16] the interaction displacement coordinates measure in the internal coordinate space the change in remaining coordinates (say R_a), required to minimize the total energy, following a fixed displacement of a selected coordinate (say R_e).

(v) Starting from the octahedral geometry towards the dissociation limit cases (MF_4^{2-} or MF_2) a reaction path is questionable. First, the selected coordinate R_a was systematically displaced by a certain step of ΔR_a. Then the corresponding optimum value of R_e^{opt} was found so that the complex relaxed to the local energy minimum. Thus a valley

on APS was found. Pairs of values $\{R_a^c = R_a^0 + n\Delta R_a; R_e^{opt}\}$ correlate along a smooth curve, where with increasing R_a^c the value of R_e^{opt} decreases. The procedure was repeated for fixed displacements of R_e and thus the second part of the valley (or the correlation curve R_a vs R_e) was obtained.

(vi) The principal factors operative in the stabilization of the complex equilibrium geometry may be analyzed on the basis of the energy partitioning. The one-centre, E_A, and the two-centre, E_{AB}, terms easily can be re-summarized:

$$E_T = \sum_A E_A + \sum_{A<B} E_{AB} = E_{mono} + E_{L-L} + E_{M-L} \tag{2}$$

where E_{mono} means the total one-centre term, E_{L-L} is the ligand–ligand and E_{M-L} the metal–ligand energy term. The corresponding formulae for the CNDO–UHF and INDO–UHF methods used are described elsewhere.[17]

(vii) In order to re-derive an analytic form of the APS in the double minimum case of the E_g state, the following assumptions were accepted: the normal vibrations (Q_1—symmetric stretching, Q_2—tetragonal distortion, Q_3—orthorhombic distortion) were considered in the harmonic approximation, and the vibronic Hamiltonian included the $E_g - (a_{1g} + e_g)$ coupling up to quadratic terms. Then the resulting first-order analytic formula for
Fig. 1. A cut of the Mexican hat type APS for $Q_1 = $ const. and $Q_3 = 0$.

APS (see appendix) is:

$$E_T^{1,2}(Q_1, Q_2; Q_3 = 0) = E_T(Q_1^0, Q_2^0) + YQ_1 + \tfrac{1}{2}K_aQ_1^2$$
$$+ \tfrac{1}{2}(K_e + 2sB)Q_2^2 + s(A - ZQ_1)Q_2 \quad (3)$$

where $s = \pm 1$. The meaning of this formula is illustrated in Fig. 1. A simple fitting of the type of

$$E_T(Q_1, Q_2) = a' + b'Q_1 + c'Q_1^2$$
$$+ d'Q_2 + e'Q_1Q_2 + f'Q_2^2 \quad (4)$$

leads to the determination of a'–f' parameters, so that the elastic force constants K_a and K_e, as well as the vibronic constants Y, Z, A and B can be evaluated.

(viii) Finally, the harmonic approximation of the energy minima in the form (1) can be combined

[a] Total energy $E_T(R_a,R_e) = -5\,200.0 - E'$(eV), where E' is listed in the table, separately for the spin multiplicity of $m = 1$ and $m = 3$. R_a and R_e are in 10^{-10} m. Energy minima are underlined.

with the double minimum type of the analytic potential (3). Then, after simple algebraic operations, the one-to-one correspondence between the set of equatorial–axial parameters and the set of vibronic parameters can be obtained (Table 1).

RESULTS

The APS of the form $E_T(R_a, R_e)$ was mapped using the step of $\Delta R = 1$ pm (Table 2, for CuF_6^{4-} see Ref. 6). Nine or more points of E_T around the energy minimum were used in order to obtain the six constants a–f of eqn (1) applying the least-squares method. The high correlation coefficient for the two-dimensional paraboloid type regression (greater than 0.9999) indicated that the harmonic approximation was well fulfilled.

The principal results obtained for the $^3A_{1g}$ and ^1E_g states of the complex NiF_6^{4-} and for the ^2E_g state of the complex CuF_6^{4-} are collected in Table

3. Although the high-spin state is preferable for NiF_6^{4-}, the CNDO–UHF method yields only a poor value for the energy separation $\Delta = E_T(^1E_g) - E_T(^3A_{1g}) = 0.007$ eV in the optimum octahedral configuration. This failure vanishes if the INDO–UHF method is used: $\Delta = 2.782$ eV. The other quantities are less sensitive to the method (CNDO vs INDO) used. For example, in the CuF_6^{4-} complex the calculated minimum points (R_a^0, R_e^0) are (1.977, 1.984) and (1.958, 1.986) for the INDO method compared with (1.991, 1.964) and (1.954, 1.982) for the CNDO method.

The interaction displacement coordinates were used in the definition of the minimum energy coordinates:

$$D_a = R_a + (d_e)_a R_e$$
$$D_e = R_e + (d_a)_e R_a \qquad (5)$$

[a] $R_0, R_a^0, R_e^0, Q_1^0, Q_2^0$ are in units of 10^{-10} m; E_{JT} in eV; Y and A in 10^{10} eV.m^{-1}; $k_{aa}, k_{ae}, k_{ee}, K_a, K_e, Z, B$ in 10^{20} eV.m^{-2} .

For example, the value of $(d_e)_a = -0.117$ means that R_e will be compressed by 11.7% of the length, if R_a is stretched. Similarly, R_a would be compressed by 26.4% relative to a given stretching of R_e, as follows from the value of $(d_a)_e = -0.264$ for the complex NiF_6^{4-}. Therefore, the interaction displacement coordinates may be accepted as quantitative characteristics in describing the plasticity of coordiantion polyhedra (the ability to undergo tetragonal distortions) in the harmonic approximation. It seems (Table 3) that the first minimum (the elongated bipyramid) corresponds to a somewhat softened, more plastic complex compared with the second minimum (the compressed form).

To open discussion of calculated vibronic parameters it must be mentioned that the formula (3) represents a cut of a Mexican hat type[3,28] of the APS. If the calculated numerical map of the APS values is consistent with such an approximate analytic form of the APS, then some additional relations will hold: the same values of vibronic parameters K_a, Y, A and Z are to be obtained for both minima. This condition is satisfactorily fulfilled for CNDO calculations of CuF_6^{4-} and INDO calculations of NiF_6^{4-}. Moreover, the vibronic parameters presented for CuF_6^{4-} are not too far from those previously reported elsewhere.[19] That method, however, was rather time consuming as it was based on the non-linear regression and a complicated functional minimization. The non-zero values of Q_1^0 indicate that the actual form of the APS is more complex compared with the simple Mexican hat type with a warping (as considered, for example, in Ref. 18).

The calculated value of K_a (the rigidity against the a_{1g}-type stretching of Q_1) is significantly higher in comparison with K_e (the rigidity vs the e_g-type distortion of Q_2). Thus the Q_2 mode may be considered as a soft mode, so that the tetragonal distortion is preferable over the symmetric expansion (compression) of an octahedron. The linear vibronic constant Y (proportional to $\partial \hat{V}/\partial Q_1$) is significantly lower in comparison with A (proporitonal to $\partial \hat{V}/\partial Q_2$), so that the linear vibronic coupling $E_g - e_g$ predominates over the $E_g - a_{1g}$ admixture. Simultaneosly, the quadratic vibronic constant Z (proportional to $\partial^2 \hat{V}/\partial Q_1 \partial Q_2$) is lower in comparison with B (proportional to $\partial^2 \hat{V}/\partial Q_2^2$) so that the prevailing of the $E_g - e_g$ vibronic coupling again is indicated.

The harmonic form of (1) or (4) leads to the following condition for the local energy minima

$$(\partial E_T/\partial R_a)_{R_e} = b + eR_e + 2cR_a = 0 \qquad (6)$$

so that an R_a vs R_e curve adopts a linear form:

$$R_a = -b/2c - R_e(e/2c) \qquad (7)$$

for fixed displacements of R_e. Since $e/2c = k_{ae}/k_{aa}$ is positive, the dependence is represented by a descending straight line. Analogically, the second dependence is obtained for fixed displacements of R_e:

$$R_a = -d/e - R_e(2f/e) \qquad (8)$$

Such a prediction is acceptable only in the nearest region of the energy minimum, because for larger displacements either $R_e \leq 0$ or $R_a \leq 0$ is obtained. In reality, the $R_e^{min} > 0$ occurs as square-planar complexes MF_4^{2-} (for $R_a \rightarrow \infty$) and $R_a^{min} > 0$ would lead to linear molecules MF_2 (for $R_a \rightarrow \infty$). Therefore, in order to obtain a correct form of the R_a vs R_e dependence at least the cubic or higher degree terms must be considered in the analytic form of APS.

Figure 2 represents the calculated dependence R_a vs R_e between the limiting MF_4^{2-} and MF_2 cases in the harmonic approximation. Also the experimental points (as they result from the X-ray structure data[20]) were included in Fig. 2. This leads to the previously reported finding[6] that the experimentally observed structures of tetragonal bipyramids are situated along the valley of the adiabatic potential surface. Thus an intrinsic disposition of the MX_6^{4-} type complex to undergo tetragonal distortions rather than to adopt an ideal octahedral configuration lies in the shape of APS. Interactions in the solid state probably amplify the manifestation of this disposition. The free-particle APS E_T is to be modified by an additional lattice potential V_L which depends on the crystal packing as well as on the quality of actual ions.[22] The most probable location of a minimum of $E_T + V_L$ lies along the valley of E_T, or in the other words, along the correlation curve R_a vs R_e. It cannot be ruled out that the free-parcicle distortions (like in the CuF_6^{4-} complex) owing to the local Jahn–Teller effect can be amplified by cooperative effects in the solid state.[3]

Finally, the energy partitioning (Fig. 3) shows that the ligand–ligand interaction E_{L-L} is insensitive to geometry changes. On the contrary, the metal-ligand interaction energy appears to be the crucial term in stabilizing the equilibrium geometry. This term consists of two contributions: the interaction energy of metal–equatorial ligands, E_{M-F_e}, and metal–axial ligands, E_{M-F_a}. These contributions exhibit a reciprocal dependence along the valley: the higher the first term, the lower the
Fig. 2. The R_a vs R_e dependence by the CNDO calculations. ●, experimental structure data; ○, calculated positions of energy minima for the free complex. (a) NiF_6^{4-}. (b) CuF_6^{4-}.

second term, and vice versa. This leads to the conception to consider the R_a vs R_e dependences as a consequence of the mutual influence of ligands mediated via the central atom,[23] in this particu-

lar case as a manifestation of the equatorial–axial influence.[5]

Fig. 3. The energy terms along the valley of APS. (a) NiF_6^{4-}. (b) CuF_6^{4-} in $^3A_{1g}$ state. (b) CuF_6^{4-} in ^2E_g state. The double minimum course of E_T for CuF_6^{4-} is not distinghished in the given scale.

APPENDIX

Complete vibronic coupling $E_g - (a_{1g} + e_g)$

The first-order perturbation theory yields an aditional term $\epsilon(Q)$ to the harmonic part of APS:

$$E_T(Q_1, Q_2, Q_3) = E_T(Q_1^0, Q_2^0, Q_3^0) + \tfrac{1}{2}K_aQ_1^2 + \tfrac{1}{2}(Q_2^2 + Q_3^2)K_e + YQ_1$$
$$- \sqrt{(A - ZQ_1)^2(Q_2^2 + Q_3^2) + B^2(Q_2^2 + Q_3^2)^2 + 2B(A - ZQ_1)Q_2(Q_2^2 - 3Q_3^2)}$$

$$E_T(Q) = E_T(Q_0) + \frac{1}{2}\sum_m K_mQ_m^2 + \epsilon(Q).$$

This is an eigenvalue of the 2×2 type of secular equation

$$\det(\mathbf{U} - \epsilon\mathbf{1}) = 0$$

where the perturbation covers linear and quadratic

terms of the Taylor expansion of the electron-nuclear operator $\hat{V}(q, Q)$:

$$U_{ij} = \left\langle \psi_i \right| \sum_m \left[\frac{\partial \hat{V}(q, Q)}{\partial Q_m}\right]_0 Q_m$$
$$+ \frac{1}{2}\sum_{m,n} \left[\frac{\partial^2 \hat{V}(q, Q)}{\partial Q_m \partial Q_n}\right]_0 Q_m Q_n \left| \psi_j \right\rangle$$

in the basis set of the electronic doublet ψ_i, $\psi_j \in E_g$. Considering only the a_{1g} (Q_1) and e_g (Q_2, Q_3) type of normal vibrations, for the matrix **U** it holds:

$$\mathbf{U} = X_aQ_1\mathbf{C}_1 + X_e(Q_2\mathbf{C}_2 + Q_2\mathbf{C}_3) + \frac{1}{2}X_{aa}Q_1^2\mathbf{C}_1$$
$$+ X_{ae}(Q_1Q_2\mathbf{C}_2 + Q_1Q_3\mathbf{C}_3) + v\frac{1}{2\sqrt{2}}X_{ee}$$
$$\times [(Q_2^2 + Q_3^2)\mathbf{C}_1 + (Q_3^2 - Q_2^2)\mathbf{C}_2 + 2Q_2Q_3\mathbf{C}_3]$$

where

$$\mathbf{C}_1 = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad \mathbf{C}_2 = \frac{1}{\sqrt{2}}\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}$$
$$\mathbf{C}_3 = \frac{1}{\sqrt{2}}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Here X_a and X_e are the linear vibronic constants and X_{aa}, X_{ee} and X_{ae} being the quadratic vibronic constants of the given type of symmetry (a_{1g} or e_g). The expression of $\langle \psi_i|[\partial^2\hat{V}(q, Q)/\partial Q_m\partial Q_n]_0|\psi_j \rangle$ type integral through a vibronic constant X_{ab} multiplied by a certain coefficient is based on the Wigner formula.[24]

The above equations may be re-written using the substitutions of

$$K_a = K_1 + X_{aa}/\sqrt{2}$$
$$K_e = K_2 + 2B$$
$$Y = X_a/\sqrt{2}$$
$$A = -X_e/\sqrt{2}$$
$$Z = X_{ae}/\sqrt{2}$$
$$B = X_{ee}/4$$

so that for an analytic form of APS the previously reported formula[19] (except the term containing Y) holds:

Using the polar coordinates of $\rho = (Q_2^2 + Q_3^2)^{1/2}$ and $\varphi = \text{arctg}(Q_3/Q_2)$ the vibronic correction term may be re-written as:

$$\epsilon(Q) = YQ_1 - \rho[(A - ZQ_1)^2 + B^2\rho^2$$
$$+ 2B(A - ZQ_1)\rho \cos 3\varphi]^{1/2}.$$

Within the $E_T(\rho, \varphi; Q_1 = \text{const.})$ picture such an APS

corresponds to a Mexican hat type function with warping. Notice, the direct product of two t-type vibrations (e.g. $t_{2g} \times t_{2g}$) yields a component within the e_g-type representation, so that some quadratic terms $\langle \psi_i | [\partial^2 V(q, Q)/\partial Q_m \partial Q_n]_0 | \psi_j \rangle$ for $Q_m, Q_n \in t_{2g}, t_{2u}, t'_{1u}, t''_{1u}$ are non-zero. Therefore, strictly speaking, an admixture of $E_g - (t_{2g} + t_{2u} + t'_{1u} + t''_{1u})$ coupling takes place.

For a vanishing coordinate Q_3 (the case of only a tetragonal distortion) it is valid that $U_{12} = 0$, so that the eigenvalues of the secular equation directly correspond to its diagonal elements U_{11} and U_{22}. Then the final formulae are obtained:

$$E_T^{(1)}(Q_1, Q_2, Q_3 = 0) = E_T(Q_1^0, Q_2^0) + YQ_1 + \tfrac{1}{2}K_a Q_1^2$$

$$+ AQ_2 - ZQ_1 Q_2 + \tfrac{1}{2}(K_e + 2B)Q_2^2$$

$$E_T^{(2)}(Q_1, Q_2, Q_3 = 0) = E_T(Q_1^0, Q_2^0) + YQ_1 + \tfrac{1}{2}K_a Q_1^2$$

$$- AQ_2 + ZQ_1 Q_2 + \tfrac{1}{2}(K_e - 2B)Q_2^2.$$

LIGAND EFFECTS ON THE REDOX POTENTIALS OF METAL CARBONYLS

RELATIONSHIP TO CO FORCE CONSTANTS IN MANGANESE(I) DERIVATIVES

J. W. HERSHBERGER and J. K. KOCHI*

Department of Chemistry, Indiana University, Bloomington, IN 47405, U.S.A.

Abstract—The reversible oxidation potentials E^0 of a single series of methylcyclopentadienyldicarbonylmanganese(I) derivatives η^5-MeCpMn(CO)$_2$L are measured for a wide variety of ligand types, including L = alkyl and aromatic amines, alkyl cyanide and isocyanide, alkene, alkyl and aryl phosphines and phosphites. The relationship of E^0 with the carbonyl force constants evaluated by the Cotton–Kraihanzel method is presented.

Oxidation and reduction are important properties of metal carbonyls since they can strongly influence the rates and course of reactions. For example, ligand substitutions and rearrangements of carbonylmetal derivatives have been shown to proceed rapidly when they are induced simply by either a one-electron oxidation or reduction.[1-5] As such, it is important to ascertain the functional relationship between the structure of metal carbonyl and its redox potential. Indeed Treichel *et al.*[6,7] recognized a linear relationship between the potential $E_{1/2}$ for the one-electron oxidation of a series of manganese carbonyls [Mn(CO)$_{6-n}$(CNR)$_n$]$^+$ with the number of alkyl and aryl isocyanide ligands varying from $1 < n < 6$. Moreover, Sarapu and Fenske[8] have analyzed the bonding properties of the methyl isocyanide and carbonyl ligands in [Mn(CO)$_{6-n}$(CNMe)$_n$]$^+$ for $0 < n < 6$ via approximate molecular orbital calculations, and have found that the values of $E_{1/2}$ do correlate extremely well with the calculated HOMO energies. It is noteworthy that they found the approximate force constants for the carbonyl stretching frequencies v(CO) evaluated by the Cotton–Kraihanzel method[9] to also correlate with the computed electron occupation of the carbonyl 5σ and 5π orbitals.

Similar relationships between the oxidation potential and the degree of substitution in the mixed carbonyl/acetonitrile complexes of chromium and tungsten, i.e. Cr(CO)$_{6-n}$(NCMe)$_n$ and W(CO)$_{6-n}$(NCMe)$_n$, have also been noted.[10,11] Several recent studies have discussed the correlation of the oxidation potentials of various metal carbonyl derivatives with the infrared data, particularly the carbonyl stretching frequencies.[12-18] Such studies have encompassed a variety of ligands, including such nitrogen-centred ones as dinitrogen, alkyl and aryl cyanides, ammonia, cyanide, thiocyanate, and azide, etc. in addition to carbon monoxide and the halides [12, 14]. The effects of phosphorus-centred ligands such as alkyl and aryl phosphines and phosphites on the potentials of metal carbonyls have also been examined.[15,16] In this context, the studies of Connelly and Kitchen[16] are particularly pertinent, since they showed that the oxidation potentials for the series of manganese carbonyls η^5-MeCpMn(CO)$_{3-b}$L$_n$ with L = phosphorus(III) alkyls, aryls, alkoxides, phenoxides, etc. were directly related to the Cotton–Kraihanzel force constants derived from the carbonyl stretching frequencies.

In order to examine the general effect associated with the use of a wide variety of ligand types on the oxidation potential of a metal carbonyl, we focussed our attention on the mono-substitution products of η^5-MeCpMn(CO)$_3$. The choice of this carbonylmetal system is particularly appropriate since the one-electron oxidation is usually reversible and allows the oxidation potential E^0 to be determined. Moreover, by focussing on a single carbonylmetal system, i.e. η^5-MeCpMn(CO)$_2$L we hoped to minimize ambiguities related to the evaluation of the force constants based on the Cotton–Kraihanzel method.[9]

EXPERIMENTAL

Synthesis of carbonylmanganese derivatives η^5-MeCpMn(CO)$_2$L

The monosubstituted carbonylmanganese derivatives η^5-MeCpMn(CO)$_2$L listed in Table 1 were prepared from η^5-MeCpMn(CO)$_2$(THF), which was generated *in situ* by irradiation of a solution of the parent tricarbonyl complex in tetrahydrofuran (THF) under argon.[19]

$$+ \quad \text{(1)}$$
The photochemical reactor consisted of a 300 cm^3 cylindrical flask with a 100 watt medium pressure Hg lamp contained in a quartz immersion well.

All preparative reactions and ligand exchange studies were carried out by benchtop manipulations under either a nitrogen or an argon atmosphere in Schlenk flasks. Many of the manganese complexes employed in this study are generally air sensitive, both in the solid state as well as in solutions. In a typical procedure, a solution of 2 g of (η^5-C$_5$H$_4$Me)Mn(CO)$_3$ in 300 cm^3 THF was deaerated, and irradiated for 50 min at 0°C. The IR spectrum of the solution indicated that ~90% of the starting material was converted to (η^5-C$_5$H$_4$Me)Mn(CO)$_2$(THF).[26] One equivalent of the appropriate ligand (L = py, MeCN, piperidine, PPh$_3$, P(C$_6$H$_4$Me-p)$_3$, P(C$_6$H$_4$Cl-p)$_3$ P(OMe)$_3$, P(OPh)$_3$, PEt$_3$, P(Me)Ph$_2$, P(OMe)Ph$_2$, CNCMe$_3$, Me$_2$-SO, AsPh$_3$, and SbPh$_3$) was added, and the solution stirred for several hours at ambient temperatures. During this period, the deep purple color of the tetrahydrofuran complex gave way to the yellow or orange color of the product. The THF was removed at reduced pressure, and the residue was taken up in ethyl ether. [When the product was not soluble in ether, chloroform was employed.] Filtration of the solution, followed by crystallization from a mixture of ether and hexane or chloroform and ethanol afforded crystalline products in 30–70% yield. For L = PEt$_3$ and P(OMe)$_3$, the products were oils, which were purified by chromatography on Florisil according to the literature description.[16] For L = SO$_2$, sulphur dioxide gas (1 atm.) was bubbled through the solution of (η^5-C$_5$H$_4$Me)Mn(CO)$_2$

‖The IR spectrum of this compound is reported in Ref. 26.

(THF) in THF with rapid stirring. The reaction was complete at room temperature within a few minutes. Crystallization of the product from a mixture of ether and hexane afforded orange crystals in 53% yield based on $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$. Since THF is not readily displaced from $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2(THF)$ by norbornene, $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2(norbornene)$ was prepared directly by the irradiation of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$ (2.0 g) in 300 cm³ of toluene containing a 20-fold excess of norbornene. The product was purified by crystallization from n-heptane, and obtained in 59% yield.

The microanalyses included in Table 1 were performed either by Midwest Microlabs, Ltd., Indianapolis, Indiana, or by Galbraith Laboratories, Inc., Knoxville, Tennessee.

The infrared spectra of the series of $\eta^5\text{-MeCpMn(CO)}_2L$ were measured in heptane solution on a Perkin–Elmer model 298 spectrophotometer.

Electrochemical measurements were performed on a Princeton Applied Research Model 173 potentiostat equipped with a Model 176 current-to-voltage converter, which provided a feedback compensation for ohmic drop between the working and reference electrodes. The high impedance voltage follower amplifier (PAR Model 178) was mounted external to the potentiostat to minimize the length of the connection to the reference electrode for low noise pickup. Cyclic voltammetry was carried out in a cell designed according to Van Duyne and Reilley.[27] The configuration of this cell is convenient for low temperature experiments since the lower portion of the cell containing the working solution could be easily submerged in the desired cold bath contained in a Dewar flask. The distance between the Pt electrode and the tip of the salt bridge was less than 2 mm to minimize ohmic drop. The reference electrode was isolated from the cold bath and maintained at room temperature ($\sim 25°C$). The voltammograms were recorded on a Houston Series 2000 X–Y recorder. CV scans were measured several minutes after agitation to ensure thermal equilibration. Electrode aging was not a serious problem in this study. Between experiments the platinum wire was soaked briefly in concentrated nitric acid, rinsed with distilled water, and dried at 110°C.

RESULTS AND DISCUSSION

The electrochemical behaviour of the manganese carbonyls in Table 1, was examined by cyclic voltammetry (CV) carried out at a stationary platinum microelectrode in acetonitrile solutions containing 0.1 M tetraalkylammonium perchlor-

ates as supporting electrolytes. The initial anodic scans for the cyclic voltammorgrams of the pyridine, triphenylphosphine, and carbon monoxide derivatives of $MeCpMn(CO)_2L$ in Fig. 1 are all characterized by ratios of the anodic and cathodic currents $(i_p{}^a/i_p{}^c)$ of unity and by anodic and cathodic peak separations $(E_p{}^a - E_p{}^c)$ of near 60 mV for reversible one-electron processes, i.e.

$$MeCpMn(CO)_2L \underset{}{\overset{E^0}{\rightleftharpoons}} MeCpMn(CO)_2L^+ + e^-. \quad (2)$$

Hereafter the average value $(E_p{}^a + E_p{}^c)/2$ will be taken as the measure of the oxidation potential E^0.[28]

The cyclic voltammetry of the piperidine and pyridine derivatives could not be examined in acetonitrile solutions owing to a rapid electrocatalytic ligand substitution described elsewhere.[29] Accordingly, the cyclic voltammograms for these complexes were recorded for acetone solutions containing 0.1 M TEAP. The difference in solvent effects between acetonitrile and acetone on E^0 for these complexes appears to be minimal since an examination of several alkyl and aryl phosphine and phosphite complexes indicated the values of E^0 to be virtually solvent independent.

The magnitude of the reversible oxidation potentials E^0 of the series of $MeCpMn(CO)_2L$ listed in Table 2 is strongly dependent upon the nature of the coordinated ligand L. Thus the nitrogen-centred ligands such as amines and nitriles effect the most negative values in the range, $-0.04\,V < E^0 < 0.19\,V$. The reversible potentials of alkyl and aryl phosphine complexes are clustered around 0.5 ± 0.1 V, but those of corresponding phosphites are significantly more positive. Among carbon-centred ligands, the values of E^0 become progressively more positive in the order: alkene (norbornene, 0.44 V) < isocyanide (tert-BuNC, 0.53 V) ≪ carbon monoxide (1.15 V). In-

[a] Cyclic voltammetry performed at a Pt microelectrode with solutions 10^{-3} M in substrate and 0.1 N in supporting electrolyte (tetraethyl-ammonium perchlorate for MeCN or acetone, tetrabutylammonium per-chlorate for THF or CH$_2$Cl$_2$). Unless otherwise noted, the scan rate was 100 mV s^{-1} and T = 22 °C. Potentials reported relative to the Cp$_2$Fe/Cp$_2$Fe$^+$ couple taken to have (E_p^{ox} + E_p^{red})/2 = 0.31 V in all solvents. [b] Scan rate = 50 mV s^{-1}, T = -55 °C. [c] Scan rate = 800 mV s^{-1}. [d] Scan rate = 200 mV s^{-1}, T = -50 °C. [e] Scan rate = 200 mV s^{-1}, T = -28 °C. [f] Scan rate = 30 mV s^{-1}. [g] Value difficult to reproduce owing to the rapid deactivation of the Pt electrode. Experimental error in voltage is ± 0.01 V. [h] Irreversible CV wave.

deed the potential of the carbon monoxide complex MeCpMn(CO)$_3$ is the most positive of the derivatives listed in Table 2. We can deduce from these trends that the ease with which various MeCpMn(CO)$_2$L are oxidized is qualitatively dependent on the σ-donor property of L and by its π-acidity. For example, among complexes with nitrogen ligands, E^0 becomes progressively more negative with increasing base strengths of L in the order: acetonitrile < pyridine ≪ piperidine. Moreover, we infer from the significantly more negative value of E^0 for MeCpMn(CO)$_2$-(CNBu-t) compared to the E^0 for MeCpMn(CO)$_3$ that the ligand basicities are in the order: t-butyl isocyanide > carbon monoxide, as elaborated by Sarapu and Fenske[8] for the series of Mn(CO)$_{6-n}$(CNMe)$_n^+$.

From the IR data presented in Table 1, we applied the method of Cotton and Kraihanzel[9] to derive the carbonyl force constants for these

carbonyl–manganese complexes. The derived force constants k(CO) are listed in Table 3, and they are plotted vs the reversible oxidation potentials in Fig. 2. The extensive scatter of the points indicate no general correlation of k(CO) with E^0 for this single series of carbonylmanganese derivatives. However a closer inspection reveals a limited correlation among the various phosphorus(III) ligands. Thus the arbitrary line drawn in Fig. 2 includes only those phosphine and phosphite ligands with a correlation coefficient of 0.86 [30]. The complexes derived from the nitrogen-centred ligands such as piperidine, pyridine and acetonitrile as well as the carbon-centred ligands such as t-butyl isocyanide, norbornene and carbon monoxide clearly lie beyond any reasonable relationship with those containing phosphorus(III) ligands.[31]

Relationship between E^0 of MeCpMn(CO)$_2$L and the Cotton–Kraihanzel carbonyl force constant for various ligands L containing phosphorus(III) centres, nitrogen centres (pip = piperidine, py = pyridine), and carbon centres as labelled. The least squares line is arbitrarily drawn only through the phosphorus(III) derivatives, see text.

Fig. 3. Comparative effects of phosphorus(III)-, nitrogen-, and carbon-centred ligands on E^0 on the series of MeCpMn(CO)$_2$L and (OC)$_5$CrL. [Data for t-Bu-NC(OC)$_5$Cr taken from Ref. 18.]

carbonyls with the Cr(CO)$_5$ moiety bound to a variety of ligands L are also known [3, 32]. Figure 3 shows the relationship between the oxidation potentials of the manganese dicarbonyls MeCpMn(CO)$_2$L with those of the corresponding chromium pentacarbonyls (OC)$_5$CrL for some of the representative ligands included in Fig. 2. The reasonable correlation is consistent with HOMO energies of both series of complexes which are affected in similar ways by amine, phosphine,

isocyanide and carbonyl ligands with different σ- and π-bonding characteristics. However the small slope indicates that the effect in the chromium carbonyls is attenuated to about a half of that in the manganese carbonyls. Thus the carbonyl force constants in (OC)$_5$CrL are also unlikely to be measures of their oxidation potentials when a broad series of donors are considered. In this connection, the recent empirical approach by Chatt et al.[13] to the prediction of redox potentials based on linear free energy relationships appears to be a more inclusive method.

30. The least squares slope is $1.14\,mdyn\,Å^{-1}\,V^{-1}$ with an intercept of $14.2\,mdyn\,Å^{-1}$.

31. The anodic CV peak potential E_p (measured at a scan rate of $100\,mV\,s^{-1}$) shows a similar correlation with k(CO), and includes all the derivatives listed in Table 1. The line for the phosphorus(III) ligands has a slope of $1.08\,mdyn\,Å^{-1}\,V^{-1}$ with an intercept of $14.1\,mdyn\,Å^{-1}$. The correlation coefficient of 0.94 is slightly better than that in Fig. 2.

Abstract—The d^5 low-spin Tc(II) complex trichloro-nitrosyl-bis(dimethylphenylphosphine)technetium(II) was studied by EPR at $295 \geqslant T \geqslant 27.2$ K. In the room-temperature spectrum well-resolved ^{99}Tc hyperfine splitting is observed indicating a ground state for the unpaired electron which is well separated from other orbital states. At low temperatures the spectrum can be fitted by an axial spin Hamiltonian. The analysis of the ^{99}Tc hyperfine splitting shows remarkable covalent interactions with the "in-plane" ligands. The ^{31}P superhyperfine splitting observed was used to get information about the overall spin density distribution in the molecular orbital of the unpaired electron.

Although coordination compounds of technetium have attracted a growing interest in view of the relevance to the field of nuclear medicine,[1] their chemistry is much less known than that of the corresponding neighbouring elements. This holds true especially for compounds in which Tc possesses low formal oxidation states. In addition, as found for nitrosyl-molybdenum(II) complexes[2] low-valent Tc nitrosyl complexes are expected to form highly active precatalysts for olefin metathesis.

In this paper we report an EPR study on the d^5 low-spin $(S = 1/2)$ complex trichloro-nitrosyl-bis (dimethylphenylphosphine) technetium (II), $TcCl_3(NO)(PMe_2Ph)_2$ (I). This study has been made to get some information about (a) the bonding situation in this compound and (b) the kind of EPR spectra to be obtained for the d^5 low-spin configuration of Tc^{2+}. There are very few well-characterized Tc(II) compounds only,[3-11] the first of which was prepared by Fergusson and Nyholm.[3] From some of the compounds—$[Tc(NH_3)_4(NO)(H_2O)]Cl_3$,[6] $[Tc_2Cl_8]^{3-}$,[9] —the EPR spectra of the undiluted isolated compounds were obtained. However, they consist of a broad unresolved line only. For $(n\text{-}Bu_4N)[Tc(NO)Br_4]$ and $(n\text{-}Bu_4N)_2[Tc(NO)(NCS)_5]$[10] the liquid-solution EPR spectra were obtained, but the spin Hamiltonian parameters were not given. Very recently, the first well-resolved frozen-solution EPR spectra were reported[11] for the Tc^{2+} low-spin complexes $[Tc(NH_3)_4(NO)H_2O]^{3+}$ and $[TcCl_5(NO)]^{2-}$. Ligand hyperfine interactions could not be detected. In addition, EPR spectra were reported for some compounds containing Tc in the oxidation states $+4$[12,13] and $+6$.[14,15]

Considering the radioactivity of Tc, EPR appears to be a very suitable method for investigating paramagnetic Tc complexes because only very small amounts of the compounds are needed. Nevertheless, Tc is one of the transition metals the EPR behaviour of which is almost unknown.

The preparation of (I) has not yet been reported in the literature, therefore, its synthesis will briefly be described in the experimental part.

EXPERIMENTAL

Synthesis of trichloro-nitrosyl-bis(dimethyl-phenylphosphine)technetium(II), $TcCl_3(NO)$ $(PMe_2Ph)_2$.

$TcCl_3(PMe_2Ph)_3$[16] (0.66 g = 1.06 mM) in benzene (120 cm^3) was boiled while NO was bubbled through the solution for 1 hr. Within 5–10 min the colour of the solution turned from orange to blue–green. After 1 hr the solvent was removed and the dark green oil was dissolved in 10 cm^3 CH_2Cl_2, filtered and treated with methanol (100 cm^3). After standing overnight black–green crystals of $TcCl_3(NO)(PMe_2Ph)_2$ were obtained. Yield: 340 mg (62%); m.p. 175–177°C. The compound can be recrystallized from CH_2Cl_2/CH_3OH.

Found: C, 37.4; N, 2.6; Tc, 19.2; Cl, 21.0. $C_{16}H_{22}Cl_3NOP_2Tc$ requires: C, 37.54; N, 2.73; Tc, 19.35; Cl, 20.79%. Vis. spectrum in CHCl$_3$: λ_{max} in nm (ϵ_{max} in 1 mol^{-1} cm^{-1}): 614 (930) and 710 (615) sh.

IR: in KBr, ν_{NO} 1770 and 1795 cm^{-1}; in CHCl$_3$, ν_{NO} = 1805 cm^{-1}.

EPR measurements. EPR spectra were recorded at room temperature, T = 130 and 27.2 K (using liquid neon) in the X-band ($\nu \approx 9.3$ GHz) with an E-112 spectrometer (Varian, U.S.A.). 10^{-3}–10^{-4} M solutions of $TcCl_3(NO)(PMe_2Ph)_2$ in CHCl$_3$ were used.

RESULTS

The X-band EPR spectrum of a CHCl$_3$ solution of (I) recorded at T = 295 K is shown in Fig. 1. It consists of 10 hyperfine lines resulting from hyperfine interaction with the ^{99}Tc nucleus (^{99}Tc, nuclear spin I = 9/2). The $m_I^{Tc} = \pm 1/2$ lines which are the smallest ones show the presence of further hyperfine interactions due to the ^{31}P ligand nuclei. However, this splitting is poorly resolved only.
Fig. 1. X band room-temperature EPR spectrum of $TcCl_3(NO)(PMe_2Ph)_2$ in CHCl$_3$.
Fig. 2. X band EPR spectrum of $TcCl_3(NO)(PMe_2Ph)_2$ in CHCl$_3$. T = 27.2 K.

In Fig. 2 the EPR spectrum of a frozen solution of (I) at T = 27.2 K is reproduced. The general features of the spectrum are characteristic for an axially symmetric, randomly oriented S = 1/2 system with parallel and perpendicular sets of ^{99}Tc hyperfine lines, as described by the spin Hamiltonian

$$\hat{H}_{sp} = \beta_e[g_{\parallel}H_z\hat{S}_z + g_{\perp}(H_x\hat{S}_x + Hy\hat{S}_y)] + A_{\parallel}^{Tc}\hat{I}_z\hat{S}_z$$
$$+ A_{\perp}^{Tc}(\hat{I}_x\hat{S}_x + \hat{I}y\hat{S}_y)$$
$$+ Q'\left[\hat{I}_z^2 - \frac{1}{3}I(I+1)\right], \qquad (1)$$

where $g_{\parallel}$, $g_{\perp}$, $A_{\parallel}^{Tc}$ and $A_{\perp}^{Tc}$ are the principal values of the $\tilde{g}$ and the ^{99}Tc hyperfine interaction tensor $\tilde{A}^{Tc}$ and Q' is the ^{99}Tc quadrupole coupling constant. These parameters were obtained by use of the usual second-order expressions;[17] Q' is small and was neglected. The $\tilde{g}$ tensor was found to be nearly isotropic within the experimental error.

In the parallel part of the spectrum the ^{99}Tc hyperfine lines are split into well resolved triplets (intensity ratio 1:2:1) arising from interaction of the unpaired electron with two equivalent ^{31}P nuclei of the phosphine ligands. ^{31}P superhyperfine splitting ("shfs") is also resolved in the perpendicular part of the spectrum. Some further resolution is to be seen on the parallel lines which should be due mainly to the interaction of the unpaired electron with the equatorial ^{35,37}Cl nuclei and, possibly, the ^{14}N nucleus of the NO ligand. Considering the linewidth this splitting was found to be smaller than 0.5 mT. The perpendicular part of the spectrum did not show any further resolution. The measured spin Hamiltonian parameters are listed in Table 1. No differences have been found between the parameters derived at T = 130 and 27.2 K.

Table 1. EPR Parameters† for $TcCl_3(NO)(PMe_2Ph)_2$ (Hyperfine coupling constants are given in $10^{-4}\,cm^{-1}$)

$\tilde{g}$	$\tilde{A}(Tc)$	$\tilde{A}(P)$
$g_{\parallel} = 2.045 \pm 0.003$	$A_{\parallel} = 214.8 \pm 2.0$	$A_{\parallel} = 23.6 \pm 1.0$
$g_{\perp} = 2.049 \pm 0.005$	$A_{\perp} = 89.2 \pm 5.0$	$A_{\perp} = 19.1 \pm 0.5$
$g_{av}\ddagger = 2.048$	$A_{av} = 131.1$	$A_{av} = 20.6$
$g_0 = 2.052 \pm 0.003$	$a_0 = 125.6 \pm 1.0$	

†Anisotropic data obtained from the 27.2 K spectrum; isotropic data (g_0, a_0) are measured at $T = 295$ K.

‡$g_{av} = (g_{\parallel} + 2g_{\perp})/3$, $A_{av} = (A_{\parallel} + 2A_{\perp})/3$.

DISCUSSION

The spectra observed are in agreement with what is expected for a Tc d^5 low-spin complex. The theory of EPR in the $d^5(t_{2g}^5)$ configuration was first put forward by Stevens[18] and then in more complete form by Bleaney and O'Brien.[19] The d^5 system is treated as a d^1 system via the hole formalism. The combined action of a low-symmetry ligand field and spin-orbit interaction resolves the sixfold degeneracy of the $^2T_2$ ground term producing three well-separated Kramers' doublets which can be written as follows[20] assuming tetragonal quantization as suggested by the structure of the complex under study:

$$-|1\rangle = \frac{1}{\sqrt{2}}(d_{xz} + id_{yz}) \tag{2a}$$

$$|-1\rangle = \frac{1}{\sqrt{2}}(d_{xz} - id_{yz}) \tag{2b}$$

$$\xi_1 = id_{xy} = \frac{1}{\sqrt{2}}(|2\rangle - |-2\rangle). \tag{2c}$$

The "effective" symmetry of the first coordination sphere of (I) can be assumed to be an axial one because of the symmetry of the tensor parameters $\tilde{g}$, $\tilde{A}_{Tc}$ of the spin-Hamiltonian observed experimentally (Table 1). Therefore, we are concerned with two different ground state situations depending on the sign and the magnitude of the ligand-field perturbation component: (a) the ground state is mainly determined by ξ_1 (2c), the other orbital states $(-|1\rangle, |-1\rangle)$ are much higher concerning their energy $(\gtrsim 10^4\,cm^{-1})$, (b) the unpaired electron occupies one of the orbital states (2a) or (2b) which are separated by spin-orbit interaction only, if axial symmetry will be assumed. Due to the magnitude of the spin-orbit coupling constant λ of Tc^{2+} $(\lambda(Tc^{2+}) = 850\,cm^{-1})$[21] case

(b) would result in a relatively small separation of (2a) and (2b) and, therefore, in short electron spin-lattice relaxation times for (I) not allowing the observation of well-resolved EPR spectra at room temperature. Therefore, according to the experimental results the ground state must be a Kramers' doublet which consists mainly of ξ_1 (2c). The assumption of a "d_{xy}" ground state is also in agreement with the ^{99}Tc hyperfine structure observed.

An interpretation of the $\tilde{g}$ tensor components in terms of molecular orbital coefficients is extremely difficult for the present case because there are more unknown quantities (ordering of energy levels and energy separations between the levels giving important contributions to the $\tilde{g}$ components, the large number of MO coefficients to be considered) than experimentally obtained ones. A comparison of the experimental spin Hamiltonian parameters with those calculated using the MO coefficients and transition energies obtained from semiempirical MO calculations (preferably Extended Hückel MO calculations) can be very helpful for these purposes.[22-24] However, good results are restricted to $3d$ metals; for $4d$ or $5d$ metals the discrepancies found are too large for a useful interpretation.[25,26] Therefore, in the following only the hyperfine interactions will be analyzed which are mainly magnetic in character allowing us to draw conclusive statements about the MO of the unpaired electron.

The ^{99}Tc *hfs* can be used to estimate the degree of covalency of the equatorial (x, y) Tc-ligand bonds. Applying the formalism given by McGarvey.[27]

$$A_{\parallel}(Tc) = -K - \frac{4}{7}\beta^2 P + (g_{\parallel} - g_e)P + \frac{3}{7}(g_{\perp} - g_e)P \tag{3a}$$

$$A_{\perp}(Tc) = -K + \frac{2}{7}\beta^2 P + \frac{11}{14}(g_{\perp} - g_e)P \tag{3b}$$

$$A_{av}(Tc) = -K + (g_{av} - g_e)P, \qquad (3c)$$

where K is a measure of the Fermi contact interaction and $P = (-)200 \times 10^{-4}\,cm^{-1}$,[27] one arrives at a value of $\beta^2 \approx 0.77$; $K = -141.1 \times 10^{-4}\,cm^{-1}$. β^2 is a measure of covalancy of the equatorial Tc-ligand bonds in the MO of the unpaired electron (contributions of the axial ligands to this MO are expected to be small because of symmetry considerations, therefore, they are neglected):

$$\psi_{MO} = \beta|4d_{xy}\rangle - \beta'|\phi_L\rangle. \qquad (4)$$

The value obtained for β^2 clearly indicates the presence of covalent interactions between Tc and the equatorial ligands.

Additional information about delocalization of "unpaired spin density" can be obtained from ligand hyperfine interactions. In the spectra a well-resolved *shfs* due to the ^{31}P nuclei of the phosphine ligands was observed which is predominantly isotropic in character. From the isotropic ^{31}P *shfs* the coefficient of the P 3s orbital "C_s" in the MO of the unpaired electron can be calculated. Using eqn (5) and $A_{av}(P)_{calc} = (8\pi/3)g_e g_N \beta_e \beta_N |\Psi_{3s}(O)|^2 = 3395 \times 10^{-4}\,cm^{-1}$,[28] C_s is found to be 0.078. This corresponds to a spin density of $C_s^2 \times 100 = 0.61\%$ in the phosphorus 3s orbital.

$$A_{av}(P)_{exp} = A_{av}(P)_{calc} \cdot C_s^2 \qquad (5)$$

In a similar way by means of eqn (6) the anisotropic part of the ^{31}P *shfs* can be analyzed to estimate the P 3p orbital contribution "C_p" to the MO of the unpaired electron.

$$A_{||}(P) - A_{av}(P) = \frac{4}{5}g_e g_N \beta_e \beta_N \langle r^{-3}\rangle_{2p} \cdot C_p^2. \qquad (6)$$

With $[A_{||}(P) - A_{av}(P)] = 3.0 \times 10^{-4}\,cm^{-1}$ and $\frac{4}{5}g_e g_N \beta_e \beta_N \langle r^{-3}\rangle_{3p} = 191.4 \times 10^{-4}\,cm^{-1}$[28] C_p is found to be 0.125. C_s^2 and C_p^2 can be used to estimate the hybridization degree "n^2" of the P 3s and 3p orbitals: $C_s^2/C_p^2 = (1 - n^2)/n^2$. A value of $n^2 = 0.72$ is obtained which is close to what is expected for sp^3 hybridization $[n^2(sp^3) = 0.75]$. This value, however, can be considered as being a rough estimation only because a correction concerning the contribution of the dipolar term $A_d(P) = g_e g_N \beta_e \beta_N / R^3$ (R = Tc–P bond length) has not been made; although, assuming $R \approx 230\,pm$ a value of $A_d^P \approx 0.85 \times 10^{-4}\,cm^{-1}$ will be calculated. A more detailed consideration appears to be not useful because of the magnitude of the experimental error which is $\pm 1.0 \times 10^{-4}\,cm^{-1}$. In contrast to this the C_s value derived from the isotropic

^{31}P *shfs* can be considered as being a good one because of the magnitude of $A_{av}(P)$ much exceeding that of the experimental error.

The predominantly isotropic character of the ^{31}P *shfs* tensor is not unexpected for the complex under study. The ^{13}C *shfs* tensors observed in a single-crystal study for the equatorial CN^- ligands of the d^5 low-spin π acceptor complex $[Cr(CN)_5NO]^{3-}$ the bonding properties of which should be closely related to those of $TcCl_3(NO)(PMe_2Ph)_2$ show a similar behaviour.[29] However, the contribution of the C 2s orbitals to the MO of the unpaired electron—$C_s \approx 0.1$—is found to be larger than that derived for the corresponding P 3s orbitals of (I) indicating more covalent interactions in $[Cr(CN)_5NO]^{3-}$. Unfortunately, for $[Mn(CN)_5NO]^{2-}$ which would be of most interest for comparison purposes, ^{13}C data are not available.[30] A comparison[23] of the electronic structures and the magnetic hyperfine interactions analyzed for the d^5 isoelectronic sequence of pentacyanonitrosyls from vanadium to iron indicates a decrease of spin delocalization as one moves from left to right in the periodic table.

It should be noted, that in the parallel part of the frozen solution EPR spectrum poorly resolved hyperfine interactions due to the $^{35,37}Cl$ nuclei and (less probably) the ^{14}N nucleus of the NO ligand could be detected. Assuming the extent of electron spin delocalization to the chlorine and the phosphine ligands to be of a similar magnitude a value of $A_{av}(Cl) \approx 9 \times 10^{-4}\,cm^{-1}$ will be expected. The actual isotropic $^{35,37}Cl$ splitting is smaller than the predicted one. Due to the less pronounced π acceptor properties of the Cl ligand with respect to PRR$_2'$ this is not unexpected. A contribution of the dipolar part to the $^{35,37}Cl$ *shfs* can be neglected because of its smallness. Considering the ^{14}N *shfs* detected for $[Mn(CN)_5NO]^{2-}$,[30] the corresponding isotropic value for (I) should not exceed $4 \times 10^{-4}\,cm^{-1}$. This value is smaller than that estimated for $A_{av}(Cl)$, therefore, the ^{14}N *shfs* is not expected to be resolved in the spectra of $TcCl_3(NO)(PMe_2Ph)_2$. *Shfs* interactions due to $^{35,37}Cl$ and/or ^{14}N were also not observed in the spectra obtained for $[Tc(NO)Cl_5]^{2-}$ and $[Tc(NH_3)_4(NO)H_2O]^{3+}$ recently reported.[11]

More insight in the bonding situation of $TcX_3(NO)(PR_3)_2$ complexes could be obtained if complexes with $X = Br$ (the $^{79,81}Br$ *shfs* coupling constants are expected to be larger by a factor 4 or 5 than the $^{35,37}Cl$ splittings because of the larger nuclear magnetic moments of $^{79,81}Br$) or diamagnetically diluted single-crystals of (I) would be available. However, we did not succeed in preparing $TcBr_3(NO)(PR_3)_2$, and single-crystals of (I)

could not be grown because of the lack of a suitable host lattice.

ON THE NET CHARGES IN CYCLOPENTADIENYL METAL COMPOUNDS

NATALIYA A. OGORODNIKOVA and AVTANDIL A. KORIDZE*

A. N. Nesmeyanov Institute of Organo-Element Compounds, Academy of Sciences,
Vavilov Street 28, Moscow, U.S.S.R.

Abstract—An attempt was made to estimate the net charges of a number of cyclopentadienyl metal compounds on the basis of ^{19}F NMR data for p-fluorophenylcyclopentadienyl metal compounds. The investigated compounds can be clearly divided into four groups according to the polarity of metal–cyclopentadienyl bond: covalent compounds (derivatives of Fe, Ru, Os, Rh and Pd) with a net charge on the η-C_5H_5 ring in the range from -0.19 to -0.29, the so-called ionic compounds (derivatives of Li, Na and K) with a net charge on the ring $-0.64 \div -0.72$, and compounds with an intermediate character of the bond (derivatives of Cu, Mg and Tl) with a net charge of $-0.44 \div -0.46$; the net charge on the rings of cyclopentadienyl manganese tricarbonyl and -rhenium tricarbonyl is near to zero. When the effective charge on the ring is near -0.44 the cyclopentadienyl metal compounds are able to dissociate into ions in solution.

The problem of the net charges even in a such well studied molecule as ferrocene has for a long time been a subject of some controversy. According to various quantum-chemical calculations the values of the net charges vary largely not only in absolute values but in sign as well, from -0.64 to $+1.80$ (see data summarized in Ref. 1).

In previous works we investigated m- and p-fluorophenylcyclopentadienyl compounds of transition and non-transition metals by ^{19}F NMR technique and estimated the electronic effects of the corresponding metal cyclopentadienyl groups as substituents in the benzene ring.[2] We studied in detail the effect of alkali metal cation, the coordinating ability of the solvent, complexing agents (TMEDA, crown-ethers), and concentration on the equilibrium between tight and solvent separated ion pairs. On the basis of data obtained for $LiC_5H_4C_6H_4F$-$m(-p)$ and $NaC_5H_4C_6H_4F$-p in hexamethylphosphoramide (HMPA) solution, electronic effect of the $C_5H_4^\ominus$-substituent as a "free ion" has been determined.[2b]

In this paper we attempt to estimate the metal–cyclopentadienyl bond polarity, based on the ^{19}F NMR data of respective fluorophenylcyclopentadienyl organometallic compounds.

RESULTS AND DISCUSSION

Our approach to estimating the net charges in cyclopentadienyl metal compounds on the basis of ^{19}F NMR data of p-fluorophenylcyclopentadienyl derivatives is based on a known linear dependence between calculated charge densities in fluorobenzenes and their ^1H, ^{13}C and ^{19}F NMR chemical shifts.[3] Thus, there is a correlation between ^{13}C chemical shifts of para-carbon atom in monosubstituted benzenes and total electron density on the carbon atom,[3a] excellent correlation between ^{19}F chemical shifts in p-fluorosubstituted benzenes and ^{13}C chemical shifts of para carbon atom in substituted benzenes[3a] and correlation between ^{19}F chemical shifts and p-^{13}C–F chemical shifts in p-fluorosubstituted benzenes.[3a]

Therefore to plot a linear dependence of the net charges on fluorine screening in p-fluorophenylcyclopentadienyl derivatives of metals, it is necessary to have data on charge distribution at least in two such derivatives. The two simplest systems were chosen: "free" p-fluorophenylcyclopentaidenyl anion[2b] and its lithium derivative.

The choice of lithium cyclopentadienyl as one of the reference system is based on the assumption that the extent of charge separation in LiC_5H_5 when going from common solvents (ethers, acetonitrile) to isolated molecule is only slightly changed. Such assumption is substantiated by the

following experimental data. The ^{19}F chemical shifts in lithium p-fluorophenylcyclopentadienyl are independent of concentration and are practically the same for such solvents as acetonitrile and THF,[2b] that have different donor centers, different "donor number" and dielectric constants. The ^{13}C chemical shifts of lithium cyclopentadienyl in these solvents, 103.8 ppm in CH_3CN, 103.2 ppm in THF,[4] and 103.59 ppm in 3:1 mixture of dimethoxyethane–deuterobenzene[5] practically coincide. The $^1J(^{13}C, \, ^1H)$ coupling constants of lithium cyclopentadienyl in these solvents, 159.5, 159.6 and 159.4 Hz respectively,[4,5] are also practically the same.

One more evidence follows from the analysis of ^{7}LiNMR data[6] according to which the ^{7}Li chemical shift of lithium cyclopentadienyl in dioxane, THF, dimethoxyethane and diglyme is essentially constant, $8.35 \div 8.68$ ppm. In this respect lithium cyclopentadienyl differs from all other studied carbanions (1-phenylallyl, 1,3-diphenylallyl, triphenylmethyl, indenyl, fluorenyl),

---

†In calculations we used known data on electron affinity values, determined by minimum energy of the electron detachment from a negative ion (Table 2).

for which the range of ^{7}Li chemical shifts in these solvents exceeds 8 ppm (from 0.66 to 8.99 ppm).

To calculate the net charge in the lithium cyclopentadienyl molecule we used eqn (1), obtained by Matcha and King[7] for determining the effective charge transfer of atoms in alkali metal halides:

$$f = 0.974448 - 0.00435(IP_m - EA_x). \qquad (1)$$

Here IP_m is the ionization potential of the metal and EA_x represents the halogen electron affinity.

First of all it was necessary to check the validity of eqn (1) for evaluating the net charges in organometallic compounds for which quantum-chemical data is available.

Table 1 lists the net charges for isolated molecules of organic derivatives of the alkai metals, calculated according to eqn (1).† The polarity of metal carbanion bond in benzyl, cyclopentadienyl and ethynyl compounds of alkali metals is higher than that of the metal–hydrogen atom bond in metal hydrides. Metal acetylides appear to be the most polar from all the listed compounds, being similar in polarity with alkali metal iodides.[7]

To our knowledge data on molecular orbital calculations of the net charges for organic deriva-

tives of Na, K, Rb and Cs are not available. The results of available calculations of the extent of charge separation in organolithium compounds are listed below.

With methyllithium the following values of the net charges on Li atom have been estimated: + 0.37,[8a] + 0.14,[8b] + 0.35,[8c] + 0.56[8d] (ab initio), + 0.37[8e] and + 0.45.[8f] The value + 0.48 (Table 1) obtained by the eqn (1) is in a good agreement with the majority of theoretical data. The net charge + 0.74 on Li atom in ethynyllithium, evaluated by the equation (1), coincides with the calculated charges +0.74[9a] and + 0.78[9b] (ab initio). In the case of allyllithium the calculated values of the effective charges on Li atom are +0.44,[10a] +0.16[10b] (ab initio), and + 0.12[10c] as compared with +0.52 value found by eqn (1). Thus the values of net charges obtained by eqn (1) for various organolithium compounds are in agreement with the available theoretical data.

On this basis we assumed the value − 0.64 calculated by eqn (1) for the net charge of the ring in lithium cyclopentadienyl (this value corresponds to ^{19}F chemical shift 11.1 ppm of lithium p-fluorophenylcyclopentadienyl[26]) and the value

− 1.0 corresponding to the fluorine chemical shift 17.9 ppm of lithium (sodium) p-fluorophenylcyclopentadienyl in HMPA ("free" cyclopentadienyl anion).[2b] So we obtained the relationship (2) defining the dependence of a bond polarity of cyclopentadienyl metal compounds on fluorine chemical shift in corresponding p-fluorophenyl derivatives

$$f = 0.05 - 0.053(\delta\,^{19}\mathrm{F}) \qquad (2)$$

where f is the net charge of cyclopentadienyl ring (in a.u.) and $\delta\,^{19}$F denotes fluorine NMR chemical shift in ppm relative to fluorobenzene.

In accordance with the relationship (2) the net charge of cyclopentadienyl ring in ferrocene is equal to − 0.26 and consequently the iron atom has partial charge of + 0.52 (Table 3). This value is in a good agreement with calculated + 0.682[11]. The net charges on Ru and Os atoms in ruthenocene and osmocene only slightly differ from the charge on the iron atom in ferrocene.

As it is seen from Table 3 the data for metallocenes of the iron subgroup are in a good agreement with the results obtained by Alexanyan et al.[12] in studying the extent of charge separation

Table 3. Effective charges (atomic units) in cyclopentadienyl compounds of metals and ^{19}F NMR chemical shifts in their p-fluorophenyl derivatives

Compound	^{19}F NMR chemical shifts[a]			Effective charges

[a] Recorded for $\sim 0.1M$ solutions in ppm relative to C_5H_5F, the positive sign indicates the shift into strong field.

[b] Adopted on the basis of measurement of ^{19}F NMR chemical shifts of p-fluorophenylcyclopentadienyl compounds of Li and Na[2b],^{7}Li NMR chemical shifts of LiC_5H_5[6], ^{13}C NMR chemical shifts and $^{13}C,^1H$ coupling constants in LiC_5H_5 and NaC_5H_5[4].

[c] Calculated by equation (1).

through analysis of absorption band intensities in vibrational spectra of sandwich compounds. The authors came to a conclusion that the bond polarity in all studied systems (bis-cyclopentadienyl derivatives of Mg, Ca, V, Cr, Mn, Fe, Co, Ni, Ru and Os) for both covalent compounds and compounds traditionally considered as ionic (derivatives of Mg, Ca and Mn) do not exceed 0.6. Unfortunately this technique does not permit a determination of the sign of the charge on the metal.

In the case of monocyclopentadienyl organometallic compounds containing other ligands as well, our approach can only help to evaluate the net charge in the ring. As it is seen from Table 3 the polarity of palladium–cyclopentadienyl and rhodium–cyclopentadienyl bonds in $Pd(C_5H_5)$ (C_3H_5) and $Rh(dien)(C_5H_5)$ complexes is closely similar to that in ferrocene, ruthenocene and osmocene. The charge of the ring in cyclopentadienyl manganese tricarbonyl and -rhenium tricarbonyl is close to zero just as in iron protonated ferrocene and $Mo(C_5H_5)_2(NO)I$.

The organometallic compounds $Cu(C_5H_5)$ (PEt$_2$Ph), $Mg(C_5H_5)Br$ and TlC_5H_5 occupy the intermediate position between the covalent derivatives of iron, ruthenium, osmium, rhodium and palladium on the one hand, and mostly ionic derivatives of alkali metals on the other hand; the net charge of the ring in these compounds is practically the same -0.45, -0.46 and -0.44 respectively.

The stereochemical approach used in our earlier work[2a] (it consists in a comparative ^{13}C NMR study of diastereotopy of cyclopentadienyl carbons in $TlC_5H_4CH(Me)Ph$, $KC_5H_4CH(Me)Ph$, and $Fe(C_5H_5)C_5H_4CH(Me)Ph$) reveals that the thallous compound in THF solution is predominantly in the form of tight ion pairs. Thus beginning with the net charge in the ring of -0.44 the cyclopentadienyl derivatives of metals may dissociate into ions in solutions.

The net charge values obtained for cyclopentadienyl compounds of metals are in a good agreement with the relative reactivity of these compounds and with their physical properties and calculated characteristics.

It should be noted that neither our conclusions

nor our quantitative appraisals are significantly changed when other reference points and other solvents are used to plot the straight line. The absolute value of the net charge of cyclopentadienyl ring in ferrocene molecule according to the relationship obtained from the value of fluorine chemical shift of "free" anion and passing through zero (fluorobenzene), is only 0.04 less than the value 0.26 adopted in discussion. With relationship obtained from fluorine chemical shifts of "free" anion and $LiC_5H_4C_6H_4F\text{-}p$ in acetonitrile this value is higher by 0.06.

Thus, on the basis of ^{19}F NMR data for p-fluorophenylcyclopentadienyl metal compounds an attempt was made to evaluate the net charges of a number of cyclopentadienyl metal compounds. According to the polarity of metal–cyclopentadienyl bond the investigated compounds can be divided into four groups: covalent compounds (derivatives of Fe, Ru, Os, Rh and Pd) with the partial charge on C_5H_5 ring in the range from -0.19 to -0.29; the so-called ionic compounds (derivatives of Li, Na and K) with a charge on the ring from -0.64 to -0.72, and compounds with an intermediate character of the bond (derivatives of Cu, Mg and Tl) with a charge on the ring close to -0.45; the net charge of the ring in cyclopentadienyl manganese tricarbonyl and -rhenium tricarbonyl is near to zero. The cyclopentadienyl derivatives of metals may dissociate into ions in solutions when the effective charge on the ring is close to value of -0.44.

THE SOLUBILITY OF URANIUM(IV) HYDROUS OXIDE IN SODIUM HYDROXIDE SOLUTIONS UNDER REDUCING CONDITIONS

JACK L. RYAN* and DHANPAT RAI
Pacific Northwest Laboratory, P.O. Box 999, Richland, WA 99352, U.S.A.

Abstract—The solubility of hydrous UO_2 in sodium hydroxide solutions containing sodium dithionite and/or Zn metal powder as reductants has been measured. The results provide no firm evidence for any amphoteric behavior of U(IV) but do set an upper limit of $K \leq 2 \times 10^{-23}$ for the hypothetical reaction:

$$U^{4+}(aq) + 5H_2O \rightleftharpoons U(OH)_5^- + 5H^+.$$
The results provide no evidence for such a reaction.

The hydrolysis behavior of metal cations is a field about which a very large degree of uncertainty exists. In particular, much of the experimental data[1] are highly questionable because of inadequate or improper experimental technique, sparcity of data points, and wide scatter in the data. Often later authors have used such poor or limited experimental data to arrive at conclusions different from and often much beyond those that the original authors were willing to make. An example of this is the calculation of the formation constants of the lanthanide tetrahydroxo complexes[1] from data on the solubility of the $Ln(OH)_3$ in NaOH solutions in which some of the original workers indicated that the experimental results were not adequate for any calculation of species formed[2] and from data of other workers that clearly does not show such a dependence of solubility on NaOH concentration or mean ionic activity[2-4] as to be able to conclude that the $Ln(OH)_4^-$ ions are even being formed.

The solubilities of the actinides at near neutral pH values are of particular importance to the geological disposal of nuclear waste. In particular, the solubility of tetravalent actinides is of importance under the reducing conditions expected in several of the proposed repository environments such as deep basalt or granite. Under these conditions, tetravalent species of U, Np and perhaps Pu become important. There has been a large effort exerted towards prediction of solubilities and modeling of actinide migration behaviour on the basis

of hydrolysis and complex formation equilibria. Much of this equilibrium hydrolysis data has come from limited and poor experimental results or has been estimated by extrapolation from other hydrolysis constants of the same metal ions by what might be considered reasonable but certainly unproven methods.

Specifically, with the tetravalent actinides, almost all of the hydrolysis data for mononuclear species beyond the MOH^{3+} species is based on old and questionable work by Gayer and Leider[5] on the solubility of what they called uranium (IV) hydroxide [actually hydrous U(IV) oxide.[6] Hydrous U(IV)oxide, $UO_{2(am)}$, is *very* easily air-oxidized, and their preparation and handling of the material leaves considerable doubts that they measured U(IV) in solution at all. In addition, their solutions were settled for 3–5 days without filtration. (It is the present authors' observation that centrifuging at 1500 G for up to 1 hr will not totally remove the Tyndall Effect from even fresh suspensions of crystalline UO_2.) They measured U concentrations at six NaOH concentrations, and after discarding two data points that did not fit their conclusions, used only four points to arrive at a first power dependence on OH^- concentration (0.14 to 0.48 M) and calculated an equilibrium constant for formation of $H_3UO_4^-$. Baes and Mesmer[1] assumed this species to be $U(OH)_5^-$ instead of $H_3UO_4^-$ and, making the totally erroneous assumption that Gayer and Leider had used $UO_2(c)$ instead of amorphous hydrous UO_2 (referred to as "$U(OH)_4$" by gayer and Leider,[5] calculated the fifth hydrolysis constant of U(IV). Then, using measured values for the first hydro-

lysis constant and the perhaps not completely unreasonable but certainly completely unproven assumption that the logarithms of the stepwise hydrolysis constants are linear with respect to the number of hydroxide ions, they calculated values for the formation constants of the $U(OH)_2^{2+}$, $U(OH)_3^+$, and $U(OH)_4(aq)$ species. Actually such a concept could be very strongly questioned on several grounds such as for example the fact that there certainly does not appear to be a uniform progression in the hydrolysis of the actinide M^{5+} or M^{6+} ions where *very* strong hydrolysis to the MO_2^+ and MO_2^{2+} ions occurs with little apparent stability for less hydrolyzed species along with a much lower tendency to further hydrolysis. In fact, the tendency of pentavalent and hexavalent actinides to form oxo rather than hydroxo species, and the fact that the tetravalent actinides precipitate as hydrous oxides rather than hydroxides[6] raises a question of whether complexes such as $U(OH)_4(aq)$ and $U(OH)_5^-$ exist at all.

Langmuir[7] repeated the same hydrolysis constant estimates for U(IV) made by Baes and Mesmer[1] including the erroneous assumption that there was no free energy change in forming $UO_2(c)$ from the amorphous "$U(OH)_4$" solid used by Gayer and Leider.[5] He calculated free energies of formation for $U(OH)_2^{2+}$, $U(OH)_3^+$, $U(OH)_4(aq)$, and $U(OH)_5^-$. It is interesting that Langmuir made the opposite assumption further on in his paper[7] to conclude that $UO_{2(am)}$, which is indeed the same as "$U(OH)_4$," is at least 7.6 kcal/mole less stable than $UO_2(c)$ and may more likely be 12.8 kcal/mole less stable. These erroneous formation constants[7] have been further used,[8] apparently without critical review, to calculate the solubility of amorphous UO_2, as a function of pH. The preposterous conclusion, in terms of well-known U(IV) chemistry, was reached and published[8] that uranium solubility at low (10^{-80}) oxygen fugacity would increase above about pH 4.5 reaching 1 g/L at pH 9.8, and 10 g/L at pH 10.8. Such conclusions appear to be the result of a total loss of contact with the reality of known actinide behaviour and a total preoccupation with the computer manipulation of formation constant data without regard to its validity.

Others[9-12] have repeated similar estimates of U(IV) hydrolysis constants or free energies of formation often giving additionally estimates of entropies, extrapolating to other tetravalent actinides, or giving values as a function of ionic strength. Most of these values are the same or very near those reported by Baes and Mesmer[1] and are based on the limited and questionable results of Gayer and Leider.[5]

Tremaine et al.[13] have made a careful attempt to measure the solubility of $UO_2(c)$ under non-oxidizing conditions at high pH. They used de-aereated and H_2 saturated LiOH solutions (about 0.003 and 0.04 M) in a flow apparatus with concentration of U by ion exchange followed by neutron activation analysis. Their U solubilities were in the range of about 5×10^{-8} to $1.7 \times 10^{-7} M$ (seventy-fold lower than the values predicted for these OH$^-$ concentrations for $UO_2(am)$ by Gayer and Leider's[5] results). Their U analyses were apparently near their detection limit due to ^{18}F interference which is directly proportional to the LiOH concentration. Also, they have shown[13] by X-ray photoelectron spectra that during their flow solubility runs below 150°, oxidation of the UO_2 surface beyond the initial 0.3 U(VI)/U(IV) (corresponding to two monolayers of UO_3) occurred up to at least 0.76 U(VI)/U(IV). Their solutions apparently also contained somewhat less than 1% carbonate relative to hydroxide, and they showed based on literature stability constants, that at $10^{-8} M$ CO_3^{2-} and 10^{-5} atm O_2 the U(VI)/U(IV) ratio in solution should be 10^7. Despite this, they have interpreted their results based on only two OH$^-$ concentrations in terms of the predominant solution species being $U(OH)_5^-$. It is our opinion that they cannot possibly have measured U(IV) solubility as long as U(VI) solid is clearly present, and it is known that U(VI) has a solubility of $\geq 10^{-3} M$ in LiOH solutions in this concentration range[14] (as it also has in $(C_3H_7)_4NOH$[15] and $(C_4H_9)_4NOH$[16] solutions).

The present work reports results of a study of the solubility of amorphous, hydrous UO_2 under anoxic, reducing, alkaline conditions at 25°. Sodium dithionite and metallic zinc were used as reductants in this study.

EXPERIMENTAL

Reagents

Water was in all cases deaerated by boiling following by thorough sparging at 25° with Ar($> 99.99\%$). A new bottle of reagent grade pellets of NaOH was opened in an Ar atmosphere, and a stock 10.5 M NaOH solution was prepared under Ar. An analysis showed 0.0152 M carbonate. A 7.5% excess of $BaCl_2$ was added, and the closed container was allowed to stand for two weeks under Ar to achieve complete precipitation and settling of the $BaCO_3$. Sodium dithionite was from Sigma Chemical and a 1 M stock solution was prepared under Ar immediately before it was used to make up the first series of solubility solutions.

U(IV) stock solution was prepared by dissolving Hanford reactor grade uranium metal in 12 M HCl (initially with solution cooling but finally with heating to 100°). The hot solution was centrifuged while slow H_2 evolution was still occurring from black residues. The solution (~ 500 g U(IV)/L and ~ 2 M HCl) was then filtered through an 250 nm Millipore Solvinert filter and stored under Ar.

General procedure

All solutions were made up and handled in an Ar atmosphere, and all solution containers were kept closed except for the minimum times necessary for makeup and sampling. Sodium hydroxide solutions (20 cm^3) were made by dilution of the stock solution, followed immediately by addition of reductant, and then of the U(IV) solution. The total U present was 0.25 mg/cm^3, and by adding it as such a concentrated stock solution, its precipitation and the neutralization of excess acid would be expected to consume only 0.005 M OH$^-$, which is 10% of the lowest hydroxide concentration used. All the sealed containers of solution plus hydrous UO$_2$ were shaken vigorously for 13 or 16 days at room temperature (21 $\pm$ 2°). At the end of this equilibration period, the still-sealed containers were centrifuged for 30 min at > 1000 G. Each container was then opened under Ar and the supernatant solution was quickly sampled by syringe. A membrane filter was immediately attached to the syringe, and the solution forced slowly through the filter. The filters in all cases except the ≥ 10 M NaOH solutions were Nuclepore Ultrafilter®, Type F, No. 1F7257, which has a 20,000 molecular weight cutoff for globular proteins (~ 2 nm pore size), and is resistant to OH$^-$ solutions. Insufficient flow of ≥ 10 M NaOH could be obtained with this filter, and Millipore Solvinert® filters UGWP with 250 nm pore size were used for these solutions.

Uranium analysis

Uranium analyses were made by laser-induced fluorescence using a Scintrex® model UA-3 uranium analyzer with the known addition technique.[17,18] The samples were pretreated by addition of excess NaOCl (while still basic so that the dithionite would not decompose before it was oxidized) and were then acidified and, except for the samples containing only Zn as reductant, taken to dryness. The residues (principally Na salts) were taken up in dilute HNO$_3$ and analyzed. The samples containing Zn only as reductant showed a high fluorescence before addition of the buffered complexant used in the method if they had been dried so were taken only to near dryness. The principal

purpose of the drying was to remove excess acid to avoid over-consuming the buffering capacity of the complexant.

Known U standards were, after addition of NaOH, Na$_2$S$_2$O$_4$, etc. taken through the above procedure with accurate recovery. These standards and those used in the known addition technique were prepared from NBS uranium metal standard. Reagent blanks corresponding approximately in composition to some of the samples yielding results below 10^{-8} M were run and gave approximately 80% of the sample values (instrument scale readings were also very low for these) indicating that the true values for samples below 10^{-8} M are in all cases less than those shown.

RESULTS AND DISCUSSION

Tremaine, et al.[13] have estimated, based on earlier stability constant estimates[19] using the Gayer and Leider[5] data for U(OH)$_5^-$, that $K = 3 \times 10^{55}$ for the reaction:

$$U(OH)_5^- + CO_3^{2-} + \tfrac{1}{2}O_2 + 3H^+ \rightleftarrows UO_2CO_3(aq) + 4H_2O. \quad (1)$$
A reasonable estimate for the carbonate concentration at their highest LiOH concentration (0.04 M) would be about 2×10^{-4} M. This would mean that an O$_2$ fugacity of less than 10^{-26} would be required to maintain a U(VI)/U(IV) ratio of one in solution. Any lower stability of U(OH)$_5^-$ (as reflected by lower U(IV) solubility) would lower the required O$_2$ fugacity by two orders of magnitude for each order of magnitude lower U(IV) solubility. This alone points to the impossibility of Gayer and Leider's results being correct since they used no reductant for O$_2$ removal at all. It is also extremely improbable that the H$_2$ used by Tremaine et al.[13] could be a kinetically sufficient reductant to achieve such low fugacities, especially at temperatures below 150°C.

The dithionite ion is known to be a strong reductant with $E_B^\circ = 1.12 V$[19] for the reaction:

$$S_2O_4^{2-} + 4OH^- \rightleftarrows 2SO_3^{2-} + 2H_2O + 2e^-. \quad (2)$$
It is known that alkaline dithionite solution reacts with oxygen rather rapidly,[20] and it was found that when 1–10 g U(VI)/L solutions in (C$_3$H$_7$)$_4$NOH were warmed with dithionite (or the related Rongolite), reduction and precipitation of U(IV) hydrous oxide occurred. Based on the above potential, it can be shown that the thermodynamic equilibrium oxygen fugacity in NaOH solutions above 0.01 M and containing 50% oxidized dithionite would be below 10^{-90}. Zinc metal is slightly

more reducing with $E_B^\circ = 1.216V^{19}$ for the reaction:

$$Zn + 4OH^- \rightleftarrows ZnO_2^{2-} + 2H_2O + 2e^- \qquad (3)$$
and the ZnO_2^{2-} ion is sufficiently stable[19], with $K = 1 \times 10^{-29}$ for:

$$Zn(OH)_2 \rightleftarrows ZnO_2^{2-} + 2H^+ \qquad (4)$$
to maintain small amounts of Zn in solution and not form $Zn(OH)_2$ at the OH^- concentrations of interest here. Zn metal will also thermodynamically keep O_2 fugacity below 10^{-90} above $0.01\ M$ NaOH, but because it is a solid may not be kinetically adequate. Using the reductants discussed above, solubility measurements were made in three series of solutions. The principal series was in dithionite solution while fewer measurements were made with zinc metal or zinc metal plus dithionite.

Carbonate was removed from the stock $10.5\ M$ NaOH with $BaCl_2$ at an $0.0012\ M$ excess. If activity coefficients are neglected (they should be greater than one in $10.5\ M$ NaOH), a CO_3^{2-} concentration in this stock solution of $5 \times 10^{-6}\ M$ is obtained based on the published[21] solubility product for $BaCO_3$. The values for the individual solutions will vary with the dilution factor from this stock solution.

Table 1 gives measured total uranium concentrations in the dithionite containing solutions of NaOH in contact with hydrous UO_2. The solubilities are shown in Figure 1 along with those of Gayer and Leider[5] as a function of mean ionic activity of NaOH using activity coefficient data of Hamer and Wu.[22] The solid line corresponds to the formation constant reported by Gayer and Leider. Over the concentration range where the Gayer and Leider measurements were made, the values measured here are all 10^3 to 10^4-fold lower than those of Gayer and Leider and all values are, as discussed in the experimental section, almost at the reagent blank level so they must be considered at the detection limit and are upper limits on the true solubility. Since they are upper limits, no significance can be placed on a possible slope in this region. At higher NaOH concentrations, there is greater than an order of magnitude scatter in the total U concentration data so again a slope cannot be determined.

Table 2 gives measured total uranium concentrations in NaOH solutions containing metallic zinc powder and hydrous UO_2. These results are also shown in Fig. 1 as a function of mean ionic activity of NaOH. The measured solubilities with Zn as a reductant are higher at low NaOH concentrations and lower at high NaOH concentrations than those with dithionite as the reductant. It was observed that at $10\ M$ NaOH, most of the sodium dithionite actually precipitated from solution. Also, because of the increasing stability of the

ZnO_2^{2-} ion relative to $Zn(OH)_2$ or ZnO at high hydroxide concentrations, it might be expected that any coating initially present or forming on the Zn surface might be more readily removed at higher alkalinity making Zn kinetically more effective at the higher hydroxide concentrations. At lower (< 1 M) NaOH concentration, the higher apparent solubilities with Zn reductant may be due to poorer kinetics of oxygen scavenging or might possibly be due to uranium complexing by ZnO_2^{2-} ion. In any case, all values are much below those predicted by the results of Gayer and Leider.[5]

Table 3 gives measured total uranium concentrations in NaOH solutions containing both dithionite and Zn metal powder. Despite the fact that the values in Table 3 are all at least two orders of magnitude lower than predicted by the results of Gayer and Leider, they are higher in all cases but one than the values for dithionite alone, and in all but one other case than values for Zn alone. The reason for this is not clear; the dithionite stock solution was 2 weeks old when used to make up the solutions used for the data of Table 3, whereas it was less than 1 hr old when used for make up of solutions in Table 1. Also, it was visually observed that the finer Zn particles dissolved during equilibration in the Zn-only suspensions (Table 2), whereas they did not appear to react at all in the dithionite–zinc mixtures (Table 3) indicating preferential consumption of dithionite in the latter.

Overall, it is much more probable that erroneously high results rather than erroneously low results will be obtained in the solubility experiments described here. In all cases here, solubility was approached from the over-saturated side. As noted earlier, very low oxygen fugacities are expected to be required to maintain U(IV) in these alkaline solutions, and since U(VI) is much more soluble than U(IV), high values would be expected if incomplete oxygen scavenging occurred. In this regard, the higher observed solubilities in dithionate solutions above 1 M OH⁻ may be due to poorer oxygen scavenging, U(VI) reduction, or precipitation kinetics in these increasingly viscous solutions. It should also be noted that CO_3^{2-} concentration is proportional to OH⁻ concentration in these solutions, and carbonate complexing is expected to increase the stability of U(VI). Any-cross-contamination resulting from working in the same inert atmosphere chamber for solution makeup with very concentrated U solutions and for solution sampling and filtering would also yield an erroneously high result.

The only way that low results could be expected would be if the analytical method did not respond to the total uranium present. All of the results given are based on more than one analysis (many on several with good agreement). In all cases, analysis was based on the technique of known addition whereby appropriate standards were added after the sample reading was obtained and a new reading measured. In addition, in many cases standards were added either to aliquots of samples which had not been pretreated or to NaOH-Na₂S₂O₄ solution, and these were taken through the entire procedure with excellent standard recovery. In order to show that soluble U was not removed by ion exchange or other reaction with the filter material, the solution shown in Table 1 as 0.295 M NaOH was, after initial sampling for filtration, resealed, and was centrifuged at > 1000 G for 24 hr and a sample taken without filtering analyzed $1.3 \times 10^{-8} M$ U vs $8 \times 10^{-9} M$ (or background level) with filtering. Thus, it must be concluded that the solubility values of $< 10^{-8} M$ in the range 0.1 to 1 m NaOH in dithionite solution are real, and that the results of Gayer and Leider are at least four orders of magntiude too high.

CONCLUSIONS

Based on the above discussion, only the lowest measured U concentrations at a given NaOH concentration should be considered as an upper

limit for U(IV) solubility. The results do not provide solid evidence for any amphoteric behavior of U(IV) despite the measured solubility values being higher above 1 M NaOH. It is by no means certain that the measured U in any of these solutions was present as U(IV). The data presented indicate that the solubility of U(IV) hydrous oxide is at least four orders of magnitude lower than predicted by the results of Gayer and Leider,[5] and that their equilibrium constant for the formation of $U(OH)_5^-$, if such indeed is a dominant species at all in this OH^- concentration range, is at least four orders of magnitude too large. In other words, $K \leq 1.7 \times 10^{-8}$ for the reaction:

$$UO_2(am) + 2H_2O + OH^- \rightleftarrows U(OH)_5^-. \quad (5)$$
Using the conservative value of Langmuir[7] for the free energy of formation of amorphous UO_2 and assuming that this applies to the 2-week old precipitated hydrous UO_2 used here, gives a limit for $\Delta G_f \geq -379.4$ kcal/mole for $U(OH)_5^-$. Using $\Delta G_f = -126.9$ kcal/mole for $U_{(aq)}^{4+}$[7,23], yields a value of $K \leq 2 \times 10^{-23}$ for the reaction:

$$U^{4+}(aq) + 5H_2O \rightleftarrows U(OH)_5^- + 5H^+ \quad (6)$$

vs a value of 10^{-16} reported by Baes and Mesmer.[1] Such a value yields a solubility of crystalline UO_2 as U(IV) of $< 10^{-14} M$ at 1 M NaOH.

NOTES

Quantum chemical calculation of $S_2O_8^{2-}$, SO_4^{2-} and $SO_4^{\cdot-}$ by INDO/$_2$ method

G. P. PIROUMIAN, G. G. GRIGORIAN and N. M. BEYLERIAN*
Yerevan State University, Yerevan 375049, U.S.S.R.

Abstract—Electron density distribution on atomic bonds S–O and O–O in persulphate ion for two different –O–O– bond lengths — 1.5 and 2.0Å using INDO/$_2$ method with parameters proposed by Pople on the BESM-6 computer have been calculated.

The results of the calculations show that the electron density is lowest on –O–O– bond, which is in accordance with experimental data. The calculations based on the assumption that $d_{O-O} \to \infty$ lead to the conclusion that the homolytic cleavage of –O–O– bond in $S_2O_8^{2-}$ ion is more probable.

In spite of the wide application of peroxides there are not many works concerning the theoretical study of their electronic structure.

The initial works deal the simplest peroxide—the hydrogen peroxide. Penney and Sutherland[1] showed the non-symmetrical distribution of charges on the –O–O– bond. Amako and Griguers[2] had calculated the length of the –O–O– bond and the angle O–OH.

Dialkyl peroxides and hydroperoxides were investigated by Ohkubo and Okado[3] who showed the –O–O– bond to be little "populated". They concluded that the peroxide bond may be attacked by nucleophilic agents. Similar data were received by Vanezawa, Kato and Yamamoto[4] and by Silbert *et al.*[5] The latter work carries the conclusion that olefins, which are π-donors, fill the lowest nonbonding orbitals of the –O–O– bond. Kucher and his colleagues[6-9] calculated the electronic structure of H_2O_2, organic peroxides and the corresponding radicals to find a relationship between electronic structure and reactivities.

The electron density and other quantum chemical parameters of benzoyl peroxide were calculated[10] and a "deficiency" of electrons was estimated in the –O–O– bond.

The ion $S_2O_8^{2-}$ has not been studied quantum chemically in spite of its wide application in many radical-chain reactions.

According to Beylerian[11] the passage of one or two electrons occurs from metal cations, having variable valence to the –O–O– bond when oxidizing with peroxides, particularly with persulphate. According to this hypothesis a complex is formed between $S_2O_8^{2-}$ and M^{n+} as a result of charge transfer from the cation to the –O–O– bond.

The aim of the present work is to calculate the $S_2O_8^{2-}$ ion and to verify the reality of the existence of electron "deficiency" on the –O–O– bond in the $S_2O_8^{2-}$ ion. The calculation was carried out through the INDO/$_2$ method with parameters proposed by Pople[12] on the BESM-6 computer.

In this method the measure of the bond strength is the value b_{AB}.[13,14]

$$b_{AB} = \sum_j^B \sum_i^A P_{ij} S_{ij},$$

where P_{ij} are the bond orders between atomic orbitals with i, j numbers, and S_{ij} are the overlapping integrals of the orbitals with i, j numbers.

The over-all indexes of bond energies in which the noneqiuivalence of different kinds of overlapping orbitals energy is considered,[15] is determined by the following formula:

$$E_{AB}^R = \sum_j^B \sum_i^A H_{ij}(P_{ij}^\alpha + P_{ij}^\beta),$$

where H_{ij} are matrix elements of frame Hamiltonian, P_{ij}^α and P_{ij}^β are matrix elements of the electron density with α and β spins correspondingly.

The geometrical parameters of $S_2O_8^{2-}$ ion were taken from Ref. 16.

In the calculations of the electron density on –O–O– bond the length of this bond was varied: 1.5; 2.0 and ∞ Å. The calculated data for the bond length $d_{O-O} = 1.5$Å, which corresponds to the crystal structure value of the ion $S_2O_8^{2-}$, are listed in Table 1.

The charge distribution on the atoms in the $S_2O_8^{2-}$ ion at $d_{O-O} = 1.5$Å is illustrated on Fig. 1.

From the results of Table 1 and Fig. 1 it is obvious that the electron density on –O–O– bond is minimum, the data concerning the bond strengths shows that the weakest is the –O–O– bond too, which breaks.

Further calculations have been carried on for $d_{O-O} = 2.0$Å (see the data of Table 2).

The charge distribution on the atoms in the $S_2O_8^{2-}$ ion at $d_{O-O} = 2.0$Å is illustrated on Fig. 2.

From the data of Table 2 and Fig. 2 we conclude that when the length becomes 2.0Å from 1.5Å E_{A-B}^R and b_{A-B} for

Fig. 1. The charge distribution on the atoms in the $S_2O_8^{2-}$ ion at $d_{O-O} = 1.5$Å.

(a)   (b)
Fig. 3. The charge distribution on the atoms in SO_4^{2-} (a) and SO_4^{-} (b).
Fig. 2. The charge distribution on the atoms in the $S_2O_8^{2-}$ ion at $d_{O-O} = 2.0$Å.

–O–O– bond diminish. It confirms the proposition about the ease of –O–O– homolysis in $S_2O_8^{2-}$ ion. In the case when $d_{O-O} = 2.0$Å, $S_{ij} = 0.2645$ and for $d_{O-O} = 1.5$Å, $S_{ij} = 0.3513$. It is deduced, that when the overlapping is more the bond strength is more too. At 2.0Å the electron density is more than when the –O–O– bond length is equal to 1.5Å.

It is probable that as a result of the increase in bond length the repulsion between oxygen atoms decreases and the formed "deficiency" is fullfilled owing to partly delocalisation of both electrons in the $S_2O_8^{2-}$ ion.

The rupture of –O–O– bond can lead to either the formation of SO_4^{-}, if the –O–O– bond ruptures homolytically, or SO_4^{2-}, if the rupture occurs heterolytically.

The charge distribution on the atoms in SO_4^{2-} and SO_4^{-} is illustrated on Fig. 3.

The values of E_Σ for SO_4^{-} and SO_4^{2-} are as follows:—

$$E_\Sigma(SO_4^{-}) = -80.5426 \text{ a.u.}$$

$$E_\Sigma(SO_4^{2-}) = -80.0606 \text{ a.u.}$$

The calculated results, which are shown on Fig. 3 and the values E_Σ of SO_4^{-} and SO_4^{2-} show, that E_Σ for SO_4^{-} is less than for SO_4^{2-} on one side, and the electrons are delocalised in the all system, on the other.

Therefore the quantum chemical calculations show that there is a "deficiency" of the negative charge on the –O–O– bond in the ion $S_2O_8^{2-}$ and it has been concluded that a

nucleophilic attack on the –O–O– bond is theoretically possible.

Tetrahedral metal complexes of [MW$_{12}$O$_{40}$]-type (M=Al^{III}, Zn^{II}) with dodecatungstate as tetrahedral ligand

KENJI NOMIYA and MAKOTO MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino-shi, Tokyo 180, Japan

Abstract—Tetrabutylammonium salts of 12-heteropolytungstates with central metal ions in a tetrahedral oxygen environment, MW$_{12}$O$_{40}$ (M=Al, Zn), have been prepared and their spectroscopic data (IR, UV and MCD) presented. IR studies in acetonitrile solution suggest that the tetrahedral structure around AlO$_4$ moiety is largely distorted, whereas the ZnO$_4$ moiety retains excellent tetrahedral symmetry.

Recently we have reported the syntheses and the spectroscopic properties of tetrahedral transition–metal complexes of [MW$_{12}$O$_{40}$]-type with dodecatungstate as tetrahedral ligand; M=Cu, Fe, Co and Co.[1,2] As an additional work, we have prepared the [AlW$_{12}$O$_{40}$]$^{5-}$ and [ZnW$_{12}$O$_{40}$]$^{6-}$ anions as tetrabutylammonium salts. These compounds were first prepared by Brown and Mair,[3–6] but no spectroscopic data have yet been reported. As a continuity of structural studies of tetrahedral complexes series of heteropolyanion, we have measured their IR spectra in a solid and in a solution, UV and MCD spectra and compared with the results of other tetrahedral complexes.

EXPERIMENTAL

Spectral measurements were performed by previously reported methods.[1,2]

H$_2$[(C$_4$H$_9$)$_4$N]$_4$[ZnW$_{12}$O$_{40}$]. Preparation of 12-tungstozincate acid was performed by modification of the method of Brown and Mair[5]. Appropriate volume of nitric acid (1 mol dm^{-3}) was added to Na$_2$WO$_4$·2H$_2$O (11.3 g, 3.4 × 10^{-2} mol) dissolved in water (80 cm^3), adjusted to pH of about 5, and the solution kept at 80–90°C with mechanical stirring, into which Zn(NO$_3$)$_2$·6H$_2$O (2.0 g, 6.7 × 10^{-3} mol) in water (140 cm^3) was added slowly over 20 hr. The solution was cooled, concentrated to about 50 cm^3, set aside overnight and filtered. The filtrate was extracted with 12N-sulphuric acid (200 cm^3) and diethyl ether (100 cm^3). The lowest layer, containing ether-adduct of the product and metatungstic acid, was taken out, added to an equal volume of water, and the ether was removed by evaporation. The solution was evaporated to dryness

and dried several hours on a steam-bath. During the drying, metatungstic acid was converted to yellow tungsten oxide, insoluble in water. The residual system was extracted with water and filtered. The process was repeated until no more yellow compound was formed. From the final aqueous solution repeated more than ten times, colourless solid 12-tungstozincate acid was obtained. The solid was added to the aqueous solution containing excess tetrabutylammonium bromide, which has been acidified by nitric acid. The precipitate was washed thoroughly with water and recrystallized from acetonitrile. Yield 3.5 g (colourless). Found: C, 19.92; H, 3.70; N, 1.46. Calc. for H$_2$[(C$_4$H$_9$)$_4$N]$_4$[ZnW$_{12}$O$_{40}$]: C, 19.79; H, 3.76; N, 1.44%.

H[(C$_4$H$_9$)$_4$N]$_4$[AlW$_{12}$O$_{40}$]. 12-Tungstoaluminate acid was prepared and purified by modification of the method of Mair and Waugh.[3] Appropriate volume of nitric acid (1 mol dm^{-3}) was added to Na$_2$WO$_4$·2H$_2$O (28.0 g, 8.5 × 10^{-2} mol) dissolved in water (240 cm^3), adjusted to pH of about 5.5, and the solution refluxed, and into which Al(NO$_3$)$_3$·9H$_2$O (5.0 g, 1.3 × 10^{-2} mol) in water (200 cm^3) was added drop by drop over 20 hr. The solution was cooled, concentrated to about 50 cm^3, stored at 6°C overnight, and filtered. The filtrate was extracted with 12N-sulphuric acid and ether. By the similar work-up to the preceding preparation, colourless solid of 12-tungstoaluminate acid was obtained (8.3 g) and converted to the tetrabutylammonium salt. It was washed thoroughly with water and recrystallized twice from acetonitrile. Found: C, 19.82; H, 3.88; N, 1.47. Calc. for H[(C$_4$H$_9$)$_4$N]$_4$[AlW$_{12}$O$_{40}$]: C, 19.98; H, 3.77; N, 1.46%.

[(C$_4$H$_9$)$_4$N]$_4$[SiW$_{12}$O$_{40}$] and [(C$_4$H$_9$)$_4$N]$_3$[PW$_{12}$O$_{40}$] were prepared by the usual methods. Found: C, 19.86; H, 3.82; N, 1.51. Calc. for [(C$_4$H$_9$)$_4$N]$_4$[SiW$_{12}$O$_{40}$]: C, 19.99; H, 3.78; N, 1.46%. Found: C, 15.77; H, 3.10; N, 1.12%. Calc. for [(C$_4$H$_9$)$_4$N]$_3$[PW$_{12}$O$_{40}$]: C, 15.99; H, 3.03; N, 1.17%.

RESULTS AND DISCUSSION

In the preparation of M=Zn and Al compounds, adjusting the pH of the starting solution with nitric acid significantly influenced the yields. However, the pH ranges allowed are relatively wide and the yields comparatively high, e.g. in comparison with the preparation of M=Cu compound.[1] Free acids have many solvated water molecules and to dry completely is difficult. When the tetrabutylammonium is employed as a counter cation, isolation and treatment become convenient and solvation can be avoided.

IR spectra. The IR spectrum of the metal–oxygen stretching region in $[ZnW_{12}O_{40}]^{6-}$ anion (Fig. 1) measured by a KBr disk shows three prominent bands, v(W–O, terminal) at $940\,cm^{-1}$, v(W–O–W, octahedral edge-sharing) at $870\,cm^{-1}$, overlapped band of $v_3(F_2)$ by Zn–O stretching motion in a tetrahedral ZnO_4 and v(W–O–W, octahedral corner-sharing) at $770\,cm^{-1}$, and one small band; $v_4(F_2)$ by O–Zn–O angle bending motion in ZnO_4 unit at $440\,cm^{-1}$. The overlapping of $v_3(F_2)$ and v(W–O–W, corner-sharing) bands has been also observed in the cases of $[MW_{12}O_{40}]$ compounds with M=Cu(II), Fe(III), Co(II) and Co(III). Because of its triply degenerate mode for perfect T_d symmetry, the spectral shape of $v_4(F_2)$ band directly reflects whether the symmetry of a ZnO_4 moiety is regular T_d or not. For such a discrimination, the spectrum of a solution rather

than of a solid is preferable, since the effects of crystal packing and/or environment are eliminated. The IR spectrum recorded in acetonitrile solution shows that the overlapped band at $770\,cm^{-1}$ is slightly separated and the $v_4(F_2)$ band retains symmetrical envelope without significant splitting. Thus, the ZnO_4 moiety can be expected to have regular tetrahedral symmetry.

On the other hand, the IR spectrum of $[AlW_{12}O_{40}]^{5-}$ anion in the solid (Fig. 2) is composed of four prominent bands and one doubly split band; the former are v(W–O, terminal) at $955\,cm^{-1}$, v(W–O–W, octahedral edge-sharing) at $885\,cm^{-1}$, which has a small shoulder at $925\,cm^{-1}$, v(W–O–W, octahedral corner-sharing) and $v_3(F_2)$ by Al–O stretching motion in AlO_4 unit, which appear at 810 and $770\,cm^{-1}$, respectively, or vice versa, and the latter $v_4(F_2)$ by O–Al–O bending motion in the AlO_4 unit at $475\,cm^{-1}$. The separation of v(W–O–W, corner-sharing) and $v_3(F_2)$ bands in the solid-state spectrum has also appeared in the $[MW_{12}O_{40}]$ with M=Si and P, but not M=Cu(II), Fe(III), Co(II) and Co(III). The spectrum measured in acetonitrile solution, as a whole, appears to be sharpened and shows the following characteristics; (1) v_4 band is doubly split as in the solid-state spectrum, (2) both v(W–O–W, corner-sharing) and v_3, with broadened envelope in the solid-state spectrum, are split, and (3) the small shoulder at $925\,cm^{-1}$ accom-
Fig. 1. IR spectra of tetrabutylammonium salt of $[ZnW_{12}O_{40}]^{6-}$ anion in a solid (KBr disk) and in acetonitrile solution.

panied with the ν(W–O–W, edge-sharing) is also observed.

The splitting of $\nu_3(F_2)$ and $\nu_4(F_2)$ bands show the lowering of symmetry in the tetrahedral AlO$_4$ moiety. Since the ν_3 and ν_4 modes are essentially independent of each other, the degeneracy of them in only one mode will be possibly split by the distortion of symmetry around the MO$_4$ unit. This has been observed in the M=Si and P compounds. However, since the ν_3 and ν_4 bands in the M=Al compound are simultaneously split, the distortion of AlO$_4$ moiety may be different from those of SiO$_4$ and PO$_4$ units. The shoulder or splitting components of corner- and edge-sharing bands of W–O–W stretching may reflect that the symmetry of W$_{12}$O$_{40}$ skeleton is also lowered.

Recently Akitt and Farthing have investigated the course of preparation of [AlW$_{12}$O$_{40}$]$^{5-}$ using ^{27}Al–NMR technique and discussed all species formed during the preparation.[7] They pointed out from the appearance of two ^{27}Al resonances in the spectrum of final product that the preparation seemed to produce two 1:12 anions, and they suggested the possibilities of its cause as follows; structural difference leading to distortion of the symmetry around the AlO$_4$ unit, protonation of the anion to give a [H$_3$AlW$_{12}$O$_{40}$]$^{2-}$, replacement of counter cation by H$_3$O$^+$, and a combination of these possibilities. Our results explicitly supported the possibility of the structural difference.

UV and MCD spectra. UV and MCD spectra in acetonitrile solution of four tetrabutylammonium salts, [MW$_{12}$O$_{40}$] with M=Al, Zn, Si and P, are shown in Figs.

Fig. 4. UV and MCD spectra of tetrabutylammonium salts of [MW$_{12}$O$_{40}$] anions in acetonitrile solution; full line for M=Si and dotted line for M=P.

3 and 4. Absorption bands at $37–38 \times 10^3$ cm^{-1} are due to the charge transfer transition within dodecatungstate lattice and are commonly observed in the dodecatungstate compounds, whether the central atom is a transition metal or not. The intensities of the Zn and Al compounds (ϵ 3.41×10^4 and 3.75×10^4, respectively) are relatively small in comparison with those of Si and P compounds (ϵ 5.08×10^4 and 5.24×10^4, respectively). MCD spectra in the UV region show apparently two positive and one negative components, where the negative one appears near the position of absorption maximum and exists between two positive ones. The positive component of high frequency region in the Zn compound has not been measured, because of spectral noise, but such a component will probably exist. This MCD pattern is characteristic of the dodecatungstates and can be distinguished from that of dodecamolybdates, which is composed of only two positive components. The intensity of each component changes with central atom, especially those of Zn compound are very small. This may be related to the strong interaction between central Zn ion and dodecatungstate lattice, the excellent T$_d$ symmetry of the ZnO$_4$ moiety, and/or a combination of them. The W–O charge transfer band, observed as one absorption, has been further resolved and found to be significantly influenced by the central metal.

A NEW TETRAHEDRALLY DISTORTED COPPER(II) COMPLEX DERIVED FROM

DISULPHIDE COUPLED N-(2-ETHANETHIOL)SALICYLIDENEIMINE

D. M. ROUNDHILL

Department of Chemistry, Tulane University, New Orleans, LA 70118, USA

Abstract - Copper(II) acetate reacts with N-(2-ethanethiol)salicylideneimine forming an ONNO chelate of α,α'-(diethylenedisulphide)-N,N'-disalicylideneimine with an uncoordinated disulphide. This copper(II) complex can also be obtained in higher yield if the thiol is first oxidized to disulphide with iodine. The geometry about copper(II) is distorted from planar to a flattened tetrahedron.

In the presence of copper(II) ions, thiols are rapidly oxidized to disulphides with the simultaneous reduction of copper to the monovalent state. Nevertheless, in view of the fact that blue copper proteins have a thiolato ligand directly bonded to copper(II),[1,2] interest remains high in exploring synthetic routes to such model complexes. Despite considerable effort toward this goal, there still remain very few well documented examples of a synthetic compound having such a coordinate linkage.[3] Many literature examples of compounds prepared from the interaction of thiols and copper(II) salts cannot be treated as valid biomimetic examples of blue copper proteins because the products have been only poorly characterized. In many cases the complexes have copper in a monovalent or mixed valence state, and only in a few cases is copper divalent. One such example is the complex N-(2-thiophenolato)-R-salicylideneimine pyridine copper(II).[4] Using this compound as a guideline we have explored the possibility of preparing an analogous copper(II) complex having an aliphatic thiolato ligand. We have thus used the compound N-(2-ethanethiol)-salicylideneimine for complexation with cupric ion.

EXPERIMENTAL

Electronic spectra were measured on a Cary 17 spectrophotometer. EPR measurements were made on a Varian E3 spectrometer. Reagents were used as supplied.

The compound N-(2-ethanethiol)salicylideneimine was prepared by first dissolving 2-aminoethanethiol hydrochloride (2.50 g, 0.022 mol) in the minimum quantity of methanol. This solution was then added to potassium acetate (5.89 g) which was dissolved in the minimum volume of ethanol. After filtration of potassium chloride, salicylaldehyde (2.51 g, 0.024 mol) was added to the filtrate, and the solution warmed for 10-15 min.[5] The resulting solution of N-(2-ethanethiol)salicylideneimine was added to copper acetate (2.45 g, 0.012 mol) dissolved in hot methanol. The precipitate which formed was extracted with hot pyridine, and the complex precipitated as a green powder by addition of hexane or diethyl ether. The filtered solid was washed with a little methanol then diethyl ether. Yield 1.4 g, 28%. Found: C, 51.23, 51.32; H, 4.35, 4.31; N, 6.77, 6.96; S, 15.56. Calc. for $C_{18}H_{18}CuN_2O_2S_2$: C, 51.23; H, 4.30; N, 6.64; S, 15.20%.

Alternatively the complex may be prepared by allowing the warm solution of N-(2-ethanethiol)salicylideneimine (0.024 mol) to cool, and then adding iodine crystals followed by copper acetate. Benzene and water were added as necessary to keep the solution homogeneous. Iodine addition was continued until there remained a faint purple colouration in the benzene layer. A dilute aqueous solution of sodium thiosulphate was then added to remove excess iodine, and the organic product extracted with benzene. The benzene solvent was removed by rotary evaporation and the residue containing α,α'(diethylenedisulphide)-N,N'-disalicylideneimine (0.012 mol) was dissolved in a methanol-acetone mixture. This solution was added to a solution of copper acetate (3.8 g, 0.019 mol) in hot methanol, and the green solid product filtered. Yield 3.6 g, 71%. The product is identical with that prepared from N-(2-ethanethiol)salicylideneimine.

RESULTS AND DISCUSSION

The compound N-(2-ethanethiol)salicylideneimine is a potential tridentate ligand which can be used to prepare thiolato complexes of metals such as nickel(II).[5] Reaction of this compound with copper(II) acetate yields a green complex in rather low yield. The electronic spectrum of this complex as a solution in pyridine shows absorptions at 10,700 cm^{-1} (ε 55), 14,900 cm^{-1} (ε 110), 21,300 cm^{-1} (ε 260), along with two intense ligand centred charge transfer bands at 27,000 cm^{-1} and 34,240 cm^{-1}. The solid state EPR

spectrum at 293K and 77K shows a broad line of width 104 ± 5 gauss centred at g = 2.090(3), a reasonable position for g_1 in copper(II) complexes.[6] Since this complex can be prepared in high yield from the disulfide it is very unlikely that the structure of this complex has a thiolato copper(II) bond. The low yield of complex when prepared from N-(2-ethanethiol)salicylideneimine [28% based on $Cu(OAc)_2 \cdot H_2O$] is a consequence of the thiol group being oxidized to disulphide, with reduction of cupric ion to the cuprous state. The oxidation product, α,α'-(diethylenedisulfide)-N,N'-disalicylideneimine, is a tetradentate ONNO ligand. Verification of this ligand structure has been made by prior oxidation of N-(2-ethanethiol)salicylideneimine to α,α'-(diethylenedisulfide)-N,N'-disalicylideneimine with iodine, followed by its use to prepare the identical copper(II) complex in higher yield (71% based on disulphide ligand). These reactions are shown in the scheme.
Scheme

Molecular models suggest that conformational strain about the diethylenedisulphide backbone of the ligand makes a planar coordination geometry about copper unfavourable, and that a tetrahedral distortion would be sterically preferable. Comparison of the electronic spectrum of this new complex with other copper(II) salicylideneimine complexes supports this contention. Increasing the steric bulk of the N-alkyl substituent causes a distortion from planar (R = n-Pr) to flattened tetrahedral (R = t-Bu).[7,8] This change is reflected in a progressive shift of the d-d electronic bands to lower energy as the copper(II) coordination geometry distorts from planar. Comparison of the electronic spectrum of this new complex with that for R = n-Pr, which has λ_{max} = 17,000 cm^{-1} (ϵ 110), or for R = t-Bu, with λ_{max} = 8,500 (ϵ 20), 13,400 (ϵ 260), 20,800 (ϵ1,500), supports a structure with a distortion from planarity approaching that found for the t-butyl substituted complex.[9,10,11]

RELATIONSHIPS BETWEEN INTERATOMIC DISTANCES AND ELECTRON NUMBERS FOR
D_{3h} TRICAPPED TRIGONAL PRISMATIC 9-ATOM CLUSTER SYSTEMS

MARION E. O'NEILL and KENNETH WADE

Chemistry Department, Durham University, South Road, Durham DH1 3LE (UK)

ABSTRACT

The polyhedron edge-bonding or -antibonding characteristics of the nondegenerate tenth and eleventh MO's of D_{3h} tricapped trigonal prismatic 9-atom homonuclear clusters like B_9Cl_9, $B_9H_9^{2-}$, Ge_9^{2-}, Sn_9^{3-} and Bi_9^{5+} can be used to rationalize the edge lengths in such clusters. Skeletal bonding is strongest, and the clusters are nearest to spherical, when there are 20 skeletal bonding electrons present, as in the cases of $B_9H_9^{2-}$ and Ge_9^{2-}. Species with one or two more or fewer electrons have expanded structures based on longer and thinner trigonal prisms.

INTRODUCTION

Most <u>closo</u> borane-type clusters like the anions $B_nH_n^{2-}$ and carboranes $C_2B_{n-2}H_n$ (n = 5 → 12) have (n + 1) skeletal electron pairs to hold their n atoms together. However, species in which the (n + 1)'th and (n + 2)'th MO's (the HOMO and LUMO of $B_nH_n^{2-}$) are non-degenerate can in principle suffer loss or gain of one or two electrons without a change of symmetry from that of the <u>closo</u> shape appropriate for (n + 1) pairs.[1] The D_{2d} dodecahedral shape of $B_8H_8^{2-}$ [2], the D_{3h} tricapped trigonal prismatic shape of $B_9H_9^{2-}$ [2], and the C_{2v} octadecahedral shape of $B_{11}H_{11}^{2-}$ [3], are all compatible with n, (n + 1) or (n + 2) skeletal electron pairs, the strongest bonding (and so most compact shape) being when there are (n + 1) pairs. We have elsewhere[1] pointed out in preliminary form that the differences between B_8Cl_8 [4] and $B_8H_8^{2-}$ [2], or between B_9Cl_9 [5] and $B_9H_9^{2-}$ [2], are consistent with the B-B bonding or antibonding characteristics of the HOMO's of $B_8H_8^{2-}$ [6] and $B_9H_9^{2-}$ [2]. Our emphasis in that earlier paper was on 8-atom clusters. Here, we illustrate and develop our argument with particular reference to 9-atom clusters, and consider how it can be extended to allow clusters of one element to be compared with those of another element of different atomic radius.

FRONTIER ORBITALS OF D_{3h} TRICAPPED TRIGONAL PRISMATIC CLUSTERS.

Molecular orbital treatments of $B_9H_9^{2-}$ [2] and of related clusters M_9^{2-} (where M = a Group IV element such as Ge, Sn or Pb)[7-9] have shown that there is a significant energy gap between the tenth and eleventh MO's, the former (the HOMO) being of a'_2 symmetry and predominantly bonding in character, the latter (the LUMO) being of a''_2 symmetry and predominantly antibonding in character. The combinations of p atomic orbitals (tangentially orientated with respect to the pseudo-spherical cluster surface) that contribute to these MO's are shown in the Figure, from which it is apparent that while the HOMO is bonding for edges of types g and h, and antibonding for edges of type f, the LUMO is precisely the reverse, bonding for edges of type f, but antibonding for edges of types g and h. Adding one or two electrons to D_{3h} $B_9H_9^{2-}$ or related clusters, or taking one or two electrons away from such a system, is expected to cause the same type of distortion if the D_{3h} symmetry is retained. Edges of type f (which surround the triangular prism faces) are expected to shorten, while those of

HOMO-a'$_2$ skeleton   LUMO-a"$_2$
Figure. D_{3h} tricapped trigonal prismatic skeleton of the 9-atom clusters B_9Cl_9, $B_9H_9^{2-}$, $C_2B_7H_9$, Sn_9^{3-} and Bi_9^{5+}, with the frontier orbitals of $B_9H_9^{2-}$.

*   Distance to capping boron; h for capping carbon is 161 pm.

**   This anion is very distorted, with one long bond of type g - see text.

types g (the prism length) and h (the links to the capping atoms) are expected to lengthen. The effect is to convert the pseudo-spherical ten electron pair system into an ellipsoidal system elongated along the 3-fold axis.

INTERATOMIC DISTANCES IN D_{3h} TRICAPPED TRIGONAL PRISMATIC CLUSTERS

The interatomic distances in a series of homonuclear D_{3h} tricapped trigonal prismatic clusters[2,5,10-12], and in the related C_{2v} symmetry carborane $C_2B_9H_{11}$,[13] are listed in the Table. The first two entries, B_9Cl_9[5] and $B_9H_9^{2-}$[2], show precisely the difference expected-- the trigonal prism of the former is longer and narrower than that of the latter. The data for the carborane $C_2B_7H_9$,[13] in which the carbon atoms occupy capping positions, when compared with those for $B_9H_9^{2-}$, show that the main effect of the carbon atoms is to drain electronic charge from the prism ends, lengthening the edges of type f and so making the prism even fatter.

Comparison with clusters of elements other than boron is facilitated by calculating the ratio of the prism edge parameters f/g. Since f is expected to shorten and g to lengthen as electrons are added or removed, this ratio provides a more sensitive guide to the effect of changing the electron numbers,[9] than the interatomic distances themselves do and allows comparisons to be made between the boron systems just considered and related metal clusters containing larger atoms. At present, there is unfortunately a dearth of information on the structures of closo anionic clusters M_9^{2-} (M = Ge, Sn or Pb).[7,8] Though these anions are believed to feature in the solution chemistry of alkali metal alloys of these metals,[7] the anions M_9^{4-}, with nido capped square antiprismatic structures, have been much more thoroughly structurally characterized. The one anion M_9^{2-} that has been structurally characterized is Ge_9^{2-},[10] and it has C_{2v} symmetry, one edge of the trigonal prism (type g) being 30 pm longer than the other two. The reason for this distortion from the ideal D_{3h} geometry is not clear, but a consequence is that the ratio of edge lengths f/g is much lower than might have been expected for a system that is believed to contain ten skeletal bond pairs (the charge on the anion was inferred from the shape and from the number of cations present).

The remaining two clusters in the Table, the odd electron system Sn_9^{3-}[11] and the eleven pair cluster Bi_9^{5+}[12] both have low values of f/g as expected for species with elongated narrow trigonal prisms, the degree of distortion from the 'ideal' geometry being greatest, again as expected, for Bi_9^{5+}, which contains two antibonding electrons, whereas Sn_9^{3-} contains only one.

With the exception of Ge_9^{2-}, which is anyway very distorted from D_{3h} symmetry, these 9-atom D_{3h} clusters thus show the sensitivity of shape to electron numbers that is expected from simple frontier orbital considerations. Structural characterisation of further examples, particularly closo systems M_9^{2-} (M = Ge, Sn or Pb), and related 19 electron clusters if these can be prepared, would help test the generality of the arguments outlined here.

ISOCYANIDE INSERTION REACTION IN ALKYLCOMPLEXES OF IRON:
A DIHAPTOIMINOACYL DERIVATIVE OF IRON (II)

Giuseppe Cardaci*, Gianfranco Bellachioma

Department of Chemistry, University of Perugia, 06100 Perugia Italy

Pierfrancesco Zanazzi

Institute of Mineralogy, University of Perugia, 06100 Perugia Italy

Abstract: The dihaptoiminoacyl complex $[Fe(CO)_2(PMe_3)_2(\eta^2\text{-}CMe=N\text{-}CMe_3)]^+$ I^- was obtained by reaction of $[Fe(CO)_2(PMe_3)_2MeI]$ and tertbutylisocyanide. The structure of the complex was determined by an X-ray structure analysis.

Isocyanides are structurally similar and isoelectronic with carbon monoxide; therefore an understanding of isocyanide insertion[1] may help our understanding of CO insertion[2]. Moreover, isocyanide insertion is not an equilibrium reaction and can give polyinsertion[3]. When there is a choice within one molecule, isocyanide insertion prevails over CO insertion, though its calculated activation energy is higher than for CO insertion[4]. This can be explained by acid catalysis[4]. Another reason may be the action of the metal, which acts as an acid toward the nitrogen atom to stabilize the dihaptostructure as an insertion intermediate. Two examples of dihaptoiminoacyl complexes are described in the literature[5]. We here describe the preparation of a complex of iron (II) showing this structure (Scheme 1).

Scheme 1 (L=PMe₃)
The reaction of $[Fe(CO)_2(PMe_3)_2MeI]$ (1) with tert-butylisocyanide in benzene (molar ratio 1/1) quickly yields $[Fe(CO)(PMe_3)_2(CNCMe_3)(COMe)I]$ (2), which ionizes to the complex $[Fe(CO)_2(PMe_3)_2(CNCMe_3)Me]^+$ I^- (3);(3) reaches an equilibrium with the dihaptoiminoacyl complex $[Fe(CO)_2(PMe_3)_2(\eta^2\text{-}CMe=NCMe_3)]^+$ I^- (4). With an excess of tert-butylisocyanide the reaction proceeds to the complex $[Fe(CO)(PMe_3)_2(CN\text{-}CMe_3)_2(COMe)]^+$ I^- (5). The complexes (3) and (4) cannot be isolated because equilibrium between them is established in the solid state, too; on the other hand the complex (4a) can be precipitated from a tetrahydrofurane solution of (3a) and (4a) obtained by exchange with $NaBPh_4$ in methanol. The elemental analyses of the complexes (4a) and (5) are in agreement with the proposed formulation.

(4a) crystallizes in the monoclinic system with a = 29.832(4), b = 12.174(3), c = 10.650 (3) Å, β = 91.45(2)°, U = 3866.6 Å^3, D_c = 1.045 g.cm^{-3}, Z = 4, space group $P2_1/n$. Intensity data were measured with a Philips PW 1100 diffractometer, using $MoK\alpha$ radiation, μ = 4.7 cm^{-1}.
Fig. 1

The structure was solved by direct method and refined by full matrix least squares method to R = 0.075 for 1628 observed reflections and 149 parameters[§]

The molecular structure of complex (4a) is shown in Fig. 1.

In addition to the Fe-PMe$_3$ and Fe-CO groups, an iminoacyl (Me-C=N-CMe$_3$)group bonded to the metal atom is observed. Relevant internuclear distances and angles are: Fe-C$_9$ = 1.940(13)Å; Fe-N = 2.007(10)Å; C$_9$-N = 1.211(14)Å; C$_9$-C$_{10}$ = 1.496(19)Å; N-C$_{11}$ = 1.523(16)Å; C$_{10}$-C$_9$-N = 139.1(13); C$_9$-N-C$_{11}$ = 137.4(12); C$_9$-Fe-N = 35.7(4). The increase of the angles C$_{10}$-C$_9$-N and C$_9$-N-C$_{11}$ with reference to a normal η^1-iminoacyl structure[5a,6] and the similar bond distances Fe-N and Fe-C$_9$ indicate a dihaptoiminoacyl structure as found in the previously described complexes[5].

The structures of the complexes (3), (4) and (5) are supported by i.r. and [1]H n.m.r. spectra (Tab. 1).

Table 1: i.r. (cm^{-1}) and ^{1}H n.m.r. (ppm)data in CH$_2$Cl$_2$

Complex	ν_{CO}	ν_{COMe}	ν_{CN}	τ_{Me}	τ_{COMe}
(2) (B)	1938(s)	1584(m)	2146(s)		7.65(s)
(3)	2027(s),1983(s)		2172(s)	8.94(t) $J_{H,P}$= 7.8 cps	
(4)	2012(s),1950(s)		1750(m)	7.04(t) $J_{H,P}$= 2.4 cps	
(5)	1982(s)	1600(s)	2175(s),2140(s)		7.56(s)

B = benzene solution; s = strong, m = medium for the i.r. spectrum;

s = singlet, t = triplet for the ^{1}H n.m.r. spectra.

In particular complex (4) shows two i.r. CO stretchings, no i.r. band in the range 2100-2200 cm^{-1}(C≡N stretchings) or in the range 1500-1600 cm^{-1} (C=N stretchings). The band at 1750 cm^{-1} is assigned to the C=N of the η^2-dihaptoiminoacyl structure. A comparison with the band observed in the other two dihapto complexes (ν_{CN}= 1654 cm$^{-1,5b}$ and ν_{CN}= 1680 cm$^{-1,5a}$), indicate that this band is strongly influenced by the dihapto structure.

The shift is to a higher frequency with respect to the C=N stretching. This trend is opposite to that observed in the dihaptoacyl complexes[7] and corresponds to the effect observed on the double bond of the cyclopropene derivatives[8]. Since the structure of cyclopropene and dihaptoiminoacyl metal are very similar, the strengthening of the double bond may be due to the partial sp hybridization on the C and N atoms, observed in cyclopropene[8] and to the quaternary iminium salt $>$C=N$<$ structure, for which a shift to higher frequencies of the C=N stretching is observed[9].

Refutation of the synthesis of tetrakis(cyclopentadienyl)cerium(IV)

G. B. DEACON,* T. D. TUONG and D. G. VINCE†
Chemistry Department, Monash University, Clayton, Victoria 3168, Australia

Abstract—Reaction of sodium cyclopentadienide with dipyridinium hexachlorocerate(IV) in tetrahydrofuran yields tris(cyclopentadienyl)cerium(III) and not tetrakis(cyclopentadienyl)cerium(IV).

The synthesis of tetrakis(cyclopentadienyl)cerium(IV) by reaction of $(pyH)_2[CeCl_6]$ with sodium cyclopentadienide has been reported.[1]

$$(pyH)_2[CeCl_6] + 4Na(C_5H_5) \rightarrow$$

$$(C_5H_5)_4Ce + 4NaCl + 2(pyH)Cl. \quad (1)$$
It has also been claimed that the same reagents (different stoichiometry) and reaction of $(C_5H_5)_4Ce$ with $(pyH)_2[CeCl_6]$ yield tris(cyclopentadienyl)cerium(IV) chloride,[2] from which a range of $(C_5H_5)_3CeX$ (e.g. X = alkyl or aryl,[3] alkoxide,[4] BH_4[5] compounds have been derived. Tetrakis(cyclopentadienyl)cerium (IV) was reported to be stable to water and dilute acids,[1] by contrast with organolanthanides in more stable oxidation states.[6,7] The compound was said to be "chemically stable" but the stability to air was not specifically mentioned.[1] The occurrence of (1) is surprising in view of the formation of tris-(cyclopentadienyl)cerium(III) from cerium tetrafluoride and $(C_5H_5)_2Mg$,[8] but receives some support from the preparation of $(C_5H_5)_3Ce(OPr^i)$ from $Ce(OPr^i)_4$ and $(C_5H_5)_2Mg$.[9] However, the properties of $(C_5H_5)_3Ce(OPr^i)$ from this source (colour, volatility, IR absorptions)[9] differ from those of the same compound prepared by alcoholysis of $(C_5H_5)_4Ce$ or $(C_5H_5)_3CeCl$,[4] and it is not easy to reconcile cleavage of $(C_5H_5)_4Ce$ by isopropanol[4] with stability to water and dilute acids.[1] These contradictions and inconsistencies have led us to reinvestigate the reported synthesis[1] of tetrakis(cyclopentadienyl)cerium(IV).

EXPERIMENTAL

Reactions were carried out under purified (with BASF 3/11 oxygen-removal catalyst and molecular sieves) nitrogen in Schlenk assemblies, and solids were handled under purified nitrogen in Vacuum Atmospheres HE 43-2 or CSIRO dry boxes. Tetrahydrofuran and petro-

leum ether were purified as described previously.[10] Dipyridinium hexachlorocerate(IV)[11] and solutions of sodium cyclopentadienide in tetrahydrofuran[12] (standardized by acidolysis) were prepared by published methods. Infrared spectra of compounds as Nujol mulls were recorded with Jasco IRA-1 or Perkin–Elmer 257 or 180 spectrophotometers. The magnetic moment was determined at room temperature by the Gouy method for a sample sealed under nitrogen.

Reaction of dipyridinium hexachlorocerate(IV) with sodium cyclopentadienide

A solution of sodium cyclopentadienide (25 mmol) in tetrahydrofuran (19 cm³) was added to a suspension of dipyridinium hexachlorocerate(IV) (5.06 mmol) in tetrahydrofuran (120 cm³) under purified nitrogen at room temperature. The mixture turned dark brown within 1.5 min and brown–black in 3–4 min. After heating under reflux for 3 hr, a white precipitate and yellow solution were obtained, and no change was observed during further heating (16 hr). Filtration and evaporation to dryness (pyridine evolved with the volatiles) gave a dirty-yellow precipitate with an infrared spectrum in agreement with that of a sample of tris-(cyclopentadienyl)(tetrahydrofuran)cerium(III) (prepared by the thallous cyclopentadienide transmetallation route),[13] which was largely insoluble in petroleum ether (see reported behaviour of $(C_5H_5)_4Ce^i$). Sublimination (210–235°C, 10^{-3} mm) gave tris-(cyclopentadienyl)cerium(III) [47%; IR identical with a sample from sublimation of authentic $(C_5H_5)_3Ce(thf)$], not decomposed at 360°C, lit.[12] m.p. 435°C, $\mu = 2.30$ BM, lit.[12] $\mu = 2.46$ BM, with the known[12] violent air sensitivity.

RESULTS AND DISCUSSION

Reaction of dipyridinium hexachlorocerate(IV) with sodium cyclopentadienide (mole ratio 1:5) in refluxing tetrahydrofuran gave the highly air-sensitive tris-(cyclopentadienyl)cerium(III) [reaction (2)],

$$2(pyH)_2[CeCl_6] + 12Na(C_5H_5) \rightarrow$$

$$2(C_5H_5)_3Ce + (C_5H_5)_2 + 4C_5H_6 + 12NaCl + 4py \quad (2)$$

†Present address: Nobel Group, ICI Australia Operations Pty. Ltd., Deer Park, Victoria, 3023, Australia.

and not the reported[1] tetrakis(cyclopentadienyl)cerium(IV) [reaction (1)]. Although a longer reaction time (19 hr) was used than that reported (10–12 hr),[1] the appearance of the reaction mixture was unchanged from 3→19 hr. The evolution of pyridine [see eqn (2)] is hardly surprising, since sodium cyclopentadienide is a strong base and the pyridinium ion an acid.

Apart from refutation of the synthesis of $(C_5H_5)_4Ce$, the present results also cast doubts on reported preparations of tris(cyclopentadienyl)cerium(IV) compounds (e.g. [2–5]) especially those derived from $(C_5H_5)_4Ce$.[2,4] Published syntheses of tetra(fluorenyl)cerium(IV)[14] and dicycloheptatrienylcerium(IV) dichloride[15] by the same workers also could not be repeated.[7]

BOOK REVIEW

Organotransition Metal Chemistry: Applications to Organic Synthesis. Stephen G. Davies, Pergamon Press, Oxford, 1982, pp. xv and 411

Organic compounds of the main Group elements have been employed in organic synthesis for at least a century. The more recent development of organotransition metal chemistry as a coherent discipline is now pointing the way to the exploitation of these compounds in a wide range of versatile organic transformations. Coordination of an unsaturated ligand to a transition metal often significantly modifies the reactivity of the ligand. Arenetricarbonyl chromium complexes, for example, are activated to attack by nucleophiles compared with the free arenes, so that a sequence of reactions involving complex formation, addition of a carbanion followed by oxidative removal of the transition metal permits nucleophilic substitution of an arene. Free alkenes normally react by electrophilic addition. η^2-alkene dicarbonylcyclopentadienyliron cations, however, add nucleophiles, and the resulting substituted alkyl group can readily be removed from the metal in a variety of ways. An important feature of reactions especially valuable in synthesis of organotransition metal complexes is the high degree of regio- and stereoselectivity with which they often proceed.

Dr. Davies is a young organic chemist who is actively engaged in research on organotransition metal compounds and their applications in organic synthesis, and is therefore well qualified to write a book on the subject. He begins with a useful general introduction considering the structures of organotransition metal complexes and the bonding within them. For a system to be useful in synthesis, complex formation and subsequent removal of the metal function must proceed readily and in high yield. Such processes are covered clearly and systematically. The versatility and range of the methods already available to the organic chemist are brought out by chapters on organometallics as protecting groups, as electrophiles and nucleophiles, in coupling and cyclisation reactions and in isomerisation of olefins and acetylenes. Organotransition metal reagents can be employed either stoicheiometrically or as catalysts. Examples of the latter method include catalysed oxidation, hydrogenation and carbonylation of alkenes and of other unsaturated organic compounds. The use of chiral complexes in effecting asymmetric syntheses is also covered.

This book is recommended. As the author states in the Preface, coverage cannot be comprehensive. The work, however, provides a clear and wide ranging account of the possibilities and potential of this exciting new area of chemistry. It could be read with profit by organic and organometallic chemists, and by postgraduate and advanced undergraduate students. The price however, will probably prevent purchase by the latter group. The book is reproduced directly from the typescript. The index could be more comprehensive, although this is counteracted by the systematic organisation of the subject matter.

PAUL POWELL

CHEMISTRY OF SUBSTITUTED SULPHURIC ACIDS — XVII. COMPLEXES OF V(III), Cr(III), Mn(II) AND Fe(II) METHYLSULPHATES

SUNITI KUMAR SHARMA*, R. K. MAHAJAN, B. KAPILA and V. P. KAPILA

Department of Chemistry, Panjab University, Chandigarh 160 014, India

Abstract—V(III), Cr(III), Mn(II) and Fe(II) methylsulphates form stable donor-acceptor complexes with nitrogen donors. 1:1 and 1:2 complexes with bipyridyl have been prepared in respect of trivalent salts and 1:2 and 1:4 metal:base complexes have been obtained in respect of divalent metal salts with bipyridyl and pyridine respectively. Electronic spectra suggest an octahedral geometry around metal ions. IR spectra of the anhydrous metal methylsulphates have been studied and assigned. The changes in the IR spectra of the methylsulphate group in different stereochemical situations have been observed.

Paul *et al.*[1–4] have prepared and characterized a few transition and non-transition metal methylsulphates. Johnson *et al.*[5] reported the complexes of some divalent transition metal methsulphates. The preparation and characterisation of the complexes of the methylsulphates of title metal ions is being reported now.

EXPERIMENTAL

Vanadium(III), chromium(III) and manganese-(II) methylsulphates were prepared as described earlier.[1] Iron(II) methylsulphate was obtained in the same way by solvolyzing $FeCl_2$ with anhydrous CH_3SO_3H. Anhydrous methylsulphuric acid was prepared conductometrically.[2]

The bipyridyl complexes were prepared by shaking a stoichiometric amount of the reactants in methanol. The contents of the reaction mixture were concentrated and the complex precipitated and washed with solvent ether. The complexes of divalent metal methylsulphates with pyridine were obtained by dissolving the anhydrous salt in excess base and then metathesizing with solvent ether. The pyridine complexes of trivalent metal methylsulphates were prepared in an analogous manner except that no precipitating/washing solvent was used; instead the excess base was pumped off by prolonged evacuation at 70°C. All the compounds were ascertained for their composition by elemental analyses. The IR spectra were run as nujol mulls on IR 621. The electronic spectra of the solids were recorded as nujol mulls by the transmittance method on DMR–21 at I.I.T. Madras. The electronic spectra of the pyridine complexes of V(III) could not be recorded as they did not offer mulls of sufficient consistency. The magnetic moments were obtained by Gouy's method at room temperature. Allowance for diamagnetic corrections has been made in all cases. The solution spectra were recorded on a Beckman DB recording spectrophotometer. In Table 1 are recorded the magnetic moments, colour and analytical data of the compounds.

DISCUSSION

The divalent and trivalent transition metal methylsulphates have an octahedral $M[O_6]$ chromophore.[1] This is explained on the basis of the presence of bridging CH_3SO_3 groups in these compounds. Recent investigations[6] on some bifunctional titanium(IV) compounds suggest that the CH_3SO_3 group is an excellent bridging group.

The coordination number, stereochemistry, etc., of the complexes, in question, have been deduced on the basis of electronic and IR spectral data.

Electronic spectra and magnetic moments. The complex, $V(CH_3SO_3)_3 . 2Bipy$ has bands at 16.0 and 18.7 kK(v_1) and a band at 30.3 kK (v_3) whereas $V(CH_3SO_3)_3 . Bipy$ has bands at 14.9 (v_1) and 25.0 and 28.6 kK (v_3). The splitting of v_1 or v_3 bands is

ascribable to the presence of low symmetry ligand fields in these compounds. The position of these bands is indicative of octahedral vanadium(III) species.[7] In as much as bipyridyl is a bidentate donor, it may be concluded that the 1:2 complex has a $V[O_2N_4]$ chromophore and the 1:1 complex, $V[O_4N_2]$ chromophore. A bridging methylsulphate provides the fourth oxygen atom in the latter case. The proposition of an ionic $CH_3SO_3^-$ group seems obligatory in the case of the bis(bipyridyl) complex. Unfortunately, due to the insolubility of these compounds in conventional organic solvents, no conductometric investigations could be carried out to ascertain the existence of ionic groups.

The electronic spectra of the chromic complexes reveal the following bands: $Cr(CH_3SO_3)_3.2Bipy$: 14.7 and 16.0 (v_1) and 22.2 kK (v_2); $Cr(CH_3SO_3)_3$. Bipy: 15.9 (v_1) and 21.7 kK (v_2); $Cr(CH_3SO_3)_3.3Py$: 15.7 and 16.3 (v_1), 22.2 (v_2) and 30.8 kK (v_3). The v_3 band in the case of the first two complexes seems to have been lost under the envelope of charge transfer bands. The proposition of octahedral chromophores seems obligatory in the light of these observations.

The electronic spectra of the complexes of manganese(II) exhibit the following bands: Mn-$(CH_3SO_3)_2.4Py$: 13.3, 15.6 and 20.0 kK and $Mn(CH_3SO_3)_2.2Bipy$: 13.8, 15.0, 20.0 and 28.6 kK, but these bands are not revealing in that the band intensities could not be measured and hence no assignments could be made.

Iron(II) methylsulphate which has been pre-pared and characterized during the course of present studies, has two bands at 6.9 and 9.3 kK, arising out of the splitting of the ^5E_g excited state due to Jahn–Teller distortion.[7] The pyridine complex has bands at 8.9 and 12.5 kK whereas the bipyridyl complex has bands at 8.5 and 11.0 kK. The position of these bands consigns a coordination number of six to the ferrous compounds. The red colour of the bipyridyl complex seems to arise because of charge transfer bands occuring in the high energy region of the visible spectrum. Thus the solution spectrum of this complex in ethylenecarbonate (in which it does not furnish ionizable CH_3SO_3 groups) reveal three intense bands at 19.5, 20.5 and 28.6 kK of intensity 2980, 2250 and 1950 $Lmole^{-1}cm^{-1}$ respectively. These are recognised as metal→ligand C.T. bands. On the basis of simplified energy level diagram depicting metal t_{2g} and ligand π^* orbitals,[7] a 10 Dq value of 9.1 kK is approximated for the mixed ligand field which is well within the range of the 10 Dq values of similar systems.

The magnetic moments (obtained at room temperature) of all the compounds are in compliance with those expected from high-spin systems.

IR spectra

The CH_3SO_3 group can act as monodentate, tridentate or a bidentate ligand. In view of this, it is necessary to foresee the changes in vibrational spectrum of the methylsulphate group in different stereochemical dispositions.

(a) The symmetry of an isolated CH₃SO₃ group is lowered from C_{3v} to C_s if it is acting as a unidentate ligand. This lowering in symmetry is expected to bring about perceptible changes in the vibrational spectrum of the methylsulphate ion. Thus the three E modes, viz., SO₃ (asym. str.), SO₃(asym. bend) and S–C(wag), may split to give rise to six bands.[5]

(b) A tridentate CH₃SO₃ group has C_{3v} symmetry which implies that it will have the vibrational spectrum similar to that of the free ion.

(c) Although a bridging methylsulphate group has a larger number of bands than the possibility (b) above, but the presence of a bridging group should be acknowledged, only if other supplementary data[8] are available.

It may be possible, therefore, to use, to some extent, IR spectrum of CH₃SO₃ group for a diagnosis of its mode of coordination. The IR spectra of the anhydrous methylsulphates of the title ions have not been studied previously and are being assigned now (Table 2). It is noteworthy that the bivalent salts have just six fundamentals (3A + 3E)

ascribable to a C_{3v} symmetry (b) for the CH₃SO₃ group. A similar situation has been observed by Johnson et al. (loc.cit.). IR spectra of a few representative complexes are also tabulated. The assignments marked (b) in Table 2 are based on the assumption of monodentate CH₃SO₃ groups.

THERMAL DECOMPOSITION OF OXOVANADIUM(IV) COMPLEXES WITH SUBSTITUTED PYRIDINES

R. LOZANO*, J. MARTINEZ, A. MARTINEZ and A. DOADRIO LÒPEZ

Departamento de Química Inorgánica, Facultad de Farmacia, Universidad Complutense de Madrid,
Madrid (3), Spain

Abstract—The kinetics of decomposition of solid complexes of bis(dibenzoylmethanato) oxovanadium(IV) with pyridine and several methyl, dimethyl and aminopyridines has been studied using differential scanning calorimetry. Activation energies have been determined and, in general show an increase with increasing basicity of the ligands. A linear relationship exists between pK_b values of the bases and the temperatures for the decomposition, except for the complexes obtained with 4 aminopyridine and 4 methylpyridine. These complexes are less stable than expected from the basicity of the ligands. These observations are discussed in terms of the nature of the metal–ligand bond.

The use of thermal methods of analysis as a technique for studying bonding and structure of coordination compounds has increased greatly in the last few years.[1] Most of the thermal studies have been limited to a determination of temperatures appropriate for drying or ignition for analysis, but some of the more recent ones have yielded a considerable volume of kinetic and thermodynamic data for reactions in solid state.[2–8]

Bowman and Rogers[9] and House *et al.*[10,11] have determined the correlation between the stability of the various transition-metal complexes with pyridine and substituted pyridines with the ligand basicity and steric factors. They found that thermal stability increased with ligand basicity and that steric effects influenced stability in a predictable manner, i.e. when methyl groups blocked the co-ordinating position, the stability decreased.

Wendlant[12] reported a decreasing trend in thermal stability as the ligand on copper(II) sulphate changed from ethylenediamine to 1,2-propanediamine and to 1,3-propanediamine.

To determine the decomposition reactions and the thermal parameters associated with them complexes of bis(dibenzoylmethanato) oxovanadium(IV) with pyridine and several substituted pyridines, were prepared in the present work. We were also interested in determining the relationship between the basicity of the ligands and the temperatures and activation energies of decomposition of the solid complexes.

EXPERIMENTAL

(a) *Materials.* Vanadium(IV) oxide sulphate, dibenzoylmethane (dbm), pyridine, 3-methylpyridine, 4-methylpyridine, 3,5-dimethylpyridine, 3-aminopyridine and 4-aminopyridine were Merck commercial products. The solvents used to prepare the complexes were Carlo Erba or Merck.

(b) *Analytical procedures.* Elemental analyses were performed with a Perkin–Elmer model 240 B. Vanadium was determined by Atomic Absorption with a Perkin–Elmer model 430 Atomic Absorption Spectrophotometer after de-

composing the complexes with concentrated HNO_3 and concentrate H_2SO_4 mixture (1:1).

The analytical data for the complexes are shown in Table 1.

(c) *Methods.* Thermal measurements were performed using a Mettler HE-20 thermobalance and a Mettler T.A. 3000 system with a Differential Scanning Calorimeter model DSC 20, samples of about 5 mg being used so as to render insignificant the degree of temperature non-uniformity within the sample. Aluminium pan was used under a dry nitrogen atmosphere. The scanning rate used was 2°C/min, and the instrument calibration was checked periodically with standard samples of indium. In all cases several runs were made and the results are shown, in Table 2.

(d) *Preparation of complexes.* The complexes of pyridine (Py), 3-methylpyridine (3-MP), 4-methylpyridine (4-MP), 3,5-dimethylpyridine (3,5-DMP), 3 aminopyridine (3-AP) and 4 aminopyridine (4-AP) with bis(dibenzoylmethano) oxovanadium(IV), VO(dbm)$_2$, were prepared as follows:

$VO(C_6H_5-CO-CH=CO-C_6H_5)_2$
Bis(dibenzoylmethano) oxovanadium(IV), (VO(dbm)$_2$) was prepared from a warm ethanol solution (15 cm³) of 0.886 g (3.95 mmol) of dibenzoylmethane which was mixed with a warm solution of 0.5 g (1.97 mmol) of vanadyl sulphate in water (10 cm³) and ethanol (5 cm³) with stirring. Lastly, NaOH 2N is added drop by drop till reaching pH = 5. Green solid was formed, which was filtered *in vacuo*, washed with ethanol and water and recrystallized from cloroform–ether solution. Green crystals were obtained and dried over P$_2$O$_5$. Yield: 79%.
$VO(C_6H_5-CO-CH=CO-C_6H_5)_2$ (C$_5$H$_5$N)
This adduct can be prepared by two ways:
(a) A solution of 0.5 g (1.97 mmol) of vanadyl sulphate in a mixture of water (5 cm³) and ethanol (3 cm³) was prepared. Another solution of 0.886 g (3.95 mmol) of dibenzoylmethane in ethanol (15 cm³) was prepared. This solution was added to the first with vigorous stirring. Lastly, 1 cm³ of pyridine was added to the resulting solution and a brown solid was formed after *ca.* 24 hr at room temperature. This solid was filtered *in vacuo*, washed with water and ethanol mixture (1:1) and dried over P$_2$O$_5$. Yield: 86%.
(b) VO(dbm)$_2$ previously synthesized was dissolved in a ethanol solution of pyridine (1 cm³) with heating. After *ca.* 24 hr at room temperature, a brown solid was formed which was separated by filtration *in vacuo* and washed repeatedly with a water–ethanol mixture, (1:1), so that one obtains a brown power which was dried over P$_2$O$_5$. Yield: 83%.
A similar preparation was realised for the corresponding

complexes with 3-MP, 4-MP, 3,5-DMP, 3-AP and 4-AP as ligands.

DISCUSSION

The primary objectives of the present study were to determine the nature of the decomposition relations
Fig. 1. Arrhenius plot of log(dH/dt) vs 1/T for VO(dbm)$_2$ 3-MP.

for a series of complexes of VO(dbm)$_2$ with pyridine and substituted pyridines, and to investigate the relationship between the basicity of the ligands and the kinetics of decomposition of the solid complexes.

The analytical data in Table 1 show that all the complexes obtained contain one molecule of ligand. The formula which most closely fits the analyses is VO(dbm)$_2$L, where L is pyridine or a substituted pyridine.

The DSC curves corresponding to the decomposition of the complexes showed only a single endothermic peak. The mass loss accompanying the endothermic transition corresponded to the loss of pyridine or a substituted pyridine in all cases with the residue being VO(dbm)$_2$. Data for the thermal parameters and mass loss determinations are shown in Table 2.

The peak temperature that corresponded to the loss of the molecule of ligand:

$$VO(dbm)_2L \rightarrow VO(dbm)_2 + L$$
was used in the correlations. This temperature is underlined in the Table 2.

The activation energies were estimated by the method of Thomas and Clarke.[13] A plot of log dH/dt vs 1/T, Fig. 1, obtained from DSC data, was indeed found to be linear for $\alpha = 0.025$ to $\alpha = 0.211$ (see Table 2).

When the decomposition proceeds in the linear region over the range of temperature scanned by a calorimeter, the use of equation:

$$-\log k = -\log(dH/dt)(1/A)$$
$$= +\frac{E_A}{2.303RT} - \log C \qquad (1)$$

(k = rate constant; A = total area of DSC peak) to compute rate constants is justified. Moreover, the activation energy derived from Arrhenius plots repre-

equation (1) to VO(dbm)$_2$ 3-MP complex.

sents the true activation energy for interfacial reaction. Figure 2 shows the Arrhenius plots constructed from DSC data using the equation (1) for VO(dbm)$_2$ (3-MP).

Pyridine and the substituted pyridines used in this study, excluding 4 aminepyridine, provide only a relatively narrow range of basicities, but the effects on the kinetics of decomposition of solid complexes are quite large. Substituted pyridines and pyridine, listed in order of decreasing base strength, were:

4-AP > 3-AP > 3.5-DMP > 4-MP > 3-MP > Py.

The pK$_b$ value reflects the basicity of the ligand

towards the proton. It may be assumed, then, that the pK$_b$ of the ligand provides a measure of the ability of the ligand to form σ bonds to metal ions[14,15] In general, as can be seen from the data in Table 2, the greater the basicity and the higher the temperature to produce the loss of the ligand. The outstanding exceptions are the 4-AP and 4-MP complexes which will be discussed later.

The plot of pK$_b$ vs decomposition temperature presented in Fig. 3, shows that, except for the 4-AP and 4-MP complexes, a very satisfactory correlation was obtained. It is obvious from this figure that temperature is linearly related to the basicity for the ligands not containing a substituent group in the 4 position. It is also readily apparent that the ligands with a methyl and an amino group in the 4 position has a pronounced effect on the stability of the solid oxovanadium(IV) complexes. This effect is not reflected by the basicity of the ligand and can be due to the existence of the resonance structures of the types:

Fig. 4. Resonance forms.

When the pyridine ring contains a methyl and an amino group in the 4 position, the complexes obtained with these ligands are less stable and decompose more easily than those not containing a substituent group in the 4 position. Since the basicity toward the proton is a reliable measure of the σ bonding and electrostatic effects, one can say that there must be a significant difference in the tendency to form metal–ligand π bonds when a methyl or an amino group are in the 4 position of a pyridine ring and however the complexes containing 4-MP and 4-AP as ligand appear to be less stable than expected from the basicity of the ligand.

In general, the greater basicity the higher activation energy for the decomposition of the complexes (Table 2). The three complexes that appear not to follow this pattern are those of 4-AP, 4-MP and 3,5-DMP,
Fig. 3. Temperature for decomposition of the Vanadium oxo-complexes function of pK$_b$. Points 1–6 correspond to complexes of Py, 3-MP, 4-MP, 3,5-DMP, 3-AP and 4-AP respectively.

which present lower values of activation energy than expected from the basicity of the ligands. The explanation of this behaviour may be due to the existence of resonance forms, as we have seen previously to the complexes with 4-AP and 4-MP as ligand, and the steric factors or inductive effect exercised by the methyl groups to the complex with 3,5-DMP as ligand.

KINETICS OF OXIDATION OF HYPOPHOSPHITE ION BY Au(III) IN HYDROCHLORIC ACID MEDIUM

KALYAN KALI SENGUPTA,* BISWANATH BASU, SHIPRA SENGUPTA and
SANGHAMITRA NANDI
Department of Chemistry, Jadavpur University, Calcutta 700032, India

Abstract—Hypophosphite ion is oxidised by Au(III) in aqueous hydrochloric acid to give phosphorus acid and Au(I). The kinetics of the reaction has been studied spectrophotometrically in the UV region at different temperatures. The oxidation of hypophosphorous acid is first order with respect to both Au(III) and substrate. Hydrogen ion has no effect on the rate in acid media (0.15–1.0) M. The energy and entropy of activations are $128 \pm 3.0 \, kJ \, mol^{-1}$ and $135.8 \pm 6.5 \, JK^{-1} \, mol^{-1}$ respectively. The results are interpreted in terms of the probable formation of intermediate Au(II).

The kinetics of the oxidation of $H_2PO_2^-$ by various metal ion oxidants in acidic and alkaline media have been published.[1–4] Au(III) compounds which are toxic in nature were used earlier[5] in the treatment of tuberculosis. However, the toxic nature of the treatment was reduced by using hypophosphite as an antidote. The mechanism of oxidation of hypophosphite ion by Au(III) has not received attention. Au(III) as an oxidant is of interest because it may behave as an one equivalent or a two equivalent oxidant in the reaction with hypophosphite ion. Since Au(III) chloride is unstable with respect to substitution[6] in alkaline aqueous medium, the reaction has been studied in hydrochloric acid solution over a wide range of experimental conditions.

EXPERIMENTAL

Reagents. The materials employed were of highest purity available. Sodium hypophosphite (NaH_2PO_2) was of E. Merck grade. Chloroauric acid (Johnson–Matthey) was used to prepare solutions of Au(III). The concentration of Au(III) was determined gravimetrically[7] and the solution was stored in the dark and used under subdued lighting conditions. Hydrochloric acid was prepared by dilution of (B.D.H.) AnalaR grade stock solution and was analysed by titration with NaOH. Lithium chloride, sodium chloride and potassium chloride were (B.D.H.) AnalaR grade materials. All the solutions were made in doubly distilled water.

Absorption spectra of Au(III) solution. The absorption spectrum of Au(III) solution in 0.1–2.0 M hydrochloric acid in the concentration range $(0.25–1.5) \times 10^{-4} \, M$ was recorded in the UV region. The spectral pattern remained unaltered with changes in the concentration of Au(III). The spectra showed two very strong bands in the ultraviolet region[8] (227 nm, $\epsilon = 35,750$ and 315 nm, $\epsilon = 5400$ $M^{-1} cm^{-1}$). Beer's law has been found to be valid in the concentration range studied.

Kinetic measurements. The reaction was carried out under pseudo-first order conditions, i.e. at high concentration of hypophosphite ion compared to that of Au(III) concentrations. The rates were determined by following the decrease in the optical density of Au(III) at 315 nm in a Perkin–Elmer (Hitachi 200) spectrophotometer equipped with thermostated holders. Other reactants and products of the reaction had negligible absorption at this wavelength. The reactants were separately equilibrated to temperature,

mixed externally and immediately transferred into a cell of path length 1 cm. There is an initial period of disturbance at the beginning of the reaction after which the reaction obeyed good first order kinetics (Fig. 1). Pseudo-first order rate constant (k_{obs}) was determined from the slope of linear portion of logarithm (optical density) vs time plot. The rate constants obtained from different determinations were within $\pm 5\%$ of each other.

RESULTS

Stoichiometry and product analysis: Au(III) was mixed with a large excess of hypophosphite ions and kept for 2 hr at $[H^+] = 1.0$ M. Analysis[9] of unreacted reductant indicated the following stoichiometry.

$$Au(III) + H_3PO_2 + H_2O \rightarrow Au(I) + H_3PO_3 + 2H^+. \quad (1)$$
Phosphite ion was identified by thin layer chromatography[10] on silica gel G (E. Merck) using the
Fig. 1. Typical pseudo-first order plots for the oxidation of hypophosphite ion by Au(III) in HCl solution. $[Au(III)] = 1.0 \times 10^{-4} M$, $[H]^+ = 1.0 M$, Temp = 50°C and $[H_2PO_2^-] = (1) \, 0.5 \times 10^{-2}$, (2) 1.0×10^{-2}, (3) 2.0×10^{-2}, (4) 3.0×10^{-2}, (5) 4.0×10^{-2}, (6) $5.0 \times 10^{-2} M$.

*Author to whom correspondence should be addressed.

mixture of methanol, ammonia, trichloroacetic acid and water as the solvent system. A control TLC experiment was also done together with hypophosphite, phosphite and phosphate from which it was confirmed that hypophosphite ion was converted only to the phosphite stage (R_f value $= 0.74$ and lit. R_f value[4b] $= 0.75$). There is no evidence of a redox reaction between the H_3PO_3 and Au(III) under the condition of the experiment. However when Au(III) was in large excess to that of the substrate and the reaction mixture was stored for several hours, further oxidation of phosphorous acid occurred leading to the formation of phosphoric acid. Gold metal is sometimes generated[6] by further reduction of Au(I) by excess of reductant and/or by the disproportionation at lower acidities (< 0.2 M). However, we have no evidence for the formation of gold metal during 2 hr in $[H^+] = 1.0$ M.

Test with vinyl compound. A solution of Au(III) (1 cm³, 1×10^{-3} M) was added to a solution containing substrate solution (2 cm³, 1.0×10^{-1} M), HCl (5 cm³, 2.0 M) and acrylamide (2 cm³, 40% w/v) and the total volume was adjusted to 10 cm³. The addition of a large volume of methanol gave a suspension indicating that the reaction of Au(III) and hypophosphite ion in acid medium induces the polymerization of acrylamide whereas neither Au(III) nor hypophosphorous acid alone induces appreciable polymerization.

Effects of reactant concentration. The reaction was studied at different Au(III) concentrations. The average pseudo-first order rate constants are $(3.04 \pm 0.12) \times 10^{-4}$ sec^{-1} at [Au(III)], [$H_2PO_2^-$], [H^+] and temperature of $(0.125 - 1.25) \times 10^{-4}$ M, 2.0×10^{-2} M, 1.0 M and 35°C respectively. This indicates that pseudo-first order rate constant is independent of initial Au(III) concentration. Several other experiments were also carried out at constant acidity and Au(III) concentrations but varying concentrations of the substrate. The rate of reaction was found to increase with increase in substrate concentration (Table 1). The plots of k_{obs} against [substrate] are linear at different temperatures passing through the origin indicating that order with respect to substrate is unity (Fig. 2) and kinetic evidence for 1:1 complex formation is insignificant. The oxidation of hypophosphite ion was also studied in hydrochloric acid medium (0.15–1.0) M. The ionic strength was held constant at 1.0 M by the addition of sodium chloride. Hydrogen ion has no effect on the rate of reaction.

Effect of salts. The influence of addition of three different salts such as lithium chloride, sodium chloride and potassium chloride was investigated. The reaction was studied at [$H_2PO_2^-$], [Au(III)] and [H^+] of 1.0×10^{-2}, 1.0×10^{-4} and 1.0 M respectively where salt concentrations were varied between the limits (0.2–1.0) M. The reaction rate is independent of added salt-concentrations. The present observation is similar to that obtained by Moodley and Nicol[12] in the oxidation of Pt(II) by Au(III) and suggests that the path involving higher chlorocomplex of Au(III) is not significant. Moreover, participation of aquo and hydroxo complexes like $AuCl_3(H_2O)$ and $AuCl_3(OH)^-$ are unlikely[13] since in those cases the rate would have decreased with the increase in both hydrogen and

chloride ion concentrations as shown below

$$AuCl_4^- + H_2O \rightleftharpoons AuCl_3(H_2O) + Cl^- \qquad (2)$$

$$AuCl_3(H_2O) \rightleftharpoons AuCl_3(OH)^- + H^+. \qquad (3)$$
Activation parameters. The second order rate constants (k_2) at different temperatures were calculated. The values of k_2 are $(1.37 \pm 0.2) \times 10^{-2}$, $(3.17 \pm 0.11) \times 10^{-2}$, $(6.3 \pm 0.25) \times 10^{-2}$ and $(14.35 \pm 1.5) \times 10^{-2} (M^{-1} \sec^{-1})$ at 35, 40, 45 and 50°C respectively. The energy of activation was calculated from log k_2 vs $1/T$ plot and has been found to be 128 ± 2.0 kJ mol^{-1}. The value of $\triangle S^*$ has been calculated to be 135.8 ± 6.5 JK^{-1}mol^{-1}.

DISCUSSION

Hypophosphite ion is oxidised to phosphorous acid stage in acid solution and further oxidation of phosphorous acid was very slow under the conditions of experiment. The addition of ammonium molybdate to the reaction mixture failed to precipitate ammonium phosphomolybdate just after the kinetic experiment indicating the absence of phosphate ion. This has been confirmed from the TLC experiment which again indicated that phosphorous acid is the product of oxidation. Hypophosphorous acid oxidations are characterised by equilibria involving active and inactive forms[2,3,11] and the active form is known to be a better electron donor than the normal form of the substrate. Hypophosphorous acid which ionises according to the equilibria.

$$H_3PO_2 \overset{K_1}{\rightleftharpoons} H^+ + H_2PO_2^- \qquad (4)$$

has a dissociation constant (K_1) of 1.0×10^{-1}. This will remain in the undissociated form in the presence of sufficient acid (~ 1.0 M). Again HAuCl$_4$ remains in equilibrium with H$^+$ and AuCl$_4^-$ in hydrochloric acid

solution $(K_2 = 1.0 \pm 0.1)$ as follows.[12,14,15]

$$H AuCl_4 \overset{K_2}{\rightleftharpoons} H^+ + AuCl_4^-. \qquad (5)$$

In the present study hydrogen ion has no effect on the rate of reaction. So even if both dissociated and undissociated species are present, they appear to have the same kinetic properties. It is suggested that the reacting oxidising species attacks the undissociated molecule of the substrate. The reaction between a metal ion and a ligand usually prefers a complex formation rather than second order mechanism[16] and the energy of activation of the former process is smaller than that of the simple second order mechanism. In the oxidation of hypophosphorous acid by some metal ions,[3-5] it has been shown that the intermediate complex is formed between the active form of the substrate and the oxidising agent

$$H_3PO_2(\text{active}) + \text{Oxidant(ox)} \overset{\text{fast}}{\underset{\text{slow}}{\rightleftharpoons}} H_3PO_2 \cdot Ox$$
$$\rightarrow \text{Reaction Product.}$$
On the other hand, in the oxidation of hypophosphorous acid by hexachloroiridate(IV)[17] kinetic evidence failed to give an indication of the formation of an intermediate complex between hypophosphorous acid and Ir(IV). Likewise, complex formation between hypophosphorous acid and Au(III) has not been observed in the present study and the rate is strictly proportional both to hypophosphorous acid and Au(III) concentrations. This is supported by the high energy of activation obtained in this study as compared to the earlier studies where 1:1 intermediate complexes were formed between metal ion and hypophosphorous acid prior to electron transfer.[1,3,4] However, Au(III) may be reudced in either one electron change or by two electron change in the slow step. The observed polymerization in acrylamide is strongly indicative of free radical intermediates in the present study. It is, therefore, suggested that the initial reaction of active form of hypophosphorous acid with Au(III) takes place producing free radicals thereby reducing Au(III) into Au(II). The evidence for the existence of Au(II) as a reaction intermediate has also been shown in earlier studies.[12,14,17] The free radical further reacts with another Au(III) and by fast step (8) gives phosphorous acid. Au(II) undergoes disproportionation and gives Au(III) and Au(I). The reaction takes place as follows where step (6) is slow and all other steps are fast.

$$(6)$$

$$+ Au(II) + H^+ \qquad (7)$$

$$[(HO)_2P:]^+ + H_2O \rightarrow H_3PO_3 + H^+ \qquad (8)$$

$$2Au(II) \rightarrow Au(III) + Au(I). \qquad (9)$$
Thus the following two electron mechanism (step 10) may be ignored in the present reaction.

$$\begin{array}{c} H \\ | \\ HO - P \\ | \\ OH \end{array} : + Au(III) \xrightarrow{slow} [(HO)_2P:^+]^+ + Au(I) + H^+. \qquad (10)$$
In the photolysis[18] of tetrachloroaurate(III)-oxalate system in aqueous acidic solution $AuCl_2^-$ and Au(O) were obtained from $AuCl_4^-$, whereas in the thermal decomposition of tetrachloroaurate(III)-oxalate system only $AuCl_2^-$ was obtained.[19] According to a number of authors[20] colloidal gold was formed when $HAuCl_4$ was exposed to UV light or sunlight and its formation was enhanced when the irradiation was carried out in the presence of reducing species for a long time. Regardless of which mechanism (6) or (10) is correct one piece of information is obtained with certainity that in hydrochloric acid solution further reduction of Au(I) does not occur under kinetic conditions and in this respect the present result is in agreement with that reported earlier by Moodley and Nicol.[12]

and

A. M. GUTIERREZ

Departamento de Química Analítica, Facultad de Ciencias Químicas, Universidad Complutense, Madrid-3, España

Abstract—The low temperature ^{1}H NMR spectra in *d*-chloroform of the ternary complexes bis-(8-quinolinato) tin(IV) dichloride, bis-(5,7 dichloro-8-quinolinato) tin(IV) dichloride, and bis-(2 methyl-5,7-dichloro-8-quinolinato) tin(IV) dichloride have been obtained. The spectra showed that for the three complexes, only two configurations were appreciably populated, their free energy differences being equal to 0.28, 0.08 and − 0.04 kcal/mol respectively. The proton chemical shifts, the ^{1}H–^{1}H coupling constants and some of the ^{1}H–^{119}Sn coupling constants have been obtained for each complex in the two configurations. An approximate computation of chemical shifts, including aromatic ring magnetic anisotropies and electric effects from polar groups, allowed the identification of the two configurations as the *cis-cis-trans* and the *cis-trans-cis* (with respect to Cl, N and O atoms), the former being the more populated one.

Some structural studies on solutions of organotin(IV) substituted 8-quinolinols can be found in the literature.[1–3] Nevertheless, complexes of this type not involving metal–carbon bonds have received much less attention, mainly due to their low solubilities.[4,5] With the use of high field NMR spectrometers, the sensitivity problems are greatly reduced, and the pattern of NMR lines simplified, so it is now possible to extend structural studies to this type of complexes.

Recently, a detailed study on the complexation of tin(IV) by 8-quinolinol and its derivatives has been reported,[6] and we have considered it interesting to investigate further the structure of these complexes by proton NMR.

In this paper, we report the low temperature ^{1}H NMR spectra in *d*-chloroform of the ternary complexes, bis-(8-quinolinato) tin(IV) dichloride (Cl_2SnQ_2), bis-(5,7-dichloro-8-quinolinato) tin(IV) dichloride $(Cl_2Sn(CQ)_2)$ and bis-(2-methyl-5,7-dichloro-8-quinolinato) tin(IV) dichloride $(Cl_2Sn(MQ)_2)$. From their analyses, the chemical shifts and the ^{1}H–^{1}H and ^{1}H–^{119}Sn coupling constants were obtained. With the help of an approximate computation of chemical shifts, the different configurations that coexist in solution were also identified.

EXPERIMENTAL

Preparation of complexes

Details of the synthesis and purification of the complexes were reported previously.[6]

Proton NMR spectra

They were recorded at 360 MHz in the Fourier mode on a Bruker WM-360 pulse spectrometer. *D*-chloroform of the highest degree of deuteration

available (99.98%, Stohler Isotope Inc.) was used to reduce the dynamic range problem originated by the residual signal from the protonated solvent. Saturated solutions corresponding to 3.0, 5.1 and 0.5 mM respectively, flip angles of 70°, 16 K of memory, 10000 scans and a relaxation delay between pulses of 2 sec were used. When needed, digital filtering of the free induction decay was used to improve signal to noise ratio (line broadening factor of 1 Hz). Alternatively, the Gauss–Lorentz multiplication was used to enhance resolution in some spectra. The chemical shifts were measured with respect to the chloroform signal, and assigned a value of 7.300 ppm. Low temperature spectra (− 30°C) were obtained with the standard Bruker accessory by flushing the sample with cool N_2 gas. The temperature was calibrated with a methanol thermometer[7] and the precision of the regulator was ± 0.5°C.

Other nuclei NMR spectra

The NMR spectra of nuclei other than proton could give supplementary information on the structure of the complexes, so attempts were made to obtain ^{13}C and [119]Sn spectra. A ^{13}C NMR spectrum of the most soluble complex (Cl_2SnQ_2) was obtained on an overnight accumulation, but the poor signal to noise ratio prevented any detailed study. Although the [119]Sn nucleus is a more sensitive one, its larger line width precludes the obtaining of spectra at these very low concentrations. In fact, our attempts to obtain a [119]Sn low temperature NOE suppressed NMR spectrum of the above mentioned complex were not successful.

Calculation of shieldings

The effect of the anisotropy of one 8-quinoline ring on the shieldings of the five protons of the other ring in the five configurations of the complex has been calculated by the method of Johnson–Bovey.[8] A FORTRAN program written in our laboratory that, from a known geometry (bond lengths and angles), calculates the shieldings originated by a phenyl ring on selected atoms, has been used. In the absence of aromaticity values for the 8-quinoline ring, the approach of two phenyl rings of additive effects was employed. An approximate geometry for the *cis-cis-trans* configuration was obtained from the dimethyl bis(8-quinolinato) tin(IV);[9] for the other configurations the geometry of the 8-quinoline ring was maintained, and right angles around the tin atom were used.

The polar Sn–Cl bonds can only affect the shielding of very close protons, and the effects will depend on the relative orientation of the Sn–Cl and C–H bonds. An inspection of a molecular model

showed that this effect can be of importance for the proton H2 in the *cis-trans-cis* configuration, and less important although noticeable for the proton H7 in the *cis-cis-trans* configuration. For other protons within the molecule the effects are very small, and in addition they tend to cancel each other in most cases. The shieldings were computed by the method of Buckingham,[10] with the approximate geometries already mentioned and $\mu(Sn–Cl) = 3.5$ D taken from the $(CH_3)_3SnCl$.[11]

Shieldings of appreciable intensity due to Van der Waals dispersions,[12,13] could arise only from atoms very close to each other. The two H2 protons in the *trans-cis-cis* configuration were the only potential candidates, and its effect if any, is to decrease their shieldings. However, any attempt to evaluate Van der Waals effects in this molecule remains speculative, because the lack of a precise knowledge of both the polarizability α of the C–H2 bond, and the distance between the two H2 protons, that directly affect the computed shieldings. Other through-space effects like magnetic anisotropies and electric moments involving the N and O atoms will not produce noticeable shieldings on any proton because of the large distances involved.

RESULTS AND DISCUSSION

Proton NMR spectra

The 360 MHz ^{1}H NMR spectra at low temperature of the three complexes are shown in Fig. 1; the spectra of the free ligands were also obtained and the centres of the multiplets are indicated in the figure. Some of the free ligand spectra at 100 MHz in d_6-dimethylsulphoxide, and at 220 MHz in d-chloroform have been reported previously.[4,14]

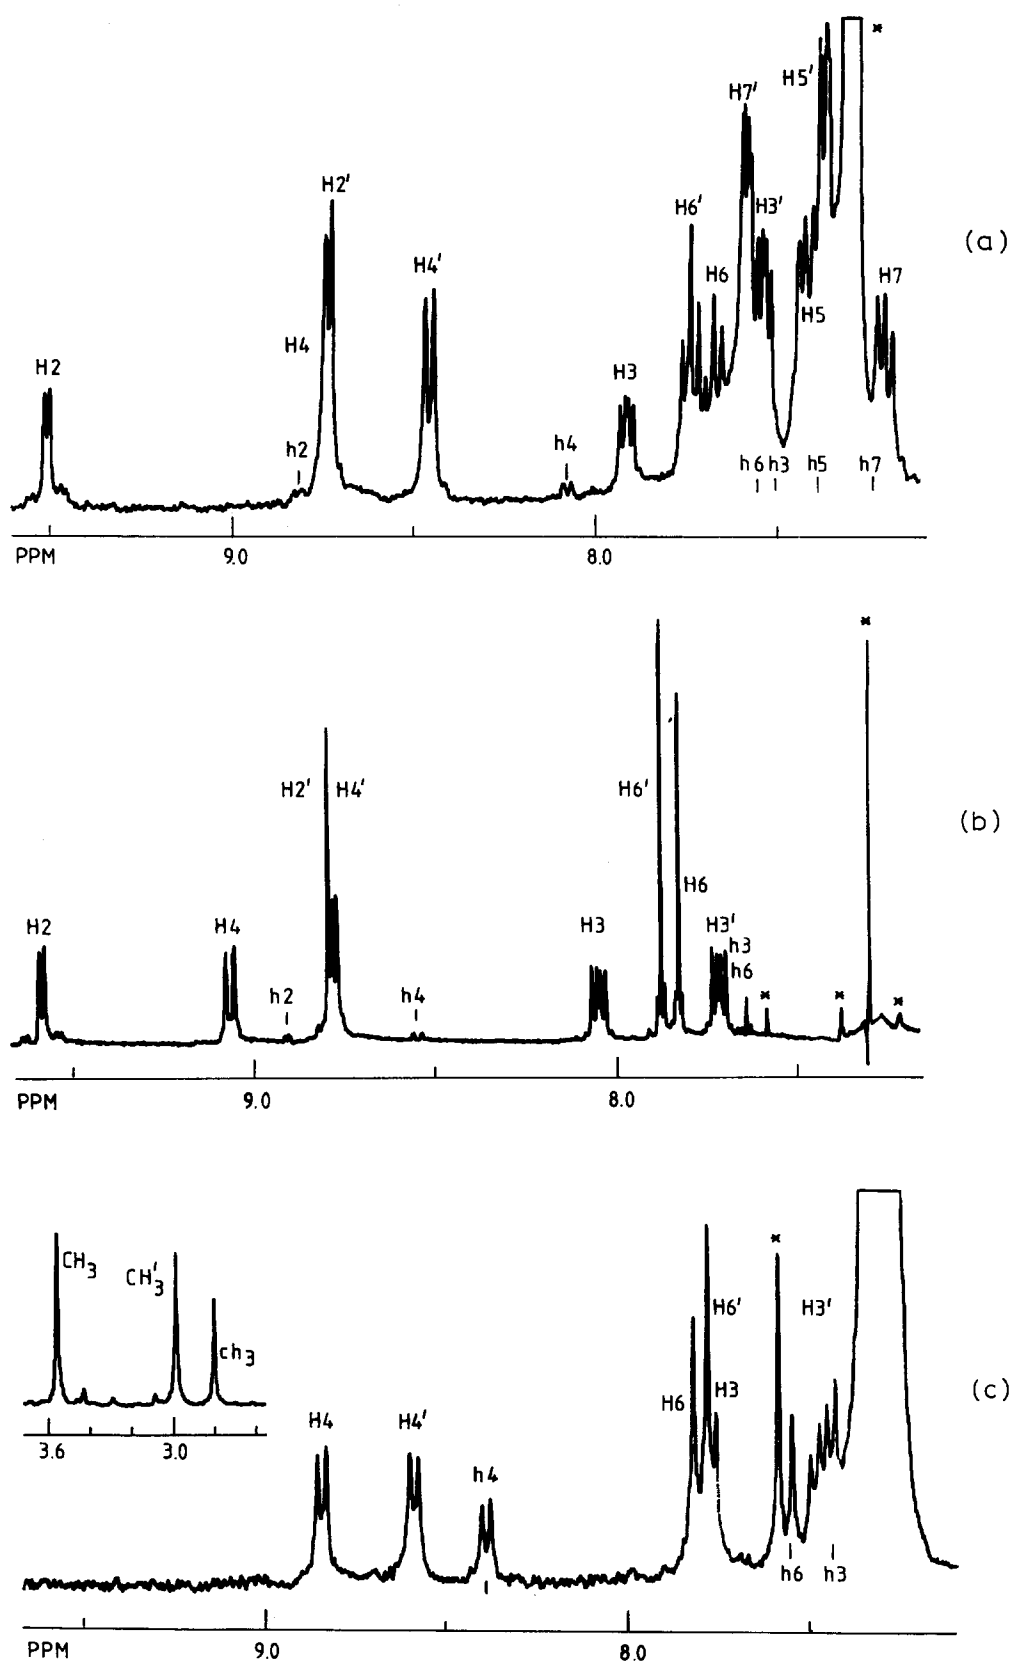
Three features are readily recognized on these spectra. First, two set of signals of unequal intensity are observed for each complex showing that two configurations are present. Second, satellite lines appear at both sides of every line, corresponding to the couplings of protons to the tin atom; the coupling constants are not large enough to distinguish between [1]H–[117]Sn and [1]H–[119]Sn couplings. Due to the poor signal to noise ratio, tin-proton couplings are observed only for two of the complexes (Tables 1 and 2). Third, only minor intensity lines from impurities of the free ligands appear in the spectra, except for the $Cl_2Sn(MQ)_2$ complex that partially decomposes when dissolved unless an excess of free MQ is added.[6] In the NMR spectrum of this last complex three additional very low intensity lines appear in the region 2.8–3.6 ppm, that must correspond to the methyl groups of the other three less populated configurations of the complex. At 360 MHz the spectra are nearly first


Fig. 1. 360 MHz ^{1}H NMR spectra at $-30°C$ of the complexes in $CDCl_3$ (a) Cl_2SnQ_2, 3.0 mM, (b) $Cl_2Sn(CQ)_2$, 5.1 mM, (c) $Cl_2Sn(MQ)_2$, 0.5 mM. Lower case letters mark the free ligands' resonances, apostrophes distinguish between the two configurations of each complex, and the asterisks mark lines from the solvent.

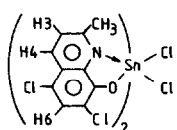
order, so they can be straightforwardly analyzed, the chemical shifts and coupling constants being shown in Tables 1–3.

As a general rule, the NMR lines of the complexes are shifted downfield with respect to the lines of the free ligands, with the only exception of the proton H2 in the more populated configuration. In addition to other effects, the coordination of chloride atoms to the tin atom could contribute appreciably to this general downfield shift, as the same effect has been reported in the ^{13}C spectra of chloroderivatives of alkyltin compounds.[15] The $^1H-^1H$ coupling constants are very similar in the two configurations of each complex, and these in turn are very close to the coupling constants of the free ligands, although slight differences beyond the experimental error are detected, in particular for the J_{23} coupling.

Tin-proton coupling constants for protons H2 and H3 are of the same order of magnitude as those reported for aryltin compounds.[16] In both complexes, Cl_2SnQ_2 and $Cl_2Sn(CQ)_2$, the $^3J(^{119}Sn-^1H)$ couplings for protons H2 and H3 were smaller in the more populated configuration, thus reflecting a variation in the dihedral angle Sn–C–C–H. Although a Karplus type relationship between the dihedral angle and the vicinal $^{119}Sn-^{13}C$ coupling constant has been established,[17] an analogous relationship for the $^3J(^{119}Sn-^1H)$ is not yet available, so that the variation cannot be evaluated quantitatively. Conversely, the $^3J(^{119}Sn-^1H)$ couplings in a given configuration are very similar, in the two complexes, which indicates that the dihedral angle Sn–C–C–H is maintained.


Stereochemistry

These hexacoordinated complexes of the type $M(L-L')_2X_2$ can exist in five different configurations[18] in solution, enantiomers being indistinguishable from the NMR point of view. The cis-cis-cis (with respect to Cl, N and O atoms) configuration has no symmetry (point group C_1), the two 8-quinoline rings are not equivalent and it should give two set of NMR signals of identical intensity. In the other four configurations, cis-trans-cis (C_2), cis-cis-trans (C_2), trans-cis-cis (C_{2v}) and trans-trans-trans (C_{2h}), the two 8-quinoline rings are equivalent and only one set of NMR signals are expected for each configuration. As only two sets of unequal intensity signals are observed for the three complexes, the presence of the cis-cis-cis configuration can be definitively discarded, and only two of the remaining four possible configurations are appreciably populated and coexist in solution. To identify them a more detailed analysis of the experimental chemical shifts is required.

The lines in the NMR spectra of the complexes are shifted with respect to their positions in the free ligand. Two types of effect contribute to these shifts. The first effect is the change in the shielding of the protons due to the coordination of the 8-quinoline ring and the chloride to the tin atom ("through bond" shifts). The second effect is the change in the shieldings due to the proximity of anisotropic groups ("through-space" shifts). The net result of these two contributions is the shift we measure in the spectrum. As "through-bonds" shieldings are difficult to evaluate a priori, no values obtained in similar tin(IV) complexes being available, the "through space" shieldings cannot be obtained by the differences in frequency between "coordinated" and "free" 8-quinoline ring protons. However, it is reasonable to suppose that these "coordination shifts" are of similar magnitude for the five different configurations of a given complex so, if chemical shift differences between configurations are considered, only through space effects do have influence. These effects can be approximately evaluated, and the comparison between observed and computed differences of chemicals shifts will provide a means to identify the configurations that coexist in solution.

Table 4 shows the shieldings computed for the five protons of the 8-quinoline ring, in the five configurations of the Cl_2SnQ_2 complex (details are

Table 3. Proton chemical shifts (δ, ppm from Cl_3CH) and $^1H-^1H$ coupling constants (J, Hz) of the two configurations of the $Cl_2Sn(MQ)_2$ complex, 0.5 mM and − 30°C (360 MHz)

given in the experimental part). The computed differences of shieldings among all possible pairs of configurations are shown in Table 5, that also includes the comparison with the experimental differences obtained from the NMR spectra. Four of the six pairs can be readily excluded and in the remaining two, the cis-cis-trans configuration is included, so its presence is definitively confirmed. It can be seen that the agreement of the pair cis-cis-trans and cis-trans-cis is very good, so the presence of the cis-trans-cis as the second configuration is strongly favoured. Although the agreement of the pair trans-cis-cis and cis-cis-trans

is considerably worse, it cannot be completely excluded on the basis of this calculation alone, due to the approximate character of both the geometry and the calculation of shieldings. Two additional reasons support the absence of the trans-cis-cis configuration. First, the experimental differences of shieldings between the two configurations are very similar for the three complexes we studied here, which indicates that the configurations that coexist in solution are the same in the three cases. In the case of the $Cl_2Sn(MQ)_2$ complex, it is very unlikely that the trans-cis-cis configuration could be appreciably populated, because of steric hin-

* $\Delta\delta_{ab}=\sigma_a-\sigma_b$, where σ's are computed shieldings and a and b refer to the numbering of configurations, both shown in Table IV.

** $\Delta\delta_{I-II}=\delta(config.I)-\delta(config.II)$; I and II refer to the two configurations of Tables I-III.

drance of the methyl groups. Second, it has been reported on other tin(IV) dichloride complexes[19,20] that the *cis* halogen configuration is favoured against the *trans*.

From all the reasons discussed we conclude that the three complexes studied here adopt the same two configurations in solution, the *cis-cis-trans* and the *cis-trans-cis*, the former being the more populated one. Free energy differences between them, obtained through the relationship[21] $\Delta G^0 = - RT \ln (p_2/p_1)$ where p_2/p_1 is the population ratio measured in the NMR spectra, were 0.28, 0.08 and $- 0.04$ kcal/mol respectively. As the temperature is raised, the two configurations begin to exchange more rapidly thus originating a broadening and shifting of lines in the NMR spectrum.

Abstract—The ESCA characterization of three similar new amorphous addition complexes of tin dichloride with tetradentate aromatic Schiff bases has been carried out. The results support the previously proposed ionic structure.

The solid state structure of addition products is generally an interesting problem, since their various properties are strictly related to it.

In this paper we present a peculiar case of solid state influence on the complexing properties of similar compounds.

The syntheses and characterization of our interest new addition complexes 1–3 of $SnCl_2$ with aromatic Schiff bases L_1-L_3 has been reported in a previous paper.[1]

L1; n = 2   1; $(SnCl_2)_2L_1$
L2; n = 4   2; $(SnCl_2)_2L_2$
L3; n = 6   3; $(SnCl_2)_2L_3$

Elemental analysis, IR, Mass Spectrometry and Conductance Measurements indicate the presence of 1:2 (ligand: $SnCl_2$) adducts, with an ionic type structure.

The nature of the chemical structure of these compounds was to be checked in the solid state, being the most important previously used techniques operating in the gas-phase (MS) and in solution (Conductance measurements).

As references compounds uncomplexed polymeric systems 4–6 have been used.

EXPERIMENTAL

Compounds 1–3 and polymers 4–6 have been prepared following the procedure described in literature.[1,2]

The Esca spectra were obtained with a KRATOS ES-300 electron Spectrometer. The measurements were performed with $Al_{K\alpha1,2}$ photon source. The vacuum in the analysis chamber was better than 10^{-8} Torr. The samples were stable in
4 : n = 2
5 : n = 4
6 : n = 6

*Author to whom correspondence should be addressed.

vacuum. Each sample was introduced into the Spectrometer both as powder stripped onto an Indium strip as well as powder pellets obtained under reduced pressure (rotary pump) and attached to a Ni–Cr wire with a silver glue.

The N 1s, O 1s, S_n $3d_{5/2}$ and Cl 2p peaks were monitored at different times of irradiation in order to detect eventual reduction processes. No sign of reduction was found for powder pellets.

RESULTS AND DISCUSSION

The Binding Energies (B.E.) of the main peaks of the compounds 1–6 are reported in Table 1.

The B.E. values of Sn $3d_{5/2}$ peak and its separation from Cl 2p and C 1s peaks are in the range of values reported for Sn (II) and Sn (IV) ions.[9] However, we found that the Sn B.E.'s[9] are lower than expected for Sn (II) chelates. This fact suggests that a higher electron density is present on the Sn ions.

The internal distances and the relative abundances of Sn 3d and Cl 2p peaks remain constant for all the adducts.

It is worth noting that while the Sn 3d peaks have a F.W.H.M. of 2.0–2.1 eV in accordance with the presence of one kind of Sn ion, the Cl_{2p} peaks are instead broad and somewhat different in shape with respect to the characteristic Cl doublet.

This fact suggests that more than one chlorine ion could be present.[8] The Sn/O ratio is about the same for the adducts 1 and 3 whereas in the case of adduct 2 it is slightly lower indicating, probably, a greater difficulty of the ligand to complex with $SnCl_2$ in this case.

There is no evidence of structure effects on the Sn and Cl B.E.'s or peak shapes on going from 1 to 3 adducts.

The C 1s bands are asymmetric in shape being a convolution of two peaks which should be separated of about 1.6 eV in energy.

In accordance with the literature,[3,4] the peak of lower energy (and higher intensity in our spectra) could be attributed to the aromatic carbons (284.8 eV) and in the same region is expected to fall the peak arising from the –CH_2– groups nonbonded to the nitrogens.

The peak at higher B.E. (and lower intensity in our spectra) is attributed to the C=N groups. In fact the B.E. values observed are almost the same to those reported in the literature.[3-5]

To this class of carbon atoms are also belonging the CH_2–N, groups.

The C 1s bands show an intensity decrease of the unresolved component at higher B.E. on going from 1 to 3 adducts. This is in accordance with the relative weight increase of the –CH_2– groups for compounds 2 and 3. The comparison with the corresponding polymers 4–6 shows that the complexation induces only minor variations in the features of C 1s bands for the compounds 2 (showing a small increasing in F.W.H.M. of the peak) and 3 (showing a more marked asymmetry) with respect to 5 and 6 polymers. The compound 1 does not show any difference with respect to 4.

The complexation is found instead to affect strongly the O 1s and N 1s spectral features.

The N 1s peaks (Fig. 1) are very large and asymmetric in shape. The reference compounds 4–6 show on the contrary a symmetric and narrower shape. The observed increasing of F.W.H.M. are of about 0.8–1.1 eV on going from 4–6 to 1–3 compounds. In general the centroid of the whole N 1s band in the 1–3 compounds is shifted by 0.7–1.3 eV from compound 1 to 3.

The N 1s bands seem to be constituted by two distinct peaks (in various relative ratios) with about the same internal shift for all the adducts (Table 1).

The peak at lower B.E. is attributed to the non-complexed nitrogen atoms (as confirmed by

Table 1.[a]

Compound	O$_{1s}$		N$_{1s}$		Sn$3d_{\frac{5}{2}}$	Cl$_{2p\frac{3}{2}}$

the very close value of the uncomplexed polymers **4–6**), while the peak at higher B.E. to the complexed nitrogen atoms. In fact, the B.E. values are comparable with those observed for Schiff base metal complexes.[6,7] The positive chemical shift for N 1s is found consistent with a decrease in electron density on the nitrogen site upon coordination to the metal.

The compound **1** shows an almost non-bonded nitrogen; on the contrary in compounds **2** and **3** the nitrogen is in prevalence bonded.

The O 1s peaks of compounds **1–3** show a symmetric shape and a homogeneous B.E. shift towards lower values, with respect to the reference compounds **4–6**. A slight increase of F.W.H.M. can be seen when considering compounds **1–3** with respect to **4–6** (2.5–2.8 eV vs 2.0–2.3 eV). This fact could be explained with the existence of a lower intensity component corresponding to the no bonded oxygen in compounds **4–6** and of a higher intensity component shifted of 1.3–1.4 eV at lower B.E. values.

In accord with such negative O 1s shift we think that in all the cases the –OH linkage is replaced by –Ō–Sn^{2+} and that for adducts **2–3** the proton could become bonded to the nitrogens.

The higher B.E. component could be due to two different contributing factors:

(a) Water contamination, comparable for the three compounds; in fact the B.E. of the water O 1s peak should be close to that one of non-bonded O 1s component.[6]

(b) An excess of base with respect the Sn available.

On the basis of the previous observations some considerations can be made about the solid state nature of our adducts:

(i) That most of the oxygen sites are complexed with the tin in all the adducts.

(ii) The Sn/Cl ratio and the relative B.E.'s are almost the same in the three compounds.

(iii) In adduct **1** most of the nitrogen sites are non-complexing, while most of them are complexing in compounds **2** and **3**.

(iv) No correlation is found for oxygen vs nitrogen bonding.

The ESCA findings support then a picture[6] of such solids as having a disordered structure of an ionic type:

$$[(L-Sn)^{2+}]SnCl_4{}^{2-}$$
in which the oxygen sites are almost completely complexed, while the nitrogen sites are more or less complexed in connection with the different molecular structure, probably due to the different steric hindrance. In fact, the length of the aliphatic chain seems to influence the availability of the nitrogens for the complexation.

The fact that the nitrogen sites are less complexed in adduct **1** with respect to **2** and **3** could be connected to the experimental finding that during the synthesis of such adducts the precipitation is immediate for compounds **2** and **3** while it occurs after some minutes in the case of compound **1**.[1]

Since in the tin (II) chemistry there is no evidence for the formation of $SnCl_4{}^{2-}$ anion we feel that both $SnCl_3{}^-$ and Cl^- are present, as suggested also by the broad Cl_{2p} peaks.[8]

2-AMINO-5-PICOLINE N-OXIDE COMPLEXES
FORMED FROM VARIOUS COPPER(II) SALTS

DOUGLAS X. WEST

Department of Chemistry, Illinois State University, Norman, IL 61761, U.S.A.

Abstract—Copper(II) complexes with 2-amino-5-picoline N-oxide (2am5PicO = L), $CuL_4X_2(X = ClO_4, BF_4,$ and $NO_3)$, CuL_2X_2 (X = Cl, Br) and $CuLX_2$ (X = Cl) have been isolated and characterized using spectral methods (i.e. IR, UV-vis and ESR). Coordination occurs via the N-oxide oxygen exclusively with the amine functional group showing only slight tendency to involve itself in hydrogen bonding to the anions. The halide complexes involve the halide ions in the coordination spheres while the polyatomic anions are not bound directly to copper. The latter compounds have monomeric, 4-coordinate CuO_4 chromophores while the former solids are apparently polymeric. Evidence for N-oxide bridging ligands in the CuL_2X_2 solids and halogen bridging in the $CuLX_2$ solid is presented.

2-alkylaminipyridine N-oxides have been shown to bond to Cu(II) primarily as monodentate ligands via the N-oxide oxygen.[1] In contrast, 2-dialkylaminopyridine N-oxides coordinate most commonly as bidentate ligands involving the amine group as well.[2] Previous workers[3] have reported the preparation and the infrared spectra of a number of transition metal complexes of the unsubstituted 2-aminopyridine N-oxide. Because of my interest in 2-substituted pyridine N-oxide complexes, additional copper complexes of this ligand were prepared and characterized by a variety of spectral methods.[4] Recently a similar study with the ligand 2-amino-4-picoline N-oxide has been communicated[5] and there were significant differences in the complexes of this methyl substituted ligand compared to 2-aminopyridine N-oxide (2amPyO). A study of the metal ion complexes of the various 2-amino-picoline N-oxides was therefore initiated, and the Cu(II) complexes of 2-amino-5-picoline N-oxide (2am5PicO) are reported here. Comparisons between these new Cu(II) solids and the previously reported ones are included. It is believed that this is the first report on metal ion complexes of 2am5PicO.

EXPERIMENTAL

The 2am5PicO was prepared by oxidizing 2-amino-5-picoline (Aldrich) with *m*-chloroperoxybenzoic acid Aldrich in acetone[6]. The preparation and characterization of the complexes were performed in an analogous manner to previous studies from this laboratory.[1,2,4,5]

RESULTS AND DISCUSSION

The unique solids isolated with 2am5PicO and the various Cu(II) salts are shown in Table 1 along with their colours, decomposition temperatures and some elemental analyses. Compounds of analogous stoichiometry and colour were isolated with 2am4PicO except for the nitrate. However, as opposed to 2am4PicO, solids analogous to $Cu(2am4PicO)_2(ClO_4)_2$ and $Cu(2am4PicO)Br_2$ have not been achieved despite repeated attempts. Molar conductivity values obtained from acetonitrile solutions are also included in Table 1. Complexes with polyatomic anions are 1 : 2 electrolytes and the halide solids are non-electrolytes.[7] Based on the similarity of colour to previously studied compounds, the complexes isolated with 4 : 1 ligand to Cu(II) mole ratios would be expected to have the four ligands bound via the N-oxide oxygens to give CuO_4 chromophores. The remaining complexes may involve bidentate ligand bonding, participation of the anion in the coordination sphere, polynuclear complex formation or some combination of these. The results of the solid state spectral studies are shown in Tables 2(IR), 3(electronic) and 4(ESR).

The two stretching modes associated with the amine function are found at higher frequencies than for the previous ligand indicating that this amino group is considerably less involved in intermolecular[8] hydrogen bonding. However, the spectra of the complexes formed from the perchlorate and tetrafluoroborate salts show both bands shifted to substantially higher energies

a. ca. 10^{-3} M solutions in CH_3CN.

confirming, not only non-coordination of the amine group, but also indicating little, if any, hydrogen bonding of this function to the polyatomic anions. Since coordinated amines generally have their bands at much lower energies (e.g. $v_a(NH_2) = 3250$ cm^{-1} when complexed to Cu(II)[9]), the lower energies of these bands for the remaining compounds are more likely due to an association with the anions as was suggested for analogous solids in previous studies.[4,5]

For 2amPyO[4] and 2am4PicO[5] the v_{NO} band was assigned to strong bands at 1195 and 1191 cm^{-1}, respectively, but this region of the spectrum of the free 2am5PicO is devoid of any bands. At higher energy there is a band of medium intensity located at 1245 cm^{-1} while a band at 1270 cm^{-1} is assignable to δCH (in plane)[10]. In the spectra of the metal complexes v_{NO} is assigned to a weak band at

comparable energies to the previous complexes.[1,4,5] The relatively high energy for v_{NO} compared to an unsubstituted ring (i.e. $v_{NO} = 1243$ cm^{-1} for pyridine N-oxide[11]) may arise from steric effects in the solid caused by the weakly hydrogen bonding amine group as well as the methyl group in the 5-position. δ_{NO} assignments are omitted from Table 2 since this band is not much shifted in the spectra of the complexes from its 838 cm^{-1} position in the ligand spectrum.

At this point the various spectral results of Tables 2–4 will be discussed for the different compounds (or pairs of compounds).

$CuL_4(ClO_4)_2$ and $CuL_4(BF_4)_2$. Both the ESR and the electronic spectra of these two compounds suggest that they have nearly identical Cu(II) centres and that the anions are not coordinated to the Cu(II). Confirming this is the presence of a

relatively broad band at 1065 cm^{-1} and a sharp band at 618 cm^{-1} in the spectrum of the perchlorate solid and similarly shaped bands at 1015 and 519 cm^{-1} in the spectrum of the tetrafluoroborate solid with the two pairs of bands assignable to v_3 and v_4 of approximately tetrahedral AX_4 species.

The v_{CuO} modes for these two solids are lower in energy than that assigned in the analogous complexes of 2am4PicO (i.e. 415–420 cm^{-1})[5] but slightly higher than the 405 cm^{-1} found for 2amPyO.[4] The higher energy of the two methyl substituted ligands is probably due to the greater electron density these substituents contribute to the ring. The 4-position being more favourable for this donation to the ring nitrogen must cause the higher values for v_{CuO} in the complexes of 2am4PicO. Another factor which could cause this higher en-

ergy is the greater steric hindrance provided by the methyl substituents to the axial coordination of the polyatomic anions.

As opposed to the orthorhombic powder spectrum of the analogous complexes for 2am4PicO[5] the ESR spectra of these solids are the typical axial type associated with a $d_{x^2-y^2}$ ground state. The value of $g_{||}$ for these complexes is slightly lower than was found for the analogous 2amPyO complexes lending support to the stronger planar bonding suggested from the Cu–O stretching frequencies. Therefore, the 5-methyl group while sterically hindering anions from interacting with the Cu(II) centre due to the "propeller-like" positions of the rings[12] does not cause significant distortion of the CuO_4 plane due to interactions between Cu(II) centres in the powder.

Solution electronic and ESR spectra indicate a

change of species in this matrix when compared to the powder spectra. For example, 10^{-3} M acetonitrile solutions show a symmetrical d–d band at ca. 15.0 kK. This shift to lower energy is probably caused by the axial addition of solvent molecules. On long standing the solution ESR spectra show a variety of Cu(II) centres. But immediate freezing of a methanol solution of the tetrafluoroborate salt yielded a spectrum whose principal species has $g_{\parallel} = 2.248$, $g_{\perp} = 2.055$ and $g_{av} = 2.119$. Additionally, $A_{\parallel}$ is ca. 175 G and is indicative of a very strong planar bonding of the four oxygen atoms. The similarity of the various g-values to the values found in the powder spectrum confirms this strong planar bonding in the powder and suggests little interaction between neighbouring centres.

While the 2amPyO showed only a broad featureless d–d envelope,[4] the complexes of 2am4PicO[5] and these solids show a low energy shoulder. Resolution of the shoulder suggests that these complexes have less tetragonal distortion (i.e. are closer to 4-coordinate).[13] Coupling the energy of the shoulder to $g_{\parallel}$ and the energy of the main band to $g_{\perp}$ allows the calculation of orbital reduction factors, k^2, and employing the equations used by previous authors[14] yields values of 0.71 for both $k_{\perp}$ and $k_{\parallel}$. This value indicates that little π-bonding is involved in the metal–ligand bonds.

In Table 5 pertinent spectral information is collected for the CuO$_4$ chromophores prepared with Cu(ClO$_4$)$_2$ and the various 2-aminopyridine N-oxides. The larger alkyl substituents on N appear to strengthen the bonding to Cu(II) based on higher energies for v_{dd} and lower values of $g_{\parallel}$. This

is probably due to greater steric hindrance which prevents interactions of the Cu(II) centre with the perchlorate anions or ligands on neighbouring Cu centres. Substitution on the ring may have a similar effect but other 2-aminopicoline N-oxide complexes and, 2-aminolutidine N-oxides, need to be studied.

Cu(L)$_4$(NO$_3$)$_2$. With 2am4PicO a nitrate solid of suitable purity was not obtained[5] whereas CuL$_3$(NO$_3$)$_2$ and CuL$_2$(NO$_3$)$_2$ were isolated with 2amPyyO[4] so that, comparisons for this nitrate solid are limited to the perchlorate and tetrafluoroborate solids of this study. The data for the three compounds in Tables 3 and 4 suggest little difference in their nature and, therefore, ionic character for the nitrate ions. Confirming this is the assignment of the following bands (cm^{-1}) associated with ionic nitrate:[15] $v_1 = 1018$ m, $v_2 = 819$ s, $v_3 = 1351$ s and $v_4 = 722$ m. Further, a single weak band is observed at 1752 cm^{-1} which is assignable to $v_1 + v_4$ of ionic nitrate.[15, 16]

CuL$_2$Cl$_2$ and CuL$_2$Br$_2$. Analogous compounds with similar colours were isolated with 2am4PicO.[5] The non-electrolytic character in acetonitrile suggests coordination of both halogen atoms. It should be noted that the energies of the v_{N-H} bands in these complexes are consistent with non-coordination of the amine function. For CuL$_2$Br$_2$ the extra shoulders on the v_{NH} bands may be indicative of some structural differences in Cu(II) centres in the lattice which is caused by steric effects.

Additionally, both v_{CuO} and v_{CuX} for each compound have at least two bands assignable to them

b. highest g-value of an orthorhombic spectrum

a. M = 2-methylaminopyridine N-oxide
E = 2-ethylaminopyridine N-oxide
P = 2-propylaminopyridine N-oxide
IP = 2-isopropylaminopyridine N-oxide

which indicates a possible mixture of species. Very recently a single crystal X-ray study of the chloride solid with 2-methylaminopyridine N-oxide has been reported[17] and it was found, upon recrystallization from a mixture of methanol and triethylorthoformate, to have a dimer structure. Briefly, the two copper atoms are bridged by two N-oxide ligands and each Cu(II) has one monodentate N-oxide ligand and one chloride ligand completing its planar portion. A second chloro ligand is in an axial position yielding a distorted square pyramid and the two pyramids are related by an inversion centre. However, this material yielded a weak monomer signal with resolved $g_\parallel$ feature suggesting that the diamagnetic dimer was serving as host for a monomeric impurity.

The ESR signal for this chloro complex also shows a resolved feature while the bromo solid has an isotropic spectrum at both temperatures with clear resolution of hyperfine (or superhyperfine) features over most of the isotropic line. Neither sample shows any features in the ($g \sim 4$) where the $\Delta M = 2$ transitions of dimers are observed. However, the observance of the resolved $g_\parallel$, as well as the fact that the spectra are a factor of more than 100 times less intense than those complexes formed from Cu(II) salts with polyatomic anions, suggest that these features are due to a monomeric impurity. Therefore, the ESR spectra are a measure of the monomer while the remaining spectral studies deal with the more concentrated dimer. In the IR spectrum of CuL_2Br_2 the additional bands found for the N–H stretching frequencies could be due to a monomeric species.

Immediate freezing of the chloro complex dissolved in methanol yields a mixture of species. The principal species present has parameters of $g_\parallel = 2.301$, $g_\perp = 2.063$ and $g_{av} = 2.146$ with $A_\parallel = 148\,G$ which do not agree with the powder values. However, these values are not inconsistent with the 4-coordinate CuO_2Cl_2 monomer which would be formed by symmetrical dissociation of a dimer analogous to the Pavkovic and Wille structure.[17]

Other infrared bands that might be expected to be observed at two different energies if the dimer structure of these complexes is analogous to that found by Pavkovic and Wille[17] are the following: ν_{NO}, ν_{CuO} and ν_{CuCl}. While two different bands are expected for the ν_{NO} mode because of bridging and non-bridging N-oxide ligands, the weakness of the bands in the spectra makes the assignment to various types of N-oxide ligands unattractive. However, both the Cu–O and Cu–X stretching frequencies have multiple bands and the lower band assigned to ν_{CuO} is likely due to a bridging

N-oxide. Additionally, the energies of the Cu–X stretching modes are consistent with terminal rather than bridging halogens suggesting a N-oxide dimer rather than a halogen bridged one.[18]

$Cu(2am5PicO)Cl_2$. While there are certainly a number of dimers of the $(CuL_2X_2)_2$ stoichiometry,[19] there have also been a large number of polymeric species of the stoichiometry $CuLX_2$ reported. In some cases these species include a solvent molecule in their coordination to reach a 5-coordinate centre at each Cu(II)[20], while in other cases a chain of dimers, often one-dimensional, has been found.[21] With this in mind it should be pointed out that again for this compound there is no indication of amine coordination based on the IR spectrum of the solid and the solid can be expected to be polymeric.

Analogous compounds formed from 2am4PicO[5] and copper(II) chloride or bromide were considered to have halogen bridges with the remaining halogen and the N-oxide ligand completing a distorted tetrahedral environment for the Cu(II) centres. Inspection of the bands assigned to ν_{CuCl} shows that the bands are higher in energy than usually assigned to a bridging halogen (i.e. $250\,cm^{-1}$).[18,22] However, for bridged tetrahedral centres the ν_{CuCl} bands would be expected to be higher in energy than for those bridging Cu(II) centres of higher coordination number. For example, ν_{CuCl} for chloro ligands bridging tetrahedral centres have been reported by one group[23] to be in the range $260–270\,cm^{-1}$ and by other authors[24] as high as $275–282\,cm^{-1}$. Additionally, $Cu_2Cl_6^{2-}$ ions with different cations have been studied extensively and it has been shown that distortion of the Cu(II) ions from square planar toward tetrahedral, which is caused by increases in cation size, causes an increase in CuCl (bridging) frequency.[25] Therefore, a structure analogous to that proposed for the 2am4PicO complexes[5] would be possible with the band at $288\,cm^{-1}$ assigned to the bridging Cu–Cl stretching mode and the other bands due to terminal $\nu_{Cu–Cl}$. Since these bands are at higher energy than was found for the previous complexes,[5] greater distortion towards tetrahedral symmetry would be expected for the present complex. Consistent with this is the low energy of the main d–d transition at $9.33\,kK$.

The ESR spectrum is essentially that of a "reversed" monomer which is thought for six-coordinate Cu(II) to be due to a d_{z^2} ground state or more commonly to tetragonally elongated complexes with adjacent Cu(II) centres aligned at right angles to each other with strong exchange interactions.[26] However, once again the ESR signal in the $g = 2$ region is quite weak and is likely due to

a monomeric impurity of lower coordination number than six.

An immediate freezing of a methanolic solution of this solid gives $g_3 = 2.332$, $g_2 = 2.095$, $g_1 = 2.070$ and $g_{av} = 2.166$ with A_3 ca. 115 G. While this species has a "typical" $d_{x^2-y^2}$ ground state spectrum, its average g-value is not greatly different from the 2.153 of the solid at the same temperature. It may be that the spectra are representative of the same species, but lacking the strong exchange interactions in the solution.[26] Compared to the previous chloro species in this study, $Cu(2am5PicO)Cl_2$ is either more tetrahedrally distorted or has a larger coordination number.

In conclusion, the ligand does not function as a bidentate group in any of the complexes, and the solids isolated from copper halide salts appear to yield dimeric products with monomeric impurities. Additionally, it has been found that the methyl group in the 5-position does not significantly alter the stereochemistry of the complexes when compared to the 2amPyO[4] and in contrast to the findings for 2am4PicO.[5]

STUDIES ON YELLOW AND COLOURLESS MOLYBDOPHOSPHATE COMPLEXES IN THE AQUEOUS SOLUTION BY LASER RAMAN SPECTROSCOPY

KATSUO MURATA* and SHIGERO IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560,
Japan

Abstract—Yellow and colourless complexes of molybdophosphate were investigated by the use of laser Raman spectroscopy. Two kinds of yellow molybdophosphates were identified in the weakly acidic solutions: 12-molybdophosphoric and 11-molybdophosphoric acid which are in equilibrium in solution at pH 1–2. When excess phosphate is present, the colourless molybdophosphate is formed. This complex exists in the solutions of pH 4–1 under the condition of excess phosphate ([P]/[Mo] > 2). This complex was confirmed to be $P_2Mo_5O_{23}^{6-}$ and is so stable that the yellow molybdophosphate is converted into the colourless by excess phosphate.

Heteropolymolybdate anion plays an important role in analytical chemistry. Most reliable method for the analysis of such elements P, Si, As and Ge is based on the formation of polynuclear hetero-polymolybdate complexes.[1-4] The formation process of heteropoly acid has been studied by various methods.[5-8] The condition, the acidity below pH 1 and the excess molybdate, were frequently requested for the determination of micro amounts of phosphorus.[9-12] The basic idea to establish the optimum condition applied for the chemical analysis has still not been completely understood. Javier *et al.* showed that on the basis of kinetic data the formation mechanism of molybdophosphoric acid was related, at the initial stage, to the interaction between phosphate and Mo(VI) followed by polymerization to form 12-molybdophosphoric acid.[13] But its formation mechanisms from isopolymolybdate is not fully understood. The purpose of the present study is to find out some species of molybdophosphate complexes and to clarify the formation mechanism of 12-molybdophosphoric acid in the aqueous solution by the use of laser Raman spectroscopy.

EXPERIMENTAL

Reagent and apparatus

Polynuclear molybdophosphate complexes were produced by means of the mixed solutions of

phosphate and molybdate. The acid used for the preparation of the solution is hydrochloric acid because both perchloric and sulphuric acid interfere with the measurements of Raman spectra of polynuclear molybdate complex. Raman spectra were measured with a JASCO R750 triple mono-chromator and JASCO R800, using 514.5 nm (Ar+ laser) as the excitation source. In order to measure quantitatively the intensity of Raman lines, an internal standard of sodium nitrate was used. The Raman lines to be observed were calibrated with those of indene.[14]

RESULTS AND DISCUSSION

(a) Yellow molybdophosphate complexes

Acidification of the mixed solutions of phosphate and molybdate leads to the formation of some molybdophosphate complexes from colourless to yellow colour. Yellow 12-molybdophosphoric acid is mostly useful in analytical chemistry. But the formation behaviour of molybdophosphate complexes has not been well understood because of complexity. The spectrophotometric investigation does not tell much about the configurational information of the chemical species in the aqueous solution. Raman measurements were attempted to obtain the acidic condition for the formation of 12-molybdophosphoric acid. Figure 1 shows three kinds of Raman spectra: (1) solid 12-molybdophosphoric acid, (2) the dissolved aqueous solution of 12-molybdo-

phosphoric acid, and (3) the acidified mixed solutions of phosphate and molybdate ($[P] = 1.0 \times 10^{-2}$ M, $[Mo] = 1.2 \times 10^{-1}$ M). Raman spectrum of 12-molybdophosphoric acid solution(2) is analogous to that of solid 12-molybdophosphoric acid(1), but is different in the intensity of the peak at 996 cm^{-1} and 975 cm^{-1}. The intensity of the peak at 996 cm^{-1} in the solution is lower than that of the solid one, and the intensity of the peak at 975 cm^{-1} is higher than that of solid 12-molybdophosphoric acid. This implies that 12-molybdophosphoric acid to be dissolved undergoes a little change in the solution. Although Raman spectra of the acidified mixed solutions vary with the acidity as shown in Fig. 1 (3), Raman spectra of the mixed solutions of pH 1.17–0.5 M HCl are similar to that of 12-molybdophosphoric acid solution(2). Hence 12-molybdophosphoric acid can also be produced in these acidic mixed solutions.

The authors focussed carefully the ν_1 line of molybdate observed over 900–1000 cm^{-1}. Raman spectra of the acidified 30 solutions (pH 6.52–2 M HCl) of molybdophosphate were normalized by the use of an internal standard (0.08 M NaNO$_3$). Concerning the mixed solutions of pH 6.52–5.15, influence of acidity on Raman spectra is similar to the case of the solutions of molybdate alone.[15] Namely the peak at 897 cm^{-1} due to MoO$_4^{2-}$ species decreases with acidification, whereas the peak at 940 cm^{-1} due to Mo$_7$O$_{24}^{6-}$ species increases. The interaction between phosphate and molybdate does not appear to be prominent, but careful observation allows us to find fine changes on Raman spectra of the mixed solution. The Raman line broadening (at 940 cm^{-1}) becomes eminent. These are much broader than those obtained from isopolymolybdate alone.[15] This must be due to the superposition of molybdophosphate complex and heptamolybdate Mo$_7$O$_{24}^{6-}$. This is also described in the next section of colourless molybdophosphate complexes.

Further acidification of the mixed solutions leads to the shift of the peak to the much higher wavenumber, and the mixed solutions become faint yellow. Then the peak at 975 cm^{-1} appears and its intensity increases in the solutions of pH 4.59–2.27 (Z = 1.48–1.70). On further acidification, the peak at 975 cm^{-1} decreases, and the peak at 996 cm^{-1} appears. The increase of the intensity at 996 cm^{-1} is based on the formation of 12-molybdophosphoric acid.[16,17] These mixed solutions exhibit characteristic yellow colour. Raman spectra indicate two species of yellow coloured molybdophosphate are main complexes in these solutions. One species at 996 cm^{-1} is
Fig. 1. Raman spectra of 12-molybdophosphoric acid in the solutions and the solid state. (1) Solid 12-molybdophosphoric acid. (2) The dissolved aqueous solution of 12-molybdophosphoric acid. (3) The acidic mixed solutions of phosphate and molybdate ($[P] = 1.0 \times 10^{-2}$ M, $[Mo] = 1.2 \times 10^{-1}$ M), (a) pH 1.46, (b) pH 1.01, (c) 1 M HCl.

12-molybdophosphoric acid. Another species has the peak at 975 cm^{-1}. In order to clarify the latter species, two precipitates of tetraethylammonium salt were obtained from the solutions of pH 2.1 and pH 1 by addition of tetraethylammonium chloride solution. The results of elementary analysis for these precipitates are given in Table 1. The precipitate from pH 1 is 12-molybdophosphate salt, as expected. The precipitate from pH 2.1 is not 9-molybdophosphate, which is known to be P$_2$Mo$_{18}$O$_{62}^{6-}$ in the solid,[18] but 11-molybdophosphate. Thus the species at 975 cm^{-1} is considered to be 11-molybdophosphoric acid. When the mixed solutions of phosphate and molybdate are acidified, 12-molybdophosphoric acid is produced via the formation of 11-molybdophosphoric acid. 12-molybdophosphoric acid is equilibrated with 11-molybdophosphoric acid in the mixed solutions of pH 1.99–1.05(Z = 1.72–2.06). 12-molybdophosphoric acid decomposes above 2 M acidity to

transform to cationic molybdate species, whose intense Raman line appears at $953\,cm^{-1}$.

(b) *Effect of phosphate concentration and colourless molybdophosphate complex*

The concentration of phosphate is also important in the formation of molybdophosphate complexes. The present author[19] and Hori[20] pointed out that excess phosphate leads to the formation of colourless or pale yellow molybdophosphate. This would be attributed to the transformation into the lower polymerized molybdophosphate species. The authors investigated the influence of phosphate concentration on Raman spectra of pH 1 molybdate solutions. The increase of phosphate concentration results in the increase of the intensity at $996\,cm^{-1}$ and the decrease of the intensity at $955\,cm^{-1}$. This clearly indicates that the phosphate added reacts with the polynuclear molybdate species[15] $Mo_{12}O_{37}^{2-}$ to produce 12-molybdophosphoric acid. The polynuclear molybdate species having the peak at $955\,cm^{-1}$ is closely correlated to the formation of 12-molybdophosphoric acid. The further increase in the concentration of

$$PO_4^{3-} + Mo_{12}O_{37}^{2-} + 2H^+ \rightleftarrows PMo_{12}O_{40}^{3-} + H_2O$$
phosphate, however, brings about the decrease of the intensity at $996\,cm^{-1}$ and the increase at $970\,cm^{-1}$. This implies that the excess phosphate produces 11-molybdophosphate. The further addition of excess phosphate induces the peak at $945\,cm^{-1}$ accompanying the disappearance of the peak at $970\,cm^{-1}$. The colouration of these mixed solutions becomes colourless via pale yellow. Colourless molybdophosphate can be stable and pre-

sent in the mixed solutions of the wide pH range. Only one species of colourless molybdophosphate having the peak at $945\,cm^{-1}$ is present in the mixed solutions of pH 4–1. As previously described [section (a)], Raman spectra of molybdophosphate change variously with the acidity in the solutions. But the excess phosphate results in no shift of the peak at $945\,cm^{-1}$ in the mixed solutions of pH 4–1. This colourless molybdophosphate was confirmed to be $P_2Mo_5O_{23}^{6-}$ species by the elementary analysis of tetraethylammonium salt obtained from pH 3. Found: C, 15.03; H, 3.81; N, 2.17; P, 4.76; Mo, 37.49. Calcd for $[(C_2H_5)_4N]_2H_4P_2Mo_5O_{23}\cdot6H_2O$: C, 14.98; H, 4.37; N, 2.18; P, 4.83; Mo, 37.43. The existence of this species $P_2Mo_5O_{23}^{6-}$ in the solution is also supported from the appearance of the break point at $[Mo]/[P] \approx 2.5$ in the plots, where the intensity at $945\,cm^{-1}$ is plotted against phosphate concentration. Therefore it is assumed that excess phosphate brings about the following equilibria.

$$11PMo_{12}O_{40}^{3-} + PO_4^{3-} \rightleftarrows 12PMo_{11}O_{37}^{3-}$$

$$5PMo_{11}O_{37}^{3-} + 17PO_4^{3-} \rightleftarrows 11P_2Mo_5O_{23}^{6-}.$$
As seen in the above description, there are two significant factors affecting the formation of molybdophosphate complexes in the aqueous solution. One is phosphate concentration, and another is acidity in the aqueous solution. When excess phosphate ($[P]/[Mo] > 2$) is present in the mixed solution of phosphate and molybdate, the species of $P_2Mo_5O_{23}^{6-}$ exists mainly in the solution of wide pH range (pH 4–1). The species of $P_2Mo_5O_{23}^{6-}$ is so stable that the addition of excess phosphate can transform 12-molybdophosphoric acid formed into 11-molybdophosphoric acid or colourless $P_2Mo_5O_{23}^{6-}$. But in the presence of equivalent amounts of phosphate ($[Mo]/[P] = 12$), the species of molybdophosphate complex varies with the acidity in the solution. Two kinds of species as the yellow molybdophosphoric acid are present in the solutions above $Z = 1.5$. The formation of 12-molybdophosphoric acid is predominant in the solution of $Z = 2.0$ and 11-molybdophosphoric acid predominantly forms in the solution of $Z = 1.7$.

The question is raised what isopolymolybdate species is mainly concerned to the formation of each molybdophosphate complex. In our previous works,[15] the formation of some isopolymolybdate species was clarified by the use of Raman spectroscopy. The formation curves of each isopolymolybdate and molybdophosphate are plotted against Z value of the solution in Fig. 2. It can be seen that the formation of $P_2Mo_5O_{23}^{6-}$, $PMo_{11}O_{37}^{3-}$

and $PMo_{11}O_{37}^{3-}$ is correlated with the species of $Mo_7O_{24}^{6-}$, $Mo_8O_{26}^{4-}$ and $Mo_{12}O_{37}^{2-}$ ($Mo_6O_{19}^{2-}$), respectively.
Fig. 2. Formation behaviour of each species in isopoly- and heteropoly molybdates by plotting the intensity of Raman line against Z value of solutions. (The formation of each species was followed at each Raman line: $Mo_7O_{24}^{6-}$, 940 cm^{-1}; $Mo_8O_{26}^{4-}$, 970 cm^{-1}; $Mo_{12}O_{37}^{2-}$, 955 cm^{-1}; $Mo_6O_{19}^{2-}$, 980 cm^{-1}; $P_2Mo_5O_{23}^{6-}$, 945 cm^{-1}; $PMo_{11}O_{37}^{3-}$, 975 cm^{-1}; $PMo_{12}O_{40}^{3-}$, 996 cm^{-1}) [P] = 1.0 × 10^{-2} M. [Mo] = 1.2 × 10^{-1} M, [NO$_3^-$] = 8.0 × 10^{-2} M.

Madrid (3), Spain

Abstract—The complex Rh(pyc)(NBD) (pyc = α-pyridinecarboxylate anion, NBD = 2,5-norbornadiene) reacts with carbon monoxide with displacement of the diolefin and formation of $Rh(pyc)(CO)_2$. Addition of triarylphosphines to the latter compound causes the formation of complexes of the type $Rh(pyc)(CO)[P(p\text{-}RC_6H_4)_3]$ (R = F, Cl, Me, MeO). The addition of iodine, bromine or methyl iodide to solutions of the monocarbonyl derivatives leads to the formation of $RhX_2(pyc)(CO)[P(p\text{-}RC_6H_4)_3]$ (X = I, Br) and $RhMeI(pyc)(CO)[P(p\text{-}RC_6H_4)_3]$ complexes.

Organometallic square-planar rhodium(I) complexes with asymmetric chelating anionic ligands having N and O as donor atoms have been reported. Those derived from Schiff's bases,[1-5] β-ketoamines,[6] 8-oxyquinoline[7-10] and aminoacids[11, 12] have been intensively investigated. On the contrary, the ability of the α-pyridinecarboxylate(pyc) group to act as a bidentate ligand has been scarcely studied, and as far as we know only the $Rh(pyc)(CO_2)$ has been described.[7]

In this paper we report the synthesis and reactions of several α-pyridinecarboxylate rhodium(I) complexes. Some oxidative addition reactions are reported. It is noteworthy to point out that previous attempts to convert some square-planar rhodium(I) complexes with salicylaldimine Schiff's bases[1] into octahedral rhodium(III) derivatives by oxidative addition reactions were unsuccessful.

EXPERIMENTAL

IR spectra were recorded on a Perkin–Elmer 325 spectrophotometer (over the 4000–200 cm^{-1} range) using KBr discs. Conductivities were measured using approx. 3×10^{-4} M acetone solution with a Philips PR 9500 conductimeter.

Synthesis of Rh(pyc)(NBD)

A stoichiometric amount of α-pyridinecarboxylic acid (Hpyc) was added to a C_6H_6 suspension of the RhCl(NBD)$_2$ complex. After addition of excess of Na_2CO_3 and stirring for 4 hr at room temperature, the yellow solid formed was filtered off, recrystallized from CH_2Cl_2:Et_2O, washed with Et_2O and air dried.

Synthesis of Rh(pyc)(CO$_2$)

Carbon monoxide was bubbled through a solution of the complex Rh(pyc)(NBD) in CH_2Cl_2 at room temperature for 30 min. After concentration, the Rh(pyc)(CO)$_2$ complex was precipitated by adding cold Et_2O. This was filtered off and recrystallized from CH_2Cl_2:Et_2O, and vacuum-dried.

Rh(pyc)(CO)[P(p-RC$_6$H$_4$)$_3$] complexes

The addition of a stoichiometric quantity of $P(p\text{-}RC_6H_4)_3$ to a yellow solution of Rh(pyc)(CO)$_2$, in the minimum amount of CH_2Cl_2, caused evolution of CO and the colour intensified. The solution was stirred at room temperature for 10 min and crystallization was induced by the addition of n-hexane. The solids thus obtained were recrystallized from CH_2Cl_2:n-hexane and vacuum-dried.

Rh(pyc)X$_2$(CO)[P(p-RC$_6$H$_4$)$_3$ complexes

A slight excess over the stoichiometric of X_2 (X = I, Br) was added to a CH_2Cl_2 solution of the corresponding Rh(pyc)(CO)[P(p-RC$_6$H$_4$)$_3$] complex. The solution was stirred for 1 hr at room temperature and crystallization was induced by the addition of Et_2O. The brown solid was filtered off, recrystallized from CH_2Cl_2:Et_2O and vacuum-dried.

Rh(pyc)MeI(CO)[P(p-RC$_6$H$_4$)$_3$] complexes

The above method was also used for the prepa-

ration of these complexes, using MeI instead of I_2, but the reaction time was 4 hr.

RESULTS AND DISCUSSION

Rhodium(I) complexes

Reaction of $RhCl(NBD)_2$[13] in benzene with an equimolecular amount of α-pyridinecarboxylic acid in the presence of sodium carbonate gave a good yield of yellow solid which was identified as Rh(pyc)(NBD) (NBD = 2,5-norbornadiene, pyc = α-pyridinecarboxylate anion). The bubbling of carbon monoxide through a dichloromethane solution of this complex, causes the displacement of the coordinated diolefin according to eqn (1):

$$Rh(pyc)(NBD) + 2CO \rightarrow Rh(pyc)(CO)_2 + NBD. \quad (1)$$
The violet dicarbonyl derivative has been previously prepared by Ugo et al.[7] by reaction of $[RhCl(CO)_2]_2$ with the anionic ligand.

Monocarbonyl complexes of the type $Rh(pyc)(CO)[P(p\text{-}RC_6H_4)_3]$ can be prepared by addition of triarylphosphines to solutions of $Rh(pyc)(CO)_2$ in dichloromethane, according to eqn (2):

$$Rh(pyc)(CO)_2 + P(p\text{-}RC_6H_4)_3 \rightarrow$$
$$Rh(pyc)(CO)[P(p\text{-}RC_6H_4)_3] + CO \quad (2)$$

$$(R = MeO, Me, F, Cl).$$
The reaction most likely proceeds via the formation of the pentacoordinated complex $Rh(pyc)(CO)_2[P(p\text{-}RC_6H_4)_3]$, which was not detected. When the reaction was performed with a stoichiometric amount or excess of diphosphine, poorly characterized yellow products without coordinated carbon monoxide were obtained.

Only one $v(CO)$ vibration was observed for all $Rh(pyc)(CO)[P(p\text{-}RC_6H_4)_3]$ complexes. It can reasonably be assumed that the isomer obtained present the phosphine trans to the pyridine nitrogen, due to the stronger trans effect of this atom. In fact an X-ray diffraction study on the related complex $Rh(oxyquinolate)(CO)PPh_3$ show the phosphine group to be trans to the heterocyclic nitrogen.[14] An inverted correlation between $v(CO)$ and the basicity of the triarylphosphine seems to be observed (Table 1). The increasing basicity of the phosphines could increase the extent of Rh–C back-bonding and, therefore, the $v(CO)$ are shifted to lower values.

The presence of the asymmetric $v(C=O)$ band of the carboxylic group in the range 1660–1680 cm^{-1} for all the above mentioned complexes, show that

this group acts as monodentate, ruling out pentacoordinated structures. Furthermore, the $v(C=O)$ values for these complexes support square-planar coordination.

All the complexes are stable in air at room temperature and were obtained in high yields. Elemental analyses (carbon, hydrogen and nitrogen) and IR data are collected in Table 1. The violet $Rh(pyc)(CO)_2$ derivative is dichroic in the solid state,[7] but Rh(pyc)(NBD) and Rh(pyc)$(CO)[P(p\text{-}RC_6H_4)_3]$ complex present yellow colour. consistent with the lack of any intermolecular rhodium-rhodium interactions in the solid state, arising from steric reasons.

Oxidative addition reactions with iodine, bromine and methyliodide

Because the relatively low value of the $v(C=O)$ band in $RH(pyc)(CO)[P(p\text{-}RC_6H_4)_3]$ complexes should give an indication of the nucleophility of these rhodium(I) complexes, we were interested to explore some oxidative addition reactions.

The addition of a slight excess of iodine, bromine or methyl iodide to dichloromethane solutions of $Rh(pyc)(CO)[P(p\text{-}RC_6H_4)_3]$ complexes leads to the formation of hexacoordinated rhodium(III) complexes (eqns 3 and 4):

$$Rh(pyc)(CO)P(p\text{-}RC_6H_4)_3 + X_2 \rightarrow$$
$$RhX_2(pyc)(CO)[P(p\text{-}RC_6H_4)_3] \quad (3)$$

$$(X = I, Br)$$

$$Rh(pyc)(CO)P(p\text{-}RC_6H_4)_3 + MeI \rightarrow$$
$$RhMeI(pyc)(CO)[P(p\text{-}RC_6H_4)_3], \quad (4)$$
As expected for these types of oxidative addition reactions, the $v(CO)$ vibration of the oxidation products is shifted in every case towards higher energies relative to the parent compound. This shift is in the 110–125 cm^{-1} range for the complexes formed by addition of iodine or bromine, and in the 80–95 cm^{-1} range for the $RhMeI(pyc)(CO)[P(p\text{-}RC_6H_4)_3]$ derivatives. The oxidative addition reactions with methyliodide, are slow enough to show that the rate of reaction increases for the more basic phosphines. The presence of a single sharp $v(CO)$ absorption in the IR spectra seems to point to the presence of only one isomer in the solid state. These complexes show the asymmetric $v(C=O)$ band of the monodentate carbonyl group in the range 1665–1680 cm^{-1}. They are stable in air at room temperature and were obtained in high yields (Table 1). All the complexes described in this paper are non-conducting in acetone or have negligible conductivity.

COORDINATION CHEMISTRY OF NEW SULPHUR CONTAINING LIGANDS—26. EIGHT COORDINATE VANADIUM(IV) AND MOLYBDENUM(IV) COMPLEXES OF 2-AMINO-1-CYCLOPENTENEDITHIOCARBOXYLATE[1]

ROBERT D. BEREMAN* and JAY R. DORFMAN

Department of Chemistry, North Carolina State University, Raleigh, NC 27650, U.S.A.

Abstract—The new difunction ligand, 2-amino-1-cyclopentenedithio-carboxylate(L), was prepared and its coordination chemistry examined to gain further insight into the reactivity of "aromatic" dithio type ligands. Reaction with $MoCl_4py_2$ and $VOSO_4$, led to the surprising eight coordinate products ML_4. The sp^2 hybridization of the ring carbon to which the CS_2 moiety is bonded apparently yields a pseudo-aromatic effect on the reactivity of this ligand. The physical properties of these new compounds are discussed.

We have been very interested in the design and syntheses of new dithiolate and dithiocarbamate as well as new monothiocarbamate ligands where non-traditional reactivity could be expected. In particular, we have shown that the suppression of the importance of potential resonance contributions (Scheme 1) to the ground state electronic structures of these classes of ligands yield novel transition element complexes.[1–5] Our work has concentrated on systems where Form C in Scheme 1 played an unimportant role in the coordination chemistry. This was accomplished in various ways but normally by the design of a peripheral ligand structure whose inherent resonance structure suppressed this form (Scheme 2).

We chose to extend this study by the in-vestigation of a new ligand, 2-amino-1-cyclopentenedithiocarboxylate (ACDA)[6–8] (Fig. 1). This ligand is interesting because of its potential dual bidentate coordinate possibilities (NS vs S_2) and because a resonance structure leading to other possible resonance structures is suppressed by the presence of the double bond involving the bridgehead ring carbon (Scheme 3). It was anticipated, that this ligand would have a parallel reactivity to dithiobenzoate and pyrroledithiocarbamate. One of the very special reactions of this class of ligands

is that of stabilizing eight-coordinate vanadium(IV) coordination compounds over the vanadyl, $V = O^{+2}$ unit.[9] For that reason, we have investigated this and the Mo(IV) system.

EXPERIMENTAL

Materials

All solvents were of reagent grade and were freshly distilled before use. $VOSO_4 \cdot 2H_2O$ was obtained from the Fisher Scientific Co. and used without further purification. $MoCl_4 \cdot 2py$ was obtained from the Climax Molybdenum Co. and was handled under an argon atmosphere using Schlenk techniques. Methylene chloride was dried over calcium chloride and stored over 4Å molecular sieves.

Preparation of compounds

(1) ACDA was prepared as previously described.[6-8]

(2) $V(ACDA)_4 \cdot 1.5H_2O$

The procedure used here was similar to that of Piovesana and Cappuccilli[10]. 2.102 g of ACDA was dissolved in 150 cm^3 of diethyl ether. The reaction mixture was stirred for 15 minutes to allow complete dissolution. 1.313 g of vanadyl sulphate was dissolved in a 50:50 v/v ethanol‖H_2O solvent system. The vanadyl solution was added dropwise to the dithioacid solution over a 15 min period. Gradually, the solution of the dithioacid (initially yellow) turns brown, then red–brown. The reaction was stirred for a total of 18 hr. A red–brown solid was collected, washed with ice-cold H_2O and dried for 60 min. (Yield—42%).

Table 1 lists the analytical data for this compound and the forthcoming compound.

(3) 0.220 g of ACDA was dissolved in 200 cm^3 of methanol which was degassed by successive freeze-thaw cycles. To this solution was added (dropwise) a methanol solution containing 0.137 g of $MoCl_4 \cdot 2py$ (py = pyridine). The solution, initially yellow, immediately turned blue and was allowed to stir for several hours. The blue–black solid was collected and dried by suction filtration washed with cold methanol, and dried in vacuo for one hour. The compound is air-stable and the blue–black colour is characteristic of 8-coordinate Mo^{4+} sulphur systems.[1] (Yield—77%). Elemental Analyses were determined by Atlantic Microlabs, Atlanta, Ga (see Table 1).

Spectroscopic measurements

All IR, optical, and esr spectra were recorded as described previously.[1-5] Second order corrections were applied to the calculation of all g values.[11]

RESULTS AND DISCUSSIONS

ACDA was reacted with vanadyl sulphate to ascertain if a labilization of the vanadyl (VO^{2+}) unit would be observed. This is a reaction which occurs when the aromatic dithiocarbamates are reacted with vanadyl salts, and is rather unusual owing to the well-known marked stability of the VO^{2+} unit. For example, direct reaction of the VO^{2+} ion with $R_2NCS_2^-$ in water gives "normal" $VO(R_2NCS_2)_2$ complexes which are five-coordinate (approximate C_{2v} symmetry).[12,13] Eight-coordinate $V(R_2NCS_2)_4$ complexes are obtained from insertion reactions of CS_2 and $V(NR_2)_4$ in dry cyclohexane, under dry, oxygen-free conditions.[14] Apart from these complexes, the vast majority of complexes involved with V(IV) chemistry incorporate the VO^{2+} unit. The usual rationale proposed for formation of non-vanadyl V(IV) complexes has been insertion of CS_2^- into the oxo-vanadium bond.[9,15] Thus, if this premise is indeed true, resonance form B(Scheme 3) should make little contribution towards the electronic structure of ACDA. To investigate this property, IR spectroscopy was employed to prove the nature of the C–S bonds. A strong band in the vicinity of 1225 cm^{-1} and a medium-intensity band at about 670 cm^{-1} have been identified by various workers as $\nu(C = S)$ and $\nu(C–S)$, respectively, in aliphatic

Table 1. Elemental analyses

Compound	Colour	%C Calc. (Found)	%H Calc. (Found)	%S Calc. (Found)
$V(ACDA)_4 \cdot 1.5H_2O$	red–brown	40.56 (40.55)	4.93 (4.98)	36.05 (36.07)
$Mo(ACDA)_4$	blue–black	39.56 (39.48)	4.40 (4.44)	35.16 (35.28)

dithioacids.[16] If a monodentate ligand were present in the putative $VL_4(L = ACDA)$ complex, frequencies closely approximating the above values would be expected. Instead, as noted in Table 2, there are two fairly strong absorptions at 900 and 950 cm^{-1}. This would strongly suggest the presence of a delocalized CS_2^- moiety. These assignments are also in accord with previous work on Ni^{2+} complexes of ACDA.[8] The characteristic bands in the IR corresponding to the $v(N-H)$ absorptions are found at 3210 and 3280 cm^{-1} in VL_4 and are within 10 cm^{-1} of the same absorptions found in ACDA. This verifies the premise that the $-NH_2$ moiety remains intact (no deprotonation occurring) and that coordination to the vanadium is unlikely. The bands attributed to $v(N-H)$ usually shift their position rather significantly to lower energy upon coordination to a transition metal. In addition, the VO^{2+} unit has a strong characteristic absorption in the IR in the range $1000-1500 \text{ cm}^{-1}$.[1,15,18] There is no such intense band in the IR spectrum of $V(ACDA)_4$. Finally, the vanadyl analog of this compound has been reported as being a green solid, but the elemental analysis obtained was not satisfactory.[19] The analysis for $V(ACDA)_4$, which is a red-brown solid, is in excellent agreement with the theoretical values (see Experimental

Section). Taken together, these pieces of data support the proposed 8-coordinate VL_4 structure. The optical data for VL_4 in CH_2Cl_2 shows a weak band at 12.1 kK and a shoulder at 19.8 kK as the only ligand field features. Both the optical data and the colour of the complex are in agreement with similar properties observed for other VS_8 chromophores.[9,20]

The VL_4 complex is presumably a V(IV) complex (d^1 system), and thus lends itself to ESR studies. The spin Hamiltonian parameters for V(A-CDA)$_4$ are summarized in Table 3. The ESR spectra of this compound both at room temperature and in frozen glasses resulted in well resolved metal hyperfine structure. The eight-line pattern is characteristic of $^{51}V(I = 7/2)$ systems. The observation that $g_\perp > g_\parallel$ is consistent with other 8-coordinate V(IV) systems, while the metal hyperfine splitting values of 150G and 53G for $A_\parallel$ and $A_\perp$, respectively, are indicative of a covalent system, and further support the presence of 8-coordination.[9,20] During the optical and ESR experiments, the colour of the solutions are the same as that of the compound in the solid state. However, over a period of about one hour, the solution changes colour from red-brown to yellow, which is the colour of the uncomplexed (ACDA) ligand. This would suggest that the VL_4 complex gradually decomposes over this time period.

These data support the predominant resonance form for ACDA as form A. This structure induces the formation of a delocalized CS_2^- unit which does indeed labilize the VO^{2+} moiety forming an 8-coordinate VL_4 complex. The mode of formation probably involves withdrawal of electron density from the $V=O$ bond by the π-system of ACDA-SH, but without further mechanistic studies, this only remains a suggestion based on similar compounds.[9,20] Single crystals of VL_4 are currently being grown for the purposes of unequivocally proving the presence of the 8-coordinate system. It is apparent that as a result of the unusual electronic character of ACDA-SH, the reactivity patterns resemble those of the aro-

matic carboxylates and aromatic dithiocarbamates, rather than aliphatic dithioacids.

To further investigate the reactivity of ACDA, this ligand was reacted with a Mo^{4+} salt, specifically $MoCl_4$ (pyridine)$_2$. The first report of the synthesis of Mo-dithio complexes appeared in 1971 when $Mo(IV)(R_2Dtc)_4$ complexes were obtained by CS_2 insertion into $Mo(NR_2)_4$ complexes.[21] Nieuwpoort et al. have obtained $Mo(IV)(R_2Dtc)_4$ complexes with R = Me, Et, i–Pr, and Ph[22]. The optical spectra of these compounds show six absorptions between 10.0 and 25.0 kK, and assignments are complicated.[22]

The IR spectrum of the product of $MoCl_4$(pyridine)$_2$ and ACDA shows two absorptions at 3210 and 3300 cm^{-1} which are assigned as ν(N–H) bands. In addition, there is no band in the 2400–2600 cm^{-1} range which is where ν(S–H) absorptions are usually found. The lack of a strong absorption in the 900–1000 cm^{-1} region is good evidence for the lack of any Mo = 0 bonds. In addition, there is no evidence of any pyridine in this compound as the very characteristic bands attributable to ν(C–H) and ν(C = C) in pyridine are also absent. The optical spectrum of this compound is very similar to other reported 8-coordinate $Mo^{4+}(d^2)$ systems[23,24] (Fig. 2). of $Mo(S_8)$ chromophores.[23] The suggested strucpound is dark blue–violet, a common characteristic of $Mo(S_8)$ chromophores[23]. The suggested structure of $Mo(ACDA)_4$ is somewhat unusual in that, as noted earlier, a limited number of $Mo(S_8)$ systems have been reported. What is novel here is the, initial source of Mo^{4+}, namely

$MoCl_4$(pyridine)$_2$. This appears to be the first report of a $Mo(S_8)$ system generated, using this reagent.

In conclusion, the reactivity of ACDA appears to parallel that of aromatic dithiocarbamates and the aromatic carboxylates. This chemistry is a result of the resonance-induced formation of a distinct CS_2^- moiety as a component of the ligand. In the aromatic carboxylates and dithiocarbamates, this $-CS_2^-$ unit is induced as a result of the peripheral aromatic system which must remain intact. In ACDA–SH, the $-CS_2^-$ formation is presumably due to the fact that this resonance contributor avoids the formation of any positive charge building upon the electronegative primary nitrogen(amine) atom. It is thus suggested that aliphatic dithioacids may behave as analogous aromatic systems do, if the peripheral electronic nature of the ligand induces the formation of the appropriate resonance form.

ESR STUDIES ON THE REACTIVE CHARACTER OF THE RADICAL ANIONS, SO_2^-, SO_3^- AND SO_4^- IN AQUEOUS SOLUTION

TOSHIHIKO OZAWA* and TAKAO KWAN†

Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan

Abstract—The reactive characteristics of the oxy anion radicals of sulphur, SO_2^-, SO_3^- and SO_4^- were investigated by use of the rapid-mixing flow technique coupled with electron spin resonance (ESR) which can detect the radicals having a lifetime of 5–100 msec. The SO_2^- reduced the aromatic nitro compounds to the corresponding anion radicals, but did not abstract the hydrogen from the saturated compounds nor add to the unsaturated compounds. The SO_3^- could add to the compounds having C=C bond, but did not abstract the hydrogen from the saturated compounds nor reduce the aromatic nitro compounds. The SO_4^- could abstract the hydrogen from the saturated compounds and also add to the unsaturated compounds having C=C bond, but did not reduce the aromatic nitro compounds. These differences of the reactivity towards the organic substrates were discussed on the basis of the difference in the distribution of the unpaired electron density of each radical anion.

It is well known that the rapid-mixing flow technique coupled with electron spin resonance (ESR) is useful to detect the short-lived radicals having a lifetime longer than a few msec. In previous papers, by use of this technique we have reported that the sulphite radical anion (SO_3^-), which is generated from Ce^{4+}-$NaHSO_3$ system, can add to the compounds having C=C[2], C≡C[3] and C=S[4] bonds to give the corresponding secondary radicals, respectively. Also, we have found that the reactive character of SO_3^- towards the compounds having C=C bond is different from that of the sulphate radical anion (SO_4^-) due to Norman *et al.*[4] and have briefly suggested that this difference may be caused by the difference in the distribution of the unpaired electron density of each radical anion.[1]

In order to clarify the reactive characters of these oxy anion radicals of sulphur in detail, we have further examined the reactions of SO_2^-, SO_3^- and SO_4^- with a number of organic substrates by use of the rapid-mixing flow technique. In this paper, we report these results.

EXPERIMENTAL

Materials. $Ce(NO_3)_4 \cdot 2NH_4NO_3$, $NaHSO_3$, $TiCl_3$ and $Na_2S_2O_8$ were purchased from Wako Pure Chemical Ind. Ltd. and used without further purification. $Na_2S_2O_4$ was obtained from Nakarai Chemicals Ltd. Organic substrates were purchased from a commercial source and used without further purification. Sulphuric acid, NaOH, and other chemical reagents were of commercial GR grade.

ESR measurements. ESR measurements were carried out on a JEOL–PE–1X ESR spectrometer (*X*-band) with 100 kHz field modulation in conjunction with a JEOL mixing chamber. The rapid mixing flow apparatus which we used was the same as that reported previously and enabled us to detect radicals having a lifetime of 5–100 msec[5–7]. The hyperfine coupling constants and the *g*-values were calibrated with an aqueous solution of Fremy's salt ($g = 2.0055$, $a^N = 13.0$ G)[8] kept in a capillary tube attached to the sample.

Procedure. All solutions were prepared from triply distilled water, and their pH was adjusted by

an aqueous solution of sulphuric acid or NaOH.

For the generation of SO_3^-, $Ce(NO_3)_4 \cdot 2NH_4NO_3$ and $NaHSO_3$ were used. The SO_2^- was generated by dissolving $Na_2S_2O_4$ in an aqueous alkaline solution. This radical is stable for more than 5 hr at room temperature.[7] The SO_4^- was obtained by the $TiCl_3$–$Na_2S_2O_8$ system, according to the method reported by Norman et al.[4]

To investigate the reaction of SO_3^- with organic substrates, two aqueous solutions were mixed: one (a) contained 0.01 M Ce^{4+} acidified to pH 2.5 by sulphuric acid and the other (b) 0.1 M $NaHSO_3$ containing various organic substrates of 0.02–0.3 M concentrations.

In the reactions of SO_2^- with organic substrates, the following two solutions were mixed: one (c) contained 0.1 M $Na_2S_2O_4$ at the pH range of 7.5–9.0 and the other (d) 0.02–0.3 M organic substrates at the pH range of 7.5–9.0.

For the reactions of SO_4^- with organic substrates at pH 2.5, one solution (e) contained $TiCl_3$ (0.01 M) and the other (f) contained $Na_2S_2O_8$ (0.1 M) and the organic substrates (0.01 M–0.3 M) which was acidified to pH 2.5 by sulphuric acid.

RESULTS

Abstraction reaction of hydrogen from saturated compounds. No change was observed in the ESR spectrum of SO_3^- (singlet line at $g = 2.0022$)[7] when the solution (b) containing the saturated

compounds such as methanol, ethanol and iso-propanol were allowed to mix with the solution (a). Likewise, in the reactions of SO_2^-, the ESR spectrum due to SO_2^- (singlet line at $g = 2.0055$)[7] was not affected by addition of these compounds. These results suggest that both SO_3^- and SO_2^- are inactive to the abstraction of hydrogen from the saturated compounds.

On the other hand, methanol radical $(\cdot CH_2OH)$[9] was observed when high concentration of methanol (0.3 M) was contained in the solution (f) and was allowed to mix with the solution (e). This radical may be formed by the following reactions,[4]

$$Ti^{3+} + S_2O_8^{2-} \rightarrow Ti^{4+} + SO_4^- + SO_4^{2-} \quad (1)$$

$$SO_4^- + CH_3OH \rightarrow HSO_4^- + \cdot CH_2OH. \quad (2)$$
This result indicates that SO_4^- is active to the abstraction of hydrogen from the saturated compounds.

Addition reactions to the compounds having C=C bond. In the reactions of SO_2^-, no spectral change could be observed by mixing the solution (c) with the solution (d) containing the olefinic compounds such as allyl alcohol, crotonic acid and fumaric acid.

The ESR spectrum of SO_3^- was completely consumed when allyl alcohol was added to the
Fig. 1. ESR spectrum observed during the reaction of SO_3^- with acrylic acid in aqueous solution at pH 2.5.

Table 1. Hyperfine coupling constants (gauss) and g-values for the radicals derived from the reaction of SO_3^- with the compounds having C=C bond

Substrate	Radical	Hyperfine splitting const. (gauss)			g
		a(α-H)	a(β-H)	a_{Me}^H	
$HO_2CCH=CHCO_2H$	$^-O_3SCH(CO_2H)\dot{C}HCO_2H$	20.7	8.1	–	2.0033
$CH_2=CHCO_2H$	$^-O_3SCH_2\dot{C}HCO_2H$	20.4	15.9	–	2.0034
$CH_2=CMeCO_2H$	$^-O_3SCMe(CO_2H)\dot{C}H_2$	23.1	–	–	2.0032
$MeCH=CHCO_2H$	$^-O_3SCH(Me)\dot{C}HCO_2H$	20.3	6.6	0.76	2.0033
$Me_2C=CHCO_2H$	$^-O_3SCMe_2\dot{C}HCO_2H$	20.5	–	–	2.0033
$CH_2=CHOCOCH_3$	$^-O_3SCH_2\dot{C}HOCOCH_3$	20.0	13.7	1.40	2.0035

Ce^{4+}-$NaHSO_3$ system, but no secondary radical could be observed. This result may indicate that SO_3^- reacts with olefinic compounds even if the secondary radicals were not observed. Perhaps the secondary radical may be formed, but not in detectable concentration. The secondary radicals were detected when acrylic acid, methacrylic acid, 3, 3-dimethylacrylic acid, crotonic acid, fumaric acid and vinyl acetate were respectively added to the Ce^{4+}-$NaHSO_3$ system. The assigned structures and the ESR parameters were summarized in Table 1.

Figure 1 shows the ESR spectrum observed by the reaction of SO_3^- with acrylic acid. Under the same experimental conditions, only very weak unanalysable resonance was detected with styrene, and there was no detectable ESR absorption with the, following compounds; acrylamide, acrolein, crotonaldehyde and acrylic acid methyl ester.

On the other hand, when crotonic acid or allyl alcohol was added to the Ti^{3-}-$Na_2S_2O_8$ system at pH 2.5, the secondary radicals shown in Table 2 were observed. Acrylic acid gave only very weak, unanalysable resonance, and fumaric acid, acrylamide, acrolein and crotonaldehyde gave no detectable ESR absorption.

Aromatic nitro compounds. Neither SO_3^- nor SO_4^- could react with aromatic nitro compounds

such as nitrobenzene, 1, 2-dinitrobenzene and p-nitrobenzoic acid.

On the other hand, when p-nitrobenzoate was allowed to mix with the SO_2^- solution at pH 9.0, the ESR spectrum of SO_2^- was completely consumed and simultaneously the secondary radical was observed (Fig. 2). This spectrum can be analyzed in terms of the parameters: $a^N(1) = 13.01$ G, $a^H(2) = 3.41$ G and $a^H(2) = 1.41$ G. These values are almost identical to those accepted for the p-nitrobenzoate anion radical.[10] Similar anion radicals were respectively observed by the reaction
Fig. 2. ESR spectrum observed during the reaction of SO_2^- with p-nitrobenzoate in aqueous solution at pH 9.0.

SO_2^- with nitrobenzene[11] or 1, 2-dinitrobenzene.[12] In these reactions, since the ESR spectrum due to the SO_2^- completely disappeared, anion radicals may be formed according to the following reaction.

$$R\text{-}C_6H_4NO_2 + SO_2^- \rightarrow (R\text{-}C_6H_4NO_2)^{\cdot -} + SO_2 \quad (3)$$
DISCUSSION

In Table 3 the reaction characteristics of the oxy anion radicals of sulphur, SO_2^-, SO_3^- and SO_4^- towards the organic substrates are summarized. From Table 3, it is apparent that these anion radicals which combine with the different number of oxygen have the different reactive character towards the organic substrates. That is, SO_4^- which has the four oxygen atoms in the radical molecule is so reactive that it can abstract the hydrogen from the saturated compounds, whereas SO_2^- which has only the two oxygen atoms in the radical molecule is not so reactive that it can abstract the hydrogen from the saturated compounds or add to the compounds having the C=C bond. The reactive character of SO_3^- is intermediate between those of SO_4^- and SO_2^-. It can add to the compounds having the C=C bond, but can neither abstract the hydrogen from the saturated compounds nor reduce the aromatic nitro compounds.

Further, it is noted that the type of the addition to the compounds having C=C bond differs considerably between SO_3^- and SO_4^- (Table 3).

Table 4. The distribution of the unpaired electron density of SO_2^-, SO_3^- and SO_4^- radical anoins

Atom Radical	S	O
SO_2^-	0.75	0.135
SO_3^-	0.62	0.13
SO_4^-	~0	0.25

The distribution of the unpaired electron density of these oxygen anion radicals of sulphur, (SO_2^-)[13], (SO_3^-)[14] and (SO_4^-)[15] has already been reported in irradiated crystals or powders. These are shown in Table 4. As is shown in Table 4, the unpaired electron density in sulphur atom decreases with the increase of the number of the oxygen combined with the sulphur atom. In the SO_4^- radical, the unpaired electron density on the sulphur atom is nearly zero, being equally distributed over the four oxygen atoms as shown by one of the four equivalent canonical structures (Fig. 3). Therefore, SO_4^- has the property of an oxygen radical and facilitates both the C–O bond formation to the C=C bond and the abstraction of hydrogen from the saturated compounds.

On the other hand, the unpaired electron density of SO_2^- is highly localized on the sulphur atom. Then, since SO_2^- is thought to act as a sulphur radical, and sulphur atom rather than an oxygen atom would take part in the reactivity of SO_2^-.
Fig. 3. A canonical structure of SO_4^-.

The distribution of the unpaired electron density for SO_3^- is similar to that for SO_2^-, but the electron density on the sulphur atom for the former is smaller than that for the latter. These facts suggest that SO_3^- has the weaker character as a sulphur radical, as compared with SO_2^-. Accordingly, SO_3^- may not have a reducing ability. However, since the addition reactions of SO_3^- to the C=C bond occur through the C–S bond formation,[1] SO_3^- is thought to be a sulphur radical rather than an oxygen radical.

From the results mentioned above, it is concluded that the difference in the characteristics of the reactivities between these three oxy anion radicals of sulphur, SO_2^-, SO_3^- and SO_4^- arises at least partly from the different distribution of the unpaired electron density among them, as suggested previously by us.[1]

Chemistry Department/Physics Department, Indian Institute of Technology,
Madras 600 036, India

Abstract—The synthesis, properties and crystal structure of bis(thiobenzoato)selenium(II) are described. The complex is formed on interaction of selenium(IV) in acid medium with thiobenzoic acid. It is highly stable towards most metal ions. Crystal structure analysis and ir spectroscopic study indicate that the selenium is covalently bonded to sulphur with weak secondary interactions between selenium and oxygen which complete an S_2O_2 coordination around selenium. There are no intermolecular interactions in the crystal structure.

The oxidation state selenium(II) is unstable and under weak complexation conditions selenium(II) will disproportionate to Se(IV) and Se(O). Thus $SeCl_2$ and $SeBr_2$ have been observed only in the gas phase. However, interaction of selenium(IV), with many sulphur(-II) compounds yields selenium(II) complexes of the sulphur ligands which in many cases are quite stable. The sulphur ligand generally reduces the selenium(IV) to selenium(II) getting itself oxidised generally to the corresponding disulphide. Excess of sulphur ligand would form stable complexes with selenium(II). The ligands which have been successfully used to stabilize selenium(II) are thiocyanate,[1] thiosulphate,[2] mercaptocarboxylic acids,[3-5] dithiocarbamates[6,7] aryl sulphonate[8] and xanthate.[9] Structural work has shown interestingly low coordination number and extensive covalent bonding in the complexes. Data on the reactivity patterns are sparse. Recent electrochemical work[10] has highlighted the extraordinary stability of the complexes of selenium(II) with mercaptocarboxylic acids. In the present work the interaction of selenium(IV) with a bidentate ligand monothiobenzoic acid was studied. The thiobenzoate anion has both oxygen and sulphur sites for coordination. Complexes of thiobenzoic acid with transition metals[11-15] and tin(IV)[16] have only been reported earlier. The formation, structural and reactivity aspects of the selenium(II) complex of thiobenzoic acid reported in this work highlight

the extreme soft acid character of selenium(II) featuring strong sulphur coordination of the ligand.

EXPERIMENTAL

Materials and methods

The chemicals used in synthetic and reaction studies were of AnalaR grade. Thiobenzoic acid used was 99% pure. Solution of the acid in methanol was freshly prepared and stored under nitrogen. Microanalyses were done by CSIRO, Melbourne, Australia. Molecular weight of the selenium(II) complex isolated was determined by Mechrolab. Model 301A vapour pressure Osmometer calibrated with benzil using benzene as solvent. IR Spectra were recorded in the range 600–4000 cm^{-1} in a Perkin–Elmer 257 unit and in the range 100–1000 cm^{-1} in a Polytech FIR 30 unit. UV-visible spectra were recorded in a Carl–Zeiss DMR 21 Spectrophotometer. Radiochemical measurements using ^{75}Se tracer were made in a Frieseke–Hofner γ-ray spectrometer provided with a 440 multichannel analyzer and a Naithal crystal.

The molar ratio of interaction between selenium(IV) and thiobenzoic acid in acid medium was determined by three different methods, viz spectrophotometry, radiochemical titration and redox potentiometry.

Spectrophotometry

The products of interaction between selenium(IV) and thiobenzoic acid showed an absorption maximum at 355 nm in benzene solution.

---

*Author to whom correspondence should be addressed.

Selenium(IV) was not extracted into benzene and freshly prepared thiobenzoic acid in benzene showed little absorption at 355 nm. Solutions of H_2SeO_3 (0.05 M in 2 N sulphuric acid medium) and to thiobenzoic acid (0.05 M) in methanol) were mixed in various ratios. 5 cm^3 of 2 N sulphuric acid and 10 cm^3 methanol were added. Benzene was added in small portions and the benzene extracts were collected and made up to 50 cm^3. The absorbance of the benzene extract was measured at 355 nm using a 5 cm cell. The absorbance vs mole ratio plot shown in Fig. 1(a) indicates the interaction ratio to be 1:4.

Radiochemical titration

^{75}Se tracer in the form of H_2SeO_3 was used. To 10 cm^3 of 0.05 M H_2SeO_3 solution in 1 M sulphuric acid labelled with ^{75}Se tracer were added different volumes of 0.05 M solution of thiobenzoic acid in methanol. The interaction products were then extracted into benzene and the activity of ^{75}Se in the benzene phase was measured. The radiochemical graph 1(b) indicates that the activity in the benzene phase levels off when the selenium(IV) to thiobenzoic acid ratio reaches 1:4.

Redox potentiometry

A solution containing 0.25 mM of selenium(IV) in 20 cm^3 methanol and 20 cm^3 2 N sulphuric acid in a beaker was titrated against a solution of 0.1 M thiobenzoic acid in methanol taken in a burette. A platinum foil was used as redox indicator electrode with saturated calomel electrode as reference. In another series of measurements the titration was done after the addition of 20 cm^3 1 M potassium bromide. The potential readings were studied. The potentiometric curves (Fig. 1c) indicate a marked inflection at 1:4 selenium(IV) to thiobenzoic acid ratio. The addition of potassium bromide helped to give an increased break apparently due to the increased oxidation potential of selenium(IV) in presence of bromide.

Suitable crystals of the selenium complex were

†Atomic Co-ordinate have also been deposited into the Cambridge Crystallographic Data Centre.

obtained by the following method for the structural analysis.

Forty cm^3 0.1 M thiobenzoic acid in methanol were added to a solution containing 2 mM of H_2SeO_3 dissolved in 125 cm^3 methanol. The precipitate formed was extracted into benzene. On evaporation of the benzene extract at room temperature two types of crystals, one needlelike and pale yellow (selenium complex) and the other stubby and colourless (the disulphide) were obtained.

Crystal data

Monoclinic, $C2/c$, $a = 24.244(4)$, $b = 4.2692(7)$, $c = 14.452(7)$ Å, $\beta = 109.95(3)°$, $V = 1406.05$ Å^3, $D_c = 1.69$ g cm^{-3}, $Z = 4$, $\mu = 6.03$ mm^{-1}. 1840 reflections with $I > 3\sigma(I)$ were recorded using a CAD-4 single crystal X-ray diffractometer with Cu$K\alpha$ radiation ($\lambda = 1.5418$ Å). Structure was solved by Patterson and difference Fourier methods. Full matrix leastsquares refinements with 1012 unique reflections gave final $R = 0.051$, $R_w = 0.054$, where the weighting scheme used was $w = 0.0422/[\sigma^2(F_0) + 0.0605|F_0|^2]$. Final difference Fourier maps gave the locations of all the hydrogen atoms which were subsequently refined. All calculations were carried out by use of SHELX-76 program.[17] Atomic parameters have been deposited with the Editor as supplementary data,† derived dimensions are given in Table 1. The molecular structure of the complex is shown in Fig. 2.

RESULTS AND DISCUSSION

Synthesis and general characteristics

The interaction between selenium(IV) and thiobenzoic acid was found to occur readily in strongly

acidic medium. There was no interaction in alkaline condition. The results of the study under acidic condition to find the interaction ratio are given in Figs. 1(a)–(c). All the three techniques, viz. spectrophotometry, radiochemical titration and redox potentiometry, unequivocally indicate the selenium(IV)-thiobenzoic acid interaction ratio as 1:4 and this considered in conjunction with the occurrence of a redox reaction as revealed by potentiometry suggests that the reaction could be represented as

$$H_2SeO_3 + 4C_6H_5COSH \rightarrow (C_6H_5COS)_2Se$$
(A)

$$+ C_6H_5COSSCOC_6H_5 + 3H_2O.$$
(B)
The compounds bis(thiobenzoato)selenium(II) (A) and the dibenzoyl disulphide (B) had different crystal habits and were isolated by fractional crystallisation using benzene as solvent. (B) was more soluble than (A). Found, complex (A): Se 22.0; S 18.0; C 47.1; H 2.72; Calc. for $C_{14}H_{10}O_2S_2Se$: Se 22.35; S 18.15; C 47.57; H 2.85%; Found, Disulphide (B): S 23.3; C60.3; H 3.09%; Calc. for $C_{14}H_{10}O_2S_2$: S 23.37; C 61.28; H 3.673%.

Bis(thiobenzoato)selenium(II) was highly soluble in most polar and non-polar organic solvents. The complex was indefinitely stable both in the solid state and solutions of organic solvents under anhydrous conditions. It melted at 120°C and decomposed to selenium and disulphide at 130°C. Aqueous methanolic solutions of the complex were unaffected by non-oxidising acids, but even mild

alkali solutions readily decomposed the selenium(II) complex into the red selenium and disulphide. Keeping the complex in contact with excess of thiobenzoic acid in aqueous methanol solutions resulted in slow formation of selenium. This is due to the reducing action of the hydrogen sulphide formed under these conditions as a result of slow hydrolysis[18] of thiobenzoic acid.

The stability of the selenium complex (dissolved in methanol) towards metal ions was demonstrated by its being unaffected by the addition of even large excess of Cu(II), Co(II) and Ni(II). Ag(I) caused displacement of selenium and subsequent complicated redox reactions only at higher temperatures, but not at 30°C. The selenium complex reacted with Hg(II) at room temperature and this work is being reported separately. The selenium(II) complex was also not affected by addition of iodide which is one of the best soft bases. The stability of the selenium-thiobenzoato complex is comparable with that of selenium(II)-carboxyliphatic thiolato complexes.[10] Addition of thioglycollic acid or β-mercaptopropionic acid to solutions of bis-(thiobenzoato)selenium(II) in methanol resulted in the formation of selenium. Thus even though the complexes of selenium(II) with thiobenzoate and β-mercaptopropionate[5] are individually quite stable, admixtures of the two complexes are unstable. This feature occurs in many mixed ligand systems in the chemistry of tellurium(II)[19] also.

Structure

The complex bis(thiobenzoato)selenium(II) was monomeric in solution as shown by vapour pressure osmometry using benzene as solvent.

The IR spectrum of selenium(II) complex (A) taken in KBr in the region 600–4000 cm^{-1} was virtually identical with that of dibenzoyldisulphide (B). This indicates the absence of oxygen coordination in the selenium complex. The $\nu_{C=O}$ for thiobenzoic acid, the dibenzoyldisulphide and the selenium complex were observed at 1690, 1685 and 1685 cm^{-1} respectively. The ν_{C-S} which occurs at 960 cm^{-1} for the sodium thiobenzoate occurs at 900 cm^{-1} in (A) and (B). This indicates that the Se–S interaction in (A) is strong and comparable to that observed for Pd–S[14] and Hg–S[11] interactions in their respective thiobenzoate complexes. The ν_{S-H} occurs as a weak band at 2560 cm^{-1} in thiobenzoic acid. This absorption is not noticed in the selenium complex. The far IR spectra of (A) and (B) are very similar excepting for an additional strong absorption at 212 cm^{-1} in (A). This is assigned to $\nu_{Se-S°}$. Thus IR data suggest strong selenium to sulphur bonding and little or no selenium–oxygen interaction in similarity with the Pd and Hg complexes

of thiobenzoic acid and in contrast with the nickel(II) complex of thiobenzoic acid in which both sulphur and oxygen are known to be coordinated from IR spectral,[11] magnetic and X-ray results.[12] The conclusions from IR and molecular weight studies of the selenium complex are fully corroborated by the results of X-ray structural analysis discussed below.

The thiobenzoate group is essentially unidentate and is covalently linked to the selenium through the sulphur. The selenium–sulphur distance (2.174 Å) is close to 2.11 Å (which is the sum[21] of the single covalent radii) and the S–Se–S angle is 105°. Both the Se–S distance and the S–Se–S angle are comparable with those reported for in the other sulphur-ligated two-coordinated selenium(II) complexes listed in Table 2. The two carbonyl oxygens are *trans* to each other with respect to the S–Se–S plane. The two Se–O distances are equal (3.11 Å). This Se–O distance in the complex is much longer than 1.80 Å the sum of the single covalent radii of Se and oxygen but well within the van der Waals Se–O distance[20] (3.42 Å). Hence, these contacts may well indicate weak Se–O secondary interactions of the type discussed by Alcock[20] in many other Se compounds. The Se–O secondary interaction in the complex is weaker than the Se–S secondary interactions noticed in the dithiocarbamate[6] and xanthate complexes[9] of Se(II). The SeS_2O_2 unit forms a pyramid with Se atom at the apex and the other four atoms forming a quadrilateral base, which is planar within 0.1 Å. The Se atom is considerably lifted out of the basal plane, the deviation being 1.28 Å. This is to be contrasted with the SeS_4 geometry in the dithiocarbamate and xanthate complexes of Se, wherein the SeS_4 is very nearly planar trapezoidal. This is attributed to the different bites of the Se–O and Se–S groups and the extent of secondary interactions. The lone pair of electrons in Se occupy positions above Se away from the S_2O_2 plane. They do not take part in any intermolecular interactions in this complex.

The C–O and C–S distances are 1.187 and 1.827 Å and compare well with other published values in similar compounds. The average C–H distance is 0.83(5) Å and the average C–C–H angle is 119(4)°. The two phenyl rings are nearly parallel to each other making an angle of 4.6(7)°.

Abstract—X-Ray analysis shows that the crystalline compounds $(Me_4N)_2[Cu_4(SMe)_6]$ (**1**), $(Me_4N)_2[Cu_4(SPh)_6]$ (**2**) and $(Me_4N)_2[Cu_4(SPh)_6]EtOH$ (**3**) all contain the [*tetrahedro*-Cu_4^I-*octahedro*-$(SR)_6]^{2-}$ molecular cage. Very well developed pale yellow crystals of (**2**) and (**3**) can be obtained directly from a mixture of copper(II) salt and excess benzenethiol with tertiary amine in alcohol. The substituents R of the $[Cu_4(SR)_6]^{2-}$ cage remove the high symmetry of the Cu_4S_6 core, and allow three configurational isomers for the cage. All known instances of this cage structure occur as the isomer which minimises the number of close contacts of substituents over the surface of the cage. Despite this, there remain intra-cage repulsive interactions between substituents, greater for R=Ph than for R=Me, which cause distortions primarily in the S–Cu–S angles which range from 105–144°. Cu–S distances are coupled, apparently electronically, to opposite S–Cu–S angles. The stereochemical analysis is extended to all known $Cu_4(SR)_6$ cages, and to alternative cage structures.

Anionic complexes $[Cu_2^IX_3]_n^{n-}$, X being a monodentate monoanionic ligand, can possess the high symmetry molecular cage structure *tetrahedro*-M_4-*octahedro*-X_6 in which each ligand bridges the edges of the tetrahedral array of M, and each metal has trigonal coordination. This structure occurs in $(Ph_3MeP)_2Cu_4I_6$,[1] in two crystalline modifications of $(Me_4N)_2[Cu_4(SPh)_6]$,[2] and in $[Cu_4(SPh)_6]^{2-}$ crystallised with Ph_4P^+.[3]

An alternative molecular cage structure type with the same stoichiometry, $[Cu_8X_{12}]^{4-}$, and the same coordination numbers, is *hexahedro*-Cu_8-*icosahedro*-X_{12} in which copper atoms as a cube lie in the faces of an X_{12} icosahedron. This structure is known only for complexes with chelating dithiolate ligands[4,5] and for related compounds with a central spherical ligand.[6–8] We have suggested[2] than an empty cage $[Cu_8(SR)_{12}]^{4-}$ with

unconnected thiolate groups would be insufficiently rigid for independent existence, a suggestion supported by the observation of increasing distortions in the series of empty cages $[M_4(SR)_6]^{2-}$, $[M_5(SR)_7]^{2-}$, $[M_6(SR)_8]^{2-}$.[9,10] It has also been suggested[4] that $[Cu_8(SPh)_{12}]^{4-}$ does not form due to repulsions between phenyl groups over the surface of the S_{12} icosahedron, but this is partially refuted by the occurrence of $[ClZn_8(SPh)_{16}]^-$ in which there is an icosahedral array of bridging SPh groups.[11] Nevertheless there remain questions about the packing of substituents R over the surfaces of molecular cages maintained by bridging ligands RS^-. We have prepared $(Me_4N)Cu_2(SMe)_3$ (**1**), with the smallest substituent R, and report here that it contains the $[Cu_4(SMe)_6]^{2-}$ molecular cage, as suggested by infrared data.[12]

Several different methods of synthesis of $[Cu_4(SR)_6]^{2-}$ have been employed. We present here previously unpublished details of our syntheses of

(Me$_4$N)$_2$[Cu$_4$(SPh)$_6$] **(2)** and its solvate (Me$_4$N)$_2$[Cu$_4$(SPh)$_6$]EtOH **(3)**, and also full details of the crystal structures of **(1)**, **(2)** and **(3)**. Compound **(2)** contains two crystallographically independent [Cu$_4$(SPh)$_6$]$^{2-}$ cages, denoted **(2a)** and **(2b)**, and therefore when (Ph$_4$P)$_2$[Cu$_4$(SPh)$_6$]^3 **(4)** is included, structural information is available for five independent molecules [Cu$_4$(SR)$_6$]$^{2-}$. This geometrical data is compared and interpreted in this paper.

The high symmetry (T$_d$) possible for the *tetrahedro*-Cu$_4$-*octahedro*-S$_6$ core of these molecules must be largely if not totally removed by the substituents R. Configurational isomerism is possible due to inversion at bridging sulphur, and is discussed here. Deviations from idealised molecular geometry are examined in terms of substituent interactions over the surface of the cage.

RESULTS AND DISCUSSION

Synthesis. The preparation of (Me$_4$N)$_2$[Cu$_4$(SMe)$_6$] **(1)** involved[12] addition of NaSMe solution in ethanol to a solution of tetramethylammonium chlorocuprate(I) complexes in ethanol/acetonitrile. The MeS$^-$/Cu(I) ratio was 4.2, and the product obtained as colourless crystals.

The preparation of (Me$_4$N)$_2$[Cu$_4$(SPh)$_6$], which is pale yellow, involved addition of copper(II) salt solution to a solution containing thiol, tertiary amine as deprotonating agent, and tetramethylammonium chloride, again using alcohol/acetonitrile solvent systems, eqn (1). At room temperature copper(II) is

$$Cu^{2+} + PhSH + R_3N + Me_4N^+ \xrightarrow{CH_3CN/ROH}$$

$$[Cu_4(SPh)_6]^{2-}(Me_4N^+) + PhSSPh + R_3NH^+ \quad (1)$$
very rapidly reduced by thiolate, and precipitates as CuSR unless excess thiolate is present. The solutions from which crystallisation of **(2)** and **(3)** (and (Me$_4$N)$_2$[Cu$_5$(SPh)$_7$]^9) occurred contained PhS$^-$/Cu(I) in ratios of 2.9–5.0, as well as PhSSPh and halide ion which are not competitive ligands.

This method allows direct production of well-formed crystals of **(2)** and **(3)**. The yields are low, and it is very likely that other, more soluble, [Cu$_x$(SPh)$_y$]$^{x-y}$ species are present in the yellow solutions. The crystallisation solutions are initially supersaturated, and it appears that nucleation rates, in addition to the PhS$^-$/Cu(I) ratio and the solvent composition, influence the variable distribution of crystalline product between **(2)** and **(3)** and (Me$_4$N)$_2$[Cu$_5$(SPh)$_7$].

(Ph$_4$P)$_2$[Cu$_4$(SPh)$_6$] **(4)** has been prepared by re-

actions **(2)**, **(3)** and **(4)**,[3]

$$[Cu(CH_3CN)_4]^+ + KSPh + Ph_4P^+$$

$$\xrightarrow[Et_2O]{CH_3CN} [Cu_4(SPh)_6]^{2-}(Ph_4P^+) \quad (2)$$

$$[Cu(CH_3CN)_4]^+ + [Cu(SPh)_3]^{2-}(Ph_4P^+)$$

$$\xrightarrow[Et_2O]{CH_3CN} [Cu_4(SPh)_6]^{2-}(Ph_4P^+) \quad (3)$$

$$[Cu_8(dts)_6]^{4-} + KSPh$$

$$\xrightarrow[Et_2O]{CH_3CN} K_2dts(s) + [Cu_4(SPh)_6]^{2-}(Ph_4P^+). \quad (4)$$
Molecular structure. Each molecular cage [Cu$_4$(SR)$_6$]$^{2-}$ contains a tetrahedron of copper atoms, with a doubly-bridging thiolate ligand across each of the six edges of the tetrahedron such each copper atom has approximately trigonal planar CuS$_3$ coordination. The Cu$_4$S$_6$ core can also be described as an octahedron of sulphur atoms with copper atoms lying at the midpoints of four faces of the octahedron, that is *tetrahedro*-Cu$_4$-*octahedro*-S$_6$ (Fig. 1a).

Fig. 1. (a) The *tetrahedro*-Cu$_4$-*octahedro*-S$_6$ core of cages [Cu$_4$(SR)$_6$]$^{2-}$. (b) The dihedral angles ϕ_M, ϕ_S in the cycles Cu$_3$S$_3$ of Cu$_4$S$_6$. The larger circles are sulphur.

An alternative description of the Cu_4S_6 core recognises four fused Cu_3S_3 cycles, each in chair conformation but distorted because the intracycle angles at Cu and S are 120° and 70.53° respectively. The distortion of the Cu_3S_3 cycle from ideal chair conformation is shown also by the dihedral angles ϕ_M and ϕ_S at the Cu–Cu and S–S chords of the cycle (see Fig. 1b), which are 115.2 and 80.0° respectively instead of the ideal 125.3°.

The configurational isomerism of $M_4(SR)_6$ due to inversion at bridging thiolate can be described in terms of the directions of the S–C vectors referenced to the four M_3S_3 cycles in pseudo-chair conformation. At each S atom the S–C vector is axial (a) to one and equatorial (e) to the other of the two chairs it shares, and the isomers are then classified in terms of the distribution of axial and equatorial S–C vectors in each of the four chairs. There are three distributions: I {aaa, aae, aee, eee}; II {aae, aae, aae, eee}; III {aae, aae, aee, aee}, shown diagramatically in Figs. 2(c)–(e). Each of the stereoisomers is enantiomeric; II has symmetry C_3, while I and III are asymmetric.

(e)

(b)
Fig. 2. (a) The M_4S_6 core, view direction close to a threefold axis. (b) $M_4(S–C)_6$, view direction parallel to the threefold axis of part (a), showing alternative directions of S–C vectors at each sulphur atom. (c), (d), (e) Diagrammatic representations, oriented as in part (b), of the configurational isomers according to the direction (arrows) of S–C bonds with respect to the S_3 triangles of the four M_3S_3 cycles; a, axial, e, equatorial; the central letter triplet refers to the underside S_3 triangle; (c) isomer I, (d) isomer II, (e) isomer III.

The molecule $[Cu_4(SMe)_6]^{2-}$ and the three independent $[Cu_4(SPh)_6]^{2-}$ molecules in (2) and (3) all occur as isomer III. This isomer occurs also in $(Ph_4P)_2[Cu_4(SPh)_6]$ (4).[3] All four crystals are centrosymmetric, containing both enantiomers of isomer III. In view of these five occurrences of the one asymmetric configurational isomer, the presentation and analysis of molecular geometry and dimensions is made with all molecules in equivalent orientation and with the same atom labelling scheme. Figure 3 shows the four molecules (1), (2a), (2b), (3), all oriented in the same manner as the isomer diagram of Fig. 2(e), and the atom labelling.[13]

The close similarity in overall configuration of the three $[Cu_4(SPh)_6]^{2-}$ molecules (2a), (2b), (3), shown in Fig. 3, cannot be attributed to influences of crystal environment, which are quite different. Figure 3 shows that there is more variation in the conformations of phenyl rings due to rotation about S–C bonds than in the orientations of the S–C vectors relative to the molecular cage framework. Nevertheless, the complete shape of molecule (2a) is very similar to that of (3). The greatest differences between the structures occur in the conformations of rings 2 and 4, and 3 and 6. These are the two pairs of ligands which are the contiguous axial pairs in the isomer {aae, aae, aee,

aee}, III. It may be noted that threefold propeller conformation of PhS ligands occurs around Cu1 and Cu2.

Intramolecular dimensions are presented and compared in Table 1. The mean values of the large populations of nominally equivalent dimensions are unexceptional. However, the main feature of

the set of cage dimensions is the occurrence of large and significant variances and excursions from mean values. In fact the cage framework is appreciably distorted from the tetrahedro-Cu_4-octahedro-S_6 ideal, and the details of the distortions allow some insight into the bonding forces in $[Cu_4(SR)_6]^{2-}$. The sample standard deviations

s,[14] (0.16Å) and range (3.67–4.33Å), of the S–S distances are proportionally much larger than the corresponding values (0.06, 2.64–2.85Å) for the Cu–Cu distances. Concomitant with this, the angles S–Cu–S (s 9.5; range 104.9–143.7°) are much more variable than angles Cu–S–Cu (s 1.6; range 70.2–76.7°). There is substantial angular flexibility in the cage bonds, occurring primarily as flapping variation of the bridging arms, affecting the S–S distances, rather than breathing variation of the CuS_3.planes affecting the Cu–Cu distances.

More detailed examination of these angular variations reveals that they are at least partly due to intramolecular repulsions between thiolate substituents. The standard deviation of S–S in $[Cu_4(SMe)_6]^{2-}$ is 0.10Å, while in the $[Cu_4(SPh)_6]^{2-}$ cages it is 0.18Å, consistent with more influential repulsive interactions between the larger phenyl groups. In all structures the S6–Cu4–S3 and S2–Cu3–S4 angles are larger than the remainder, and these are the only two angles which are subtended by an axial–axial pair of ligands. In the $[Cu_4(SPh)_6]^{2-}$ cages these two angles are 7–15° greater than the corresponding values for $[Cu_4(SMe)_6]^{2-}$. Concomitant with this, the S–Cu–S angles subtended by equatorial–equatorial pairs of

Mean (48) = 110.0°   s = 4.3°

ligands are consistently small in the $[Cu_4(SPh)_6]^{2-}$ cages, but not in $[Cu_4(SMe)_6]^{2-}$. Statistical consideration of all S–Cu–S angles in the $[Cu_4(SPh)_6]^{2-}$ cages according to substituent relative configuration yields:

a–a substituents, mean 138.0° (s 4.1°)
a–e substituents, mean 118.3° (s 6.2°)
e–e substituents, mean 108.1° (s 2.1°)

Corresponding mean values of S–Cu–S for $[Cu_4(SMe)_6]^{2-}$ are 128.0 (0.4); 118.0(5.4); 119.6(1.1) respectively. It can be concluded that intramolecular repulsions between phenyl substituents cause large angular distortions at trigonal copper, that corresponding repulsions between methyl substituents are much less, and that *inter*-molecular interactions between substituents also induce angular distortions primarily at the copper atoms.

The Cu–S distances in Table 1 range from 2.247 to 2.349Å, a difference almost as large as that between digonally (2.160Å) and trigonally (2.270Å) coordinated copper in $[Cu_5(SPh)_7]^{2-}$.[9] In the $[Cu_4(SR)_6]^{2-}$ structures the Cu–S distances reflect the variation of opposite S–Cu–S angles in the distorted trigonal coordination
A plot of all 48 pairs d,θ reveals fair linear correlation, with some distinction between the SMe and SPh compounds. Linear regression, d = aθ + b, yields a = 2.90 × 10^{-3}Å deg^{-1}, b = 1.93 Å, r(correlation coefficient) = 0.84, for the 12 Cu–SCH$_3$ bonds in (1), and a = 2.05 × 10^{-3}Å deg^{-1}, b = 2.04Å, r = 0.75, for the 36 Cu-SPh bonds in (2a), (2b) and (3). This geometrical phenomenon must be largely electronic in origin. The regression analyses yield Cu–SCH$_3$ = 2.278 Å and Cu–SPh = 2.290 Å for ideal trigonal coordination.

All copper atoms in the five [Cu$_4$(SR)$_6$]$^{2-}$ molecules are located slightly *outside* the linked S$_3$ coordination planes of the S$_6$ octahedron. Details are given in Table 2, the mean displacement for all 20 copper atoms being 0.07Å. This effect will relieve slightly the acute angles at the sulphur atoms. We see no geometrical reason for including significant bonding interactions between copper atoms in [Cu$_4$(SR)$_6$]$^{2-}$, particularly in view of the outward displacements of the copper atoms, and the Cu–Cu distances (Table 1) which are long, as we have argued previously.[1,9]

[d] This angle may range only between 90° and the complement of the corresponding angle

The geometrical structure around the sulphur atoms in $[Cu_4(SR)_6]^{2-}$ molecules also relates to the bonding in the cage and the difference between alkyl- and aryl-thiolate ligands in bridging positions. The stereochemistry at sulphur is necessarily distorted from pseudotetrahedral by the very acute Cu–S–Cu angle, which is 73.5 for both ligand types. However the data in Table 2 on the angles between the S–C vectors and the normals to the CuSCu planes at the bridging thiolate ligands show clear distinction between $[Cu_4(SMe)_6]^{2-}$, where the mean value of this angle is 15.1° (s 3.5°), and the molecules $[Cu_4(SPh)_6]^{2-}$ where the mean value is 27.0° (s 3.1°). The latter value is closer to the tetrahedral ideal of 35.3°. Close examination reveals that in both cases the acuteness of bonding at the bridging sulphur is clearly not due to steric repulsions between the substituents (in fact in $[Cu_4(SMe)_6]^{2-}$ the more acute bonding occurs at S4 and S6 where it *decreases* intramolecular separations between methyl groups). The differentiation between bridging methanethiolate and bridging benzenethiolate is more likely to be electronic in origin.

Angles relating to rotation of the SPh rings about the S–C vectors are also contained in Table 2. The similarity of conformation between molecules (2a) and (3) is again apparent.

In (3) the ethanol is not hydrogen bonded, and is poorly defined crystallographically.

Alternative cage structures. $[Cu_4(SR)_6]^{2-}$ is the smallest three-dimensional cage structure known and possible with monodentate ligands. There are limitations to the flexibility of the cage framework, and the angular distortions reported here are smaller than those observed in larger cage structures with bridging thiolate ligands.[9,10] The correlation of angular distortion with cage size allows straightforward rationalisation of the non-observation of the *hexahedro*-Cu₈-*icosahedro*-(SR)₁₂ cage structure shown in Fig. 4. The connectivity of linked coordination trigonal planes in $[Cu_4(SR)_6]^{2-}$ is around empty triangles as shown schematically in Fig. 5(a), while in $[Cu_8(SR)_{12}]^{4-}$ the coordination triangles are linked around empty quadrilaterals (Fig. 5b). The flexibility of the latter arrangement is much greater than that of the former. Indeed, $[Ag_6(SPh)_8]^{2-}$ contains four coordination trigonal planes linked as in Fig. 5(b), but with additional struts (additional digonal metal atoms bridging vertices) as shown schematically in Fig. 5(c), and yet is still very heavily distorted in the crystal.[10] Hypothetical $[Cu_8(SR)_{12}]^{4-}$, without such support, would have insufficient rigidity for independent existence. The Cu_8S_{12} framework oc-
Fig. 4. The idealised *hexahedro*-M₈-*icosahedro*-SR)₁₂ structure. The six chelate linkages between sulfur atoms are denoted as . . . . . .

curs only when the quadrilaterals of Fig. 5(b) are braced (by chelation) as shown in Fig. 5(d) and Fig. 4.

An alternative means of structural stabilisation is a central spherical ligand.[6–8,11,15] We note that the compounds $(Me_4N)_2[Cu_4(SR)_6]$ R = Me, Ph crystallised from solutions containing excess Cl⁻ which might have served this function, but it appears that three bridging thiolate ligands saturate the coordination of copper(I) in these compounds.

Two other instances of the *tetrahedro*-Cu₄-*octahedro*-S₆ cage structure have been reported. One occurs with the monodentate thiocarbonyl ligand thiourea (tu) in $[Cu_4(tu)_6]$ $(NO_3)_4 4H_2O$.[16] Geometrically the $[Cu_4(tu)_6]^{4+}$ cage is similar to the $[Cu_4(SR)_6]^{2-}$ cage, in the pyramidal stereochemistry around bridging sulphur and the adoption of configurational isomer III, {aae, aae, aee, aee}. In addition, there is a' variability of S–Cu–S angles in $[Cu_4(tu)_6]^{4+}$, and the Cu atoms are further (0.07, 0.20, 0.23, 0.36Å) outside their trigonal coordination planes, a difference which leads to longer Cu–Cu distances (2.83–3.09Å).

The similarity of geometrical structure in $[Cu_4(tu)_6]^{4+}$ and $[Cu_4(SR)_6]^{2-}$ prompts inquiry about similarity of bonding at bridging sulphur. This would require substantial delocalisation of positive charge onto peripheral atoms in $[Cu_4(tu)_6]^{4+}$. The greater Cu–Cu distances in

$[Cu_4(tu)_6]^{4+}$ and the observation that these copper atoms will coordinate to additional thiourea ligands yielding $[Cu_4(tu)_9]^{4+}$ [16] and $[Cu_4(tu)_{10}]^{4+}$,[17] support the expected difference in bonding between uncharged thiourea and anionic thiolate in $[Cu_4(tu)_6]^{4+}$ and $[Cu_4(SR)_6]^{2-}$.

The Cu_4S_6 cage core also occurs in the chelate complex $[Cu_4(SP(Ph)_2NP(Ph)_2S)_3]^{+}$,[18] in which the ligand restricts the cage geometry.

EXPERIMENTAL

Synthesis. The preparation of (1) has been described.[12] Reagent grade solvents and reactants were used, without any special purification. All solutions were prepared and maintained in an atmosphere of dinitrogen.

Three compounds, $(Me_4N)_2[Cu_4(SPh)_6]$ (2), as pale yellow blocks, $(Me_4N)_2[Cu_4(SPh)_6]EtOH$ (3), as very pale yellow needles, and $(Me_4N)_2$ $[Cu_5(SPh)_7]^9$, crystallise from solutions of very similar composition, and frequently crystallise simultaneously from the one preparative solution. On the basis of a large number of preparative experiments it appears that solvent composition, temperature, and rate of nucleation are the main factors which determine the predominant product, but it has not yet been possible to devise reproduceable methods for crystallisation of (2) or (3) alone. In practice this is not a serious deficiency, as both compounds can be grown directly from the

(5b)

reaction mixture as large crystals which can be easily separated manually.

The following are representative experiments.

(a) A solution containing benzenethiol (6.0 g, 54 mmol), tri-*n*-butylamine (9.5 g, 51 mmol) and tetramethylammonium chloride (4.5 g, 41 mmol) in a mixture of absolute ethanol (100 cm³), methanol (50 cm³) and acetonitrile (30 cm³), was prepared at 50°C. To this a solution of copper(II) nitrate trihydrate (3.3 g, 13.7 mmol) in absolute ethanol (50 cm) was added rapidly with efficient stirring. Any precipitated CuSPh redissolved within about 2 min at 50°C, when the flask was sealed and allowed to cool slowly without disturbance. Crystallisation began almost immediately, and was allowed to continue for 3 days at room temperature. The product for (3.6 g) was separated,

washed with chloroform, and dried in nitrogen at 1 atm. It consisted of approximately equal amounts of pale yellow blocks (**2**) and needles (**3**).

(b) A yellow solution with the following composition was prepared as in (a): PhSH (6.0 g), Bu$_3$N (9.5 g), Me$_4$NCl (4.5 g), Cu(NO$_3$)$_2$3H$_2$O (2.4 g, 9.9 mmol), absolute ethanol (250 cm^3), methanol (25 cm^3), acetonitrile (50 cm^3). Crystallisation began soon after the commencement of cooling from 60°C, and was completed during 2 days at 0°C. The product, washed with CHCl$_3$ and dried with nitrogen gas, was almost totally (**2**) as well formed pale yellow blocks. Yield *ca.* 2.5 g. This crystallisation mixture contained a higher PhS$^-$/Cu ratio than in (a).

(c) In similar manner the following yellow solution containing *n*-propanol was prepared: PhSH (6.0 g), Bu$_3$N (9.5 g), Me$_4$NCl (4.5 g), Cu(NO$_3$)$_2$3H$_2$O (2.4 g), absolute ethanol (70 cm^3), *n*-propanol (180 cm^3), methanol (25 cm^3) acetonitrile (75 cm^3). Crystallisation began 1 hr after slow cooling from 60°, and was allowed to continue for 2 days at room temperature. The product contained mainly beautiful large blocks of (**2**), together with smaller bright yellow blocks of (Me$_4$N)$_2$[Cu$_5$(SPh)$_7$].

Needles of (**3**) contain solvent which is readily lost on pumping or open exposure at room temperature. *Anal.* (**2**): Calc. for (Me$_4$N)$_2$Cu$_4$(SPh)$_6$: C, 49.98; H, 5.15; N, 2.65; Cu, 24.03; S, 18.19. Found: C, 49.86; H, 5.31; N, 2.70; Cu, 24.00; S, 18.36.

The presence of ethanol in (**3**) was established by diffraction analysis, for which a single crystal was sealed in a capillary tube together with crushed crystals of the same compound.

Crystals of (**2**) and (**3**) react with oxygen, developing a dark brown coating after 24 hr at room temperature. Both compounds are soluble in acetonitrile and acetone to give pale yellow solutions, and in pyridine to give a strongly yellow solution, all solutions being decomposed rapidly by oxygen. Recrystallisation of (**2**) or (**3**) is complicated by dissociation to CuSPh, which is insoluble.

Crystallography. The following general information applies to the three crystals. Data were collected at 294 K; scattering factors for uncharged atoms were from International Tables,[19] all least squares calculations minimised $\Sigma w(|F_0| - |F_c|)^2$; residuals quoted are $R = \Sigma \|F_0| - |F_c\|/\Sigma|F_0|$, $R_w = [\Sigma w(|F_0| - |F_c|)^2/\Sigma w|F_0|^2]^{1/2}$; in both SPh compounds phenyl ring hydrogen atoms were maintained at calculated positions with thermal parameters equal to those of connected atoms; a common atom labelling scheme is used for the three crystals (see Fig. 3).

Compound (**1**). (Me$_4$N)$_2$[Cu$_4$(SMe)$_6$], C$_{14}$H$_{42}$-Cu$_4$N$_2$S$_6$, M = 685.00; colourless hexagonal plates, trigonal space group P3c1 (no. 158); a = 16.777(2), c = 17.540(2)Å, γ = 120°, U = 4275.5Å, D$_M$ = 1.60 gcm^{-3} (flotation in *n*-hexane/1,3-dibromopropane), Z = 6, D$_{calc}$ = 1.60 gcm^{-3}; F(000) = 2112. Nickel filtered CuK$_\alpha$ radiation, λ = 1.5418Å, μ = 74.2 cm^{-1}; crystal habit {001}{110}{120} {$\bar{1}$21}($\bar{1}\bar{1}$1), specimen dimensions 0.33 × 0.32 × 0.20 mm. Intensity data (Siemens AED diffractometer) to θ_{max} 65° by $\theta/2\theta$ scan, with intensity standard decreasing 1→0.9. Decay and analytical absorption corrections were applied, I = N$_p$ − N$_b$, σ(I) = [N$_p$ + N$_b$ + (0.04N$_p$)^2]$^{1/2}$, yielding 2380 unique reflections with I/σ(I) > 2.58.

Structure determination was effected by MULTAN and difference Fourier methods. It was found that one cation (N4) occupied a general position while the second was situated about a set of special positions. Each atom lying on the threefold axis was assigned a multiplicity of one-third. Refinement of parameters, initially with unit weights and isotropic temperature factors for all atoms, returned R = 0.158. In subsequent least squares w = 4|F$_0$|^2/σ^2(F$_0^2$) and anisotropic temperature factors were assigned to the copper and sulfur atoms, converging at R = 0.057. The carbon atoms attached to N3 and the tetramethylammonium ions on special positions did not refine well, and therefore were repositioned by difference Fourier and not refined further. The final refinement, with anisotropic temperature factors assigned to all non-hydrogen atoms in the anion and in the cation at general position, converged at R = 0.041, R$_w$ = 0.046.

Compound (**2**). (Me$_4$N)$_2$[Cu$_4$(SPh)$_6$], C$_{44}$H$_{54}$-Cu$_4$S$_6$N$_2$, M = 1057.47, pale yellow blocks, monoclinic space group P2$_1$/c, a = 23.733(3), b = 12.428(2), c = 35.853(4)Å, β = 106.84(2)°, U = 1.0121 × 10^{4}Å^3, Z = 8, D$_{calc}$ = 1.39 gcm^{-3}. Nickel filtered CuK$_\alpha$ radiation, μ = 43.7 cm^{-1}, crystal habit {100}{001}{101}{102}, specimen dimensions 0.17 × 0.25 × 0.31 mm. Intensity data (Siemens AED diffractometer) by $\theta/2\theta$ scan, with corrections for absorption and for intensity loss due to appreciable crystal decay, 7234 intensity measurements yielded 4110 unique reflections with I/σ(I) > 2.58.

The structure was determined by MULTAN and Fourier methods, and refined by blocked matrix least squares, w = [σ(F$_0$)]$^{-2}$. Refinement with anisotropic temperature factors for copper and sulfur atoms converged at R = 0.111, R$_w$ = 0.089 for 3598 reflections with sinθ/λ > 0.2. A difference Fourier revealed peaks (maximum electron density

$2.6\text{e}\text{Å}^{-3}$) near the copper atoms, attributed to errors in the data caused by the X-radiation damage to the crystal, and also some evidence for a partially occupied alternative Me_4N^+ cation site. In view of the limited quality of the data, further modelling of the structure was not attempted. In the final least squares cycle all positional parameters for atoms bonded together were included in the same block: $R = 0.105$, $R_w = 0.085$ (3598 data, $\sin\theta/\lambda > 0.2$).

Compound (3). $(Me_4N)_2[Cu_4(SPh)_6].C_2H_5OH$, $C_{46}H_{60}Cu_4S_6N_2O$, $M = 1103.54$, pale yellow needles losing solvent on exposure, monoclinic spacegroup $P2_1/a$, $a = 19.125(2)$, $b = 15.433(1)$, $c = 17.500(2)\text{Å}$, $\beta = 103.73(1)°$, $U = 5017.6\text{Å}^3$, $Z = 4$, $D_{calc} = 1.46\,\text{gcm}^{-3}$. Monochromatised MoK_α radiation, crystal habit $\{011\}$, $\{001\}$, $\{100\}$, specimen dimensions $0.20 \times 0.22 \times 0.38$ mm, specimen sealed in capillary with crushed sample to prevent solvent loss, intensity data (Syntex $P_{\bar{1}}$ diffractometer) by $\theta/2\theta$ scan. Corrections for absorption, found by psi-cans to cause less than 6% variation in F^2 (2.5% in F), were not applied. The data set contained 3370 independent reflections with $I > 2\sigma(I)$. The structure was solved by MULTAN and Fourier methods, and refined normally $(w = [\sigma(F)]^{-2})$ with anisotropic thermal parameters for all non-hydrogen atoms. The oxygen and carbon atoms of the ethanol were not well defined, with large thermal motion. On completion of refinement, $R = 0.044$, $R_w = 0.054$, and $[\Sigma w(\Delta F)^2/(m - n)]^{1/2} = 1.21$, for 3370 reflections (m) and 532 variables (n).

Atomic coordinates and thermal parameters for the three structures have been deposited with the Editor as supplementary material; copies are available on request. Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

LIGAND EXCHANGE PROCESSES IN SOME IRON–SULPHUR-CARBONYL AND -NITROSYL COMPLEXES

ANTHONY R. BUTLER, CHRISTOPHER GLIDEWELL,* ANDREW R. HYDE
JOSEPH McGINNIS and JULIE E. SEYMOUR
Chemistry Department, University of St. Andrews, St. Andrews, Fife KY16 9ST, Scotland

Abstract—The complex $[Fe_2(SMe)_2(CO)_6]$ undergoes stepwise exchange with Et_2S_2 to yield successively $[Fe_2(SMe)(SEt)(CO)_6]$ and $[Fe_2(SEt)_2(CO)_6]$. Carbonyl complexes $[Fe_2(SR)_2(CO)_6]$ are efficiently converted to the nitrosyls $[Fe_2(SR)_2(NO)_4]$ by the action either of NO gas or of methanolic sodium nitrite: the analogous species $[Fe_2S_2(CO)_6]$, $[Fe_2S_2(CO)_6]^{2-}$, and $[Fe_3S_2(CO)_9]$ all, with methanolic nitrite, yield $[Fe_4S_3(NO)_7]^-$. This anion, $[Fe_4S_3(NO)_7]^-$, reacts with sulphur to give the cubane-like $[Fe_4S_4(NO)_4]$: the synthesis of its selenium analogue, $[Fe_4Se_3(NO)_7]^-$ is described. The complexes $[Fe_2(SR)_2(NO)_4]$ (R = Me, Et, Pr^n, Pr^i, Bu^t, $PhCH_2$) all consist of two isomers in solution, presumed to have structures of C_{2h} and C_{2v} symmetry: activation parameters for the $C_{2h} \rightleftharpoons C_{2v}$ reaction are reported.

In recent years a wide range of iron–chalcogen-carbonyl complexes, containing terminal carbonyl ligands bonded to an iron–chalcogen core, have been synthesized:[1–7] these complexes have been studied primarily from the standpoints of structural characterization in the solid state,[7–11] and in the case of the *S*-alkylated complexes $[Fe_2(SR)_2(CO)_6]$, of their fluxional behaviour in solution.[5,6] Closely analogous to, and formally isoelectronic with the $[Fe_2(SR)_2(CO)_6]$ are the nitrosyls $[Fe_2(SR)_2(NO)_4]$:[12,13] these are the esters of Roussin's red salt $[Fe_2(S_2)_2(NO)_4]^{2-}$,[14] and the structure of the ethyl ester in the solid state has been determined.[15] A further analogy between the carbonyls and nitrosyls is provided by the anion $[Fe_2S_2(CO)_6]^{2-}$,[16,17] whose chemistry has been compared with that of $[Fe_2S_2(NO)_4]^{2-}$.

We have demonstrated[18] a simple method for converting $[Fe_2(SMe)_2(CO)_6]$ into $[Fe_2(SMe)_2(NO)_4]$, and have sought to exploit this type of conversion as a means of preparing a range of derivatives $[Fe_2(SR)_2(NO)_4]$, from the readily accessible carbonyls: one of our objectives was to explore routes to suitably functionalised nitrosyl complexes which might have solubility characteristics similar to those of the salts of $[Fe_4S_3(NO)_7]^-$,

which are freely soluble both in water and in many of the common organic solvents.[14] In the present paper we report upon the exchange reactions of $[Fe_2(SR)_2(CO)_6]$ with disulphides $R_2'S_2$; on the nitrosylation not only of $[Fe_2(SR)_2(CO)_6]$, but of a number of other iron–sulphur-carbonyl species also; on the inter-conversion of some tetra-iron complexes; and finally on the results of a variable-temperature NMR study of $[Fe_2(SR)_2(NO)_4]$ for R = Me, Et, Pr^n, Pr^i, Bu^t, and $PhCH_2$.

RESULTS AND DISCUSSION

Di-iron complexes

An attractive possibility for the synthesis of compounds $[Fe_2(SR)_2(CO)_6]$ in cases where the thiol RSH and the disulphide RSSR are of low volatility is the exchange reaction with $[Fe_2(SMe)_2(CO)_6]$ (eqn 1).

$$Fe_2(SMe)_2(CO)_6 + RSSR \rightarrow$$
$$Me_2S_2 + Fe_2(SR)_2(CO)_6. \quad (1)$$
This possibility was investigated initially for the case of R = Et. Although $[Fe_2(SEt)_2(CO)_6]$ is indeed formed, the reaction does not proceed as shown in eqn (1); when the composition of the reaction mixture was monitored over time by mass spectrometry, it was clear that the product initially formed was the mixed alkyl thiolate disulphide

---

*Author to whom correspondence should be addressed.

$[Fe_2(SMe)(SEt)(CO)_6]$, and that the formation of the di-ethyl product was very much slower (eqn 2).

$$Fe_2(SMe)_2(CO)_6 \xrightarrow{Et_2S_2} Fe_2(SMe)(SEt)(CO)_6$$

$$\xrightarrow{Et_2S_2} Fe_2(SEt)_2(CO)_6. \qquad (2)$$
A number of distinct mechanistic possibilities for the formation of the intermediate $[Fe_2(SMe)(SEt)(CO)_6]$ were examined: exchange between Me_2S_2 and Et_2S_2 to yield MeSSEt was found to be extremely slow, and could therefore be ruled out. For effective exchange between pairs of disulphides, catalysis by SH^- or SR^- is necessary.[19] Similarly, it was found that in the reaction between $[Fe_2(SMe)_2(CO)_6]$ and $[Fe_2(SEt)_2(CO)_6]$, the formation of $[Fe_2(SMe)(SEt)(CO)_6]$ was very much slower, under identical conditions, than the formation of the mixed compound from $[Fe_2(SMe)_2(CO)_6]$ and Et_2S_2: this observation, and the fact that a mechanism involving exchange between the two di-iron complexes would require the formation of $[Fe_2(SEt)_2(CO)_6]$ to precede, rather than follow, the formation of $[Fe_2(SMe)(SEt)(CO)_6]$, allows the elimination of this possibility.

There remains the possibility of the stepwise replacement of SR groups, with concommitant formation of EtSSMe (eqn 3).

$$Fe_2(SMe)_2(CO)_6 + Et_2S_2 \longrightarrow EtSSMe$$
$$+ Fe_2(SMe)(SEt)(CO)_6. \qquad (3)$$
This was confirmed by the identification by GC/MS of EtSSMe amongst the reaction products, and by following the rate of its formation alongside the rate of formation of $[Fe_2(SMe)(SEt)(CO)_6]$. Since simple thiols RSH do not participate in such an exchange process, despite the volatility of MeSH (eqn 4):

$$Fe_2(SMe)_2(CO)_6 + RSH \nrightarrow MeSH$$
$$+ Fe_2(SMe)(SR)(CO)_6 \qquad (4)$$
we conclude that the exchange depends upon the supernucleophilicity (α effect) arising from the two adjacent sulphur atoms (eqn 5).

Having demonstrated the occurrence of RS exchange we then turned to a more complex RSSR species, the disulphide $(MeOCOCH_2S)_2$ derived from methylthioglycolate by oxidation.[19] Surprisingly this showed no exchange with $[Fe_2(SMe)_2(CO)_6]$ under conditions in which Et_2S_2 had reacted readily: possibly the carboxyl groups reduce the nucleophilicity of the disulphide group sufficiently to prevent effective reaction. Consequently, in order to attempt the preparation of $[Fe_2(SCH_2COOMe)_2(CO)_6]$, we reverted to the reaction of $Fe_2(CO)_{12}$ with R_2S_2:[12] when the disulphide was in 5-fold excess, the desired product was obtained, although contaminated with the excess of the disulphide. On the other hand when the $Fe_3(CO)_{12}$ was in 2.5 fold excess, the compound $[Fe_2(SCH_2COOMe)_2(CO)_6]$ was formed in only very low yield, after 2 hr reflux and the major products were $[Fe_2S_2(CO)_6]$ and $[Fe_3S_2(CO)_9]$: on longer reflux (e.g. 5 hr), $[Fe_2(SCH_2COOMe)_2(CO)_6]$ increased in abundance at the expense of $[Fe_2S_2(CO)_6]$ and $[Fe_3S_2(CO)_9]$. This reaction is thus rather reminiscent of those, studied by King,[20] of $Fe_3(CO)_{12}$ and episulphides. The product of King's reactions turned out[11] to be a 1:1 compound of $[Fe_2S_2(CO)_6]$ and $[Fe_3S_2(CO)_9]$: this compound survived sublimation unchanged, although in our own system the two components are readily separable by chromatography. The results of the $[Fe_3(CO)_{12}/(SCH_2COOMe)_2$ reaction suggested that the compounds $[Fe_2S_2(CO)_6]$ and $[Fe_3S_2(CO)_9]$ might be intermediates: alternatively their disappearance as the reaction proceeds could be due simply to decomposition rather than to consumption by reaction with R_2S_2 with concommitant formation of $[Fe_2(SR)_2(CO)_6]$. We find in fact that the reactions of $[Fe_2S_2(CO)_6]$ and of $[Fe_3S_2(CO)_9]$ with $(SCH_2COOMe)_2$ do not yield any $[Fe_2S_2(SCH_2COOMe)_2]$ so that these iron-sulphur carbonyls are not intermediates in the formation of the Roussin-type ester. On the other hand both are formed by reaction of $Fe_3(CO)_{12}$ with elemental sulphur, and both slowly decompose (presumably to carbon monoxide and iron sulphides) on reflux alone: their formation therefore represents merely a side reaction in this process.

Finally we note for the sake of completeness that

$$(5)$$
Table 1. Nitrosation reactions

Reactant	Method [a]	Product	Yield/%
$Fe_2(CO)_9$	A	$Fe(CO)_2(NO)_2$	b

a. For identification of procedures A, B, C, see experimental part.

b. Volatile product; yield not measured.

c. Yield for room temperature reaction: yield rises to 92% if mixture refluxed

     during passage of NO (see text).

d. Trace only of nitrosylated product, not identified.

$[Fe_2(SMe)_2(NO)_4]$ can be prepared by reaction of Me_2S_2 with $Fe(NO)_2(CO)_2$ (eqn 6)

$$2Fe(NO)_2(CO)_2 + Me_2S_2 \rightarrow Fe_2(SMe)_2(NO)_4 + 4CO. \tag{6}$$
This preparation is entirely analogous to that for the selenium–iron complex $[Fe_2(SeEt)_2(NO)_4]$, reported by Hieber and Beck.[21] This reaction, and that of $Hg[Fe(CO)_3NO]_2$ with elemental sulphur to yield $[Fe_4S_4(NO)_4]$,[22] both conducted under reflux at high temperature, both involve complete displacement of carbonyl ligands and complete retention of nitrosyl ligands, and, as such, must testify to the extreme robustness of the (FeNO) fragment in these complexes. This very strong binding of the nitrosyl ligand to iron has been remarked upon previously,[23] and seems, in diamagnetic complexes at least, not to be dependent upon any particular formal oxidation state of the iron: in all these systems, the nitrosyl is formally present as NO^+.

Nitrosylation reactions

Reaction of $Fe(CO)_5$ with nitrite in alkaline aqueous methanol yields[24] the anion $[Fe(CO)_3NO]^-$, readily isolable as its mercury derivative

$Hg[Fe(CO)_3NO]_2$: further treatment of the anion with nitrite in the presence of a weak acid, such as acetic acid yields the neutral $[Fe(CO)_2(NO)_2]$, where the overall reaction represents replacement of three carbonyl groups with two nitrosyl groups. Since many of the known iron–sulphur-carbonyl complexes contain $Fe(CO)_3$ fragments in which all the carbonyl ligands are terminal,[7,9–11,15] we have explored the reactions of a number of such complexes with methanolic nitrite. The results of this study are summarised in Table 1, along with those for some similar nitrosation reactions which use NO as the nitrosating agent.

The binary carbonyls $Fe_2(CO)_9$ and $Fe_3(CO)_{12}$ were studied first, to establish the generality of this procedure: both carbonyls yield $[Fe(CO)_2(NO)_2]$ as the only iron-nitrosyl product. The complexes $[Fe_2(SR)_2(CO)_6]$ (R = Me, Et) both readily yield the analogous nitrosyl with Procedure A (see Experimental for details), as does $[Fe_2(SMe)_2(CO)_6]$ when subjected to Procedure B, (nitrosation by NO gas). At room temperature or below, the use of NO gas in an organic medium does not effect complete conversion of $[Fe_2(SMe)_2(CO)_6]$ to $[Fe_2(SMe)_2(NO)_4]$, but separation of the two complexes was readily achieved by fractional crystallisation. However if

the mixture is refluxed during the passage of the NO gas, no carbonyl complex remains, and the conversion is almost quantitative, giving a 92% yield of [Fe$_2$(SMe)$_2$(NO)$_4$].

The complexes [Fe$_2$S$_2$(CO)$_6$], [Fe$_2$S$_2$(CO)$_6$]$^{2-}$, and [Fe$_3$S$_2$(CO)$_9$] all yield the anion of Roussin's black salt,[14] [Fe$_4$S$_3$(NO)$_7$]$^-$ in good yield when nitrosylated according to Procedure A: in the case of [Fe$_2$S$_2$(CO)$_6$]$^{2-}$ as reactant the anion [Fe$_4$S$_3$(NO)$_7$]$^-$ is accompanied by a low yield of [Fe$_2$S$_2$(NO)$_4$]$^{2-}$, the anion of Roussin's red salt.[14] Reaction of these three complexes with NO gas in an inorganic solvent (Procedure B) effects negligible nitrosylation, whereas reaction of [Fe$_3$S$_2$(CO)$_9$] with NO gas in an alkaline medium again gave an excellent yield of [Fe$_4$S$_3$(NO)$_7$]$^-$. In addition to these observations, we note that the action of NO gas upon [Fe$_2$(SCF$_3$)$_2$(CO)$_6$] has been reported[25] to give [Fe$_2$(SCF$_3$)$_2$(NO)$_4$]. In view of the readily available carbonyl complexes [Fe$_2$(SR)$_2$(CO)$_6$], this preparation of the analogous nitrosyl species provides an efficient alternative route to these complexes.

While we cannot suggest with confidence the identity of any intermediates in these nitrosylation reactions, we note that an equimolar mixture of [Fe$_2$(SMe$_2$)(CO)$_6$] and [Fe$_2$(SEt)$_2$(CO)$_6$], when nitrosylated by procedure A gave no evidence for the formation of the mixed species [Fe$_2$(SMe)(SEt)(NO)$_4$], despite a 4 hr reflux. This suggests that the Fe$_2$S$_2$ framework remains intact, with no formation either of monomeric fragments [Fe(SR)(CO)$_3$] or [Fe(SR)(NO)$_2$] or of ions RS$^-$ + Fe(CO)$_3^+$ or Fe(NO)$_2^+$: in contrast the μ-iodo complex Fe$_2$I$_2$(NO)$_4$ has been shown to ionise completely to Fe(NO)$_2^+$ and I$^-$.[26]

Tetra-iron complexes

The first example of a tetra-nuclear iron-sulphur nitrosyl to be characterised was the anion [Fe$_4$S$_3$(NO)$_7$]$^-$ of Roussin's black salt,[14] the crystal structures of two of whose salts have been determined[27,28] Reaction of salts of this anion with elemental sulphur in refluxing toluene leads to formation of the cubane-like complex [Fe$_4$S$_4$(NO)$_4$], first prepared by reaction of Hg[Fe(CO)$_3$NO]$_2$ with elemental sulphur.[22] This reaction could be simply the completion of the Fe$_4$S$_4$ framework by addition of a sulphur to the existing Fe$_4$S$_3$ framework, or alternatively, it might proceed by means of a large scale fragmentation and subsequent re-formation of the iron–sulphur skeleton.

The reaction of the mercurial Hg[Fe(CO)$_3$NO]$_2$ with elemental selenium similarly yields a black, rather labile compound whose IR and UV spectra are very similar to those of [Fe$_4$S$_4$(NO)$_4$] [ν(NO),

1785 cm^{-1}; λ(max), 270 nm] and which may be the analogous [Fe$_4$Se$_4$(NO)$_4$], although we have not succeeded in obtaining an analytical sample of this material. On brief (e.g. 2hr) reflux of the mercurial with selenium, no such compound is formed. Reaction of salts of [Fe$_4$S$_3$(NO)$_7$]$^-$ with elemental selenium in refluxing toluene again gives a material having the characteristic IR and UV spectra of the cubane species. This latter could be either [Fe$_4$S$_3$Se(NO)$_4$] if the reaction simply involves framework completion, or it could be a more complex mixture of species [Fe$_4$S$_x$Se$_{4-x}$(NO)$_4$] if the reaction proceeds by fragmentation and reformation. Further study of this point is in progress.

In contrast to its reaction with elemental sulphur, the mercurial Hg[Fe(CO)$_3$NO]$_2$ reacts with aqueous methanolic polysulphide solutions at room temperature to yield salts of [Fe$_4$S$_3$(NO)$_7$]$^-$; these conditions are not sufficiently vigorous to effect the further conversion of [Fe$_4$S$_3$(NO)$_7$]$^-$ to [Fe$_4$S$_4$(NO)$_4$]. We note that the reverse conversion of [Fe$_4$S$_4$(NO)$_4$] to [Fe$_4$S$_3$(NO)$_7$]$^-$ has also been effected.[28]

Just as reaction of a solution of ammonium sulphide and nitrite with iron(II) yields salts of [Fe$_4$S$_3$(NO)$_7$]$^-$, so also a solution of sodium hydrogen-selenide and nitrite reacts with iron(II) to yield the anion [Fe$_4$Se$_3$(NO)$_7$]$^-$, characterised spectroscopically and by elemental analysis of its tetraphenylarsonium salt. Further study of this material is in progress and will be reported upon in due course.

NMR spectra

In Table 2, we record the ^{1}H and ^{13}C NMR assignments for [Fe$_2$(SMe)$_2$(CO)$_6$] and [Fe$_2$(SEt)$_2$(CO)$_6$]: the proton data for the methyl derivative have been reported previously.[2,5,6] The ^{13}C shifts of the methyl groups are of interest for the large difference between the two non-equivalent methyl carbons in the *anti* isomers. This phenomenon is observed also for the methylene carbons in the *anti* isomer of [Fe$_2$(SEt)$_2$(CO)$_6$] where one of the CH$_2$ carbons has a chemical shift similar to those of the methyl carbons in this compound: off-resonance decoupling was required to assign the shifts in the *anti* isomer. For neither of these compounds were we able to establish by NMR methods the activation parameters for the *anti* $\rightleftharpoons$ *syn* interconversion, as at elevated temperatures, decomposition was sufficiently rapid to prevent the recording of adequate NMR spectra. Conversion of either isomer of either compound to an equilibrium mixtura of *syn* and *anti* isomers is quite rapid, being complete for example after 10 min reflux in benzene solution. At ambient temperatures the carbonyl groups ex-

hibit fluxional behaviour: the low temperature behaviour has been discussed.[6]

Table 3 contains ^1H and ^{13}C chemical shifts for the analogous nitrosyl species [$Fe_2(SR)_2(NO)_4$]: we have not yet succeeded in recording ^{14}N or ^{15}N shifts for this series. These are two points of particular interest associated with these data. First, there is for the examples of $R = CH_3$, C_2H_5 and $PhCH_2$, a considerable solvent-induced chemical shift difference observed for the protons on changing the solvent from chloroform-d to toluene-d_8. In the methyl derivative this shift is *ca.* 0.6 p.p.m., and in the ethyl derivatives *ca.* 0.4 p.p.m. for the methyl protons and *ca.* 0.5 p.p.m. for the methylene protons: in the benzyl derivative, the solvent shift for the methylene protons is *ca.* 0.35 p.p.m., and for the phenyl protons which appear as a single unresolved absorption at 80 MHz, the shift is again 0.35 p.p.m. In every case, the proton chemical shift is lower in toluene than in chloroform, but the solvent-induced shifts in the ^{13}C resonances seem to be very modest in magnitude. A possible interpretation of the large proton solvent-induced shifts is in terms of the paratropic ring current in the solvent toluene, but this idea requires rather specific mean orientations of the solvent molecules around a solute molecule: we have not yet investigated systematically the solvent effects on the chemical shifts of these complexes. Regardless of the solvent, there is a steady shift to low field of the C–S resonance as R varies from Me to Bu^t.

The second noteworthy feature is the observation of the splitting of many, but not all, of the proton and carbon signals. For example, when R = Me, two similar spectra, of identical intensity are observed in toluene, but only one in chloroform. Similar splittings have been observed previously,[29] and interpreted in terms of equally abundant C_{2v} and C_{2h} isomers. The observation of a

single spectrum is due either of accidentally identical chemical shifts or to fast equilibration between isomers, rather than to the presence of a single isomer. In our preliminary account of the formation of [$Fe_2(SMe)_2(NO)_4$] from [$Fe_2(SMe)_2(CO)_6$],[18] we observed only a single ^1H spectrum, having chosen chloroform as our NMR solvent. This observation, together with that of apparent chromatographic homogeneity, led us to the belief that only one isomer was present: since the X-ray analysis of [$Fe_2(SEt)_2(NO)_4$] revealed the presence only of the C_{2h} isomer,[15] we inferred that this was the isomer present in solution. This belief of a single isomer was strengthened by the observation of only a single ^{13}C chemical shift in chloroform solution (Table 3).

However, it is clear from the spectra in toluene solution that there are indeed two isomers present in solution for all of this series, and using variable-temperature ^1H spectroscopy we have measured the activation energies in toluene solution for the $C_{2h} \rightleftharpoons C_{2v}$ isomerisation process. The relevant data, all derived from solutions in toluene-d_8 are given in Table 4. Distinct coalescence temperatures were determined for the CH_3 and CH_2 protons in the ethyl compounds, giving $\Delta G^\ddagger$ values identical within experimental uncertainty. Replacement of one hydrogen in the methyl derivative by an alkyl group to give the ethyl or *n*-propyl derivatives causes a modest reduction in $\Delta G^\dagger$ of some 2.5 kJ mol^{-1}: double replacement to yield the *iso*-propyl derivative causes a much bigger reduction in $\Delta G^\ddagger$ of almost 20 kJ mol^{-1}. When all three hydrogens have been replaced, as in the *t*-butyl derivative, no splitting of the ^1H signal is observed in toluene solution even at 223 K, suggesting for any reasonable values of Δv, an upper limit for $\Delta G^\ddagger$ in this case of around 50 kJ mol^{-1}.

Our observation (see above) that [$Fe_2(SR)_2$-

(NO)$_4$] undergoes neither dissociation to form monomeric [Fe(SR)(NO)$_2$] nor ionisation to Fe(NO)$_2^+$ and SR$^-$ makes it virtually certain that the rate processes we have observed are indeed those for the C$_{2h} \rightleftharpoons$ C$_{2v}$ isomerisation. We intend to report further on the interesting solvent dependence of these spectra in a future communication.

EXPERIMENTAL

Literature methods were employed for the preparation of [Fe$_2$S$_2$(CO)$_6$][1], [Fe$_2$S$_2$(CO)$_6$]$^{2-}$,[16] [Fe$_3$S$_2$(CO)$_9$][1], [Fe$_2$(SMe)$_2$(CO)$_6$]^2 and Hg[Fe(CO)$_3$NO]$_2$;[24] [Fe$_2$(SEt)$_2$(CO)$_6$] was prepared in a manner similar to that for [Fe$_2$(SMe)$_2$(CO)$_6$] and for each of these compounds, two isomers were separable by chromatography. Evidence was obtained for a third, minor, component in the chromatography of [Fe$_2$(SMe)$_2$(CO)$_6$], but adequate characterisation was not achieved owing to the tiny amount of material isolated.

NMR spectra were recorded using Varian CFT-20 and Bruker WP-80 instruments. For both [Fe$_2$(SMe)$_2$(CO)$_6$] and [Fe$_2$(SEt)$_2$(CO)$_6$] full NMR spectral assignments (^{1}H and ^{13}C) were made for both isomers, by use of off-resonance decoupling: the NMR spectral data for these compounds are given in Table 2.

Nitrosylation, Procedure A

In a typical reaction, the carbonyl complex (24 mmol) and sodium nitrite (6.0 g) were added to a solution of sodium hydroxide (10.0 g) in a mixture of water (50 cm^3) and ethanol (25 cm^3). The mixture was then stirred and refluxed under nitrogen for 4 hr. After cooling to ca. 30°C, the mixture was acidified with 1 : 1 acetic acid/water (approx. 30 cm^3). The resulting mixture was evaporated to dryness: the solid was extracted firstly with CH$_2$Cl$_2$ (6 × 50 cm^3), and secondly with water (2 × 100 cm^3). The methylene chloride extract was washed with water (2 × 50 cm^3), dried over Na$_2$SO$_4$, and evaporated to dryness: recrystallisation from 1 : 1 CH$_2$Cl$_2$/MeOH yielded Fe$_2$(SR)$_2$(NO)$_4$. Tha aqueous extract was extracted with ether (4 × 50 cm^3), and the ether layer was dried over Na$_2$SO$_4$, and evaporated to yield Na[Fe$_4$S$_3$(NO)$_7$]: to the residual aqueous layer was added an aqueous solution of Ph$_4$As$^+$Cl$^-$; the resulting precipitate was filtered off, and dissolved in CH$_2$Cl$_2$; after drying over Na$_2$SO$_4$ and evaporation, recrystallisation from CH$_2$Cl$_2$ yielded (Ph$_4$As)$_2$[Fe$_2$S$_2$(NO)$_4$].

Procedure B

Typically, the carbonyl complex (10 mmol) was dissolved in CH$_2$Cl$_2$ (50 cm^3), and the solution

purged with nitrogen. Nitric oxide was bubbled through the solution for 1 hr, and the solution was evaporated to dryness. The work-up then follows that described for Procedure A. When the substrate was [Fe$_2$(SMe)$_2$(CO)$_6$] the product was a mixture of [Fe$_2$(SMe)$_2$(CO)$_6$] and [Fe$_2$(SMe)$_2$(NO)$_4$], separated by differential crystallisation using light petroleum (b.p. 40/60°C).

Procedure C

This was similar to Procedure A, except that the nitrogen gas stream was replaced by a nitric oxide stream, and the sodium nitrite was omitted from the reaction medium.

Preparation of salts of Fe$_4$Se$_3$(NO)$_7^-$

(a) Sodium salt

A mixture of 7 g selenium and 50 cm^3 water was stirred under N$_2$: a solution of 7 g NaBH$_4$ in 50 cm^3 water was added dropwise with stirring. Vigorous evolution of H$_2$ occurred, and after this had subsided the solution was allowed to cool, giving a clear grey solution above a precipitate of Na$_2$B$_4$O$_7$.10H$_2$O. NaNO$_2$ (8 g) was added with stirring, and the solution turned dark red. The solution was boiled and 20 g of FeSO$_4$.7H$_2$O in 160 cm^3 water was added in one portion, followed by slow addition of 35 cm^3 of 25% NH$_3$ solution. The solution was then boiled for 30 mins, filtered hot, cooled, and filtered a second time. The cold filtrate was extracted with ether, and the dried extracts evaporated to yield the sodium salt of Fe$_4$Se$_3$(NO)$_7^-$.

(b) Ph$_4$As$^+$ salt

Equimolar quantities of Na[Fe$_4$Se$_3$(NO)$_7$] and Ph$_4$AsCl.H$_2$O were dissolved in water, and the solutions mixed. The whole was extracted with chloroform, and the dried extract was evaporated. The resulting solid was recrystallised from methanol to yield Ph$_4$As[Fe$_4$Se$_3$(NO)$_7$] as shiny black crystals. Found: C, 27.2; H, 1.8; N, 9.2; Fe, 22.3; Se, 22.6. Calc. for C$_{24}$H$_{20}$AsFe$_4$N$_7$O$_7$Se$_3$: C, 27.4; H, 1.9; N, 9.3; Fe, 21.2; Se, 22.5%. UV/visible spectrum: λ/nm(ϵ/lmol^{-1}cm^{-1}): 570(2700), 432(10000), 360(16000), 279(27000). IR spectrum, ν(NO)/cm^{-1}: 1790 m, 1690 s, 1720 m.

Iron and selenium were determined by atomic absorption, using the hydride method for selenium.

STUDIES IN THE FLEXIBILITY OF MACROCYCLIC LIGANDS. CRYSTAL AND MOLECULAR STRUCTURE OF 2,13-DIMETHY1-3,6,9,12,18-PENTAAZABICYCLO (12.3.1) OCTADECA-(18),14,16-TRIENE-DICHLOROION (III) HEXAFLUOROPHOSPHATE

MICHAEL G. B. DREW*, DAVID A. RICE* and SIDIK BIN SILONG

Department of Chemistry, University of Reading, Whiteknights,
Reading RG6 2AD, England

Abstract—The crystal structure of the title compound $[FeL^2Cl_2][PF_6]$ is reported. Crystals are monoclinic with $a = 11.747(9)$, $b = 16.051(11)$, $c = 11.964(10)$Å, $\beta = 98.1(1)°$, $Z = 4$, Spacegroup $P2_1/n$. 1173 independent reflections above background have been refined to R 0.09. The coordination geometry around the Fe(III) ion is pentagonal bipyramidal with the two chlorine atoms in axial positions [Fe–Cl 2.348(7), 2.354(7)Å]. The five donor nitrogen atoms of the macrocycle form a pentagonal girdle with lengths in the range 2.20(2)–2.25(2)Å. The macrocycle conformation is compared to that found in $[CuL^2]^{2+}$ and $[CoL^2Cl]^{2+}$ where the $5N$ donor set provides respectively trigonal bipyramidal and square pyramidal environments and also to that found in the comparable 7–coordinate $[FeL^1(NCS)_2]^+$ where L^1 is the related pentaene.

The coordinative properties of macrocyclic ligands are dependent upon a number of factors. Three of the most important ones are the size of the "hole" or site in the ring, the degree of flexibility of the ligand and finally the nature of the donor atoms; i.e. do they form a "hard" or "soft" set. In this study we wished to extend our investigation into the effects of changing the flexibility of the ligand while keeping the donor set constant and to investigate whether the hole size of the macrocycle varied with conformation.

Suitable ligands for our comparative study are L^1 and its reduced form L^2 in which the imine groups have been hydrogenated.

The rigid 15–membered macrocycle L^1 forms complexes with metal ions ranging in ionic radii from 0.64Å (Fe^{3+}) to 1.18Å (Pb^{2+}); these being synthesised by allowing 3,6–diazaoctane 1,8–diamine to react with 2,6–diacetylpyridine (1:1 molar ratio) in the presence of a metal ion. The list of ions that have been successfully used are Mg^{2+}, Mn^{2+}, Fe^{3+}, Fe^{2+}, Co^{2+}, Zn^{2+}, Sn^{2+}, Cd^{2+}, and Pb^{2+}.[1-4] In these structures, L^1 forms a pentagonal girdle around the metal and with two axial anions
L^2
L^1

provides a pentagonal bipyramidal environment for the metal. Ni^{2+} and Cu^{2+} ions are unsuited to this geometry and their complexes cannot be prepared directly by template synthesis but only by

1053

trans-metallation. Crystal structures of several compounds including L^1 have been reported namely $[(FeL^1(NCS)_2) \cdot (ClO_4)]$,[1] $[FeL^1(NCS)_2]$,[2] $[FeL^1(H_2O)Cl \cdot (ClO_4)]$,[3] $[(Mg(L^1)(H_2O)_2)Cl_2]$.[4] The rigid nature of L^1 ensures that the specific stereochemistry preferred by the ion cannot necessarily be fulfilled.

However the macrocycle L^1 can be hydrogenated to give the more flexible macrocycle L^2. We have studied the structures of L^2 complexes with the aim of observing the effect of the increased flexibility on going from L^1 to L^2. Two structures we have reported are $[(CuL^2)(PF_6)_2]$[5] in which the donor atoms form a trigonal bipyramid and $[(CoL^2Cl)(ClO_4)_2]$[5] where an approximate square pyramid is formed by the donor atoms of the ligand. Both Cu^{2+} and Co^{3+} have preferred stereochemistries arising from their d^n configuration and so these structures cannot be directly compared to the 7–coordinate L^1 analogues.

However we now present a study of an Fe^{3+} complex of L^2 that via comparison with the structure of $[(FeL^1(NCS)_2)(ClO_4)]$[2] allows a discussion of the effect of flexibility on the mode of coordination. The Fe^{3+} ion being high spin has no CFSE effect to mask ligand preferences as have Cu^{2+} and Co^{3+}.

DISCUSSION OF THE STRUCTURE

The geometry of the cation $[FeL^2Cl_2]^+$ is illustrated in Fig. 1, together with the atomic numbering scheme. The iron atom which is in the cavity of the macrocycle has an approximately pentagonal bipyramidal coordination sphere; the chlorine atoms being in the axial sites.

The geometry of the macrocycle can be compared with that of the unsaturated L^1 in $[FeL^1(NCS)_2]$. The maximum deviation of a contributing atom from the FeN_5 plane is 0.23 Å in the
L^2 structure compare compared to 0.11 Å in L^1. The mean Fe–N distance in the present structure is 2.252 Å compared to 2.228 Å. This increase is presumably a consequence of the increase in the two C–N bond lengths and the resultant puckering which creates a larger hole for the metal ion. We have calculated the macrocycle hole sizes using the criterion of Tasker et al.[7] This method involves calculating the macrocycle hole size as twice the mean distance of the donor atoms from their centroid. In these pentagonal bipyramidal structures the values are 4.50 Å for L^2 and 4.45 Å for L^1.

A comparison of the torsion angles in the two structures in Table 2 shows considerable agreement with the variations as expected concentrated on the C(2)–N(3) and N(12)–C(13) bonds. The values found for $[FeL^2Cl_2]$ are not particularly strained and confirm the stability of the saturated complex.

The 7–coordinate structure observed for $[FeL^2Cl_2]$ is particularly interesting as both 5- and

6-coordinate structures are possible. Nuclear charge on the high spin Fe(III) ion combined with its relatively large radius and lack of octahedral CFSE are factors which favour the coordination of the two additional monodentate anions.

The two metal ions Fe^{3+} and Co^{3+} have similar ionic radii (0.65, 0.61 Å) and yet very different stereochemistries are observed with L^2. In $[CoL^2Cl]^{2+}$ the macrocycle is folded and the metal is 6-coordinate. The folding reduces the hole size from 4.50 to 3.74 Å; the Co–N distances fall within the range 1.81–2.00 Å. So one possible reason is that the small increase in size going from Co^{3+} to Fe^{3+} makes this conformation unsuitable. In addition, the CFSE values for Co^{3+} favour octahedral (– 24 Dq) over pentagonal bipyramidal (– 15.5 Dq). Examination of the torsion angles in the octahedral conformation show no obvious strains. The $[CuL^2]^{2+}$ complex ion is trigonal bipyramidal. The Cu^{2+} ion forms a variety of stereochemistries and CFSE values for a range of them are – 6.0 Dq (octahedral), – 14.3 Dq (square planar), – 9.2 Dq (square pyramidal) – 7.1 Dq trigonal bipyramidal) and – 4.9 Dq (pentagonal bipyramidal). Thus the order of favoured stereochemistries is square-planar (S) > square pyramidal (SP) > trigonal bipyramid (TBP). The square planar conformation is unlikely as it is doubtful that a square planar array of nitrogen atoms could be provided by L^2 as any such system

designed to provide such an array would bring a fifth atom into close proximity. However as is apparent from the Co structure, L^2 can provide a square pyramidal environment for a metal. Indeed looking at the torsion angles that are observed in $[CuL^2]^{2+}$ we can conclude that the TBP conformation is particularily strained. In particular the C(19)–C(2)–N(3)–C(4) and C(4)–C(5)–N(6)–C(7) angles of – 8.8° and – 129.3° signify eclipsed conformations. On the basis of CFSE and macrocycle conformation then, the TBP is less favoured than the SP.

The only conclusion we reach is that the hole size provided by the macrocycle in the TBP conformation is more suited to the size of the Cu^{2+} ion. Thus the macrocycle hole size provided by the TBP conformation is 4.05 A, considerably larger than for the SP conformation (3.74 A). As the Cu^{2+} ion radius at 0.73 Å is somewhat larger than Co^{2+} then it would seem that the larger hole provided by the macrocycle in the TBP conformation is necessary for complexation.

CONCLUSIONS

By comparison of the three structures $[CoL^2Cl]^{2+}$, $[CuL^2]^{2+}$ and $[FeL^2Cl_2]^+$ we have shown that both crystal field affects, and the size of hole are important in the deciding of the stereochemistries observed with the flexible macrocycle ligand L^2. This work also examines the method of

Tasker *et al.*[7] for the calculation of macrocycle hole size. Unlike the examples in Ref. 7, the present work demonstrates how the size can vary considerably (3.74–4.10 Å) with the conformation of the macrocycle. It seems clear therefore that the calculation can only be used with rigid macrocycles or when the conformation has been established by X-ray diffraction.

EXPERIMENTAL

Preparation. The ligand was synthesized following the method of Ref. 6 and recrystallised from an acetonitrile–diethyl ether mixture.

Crystal data

$C_{15}H_{27}N_5Cl_2PF_6F_e$, $M = 548.9$, Monoclinic, $a = 11.747(9)$, $b = 16.051(11)$, $c = 11.964(10)$ Å, $\beta = 98.1(1)°$, $U = 2233.3$ Å^3, $d_c = 1.64$, $d_m = 1.63$, $Z = 4$, $\lambda(Mo-K\alpha) = 0.7107$ A, $\mu = 10.69$ cm^{-1}. Spacegroup $P2_1/n$ from the systematic absences $h0l$, $h + l = 2n + 1$, $0k0$, $k = 2n + 1$.

A crystal of approximate shape 0.12*0.75* 1.00 mm was mounted on a Stoe STADI2 diffractometer and intensity data was collected via variable width w scan. Background counts were 20s and the scan rate of 0.033°/s was applied to a width of $(1.5 + \sin \mu / \tan \theta)$. The maximum 2θ value was 45°. 1948 independent reflections were measured of which 1173 with $I > 2\sigma(I)$ were included in subsequent calculations. The structure was determined by heavy atom methods. The structure was refined using full matrix least square methods with Fe, Cl, N, P anisotropic and F, C isotropic. The PF_6^- anion was disordered. Two rigid octahedra were refined with occupancy factors of x and 1-x. x refined to 0.70(2). The hydrogen atoms in the cation were placed in trigonal or tetrahedral positions but were given a common thermal parameter. Apart from those on methyl groups which were refined as rigid groups but those on the same carbon atom were given a common thermal parameter weighting scheme was chosen to give equivalent values of $w\Delta^2$ over ranges of F_0 and $\sin \theta / \lambda$. This was $w = 1/(\sigma^2(F) + 0.003 \, F^2)$ where $\sigma(F)$ was taken from counting statistics. Scattering factors were taken from Ref 8. Calculations were made using Shelx76[9] on the CDC7600 Computer at the University of Manchester Computer Centre. The final R value was 0.09 (R_W 0.09). Dimensions in the metal coordination sphere are given in Table 1. Atomic parameters, thermal parameters and a list of structure factors have been deposited with the Editor as supplementary material; copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

NOTE

Synthesis and spectroscopic studies of europium chelate complexes

GILBERTO F. DE SÁ

Departamento de Física e Departamento de Química, da Universidade Federal de Pernambuco, Cidade
Universitária, 50000 Recife, PE—Brasil

Abstract—The synthesis of the mixed complexes of the europium ion with 2-pyridylcarbinol-N-oxide,
and 2,2′-dipyridyl and 1,10-phenanthroline were prepared. The compounds, were characterized by means
of chemical analyses, vibrational spectra, molar conductivities, and electronic spectra. The emission of the
[EuL₃, phen] complex at 10 K is very intense and an assignment of the point symmetry of the Eu(III) ion
has been made.

The complexes formed between transition metal ions and 2-pyridylcarbinol-N-oxide (HL) have been discussed recently.[1] The present note deals with the synthesis and some spectroscopic properties of the mixed complexes formed between the europium ion, 2-pyridylcarbinol-N-oxide, and 1,10-phenanthroline or 2,2′-dipyridyl. In principle, complexes of the formula LnL₃ (which have not been isolated) are coordinately unsaturated and could function as "shift reagents".[2] The utility of the shift depends, of course, on their ability to bind one or more additional ligands which have a site of Lewis basicity.

To a warm ethanolic solution of 3.0 mmol. of HL were successively added 10 cm³ of an ethanolic solution containing 1.0 mmol. of lanthanide perchlorate and 15 cm³ of an ethanolic solution containing 1.0 mmol of 2,2′-bipyridyl or 1,10-phenanthroline. The solution was evaporated under vacuum to an oily residue. This was triturated with several portions of petroleum until a solid began to form. The solution was then cooled to −5°C for 24 hr. The compound was purified by recrystallization from dioxane. The vibrational spectra and molar conductivities were obtained and discussed as previously reported.[3] Emission spectra were obtained with a Spex 1702 double monochromator using an Argon laser as excitation source at 4765 and 4880 Å.[4]

The analytical data for the europium, carbon, hydrogen, and nitrogen of the compounds were performed by PCR, Inc. and by the microanalytical Lab. of the UPS. Experimental data are in good agreement with the theoretical values (Found: C, 54.72; H, 4.91; N, 8.93; Eu, 19.37. Calc. for [EuL₃, phen]: C, 54.85; H, 4.82; N, 8.88; Eu, 19.28%) and (Found: C, 52,26; H, 4.94; N, 9.61; Eu, 20.74. Calc. for [EuL₃, bipy]: C, 52.06; H, 4.88; N, 9.48; Eu, 20.58%).

The [EuL₃, bipy] complex shows highly intense fluorescence, that can be just observed with sunlight. The results obtained from the measurements of the emission spectrum of the [EuL₃, phen] complex at 10 K are shown in Table 1 along with the suggested assignments of the $^5D_0 \rightarrow {}^7F_{1,2}$ transitions. The most intense transitions is $^5D_0 \rightarrow {}^7F_2$, followed by $^5D_0 \rightarrow {}^7F_1$ and by a weak $^5D_0 \rightarrow {}^7F_0$. The $^5D_0 \rightarrow {}^7F_0$ (~580.4 nm) transition is strictly forbidden in D_2 symmetry if it is considered to be of electric dipole origin, however this has now been discussed.[5] In fact, the inclusion of J mixing to evaluate the matrix elements of the "pseudo-quadrupolar" interaction[6–8] may be of great value in interpreting the $^5D_0 \rightarrow {}^7F_0$ intensity as observed in the present work.

The dominant geometries for eight coordination complexes are those derived from the square anti-

Table 1. Allowed transitions between selected states in D_{4d}, D_{2d} and D_2 symmetries.

Transition	D_{4d}	D_{2d}	D_2	Assignments (nm)		
$^5D_0 \rightarrow {}^7F_1$	$A_1 \rightarrow A_2$	$A_1 \rightarrow A_2$	$A \rightarrow B_1$			
		$A_1 \rightarrow E$	$A \rightarrow B_2$	590.9	592.9	595.6
			$A \rightarrow B_3$			
$^5D_0 \rightarrow {}^7F_2$	$A_1 \rightarrow E_2$	$A_1 \rightarrow B_2$	$A \rightarrow B_1$			
		$A_1 \rightarrow E$	$A \rightarrow B_2$	614.5	615.4	616.7
			$A \rightarrow B_3$			

(HL)
prism (D_{4d}) or the dodecahedron (D_{2d}).[9] Both of these can give rise to structures that possess D_2 symmetry. A summary of the crystal-field splitting for the dominant angular momenta, J, in D_{4d}, D_{2d} and D_2 symmetries together with the transition allowed for magnetic dipolar selection rules ($^5D_0 \rightarrow {}^7F_1$) or electric dipolar selection rules ($^5D_0 \rightarrow {}^7F_2$) appears in Table 1. The emission spectrum is in agreement with what would be expected of Eu^{3+} in a D_2 environment but unfortunately it is not possible to choose between the structure which is derived from antiprism and that which is derived from the dodecahedron.

The spectra of [EuL$_3$, phen] and [EuL$_3$, bipy] in solution show that the ions preserve the same symmetry. This is confirmed by the emission spectra of the powders at room temperature which show the same broadening as the solution fluorescence spectra, indicating a vibronic induced and solvent interaction broadening. At similar concentrations these europium complexes were tested and are more effective shift reagents than the often used Eu(fod)$_3$.[10] However, the low solubility of the former in the usual deuterated solvents their use as a appropriate shift reagents. At the moment, other solvents are being examined.

In conclusion, the interpretation of vibrational spectra and the conductivity data agree with the formulation [EuL$_3$, bipy] and [EuL$_3$, phen] for the complexes and complement the octacoordination structure with D_2 symmetry predicted from the splittings of the fluorescent transitions.

NOTE

Spin-crossover phenomena in tris(trifluoronicotinoylacetonato) iron (III)

A. A. ADIMADO
Department of Chemistry, University of Ibadan, Ibadan, Nigeria

Abstract—Tris(trifluoronicotinoylacetonato) iron(III) has been shown to exhibit spin-crossover phenomenon between $^6A_{1g}$ and $^2T_{2g}$ terms which are about 322 cm^{-1} apart.

Tris (dialkyldithiocarbamato) iron(III) complexes first reported by Cambi et al.[1–3] are probably the most extensively studied examples of iron(III) showing the spin-crossover phenomenon between the $^6A_{1g}$ and $^2T_{2g}$ terms. High-spin, low-spin and intermediate spin situations can be attained and the thermal equilibrium between the two extreme cases have also been examined in suitable examples.[4,5] Tweedle and Wilson[6] studying magnetic properties of [Fe(Sal$_2$trien)]PF$_6$ in acetone solution reported $\Delta H = 4.62$ kcal mol^{-1} and an entropy, $\Delta S = 16.46$ e.u. for the $^2T_{2g} \rightleftarrows {}^6A_{1g}$ equilibrium. This process in the solid state is estimated to have a spin–state lifetimes,[6] $\tau \gtrsim 10^{-7}$ s.

The first examples of iron(III) β-diketonates exhibiting this phenomenon were found in tris(monothio-β-diketonato) iron(III) complexes,[7] having moments of 4.35–5.75 B.M. at 300K and 2.24–2.80 B.M. at 87K. These are complexes with FeS$_3$O$_3$ chromophores. In this work, the magnetic behaviour of tris(trifluoronicotinoylacetonato) iron(III) has been examined between 87 and 300K; and some thermodynamic parameters have been calculated in order to compare the FeS$_3$O$_3$ and FeO$_6$ chromophores.

EXPERIMENTAL

The ligand 4,4,4-trifluoro-1-(3-pyridyl)-1,3-butanedione (Htfpybd) was obtained from Eastman Organic Chemicals. The preparation of the iron(III) complex, Fe(tfpybd)$_3$ is reported elsewhere.[8] C$_{27}$H$_{15}$F$_9$FeN$_3$O$_6$, mpt., 189–190°. Found: C, 45.62 H, 2.52 N, 5.46 Fe, 7.85. Calc: C, 45.96 H, 2.29 N, 5.96 Fe, 7.92%. The magnetic susceptibility values were measured between 300 and 80K using a Gouy balance. At 293K, the susceptibilities ($\chi_A/10^6$) at field strength 6310, 5804 and 3304 Gauss gave values 5802, 5835 and 5819 c.g.s. units respectively. The susceptibilities are therefore independent of field strength and suggest the absence of ferromagnetic impurities in Fe(tfpybd)$_3$ complex.

RESULTS AND DISCUSSION

Iron(III) has a high-spin $^6A_{1g}$ ground state with a normal moment of about 5.92 B.M. which corresponds to five unpaired electrons whilst its low-spin $^2T_{2g}$ ground state with a normal moment of about 2.30 B.M. corre-

sponds to one unpaired electron. Since the $^2T_{2g}$ ground state retains some orbital angular momentum, moments may range in value from μS to μS + L, the exact value depending on the temperature of measurements and the magnitude of the spin-orbit coupling.

Assuming a dynamic $^2T_{2g} \rightleftarrows {}^6A_{1g}$ process is operative in the solid state:

$$^2T_{2g} \rightleftarrows {}^6A_{1g} \qquad (1)$$

If α is the fraction or population of high-spin state then $(1 - \alpha)$ represents low-spin state.

$$\mu_{obs}^2 = \alpha(5.92)^2 + (1 - \alpha)(2.30)^2 \qquad (2)$$

$$\text{Keq} = \frac{\alpha}{1 - \alpha}. \qquad (3)$$

The variation of ln Keq with the T^{-1} can be used to obtain ΔH and ΔS changes. A typical plot for Fe (tfpybd)$_3$ is presented in Fig. 1. The best straight line was obtained by the least-squares fitting procedure and the average deviation from the least squares calculations is $\pm 15\%$. The magnetic moment of Fe(tfpybd)$_3$ at 293K was found to be 3.69 B.M., independent of field strength, and corresponds to only 27% of the high-spin form.

A plot of ln Keq with T^{-1} yields $\Delta H = 0.92$ kcal mol^{-1} and $\Delta S = 1.68$ cal mol^{-1} K^{-1} (Table 2). Assuming that ΔH values obtained in Table 2 are a measure of the $^2T_{2g} - {}^6A_{1g}$ separation, it is observed that the $^6A_{1g}$ term in the FeO$_6$ chromophore lies at 322 cm^{-1} above the ground $^2T_{2g}$ term whilst this varies between 170 and 685 cm^{-1} for the FeS$_3$O$_3$ chromophore. This separation compares favourably with those of FeS$_6$ chromophore in dithiocarbamates, quoted by Ewald et al.[5] (500 cm^{-1}), Hall and Hendrickson[9] (204 cm^{-1}).

The observed entropy change of 1.68 e.u. for Fe (tfpybd)$_3$ is small as expected but not that predicted by change in spin multiplicity alone ($\Delta S = R\ln 3$) which gives a theoretical value of 2.16 cal mol^{-1} K^{-1}. Although only electronic entropy predominantly contributes to the $^2T_{2g} \rightleftarrows {}^6A_{1g}$ process, there could be some other effects such as changes in bond lengths and/or angles which cause the deviations of ΔS from the
Fig. 1. Plots of ln K vs reciprocal of temperature.

NOTE

Complex formation of 1,4,7,10-tetraoxacyclododecane with alkali metal ions studied by ^{13}C spectroscopy

EILIF AMBLE and ERIK AMBLE*†
Kjemisk Institutt, Universitetet i Oslo, Oslo 3, Norway

Abstract—Complex formation of 1,4,7,10-tetraoxacyclododecane (12-crown-4) with lithium, sodium and potassium salts in methanol solution was investigated. The strong influence of complexing on the chemical shift of the single ^{13}C NMR line permitted titration of the ligand with alkali metal salts. Concentration stability constants of the complexes were obtained by a computerized iterative least squares method. Na^+ and K^+ form both 1 : 1 and 1 : 2 complexes, $\log K_1 = 2.1$ and $\log K_2 = 3.8$, $\log K_1 = 1.7$ and $\log K_2 = 2.4$ respectively. Li^+ is complexed weakly. Assuming 1 : 1 stoichiometry the complex stability constant is estimated to be < 1.

NMR spectroscopy has been extensively applied to investigate complex formation between alkali and alkaline earth metal ions and electrically neutral ligands.[1-3] Recently the conformations of free and complexed oligoethers have been studied using ^{13}C NMR spectroscopy.[4] Significant chemical shift differences were observed due to conformational rearrangements following complex formation. These findings were interpreted on the basis of empirical γ and δ-effects on the chemical shift.[5] The most dramatic upfield ^{13}C chemical shift was found for 1,4,7,10-tetraoxacyclododecane (12-crown-4).[6,7] It was therefore possible to study in some more detail the complexing of various alkali metal salts with 12-crown-4. We report here our efforts to determine quantitatively the complex stabilities by least squares approximation of the obtained data.

PRINCIPLE OF THE METHOD

The interaction between the ligand 12-crown-4 (L) and alkali metal ions (M) taking into account both 1:1 and 1:2 complexes is defined by eqns (1)–(4).

$$L + M \rightleftharpoons LM \tag{1}$$

$$LM + L \rightleftharpoons L_2M \tag{2}$$

$$K_1 = \frac{[LM]}{[L][M]} \tag{3}$$

$$K_2 = \frac{[L_2M]}{[L]^2 \cdot [M]} \tag{4}$$

If the exchange rate between the three different environments of the ligand is rapid, the observed chemical shift δ_{obs} represents a weighed average and eqn (5) is valid.

$$\delta_{obs} = \frac{[L]}{[L_0]} \delta_L + \frac{[LM]}{[L_0]} \delta_{LM} + \frac{2 \cdot [L_2M]}{[L_0]} \delta_{L_2M} \tag{5}$$

where $[L_0] = [L] + [LM] + 2 \cdot [L_2M]$, $[M_0] = [M]$

$+ [LM] + [L_2M]$, δ_L, δ_{LM} and Δ_{L_2M} are the chemical shifts of the free ligand, the 1 : 1 and the 1 : 2 complex respectively.

The induced chemical shift by complex formation $\Delta\delta_{obs} = \delta_{obs} - \delta_L$ is expressed by eqn (6).

$$\Delta\delta_{obs} = \frac{[LM]}{[L_0]} \Delta\delta_{LM} + \frac{2 \cdot [L_2M]}{[L_0]} \Delta\delta_{L_2M} \tag{6}$$

where $\Delta\delta_{LM}$ and $\Delta\delta_{L_2M}$ are the chemical shifts of the complexes relative to δ_L.

Substitution of [L], [L_2M] and [M] in eqns (1)–(4) by [LM] yields

$$\left\{K_2 - 4 \cdot \frac{K_2^2}{K_1^2}\right\}[LM] - \left\{4 \cdot \frac{K_2}{K_1} - K_1 + 2\right.$$

$$\times K_2[M_0]\Big\}[LM] + \{K_2[L_0](2[M_0] - [L_0]) - K_1([L_0]$$

$$+ [M_0]) - 1\}[LM] + K_1[L_0][M_0] = O. \tag{7}$$

From eqn (7) [LM] can be calculated as a function of experimental values $[M_0]$ and $[L_0]$ for assumed values of K_1 and K_2.

The experimental procedure consists of measuring $\Delta\delta_{obs}$ as a function of changing concentrations $[M_0]$ while $[L_0]$ is kept constant, leading to titration curves shown in Fig. 1. The accompanying variations in ionic

Fig. 1.

†Present address: Rumen Kjemi A/S, P.B. 23 Refstad, Oslo 5, Norway.

strength are neither expected to influence the ^{13}C chemical shifts nor the complexation constants over the titration range.[5,8] Therefore, approximation of these data by calculated values of $\Delta\delta_{obs}$ based on eqns (6) and (7) is possible and yields K_1, K_2, $\Delta\delta_{LM}$ and $\Delta\delta_{L_2M}$.

The mathematical analysis of the data represents an extension of the method of Creswell and Allred for 1:1 complexes. With assumed values for K_1 and K_2 values for [LM] can be calculated for all data points using eqn (7). Only real roots [LM] $\leq$ [M$_0$] have physical significance. Least squares approximation of $\Delta\delta_{obs}$ (eqn 6) using these calculated values for [LM] yields estimates for $\Delta\delta_{LM}$ and $\Delta\delta_{L_2M}$.

In principle this procedure can be repeated with new values for K_1 and K_2 until the best fit and hence the optimal K_1 and K_2 are found. However, considerable computing time can be saved by applying a modified trial and error iteration. It is easily seen that the amount of 2:1 complex is predominant for small values of [M$_0$]. This means that K_2 is dominating on the lower part of the titration curve. Therefore only one of the two constants K_1 and K_2 is varied at a time and only the part of the data used where this constant has a substantial impact on the value of $\Delta\delta_{obs}$. When e.g. an optimal K_2 for a chosen K_1 is found using the lower part of the titration curve, i.e. small [M$_0$]/[L$_0$], this value for K_2 is used for the determination of an improved value for K_1 using the upper part of the data. This procedure of shifting between the two parts of the data is repeated with new values of K_1 and K_2 until the best pair of stability constants and the corresponding values of $\Delta\delta_{LM}$ and $\Delta\delta_{L_2M}$ are found.

RESULTS AND DISCUSSION

The ^{13}C NMR chemical shift of the single line of 12-crown-4 was measured in solutions containing varying amounts of alkali metal salts. Plots of the induced chemical shift $\Delta\delta_{obs}$ vs the relative metal ion concentration [M$_0$]/[L$_0$] are shown in Fig. 1. As it is seen the three alkali metal ions gave rise to very different titration curves.

Sodium ions had a strong effect on $\Delta\delta_{obs}$ already at low concentrations. The plot rises almost linearly until 0.5 equivalents have been added. After a sharp bend only small changes were observed. These findings indicate that the formation of a 2:1 sandwich complex is preferred.

Increasing concentrations of potassium ions also led to substantial induced chemical shifts. However, the plot exhibits a smaller curvature. It is thus not possible to estimate visually which complex stoichiometry is predominant.

Finally upon addition of Li$^+$ only very small induced chemical shifts were observed.

The results of the iterative least squares analysis of these data are listed in Table 1.

It is seen that both sodium and potassium ions lead to 1:1 complexes with comparable strength. Note also that the induced upfield shifts $\Delta\delta_{LM}$ are similar suggesting that 12-crown-4 adopts essentially the same conformation in both complexes.

However, sodium forms a considerably more stable sandwich 2:1 complex than potassium, the calculated values for log K_2 being 3.8 for Na$^+$ and 2.4 for K$^+$. Furthermore the values for the induced chemical shift is by far the biggest in the 2:1 complex with Na$^+$.

Table 1.

	Na$^+$	K$^+$
log K_1	2.1	1.7
log K_2	3.8	2.4
$\Delta\delta_{LM}$	66.5 Hz	65.5 Hz
$\Delta\delta_{L_2M}$	82.3 Hz	58.5 Hz

Both results reflect the ideal size of 12-crown-4 for the formation of a sandwich complex with sodium ions in solution, as it has been suggested on the basis of X-ray crystallography.[11–13]

The smaller upfield shift observed for the 2:1 complex with K$^+$ and the weaker binding of this ion are in good accord with the necessary conformational adjustment of the ligand to this bigger ion.

The data from Li$^+$ titration could not be analyzed by the described method. However, an estimate for K_1 was obtained under the hypothesis that only a 1:1 complex is formed and that its chemical shifts is similar to the one of the other 1:1 complexes. Using these assumptions, a comparison of the observed shifts with values calculated for various K_1 values lead to the estimate: $K_1 < 1$. This result leads to the surprising conclusion that 12-crown-4 faces strong competition by methanol in solvating Li$^+$, demonstrating that this twelve membered ring system is not ideal for complexing such a small ion.

It has thus been shown that simple estimates based on correlations between ring size and ionic radius, which would predict a rather stable 1:1 lithium complex, are not possible when conformational changes accompany complex formation.

In conclusion we claim to have demonstrated that ^{13}C NMR might be a useful tool for the quantitative determination of complexing of crown ethers and their amino analogues.[14]

NOTE

Correlation of closo-carborane ^{11}B–H spin-coupling constants with structural features including cage "umbrella" angle

WILEY JARVIS, Z. JEAN ABDOU and THOMAS ONAK*

Department of Chemistry, California State University, Los Angeles, CA 90032, U.S.A.

Abstract—The magnitude of $^1J(^{11}B^1H)$ values for the closo-carboranes are correlated to structural characteristics. Among the various parameters considered, both the number of adjacent cage carbon atoms and cage "umbrella" angle appear to contribute significantly to changes in the observed spin-coupling constants with smaller cage umbrella angles contributing to higher $J(^{11}B–H)$ values. A derived empirical method enables the prediction, or confirmation, of certain NMR assignments in those instances where some uncertainty previously existed.

Previous investigations of element–hydrogen spin–spin coupling have well established that the numerical value of $^1J(XH)$ becomes greater with increasing s-orbital character of the X–H bond. In the cases of compounds containing boron–hydrogen bonds two studies[1,2] have attempted to relate $^1J(^{11}B^1H)$ with MO-determined element s-orbital electron population. However, within the closo polyhedral carborane series $C_2B_nH_{n+2}$, only three of these compounds ($n = 3$–5) have heretofore been considered in this manner. And although the obtained correlations were reasonably satisfactory, an extension of these MO approaches to other isomers within these polyhedral systems and to the remainder of the series, $n \leqslant 10$, would have very limited quantitative predictive value. Until easily accessible and accurate values of s-electron populations become available we present another approach, empirical in nature, for the prediction of $^1J(^{11}B^1H)$ values of closo-carboranes. In the present study, certain structural characteristics of the cage compounds are correlated with the magnitude of $^1J(^{11}B^1H)$.

EXPERIMENTAL AND DATA

Nuclear magnetic resonance data

Although apparent $^1J(^{11}B^1H)$ constants for the closo-carboranes (Fig. 1) listed in Table 1, column 6, have been previously reported in the literature, it was highly desirable for the purpose of the present study to establish these values within an error of $\leqslant \pm 2$ Hz. The literature values for each of the following: $1,5\text{-}C_2B_3H_5,$[3,4] $1,2\text{-}C_2B_4H_6,$[4] $1,6\text{-}C_2B_4H_6,$[4,5] $2,4\text{-}C_2B_5H_7,$[3,6–9] $1,7\text{-}C_2B_6H_8,$[10] $1,6\text{-}C_2B_7H_9,$[11,12] $1,6\text{-}C_2B_8H_{10},$[9,12]

$2,3\text{-}C_2B_9H_{11},$[13–15] $1,2\text{-}C_2B_{10}H_{12},$[16] $1,7\text{-}C_2B_{10}H_{12}$[16] and $1,12\text{-}C_2B_{10}H_{12},$[17] were rechecked by ^{11}B and ^{1}H NMR spectra which were recorded by, variously, Varian HA-100 and Bruker WP-60 spectrometers in our laboratories as well as by the Bruker WM-500 spectrometer at the Southern California Regional Facility, California Institute of Technology. The average estimated error for the observed J values reported in Table 1 is within $\pm 1\%$ ($\sim 80\%$ confidence), within $\pm 1.5\%$ (with $> 95\%$ confidence).

Structural data

Umbrella angles, Table 1, column 4, were calculated from known structural coordinates for all of the cited closo-carboranes: $1,5\text{-}C_2B_3H_5,$[18] $1,2\text{-}C_2B_4H_6,$[18] $1,6\text{-}C_2B_4H_6,$[18] $2,4\text{-}C_2B_5H_7,$[18] $1,7\text{-}C_2B_6H_8,$[19] $1,6\text{-}C_2B_7H_9,$[20] $1,6\text{-}C_2B_8H_{10},$[21] $2,3\text{-}C_2B_9H_{11},$[22] $1,2\text{-}C_2B_{10}H_{12},$[18] $1,7\text{-}C_2B_{10}H_{12}$[18] and $1,12\text{-}C_2B_{10}H_{12}.$[18] These calculations were performed using PROPHET computer programs (CRYST, EDITMODEL, MAST) made available by the National Institutes of Health. It is estimated that the reliability of the structural data used for the calculated umbrella angles results in an error within $\pm 0.5\%$ of values of θ (for the definition of θ, see below).

RESULTS AND DISCUSSION

An examination of the data in Table 1 (see columns 3, 4 and 6) leads to the conclusion that the value of $^1J(^{11}BH)$ is dependent (a) on the number of cage carbon atoms, C, bonded to the boron atom of the B–H bond under consideration, and (b) on the magnitude of a cage "umbrella" angle, θ. The term "umbrella" angle describes the (average) interior angle of a conical, or near-conical, shaped figure having the boron atom of a

Fig. 1. Cage Structures of the closo-carboranes. (a) $1,5\text{-}C_2B_3H_5$, (b) $1,2\text{-}C_2B_4H_6$, (c) $1,6\text{-}C_2B_4H_6$, (d) $2,4\text{-}C_2B_5H_7$, (e) $1,7\text{-}C_2B_6H_8$, (f) $1,6\text{-}C_2B_7H_9$, (g) $1,6\text{-}C_2B_8H_{10}$, (h) $2,3\text{-}C_2B_9H_{11}$, (i) $1,2\text{-}C_2B_{10}H_{12}$, (j) $1,7\text{-}C_2B_{10}H_{12}$ (k) $1,12\text{-}C_2B_{10}H_{12}$.

given B–H bond at the apex, and bonds to neighbouring cage atoms as the radial frame:
The value of θ is determined by averaging values of 2β for all B–Z bonds of any given boron:
The concept of using an "umbrella angle" for the present study involving cage carborane compounds can be considered similar to the use of C–C–C interatomic bond angles in correlating J(CH) values for organic ring systems.[23] In the latter studies it was found, of course, that smaller C–C–C angles resulted in higher J(CH) values; the simple explanation for this correlation involves greater p-orbital involvement of the CH carbon atom electrons toward ring C–C bonding resulting in greater s-orbital density in the CH bond external to the ring.[23] An extension of this reasoning to cage carboranes is consistent with the association of smaller umbrella angles with larger J(^{11}B–H) values for any particular boron site. A study of Table 1, cf columns 4 and 6, bears this out.

Linear relationships of the type J(^{11}B–H) = Aθ + B, when applied to the data in Table 1, columns 3, 4 and 6, yield:

$$J(^{11}\text{B–H}) = -2.08(\theta) + 394 \quad \text{when } C = 0 \quad (1)$$

$$J(^{11}\text{B–H}) = -0.0621(\theta) + 172 \text{ when } C = 1 \quad (2)$$

$$J(^{11}\text{B–H}) = -0.333(\theta) + 214 \quad \text{when } C = 2 \quad (3)$$

	4,5,7,11	1	116	165	164
	8,10	0	117	151	151
	9,12	0	117	151	151
$1,7-C_2B_{10}H_{12}$	2,3	2	114	177	178
	4,6,8,11	1	116	165	165
	5,12	1	116	165	162
	9,10	0	117	151	151
$1,12-C_2B_{10}H_{12}$	2-11	1	116	165	165

where C is the number of contiguous cage carbon atoms. Fusing the three separate equations into a single expression gives eqn (4):

$$^1J(^{11}BH) = \frac{-2.08(13.4)^{C^2}(\theta)}{449^C} + \frac{394(1.69)^{C^2}}{3.87^C}. \quad (4)$$

This relationship predicts with reasonable precision J(^{11}B–H) values (Table 1, column 5) for nearly all BH sites in the neutral *closo*-cage compounds.

In the case of $2,3-C_2B_9H_{11}$ there previously existed some uncertainty about the chemical shift assignments (and also therefore J values) of B(8,9) and B(10,11); the observed J(BH) values for the two doublets were observed to be 172 and 150 Hz. Since the areas for each were identical, unambiguous assignments were not possible. It is clear from the calculated J(BH) values using eqn (4), that the higher J(BH) can be assigned to cage

positions 8 and 9 and the lower J(BH) value thus belongs to positions 10 and 11.

Though the area "2" B–H resonances for the 1,2- and 1,7-isomers of $C_2B_{10}H_{12}$ have been previously assigned from substituent studies[16] ambiguity still exists; but it is reassuring that the J(BH) values predicted from eqn (4), are in complete accord with this assignment, (Table 1, cf columns 5 and 6).

Two predicted J(BH) values, those for the B(3,4)-H of $1,7-C_2B_6H_8$ and the B(10)-H of $1,6-C_2B_8H_{10}$, are sufficiently different from the reported experimental values to warrant comment. The $1,7-C_2B_6H_8$ is the only *closo*-carborane in the present study in which there is strong suspicion of rapid cage fluxional behaviour.[24,25] Thus the application of eqn (4), to this situation, where an umbrella angle is obtained from static geometrical data, may be unreasonable. Incomplete experimental data and assignments for $1,6-C_2B_8H_{10}$ makes speculation

difficult for the J(BH) discrepancy, experimental vs predicted.

The magnitude of J values for all the compounds mentioned here could show some dependence on variables other than those, C and θ, in eqn (4). However, our attempts to correlate the available coupling constant data with parameters such as cage-atom coordination number and cage bond delocalization (e.g. antipodal effects)[26] were inefficacious and did not indicate any discernible dependency of $^1J(^{11}B^1H)$ on these particular factors.

Also, an attempt to relate $^1J(^{13}C^1H)$, for the cage carbon atoms, to any or all of the parameters discussed above proved unproductive due to the scarcity of available data points.

NOTE

Synthesis and characterization of sodium-tetramethylammonium decamolybdate

EWA K. HODOROWICZ and STANISLAW A. HODOROWICZ*
Department of Chemistry, Jagiellonian University, Krakow, Poland

Abstract—Sodium-tetramethylammonium decamolybdate in acidified solution has been crystallized. Chemical analysis, thermogravimetric and X-ray studies have been performed.

When normal tungstate or molybdate solutions are acidified, various polyanions of increasing degrees of condensation are obtained according to different acidifications and other conditions. In the recent years using specific organic cations new forms have been isolated.[1] In particular, Souchay et al.[2] described the formation of dodecatung state $[H_{16}W_{12}O_{48}]^{8-}$ in aqueous solution acidfied to $Z = 1.33$ (the degree of acidity Z is defined as $Z = [H^+]/[W]$) in the presence of tetramethylammonium ions. In our investigations we have found that in conditions similar to those used by Souchay two different forms of polytungstate crystallized. One of these species was formulated as metadodecatungstate $[N(CH_3)_4]_6W_{12}O_{39}(H_2O)_6$,[3] and the other as sodium tetramethylammonium decatungstate $Na_6[N(CH_3)_4]_3[W_{10}O_{34}(OH)](H_2O)_8$.[4,5] Now we report new data for polymolybdate precipitated from solution under the above-mentioned conditions.

EXPERIMENTAL

The crystallization was carried out at concentration 0.250 M molybdate and the degree of acidity $Z = 1.33$. First a sodium molybdate dihydrate (POCh Gliwice, Poland) solution in 2 M tetramethylammonium chloride was prepared. This solution was treated with the calculated amount of 1 N HCl in 2 M tetramethylammonium chloride and next it was left for crystallization at 25°C. After several days a white crystalline precipitate was obtained, filtered off, washed with ethanol, dried in the air and placed in a desiccator over $CaCl_2$.

The crystals were then examined microscopically. No difference in the form of crystals was observed. All crystals were very small plates.

The precipitate was analyzed chemically. Molybdenum was determined by the gravimetric method after Busev[6] as $PbMoO_4$. Sodium was determined indirectly as

Na$_2$O from the sum of the MoO_3 and Na_2O. The nitrogen, carbon and hydrogen were determined on a Perkin–Elmer automatic CHNO analyzer.† The compound was subjected to X-ray powder diffraction analysis in a 100-m Guinier–Hägg camera equipped with a quartz monochromator to provide clean Cu-K$_{\alpha 1}$ radiation. Platinum powder ($a = 3.9238 \pm 0.0003$ Å, 25°C) was used as an internal standard. Quantitative intensity data were obtained on a DRON-2 (Burevestnik, U.S.S.R.) diffraction with nickel-filtered copper radiation.

The thermogravimetric measurements were performed in the air and in argon within the temperature range 25–800°C using model OD-12, MOM Budapest derivatograph. Samples of 300 mg were heated at rates 5°/min and the galvanometer sensitivity DTA = 1/3 and DTG = 1/3. The density of the crystals was determined by the pycnometric method using carbon tetrachloride.

RESULTS AND CONCLUSIONS

The result of analysis: Mo = 50.03 ± 0.1%, $MoO_3 + Na_2O = 84.05 \pm 0.05\%$, N = 2.21 ± 0.02%, C = 7.55 ± 0.02% and H = 2.25 ± 0.04% indicate that the molar ratio $MoO_3 : Na_2O : N : C : H$ is equal to 3.30 : 0.92 : 1 : 3 : 3.98 : 14.15.

The powder patterns obtained are very similar to those of previous reported sodium-tetramethylammonium decatungstate.[4] They can be indexed in the orthorhombic system with lattice parameters $a = 16.43(2)$, $b = 21.67(3)$ and $c = 13.78(3)$ Å. These parameters were derived by the least-squares procedure from a refinement based on 25 coincidence-free reflections. Table 1 lists the population of both experimental and theoretical interplanar spacings for 34 successive reflections.

The density of crystals at temperature 25 ± 0.5°C is 2.57 ± 0.02 gcm^{-3}. The volume of the unit cell is 4908 Å^3 and its mass is 12613×10^{-24} g. The multiplicities possible of the molecules per unit cell for the ortho rhombic system are only 1, 2, 4 and 8. For these values the molecular weights are 7598, 3799, 1899 and 950, respectively. By comparison of these data with the results of chemical analysis the most probable formula for the

†These measurements were carried out in the Regional Laboratory of Physicochemical Analysis and Structural Research, Jagiellonian University, Kraków, Poland.
Fig. 1. Thermal analysis curves for sodium-tetramethylammonium decamolybdate under air.

compound obtained seems to be a decamolybdate, $3Na_2O \times 1.5[N(CH_3)_4]_2O \times 10MoO_3 \times 3.5H_2O$. Calculated values for this formulae are: $Mo = 49.\overset{.}{5}9\%$, $Na_2O + MoO_3 = 84.01\%$, $N = 2.17\%$, $C = 7.45\%$, $H = 2.24\%$; molecular weight 1935; X-ray density $2.62\ gcm^{-3}$.

Thermal analysis curves are given in Fig. 1. The TG curve shows that the loss in mass occurs in two steps. The endothermal effect with a minimum at 265°C corresponds to the loss of three water molecules. The DTA exothermic peak above 300°C (it was endothermic in argon) is connected with decomposition of the tetramethyl ammonium cation and probably with further dehydration. A quite new diffraction pattern, probably of the crystalline phase $3Na_2O \times 10MoO_3$, appears over the temperature range 300–400°C. Above 490°C further structural changes occur and then new phase melts at 520°C.

The results obtained show that in sodium molybdate solutions acidified to $Z = 1.33$, in the presence of tetramethylammonium chloride only decamolybdate $3Na_2O \times 1.5[N(CH_3)_4]_2O \times 10MoO_3 \times 3.5H_2O$ is formed. This compound is not reported so far in the literature and it is presumably a true analogue* of the sodium-tetramethylammonium decatungstate $Na_6[N(CH_3)_4]_3[W_{10}O_{34}(OH)] \times 8H_2O$.

NOTE

Ion-pairing and optical activity of diastereomeric zinc(II) 1, 10-phenanthroline, S-valinate systems

A. DECINTI* and G. LARRAZÁBAL

Departamento de Análisis Químico, Facultad de Ciencias Básicas y Farmacéuticas, Universidad de Chile, Santiago, Chile

Abstract—A series of S-valinatobis(1, 10-phenanthroline)zinc salts in methanolic solution have been prepared and their conductivities and ORD spectra measured. A positive linear correlation of optical rotation with conductance was found for salts of non-chelating counter anions. From the application of the Yoe-Jones method on the system Zn, phen, S-val$^-$, Cl$^-$ it was concluded that the counter anion dependence of the optical activity is connected mainly with heterocyclic ligand counter anion exchange equilibria.

A previous report from this laboratory described the preparation and optical properties of 1:2:1 mixed complex salts of zinc, 1, 10-phenanthroline and chiral aminoacidates.[1] In methanol these compounds exhibit aromatic exciton activity which presumably arises from a small difference in stability of the diastereomeric forms of the 1:2:1 mixed chelate ions. The intensity of such an effect depends upon the chiral ligand and, to a lesser extent, on the counter anion.[2]

A comparative study of counter anion effects on the optical activity of the above diastereomeric systems may provide evidence on ion pair associations in hydroxylic solvents as well as on the ligand ability of some anions. In this work we studied the counteranion dependence of the optical activity of the system Zn:1, 10-phenanthroline:S-valinate = 1:2:1, with a number of organic and inorganic anions in methanol. Preliminary results on this subject have been reported.[2] However, modifications of the preparative procedures and more data have slightly changed the earlier preliminary results.

EXPERIMENTAL

Salts of the mixed chelate ion [Zn(phen)$_2$(S-val)]$^+$ were prepared as 7.07×10^{-3} M solutions in methanol by the following reactions:

$$ZnSO_4 \cdot 7H_2O + \tfrac{1}{2}Ba(OH)_2 \cdot 8H_2O + 2phen \cdot H_2O$$

$$+ \tfrac{1}{2}BaX_2 \cdot 2H_2O + S\text{-valH} \rightarrow$$

$$[Zn(phen)_2(S\text{-val-}]X + BaSO_4 + 15H_2O$$
where X$^-$ = Br$^-$, Cl$^-$ or CH$_3$CO$_2^-$, and

$$ZnSO_4 \cdot 7H_2O + Ba(OH)_2 \cdot 8H_2O + 2phen \cdot H_2O$$

$$+ \tfrac{1}{n}H_nX + S\text{-valH} \rightarrow$$

$$[Zn(phen)_2(S\text{-val})]X\frac{1}{N} + BaSO_4 + 19H_2O,$$
where X = gly$^-$, S-val$^-$, benzoate, salicylate$^-$, salicylate^{2-}, o-phthalate, m-nitrobenzoate, p-nitro benzoate, o-amino benzoate, m-amino benzoate or p-amino benzoate. The nitrate was obtained from bromide by metathesis with silver nitrate.

Stoichiometric mixtures of chromatographically homogeneous-S-valine and appropriate analytic reagent grade chemicals were stirred ultrasonically in methanol at room temperature and were heated to boiling point for 10 min. After cooling this procedure was repeated to ensure completion of reaction. Barium sulfate was removed by suction filtration. The solutions were reduced by evaporation to appropriate volumes and were standardized to 7.07×10^{-3}M Zn(II) at 25°C. At least three preparations were made with each counteranion. The optical rotatory dispersion spectra (ORD) of these solutions were run at 25°C over the range 330–400 nm on a modified Perkin–Elmer 141 polarimeter using a thermostated cell. Conductivity measurements at 25°C were made using a Wayne Kerr B 221 universal bridge, with an immersion cell (cell constant = 1.44). Differences in the small amounts of water derived from the salts did not affect the measurements.

The accuracy of the preparative procedures was tested gravimetrically or by counteranion exchange. Schematically, these were: SO$_4^{2-}$/Cl$^-$, SO$_4^{2-}$/p-amino benzoate, Br$^-$/NO$_3^-$, Cl$^-$/NO$_3^-$, salicylate^{2-}/salicylate$^-$ and S-valinate/acetate.

---

*Author to whom correspondence should be addressed.

The dependences of optical activity and conductivity on complex ion concentration were studied by diluting solutions of the chloride form of the cation salt. Yoe and Jones's molar-ratio type studies[3] of optical activity and conductivity of the system Zn, phen, S-val$^-$, Cl$^-$ were also performed. These experiments were carried out on series of individual preparations.

RESULTS AND DISCUSSION

A nearly linear concentration dependence of optical rotation over a range of the UV region was observed for chloride salt solutions (Fig. 1). Hence, the equivalent specific rotation of the diastereomeric system in presence of each counteranion reflects the concentration of 1:2:1 species, i.e. free cations plus paired cations. An essential requirement of this assumption is that ion-pairing between the 1:2:1 diastereomeric cations and the counterions does not significantly affect the exciton coupling, such an interaction being merely electrostatic or of the solvent structure-enforced ion-pairing type.[4] The aromatic anions o-amino benzoate, m-nitrobenzoate and p-nitrobenzoate made the samples almost opaque below 355 nm, modifying the typical shape of the ORD spectra. Although this effect might be attributed to some type of charge transfer interaction involving the aromatic systems, there is a long wavelength tail of the UV spectra of these anions giving considerable absorbance up to 355 nm. Hence, the changes in the typical shape of the ORD spectra in the presence of these anions were assumed to be unrelated to aromatic exciton coupling. However, in order to include the benzoate derivatives in the counteranion series, α values at 400 nm were used; but for the concentration ratio dependence studies, α values at 355 nm or 350 nm were used.

The equivalent specific rotation ($[\Phi]_{400\,nm}^{25°}$) and equivalent conductance (Λ) data are listed in Table 1 with the average deviations. There are two points to be made about these data: (1) The [Φ] and Λ values tend to exhibit

parallel dependences on the counteranion nature. (2) The potentially chelating counteranions give the lowest [Φ] and Λ values. A linear correlation of these data by regression analysis is shown in Fig. 2, where the least squares line was calculated excluding the chelating anions. This figure shows that the effects of chloride, bromide and nitrate on the optical activity of the system are very similar. The conductivity sequence $NO_3^- > Br^- > Cl^-$ follows the limiting ionic conductance of these ions in methanolic solutions.[5,6] On the other hand, the decrease of optical rotation of the diastereomeric system in the presence of SO_4^{2-} or a carboxylate counterion could be ascribed to greater ligand-counteranion exchange, which decreases the equilibrium concentrations of the 1:2:1 species. The presence in the system of S-val$^-$ as a counteranion excludes the effects of the chiral ligand-counteranion exchange equilibrium. Hence, the point for specific rotation and conductance values of the S-val$^-$ counteranion salt falling close to the correlation line (Fig. 2) suggests that for non chelating counteranions the main exchange equilibria must involve the heterocyclic ligand. The deviation from the least squares line for the glycinate salt could be ascribed to a glycinate-S-valinate exchange resulting in approximately half of the S-valinate being outside the coordination sphere. (The S-val$^-$: gly$^-$ equivalent specific rotation ratio is 1.97, whereas the similar equivalent conductance ratio is 0.99.) Furthermore, the deviation observed for o-phthalate could be indirect evidence for formation of a seven membered Zn-o-phthalate chelate ring.

These considerations agree with evidence on the system Zn, phen, S-val$^-$, Cl$^-$, Fig. 3 and 4. Figure 3 shows that the species which predominantly account for the optical activity of the system are the 1:2:1 diastereomeric complexes; the increase of conductivity with increasing [phen]:[Zn] can be ascribed to a 1, 10-phenanthroline-chloride exchange. Also, this increase

of conductivity suggests that the 1:2:1 species form less stable ion pairs than [Zn(phen)(S-val)]⁺. (For the latter species formation of a pentacoordinate inner complex with chloride ion is also possible.) The base strength dependent sequence observed for some univalent counteranions of similar size, i.e. the benzoates, tends to support the view that 1:1:1 species is involved in an inner sphere ion-pairing interaction (Fig. 5). The results in Fig. 4 conclusively confirm the preponderance of equilibria involving diastereomeric 1:2:1 cations as causes of residual exciton activity. Moreover, the concentration dependences shown in Figs. 3 and 4

suggest that S-valinate has a greater chelating ability than 1, 10-phenanthroline in methanol.

For non chelating univalent counterions (X⁻) the results may be treated using the following approximations:

Mass balance of 1:2:1 species gives

$$[\Delta^+] + [\Delta^+X^-] + [\Lambda^+] + [\Lambda^+X^-]$$
$$= ([\Delta^+] + (\Lambda^+])(1 + K_2[X^-]) \quad (1)$$

where Δ^+ and Λ^+ are the diastereomeric helical mixed chelate ions, and the same ion pair formation constant,
Fig. 5. Correlation of equivalent specific rotation (at 400 nm) with pK_a for some carboxylate salts of $[Zn(phen)_2(S\text{-val})]^+$. (Correlation coefficient = 0.95.)
Fig. 6. Effect of tetraethylammonium chloride on the optical activity of S-valinato bis(-phenanthroline)zinc(II) chloride in methanol. (α at 350 nm, 20°C and l = 5 cm; 1.06×10^{-3} M.)

K_2, is assumed for both. By introducing the formation constants

$$K_\Delta = \frac{[\Delta^+]}{[Zn(phen)(S\text{-val})^+][phen]} \quad (2)$$

and

$$K_\Lambda = \frac{[\Lambda^+]}{[Zn(phen)(S\text{-val})^+][phen]}. \quad (3)$$

Equation (1) becomes

$$[\Delta^+] + [\Delta^+X^-] + [\Lambda^+] + [\Lambda^+X^-] = [Zn(phen)$$

$$(S\text{-val})^+][phen](K_\Delta + K_\Lambda)(1 + K_2[X^-]). \quad (4)$$

If the ion-pairing of the $1:1:1$ species is also considered, eqn (4) becomes

$$\frac{[\Delta^+] + [\Delta^+X^-] + [\Lambda^+] + [\Lambda^+X^-]}{[Zn(phen)(S\text{-val})^+] + [Zn(phen)(S\text{-val})^+X^-]}$$

$$= \frac{[Zn(phen)_2(S\text{-val})^+]_{total}}{[Zn(phen)(S\text{-val})^+]_{total}}$$

$$= \frac{(K_\Delta + K_\Lambda)(1 + K_2[X^-])[phen]}{1 + K_1[X^-]}. \quad (5)$$

In this approximation the equilibria involving S-valinate exchange are disregarded. According to this scheme, the residual excitonic activity should increase with the concentration of heterocyclic base, in agreement with results (Fig. 3). Moreover, according to Fig. 3, $K_1 > K_2$. Hence a decrease of excitonic optical activity should result from an increase of counteranion concentration, as shown in Fig. 6 for the effect of tetraethylammonium chloride.

The specific rotation of the system in the presence of each counteranion may be represented by

$$[\Phi]_{exp} \sim \frac{1}{C}([\Delta^+] + [\Delta^+X^-])[\Phi_{e\Delta}]$$

$$\frac{1}{C}([\Lambda^+] + [\Lambda^+X^-])[\Phi_{e\Lambda}] + [\Phi_a] \quad (6)$$

where $[\Phi_{e\Delta}]$ and $[\Phi_{e\Lambda}]$ are the excitonic contributions of the diastereomeric chelates; $[\Phi_a]$ is the contribution of the chelated S-val$^-$ ($1:2:1$ species plus $1:1:1$ species); C is the total concentration of Zn(II), and all the S-val$^-$ is assumed to be chelated. Combination of eqns (2)–(4) and (6) gives

$$[\Phi]_{exp} \sim \frac{[Zn(phen)_2(S\text{-val})^+]_{total}(K_\Delta[\Phi_{e\Delta}] + K_\Lambda[\Phi_{e\Lambda}])}{C(K_\Delta + K_\Lambda)} + [\Phi_a]. \quad (7)$$

Hence, the specific excitonic rotation for the equilibrium mixture of diastereomeric cations would be

$$[\Phi_{em}] \sim \frac{K_\Delta[\Phi_{e\Delta}] + K_\Lambda[\Phi_{e\Lambda}]}{K_\Delta + K_\Lambda}. \quad (8)$$

According to these approximations the diastereomeric mixture could be treated as a single optically active species since

$$[Zn(phen)_2(S\text{-val})^+]_{total} \sim ([\Phi]_{exp} - [\Phi_a])C/[\Phi_{em}].$$

Specific rotation and conductance appear to be linearly correlated in the counteranion series (Fig. 2) probably because they depend in a similar way upon the concentration of $1:2:1$ species. If the equilibrium system in a $1:2:1$ cation salt solution is regarded as a mixture of $1:2:1$ and $1:1:1$ cation salts, the conductance should increase with the $(1:2:1):(1:1:1)$ total concentration quotient since $K_1 > K_2$ and the effects of ion-pairing on conductance tend to predominate over the differences in equivalent specific anionic conductances (as can be noticed on comparing conductances of the complex salts with conductances of sodium salts, Fig. 2). Hence, eqn (5) would be also in agreement with the correlation shown in Fig. 2.

NOTE

Adducts of tin tetrahalides with monodentate Schiff bases

JOSÉ A. GARCÍA-VÁZQUEZ,* MANUEL LÓPEZ-BECERRA and JOSÉ R. MASAGUER

Departamento de Química Inorgánica, Facultad de Ciencias, Universidad Autónoma, Canto Blanco,
Madrid (34), Spain

Abstract—Complexes of tin tetrachloride and tetrabromide with N-(dimethylphenyl)benzalaldimines have been synthesized and characterized by electronic, infrared and Raman spectroscopy. The vibrational data have been interpreted in terms of *trans*-octahedral structure.

Transition metal complexes of Schiff bases which apart from the imine group have other functional group, usually –OH, sufficiently near to the N donor atom to be able to form a chelate ring, have been studied extensively.[1-3] Comparatively little attention has been given to systems in which the Schiff base is a monodentate ligand and the metal is a non-transitional element.[4,5]

In this work we describe the preparation and characterization of the complexes resulting from the reaction of tin tetrachloride and tetrabromide with Schiff bases derived from benzaldehyde and substituted anilines.

In Scheme 1, $R = 2,3$-di-CH_3(**I**); $2,4$-di-CH_3(**II**); $2,5$-di-CH_3(**III**); $2,6$-di-CH_3(**IV**); $3,4$-di-CH_3(**V**) and $3,5$-di-CH_3(**VI**).
Scheme 1.

EXPERIMENTAL

Tin(IV) chloride and bromide were Merck products; benzaldehyde and amine was a Fluka product. Pure reagents and solvents (C. Erba) have been used and, when necessary, have been purified and/or dried according to standard procedures. Schiff bases were prepared by refluxing equimolecular amounts of the amine and aldehyde in benzene until the theoretical amounts of water was collected in a Dean–Stark trap followed by distillation of the product under reduced pressure.

The preparation of complexes has been carried out in a dry-box under N_2 atmosphere, using anhydrous solvents, according to the following procedure; 2 mmole of

SnX₄, dissolved in about 25 cm³ of carbon tetrachloride, was added dropwise to a solution of the appropiate amount of the Schiff base (4 mmole in 25 cm³ of CCl_4) under continuous stirring and the mixture was kept stirring at room temperature for about 3–5 hr. The precipitate was filtered off, washed with carbon tetrachloride and cyclohexane, and dried *in vacuo* at room temperature. The tin was estimated gravimetrically as SnO_2. The C, H and N analyses were made with a conventional microanalyzer.

The electronic spectra were recorded on a Pye Unicam SP8-100 spectrometer. IR spectra were recorded with a Perkin–Elmer 180 spectrophotometer. The adducts were prepared as Nujol mulls and placed between CsI or polyethylene windows. The Raman spectra were recorded in a Jarrell–Ash spectrophotometer model 25–300, using HE–Ne laser (25 mw, 623.8 nm line) and placing the sample into capillary tubes in order to avoid hydrolysis.

RESULTS AND DISCUSSION

The elemental analyses (Table 1) indicate the general formulae of the complexes to be $SnX_4 \cdot 2L$ where $X = Cl$ or Br.

The UV absorption spectrum of Schiff bases in different solvents shows the existence of several bands. The lowest energy band *ca.* 320 nm have been assigned to $\pi_1 \rightarrow \pi_1^*$ transition of imine group. The second one *ca.* 260 nm has been reported to be due to the transition within the phenyl ring orbitals of the benzal portion $(\pi_2 \rightarrow \pi_2^*)$.[6-8] It was not possible to observe the $n \rightarrow \pi^*$ imine transition band, probably because they are included in the envelope of a higher intensity band.[6] It is obvious that none of these transitions will be pure as a consequence of conjugation of the unshared pair of electrons on the nitrogen atom with the π orbitals of the imine and phenyl groups.

In the complexes a bathocromic shift takes place for these transitions (Table 2) probably due to the localization of nitrogen lone-pair electrons as the complex is form. A similar behaviour has been found by

Brocklehurst[7] when the nitrogen lone pair electrons are localized by protonation or nitrone formation. This shift may be interpreted as indicative of the bond of the imino-nitrogen to the metal.

The ligand band in the region 1623–1639 cm^{-1} in infrared and Raman to which a high $v(C=N)$ contribution may be assigned shifts to higher frequencies in all the adducts (Table 3) indicating that the coordination of SnX_4 is effected through the azomethine nitrogen of the ligands and this may be interpreted as a consequence of increased bond order in the carbon to nitrogen link. An analogous behaviour has been found for several adducts of Schiff bases.[9,10]

For these adducts, there are two probable configurations; one is the cis-form with C_{2v} symmetry for the skeleton and the other is the trans-form with D_{4h} symmetry. In theory a trans configuration having two stretching modes, one $v(Sn-X)(E_u)$ and one $v(Sn-N)(A_{2u})$ IR active, and three stretching modes, two $v(Sn-X)(A_{1g} + B_{1g})$ and one $v(Sn-N)(A_{1g})$ Raman active that should be readily distinguishable from a cis molecule with six IR and Raman active vibrations, four $v(Sn-X)(2A_1 + B_1 + B_2)$ and two $v(Sn-N)(A_1 + B_2)$. However as can be seen (Table 4), the number of the bands and their position suggest that these complexes have a trans-configuration or D_{4h} symmetry. The IR spectra are strikingly similar in the metal–halogen stretching region and are characterized by an intense band with a weak shoulder which appears in the region 320–330 cm^{-1} for chloride complexes and ca. 100 cm^{-1} lower for bromide complexes. The appearance of a shoulder band may indicate the splitting of the doubly degenerate Sn-X stretching mode (E_u) due to lowering of the D_{4h} symmetry in the solid state.[11] The $v(SnCl)$ are in good agreement with the range predicted by several authors[11-13] for the six-coordinated adducts of tin tet-

rachloride (usually 360–300 cm^{-1}). Also the ratio $v(SnBr)/v(SnCl)$ comes out to be 0.63–0.71 which is within the range accepted for complexes having similar coordination. The band at ca. 300 cm^{-1} in the spectra of $SnCl_4 \cdot 2L$ and $SnBr_4 \cdot 2L$ is tentatively assigned to the $v(SnN)$, since the positions of these bands are not likely to be different in the two spectra. The Raman spectra of these complexes confirm these conclusions. An intense Raman line, non-coincident with the strong IR band and at lower frequency accompanied by a weaker line at ca. 50 cm^{-1} to lower frequency appears in each case. This is the same type of spectrum as that found for other SnX_4 adducts.[14,15] The strong Raman line can be assigned to the A_{1g} $v(Sn-X)$ mode and it weaker counterpart to the B_{1g} mode of a trans D_{4h} skeleton. The frequency shift of the A_{1g} mode of a trans adduct accompanying the halogen substitution, also confirms our assignment by the constancy of the ratio $v(SnBr)/v(SnCl)$; this ratio is close to $(\mu_{Br}/\mu_{Cl})^{\frac{1}{2}} = 0.66$, as expected in the harmonic potential approximation.[14]

NOTE

PREPARATIONS OF SOME TRIBUTYLTIN PHOSPHATES

J.L. LECAT and M. DEVAUD*

I. N. S. C. I. R., BP 08, 76130 MONT SAINT AIGNAN, FRANCE

ABSTRACT

Different complex tributyltin organophosphates have been prepared; in some cases the organotin cation is directly linked to the phosphate group, in other cases it is linked to a carboxylate or to a thioate function in a RO–P substituent. The direct phosphorylation of a tributyltin hydroxy salt is only possible for a marked covalent salt. Intramolecular rearrangements were observed.

The combination of the tributyltin group (a well-known fungicide) to an organophosphate with similar properties gives the compound a wide spectrum of toxicity. Numerous organotin phosphates have therefore already been described in the literature[1-3]. We report here on the syntheses of some new tributyltin organophosphates which are in fact parents of organophosphorus pesticides. They were prepared by direct action of organophosphorus acid or salt on bis(tributyltin)oxide (TBTO) or tributyltin chloride (TBTCl). Direct phosphorylation of a tributyltin hydroxy salt was found to be difficult and could be used only in a few cases.

EXPERIMENTAL

^1H and ^{31}P NMR chemical shifts are expressed in δ units, referenced to TMS and a 85% H_3PO_4 solution. Butyl protons are not reported.

Chromatograms (glc) were carried out on a SE30 column at 150°C, allowing the identification of Bu_4Sn and TBTCl formed in some reactions.

The C, H, N analyses are reported in the table.

The tributyltin compounds used in this work were prepared by adding TBTO (0.1 mole) to a solution of acid (0.2 mole) in acetone or benzene (100 cm^3) in the presence of calcium sulphate[9] (10g) under refluxing conditions for 3h. The product was isolated after filtration and evaporation of the solvent.

Bis(tributyltin) 2-aminoethyl phosphate 1 was obtained by decantation after addition of 50 cm^3 of acetone solution of TBTCl (11.6 g, 35.6 mmol) to 100 cm^3 of aqueous solution of dipotassium 2-aminoethyl phosphate (3,9g, 17.8 mmol)– NMR:δ ppm: 3.7 t(2) 2.75 t(2)

Tributyltin bis(2-bromophenylamido)phosphate 3 Potassium bis(2-bromophenylamido)phosphate (prepared by action of 2-bromoaniline (37.2g, 0.216 mole) on phosphoryl trichloride (15.3g, 0.1 mole) in 200 cm^3 of ether at 0°C, followed by hydrolysis in 200 cm^3 of alcoholic potassium hydroxide (0.1 mole)) and TBTCl (0.1 mole) were heated for 30 min in refluxing ethanol. After KCl filtration and ethanol evaporation, compound 3 was recovered as a liquid.

* Author for correspondence

Tributyltin bis(dimethylamido)phosphate 4 was precipitated by adding 100 cm^3 of acetone
solution of TBTCl (33.8 mmol) to 50 cm^3 of an aqueous solution of the potassium salt(33.8
mmol) obtained from hydrolysis of bis(dimethylamido)chlorophosphate- NMR:δ ppm: 2.45 d(12)

Tributyltin ethyl (diethoxydithiophosphoryl)succinate 5 - The hydrogen ester was obtained by
the Chen method[4]. Compound 5 was prepared by action of TBTO on the hydrogen ester under
acetone reflux and in the presence of calcium sulphate - NMR:δ ppm: 4.2 m(7) 2.95 d(2)

Bis(tributyltin) 2,4,5-trichlorophenyl thiophosphate 6 - The thiophosphorylation was carried
out according to the literature[8]. Two equivalents of triethylamine and of tributyltin
glycolate were then introduced at - 17°C. After stirring for 90 min at room temperature, the
mixture was treated with a 2% sodium carbonate solution and then extracted by petroleum
ether. After evaporation of solvent, compound 6 was isolated in liquid form.

Phosphorylation of tributyltin compounds - The phosphorylation was carried out by adding
28.6 mmol of each of the two reactants, potassium carbonate (15g) and in some cases copper
powder (0.1g) in 150 cm^3 of solvent (PhH or THF). After stirring for 2h, the mixture was
filtered, evaporated and analysed.

Tris(tributyltin) tris(2,3,5-trichloro-S-pyridyl) tetra(thiophosphate) 15 - Chlorpyrifos
(5g, 14.2 mmol) and tributyltin glycolate (10.4g, 28.5 mmol) were heated at 130°C for 2h
under reduced pressure. Compound 15 slowly precipitated after addition of methanol-
Molecular weight by vapour osmometry : Found (1620 ± 200)g, Calc.: 1810g.

RESULTS AND DISCUSSION

Compounds 1, 3 and 4 were obtained by action of the potassium salt on TBTCl. The
structure of 1 was corroborated by the disappearance of ν(P=O) band and the value of ^{31}P
chemical shift[7]. 1 was slowly hydrolysed, the appearance on the IR spectrum of the two
deformations δ(NH$_2$) and δ(NH$_3^+$) at 1670 and 1590 cm^{-1}, which were also observed for the
potassium hydrogen salt, is consistent with the following reaction:

$$(NH_2CH_2CH_2O)PO(OSnBu_3)_2 + H_2O \longrightarrow (NH_2CH_2CH_2O)PO(OH)(OSnBu_3) + 1/2 \text{ TBTO} \qquad (1)$$

$$\underset{1}{} \qquad\qquad\qquad\qquad \underset{2}{}$$

$$\delta^{31}P = -4.9 \text{ ppm} \qquad\qquad\qquad \delta^{31}P = -6.4 \text{ ppm}$$
The two amidophosphates 3 and 4 are easy to prepare and stable. Their structures
were monitored by their IR spectra.

Compound 5 was synthesized by action of TBTO on the organophosphorus acid in the
presence of calcium sulphate as drying agent[9]. The IR spectrum showed that the carboxylate
group is monodentate and that there is no coordination between the ester function and the
tin atom:

$(EtO)_2PS(S-CHCOOEt \quad)$ $\nu(C=O) = 1740 \ cm^{-1}$ $\nu_{as}(COO) = 1660 \ cm^{-1}$

           $|$
   $\underset{\sim}{5}$ $CH_2COOSnBu_3$ $\nu(P=S) = 830-810 \ and \ 660 \ cm^{-1}$
The third method of preparation investigated was the direct phosphorylation of a tributyltin compound.

The phosphorylation of two equivalents of tributyltin glycolate by dichloro-2,4, 5-trichlorophenyl thiophosphate was probably accompanied by the rapid hydrolysis of the condensation product in the course of preparation. The compound $\underset{\sim}{6}$ which was formed underwent a slow intramolecular rearrangement which was revealed by gas chromatographic analysis.

$$(Cl_3C_6H_2O)PS(OSnBu_3)_2 \quad \longrightarrow \quad (Cl_3C_6H_2O)SP\underset{O}{\overset{O}{\diagup}}SnBu_2 + Bu_4Sn \qquad (2)$$

       $\underset{\sim}{6}$ $\underset{\sim}{7}$
The action of tributyltin 2-hydroxyethane thioate on chlorophosphates of general formula Y_2PXCl with $X = S$ or O and $Y = OEt$, OCH_2CCl_3 or NMe_2 depends on the solvent and the Y substituent.

For $X = S$ and $Y = OEt$, compound $\underset{\sim}{8}$ was obtained in benzene in the presence of potassium carbonate and copper powder. In the absence of copper, an isomerisation P=S/P=O, responsible of the appearance of the $\nu(P=O)$ at $1250 \ cm^{-1}$, was observed. In THF, the partially isomerised potassium salt, revealed by its IR spectrum, was isolated.

$(EtO)_2PSCl$

    $+$

$HOCH_2CH_2SSnBu_3$

$\overset{PhH, \ Cu}{\longrightarrow} (EtO)_2PS(OCH_2CH_2SnBu_3) \quad \underset{\sim}{8} \quad \nu(P=S) = 815-790, \ 675 \ cm^{-1}$

                                                (3)

$\overset{THF}{\longrightarrow} (EtO)PO(OK)(SCH_2CH_2OH) + (EtO)PS(OK)(OCH_2CH_2OH) \quad \underset{\sim}{9}$

      $\nu(OH)=3400 \ cm^{-1} \quad \nu(PO_2^-)=1145 \ cm^{-1} \quad \nu(P=S)=790-760,660 \ cm^{-1}$
For $X = O$ and $Y = OCH_2CCl_3$, in the same conditions, potassium bis(2,2,2-trichlordethyl)phosphate $\underset{\sim\sim}{10}$ always precipitated. The second product of the reaction was the initial organotin compound or TBTCl in the presence of copper powder. The great insolubility of the salt $\underset{\sim\sim}{10}$ is responsible for the lack of reaction with TBTCl.

For $X = O$ and $Y = NMe_2$, product $\underset{\sim\sim}{11}$ decomposes slowly following reaction (4). The 1,4-dithiacyclohexane was identified by its NMR spectrum; its formation possibly involved a sulphonium cation[5].

$$(Me_2N)_2PO(OCH_2CH_2SSnBu_3) \quad \longrightarrow \quad (Me_2N)_2PO(OSnBu_3) + S\underset{CH_2CH_2}{\overset{CH_2CH_2}{\diagup \diagdown}}S \qquad (4)$$

      $\underset{\sim\sim}{11}$ $\underset{\sim}{4}$
Similarly, the phosphorylation of tributyltin 4-amino salicylate did not give the desired product. In THF, the dipotassium salt $\left[NH_2C_6H_3(COOK)O\right]PS(OEt)(OK)$ $\underset{\sim\sim}{12}$ of the O-phosphorylated product precipitated. In benzene, both hydroxy and amino functions reacted; the 4-amino salicylic acid which was formed crystallised. In the remaining liquid there was, as well, a slow rearrangement between TBTCl formed in the reaction and compound $\underset{\sim\sim}{13}$ according to reaction (5).

$$(EtO)_2PSNH\!-\!\!\!\langle\bigcirc\rangle\!\!-\!COOSnBu_3 + TBTCl \longrightarrow (EtO)_2PSNH\!-\!\!\!\langle\bigcirc\rangle\!\!-\!COO\!-\!SnBu_2 + Bu_4Sn \qquad (5)$$

  $\underset{\sim\sim}{13}$ $OPS(OEt)_2$ $\underset{\sim\sim}{14}$ $|$

                                                               $OPS(OEt)O$

$\delta^{31}P$ ppm : $\underset{\sim\sim}{12}$: $- 57.3$ $\underset{\sim\sim}{13} + \underset{\sim\sim}{14}$: $- 68.8$ -60.8 and $- 56.5$
Tetrabutyltin was detected by its chromatographic peak. The constitution of the mixture $\underset{\sim\sim}{13} + \underset{\sim\sim}{14}$ was monitored by the ^{31}P spectra. The ^{31}P chemical shift decreases when an OR group

is replaced by a NR_2 group; it increases in an ionic salt or in an aromatic phosphate[7]. We therefore attribute the major signal at - 68.8 ppm to the structure $Ar-NH-PS(OEt)_2$, the signal at - 60.8 ppm to the group $Ar-O-PS(OEt)_2$ and the signal at - 56.5 ppm to the ionic group $Ar-O-PS(OEt)^-$.

In the same conditions, 4-nitro-2-hydroxy, 2,4-dihydroxy and 4-hydroxy benzoate of tributyltin gave the potassium salt of the acid only.

These different experiments showed that the direct phosphorylation of a tributyl-tin hydroxy salt does not generally give the expected product because the nucleophilic attack on the phosphorus atom can occur by the salt function if this is too ionic. For this reason, the best results were obtained in benzene solutions.

The transesterification of an organic commercial phosphate $(RO)_2PSY$ by tributyl-tin glycolate was not successful.The desired product $(RO)_2PSY(OCH_2COOSnBu_3)$ which was formed transiently was solvolysed by the ROH alcohol resulting from the reaction, and hydrolysed by water formed by dehydration of glycolate. In the case of chlorpyrifos, we isolated the unknown tetra(thiophosphate) 15.

The direct substitution of an ethyl group in triethylphosphate by trimethyltin has been achieved recently by heating trimethyltin halogenide with the phosphate[6]. We observed that this reaction cannot work with the tributyltin moiety, possibly because the covalent character of the tributyltin halogenide is too high.

In conclusion, we must underline the difficulties entailed in the preparation of complex tributyltin phosphates. The most stable compounds are monotributyltin which contain an amido group and could constitute products with interesting anti-fouling properties.

Beirut, Lebanon

Abstract

The condensation of o-aminobenzenthiol with 2-thiophenecarboxaldehyde
yields 2-thiazolin-2-ylthiophene rather than the expected Schiff base.
However, upon reaction with metal ions, the thiazoline rearranges to
the expected thiolate Schiff base. Complexes of the Schiff base with
Ni(II), Cu(II), Zn, Cd, Pb(II), Ag(I) and Pd(II) have been isolated
and characterized.

It is well established now that the condensation of an aldehyde with an aminethiol, such as
o-aminobenzenthiol, does not yield the Schiff base as would the amine if no thiol group was
present. The sulphur atom of the thiol group tends to form another S-C bond. Cyclization
takes place with the resulting formation of a thiazole (as in the case of 2,6-pyridinedicar-
boxaldehyde[1]) or a thiazoline (as in the case of 2,5-thiophenedicarboxaldehyde[2]).The purpose
of the present work was to check the behaviour of 2-thiophenecarboxaldehyde and to investi-
gate the reactions of the resulting thiazoline or thiazole with metal ions.

Experimental

Preparation of 2-thiazolin-2-ylthiophene: A solution of 2-thiophenecarboxaldehyde 6.72g,
0.06 mole) in ethanol (12 cm^3) was treated with o-aminobenzenethiol (7.50g, 0.06 mole) in
ethanol (12 cm^3). The mixture was refluxed for 3½ hrs. Concentration of the solution led
to the formation of a pale yellow product which was recrystallized from ethanol. Yield;6.92g
(53%). M.pt. 94-95°C. Found: C, 60.53; H, 3.69; N, 6.48; S, 29.36. Calc. for $C_{11}H_9NS_2$;
C, 60.24; H, 4.13; N, 6.39; S, 29.24%. IR spectrum: ν_{NH} at 3300 cm^{-1}.

Oxidation of 2-thizaoline-2-ylthiophene: Oxidation was carried out by bubbling air for four
hrs in a benzene solution of 2-thizaoline-2-ylthiophene. The oxidation product was 2-thia-
zol-2-ylthiophene. Found: C,60.83; H, 3.30; N, 6.46; S, 29.51. Cal. for $C_{11}H_7NS_2$; C, 60.80;
H, 3.25; N, 6.45; S, 29.14%. No band was observed in the IR spectrum above 3100 cm^{-1}, indi-
cating the absence of ν_{NH}.

---

[*] Author to whom correspondence should be addressed.

<u>Reactions of 2-thiazoline-2-ylthiophene with metal ions</u>: The ligand was reacted with the metal ions investigated according to the following procedures:

(i) A hot solution of the ligand (0.219 g, 1 mmole) in ethanol (7 cm^3) was added to a hot solution of the metal salt (0.4 mmoles) in ethanol (10 cm^3). The precipitate that was formed was filtered off, washed with ethanol and ether, respectively, and dried in vacuo over P_2O_5. This procedure was followed for the reactions of $CuCl_2.2H_2O$, $Pb(CH_3COO)_2$, $Cd(CH_3COO)_2.2H_2O$, $Zn(CH_3COO)_2.2H_2O$ and $Cu(CH_3COO)_2.H_2O$. Acetone was used as a solvent in the reaction of $Cu(ClO_4)_2.6H_2O$.

The same procedure was applied for the reaction of $AgClO_4$ except that the reaction mixture had to be stirred for two hours at room temperature in order to precipitate the product.

(ii) The reaction of the ligand with dichloro-bis-(benzonitrile)palladium(II) was carried out by stirring a mixture of benzene solutions of the ligand and the Pd(II) complex for one hour at room temperature. The product obtained was filtered off and washed with benzene, then dried in vacuo over P_2O_5.

(iii) Bis-(acetylacetonato) nickel(II) was reacted with the ligand by mixing boiling benzene solutions of Ni(accac)$_2$.H$_2$O and the ligand. An immediate wine-red colouration was observed. The mixture was concentrated in a hot water bath and petroleum ether (110-120°C) was added. The reddish-brown precipitate that separated was filtered off, washed with petroleum ether, and dreid in vacuo over P_2O_5.

Results and Discussion

The reaction of 2-thiophenecarboxaldehyde with <u>o</u>-aminobenzethiol afforded a product whose IR spectrum shows a band at 3300 cm^{-1} (assigned to ν_{NH}) but no absorption at 2600 cm^{-1} (the ν_{SH} region). Thus the Schiff base 2-thiophen-2-yl-{N(phenylen-2-thiol)aldimine} $\underset{\sim}{I}$ is ruled out. By comparison with the behaviour of 2,5-thiophenedicarboxaldehyde[2] the product is characterized as 2-thiazolin-2-ylthiophene($\underset{\sim}{II}$). This is further substantiated by the absence of $\nu_{C=N}$ in the IR spectrum of the product. The $\nu_{C=N}$ band is observed in the oxidized product 2-thiazol-2-ylthiophene($\underset{\sim}{III}$) at 1590 cm^{-1}. The ν_{NH} disappeared in the thiazole($\underset{\sim}{III}$). Both the thiazoline $\underset{\sim}{II}$ and the thiazole $\underset{\sim}{III}$ have not hitherto been reported.

* (Calc); ** SB is 2-thiophen-yl-{N-(phenylen-2-thiolate)aldimine}

The results of the reactions of 2-thiozolin-2-ylthiophene II with some metal ions are listed in Tables I and II along with the elemental analyses of the reaction products. The behaviour of 2-thiazoline-2-ylthiophene II is distinctly different from that of the corresponding 2,6-pyridine dithiazole (and dithiazoline) and 2,5-thiophene dithiazoline. The reactions of transition metal ions with 2,6-pyridine dithiazole result generally in the formation of complexes in which the thiazole rings remain intact. The ligand behaves simply as a disubstituted pyridine bonded to the metal through the pyridine nitrogen[1]. With 2,5-thiophene dithiazoline, however, one or both of the thiazoline rings may open, depending on the stoichiometric requirements of the complexes[2]. This may be due to the reluctance of the thiophene sulphur atom to bond to the metal ions. It has been observed that while

2,6-pyridinedicarboxaldehyde readily forms complexes with several transition metal ions[3], no complexes could be obtained from the reaction of 2,5-thiophenedicarboxaldehyde with metal ions[4].

The reactions of 2-thiazolin-2-ylthiophene with the metal ions investigated in this work are invariably accompanied with the opening of the thiazoline ring and the re-arrangement of the ligand to the Schiff base 2-thiophen-yl-{N-(phenylen-2-thio)aldimine}(I). Thus the complexes obtained were of the form MSBX (M = Cu, Pd; X = Cl; M = Cu, Cd; X = acetate) and M(SB)$_2$ (M = Pb, Zn, Ni). SB stands for the conjugate base of the Schiff base I. The perchlorates of Cu(II) and Ag(I) afforded the complexes Cu$_3$(SB)$_4$(ClO$_4$)$_2$·2H$_2$O and Ag$_4$(SB)$_3$ClO$_4$·H$_2$O, respectively. The Schiff base ligands in these latter complexes bridge the metal ions. No absorption above 3100 cm^{-1} occurred in the spectra of the an-hydrous complexes, indicating the absense of NH bonding. Moreover, $\nu_{C=N}$ was invariably observed about 1590 cm^{-1}. These observations along with the elemental analyses, support the formulation of the ligand as the anion of the Schiff Base I.

The complex Pd(SB)Cl·H$_2$O was decomposed with aqueous KCN and the organic ligand was recovered. It was identified as the original thiazoline II. Thus in the absence of metal ions the free Schiff base apparently rearranges in a fast reaction to the more favoured thiazoline.

NOTE

Preparation and Thermal Decomposition of Dineophylplatinum(II) Complexes; δ-Hydrogen

Migration Controlled by the Nature of Ancillary Ligands.[+]

By David C. Griffiths and G. Brent Young,*

Chemistry Department, Imperial College of Science and Technology,

London, SW7 2AY.

The novel complexes $L_2Pt(CH_2CMe_2Ph)_2$ $[L_2 = 1,5$-cod, $2,2'$-bipy, $2,2'$-bipym; $L = PEt_3$, $PPh_3]$ readily undergo cyclisations to afford $L_2Pt(2\text{-}C_6H_4CMe_2CH_2)$ with elimination of tert-butylbenzene at rates dependent on L_2; reaction is fastest for the bulky monodentate Ph_3P, while chelating ligands generally decrease lability.

Hydrogen migrations provide some of the major rearrangement paths for organotransition metals. The[1] β-elimination is especially facile for alkyl-metals and has received much attention.[1] Where this option is suppressed, however, it may be supplanted by an α-hydrogen abstraction[2] or, as has emerged more recently, migration from a more remote γ-[3] or δ-carbon.[3,4] We now report a δ-elimination from a novel dialkylplatinum(II) precursor L_2PtR_2, which affords a platinacyclopent-2-ene. We have discovered that the facility of the transformation is critically dependent, inter alia, on the ancillary ligand L (Scheme).

Dineophyl(1,5-cyclooctadiene)platinum(II), 1a, is obtained as colourless crystals from the reaction of excess neophylmagnesium chloride with (cod)PtCl$_2$ in tetrahydrofuran at temperatures not exceeding ambient (yield 68%). ^{1}H n.m.r. parameters appear in Table 1. Particularly diagnostic of 1a are the 1:4:1 triplets at 3.87 ppm $[^2J_{Pt-H} = 38$ Hz] and 2.24 ppm $[^2J_{Pt-H} = 88$ Hz], characterising the platinum-bound alkene and methylene hydrogens, respectively.

When a toluene solution of 1a is heated, smooth quantitative conversion to the platinacyclopentene 2a is observed, with concomitant liberation of an equivalent amount of tert-butylbenzene. These events may be followed conveniently by ^{1}H n.m.r. spectroscopy; 2a has two distinct platinum-bound alkene environments which generate 1:4:1 resonance patterns at 4.64 $[^2J_{Pt-H} = 44$ Hz] and 5.08 ppm $[^2J_{Pt-H} = 37$ Hz], while the metallacyclic methylene hydrogens appear at 2.29 ppm $[^2J_{Pt-H} = 88$ Hz] (Table 1).[5]

The diene ligand in 1a can be replaced by a variety of nitrogen and phosphorus donor ligands. Treatment of a chloroform solution of 1a with 2,2'-bipyridyl yields 1b. If reaction is conducted at room temperature, however, metallacyclisation occurs at an appreciable rate and 2b is the predominant product. Optimal preparation of bright red, crystalline 1b involves reaction at 10°C in toluene with a large excess (ca. 50-fold) of 2,2'-bipyridyl and with rigorous exclusion of air.[6] Reaction is complete in 4 days. In notable contrast toluene solutions of the corresponding 2,2'-bipyrimidyl derivative 1c

---

[+]"neophyl" = 2-methyl-2-phenylpropyl

*To whom correspondence should be addressed.

are thermally inert at ambient temperatures, even in air. Wine-red crystals are recovered after 10 days' reaction of equivalent 1a and bipyrimidyl. Temperatures in excess of 40 C are required to generate 2c at significant rates. In the ^{1}H n.m.r. spectrum of a toluene-d_8 solution, the methylene triplet at 2.73 ppm for 1c is replaced by another at 2.88 ppm (ultimately of 50% relative intensity) while the methyl resonance of tert-butylbenzene (1.14 ppm) appears simultaneously.

Displacement of 1,5-cyclooctadiene by tertiary phosphine ligands is much more rapid; metathesis is complete at 20°C in 2-24 hours. Dineophyl-bis(triethylphosphine)platinum(II), 1d, can be isolated as colourless prisms. This derivative undergoes cyclisation at 35°C in toluene to give 2d. In this case, ^{31}P n.m.r. spectroscopy is more convenient as a reaction monitor; the 1:4:1 triplet for 1d gives way to a corresponding triplet of AB quartets, characteristic of 2d (Table 1).

Interaction of 1a with triphenylphosphine, on the other hand, leads directly to 2e. The intermediate dialkyl 1e is too labile even at 0°C to be isolated. It can, however, be detected as a transient intermediate by ^{31}P n.m.r. spectroscopy (Table 1) in freshly mixed solutions of 1a and a large (ca. 5-fold) excess of triphenylphosphine.

The metallacyclisations conform to first order kinetics. Rate constants are presented in Table 2 (reaction of 1d is too rapid at 60°C for its rate to be reliably measured by ^{31}P n.m.r. spectroscopy). We are now engaged in extensive kinetic studies aimed at elucidating the mechanism of the rearrangement but some preliminary comments are pertinent.

Although decomposition solvents and temperatures do not coincide, the indications are that neophyl complex 1d is appreciably more labile than its neopentyl-[3b] and 2,2-dimethylbutylplatinum[4d] analogues. Cyclisation of 1d to give 2d is retarded by the presence in solution of triethylphosphine, in accord with a pathway in which phosphine dissociation normally occurs prior to cyclisation.[3b,4d] Significantly, ring-closure in complexes with chelating ligands, 1a-1c, is uniformly much slower, although we have yet to examine fully the effect of a bidentate diphosphine for more legitimate comparison.[7]

The rate constant for formation of 2e from 1e is estimated to be $\geq 4.0 \times 10^{-4}$ sec^{-1} at ambient temperature, in the presence of a five-fold excess of triphenylphosphine. Under analogous conditions, cyclisation of 1d is negligibly slow. The two phosphines differ appreciably in bulk[8] and the contribution of steric congestion in controlling cyclisation and elimination in related dineopentylplatinum complexes has been emphasised.[9] Whether the rate-difference reflects easier phosphine dissociation or crowded transition state geometry has yet to emerge. Electronic disparities, moreover, cannot be entirely discounted.

Bipyridyl and the nominally isosteric bipyrimidyl, however, do create different electronic environments at the metal, on the evidence of u.v./visible spectra. The lowest energy metal ligand charge transfer transition ($d\pi$-π*) which appears at 477 nm for 1b is shifted to lower energy at 502 nm in the bipyrimidyl analogue 1c.[10] In spite of this , we detect no significant rate-difference in their metallacyclisations.

Related cyclisations of dialkylplatinum complexes have been proposed to involve transient hydridoalkylplatinum(IV) intermediates,[3,4] and a hydridoiridium(III) product of neophyl cyclisation has recently been isolated.[3c] The thermal rearrangement of 1a is remarkable for its cleanness, in view of the lability of cyclooctadiene derivatives of Pt(IV) towards alkene loss,[11] and the complicated thermolytic behaviour of previously observed (cod)PtR$_2$.[12]

Under the relatively mild conditions required for these reactions, the metallacyclopent-2-ene is the only significant organometallic product. At present, we detect neither metallacyclobutane formation[3] (via attack on ligand methyl substituents) nor rearrangement to 2-tert-butylphenylplatinum species,[13] to any appreciable extent. Moreover, we have observed no coupling or deuterium-abstraction products ascribable to free radical participation. The rates and products of thermal decomposition of 1 are, however, affected by the presence of dioxygen, and by the use of halo-carbon solvents. The mechanistic significance of these observations is being explored. We are, in addition, studying the related, but comparatively less labile, asymmetric dialkyl $L_2Pt(Me)(CH_2CMe_2Ph)$, 3, which affords 2 by elimination of methane.

REACTIONS OF ETHYL- AND PHENYLLANTHANIDE σ COMPLEXES WITH N,N-DIMETHYLBENZAMIDE AND BENZALDEHYDE

KAZUHIRO YOKOO, YUZO FUJIWARA,[*] TOSHIHIRO FUKAGAWA and HIROSHI TANIGUCHI

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan

Abstract—Metallic Pr, Nd and Dy reacted with iodoethane at room temperature or 65°C in tetrahydrofuran (THF) but Gd, Ho and Er did not. The reaction of PhLnI complexes (Ln=Eu, Sm, Yb) with N,N-dimethylbenzamide gave benzophenone in good yields whilst the reaction of EtSmI with benzaldehyde afforded reduction and coupling products of benzaldehyde.

The formation of complexes of type RLnI by the lanthanides (Ln) such as Ce, Sm, Eu and Yb was first reported by Evans et al.[1] We have reported reactions of phenylytterbium iodide (PhYbI) with carbonyl compounds.[2,3] We wish to report here the reactivity of Pr, Nd, Gd, Dy, Ho and Er to iodoethane, and the reactions of RLnI with N,N-dimethylbenzamide and benzaldehyde.

Each lanthanide metal was allowed to react with iodoethane in THF at room temperature or 65°C. The results are listed in Table 1, and the data in the table show that Pr, Nd and Dy react with iodoethane to give coloured solutions which presumably contain EtLnI σ complexes, whereas Gd, Ho and Er did not react.

Table 1. Reactivity of rare earth metals to iodoethane

Ln	Pr	Nd	Gd	Dy	Ho	Er
Reacts	yes[a]	yes[b]	no[b]	yes[b]	no[b]	no[b]

[a]Reaction temp: room temperature. [b]Reaction temp: 65°C.

That Yb reacts easily with organic halides such as iodoethane or iodobenzene to give divalent RYbI σ-complexes[1] is due to filled f^{14} electronic configuration of Yb^{2+}.

The chemical behaviour of RLnI, prepared in situ, toward N,N-dimethylbenzamide and benzaldehyde was investigated. The reactions of PhYbI complexes with dimethylbenzamide gave benzophenone in good yields. The results are summarized in Table 2. For comparison, the

Table 2. Reactions of PhLnI with N,N-dimethylbenzamide

[a]Yields are based on metal. [b]Yields are based on PhI. [c]Refluxed for 2 h.

result with the Grignard reagent, phenylmagnesium iodide, is also listed (run 5), which shows that the reactivity of Eu and Yb complexes toward the benzamide is higher than that of the Grignard reagent. The RSmI complex did not react with the benzamide (run 4) but it was

found to cause reduction and coupling of benzaldehyde to give benzyl alcohol, benzoin, benzyl benzoate, and hydrobenzoin in 10, 18, 8 and 1% yields, respectively. This reductive nature of Sm^{2+} is attributed to the lower potential of Sm: Sm^{3+}/Sm^{2+} -1.55 V, Yb^{3+}/Yb^{2+} -1.15 V and Eu^{3+}/Eu^{2+} -0.43 V.[1] In the reaction of RSmI with PhCHO, one electron transfer from Sm^{2+} to

$$Et-Sm-I \quad + \quad PhCHO \xrightarrow[\text{r.t.}]{\text{THF}} PhCH_2OH \quad + \quad \underset{\underset{OH \quad O}{|}}{Ph-\overset{H}{\underset{|}{C}}-\overset{O}{\underset{||}{C}}-Ph} \quad + \quad \underset{\underset{H}{|}}{Ph-\overset{O}{\underset{||}{C}}-O-\overset{H}{\underset{|}{C}}-Ph}$$

$$+ \quad \underset{\underset{OH \quad OH}{|\quad|}}{Ph-\overset{H}{\underset{|}{C}}-\overset{H}{\underset{|}{C}}-Ph}$$
PhCHO would occur to give a radical anion $Ph-\overset{\cdot}{C}H-O^-$ which undergoes the coupling reaction.[4]

EXPERIMENTAL

Metals

Samarium, gadolinium and ytterbium were ca. 40 mesh powders from Research Chemicals. Praseodymium, neodymium, dysprosium, holmium and erbium ingots (Research Chemicals) were freshly cut.

Reaction of lanthanide metals with iodoethane

In a 50-cm³ centrifuge tube, 0.5 mg-atom of lanthanide metal and a magnetic stirring bar were placed under air and the tube was sealed with a serum cap. After the tube was dried by heating under nitrogen, 1 cm³ of THF, which was freshly distilled under nitrogen from sodium benzophenone ketyl, was added by a syringe. Then 1.0 mmol of iodoethane was added slowly to the tube at room temperature or 65°C and the mixture was stirred at room temperature or 65°C (see Table 1). Colour of the resulting solutions are light brown (Pr), grey (Nd) and grey-green (Dy).

Reaction of PhLnI with N,N-dimethylbenzamide

In the similar manner as above, reactions were performed adding dimethylbenzamide (0.5 mmol) to the THF solution of PhLnI, prepared from lanthanide metal and iodobenzene at -20°C in 3 cm³ of THF. The mixtures were stirred overnight and then in some cases (see Table 2) refluxed for 2 h. The resulting mixtures were quenched by 2N-HCl and the products were extracted by ether. From the ethereal layer benzophenone was obtained and sometimes a trace amount of triphenylcarbinol was also detected by GLC.

Reaction of EtSmI with benzaldehyde

Reaction was carried out using Sm (0.5 mg-atom), iodoethane (1.0 mmol) and benzaldehyde (0.5 mmol) in THF (2 cm³) at room temperature with stirring overnight. The products were separated by medium-pressure column chromatography (silica gel) and identification of the products was done by comparison with authentic samples.

CATIONIC CARBONYL COMPLEXES OF MANGANESE (I) WITH NITRILES AND DINITRILES

F.J. García Alonso, V. Riera*

Department of Inorganic Chemistry, University of Valladolid, Spain

(Received 5 May ; accepted 16 June 1983)

ABSTRACT The reaction of $Mn(CO)_5OClO_3$ with nitriles, L, and dinitriles, L-L, in a wide variety of conditions affords cationic pentacarbonyls, $[Mn(CO)_5(L)]ClO_4$ and $[Mn(CO)_5(L-L)]ClO_4$ and fac-tricarbonyls, $[Mn(CO)_3(L)_3]ClO_4$ and $[(CO)_3Mn(\mu L-L)_3Mn(CO)_3](ClO_4)_2$

RESULTS AND DISCUSSION The reaction of $Mn(CO)_5OClO_3$ with nitriles, (1/3 molar ratio) in refluxing $CHCl_3$ gave cationic tricarbonyl derivatives fac-$[Mn(CO)_3(L)_3]ClO_4$[1], (L: EtCN, $CH_2=CHCH_2CN$, PhCN, $PhCH_2CN$). In CH_2Cl_2 at room temperature the reaction gave a mixture of pentacarbonyls $[Mn(CO)_5(L)]ClO_4$ (which are initially formed) and the tricarbonyls fac-$[Mn(CO)_3(L)_3]ClO_4$; from the resulting solutions pure pentacarbonyls were isolated in low yield; by using equimolecular ratio, at -10°C, the formation of fac-tricarbonyl was greatly reduced, but the yields were not improved due to the low solubility of the precursor neutral perchlorate. All attempts to promote further substitution have failed; use of EtOH as solvent led to the formation of a fac-tricarbonyl derivative, possibly fac-$[Mn(CO)_3(EtOH)_3]ClO_4$, not previously described, which could not be characterized since it was obtained as an oil by solvent evaporation; IR (cm^{-1}) ν CO (CH_2Cl_2) 2040 s, 1935 br,s.

Similar reactions with dinitriles L-L, (L-L: $NCCH_2CN$, $NCCH_2CH_2CN$, $NCCH_2CH_2CH_2CN$, $o-C_6H_4(CN)_2$), in CH_2Cl_2 at room temperature in 1/3 ratio led to precipitation of white-yellow solids, identified by IR spectroscopy as mixtures of the corresponding penta- and tricarbonyl derivatives. Attempts to separate pure pentacarbonyls by succesive recrystallizations were unsuccesful, although analytical data are very close to the expected for $[Mn(CO)_5(L-L)]ClO_4$. The $Mn(CO)_5OClO_3$ reacted with a three fold excess of dinitriles L-L in refluxing $CHCl_3$ giving, through the intermediate pentacarbonyls, the tricarbonyls fac-$[(CO)_3Mn(\mu L-L)_3Mn(CO)_3](ClO_4)_2$, which must be dimers in accordance with conductivity data at various concentrations, and their structures are probably those in which the dinitriles are bridging two $Mn(CO)_3$ groups.

The pentacarbonyls show four ν CO bands in CH_2Cl_2 or in $CHCl_3$. Although uncommon, since IR spectra of pentacarbonyls usually exhibit only three absorptions $(2 A_1 + E)$ in the ν CO region, this behaviour is not unique and some pentacarbonyls can be found in the literature with four ν CO bands[2]. Using the Cotton-Kraihanzel method[2], the B_1 band which is not IR active for rigorous C_{4v} symmetry, must appear at 2106 cm^{-1} which supports the view that the band at 2122 cm^{-1} may be the B_1 mode. The weak ν CN absorptions of coordinated nitriles, at higher wavenumbers than that of free ligands, indicate that all the nitriles and dinitriles are bound to the metal through the nitrogen.

EXPERIMENTAL All the reactions were carried out under N_2 and in absence of light.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry. 8th Edition Sn—Organotin Compounds. Part 10. Mono- and Diorganotin-Sulfur Compounds. Published by the Gmelin Institute for Inorganic Chemistry of the Max Planck Society for the Advancement of Science. Springer-Verlag. Springer–Heidelberg–New York. 1983. xi + 352 pp. DM 993. US $ approx. 397.20.

Previous volumes on organotin compounds in this series have dealt with tetraalkyltins, trialkyltin hydrides, and alkyltin halides and pseudohalides. Volume 9 covered trialkyltin-sulphur compounds, and this companion volume covers the mono- and di-alkyltin compounds of sulphur, and the few organo–selenium and organotin–tellurium compounds which are known; and it ends with the sentence: "Organotin–Polonium Compounds: No organotin–polonium compound has yet been prepared". The literature is covered up to the end of 1980.

This volume follows the established form for the series, which is now written wholly in English. The entry for $(CH_3)_2Sn(SCH_3)_2$, the first in the book can serve as an example. It covers more than two pages and includes 17 references. The first paragraph deals with the preparative methods the second with physical properties, and the third with spectroscopic properties. ^1H NMR, and IR and Raman data are tabulated. Two paragraphs then cover chemical reactions, and the final one deals with applications: indeed the industrial applications provide an important aspect of this volume, as the dialkyltin organosulphur compounds are widely used as stabilisers of p.v.c.

Related compounds are collected together in tables, and there is a formula index covering 70 pages.

Organotin chemists who have access to these volumes are indeed fortunate, and will salute the industry of Herbert and Ingeborg Schumann who write them. The next volumes, which will cover the centrally-important organotin–oxygen compounds are eagerly awaited.

DEPOLYMERIZATION KINETICS OF $Ru_4(OH)_4^{8+}$ AND CHARACTERIZATION OF THE REACTION PRODUCT: DIMERIC Ru(III) ION

W. D'OLIESLAGER*, L. HEERMAN and M. CLARYSSE

Laboratorium voor Radiochemie, Katholieke Universiteit Leuven, Celestijnenlaan 200F, 3030 Heverlee, Belgium

Abstract—Perchloric acid solutions of $Ru_4(OH)_4^{8+}$ were prepared by the controlled-potential reduction of Ru(IV) at platinum electrodes in a high-speed coulometric cell. The solution spectrum of $Ru_4(OH)_4^{8+}$ is reported. Tetrameric Ru(III) ion decomposes in a reaction which is first-order with respect to its concentration, but independent of the acidity, to another species of the same valence state which is believed to be a dimeric ion ($Ru_2(OH)_2^{4+}$ or similar).

Electrochemical reduction of this species yields Ru^{2+} which can be reoxidized only to Ru^{3+}, the most stable of the Ru(III)-aquo ions.

Ruthenium(IV) exists in non-complexing media (e.g. acid perchlorate solutions) as a tetrameric ion, formulated as $Ru_4(OH)_{12}^{4+}$ (or $Ru_4O_6^{4+}$, etc.).[1,2] On platinum rotating disk electrodes, two reversible waves are observed for the reduction steps Ru(IV)→Ru(3.5)→Ru(III), each wave being the sum of two one-electron steps:[3]

products possibly are formed in less acidic solutions. The further reduction of tetrameric Ru(III)-ion to Ru(II) occurs at more cathodic potentials and can be observed only on mercury electrodes.[4-6] According to this scheme, tetrameric Ru(III)-ion slowly decomposes into another more stable species of the same valence state which was

1st wave

$$Ru_4(OH)_{12}^{4+}(IV) \xrightarrow{\underline{0.650\ V}} Ru_4(OH)_{10}^{5+}(3.75) \xrightarrow{\underline{0.656\ V}} Ru_4OH_8^{6+}(3.5)$$
$$\overline{\qquad\qquad 0.653\ V \qquad\qquad}$$

2nd wave

$$Ru_4(OH)_8^{6+}(3.5) \xrightarrow{\underline{0.493\ V}} Ru_4(OH)_6^{7+}(3.25) \xrightarrow{\underline{0.455\ V}} Ru_4OH_4^{8+}(III)$$
$$\overline{\qquad\qquad 0.469\ V \qquad\qquad}$$

$$Ru_4(OH)_4^{8+}(III) \xrightarrow{k_1} 2Ru_2(OH)_2^{4+}(III). \qquad (1)$$
Potentials (vs. nhe) and species are given for 1.0 M HClO₄ solutions (the high charge on these ions most probably is reduced by perchlorate complex or ion-pair formation); more hydrolized

hypothesized to be a dimeric species (*vide infra*).[3] The existence of such a follow-up chemical reactions was already indicated by Wehner and Hindman[7] who noticed profound changes in the UV absorption spectrum of Ru(III) solutions prepared by electrolytic reduction of Ru(IV) at platinum electrodes, when stored at 0°C under an inert atmosphere (see also Refs. 1 and 3).

*Author to whom correspondence should be addressed.

This paper reports on the depolymerization kinetics of $Ru_4(OH)_4^{8+}$ and on the electrochemical reduction of its decomposition product (dimeric Ru(III)-ion).

EXPERIMENTAL

Acid perchlorate solutions of Ru(IV) were prepared and analyzed as described previously.[3]

Solutions of tetrameric Ru(III)-ion for spectrophotometric studies were prepared, in an air thermostat under inert atmosphere, by electrolysis at a platinum gauze electrode in a high-speed coulometric cell ($p \simeq 3.5 \times 10^{-2} sec^{-1}$; for a definition of p, see Bard[8]); complete electrolysis was achieved in about 180–200 sec. The solution was then transferred immediately to a spectrophotometer cell and the spectral changes were recorded as a function of time (Beckman Acta M IV spectrophotometer). The spectrum of $Ru_4(OH)_4^{8+}$ was obtained by recording a spectrum immediately after the preparative electrolysis and correcting it for the small amount of dimer (less than 5% at 0°C) already formed during the electrolysis time. The concentration of the dimer was estimated by treating the mass transfer and the follow-up chemical reaction during the electrolysis as a system of consecutive first-order reactions using experimental values of p and k_1 (*vide infra*).

Electrochemical experiments were carried out using a PAR Model 303 SMDE (static mercury drop electrode) and a PAR Model 174A polarographic analyzer; other experimental details have been reported elsewhere.[3]

RESULTS AND DISCUSSION

The spectra of tetrameric and dimeric Ru(III)-ions are shown in Fig. 1. The spectrum of dimeric Ru(III) contains a single peak at 290 nm ($\epsilon_D^{290} = 2360 \pm 50$), in agreement with the work of Wallace and Propst[1] (Wehner and Hindman[7] reported a peak at 300 nm). The spectrum of tetrameric Ru(III)-ion, not previously reported in the literature, exhibits plateaus at 285–310 nm and 390–405 nm ($\epsilon_T^{400} = 730 \pm 10$) (the formal molar absorptivities were calculated using the analytical concentration of ruthenium, C_{Ru}).

The depolymerization kinetics of tetrameric Ru(III)-ion was studied by recording the spectral changes at 290 nm and plotting $\log(\epsilon_D^{290}C_{Ru} - A^{290})$ vs time, as is shown in Fig. 1, inset; from the mass balance and the postulate of additive absorbances it follows that $(\epsilon_D^{290}C_{Ru} - A^{290})$ is proportional to the concentration of $Ru_4(OH)_4^{8+}$ (this is true, irrespective of whether the product of the follow-up chemical reaction is a dimeric ion or not). Such plots were linear over at least two to three half-
Fig. 1. Absorption spectrum of (1) $Ru_4(OH)_4^{8+}$ and (2) $Ru_2(OH)_2^{4+}$ in 1.0 M $HClO_4$ solution. Inset. Decomposition kinetics of $Ru_4(OH)_4^{8+}$: plot of $\log(\epsilon_D^{290}C_{Ru} - A^{290})$ vs time (0°C).

lives, as expected for a reaction that is first order with respect to the concentration of $Ru_4(OH)_4^{8+}$. The rate constant k_1 was found to be independent of the solution acidity over the range $0 \leq pcH \leq 2$. Values of k_1 are 2.37 (± 0.03) $\times 10^{-4} sec^{-1}$(0°C), 9.82(± 0.20) $\times 10^{-4} sec^{-1}$ (15°C) and 2.47 (± 0.06) $\times 10^{-3} sec^{-1}$(25°C); the energy of activation is calculated as 63 kJ/mole. Furthermore, it was established by direct potentiometry (using glass electrodes) that protons are neither consumed nor liberated in the reaction. These facts seem to suggest that the stoichiometry of the follow-up chemical reaction is adequately represented by (1); it must be stressed however that an unquestionable proof of the existence of a dimeric Ru(III) aquoion has not been given thus far.

Methods such as ion exchange, solvent extraction and potentiometry cannot be used, at least in perchloric acid solutions, to investigate the ionic nature of this Ru(III) species since it is slowly oxidized by perchlorate ion (Wehner and Hindman[7] already implicitly dismissed the possibility that the species is a chloro-complex, chloride being produced in the oxidation reaction).

Some indirect evidence for the existence of a dimeric Ru(III) species was obtained from the following experiment.

A solution of 2, 2'-bipyridine in toluene

$(10^{-3}$ M) was added to a solution of "stable" Ru(III) (absorption maximum at 290 mμ). The organic ligand was slowly extracted into the aqueous phase with formation of an intensely green coloured complex. The aqueous phase was then 50-fold diluted with acetonitrile and the spectrum was recorded; the complex absorbs at 410 nm and 640 nm. According to Weaver et al.,[9] a high intensity, low energy band at about 650 nm is characteristic for oxo-bridged dimers such as $[(bipy)_2(H_2O)RuORu(H_2O)(bipy)_2]^{4+}$ (these authors preferred the diaquo-μ-oxo formulation over the di-μ-hydroxy formulation proposed by Dwyer et al.[10] for similar 1, 10-phenanthroline complexes).

The electrochemical reduction of dimeric Ru (III) has been studied by polarography (sampled DC) and cyclic voltammetry. Over the acidity range $0 \le pcH \le 2$, a single polarographic wave is observed with $E_{\frac{1}{2}} = -0.290$ V vs SCE (for 1.0 M $HClO_4$ solutions and $t = 1$ s). The electrode reaction involves one electron per ruthenium atom and, therefore, corresponds with the reduction step dimeric Ru(III)→Ru(II). The number of electrons involved in the reduction was estimated by comparing the diffusion current with the diffusion currents for the reduction steps of Ru(IV) under identical conditions of concentration, drop time, etc., a direct determination by controlled potential

coulometry is impossible since Ru(II) is oxidized by perchlorate ion during the experiment. The half-wave potential is independent of the ruthenium concentration but shifts to more negative values if the solution acidity is decreased $(dE_{\frac{1}{2}}/dlog c_{H^+} = -0.044$ V/decade). Furthermore, the half-wave potential shifts to more negative values for shorter drop times $(dE_{\frac{1}{2}}/dlog t = -0.022$ V/decade), which indicates the irreversibility of the electron transfer process. The cyclic voltammogram obtained for a solution of dimeric Ru(III) at the HMDE, shown in Fig. 2, exhibits a single reduction peak A on the first scan but the corresponding anodic peak is absent on the reverse sweep (as expected for an irreversible reaction); instead, a new reversible couple B/C is produced which can be identified with the Ru^{3+}/Ru^{2+} couple $(E_{\frac{1}{2}} = 0.002$ V vs SCE) in good agreement with the measurements of Mercer and Buckley.[11] During successive scans, the height of peak A decreases while the height of peaks B/C increases; similarly, the ratio of the peak heights A/B(C) increases at slower scan rates. These observations are in agreement with a reaction scheme where the irreversible charge transfer step is followed by a chemical reaction, such as

$$(Ru-O + Ru)^{4+} \xrightarrow[\text{irreversible}]{2e^-,\,6H^+} (Ru-\overset{\overset{\displaystyle H}{|}}{O}-Ru)^{3+}$$

$$\xrightarrow[k_2]{1H^+} 2Ru^{2+}.$$
Obviously, the overall reaction is the reduction of dimeric Ru(III) to Ru^{2+} which can be reoxidized to Ru^{3+}, the most stable of the Ru(III)-aquo-ions.

Abstract—The crystal and molecular structures of c-Hex-DAB (c-hexyl-N=C(H)–C(H)=N-c-hexyl; DAB = 1,4-diaza-1,3-butadiene) and of trans-[PdCl$_2$(PPh$_3$)(t-Bu-DAB)] are reported. Crystals of c-Hex-DAB are monoclinic with space group $C_{2/c}$ and cell constants: $a = 24.70(1)$, $b = 4.660(2)$, $c = 12.268(3)$ Å, $\beta = 107.66(4)°$, $Z = 4$. The molecule has a flat E-s-trans-E structure with bond lengths of 1.258(3) Å for the C=N double bond and 1.457(3) Å for the central C–C′ bond. These bond lengths and the N=C–C′ angle of 120.8(2)° indicate that the C- and N-atoms are purely sp^2-hybridized and that there is little or no conjugation within the central DAB skeleton. Crystals of trans-[PdCl$_2$(PPh$_3$)(t-Bu-DAB)] are triclinic with space group $P\bar{1}$ and cell constants: $a = 17.122(3)$, $b = 18.279(3)$, $c = 10.008(5)$ Å, $\alpha = 96.77(2)$, $\beta = 95.29(3)$, $\gamma = 109.79(2)$. $Z = 4$. The t-Bu-DAB ligand is coordinated to the metal via one lone pair only. In this 2e; σ-N coordination mode the E-s-trans-E conformation of the free DAB-ligand is still present and the bonding distances within the DAB-ligand are hardly affected. [C=N: 1.261(10) Å; C–C′: 1.479(10) Å (mean).] The Pd–N-, N=C- and central C–C′-bond lengths are compared with those found in other metal -R–DAB complexes.

During the last few years much attention has been paid to the coordination properties of cumulated and conjugated hetero double bond systems such as:

pseudo allenes, e.g. (R)N=C(H)–N(R)$^-$,[1a,2] O=C(R)–O$^-$,[1a,2] (R)N=N–N(R)$^-$,[1a,2] (R)(R′)C=S=O,[1b] (R)N=S=O,[2c] (R)N=S=N(R);[2c]

pseudo butadienes, e.g. (R)N=C(H)–C(OEt)=O,[1c] (R)N=N–N=N(R),[1d,2a,b] (R)N=C(H)–C(H)=N(R).[2a,2b,3]

The use of 1,4-disubstituted-1,4-diaza-1,3-butadiene (R–DAB), a member of the group of α-diimines (see Fig. 1), has been especially successful and many new R–DAB-metal complexes have been synthesized.[3,4,8,9]

If one compares R–DAB with other α-diimines, it is clear that the R–DAB ligand is much more versatile in coordination behaviour. It is not only possible to donate the free electron pair on each of the nitrogen atoms, but also to use the π-electrons for coordination. As expected this use has not been observed for 2,2′-bipyridine and 1,10-phenanthroline, because here the π-electrons are part of an aromatic system. With R–DAB as a ligand, changes on the metal centre can be accommodated by changing the coordination
Fig. 1. Some well known α-diimines. 1,10-phenanthroline (a), 2,2′-bipyridine (b), pyridinealdimine (c), R–DAB (d).

mode of R–DAB. For example, loss of a CO-group from CoMn(CO)$_7$(R–DAB) results in a change of the R–DAB coordination from the 4e; σ-N, σ-N′- to the 6e; σ-N, σ-N′, η^2-C=N′-coordination mode.[3]

The various coordination modes of R–DAB are shown in Fig. 2. Figure 2(a) illustrates the σ-N monodentate (2e donor mode) which has been postulated in

_____

*Author to whom correspondence should be addressed.
Fig. 2. The coordination modes of the R–DAB ligand: 2e; σ-N (a), 4e; σ-N, σ-N' bridging (b), 4e; σ-N, σ-N' chelating (c), 6e; σ-N, σ-N', η^2-C=N' or σ-N, μ-N', η^2-C=N' (d), 8e; σ-N, σ-N', η^2-C=N, η^2-C=N' (e), 4e; η^2-C=N, η^2-C=N' (f), 2e; σ-C (g).

e.g. *trans*-[PdCl$_2$(*t*-Bu–DAB)$_2$][5] and is found in *trans*-[PdCl$_2$(PPh$_3$)(*t*-Bu–DAB)] (this report). Until now the σ-N, σ-N'-bridging (4e donor) mode (Fig. 2b) has only been found in d^8-metal complexes of Pt(II), Pd(II), Rh(I), e.g. in [{PtCl$_2$(PBu$_3$)}$_2$(*t*-Bu–DAB)].[4] The σ-N, σ-N'-chelate (4e donor) mode (Fig. 2c) is the most common one and has been found in many low-valent metal complexes.

Relatively few examples are known in which the R–DAB also uses its π-electrons for coordination, though in the last few years the number has been growing rapidly. The σ-N, σ-N', η^2-C=N' or σ-N, μ-N', η^2-C=N' coordination (6e donor) mode, depicted in Fig. 2(d), has been observed in MM'(CO)$_6$(DAB) (M=M'=Fe, Ru, Os; M=Mn, Re; M'=Co) and Ru$_2$(CO)$_4$(DAB)$_2$ complexes.[3,6,7] The σ-N, σ-N', η^2-C=N, η^2-C=N' coordination (8e donor) mode (Fig. 2e) in which the DAB uses its maximum number of 8 electrons for coordination has been found in Ru$_2$(CO)$_4$(μ-C$_2$H$_2$)(DAB), Ru$_4$(CO)$_8$(DAB)$_2$ and Mn$_2$(CO)$_6$(DAB).[8–10]

The bonding situation recently found in Ru$_3$(CO)$_9$(*c*-Hex–DAB) can best be described as being intermediate between the 6e- and 8e-donor mode[11] because one C=N side of the DAB is strongly η^2-C=N bonded, while the other side is bonded only very weakly.†

In the free R–DAB ligand the conformation at the C=N bonds is the E(*anti*) one. This conclusion was based on IR, NMR, and dipole-moment measurements[14–16,19] and on an electron diffraction study in the gas phase on *t*-Bu–DAB.[17] This configuration is also found in all metal-R–DAB complexes. The conformation of the C–C'-bond is not quite clear. In the gas phase 20% of the *t*-Bu–DAB molecules has a *s-trans* conformation (torsion τ = 180°), while 80% has a gauche conformation

(τ = 65°).[17] In solution conformations are present with torsion angles between 90 and 140° according to dipole-moment measurements.[16] Such a torsion around the C–C' bond is also found in diketones.[18] IR, Raman, UV and PES measurements on the other hand support the conclusion that the free R–DAB molecule predominantly exists in a *s-trans* conformation.[14,19,20] MO calculations on R–DAB and related hetero-butadienes such as biacetyl[21] and 2,2'-bipyridine[22] also give the *s-trans* conformer as the most stable one.[23]

In order to obtain both the conformation of the free ligand in the solid state, as well as precise bond lengths and angles, we have carried out an X-ray study of *c*-Hex–DAB: *c*-Hex–N=C(H)–C(H)=N-*c*-Hex. The data on bond lengths and angles obtained are more precise than those obtained earlier via a diffraction study in the gas phase on *t*-Bu–DAB.[17] Accordingly we have now a better point of reference for the interpretation of the molecular distances in the R–DAB ligand in a great number of metal-R–DAB complexes for which the crystal structures are known.

In order to see if 2e; σ-N-coordination affects the geometry of, or bonding distances within the R–DAB ligand, we have also completed an X-ray investigation on *trans*-[PdCl$_2$(PPh$_3$)(*t*-Bu–DAB)]. This compound's crystal structure also represents the first example in which the R–DAB ligand is bonded in the 2e; σ-N bonding mode fashion (Fig. 2a). This coordination mode as well as the dynamic properties of *trans*-[MCl$_2$(PR$_3$)(*t*-Bu–DAB)] (M = Pt, Pd; R = aryl) in solution have already been put forward on basis of ^{1}H, ^{13}C-, ^{31}P-, ^{15}N- and ^{195}Pt–NMR measurements.[5,24]

†Other bonding possibilities are: η^2-C=N, η^2-C=N' coordination mode (4e-donor) (Fig. 2f), which has been proposed for cyclic α-diimine systems,[12] while in 1,4-diaza-1,3-butadiene-2-yl-complexes there is a bond between a central C-atom of the R–DAB and the metal (Fig. 2g).[13]

EXPERIMENTAL

Syntheses

Synthesis of *c*-Hex–DAB,[24] and *trans*-[PdCl$_2$(PPh$_3$)(*t*-Bu–DAB)][5] have been carried out according to literature methods. Recrystallization from diethyl ether and dichloromethane/pentane, respectively, yielded single crystals suitable for X-ray measurements.

Data collection and structure determination of 1,4 - di-cyclohexyl - 1,4 - diaza - 1,3 - butadiene, $C_{14}H_{24}N_2$

Crystals of c-Hex–DAB are monoclinic with space group $C_{2/c}$ with 4 molecules in a unit cell of dimensions $a = 24.70(1)$, $b = 4.660(2)$, $c = 12.268(3)$ Å and $\beta = 107.66(4)°$. A total of 1150 intensities were measured on a NONIUS CAD 4 diffractometer using graphite mono-chromated CuK_α radiation, 326 of which were below the 2.5σ(I) level and were treated as unobserved. No absorption correction was applied (crystal dimensions $0.3 \times 0.3 \times 0.05$ mm; $\mu = 4.54$ cm^{-1}). The structure was solved by means of the symbolic addition programme set SIMPEL.[25] Refinement proceeded by block-diagonal least-squares calculations, anisotropic for C and N, isotropic for H. The H-atoms were located in a ΔF-synthesis. The final R value for the 824 observed reflexions was 0.055. A weighting scheme $\omega = (0.66 + F_0 + 0.011\ F_0^2)^{-\frac{1}{2}}$ was used and extinction corrections

$$F^{corr} = F\left(1 + g\frac{1 + \cos^4 2\theta}{1 + \cos^2 2\theta/\sin 2\theta}\right)^{-\frac{1}{4}}$$

with $g = 1.2 \times 10^{-5}$ were applied.†

trans-[PdCl$_2$(PPh$_3$)(t-Bu–DAB)], $C_{28}H_{35}Cl_2N_2PPd$

Crystals of the title compound are triclinic with space-group P$\overline{1}$ and cell constants $a = 17.122(3)$, $b = 18.279(3)$, $c = 10.008(5)$ Å, $\alpha = 96.77(2)$, $\beta = 95.29(3)$, $\gamma = 109.79(2)$. There are four molecules in the unit cell, that is two in the asymmetric unit. A total of 7979 reflexions were measured on a NONIUS CAD 4 diffractometer using graphite mono-chromated MoK_α radiation, 1762 of which were less than 2.5σ(I) and were treated as unobserved. No absorption correction was applied (crystal dimensions $0.4 \times 0.2 \times 0.25$ mm; $\mu = 8.90$ cm^{-1}) The positions of the two Pd-atoms in the asymmetric unit were derived from an E^2-Patterson synthesis. A ΔF-synthesis based on the contributions of the Pd-atoms revealed the remaining non-hydrogen atoms except those of the methyl groups. These showed up in a subsequent ΔF-synthesis as rather diffuse peaks. Anisotropic block-diagonal least-squares refinement reduced R to 0.057. A ΔF-synthesis at this stage indicated the hydrogen atoms, except those of the tert-butyl groups, and made clear that these methyl groups are subject to disorder. Since it was not possible to devise a satisfactory description for this disorder we have not introduced it in the model. Continued refinement with 34 non-methyl hydrogen atoms fixed at their calculated positions, converged to R = 0.049 for the 6217 observed reflexions. A weighting scheme $\omega = (1.0 + F_0 + 0.018\ F_0^2)^{-\frac{1}{2}}$ was used and the anomolous scattering of Pd was taken into account. Computer programmes were taken from the X-RAY system[26] and PLUTO.[27]†

RESULTS AND DISCUSSION

The molecular geometries of c-Hex–DAB and *trans*-[PdCl$_2$(PPh$_3$)(t-Bu–DAB)] are depicted together with the atomic numbering in Figs. 3 and 4 respectively.

†*Supplementary Material* consists of a list of the final coordinates and equivalent isotropic thermal parameters and anisotropic thermal parameters of c-Hex–DAB and of *trans*-[PdCl$_2$(PPh$_3$)(t-Bu–DAB)]. Copies are available on request from the Editor at Queen Mary College. Atomic coordinates have also been deposited with the Cambridge Crystallographic Centre.

Molecular geometry of c-Hex–DAB

The bond distances and angles of c-Hex–DAB are listed in Table 1. In the solid state the molecular geometry of the R–DAB molecule is centrosymmetric with a flat E-s-$trans$-E conformation; deviations from the least-squares plane through C(2)–N(1)=C(1)–C(1')=N(1')–C(2') are less than 0.002(2) Å. This conformation is different from that found in the gas phase[17] (*vide supra*), but corresponds well with that predicted by MO-calculations.[23] The bond distances of C(1)–C(1') and C(1)–N(1) (1.457(3) and 1.258(3) Å respectively) are very near to the C(sp^2)–C(sp^2) and C(sp^2)=N(sp^2) standard single and double bond lengths (1.48 and 1.27 Å, respectively)[28] which would imply little conjugation in the central N=C–C=N-part of the c-Hex–DAB molecule. The cyclohexyl ring is in a chair conformation with an average C–C distance of 1.517(6) Å and an average C–C–C angle of 111.4(4)°. The angle between the planar part C(3)C(4)C(6)C(7) of the cyclohexyl ring and the flat N=C–C=N part is 88°.

Molecular geometry of trans-[PdCl$_2$(PPh$_3$)(t-Bu–DAB)]

The crystal structure of this compound contains two independent, but very similar molecules, A and B. Some bond lengths and -angles are listed in Table 2.†

The Pd-coordination plane in *trans*-[PdCl$_2$(PPh$_3$)(t-Bu–DAB)] is approximately square planar; deviations from the least-squares plane through Pd, Cl(1), Cl(2), N(1) and P are less than 0.091(1) and 0.109(2) for molecules A and B re-

spectively. This coordination plane makes an angle of 87.4° (mean) with the N=C–C=N plane. The conformation of the 2*e*; σ-N coordinated *t*-Bu–DAB molecule is the *E-s-trans-E* one, which is the same as in the free ligand.

The N=C–C=N skeleton is approximately planar; deviations from the least squares plane are less than 0.005(6) and 0.029(8) Å for molecules A and B, respectively.

The above mentioned coordination mode of the *t*-Bu–DAB-ligand brings the H(20) atom into the neighbourhood of the Pd-atom, above the coordination plane. The calculated distances are 2.60 and 2.58 Å for molecules A and B, respectively, which is less than the sum of Van der Waals radii for Pd and H, being 3.1 Å.[29] This geometry is similar to that found in [*trans*-{PtCl₂(PBu₃)}₂(*t*-Bu–DAB)] in which the *t*-Bu–DAB is bridged bonded[4] (see Fig. 2b). The extreme low field shift (9.91 ppm) of this H(20) atom

in ¹H NMR measurements indicates that the same conformation is present in solution.[5] The Pd ... H interaction can be best described as a very weak one.[4,5]

The Pd–Cl bond distances are comparable with those found in other complexes with a *trans* Cl–Pd(II)–Cl configuration: they all fall in the range 2.29–2.31 Å,[30] being equal to the sum of the covalent radii for Pd and Cl.[29]

The Pd–P bond distances (2.241(2) and 2.244(2) for molecules A and B respectively) compare well with other Pd(II)–P distances in complexes in which there is a nitrogen donor ligand *trans* to the phosphine.[31] The Pd–N bond distances of 2.130(7) and 2.126(5) Å for molecules A and B respectively are exceptionally long. In other Pd(II) complexes with a P-atom in *trans* position, Pd(II)–N bond distances are normally 2.06 Å[31a] and in Pd(II)Cl₂(imine)₂ complexes, Pd–N(imine) bond distances are found between 2.01

and 2.05 Å.[30] The longest previous Pd(II)–N(sp^2) bond distance, to our knowledge, is 2.092(9) Å found in [PdBr(PPh$_3$)(pyridine)]$_2$.[31b]

Comparison of structural data of the N=C–C=N-skeleton in free and metal coordinated R–DAB ligands may provide an answer as to the extent of σ- and π-bonding operative in their complexes.

Figure 5 shows that π-backbonding in either the σ-N-monodentate or σ-N, σ-N′-chelate coordination fashion, comprises interaction of the ligands LUMO with a filled metal d-orbital. Any contribution of this backbonding would then lead to (i), shortening of the M–N- and C–C′- and (ii), lengthening of the C=N-bondlengths.† These trends have indeed been observed for the C=N- and C–C′- but not for the M–N-bond lengths‡ in a variety of complexes where π-backbonding can be expected to be operative.[2b] This expectation is justified by the presence in these complexes of a metal in a low formal oxidation state in combination with either a R–DAB ligand with enhanced π-accepting properties (e.g. if R = aryl)[35] or other ligands with poor π-accepting capacity. In trans-[PdCl$_2$(PPh$_3$)(t-Bu–DAB)] none of the features favouring π-backbonding are present. This seems to be reflected by the similarity of the C=N- and C–C′-bond lengths in σ-N-bonded t-Bu–DAB, i.e. 1.265(10) and 1.478(10) Å, when compared with those found for free c-Hex–DAB, i.e. 1.258(3) and 1.457(3), respectively. Such data indicate that in the absence of π-backbonding, pure σ-N-coordination does not affect the C=N- and C–C′-bond lengths. This conclusion is supported by the C=N- and C–C′-distances found in e.g. [PtCl$_2$(PBu$_3$)]$_2$(t-Bu–DAB)[4] and [PtCl$_2$(C$_2$H$_3$C$_6$H$_5$)(t-Bu–DAB)][2b] containing σ-N, σ-N′ bridge and σ-N, σ-N′-chelate bonded t-Bu–DAB ligands, respectively.

---

†This bond length behaviour in the metal-heterobutadiene system is particularly found in metal-tetraaza-1,3-butadiene complexes. Tetraaza-1,3-butadiene, R–N=N–N=N–R, has a LUMO with the same character as that of R–DAB and an even stronger π-backbonding capacity,[32] which results in shorter M–N- and central N–N′- and long N=N-bond lengths in their complexes.[1d]

‡In [MnBr(CO)$_3$(c-Hex–DAB)] the C=N-, C–C′- and Mn–N-bond lengths are 1.28, 1.49 and 2.05 Å, respectively,[33] whereas in [Mn(t-Bu–DAB)$_2$] these bond lengths are 1.32, 1.38 and 2.06 Å.[34]

Abstract—Variable temperature ^{1}H NMR spectroscopy has been used in the study of 1,3-intramolecular shifts of the M(CO)₅ moiety in complexes of the general formula [M(CO)₅L], (M = Cr or W), L = SCH₂SCH₂SCH₂, SCH₂SCH₂CH₂CH₂ and SCH(Me)SCH₂CH₂CH₂. For the 1,3,5-trithian complexes precise energy barriers for the process have been obtained by detailed computer simulation of the static and dynamic spectra. Our results suggest that the magnitude of ΔG$^+$ (298.15 K) for the 1,3-shift is largely dependent upon the skeletal flexibility of the ligand system. In this context we have investigated the X-ray crystal structure of the highly substituted trithian complex [W(CO)₅{β-SCH(Me)SCH(Me)SCH(Me)}].

In 1975 Schenk and Schmidt[1] reported a novel fluxional phenomenon in the Group VI metal pentacarbonyl complexes of β-2,4,6-trimethyl–1,3,5-trithian; [M(CO)₅{SCH(Me)SCH(Me)SCH(Me)}] (M = Cr and W). Line shape changes in the 60 MHz ^{1}H NMR spectra between − 10 and + 30°C implied an equilibration of the three methylene protons, along also with the equilibration of the three methyl groups. This was suggested to be a consequence of an intramolecular commutation of the M(CO)₅ moiety over all three donor sulphur atoms. The analogous motion was not, however, observed in the unsubstituted ring complexes [M(CO)₅(SCH₂SCH₂SCH₂)] (M = Cr and W); the NMR ^{1}H spectra at + 30°C were consistent with the heterocyclic ligand 1,3,5-trithian coordinating to a M(CO)₅ group via a single sulphur atom.

By detailed computer simulation of static and dynamic spectra we have previously calculated and reported[2] accurate Arrhenius and Eyring activation parameters for the above "1,3-shift" of an M(CO)₅ moiety in the complexes [M(CO)₅{SCH(Me)SCH(Me)SCH(Me)}] (M = Cr and W). It was postulated that these complexes undergo 1,3-shifts rapidly at room temperature, whereas those of the 1,3,5-trithian and 1,3-dithian are static at this temperature, because of the ring conformation of β-2,4,6-trimethyl-1,3,5-trithian. We suggested that steric factors force the M(CO)₅ group into an axial

position, the corresponding equatorial conformer being highly unfavoured. In the axial complex the other sulphur lone pairs are ideally placed for a facile 1,3-shift. By contrast, in the other (non-methyl substituted) complexes, ring reversal and inversion of configuration at the sulphur atoms (both processes are fast at room temperature), change the relative positions of the M(CO)₅ group and sulphur atom lone pairs, thus reducing the probability of a 1,3-shift.

We now report the X-ray crystal structure of [W(CO)₅{SCH(Me)SCH(Me)SCH(Me)}], confirming ease of access for the 1,3-shift of the W(CO)₅ moiety. Furthermore, we have now carried out dynamic NMR studies on the complexes [M(CO)₅L] (M = Cr or W; L = SCH₂SCH₂SCH₂, SCH₂SCH₂CH₂CH₂ and SCH(Me)SCH₂CH₂CH₂, which are found to undergo 1,3-shifts at well above room temperature. Accurate energy barriers (ΔG$^+$) have been obtained for this process in the two complexes of 1,3,5-trithian, and are compared with the corresponding β-trimethyl-trithian complexes.

EXPERIMENTAL

Preparations

Ligands were prepared using literature procedures 1,3,5-trithian,[3] β-2,4,6-trimethyl-1,3,5-trithian,[4] 1,3-dithian,[5] 2-methyl-1,3-dithian.[6] The complexes [M(CO)₅{SCH(R)SCH(R)SCH(R)}](M = Cr or W, R = H or Me) and [M(CO)₅(SCH₂SCH₂SCH₂)] (Me = Cr or W) have been previously reported.[7,8] [M(CO)₅{SCH(Me)SCH₂CH₂CH₂}] (M = Cr or W), are hitherto unknown and were prepared by a general method for the synthesis of [M(CO)₅L] complexes described by Connors *et al.*[9]

*Author to whom correspondence should be addressed.

All reactions and manipulations were performed under an atmosphere of dry nitrogen. Freshly distilled nitrogen purged anhydrous solvents were used, as solutions of the complexes were noted to decompose rapidly on exposure to air. The yellow crystalline solids were however fairly stable in the atmosphere, and were all obtained in 30–60% yield (Table 1).

Spectroscopic studies

IR spectra of the metal carbonyl region of the complexes were obtained on a Perkin–Elmer 299B spectrophotometer. Variable Temperature NMR spectra were recorded at 5–10°C intervals on a JEOL MH-100 spectrometer. A JES–VT-3 unit was used to control the probe temperatures, which were measured, using a Comark digital thermometer type 5000 attached to a Cu/Cu–Ni thermocouple, to an accuracy of at least $\pm 1°C$.

Due to the decomposition of solutions of the complexes in air, all NMR samples were made up by adding the crystalline complex to an NMR tube fitted with a Taperlok (Wilmad Glass Co. Inc.) joint. The appropriate solvent (C_6D_6 or C_2Cl_4) and hexamethyldisiloxane were then distilled into the tube under vacuum, which was then filled with dry nitrogen.

Crystallographic studies

Crystal data: $C_{11}H_{12}O_5S_3W$; triclinic, $a = 9.704(4)$, $b = 13.041(2)$, $c = 14.073(3)Å$, $\alpha = 88.55(2)$, $\beta = 72.85(3)$, $\gamma = 81.39(3)°$, space group $P\bar{1}$, $Z = 4$, $D_c = 1.988\,\text{g cm}^{-3}$, $F(000) = 960$. Mo-K_{α_1} radiation, $\lambda = 0.71069Å$, $\mu = 69.30\,\text{cm}^{-1}$. Data collection: Nonius CAD4 four circle diffractometer. 3140 independent reflections of which 2427 had $I > \sigma(I)$. The three standard reflections showed an uneven and unrecoverable loss of intensity (averaging about 10%) during collection.

Structure solution and refinement

The structure was solved using a multi solution tangent formula procedure[10] and was refined with a full matrix least squares analysis. Hydrogen atoms were located geometrically, and the refinement, with anisotropic temperature parameters on all non-hydrogen atoms, converged with $R = 0.081$.†

RESULTS

The Crystal Structure of [W(CO)$_5$ $\{\beta$-$\dot{S}CH(Me)SCH(Me)\dot{S}CH(Me)\}]$.

The crystal of the above complex contains two unique molecules I and II, as shown in Fig. 1.

In each of these the tungsten atom has an octahedral coordination sphere with the carbonyl groups at five sites and a sulphur atom of the methyl substituted trithian ligand at the sixth position. Selected bond lengths and bond angles are given in Table 2.

In both complex molecules the ligand is the β-form of 2,4,6-trimethyl-1,3,5-trithian, which has the chair conformation, and three methyl groups in the equatorial positions. The S–C, and similarly C–Me bond lengths are not significantly different (mean 1.81(4) and 1.52(6)Å respectively) in I and II. These compare with mean lengths of 1.81(8) and 1.51(3)Å in the free ligand.[11] The coordinated sulphur atom uses only one

of its lone pairs of electrons to form the W–S bond, namely the pair that is "axial" with respect to the ligand methyl groups. The sum of the interbond angles at this sulphur atom is 328(2)° and 331(2)° for molecules I and II respectively, demonstrating its near exactly tetrahedral nature.

The W–S bond lengths (mean 2.553(5)Å) compare well with 2.556(8)Å in a similar bond in thiomorpholin-3-thione-pentacarbonyltungsten,[12] and it is only slightly less than the sum of the covalent radii values of sulphur and tungsten (1.04 and 1.58Å respectively).[13,14]

Any distinction between W–C bonds of the carbonyl groups *cis* and *trans* to the ligand atom is not well defined, in comparison with those in structures reported for some analogous complexes.[12,15,16] Consequently, there is no really observable *trans* effect. The variation in W–C ($1.84(3) - 2.11(3)Å$) of the four pseudo planar carbonyl groups may well reflect the erratic decomposition of the crystal, it was originally a gold orange and changed to an opaque black under the action of X-rays.

The two unique molecules differ essentially in a rotation of 23° about the W–S bond; an equivalent OC–W–S–C(Me) torsional angle in the two molecules is 173° and 150° for molecules I and II respectively. This places the two methyl groups closest to the tungsten atom in an approximately staggered conformation relative to the *cis* carbonyl groups.

Variable temperature ^1H NMR studies

The spectra of each type of ligand complex are best described individually.

1,3,5-Trithian complexes

The spectra of these complexes [M(CO)$_5$ ($\dot{S}CH_2SCH_2SCH_2$)] at room temperature are as reported previously.[1] The occurrence of two singlets in an intensity ratio of 2 : 1 (with the most intense resonance at high frequency) is consistent with: (i) The trithian ligand coordinating via one of its sulphur atoms to the single M(CO)$_5$ moiety, (ii) the complexes undergoing rapid sulphur atom inversion and six-membered ring reversal to equilibrate axial hydrogen environments on individual ring methylene groups.[2]

Increase of temperature above ambient caused identical changes in both the chromium and tungsten complexes. The two ^1H singlets were observed to broaden and coalesce (*ca.* 75 and 87°C for the chromium and tungsten complexes respectively), eventually giving rise to a sharp singlet on further increase in probe temperature. A non-exchanging sharp singlet, attributable to the free ligand, was observed throughout the temperature range studied.

The above reversible spectral changes, along with the absence of free ligand exchange imply an equilibration of all methylene hydrogen environments by an intramolecular commutation of the M(CO)$_5$ moiety over all sulphur atom coordination sites via a series of 1,3-shifts. A diagrammatical representation of this is given in Fig. 2 (the M(CO)$_5$ group is shown axial to the ligand for reasons to be discussed later).

The full dynamic nuclear spin problem for this system is shown in Fig. 2. A lack of long-range coupling, however, permits the reduction of the complex situation to a simple A(66.6%) $\rightleftharpoons$ B(33.3%)

---

†Copies of atomic co-ordinates, thermal parameters and observed and calculated structure factors has been deposited as supplementary material with the Editor from whom copies are available on request. Atomic co-ordinates have also been deposited at the Cambridge Crystallographic Data Centre.

according to the Arrhenius and Eyring equations (using least squares fitting), yielded the activation parameters for the 1,3-shift process. These are reported in Table 4 along with those previously obtained[2] for the complexes [M(CO)₅{$\overline{SCH(Me)SCH(Me)SCH(Me)}$}] (Me = Cr or W).

The Arrhenius plot for the intramolecular 1,3-shift in the pentacarbonylchromium(O) complex of 1,3,5-trithian is shown in Fig. 4.

1,3,-Dithian and 2-methyl-1,3-dithian complexes

The room temperature ¹H NMR spectra in C_6D_6

of the complexes [M(CO)₅($\overline{SCH_2SCH_2CH_2CH_2}$)] (M = Cr or W), show a singlet and three complex multiplets in an intensity ratio of 1:1:1:1. The latter are attributable to the -(CH₂)₃-portion of the heterocyclic ligand. An examination of molecular models shows this to be an AA′BB′CC′ spin system. This simplified system is generated from the room temperature equilibration of two ABCDEF type spin systems by rapid ring reversal and ligand sulphur atom inversion (see Fig. 5). These belong to the two structures possible for each of the 1,3-dithian complexes; the M(CO)₅ moiety can be axial or equatorial

to the ligand ring. Thus, equatorial and axial protons on methylene C$_4$ (and likewise those on C$_5$ and C$_6$) achieve chemical (but not magnetic) equivalence as a result of the above two rapid fluxions, generating a "pseudo-plane" of symmetry in the ligand ring. However, in the methyl substituted complexes [M(CO)$_5$$\{$$\overline{SCH(Me)SCH_2CH_2CH_2}$$\}$] (M = Cr or W), the substituent on C$_2$ destroys this symmetry element, which results in the retention of an ABCDEF spin system. This explains the considerably increased complexity of the -(CH$_2$)$_3$-multiplets observable in the room temperature spectra of the 2-methyl-1,3-dithian complexes.
Heating C$_6$D$_6$ solutions of the above four complexes to ca. 90°C resulted in only a slight broadening of the multiplets, but changing the solvent to

d^8-toluene, and increasing the temperature to 120°C produced extensive changes in the spectra line shapes. The resonances arising from the methylene protons on C$_4$ and C$_6$ (which occur at high frequency w.r.t. the C$_5$ multiplet) were observed to partially coalesce, and simultaneously the C$_5$ methylene proton multiplet broadened.

Such spectral changes are consistent with the commencement of the equilibration of the two 4,6-carbon methylene environments; AA'BB'CC' ⇌ CC'BB'AA' in the 1,3-dithian complexes (see Fig. 6), ABCDEF ⇌ EFCDAB in the 2-methyl-1,3-dithian complexes. This indicates that the M(CO)$_5$ moiety has started to commute between the two 1,3-positional sulphur atoms. Unfortunately a further rise in the probe temperature produced braodened free ligand lines in the spectra indicative of the commencement of *inter*molecular ligand exchange and thermal degradation of the complexes. This is also indicated by the irreversible colour change of the solutions from yellow to brown. As total coalescence could not be obtained we were unable to carry out a full line shape analysis, and can report only the qualitative observation of 1,3-shifts without numerical data for activation parameters. It

Fig. 6. The effect of M(CO)$_5$ 1,3-shifts on the -(CH$_2$)$_3$-environment in the complexes [M(CO)$_5$ $\overline{SCH_2SCH_2CH_2CH_2}$)] (M = Cr or W).

is notable, however, that ΔG^+ for a shift in the 1,3-dithian complex is higher than in the corresponding 1,3,5-trithan complex; a factor which may be associated with the reduced probability of access to a suitably placed sulphur atom for the 1,3-shift.

DISCUSSION

Of all the activation parameters, ΔG^+ has been recognised as the least susceptible to temperature and rate errors.[17] We therefore base our discussion of the relative ease of 1,3-shifts in these complexes upon the ΔG^+ (298.15 K) values listed in Table 4.

The intramolecular nature of the 1,3-shift in these complexes is indicated by the absence of exchange with added free ligand, and is confirmed by the numerical values of $\log_{10}A$ and ΔS^+ (Table 4), these being all close to 13 and 0 respectively.

The X-ray crystal structure of the complex pentacarbonyl-β-2,4,6-trimethyl-1,3,5-trithiantungsten(O) would appear to confirm our previous reasoning[2] as to why the $M(CO)_5$ moiety undergoes rapid 1,3-shifts at ambient temperatures in the complexes $[M(CO)_5 \{\overline{SCH(Me)SCH(Me)SCH(Me)}\}]$ (M = Cr or W), but not in those of 1,3,5-trithian etc. The rigid chair conformation of β-2,4,6-trimethyl-1,3,5-trithian with all methyl groups equatorial, forces the $M(CO)_5$ group to adopt exclusively the sterically less hindered axial position. Low temperature ^1H NMR spectra of the complexes $[M(CO)_5\{\overline{SCH(Me)SCH(Me)SCH(Me)}\}]$ (M = Cr and W) showed the predominance ($> 95\%$) of one of the two possible conformers, thereby virtually certainly confirming the retention of the solid state conformation in solution. In such a structure the axial lone pairs of unco-ordinated sulphur atoms are held at a constant distance from the $M(CO)_5$ moiety, and further, are directed in such a way as to greatly facilitate a 1,3-shift via an easily accessible seven coordinate intermediate. In the complexes $[M(CO)_5(\overline{SCH_2SCH_2SCH_2})]$ [M = Cr or W], however, ring reversal and ligand sulphur atom inversion interconvert conformers of similar ground state energy, thus changing the ideal relative positioning of $M(CO)_5$ groups and sulphur lone pairs. This increase in ligand "flexibility" makes the probability of a commutation more remote, and is reflected by an increase in ΔG^+ of ca. $10\,kJ\,mol^{-1}$ between the trimethyl substituted and the unsubstituted trithian complexes.

The suggestion that ligand "flexibility" is a major influential factor in determining the magnitude of ΔG^+ for 1,3-shifts across a $-S-CH_2-S-$ ligand system, is further supported by the following examples

of pentacarbonyltungsten complexes which are ordered in terms of increasing flexibility, and also increasing ΔG^+ values

$[W(CO)_5\overline{SCH(Me)SCH(Me)SCH(Me)}]$,

$$68.47 \pm 0.02,^2;$$

$[W(CO)_5(\overline{SCH_2SCH_2SCH_2})]$, 78.33 ± 0.26^{18};

$[W(CO)_5(\overline{SCH_2SCH_2SCH_2SCH_2})]$, 83.44 ± 0.58^{19};

$[W(CO)_5(MeSCH_2SMe)]$, 84.65 ± 0.66^{20}; $kJ\,mol^{-1}$.
In all of these classes of complex it is notable that activation energies for pentacarbonylchromium complexes are consistently ca. $3\,kJ\,mol^{-1}$ lower than their tungsten analogues.

INTERACTIONS OF ANTIMONY(III) HALIDES WITH AMIDES AND TETRAMETHYLUREA IN 1,2-DICHLOROETHANE SOLUTION

CLAUDIO AIROLDI*, PEDRO L. O. VOLPE and JOSEFA M. M. de M. LIRA†

Instituto de Química, Universidade Estadual de Campinas, 13100 Campinas, São Paulo, Brasil

Abstract—The interactions of SbCl₃, SbBr₃ and SbI₃ with N,N-dimethylformamide (DMF); N,N-dimethylacetamide (DMA) and tetramethylurea (TMU) have been studied in 1,2-dichloroethane solution. The equilibrium constants and the respective variations of enthalpy for 1:1 and 1:2 species were obtained by means of the incremental calorimetric titration technique. From ΔH_i° values, the acidity order $SbCl_3 > SbBr_3 > SbI_3$ and the basicity order $TMU > DMA > DMF$ were established. The ionization in solution such as autocomplex formation and halides displacement are discussed using conductometric titration values.

The majority of *p*-block elements in lower valence states have a lone electron pair which gives rise to an irregular coordination in the adduct formed. This lone pair of electrons in antimony(III) halides is considered to be predominantly of *s*-character, due to the fact that in SbX_3 molecules the X–Sb–X angles are 97–99°.[1] These figures indicate that the Sb–X bond involves mainly the metal *p*-orbitals. The lone pair leads to a high electron density close to the metal, in spite of the difference in electronegativities of the atoms in the metal–halide bond and consequently, it should be difficult to accommodate a Lewis base in the coordination sphere. For 1:1 adduct formation a rehybridisation is required to arrange the new ligand in a trigonal–bipyramidal geometry, where the lone pair is lying in an equatorial position. Identically, with two molecules of bases an octahedral geometry is formed, the lone pair occupying one site of coordination. X-Ray structure determinations of SbCl₃ adducts of aniline[2], tetramethylthiourea[3] and triphenylarsine[4] illustrate this behaviour, where the strain of the lone pair causes a highly distorted geometry.

The Lewis acid properties of these metal halides are displayed by an increase in coordination number of the metal through the formation of a σ ligand–metal bond. In solution this behaviour can be illustrated by the interaction of SbCl₃ with some aliphatic and aromatic amides.[5] Molecular adducts are formed in 1:1 and 1:2 stoichiometries, these reactions being followed by vibrational spectroscopy. The relative donor ability of the amides toward $SbCl_3$ as a fixed acid was established by means of carbonyl and antimony–chloride frequency shifts. Thus, in benzene the order is DMA > DMF > NMA (NMA = N-methylacetamide), which reverses in a polar solvent such as chloroform. In agreement with these results,

in an aprotic solvent the basicity order TMU⟩DMA⟩DMF was recently obtained using a calorimetric technique.[6]

Thermodynamic parameters involving the equilibrium between SbX_3, dissolved in 1,2-dichloroethane and a series of ligands have been calorimetrically obtained.[7] Among these ligands, there are oxygen donors such as pyridine N-oxide, dimethyl sulphoxide and triphenylphosphine oxide, which showed successive formation of 1:1 and 1:2 adducts in distinct steps, where $X_1 > X_2$. No abrupt difference was observed in the enthalpies of these steps of coordination. The ligands Ph_3PO and C_5H_5NO gave high stability constants at the first step of complexation, in comparison with the analogous phosphorus and nitrogen donors, which presented small enthalpies of formation. However, three moles of aliphatic amines reacted quantitatively with metal–halides to produce very large exothermic enthalpy changes. In this case, it was suggested that the aliphatic amines are coordinated to the halogen in the adducts rather than to the metal.

In this paper, SbX₃ were calorimetrically titrated with N,N-dimethylformamide (DMF); N,N-dimethylacetamide (DMA) and tetramethylurea (TMU) in the assumed inert solvent 1,2-dichloroethane. From the incremental calorimetric titration results, the stability constants and the variation of enthalpy for the two steps of coordination of these oxygen donors ligands were calculated.

EXPERIMENTAL

Materials. All solvents for preparation of metal halides, for calorimetry and for conductance measurements were carefully dried, distilled and stored over molecular sieves. N,N-dimethylformamide;[8] N,N-dimethylacetamide[9] and tetramethylurea[10] were previously distilled and dried over barium oxide or sodium carbonate. After standing overnight these solvents were distilled through an efficient column under reduced pressure, collecting the fractions at 36°C and 30 mmHg; 30°C and 6 mmHg and 80°C and 30 mmHg for DMF, DMA and TMU, respectively. After distillation these solvents were stored over molecular sieves. All the manipulations concerning the metal halides were

carried out under an atmosphere of dry nitrogen on a vacuum line or in a dry-box. Antimony chloride (Carlo Erba) was purified by sublimation in vacuum, giving a melting point of 73°C, literature 73°C.[11] Antimony tribromide was prepared from the reaction of antimony with an excess of bromine in carbon disulphide under an atmosphere of nitrogen. When the antimony vanished, the solution was pumped to dryness and the solid was crystallized twice in carbon disulphide to give a product of melting point 96°C, literature 96°C.[12] Antimony triiodide was prepared by means of a direct reaction of the metal and iodine in benzene. After filtration the product was dried *in vacuo* and recrystallized in toluene, giving a melting point 170°C, literature 170°C.[12]

Calorimetric measurements. All calorimetric experiments were performed with the solvent 1,2-dichloroethane by means of a LKB 8700-2 precision calorimetric system. The titrand solution at $(25.00 \pm 0.05°C)$ was incrementally added to $90.0 \, \text{cm}^3$ of the desired solution, already in the calorimeter vessel and the heat recorded or described previously.[13,14] The calorimeter's performance was checked using the enthalpy of titration of hydrochloric acid with tris(hydroxyamino)methane.[15] The metal halides were titrated twice with each of the three ligands. In a typical example, an $SbCl_3$ solution $(1.30 \times 10^{-2} \, \text{moles} \cdot \text{l}^{-1})$ was titrated with a DMF solution of $0.15 \, \text{moles} \cdot \text{l}^{-1}$. A new titration of the same $SbCl_3$ solution was carried out with a DMF solution $1.16 \, \text{moles} \cdot \text{l}^{-1}$. The final volume in each case was *ca.* $100 \, \text{cm}^3$ and the relative number of moles of $SbCl_3$ to the number of ligand was 1.3/1 and 10/1 with between 15 and 25 points.

The net enthalpy for each increment of titrand (Q_A) was calculated after subtracting the heat of dilution. The effect produced by the ligand solution was determined when its solution was added to $90.0 \, \text{cm}^3$ of 1,2-dichloroethane (Q_B). The heat of dilution of the metal halide solution was calculated after the addition of solvent to the calorimeter vessel containing $90.0 \, \text{cm}^3$ of the halide solution (Q_C). Thus, the variation of enthalpy due to the chemical reaction (Q_{obs}) can be obtained by: $Q_{obs} = Q_A - Q_B - Q_C$. The K_1, K_2, ΔH_1 and ΔH_2 values are related to the interactions of metal halides (SbX_3) with the ligands (L):

$$SbX_3 + L = SbX_3 \cdot L; \quad K_1, \; \Delta H_1^\circ$$

$$SbX_3 \cdot L + L = SbX_3 \cdot 2L; \quad K_2, \; \Delta H_2^\circ$$
where $K_1 = |SbX_3 \cdot L|/|SbX_3||L|$ and $K_2 = |SbX_3 \cdot 2L|/|SbX_3 \cdot L||L|$. A previously described procedure of calculation was followed to find, K_1, K_2, ΔH_1° and ΔH_2° values. This method consists in adjusting the points of the titrations of the calculated curve (Q_{calc}) to the experimental one (Q_{obs}). In this procedure the function $U = \Sigma (Q_{obs} - Q_{calc})^2$ is minimized by using a least square programme.[13,14]

Conductance measurements. The metal halides were conductometrically titrated at $(25.00 \pm 0.02°C)$ with the ligands in 1,2-dichloroethane to high concentration of metal halide/ligand; i.e. about 1/10. In these series of measurements a Metrohm Herisau Konduktoskop E 365 bridge was used.

RESULTS AND DISCUSSION

The progress of the reaction between the metal halides SbX_3 (X = Cl, Br, I) and the ligands L (L = DMF, DMA, TMU) was studied in 1,2-dichloroethane, which is considered to be a very poor interacting solvent. The results of a typical calorimetric titration are listed in Table 1 and the enthalpies of dilutions Q_B and Q_C are given in Tables 2 and 3, respectively. The plot of the heat obtained against the volume is presented in Fig. 1. From these incremental calorimetric titrimetry values the thermo-

dynamic parameters of Table 4 were calculated. In an attempt to obtain information about the ionic behaviour in 1,2-dichloroethane, the metal halides were conductometrically titrated in the same range of concentration as that carried out in the calorimetry measurements. The plot of Fig. 2 represents the ionic character of the metal halides when titrated with tetramethylurea. were calculated from values of K_1 and K_2 obtained from the titrations.

The halides SbX$_3$ (X = Cl, Br) interact exothermically with the amides. However, SbI$_3$ produces an endothermic effect in this process except with DMA in high concentration. In all cases the dilution leads to an endothermic effect more pronounced with SbI$_3$, in spite of its lower concentration, due to its reduced solubility in the solvent.

Calorimetric measurements between SbX$_3$ and DMA have been previously obtained[16] with the following $\Delta H_1^{\ominus}$ values: −35.98 (SbCl$_3$), −30.96 (SbBr$_3$) and −31.80 (SbI$_3$) kJ mol^{-1}, which are comparable with our results. From these values the authors did not establish any acidity order for these metal halides. In the mean time, our $\Delta H_1^{\ominus}$ results (Table 4) demonstrate that TMU is a more suitable base to differentiate the acidity properties of the metal halides, giving the order SbCl$_3$ > SbBr$_3$ > SbI$_3$, as is also observed with triphenylphosphine oxide.[7] This behaviour is associated with the donor number of the ligands.[17] Whereas DMF and DMA have the values 26.6 and 27.8, respectively, leading to similar enthalpies; TMU with donor number 31, leads to a different $\Delta H_1^{\ominus}$ values.

The enthalpies values listed in Table 4 show an increase from DMF to TMU, reflecting the increasing donor number of these ligands. In all cases the basicity order TMU > DMA > DMF can be proposed, since any metal halide is fixed as acceptor. This sequence of basicity is clearly seen with SbCl$_3$. On the other hand, the same sequence was previously established for the interaction of this acid with the above bases by means of the reactions in condensed phase,[6] viz.   SbCl$_3$(s) + L(ℓ) = SbCl$_3 \cdot$ L(ℓ, s); $\Delta H_R^{\ominus}$: −27.82 ± 0.15; −37.96 ± 0.16 and −44.86 ± 0.27 kJ mol^{-1} for DMF, DMA and TMU, respectively.

The metal halides in the concentration range of the calorimetric titrations give the same specific conductivity of the net solvent, thus they maintained their

characteristic molecular properties in this medium. Although the metal halides present some degree of dissociation during the conductometric titrations with the ligands, the molar conductivity is much below that of 1:1 electrolyte type behaviour.[18] Figure 2 shows a conductometric titration of SbX$_3$ with TMU. The conductance results reveal the donor–acceptor complex formation, which depends on the donor properties of the ligand, the polarizability and the energy of Sb–X bond. The highest conductance values observed for SbI$_3$ (Fig. 2) fit very well with the most basic ligand and the characteristics of Sb–I bond.

The stability constant values of K_1, for the formation of the adducts of SbCl$_3$, increase from TMU to DMF, which is the inverse order of the donor ability of the ligands. This enhancement of the equilibrium constant in that sequence suggests that the autocomplex should be formed, producing ionic species in solution, with a consequent decrease of the amount of the adduct formed. This fact can be explained in considering the equations of formation of adduct and autocomplex:[19]

$$SbCl_3 + L \rightleftharpoons SbCl_3 \cdot L;$$

$$K_1 = [SbCl_3, \cdot \ L]/[SbCl_3][L]$$
$$2SbCl_3 \cdot L \rightleftharpoons SbCl_2L_2^+ + SbCl_4^- ;$$

$$K_e = [SbCl_2L_2^+][SbCl_4^-]/[SbCl_3 \cdot L]^2.$$

The autocomplex is more easily formed with TMU due to its highest donor power. In this way the K_1 value turns out to be the smallest among these values. For the second step of complexation TMU and DMF present $K_2 < K_1$, which are normally interpreted by statistical effects. Thus, K_2 values for both ligands suggest the predominance of SbCl$_3 \cdot$ 2L species in solution due to the reaction SbCl$_3 \cdot$ L + L $\rightleftharpoons$ SbCl$_3 \cdot$ 2L. However, the highest K_2 value for DMA indicates an ionization in solution with the

displacement of chloride: $SbCl_3 \cdot DMA + DMA$ $\rightleftarrows [SbCl_2 \cdot 2DMA]^+ + Cl^-$. These results corroborate with that found in the conductance titrations, where DMA presents a higher conductance in comparison with other ligands. This behaviour also affects the interaction of $SbBr_3$ and DMA, where the K_1 value suggests the presence of ionic species in solution due to autocomplex formation: $2SbBr_3 \cdot DMA \rightleftarrows [SbBr_22DMA]^+ + [SbBr_4]^-$. A decrease of this constant is observed with DMF and TMU; such results indicating the predominance of the formation of the adduct: $SbBr_3 + L \rightleftarrows SbBr_3 \cdot L$. In examining K_2 for this system, higher values are shown for TMU and DMF. The displacement of bromide for these bases can be suggested as: $SbBr_3 \cdot L + L \rightleftarrows [SbBr_2 \cdot 2L]^+ + Br^-$. The lowest K_2 value for DMA favours an equilibrium in the course of adduct formation $SbBr_3 \cdot DMA \cdot + DMA$ $\rightleftarrows SbBr_3 \cdot 2DMA$.

The equilibrium constants involving the ligands and SbI_3 are all large in value (Table 4). The first species formation suggests that it might have an auto-association in solution. As previously described ionized species should prevail in solution, being more accentuated with DMA. For the second step of complexation, for all cases, an ionization occurs with exchange of ligand, with predominance of ionic species in solution. This fact is consistent with the conductometric data which show that SbI_3 presents the highest degree of conductivity among the metal halides and that DMA more easily displaces the halides from SbX_3. The conductivity order for the trihalides is $SbI_3 > SbBr_3 > SbCl_3$ and for the amides the displacement order of halide is $DMA > TMU > DMF$.

MAGNETIC AND ELECTRONIC CHARACTERIZATION OF 2:1 COPPER(II) COMPLEXES OF A SERIES OF AMINOCARBOXYLIC ACIDS

N. F. ALBANESE† and H. M. HAENDLER*

Department of Chemistry, University of New Hampshire, Durham, NH 03824, U.S.A.

Abstract—Copper(II) complexes with L-(−)-proline, pipecolinic acid, picolinic acid, anthranilic acid, 4-chloranthranilic acid, 3,5,-dichloroanthranilic acid, 4-nitroanthranilic acid, N-phenyl-anthranilic acid, and flufenamic acid anions were prepared and characterized. The copper complexes of the anions of proline, pipecolinic acid, and picolinic acid are soluble in polar solvents and display frozen solution EPR spectra with axial resonance parameters. The copper complexes of the ring-substituted anthranilates are highly insoluble or only slightly soluble in a few solvents. The EPR spectra of the copper-doped zinc(II) analogues of these complexes display various degrees of rhombicity in their EPR parameters. The N-substituted anthranilates form insoluble complexes in aqueous solution which readily dissolve in organic solvents and undergo dimerization.

The anion of anthranilic acid (o-aminobenzoic acid) is a unique ligand which forms highly insoluble complexes suitable for gravimetric determination of transition metals. Despite the insolubility of anthranilate complexes, the bis(anthranilato)copper(II) complex is pharmacologically active as an anti-inflammatory agent[2], and rhodium and other metal complexes with the anthranilate anion have unusual catalytic properties.[3]

In 1975, Lange and Haendler[4] reported the crystal and molecular structure of bis(anthranilato)copper(II). The local coordination geometry is a distorted octahedron, with two amino nitrogens and two carboxylate oxygens occupying the equatorial coordination sites in a *trans* configuration. A carbonyl oxygen from a ligand on an adjacent complex molecule occupies each axial coordination site. The polymeric, carboxylate-bridged network is further stabilized by hydrogen bonds, and undoubtedly accounts for the unusual insolubility of this complex.

A study of the copper(II) complexes with a series of aminocarboxylate ligands that are structurally related to anthranilic acid is reported here. The objective of this study is the comparison of the electronic and magnetic properties of these complexes, and the correlation of these properties with structural differences. Due to the insolubility of some of these complexes, the complexes were studied in both solution and the solid state. Further X-ray crystallographic study has been initiated.

EXPERIMENTAL

Preparation of complexes

Aqueous solutions of the ligands were prepared by dissolving the free acid in a slight excess of dilute sodium hydroxide solution and adjusting the pH to 6–7 with dilute acid. The filtered ligand solution was added to an aqueous solution of copper(II) acetate in a 2:1 ligand–metal mole ratio. The complexes, except those of L-(−)-proline and pipecolinic acid, precipitated immediately as fine powders. The prolinato and pipecolinato complexes are extremely water soluble, but were isolated by gradual addition of less polar organic solvents to the aqueous solution. The products were collected by vacuum filtration, washed, and air dried. Copper-doped zinc(II) and nickel(II) complexes were prepared in the same manner, using approx. 5 mol% copper(II) acetate in nickel (II) or zinc(II) acetate.

Reagent grade methanol and benzene were stored over 4A molecular sieves and used without further purification to prepare solutions of the complexes. Reagent grade dioxane was not pretreated. N,N'-dimethylformamide (DMF) was carefully prepurified immediately prior to use.[5]

Table 1. Ligands and corresponding complexes

Parent Ligand	IUPAC Name	Empirical Formula of Complex	Color of Solid Complex	% Composition Calculated		% Composition Observed	
				M	N	M	N
L-(−)-proline	L-pyrrolidine-2-carboxylic acid	$Cu(pro)_2 \cdot 2H_2O$	dark purple	19.4	8.5	18.7	8.2
pipecolinic acid	2-piperidine-carboxylic acid	$Cu(pip)_2 \cdot 2H_2O$	blue	17.9	7.9	17.8	7.8
picolinic acid	2-pyridine-carboxylic acid	$Cu(pic)_2$	purple	20.6	9.1	20.9	9.1

a) Nickel and zinc complexes doped with 5 mol% copper

b) Prepared by recrystallization of $Cu(panth)_2$

c) Prepared by thermal decomposition of corresponding methanol solvate

d) Prepared by recrystallization of $Cu(fluf)_2$

Hereafter, the complexes are designated by the empirical formulae listed in Table 1 with the ligand abbreviations shown.

Elemental analysis

Composition of the complexes was determined by C,H,N and metal analysis. Metal content was determined gravimetrically by the anthranilate or ethylenediamine method.[1]

Magnetic susceptibility

The magnetic susceptibility of complexes in the solid state was measured by the Gouy method.[6] Measurements were performed at room temperature in a magnetic field of 5.8 kG. The calibration constant, β, was determined using $HgCo(CNS)_4$ and checked against $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$. Susceptibilities were corrected for the temperature independent paramagnetism of the copper(II) ion ($N_\alpha = 60 \times 10^{-6}$ cgsu).

Visible spectroscopy

Solution spectra were recorded on the Cary 14 scanning spectrophotometer using matched quartz cells (1 cm pathlength) with pure solvent in the reference beam. Diffuse powder reflectance data were collected using a Beckman Model DU Quartz Spectrophotometer with reflectance attachment 2580. The reflectance was measured relative to the reflectance of magnesium carbonate.

X-Ray diffraction

X-Ray powder diffraction photographs were taken with a Philips 57.3 mm camera, and were exposed with nickel-filtered Cu K_α radiation ($\lambda = 1.5418$ Å). Samples were contained in 0.3 mm glass capillaries.

Electron Paramagnetic Resonance (EPR) spectroscopy

EPR spectra were recorded on the Varian E-4 spectrometer operating at X-band frequency (9.5 GHz) with 100 kHz field modulation. The

magnetic field was calibrated with a proton nuclear magnetic resonance gaussmeter. Diphenyl-picrylhydrazine (DPPH, $g_0 = 2.0037 \pm 0.0002$)[7] was used as a microwave frequency marker. Cylindrical quartz tubes (3 mm I.D.) were used to contain all powder samples, all dioxane and benzene solutions at room temperature, and all solutions at liquid nitrogen temperature. A quartz flat cell was used for DMF and methanol solutions at room temperature. Instrument settings were selected to avoid power saturation, overmodulation, and lineshape distortion.

EPR parameters were refined by computer simulation of spectra using a FORTRAN program for $S = \frac{1}{2}$ systems.[8] Simulations were performed with a nitrogen hyperfine interaction from two magnetically equivalent nitrogen donor atoms with couplings of $8-10 \times 10^{-4}$ cm^{-1}. Additional refinement was achieved by including various hydrogen atom hyperfine couplings of $1-4 \times 10^{-4}$ cm^{-1}.

The temperature dependence of the intensity of the spin triplet EPR signal of Cu(panth)$_2$·MeOH and Cu(fluf)$_2$·MeOH was measured with a Bruker VT2000 variable temperature controller and Bruker ER200D spectrometer. A nonlinear least-squares program was used to obtain values of $-2J$ by fitting the experimental signal intensity data to the Bleaney–Bowers equation[9]

$$\chi_m = \frac{g^2 N \beta^2}{3kT} \cdot \frac{1}{1 + \frac{1}{3}\exp(-2J/kT)} + N_\alpha$$

where the signal intensity is proportional to the molar susceptibility, χ_m.

Calculation of bonding parameters

Molecular orbital theory has been applied to the interpretation of EPR spectra of transition metal complexes. The theory and derivation of the equations that follow are discussed more completely elsewhere.[10-15]

In D_{4h} symmetry, assuming a $d_{x^2-y^2}$ ground state, the g and A values are predicted by

$$g_\parallel - 2.0023 = \frac{-8\lambda\alpha\beta_1}{\Delta E_{d_{x^2-y^2}\to d_{xy}}} \{\alpha\beta_1 - \alpha'\beta_1 S$$
$$- \alpha(1 - \beta^2)^{1/2} T(n)/2\}$$

$$g_\perp - 2.0023 = \frac{-2\lambda\alpha\beta}{\Delta E_{d_{x^2-y^2}\to d_{xz,yz}}} \{\alpha\beta - \alpha'\beta S$$
$$- \alpha'(1 - \beta^2)^{1/2} T(n)/2\}$$

$$A_\parallel = P\{\alpha^2(-K_0 - \tfrac{4}{7}) + (g_\parallel - 2.0023)$$
$$+ \tfrac{3}{7}(g_\perp - 2.0023)\}$$

where λ is the spin orbit coupling constant, which is less than the free ion value $\lambda_0 = 828$ cm^{-1}, S is the overlap integral, $T(n)$ is a function primarily of $s-p$ hybridization of ligand orbitals, P is the electron–nuclear dipole coupling term, which is less than the free ion value $P_0 = 0.36$ cm^{-1}, and $K_0 = 0.43$ is the Fermi contact term. Typical values of S and $T(n)$ are 0.076 and 0.333 for oxygen donor atoms, and 0.093 and 0.220 for nitrogen donor atoms, respectively.[11] The energies of the individual electron transitions $(\Delta E_{d_{x^2-y^2}\to dxy}$, $\Delta E_{d_{x^2-y^2}\to dxz,yz}$, etc.) were approximated by the energies from the absorption peaks in the visible spectra of the complexes in solution or in the reflectance spectra of the complexes as polycrystalline solids. The so-called bonding parameters are the mixing coefficients of the molecular orbital wavefunctions constructed by taking linear combinations of ligand atomic orbitals and metal 3d orbitals. The primed symbols refer to ligand antibonding orbitals, and the unprimed symbols to metal antibonding orbitals. Normalization of orbitals yields $\alpha^2 + \alpha'^2 = 1$ for in-xy-plane σ-bonding orbitals (neglecting overlap), $\beta_1^2 + \beta_1'^2 = 1$ for in-xy-plane π-bonding orbitals, and $\beta^2 + \beta'^2 = 1$ for out-of-xy-plane π-bonding orbitals. When α^2, β_1^2, or β^2 is equal to one, bonding in the corresponding orbital is ionic; values of 0.5 indicate that bonding is covalent. The degree of covalency can be used to compare the molecular structure of a series of related complexes in similar media.

When xy-anisotropy in g is observed, the above equations must be replaced by the ones appropriate for crystal field symmetries lower than D_{4h}. In D_{2h} symmetry the in-xy-plane anisotropy arises from splitting of the d_{xz} and d_{yz} orbital energy levels, while in C_{2v} symmetry the anisotropy is also due to mixing of $d_{x^2-y^2}$ and d_{z^2} orbital character. The equations which predict the g and A values are[11,12]

$$g_z - 2.0023 = \frac{-8\lambda\alpha^2\beta_1^2(\cos^2\delta)}{\Delta E_{d_{x^2-y^2}\to d_{xy}}}$$

$$g_y - 2.0023 = \frac{-2\lambda\alpha^2\beta^2(\cos\delta + \sqrt{3}\sin\delta)^2}{\Delta E_{d_{x^2-y^2}\to d_{xz}}}$$

$$g_x - 2.0023 = \frac{-2\lambda\alpha^2\gamma^2(\cos\delta - \sqrt{3}\sin\delta)^2}{\Delta E_{d_{x^2-y^2}\to d_{yz}}}$$

$$A_z = P[-K\alpha^2 - (\tfrac{4}{7})\alpha^2(\cos 2\delta) + (\tfrac{3}{7})\lambda\alpha^2\gamma^2(\cos 2\delta$$
$$+ (\sqrt{3}/3)\sin 2\delta)/\Delta E_{yz} + (\tfrac{3}{7})\lambda\alpha^2\beta^2(\cos 2\delta$$
$$- (\sqrt{/3})\sin 2\delta)/\Delta E_{xz} + 8\lambda\alpha^2\beta_1^2$$
$$\times (\cos^2\delta)/\Delta E_{xy}]$$

where β^2 and γ^2 are the bonding parameters for out-of-xy-plane π-bonding via the d_{xz} and d_{yz} orbitals, respectively, and $\cos \delta$ and $\sin \delta$ are coefficients for $d_{x^2-y^2}, d_{z^2}$ orbital mixing. In D_{2h} symmetry $\cos \delta = 1$ and $\sin \delta = 0$.

The bonding parameters were calculated by an iterative method. A $d_{x^2-y^2}$ ground state was assumed in all cases. All calculations employed $\lambda_0 = 828 \, \text{cm}^{-1}$ because it is difficult to predict the extent of reduction of the spin orbit coupling constant. If no xy-anisotropy in g was observed, the equations for D_{4h} symmetry were used. If xy-anisotropy in g was observed, the equations for C_{2v} symmetry were used, starting with $\cos \delta = 1$. If β_1^2, β^2, or γ^2 was greater than one, the degree of mixing was increased by small increments to obtain the best fit.

RESULTS

Stoichiometry of the complexes

Complexes with a 2:1 ligand–metal mole ratio were prepared. The results of elemental analysis for N and metal content are in agreement with the empirical formulae listed in Table 1. IR spectra of the complexes in Nujol mulls between KBr plates were recorded on a grating spectrophotometer. The amine stretching vibrations of every copper, nickel, and zinc complex were shifted to lower frequency relative to the corresponding free acid, demonstrating that coordination through nitrogen occurs in each complex.

X-Ray powder patterns

The diffraction data are compiled elsewhere.[16] For each ligand it was found that the powder patterns of the corresponding copper and zinc complexes were different. The Ni(panth)$_2$ complex, as prepared, is amorphous. The powder patterns of Ni(anth)$_2$ and Zn(anth)$_2$ are the same, but the powder pattern of Ni(fluf)$_2$ differs from that of Zn(fluf)$_2$.

Single crystals of bis(pipecolinato)copper(II) dihydrate have been grown and a full X-ray structure determination is in progress.

Solubility

The solvents used to test solubility were DMF, methanol, dioxane, and benzene, listed in decreasing order of dielectric constant. Cu(canth)$_2$, like Cu(anth)$_2$, is insoluble in each of these solvents, whereas Cu(pro)$_2 \cdot 2H_2O$, Cu(pip)$_2 \cdot 2H_2O$, and Cu(pic)$_2$ are soluble only in methanol, DMF, and water. Cu(panth)$_2$ and Cu(fluf)$_2$ are insoluble in water, but soluble in all the organic solvents. The complexes Cu(panth)$_2 \cdot$MeOH and Cu(fluf)$_2 \cdot$MeOH were obtained from methanol solutions of

Cu(panth)$_2$ and Cu(fluf)$_2$, respectively. Cu(d-canth)$_2 \cdot 2H_2O$ and Cu(nanth)$_2$ were slightly soluble in DMF and dioxane, but not in methanol or benzene.

Visible spectra

The spectral data are listed in Table 2. Cu(pro)$_2 \cdot 2H_2O$, Cu(pip)$_2 \cdot 2H_2O$, and Cu(pic)$_2$ absorb around 600 nm in DMF and methanol solution. All the other soluble complexes absorb at much longer wavelengths. The spectra of the benzene and dioxane-soluble complexes are dominated by an intense absorption below 400 nm which is presumably a ligand band or ligand–metal charge transfer band. A shoulder on this intense band is observed near 400 nm for Cu(panth)$_2$ in dioxane and Cu(fluf)$_2$ in benzene. Powder reflectance data are also listed in Table 2. Well-resolved peaks at 675, 625, and 575 nm were observed for Cu(pro)$_2 \cdot 2H_2O$. The reflectance data of the dimeric complexes, Cu(panth)$_2 \cdot$MeOH and Cu(fluf)$_2 \cdot$ MeOH, exhibit peaks near 675 and 475 nm. The other complexes exhibit a single broad peak in their reflectance data.

Magnetic susceptibility

The magnetic susceptibility data for the polycrystalline complexes are summarized in Table 3. The magnetic moments of the copper complexes are in the range 1.8–2.0 B.M., excluding Cu(p-anth)$_2 \cdot$MeOH and Cu(fluf)$_2 \cdot$MeOH. The observed moment of Cu(anth)$_2$ falls between values of 1.84[17] and 2.0 B.M.[18] previously reported for this complex. The reduced room temperature magnetic moments of Cu(panth)$_2 \cdot$MeOH and Cu(fluf)$_2 \cdot$MeOH are indicative of spin–spin coupling and suggest that these complexes have a dimeric structure similar to that of copper(II) acetate, which has a room temperature magnetic moment of 1.39 B.M.[19] Grigor'eva et al.[20] observed room temperature magnetic moments of 1.35 and 1.40 B.M., respectively, for N - 2,3 - dimethyl - phenyl - anthranilate and flufenamate complexes isolated from aqueous DMF solution.

The observed magnetic moments of Ni(anth)$_2$ and Ni(panth)$_2$ fall within the range of values typically observed for nickel(II) complexes with octahedral geometry (i.e. 2.9–3.4 B.M.).[21] Magnetic moments of 3.2 and 3.4 B.M. were reported previously for Ni(anth)$_2$.[18,22] Although the observed magnetic moment of Ni(fluf)$_2$ is lower than those typically observed for complexes with tetrahedral or octahedral geometry, square planar complexes are normally diamagnetic.[21] Dimerization or polymerization leading to antiferromagnetic spin coupling is suggested, but addi-

EPR spectra of the undiluted powders

The parameters from the room temperature EPR spectra of the magnetically undiluted polycrystalline copper(II) complexes are summarized in Table 4. According to the classification scheme of Hathaway and Billing,[11] the spectra of $Cu(pip)_2 \cdot 2H_2O$, $Cu(panth)_2$, and $Cu(fluf)_2$ are isotropic whereas $Cu(pro)_2 \cdot 2H_2O$ has a lineshape corresponding to an "exchanged-coupled" spectrum. Sastry and Sastry[23] demonstrated that a small ferromagnetic exchange coupling occurs in crystalline $Cu(pro)_2 \cdot 2H_2O$ with $2J = +0.108 \, cm^{-1}$. The spectrum of $Cu(dcanth)_2 \cdot 2H_2O$ has rhombic parameters. In the other complexes which have $g_1 \geq 2.04$, the copper atom is probably in an axially symmetric environment of square planar or elongated octahedral geometry. The observed g-values of $Cu(anth)_2$ are in excellent agreement with values reported by Ismailov.[17]

The EPR spectra of $Cu(fluf)_2 \cdot MeOH$ and $Cu(p-anth)_2 \cdot MeOH$ exhibit zero field splitting (Fig. 1) characteristic of the triplet state of copper(II) dimers. A low intensity signal near 3200 G that appears at low temperature is the singlet state absorption of residual monomer species. Only four principal $\Delta m_s = \pm 1$ resonance fields are expected in the triplet spectrum when the rhombic component of the zero field splitting is zero.[24] The four resonance fields in each spectrum are $H_{Z1} = 0$, $H_{X1} = 378$, $H_{X2} = 4622$ and $H_{Z2} = 5757G$ for $Cu(fluf)_2 \cdot MeOH$, and $H_{Z1} = 0$, $H_{X1} = 541$, $H_{X2} = 4622$ and $H_{Z2} = 5465G$ for $Cu(panth)_2 \cdot MeOH$. Averaged values of D calculated from[24]

Table 4. Powder g-values

Complex	g_1	g_2	g_3
$Cu(pro)_2 \cdot 2H_2O$	2.06	2.17	-
$Cu(pip)_2 \cdot 2H_2O$	2.11	-	-
$Cu(pic)_2$	2.06	2.17	-
$Cu(anth)_2$	2.07	2.25	-
$Cu(canth)_2$	2.07	2.25	-
$Cu(dcanth)_2 \cdot 2H_2O$	2.06	2.19	2.31
$Cu(nanth)_2$	2.05	2.26	-
$Cu(panth)_2$	~2.1	-	-
$Cu(fluf)_2$	~2.1	-	-

a) Estimated uncertainty: ± 0.005.
Fig. 1. EPR spectra of polycrystalline $Cu(p-anth)_2 \cdot MeOH$ (A), and $Cu(fluf)_2 \cdot MeOH$ (B) at liquid nitrogen temperature.

$$H_{X1}^2 = (g_e/g_x)^2(H_0 - D/(g_e\beta))H_0$$

$$H_{X2}^2 = (g_e/g_x)^2(H_0 + D/(g_e\beta))H_0$$

$$H_{Z1}^2 = (g_e/g_z)^2(H_0 - D/(g_e\beta))^2$$

$$H_{Z2}^2 = (g_e/g_z)^2(H_0 + D/(g_e\beta))^2$$

are $0.30 \pm 0.03 \, cm^{-1}$ for $Cu(panth)_2 \cdot MeOH$, and $0.28 \pm 0.01 \, cm^{-1}$ for $Cu(fluf)_2 \cdot MeOH$ using $g_x = g_y = 2.07$, $g_z = 2.34$ (assumed values) and $hv = 0.3195 \, cm^{-1}$ (from the DPPH frequency mark).

The magnitude of the zero field splitting is temperature independent, but at liquid nitrogen temperature, the copper hyperfine structure in the H_{Z1} and H_{Z2} resonance fields is well-resolved. The seven-line pattern arises from the interaction of two equivalent $I = \frac{3}{2}$ copper nuclei with the triplet state ($S = 1$) of the two unpaired electrons in the dimer unit. The observed splitting is about $70-80G$ or roughly $a_\parallel/2$. The singlet–triplet energy separation ($-2J$) obtained from the least-squares non-linear regression fit of the temperature dependence of the signal amplitude of the H_{X2} resonance field to the Bleaney–Bowers equation is $213 \, cm^{-1}$ for $Cu(fluf)_2 \cdot MeOH$, and $375 \, cm^{-1}$ for $Cu(p-anth)_2 \cdot MeOH$ (Fig. 2). Grigor'eva et al. reported $-2J = 240 \, cm^{-1}$ for the flufenamate complex.[20]

EPR spectra of dilute solutions

EPR parameters from spectra of dilute solutions are listed in Table 5. In methanol and DMF solution at room temperature, the prolinato, pipecolinato, and picolinato complexes display the typical isotropic spectrum of copper with four hyperfine lines arising from the interaction of the

a) Solutions about 1.5×10^{-3} M. Values of g and A refined by computer simulation. Estimated uncertainty in g-values is $\pm$ 0.001. The copper hyperfine couplings are reported as isotope-weighted averages (69.09% ^{63}Cu, 30.91% ^{65}Cu) in units of 10^{-4} cm^{-1}. Estimated uncertainty in A_z is $\pm$ 0.5×10^{-4} cm^{-1}; greater incertainty in Ax, Ay.

b) From spectra recorded at room temperature ($\sim$22°C).

c) From spectra recorded at liquid nitrogen temperature.

d) See text for definitions.

e) Approximate values not refined by simulation.

unpaired electron with the copper nucleus. The corresponding anisotropic frozen solution spectra have axial parameters (Table 5). Axial symmetry is most commonly observed for copper(II) complexes, especially with amino acids.[11,25-28] For these three complexes, the solvent has a more pronounced effect on the g and A values than does the ligand. Ammeter et al.[29] described the dependence

of g-values, hyperfine coupling constants, and electron transition energies on the host lattice for bis(picolinato)copper(II).

The room temperature EPR spectra of Cu(n-anth)$_2$ and Cu(dcanth)$_2$·2H$_2$O in DMF are broadened, and the copper hyperfine structure is poorly resolved. The frozen solution spectrum of the dichloroanthranilate complex suggests the pres-

ence of more than one species. The frozen solution spectrum of the nitroanthranilate complex more closely resembles the spectra of the prolinate, pipecolinate, and picolinate complexes than that of the dichloroanthranilate complex.

The room temperature EPR spectra of CuL_2 and $CuL_2 \cdot MeOH$ ($L =$ panth or fluf) complexes in methanol and DMF are severely broadened. In benzene and dioxane, a broad absorption in the $1500-2000G$ region probably arises from forbidden transitions of loosely coupled dimers. Relatively sharp features near $3200G$ in the dioxane spectra suggest that monomers are also present. At liquid nitrogen temperature, the frozen solution spectra of these complexes in DMF, methanol, and dioxane are the typical anisotropic spectra characteristic of monomeric copper(II) complexes. In frozen benzene solution, a broad isotropic signal near $3130G$ was observed for the N-phenylanthranilate complex, whereas no signal could be detected for the flufenamate complex. Evidently, association of complex molecules occurs in solution, but solvents with coordinating ability can disrupt aggregate or dimer formation.

EPR spectra of copper-doped zinc(II) complexes

Parameters from the EPR spectra of the polycrystalline copper-doped zinc(II) host complexes at liquid nitrogen temperature are listed in Table 6. The degree of xy-anisotropy is greatest for the dichloroanthranilate and nitroanthranilate complexes. The degree of $d_{x^2-y^2} - d_{z^2}$ orbital mixing appears to be the greatest for the nitroanthranilate complex. The spectra from the $Zn(panth)_2$ and $Zn(fluf)_2$ host complexes are different in overall appearance compared to the other anthranilates. The linewidths are narrower, the xy-anisotropy is small or zero, $g_\| > 2.4$, and σ-bonding orbitals have reduced covalent character ($\alpha^2 \sim 0.82$ vs

$\alpha^2 \sim 0.75$ for the anthranilates). In-xy-plane π-bonding has very little covalent character in all these complexes ($\beta_1^2 \sim 1.0$).

DISCUSSION

Complexes described in this series can be separated into the following categories

(1) *Five-membered chelate ring structures.* These complexes which include $Cu(pro)_2 \cdot 2H_2O$, $Cu(pip)_2 \cdot 2H_2O$, and $Cu(pic)_2$, bear little relation to $Cu(anth)_2$ and the other complexes in solubility and spectral characteristics. The EPR parameters of these complexes are axially symmetric with $g_\perp = 2.05-2.06$, $g_\| = 2.25-2.26$, $A_\| = 178-191 \times 10^{-4}\,cm^{-1}$ and $\alpha^2 = 0.81-0.85$, $\beta_1^2 = 0.78-0.87$ and $\beta^2 = 0.66-0.76$. Visible absorption maxima are around $600\,nm$ in solution. X-Ray crystallographic studies of $Cu(pic)_2 \cdot 2H_2O$, in which the water molecules are interstitial, and of $Cu(pro)_2 \cdot 2H_2O$ have shown that the local coordination geometry of each complex in the solid state is elongated octahedral.[30,31] However, the axial bond lengths in these complexes are much longer than the axial bond length in $Cu(anth)_2$.[4]

(2) *Monomeric six-membered chelate ring structures.* The variously substituted anthranilate ligands form complexes of this type, but the N-substituted anthranilates also form dimeric complexes. With the exception of $Cu(nanth)_2$ in DMF which has $g_\| = 2.282$ and thus probably has elongated octahedral geometry as do the prolinate, pipecolinate, and picolinate complexes, these complexes have $g_\| > 2.3$, $A_\| > 170 \times 10^{-4}\,cm^{-1}$ and exhibit various degrees of xy-anisotropy. Two types of coordination geometry are evident.

(a) *Distorted tetrahedral.* This geometry probably occurs for the dichloroanthranilate, N-phenylanthranilate, and flufenamate complexes in solution. These complexes are characterized by

Table 6. EPR parameters for copper(II) in zinc(II) host complexes

Complex	EPR Parameters[a]						Bonding Parameters[b]				
	g_x	g_y	g_z	A_x	A_y	A_z	α^2	β_1^2	β^2	γ^2	$\cos\delta$

a) From spectra of polycrystalline samples recorded at liquid nitrogen temperature. Parameters refined by computer simulation. Estimated uncertainty in g is ± 0.001. Copper hyperfine couplings are reported as isotope-weighted averages in units of $10^{-4}\,cm^{-1}$. Estimated uncertainty in A_z is $\pm 0.5 \times 10^{-4}\,cm^{-1}$. Greater uncertainty in A_x and A_y.

b) See text for definitions.

$g_\parallel = 2.36\text{–}2.38$, $A_\parallel = 143\text{–}164 \times 10^{-4}\,\text{cm}^{-1}$, and exhibit a pronounced solvent dependency in their EPR parameters. The EPR parameters show xy-anisotropy when the complexes are in MeOH and dioxane solution, but not in DMF. The N-phenyl-anthranilate and flufenamate complexes in dioxane show greatly reduced covalent character in both σ- and π-bonding orbitals compared to all the other complexes in Table 5. Numerically, the shift to larger $g_\parallel$ values observed for these complexes is related to their smaller electron transition energies relative to the prolinate, pipecolinate, and pico-linate complexes.

The $d_{x^2-y^2}$ ground state is not easily distinguished from the d_{xy} ground state in C_4, C_{4h}, D_4, D_{4h}, C_{4v}, or D_{2d} symmetry on the basis of EPR parameters without the benefit of polarized single-crystal electronic spectra. However, the visible and EPR spectral data are consistent with distorted tetrahedral geometry for these complexes. The geometry is probably more nearly square planar or elongated octahedral when DMF is the solvent. The weaker donor solvents, MeOH and dioxane, probably allow twisting of bond angles in the equatorial plane to a more tetrahedral arrangement. The tetrahedral distortion is more evident in dioxane than in MeOH.

(b) *Rhombically-distorted elongated octahedral*. This geometry probably occurs in the zinc host complexes with the anthranilate, chloro-anthranilate, dichloroanthranilate, and nitro-anthranilate ligands. The EPR parameters of the copper(II) ion in these host environments are strongly dependent on the nature of the ligand substituents, and show pronounced xy-anisotropy, some degree of $d_{x^2-y^2} - d_{z^2}$ orbital mixing, little covalent character in the in-xy-plane π-bonding orbitals, and variable covalent character in the out-of-xy-plane π-bonding orbitals. This degree of variation in the EPR parameters would not be expected if the octahedral coordination environment was completed by "axial" coordination of carboxylate oxygens from adjoining complex molecules as it is in Cu(anth)$_2$.[4] Thus, the chloro and nitro substituents are probably involved in coordination, although whether they occupy "axial" or "equatorial" sites, and whether *cis* or *trans* configurations occur must be determined by full X-ray crystal and molecular structure analysis.

(3) *Dimeric structures*. The N-substituted an-thranilates form dimeric as well as monomeric complexes in solution and in the solid state. The Cu(panth)$_2$·MeOH and Cu(fluf)$_2$·MeOH complexes in the solid state exhibit zero field splittings in their triplet EPR spectra and exchange energies comparable to those of copper(II) acetate and

other carboxylate-bridged dimers.[19,32] It was suggested in earlier studies that the dimer might be held together by bridging hydrogen bonds between the amine group and the carboxylate oxygen (i.e. $-\text{N-H}\text{---O=C-}$).[20,33–35] However, hydrogen bond-bridged dimers of copper(II) complexes with amino alcohols exhibit small exchange energies ($-2J < 100\,\text{cm}^{-1}$) and large copper–copper separations ($> 5\,\text{Å}$).[36] X-ray crystallography showed that the copper–copper separation in CuL$_2$·DMF (HL = N-(2,3-dimethylphenyl)-anthranilic acid) is $2.613\,\text{Å}$.[37,38]

The EPR parameters of the copper(II) ion in the zinc host complexes Zn(panth)$_2$ and Zn(fluf)$_2$, are distinct in that $g_\parallel > 2.4$. Whereas the copper(II) ion in zinc(II) acetate has $g_\parallel = 2.344$,[39] the typical range of $g_\parallel$ values for dimeric copper(II) carbox-ylates is $2.32\text{–}2.42$.[32] Thus, the zinc complexes are probably carboxylate-bridged dimers. Possible structures for the water-insoluble monomeric Cu(panth)$_2$ and Cu(fluf)$_2$ complexes and the corresponding nickel(II) complexes are not obvious from the data presented above.

CONCLUSION

The copper(II) complexes of ligands which are structurally related to anthranilic acid display a wide variation in solubility behaviour and magnetic characteristics. Further X-ray crystallographic work is warranted.

Abstract—Extracts with tri-*n*-octylammonium chloro complexes of Cu(II), Zn(II) and Co(II) of various compositions, including the *N*-deuterated compounds, were prepared and investigated by IR spectroscopy and conductivity measurements. Besides the well-known 2:1-complexes $(TOAH^+)_2MCl_4^{2-}$, for which new assignments of νNH frequencies are given, complexes with a stoichiometric ratio TOA:M > 2 were found. Their cations contain the groups $(TOA\ldots Cl\ldots HTOA)^+$ and $TOAH^+$ and they are supposed to be 3:1-complexes $(TOA\ldots Cl\ldots HTOA)^+ TOAH^+ MCl_4^{2-}$. The IR spectrum of the 1:1-complex $TOAH^+ CuCl_3^-$ is given. The occurrence of the analogous 1:1-complex $TOAH^+ ZnCl_3^-$ could not be detected under the preparative conditions used.

In preceding studies[1,2] the occurrence and conditions of formation of various extractable halo complexes in the system tri-*n*-octylammonium chloride/C_6H_6 or $C_6D_6 - MX_3 - HX[M = In(III)$, Fe(III) or Ga(III); X = Cl, Br or I] were investigated by means of loading experiments, IR spectroscopic investigations and measurements of the conductivity of the metal bearing extracts.

With the knowledge derived from these studies work was extended to the corresponding chloro complexes of Cu(II), Zn(II) and Co(II).

Previous solvent extraction studies[3–7] on such systems (or similar ones) stated the formation of 2:1-complexes $(R_3NH^+)_2MCl_4^{2-\dagger}(M = Cu$, Zn or Co). Aguilar *et al.*[8,9] proposed in the case of Zn besides the 2:1-complex a 3:1-complex $(R_3NHCl)_3ZnCl_2$, based on distribution data treated by means of the LETAGROP program. IR spectroscopic investigations on the 2:1-complexes

were performed with the aim to elucidate their structure.[4,5,10–12] However, the published data concerning the positions and assignments of the νNH frequencies are uncertain or contradictory and therefore reliable conclusions cannot be drawn.

The present study involves the investigation of Cu(II), Zn(II) or Co(II) bearing TOA extracts of various compositions by IR spectroscopy and conductivity measurements to determine the type of the complexes formed. For the sake of completion and extension of the arguments, analogous extracts were prepared starting from the corresponding *N*-deuterated systems (among them also Fe(III) bearing extracts).

EXPERIMENTAL

The reagents $CuCl_2.2H_2O$, $ZnCl_2$, $CoCl_2.6H_2O$, HCl and C_6H_6 were of analytical grade. Deuterium chloride (20% DCl in D_2O, 99.9%) was supplied by VEB Berlin–Chemie, Berlin–Adlershof. Quality and supply of the other reagents used are given elsewhere.[1,2]

The preparation of the extracts and the measurements of the IR spectra and conductivities were carried out as described earlier[1,2] The distribution coefficients D_M were determined using ^{64}Cu, ^{65}Zn and ^{60}Co, respectively. The extracts prepared for IR spectroscopy and their preparation conditions are compiled in Table 1. In most cases these extracts were duplicated with benzene and deuterobenzene as diluents, written in Table 1 "C_6H_6/C_6D_6". In the deuterated systems (aqueous phases with D_2O and DCl) $CuCl_2$, $ZnCl_2$ and

$CoCl_2$ were used as anhydrous salts. The extracts for the conductivity measurements were prepared in the same or an analogous way, respectively, but with benzene as diluent only.

IR SPECTRA

The IR spectra of the extracts were taken in the range 1800–3800 cm^{-1}. They are given in Figs. 1 and 2. The wave numbers of the νNH and νND absorptions are summarized in Table 2.

The νNH bands of the 2:1-complexes
Fig. 1. IR spectra of the extracts (the numbers refer to Table 1). (a) 1, 7, 15. (b) ···· 2; ———8, 17. (c) ———3; ····· 4. (d) ———9; ····· 10. (e) 5, 11, 18. (f) 6, 12, 19. (g) ——— 20; ····· taken from (1). (h) ——— 21; ···· taken from (1).

$(TOAH^+)_2MCl_4{}^{2-}$ (M = Cu, Zn and Co, resp.) appear in the spectra uniformly as a double peak at $2740/2790\ cm^{-1}$, moreover, an evident broadening of the νCH bands in the short wave region at $3000\ cm^{-1}$ is observed. The IR spectra of the deuterated complexes $(TOAD^+)_2MCl_4{}^{2-}$, however, show only a single νNH band at $2180\ cm^{-1}$ (Zn, Co) and $2190\ cm^{-1}$ (Cu), respectively. Hence it follows that the νNH band in the spectra of the non-deuterated complexes is perturbed by over-

lapping with absorptions of the octyl groups, and thus the peaks occurring in this region do not reflect true shape and position of the νNH band. The peak at $2740\ cm^{-1}$ has to be considered as a coincidental amplification by a vibration which is to be assigned to the octyl groups, because it occurs in the IR spectrum of the free TOA, too. Thus the assignments given in earlier work[10] could not be confirmed.

The spectra of the 2:1-complexes show very weak absorptions at 3520, 3635 and $3680\ cm^{-1}$ indicating very small quantities of water in the extracts. The assignments for such absorptions were given in Ref.[2]

The IR spectra of the extracts with a stoichiometry which approximates that of the 1:1-complexes of Cu and Zn respectively, exhibit essential differences. In the Cu bearing non-deuterated extract the νNH band, in spite of the nearness to the strong νCH absorptions, is found at $3015\ cm^{-1}$, i.e. in the region expected for an 1:1-complex. The corresponding band of the deuterated extract is the νNH band at $2260\ cm^{-1}$. Its

+) Apparent frequency; ++) 3:1-complex supposed; +++) Taken from /1/

position is clearly distinguished from the position of the corresponding νND band of the 2:1-complex of Cu (2190 cm^{-1}). Absorptions between 2700 and 2800 cm^{-1} point to considerable quantities of 2:1-complex in the extract. In general, however, these IR spectra demonstrate the existence of the 1:1-complex TOAH$^+$CuCl$_3^-$ (or TOAD$^+$CuCl$_3^-$).

The Zn bearing extracts show a different picture. Their νNH and νND absorptions coincide almost entirely with those of the corresponding 2:1-complexes, although the stoichiometric ratio TOA:M of the extracts approximates 1(0.25 M TOA; 0.20M Zn$_{(org)}$). Absorptions corresponding to the 1:1-complex of Cu are detectable only as broadenings of the νNH bands and the νND band respectively, when a direct comparison of the spectra is performed. It is obvious, that in the case of Zn the equilibrium of the reaction

$(\text{TOAH}^+)_2\text{MCl}_4^{2-}{}_{(org)} + \text{MCl}_{2(w)} \rightleftharpoons 2\text{TOAH}^+ \text{MCl}_3^-{}_{(org)}$

is shifted strongly to the left side of the equation. A simultaneous extraction of ZnCl$_2$.nH$_2$O, indicated by the occurrence of a νOH band at 3460 cm^{-1}, suggests a complex stoichiometry of approximately 1:1. To elucidate the question, whether there are additional complexes with molar ratio TOA:M > 2 besides the well-known 2:1-complexes of Cu, Zn and Co or not, extracts with a stoichiometric ratio TOA:M = 3:1 were

prepared. The IR spectra of the non-deuterated extracts show, besides the absorption at 2790 cm^{-1}, the three peaks of the νNH vibration at 2500 (as shoulder), 2558 and 2615 cm^{-1}. These three peaks appear with almost constant frequencies in the IR spectra of all complexes comprising the group (TOAH... Cl... HTOA)$^+$.[1,2] This points to the existence of a further complex, which must comprise that group. The increased absorption in the region about 2400 cm^{-1} (compared with the IR spectra of the 2:1-complexes) and a weak νOH band at 3420 cm^{-1} indicate the presence of quantities of the simple salt TOAH$^+$Cl$^-$.H$_2$O. This involves that equimolar quantities of 2:1-complex are present due to the extract stoichiometry 3:1.

Figure 2 shows the IR spectra of Zn bearing extracts with molar ratios TOA:Zn 2:1, 3:1 and 4:1. Carbon tetrachloride was used here as diluent. With increasing excess of TOA the intensity of the νNH band in the region about 2500–2615 cm^{-1} increases, too. The extract with the stoichiometry 4:1 exhibits an even greater increase in the absorption in the region about 2400 cm^{-1}, compared with the spectrum of the extract 3:1. Moreover, νOH bands of associated and free H$_2$O respectively appear distinctly at 3420 and 3680 cm^{-1}. This indicates the presence of considerable quantities of TOAH$^+$Cl$^-$.H$_2$O in the extract.

Going back to Fig. 1 there can be seen in the spectra of the deuterated extracts with the stoichiometric ratio 3:1 that, apart from the weak shoulder at 2500 cm^{-1}, the νNH bands at 2558 and 2615 cm^{-1} are uniformly shifted to 1998 and 2043 cm^{-1} (νND). Thus it is clearly shown, that these peaks indeed mutually represent the group (TOAH...Cl...HTOA)$^+$ or (TOAD...Cl...DTOA)$^+$ and belong together. The absorption at 2170 cm^{-1}, which is likewise to be assigned to a νND vibration, corresponds to the νNH absorption at 2790 cm^{-1} in the spectrum of the non-deuterated extract.

The Fe(III) bearing extracts confirm the assignments stated for the νNH and νND bands. There is a good agreement between the νNH/νND ratios of the 1:1-complexes of Fe(III) and Cu. The same holds for the 2:1-complex of Fe(III) on the one hand and for the complexes of Cu, Zn and Co comprising the group. (TOAH...Cl...HTOA)$^+$ or (TOAD...Cl...DTOA)$^+$ on the other. The shift of the νNH band of the 2:1-complex of Fe(III) with deuteration shows the correlation of the peaks of this band very distinctly.

CONDUCTIVITY MEASUREMENTS

Earlier[13] it was pointed out for the case of some trivalent metals that there is an unambiguous correlation between the values of the specific conductivity κ (and of the dielectric constant ϵ, too) and the molar ratio TOA:Metal$_{(org)}$, which offers an additional possibility to characterize and identify the extracted species. Thus κ values of the extracts were also determined in the present work. They are given in Table 3.

The measured values of κ show a distinct decrease in the order Fe(III)-complexes > 3:1-complexes > 2:1-complexes. The top values for Fe(III) are not surprising, because it is well known, that complexes with such univalent anions exhibit essentially higher κ values than corresponding complexes with bivalent anions.[13] The values of the extracts with the stoichiometry 3:1 are clearly differentiated from those of the 2:1-complexes thus indicating another kind of complex. A striking difference is observed among the 2:1-complexes, where the κ value of the Cu-complex considerably exceeds the nearly equal values of the Zn- and Co-complexes. The κ value of the extract with the 1:1-complex of Cu is somewhat higher than that of the 2:1-complex, but does not reach the value of the 1:1-complex of Fe(III). Therefore it may be supposed that this extract consists of a mixture of 1:1- and 2:1-complex. This assumption agrees with the IR spectroscopic findings. The extract which should contain the 1:1-complex of Zn has a κ value somewhat lower than the value of the 2:1-complex thus giving no evidence for the existence of the 1:1-complex.

CONCLUSION

It has been shown, that in addition to the well-known 2:1-complexes (TOAH$^+$)$_2$MCl$_4^{2-}$ of Cu, Zn and Co complexes bearing these metals can occur, which exhibit an increased stoichiometric ratio TOA:M and include the group (TOAH...Cl...HTOA)$^+$. The occurrence of this group and the simultaneously detectable TOAH$^+$-group in extracts with the stoichiometric ratio 3:1 are certainly not complete evidence for the existence of a defined 3:1-complex with the composition (TOAH...Cl...HTOA)$^+$TOAH$^+$MCl$_4^{2-}$. On the other hand Aguilar *et al.*[8,9], as already mentioned, proposed 3:1-complexes as a result of their work on the system R$_3$NH$^+$Cl$^-$/C$_6$H$_6$ − ZnCl$_2$ − LiCl − HCl (R = *n*-hexyl, *n*-octyl and *n*-dodecyl, resp.) with Zn concentrations from tracer amounts

‡Taken from[1]

up to 0.0135 M. The increasing concentration of $(TOAH \ldots Cl \ldots HTOA)^+$-groups when going from the 3:1 to the 4:1 ratio is the result of the equilibrium between $TOAH^+$, $TOAH^+Cl^-$ and $(TOAH \ldots Cl \ldots HTOA)^+$ and does not necessarily show a distinguishable 4:1-complex.

A striking constancy of the ratios $\nu NH/\nu ND$ is observed for all complexes investigated. Complexes with weak H bonds ($\nu NH > 3000\ cm^{-1}$) exhibit the ratio 1.33–1.34, such with medium strong H bonds ($\nu NH\ 2500$–$2800\ cm^{-1}$) 1.28 (see ref.,[14] due to the well-known weakening of the H-bond by deuteration. This is valid not only for the complexes with Cu, Zn, Co and Fe(III), but also for corresponding complexes bearing the elements Sn(II, IV) and Sb(III, V).[15] Knowing the constancy of these ratios the apparent frequencies of the νNH vibration of some complexes at $2790\ cm^{-1}$ can be corrected into true frequencies: Cu-2:1-complex $2800\ cm^{-1}$; Zn- and Co-2:1-complex $2790\ cm^{-1}$; Cu-, Zn- and Co-3:1-complex $2780\ cm^{-1}$. The reasons for the essentially higher κ value of the Cu-2:1-complex (in comparison with those of the Zn- and Co-2:1-complexes) are not clear. The differences of the strength of the H bonds as shown by the νNH frequencies are insignificant. Statements on the anion structures in complexes of the type $(R_3NH^+)_2MCl_4^{2-}$ ($CuCl_4^{2-}$: D_{2d}[4], C_{2v}[5]; $ZnCl_4^{2-}$: not clear; $CoCl_4^{2-}$: C_{2v}[5], cannot verify the particular behaviour of the Cu-2:1-complex, too.

REARRANGEMENT OF 2-(2-THIENYL)BENZOTHIAZOLINE IN THE PRESENCE OF THIOPHILIC METAL IONS

L. F. CAPITÁN-VALLVEY* and P. ESPINOSA

Department of Analytical Chemistry, Faculty of Sciences, University of Granada, Granada, Spain

Abstract—2-(2-thienyl)Benzothiazoline and 2-(2-thienyl)benzothiazol have been synthesized and characterized by several techniques (IR, NMR, UV–VIS, MS) and elemental analysis. The reactions of a solution of 2-(2-thienyl)benzothiazoline with Zn, Cd, Hg(II) and Pb(II) ions have been studied. The spectral studies of the isolated complexes showed that the rearrangement of the benzothiazoline to the Schiff base, N-2-mercaptophenyl-2'-methyleneimine, had occurred. The factors influencing this rearrangement are discussed. Several complexes of 2-(2-pyridyl)benzothiazoline with Cd and Pb(II) were synthesized for purposes of comparison.

It has been well established that condensation of *o*-aminobenzenethiol with a carbonyl compound does not normally lead to the isolation of the corresponding Schiff base, but thiazoline or benzothiazoline is obtained.[1–4] However, several workers[2–13] have shown that in alkaline solution or in the presence of metal ions the cyclic structure of the above thiazoline or benzothiazoline rearranges to give Schiff base metal complexes. The role played by the metal ion in these rearrangements has been discussed by Thompson[14] and Lindoy.[15]

We are interested in the study of the complexing abilities and analytical applications of heterocyclic azomethines derived from pyridine - 2 - aldehyde, thiophen - 2 - aldehyde and pyrrol - 2 - aldehyde. Some results have been previously reported.[16–18] In this paper, we present some of the results found in the study of 2 - (2 - thienyl)benzothiazoline.

RESULTS AND DISCUSSION

Structure and spectral and thermal properties of the ligand

Condensation of *o*-aminobenzenethiol with thiophen - 2 - aldehyde in ethanol results in formation of 2 - (2 - thienyl)benzothiazoline (**I**).

The IR spectrum of (**I**) shows a band of medium intensity at 3280 cm^{-1} assignable to N–H stretching vibration[1,4,18] and an intense band at 920 cm^{-1} due to the C–S–C linkage.[19] The appearance of

these bands and the absence of v(S–H) IR absorption band in the region 2600–2550 cm^{-1} confirm the existence of benzothiazoline structure. Two bands of medium intensity at 1585 and 1545 cm^{-1} can be assigned to the thiazoline ring vibrations.

The NMR spectrum of (**I**) shows the NH proton signal as a broad signal at 4.5 ppm. No signals, even weak, of the open ring tautomer (**II**) can be detected. The other protons of (**I**) appear as a complex multiplet centered at 7.32 ppm. The integration curve is correct (1:8).

The mass spectrum of (**I**) shows the molecular peak (M˙$^{+}$) at m/e 219 (45%) and the base peak (M˙$^{+}$ − 2). Other important peaks are: 218 (60.2%), 136 (22.6%), 108 (34.4%), 83 (20.6%) and 45 (24.7%).

The thermal behaviour of (**I**) has also been studied. The DTG curve shows an endothermic peak at 96°C (melting of the compound) followed by a small exothermic effect at 127°C that was supposed to be due to the transformation in 2 - (2 - thienyl)benzothiazol (**III**) by the loss of an hydrogen molecule from (**I**) (Scheme 1).

By heating (**I**) at 127°C an intense orange crystalline compound is formed. In the IR spectrum of this compound the following was observed: (1) the absence of an absorption which can be assigned to v(N–H) mode, (2) three strong bands at 1477, 1436 and 1417 cm^{-1}, and two bands of medium intensity at 1590 and 1540 cm^{-1} (benzene and thiazol ring vibrations),[30] (3) a strong band at 913 cm^{-1}

Scheme 1.

assignable to the C–S–C linkage. The synthesis of 2 - (2 - thienyl)benzothiazol (see Experimental) and further comparison of the IR and NMR spectra of both compounds confirm our previous supposition.

The electronic spectrum of (I) (Fig. 1) shows a band at 318 nm ($\epsilon = 12210\ 1.\ mol^{-1}\ cm^{-1}$) and an inflexion (shoulder) at 255 nm ($\epsilon = 9600\ 1.\ mol^{-1}\ cm^{-1}$) which fully support the typical spectrum of the cyclic form of benzothiazoline.[21,22] The position of this band remains unchanged with the pH.

Conversion to the Schiff base form is favoured by treatment of a solution of (I) in ethanol with alkali or sodium ethoxide. The addition of base is accompanied by the appearance of an intense band in the visible region (Fig. 2). We attribute this band to absorption by the sodium salt of the rearranged form (Schiff base) of the ligand (n–π^* or π–π^* transitions of the double bond of the azomethine group). The addition of a large excess of sodium leads to an increase in intensity and a small bathochromic shift of this band. This is in accord with the observations of other authors.[3,4,7,22-24]

Therefore, we conclude that in solution the ligand exists as an equilibrium mixture of (I) and (II) where the benzothiazoline form seems to predominate almost exclusively. There is a partial conversion to the Schiff base form in the presence of a large excess of sodium. This conversion is being studied quantitatively; our results will be reported in due course.

Rearrangement of the ligand in the presence of metal ions

Reaction of a solution of (I) in ethanol with zinc acetate at room temperature yields a red crystalline complex whose composition is $Zn(C_{11}H_8NS_2)_2$. The IR spectrum of this complex does show absorp-

Scheme 2.

tions at 1585, 1566, 1557 and 1548 cm⁻¹ (Table 1) which can be ascribed to imine and aromatic ring vibrations. On the other hand, no C–S–C linkage band (characteristic of the closed ring structure) appears. These results indicate that the zinc ions promote the rearrangement of (I), so that the zinc complex of the tautomeric Schiff base is obtained (Scheme 3).

(IV) was also prepared by reaction of thiophen - 2 - aldehyde with a suspension of bis(o-aminobenzenethiolo) zinc in ethanol. However, the reaction progress slowly and it is difficult to establish its mechanism. Finally, (IV) was obtained by reaction of thiophen - 2 - aldehyde and o-aminobenzenethiol in the presence of zinc acetate. The mass spectrum of (IV) exhibited the band of isotopic peaks centred around the major peaks at m/e 500 (^{64}Zn), 502 (^{66}Zn) and 504 (^{68}Zn).

Reaction of a solution of (I) in ethanol with cadmium acetate yields a yellow compound whose composition is Cd_2 $(C_{11}H_8NS_2)_2$ $(CH_3–COO)$, (V). The IR spectrum of (V) shows two strong broad bands at 1548 and 1410 cm⁻¹ assignable to v(C=O)

and v(C–O) of the carboxylate vibrations, respectively. The position of these bands and the Δv value (138 cm⁻¹) indicate the presence of a bridging acetate group in the molecule of this complex.[25-28] Another important question is to determine the nature of the ligand in this complex. The IR spectrum exhibits no band at 920 cm⁻¹ (in the 1000–900 cm⁻¹ range only two very weak bands appear). The absence of this band suggests that in the presence of Cd ions (I) rearranges to give the Schiff base complex (V) (Scheme 4). The band corresponding to a complexed C=N stretching mode could not be identified because of the presence of a broad intense band (due to the v(C=O) vibration) in the same spectral region. Unfortunately, (V) was insufficiently soluble in nonpolar solvents for NMR studies and insufficiently volatile for mass spectral characterisation.

(V) was also obtained allowing to occur the formation of the ligand (from thiophen - 2 - aldehyde and o-aminobenzenethiol) in the presence of cadmium acetate.

The treatment of a strongly basic solution of (I)

Scheme 4.

in ethanol with cadmium acetate yields (V) from an orange solution. However, the colour of the reaction solution seems to indicate the existence of another different complex. This complex could only be isolated by reaction of a large excess of thiophen-2-aldehyde with a suspension of bis(o-aminobenzenethiolo) cadmium in ethanol. The orange crystalline compound thus obtained has the composition $Cd(C_{11}H_8NS_2)_2$, (VI) (Scheme 5). It can be seen from the IR data (Table 1) that the reaction occurs to yield the corresponding Schiff base complex.

Thiophen - 2 - aldehyde reacted with o-aminobenzenethiol in the presence of mercury and lead acetates, respectively, to give crystalline complexes of the type $M(C_{11}H_8NS_2)_2$. The mercury complex (VII) can also be obtained by reaction of thiophen - 2 - aldehyde with a suspension of bis(o-aminobenzenethiolo) mercury (II) in ethanol (see Experimental). The IR data do show that in

both complexes the ligand has rearranged to the imine form (Scheme 6).

On the other hand, there is no indication in any of the previous complexes of participation in bonding of the thiophen sulphur atom.

As mentioned above the complexes (V), (VI), (VII) and (VIII) are of light colour and (IV) is intense red, and all contain the ligand in the imine form. Lindoy and Livingstone,[3] in a study of the rearrangement of 2-(2-pyridyl)benzothiazoline by metal ions, have pointed out that the light colour of the complexes suggests that the benzothiazoline has not rearranged to the Schiff base. In this case, they have postulated that the solids contain the deprotonated form of benzothiazoline as ligand. In order to find spectral evidences useful in our study, we have synthesized the following complexes of 2 - (2 - pyridyl)benzothiazoline : Acetato (N - 2 - thiolophenyl - 2' - pyridylmethyleneimine) cad-

(VI)

Scheme 5.

M = Hg . VII
M = Pb . VIII
Scheme 6.

mium, **(IX)** (yellow); Chloro 2 - (2 - pyridyl)benzo-thiazolinato cadmium, **(X)** (yellow); Bis (N- 2 - thiolophenyl-2′ - pyridylmethyleneimine) cadmium, **(XI)** (intense red); Acetato bis (N - 2 - thiolophenyl - 2′ - pyridylmethyleneimine) lead (II), **(XII)** (intense red). On the basis of IR and UV–VIS spectra it is not possible distinguish the arrangement of the ligand in each of these complexes. However, from the IR spectra of **(IX)** and **(XII)** we think that a bridging acetate group is present in both complexes [**(IX)**: $v(C=O)$ and $v(C–O)$ appear at 1562 and 1405 cm^{-1} respectively, $\Delta v = 157$ cm^{-1}; **(XII)**: $v(C=O)$ and $v(C–O)$ appear at 1540 and 1400 cm^{-1} respectively, $\Delta v = 140$ cm^{-1}].

Finally, we suggest the use of **(I)** as colorimetric reagent for the ions determination in view of the intense colours of some complexes in DMF (Table 2). Thabet and Tabibian[29] reported a highly sensitive and selective method for the micro-determination of zinc, and we have studied the use of the ligand for determination of Hg(II) by extraction of the complex into chloroform ($\lambda = 364$ nm, $\epsilon = 6200$ l. mol^{-1} cm^{-1}) with successful results.

EXPERIMENTAL

Analyses and physical measurements

Chemical analyses were performed by Department of Analyses and Instrumental Techniques (University of Granada). Conductance measurements were made with a Conductivity Meter Radiometer Type CDM 2e. Thermogravimetric measurements were performed with a Setaram GDTD-10 thermoanalyzer fitted with a B-70 electrobalance with thermocouples of Pt/Pt–Rh in an alumine base. IR spectra were recorded with a Beckman 4240 IR Spectrophotometer in the 4000–250 cm^{-1} range using the KBr pellets technique. UV–VIS spectra were recorded with a Beckman Acta III Spectrophotometer using 1 cm quartz cells. NMR spectra were recorded with a Hitachi Perkin–Elmer

R-20 NMR equipment in CDCl$_3$ using TMS as internal reference. MS spectra were recorded with a Hewlett–Packard 5930 A Mass Spectrometer (70 eV).

Syntheses

2 - (2 - thienyl)benzothiazoline. This ligand was prepared by two routes: (1) As Thabet and Tabibian previously reported.[29] These authors recrystalized the compound from low-boiling petroleum ether. However, we use more successfully a mixture of low-boiling petroleum ether–ethanol (4:1); m.p. 94–95°C; yield 50%. Found: C, 60.66; H, 3.97; N, 6.39. Calc. for C$_{11}$H$_9$NS$_2$:C, 60.24; H, 4.13; N, 6.39%. (2) Thiophen - 2 - aldehyde (0.05 mol) in ethanol (20 cm^3) was added to o-aminobenzenethiol (0.05 mol) in ethanol (20 cm^3). The solution was heated under reflux for 30 min, then allowed to cool and finally 40 cm^3 of distillated water (cooled to 5°C) was added slowly with stirring. The suspension was let stand at 0°C for several hours and by this time a pale yellow crystalline compound had formed. This product was repeatedly washed with a mixture ethanol–water (1:1); m.p. 95–96°C; yield 75%. Found: C, 60.40; H, 4.10; N, 6.45%.

2 - (2 - thienyl)benzothiazol. This compound was prepared using the method of Miller *et al.*[20] in the preparation of other benzothiazoles.

FeCl$_3$ (0.444 g) in ethanol (15 cm^3) was added to 2 - (2 - thienyl)benzothiazoline (0.5 g) in ethanol (20 cm^3). The solution was heated under reflux, then it was allowed to cool at room temperature and distillated water (cooled to 5°C) was added; the product formed as yellow crystals. Found: C, 60.7; H, 3.4; N, 6.6. Calc. for C$_{11}$H$_7$NS$_2$: C, 60.8; H, 3.25; N, 6.45%.

The NMR spectrum of this compound exhibits only a complex multiplet centered at 8.05 ppm.

Bis(N - 2 - thiolophenyl - 2′ - thienylmethyleneimine) zinc. Zinc acetate dihydrate (0.11 g) in ethanol (15 cm^3) was added to 2 - (2 - thienyl) benzothiazoline (0.25 g) in ethanol (20 cm^3). Red crystals of the complex were deposited from an intense red solution. Then, the red crystals were separated by suction, washed with ethanol and distillated water, and dried *in vacuo* over CaCl$_2$; yield 0.114 g (45.3%). Found: C, 52.70; H, 3.27; N, 5.60; Zn, 13.00. Calc. for Zn(C$_{11}$H$_8$NS$_2$)$_2$: C, 52.64; H, 3.21; N, 5.58; Zn, 13.02%.

This compound was prepared as above except that the formation of the ligand from thiophen - 2 - aldehyde and o-aminobenzenethiol (1.25 g) was carried out in the presence of zinc acetate dihydrate (1.12 g) in hot ethanol (40 cm^3); yield 2.1 g. Found: C, 52.80; H, 3.34; N, 5.61; Zn, 12.96%.

a Key : In DMF

Finally this compound was also prepared by condensing thiophen - 2 - aldehyde (2 cm³) with a suspension of bis(o-aminobenzenethiolo) zinc† (0.313 g) in ethanol (50 cm³). The resulting suspension was heated for 6 hr. The product formed as red crystals; yield 60%. Found: N, 5.56; Zr 12.95%.

Acetato[bis(N - 2 - thiolophenyl - 2' - thienylmethyleneimine) cadmium]. Cadmium acetate dihydrate (0.14 g) in ethanol (10 cm³) was added to 2 - (2 - thienyl)benzothiazoline (0.23 g) in ethanol (20 cm³). A pale yellow compound was deposited from intense orange solution. The complex was separated by suction, washed with ethanol and ethanol–water (1:1), and dried *in vacuo* over CaCl₂; yield 0.43 g (48.9%). Found: C, 40.10; H, 2.9; N, 3.76; Cd, 31.00. Calc. for Cd₂(C₁₁H₈NS₂)₂–(CH₃COO): C, 40.01; H, 2.66; N, 3.89; Cd, 31.20%.

This compound was also prepared as follows: thiophen - 2 - aldehyde (0.46 g) and o-aminobenzenethiol (0.53 g) were refluxed together in ethanol (20 cm³) for 5 min. Cd(CH₃COO)₂. 2H₂O (0.82 g) in ethanol (20 cm³) was then added and the mixture was heated for 20 min. The mixture was then cooled and filtered. The pale yellow compound obtained was washed with ethanol–water (1:1), and dried *in vacuo* over CaCl₂; yield 60%. Found: C, 40.20; H, 2.84; N, 3.8; Cd, 30.9%.

Bis (N - 2 - thiolophenyl - 2' - thienylmethyleneimine) cadmium. This compound was prepared by condensing thiophen - 2 - aldehyde (4 g) with a suspension of bis(o-aminobenzenethiolo) cadmium† (0.5 g) in ethanol (40 cm³). The resulting suspension was refluxed for 8 hr. The product formed as orange crystals was filtered and washed with ethanol; yield 60%. Found: C, 48.23; H, 2.84; N, 4.96; Cd, 21.00. Calc. for Cd(C₁₁H₈NS₂)₂: C, 48.13; H, 2.94; N, 5.10; Cd, 20.47%.

Bis (N - 2 - thiolophenyl - 2' - thienylmethyleimine) mercury(II). This compound was prepared allowing that the formation of the ligand from thiophen - 2 - aldehyde (0.22 g) and o-aminobenzenethiol (0.25 g) was carried out in the presence of mercury acetate (0.32 g) in hot ethanol (50 cm³). The complex formed as yellow crystals; yield 0.383 g (60%). Found: C, 42.00; H, 2.63; N, 4.44. Calc. for Hg(C₁₁H₈NS₂)₂: C, 41.5; H, 2.53; N, 4.4%.

This compound was also prepared by condensing thiophen - 2 - aldehyde (1.5 g) with a suspension of bis (o-aminobenzenethiolo) mercu-

ry(II)† (0.5 g) in ethanol (30 cm³); yield, 100%. Found: C, 41.8; H, 2.59; N, 4.40%.

Bis (N - 2 - thiolophenyl - 2' - thienylmethyleneimine) lead(II). Thiophen - 2 - aldehyde (1.1 g) and o-aminobenzenethiol (1.2 g) were refluxed together in ethanol (30 cm³) for 5 min. Pb(CH₃–COO)₂·3H₂O (1.86 g) in ethanol–water (5:1, 30 cm³) was then added and the mixture was refluxed for a further 30 min. The resulting solution was cooled at room temperature. The orange–yellow product which precipitated was filtered off, washed with ethanol–water and dried *in vacuo* over CaCl₂; yield, 60%. Found: C, 40.76; H, 2.64; N, 4.35; Pb, 32.73. Calc. for Pb(C₁₁H₈NS₂)₂: C, 41.04; H, 2.50; N, 4.35; Pb, 32.18%.

Aceto [bis (N - 2 - thiolophenyl - 2' - pyridylmethyleneimine) lead (II)]. Pyridine - 2 - aldehyde (1.6 g) and o-aminobenzenethiol (1.9 g) were refluxed together in ethanol (20 cm³) for 10 min. Pb(CH₃–COO)₂. 3 H₂O (4.8 g) in ethanol–water (6:1, 35 cm³) was then added and the mixture was refluxed for a further 60 min. The intense red solution was let stand at 0°C for several hours. The complex formed as intense red crystals; yield; 60%. Found: N, 6.20; Pb, 46.16. Calc. for Pb₂(C₁₂H₉N₂S)₂(CH₃–COO): N, 6.23; Pb, 46.04%.

Bis (N - 2 - thiolophenyl - 2' - pyridylmethyleneimine) cadmium. Cd(NO₃)₂·4H₂O (0.16 g) in ethanol (10 cm³) was added to an alkaline solution of 2 - (2 - pyridyl)benzothiazoline (0.22 g) in ethanol (25 cm³). Intense red crystals of the complex were deposited from a deep red solution; yield, 60%. Found: N, 10.20; Cd, 21.12. Calc. for Cd(C₁₂H₉N₂S)₂: N, 10.39; Cd, 20.85%.

Acetato (N - 2 - thiolophenyl - 2' - pyridylmethyleneimine)cadmium. This compound was prepared as previously described.³ Found: N, 7.8; Cd, 31.76. Calc. for C₂₆H₂₁N₄O₂S₂Cd₂: N, 7.88; Cd, 31.64%.

Chloro 2 - (2 - pyridyl)benzothiazolinato cadmium. This compound was prepared as previously described.³ Found: N, 7.70; Cd, 31.8. Calc. for C₁₂H₉N₂SCdCl: N, 7.76; Cd 31.12%.

Molar conductance data (ohm⁻¹ cm² mol⁻¹)*in DMF at* 25°C. (IV), Λ = 3; (V), Λ = 2.8; (VI), Λ = 0.5; (VII), Λ = 2; (VIII), Λ = 2.5; (XII), Λ = 2.4. In view of Λ_M values, the complexes can be regarded as non-electrolytes.

Abstract—The diacetyl-(DAHP), benzil-(BHP) and benzoylethane-(BEHP) derivatives of 3-hydrazino-4-benzyl-6-phenylpyridazine have been prepared and characterized. Their acid-base properties and their equilibria with transition metal ions in 75% dioxan–water solvent at 30°C have been investigated by pH titrimetry. The role of proton and metal ion solvation by the organic solvent has been discussed in view of the results obtained for the lanthanide-BHP systems in different media. Probable structures of the metal chelates are given based on potentiometric data and spectral results for the solid copper chelates. The possibility of forming MHL species were inferred from electronic absorption measurements at different pH values. The use of BHP as an analytical reagent for the determination of copper spectrophotometrically or as a metallochrom indicator in the complexometric titration of Cu(II) ion is also discussed.

Previous studies[1] in this laboratory of the sequestering properties of benzoylacetone derivative of 3-hydrazino-4-benzyl-6-phenylpyridazine (BAHP, structure I) with transition and lanthanide metal ions have demonstrated quantitatively the capability of forming *bis*-chelates with the ligand behaving as a monoprotic acid. Under drastic conditions of reflux with copper salts, the ligand loses two gram equivalents of hydrogen-probably those of the enolic and hydrazo groups-and behave as a diprotic species.

These class of compounds are related structurally to the corresponding azo-pyrazolone dyes (structure II)[2,3] and differs only in the positions of the azo (or hydrazo) group relative to the nitrogenous nucleus. Although both types of ligands are capable of forming strong (N=N)→M bonds, however, the simultaneous participation of the pyrazolone ring nitrogen in the coordination

with the metal ion is questionable particularly in the presence of an acidic or basic group (A) ortho to the azo group.

I
In the present report, the chelating ability of the diacetyl (DAHP), benzoylethane (BEHP) and benzil (diphenylethanedione; BHP) derivatives of the chromophoric nucleus 3-hydrazino-4-benzyl-6-

phenylpyridazine have been measured. Each compound retains at least a portion of the basic structure of **BAHP**, namely the hydrazino-pyridazine group but substituting the β-diketone with either a ketonic compound or a diketyl derivative.

crystals obtained were filtered, washed with ethanol and recrystallised from benzene. The average yield in each case is approx. 70%. The elemental analysis results for C, H and N are shown in Table 1.

(ii) *Preparation of the copper complexes*

A mixture of equimolar amounts of the ligand and copper nitrate in 75% dioxan–water solvent was refluxed for 30 min. After a while, the complex separated as a purple solid. This was filtered, washed with ether and dried under vacuum. The full analysis of the species prepared is shown in Table 1.

by distillation.[6] Dimethylformamide was purified by following the procedure recommended by Mo-skalyk, et al.[7] Acidic impurities of formic acid were removed by stirring the crude reagent with Dowex-1 resin in the hydroxyl form.

(iv) Procedures

Potentiometric titrations and the experimental conditions are essentially the same as described in the first part of this series.[1] The temperature was 30°C and the ionic strength was maintained at 0.10 M with KNO_3. In all cases, the metal to ligand ratio was kept at 1:2 with the metal concentration 10^{-3} M. All the measurements were taken either in 75% (v/v) dioxan–water, dimethylformamide–water or methanol–water solvent. In the case of dioxan–water solvent measurements, the value of

hydrogen ion concentration was derived from pH values after adding a correction of 0.28.[8] Values of the activity coefficients, γ_+, for the hydrogen ion in methanol–water or DMF–water were calculated from the extended Debye–Hückel equation

$$\log \gamma_+ = -\frac{|Z_1 Z_2| 1.29 \times 10^6 \sqrt{2\mu}}{(\epsilon T)^{3/2}} \Big/ \left(1 + \frac{35.56°\alpha°\sqrt{2\mu}}{(\epsilon T)^{1/2}}\right)$$

where, μ = ionic strength, T = absolute temperature, Z_1 and Z_2 are the charges for the positive and negative ions and $\alpha°$ = the mean ionic parameter. The value of 6 Å was used for $\alpha°$.[10] The dielectric constant, ϵ, for the mixed solvent was calculated using the relationship
Fig. 1. Potentiometric Titration cruves of BHP and its complexes with Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and UO_2^{2+} ions at 30°C in 75% dioxan–water solvent. [L] = Free ligand, a = moles of base added per mole of BHP, [M] = 10^{-3} M; [L] = 2×10^{-3} M.

$$P_{12} = P_1 f_1 + P_2 f_2$$

$$= f_1 (M_1/d_1)\left(\frac{\epsilon_1 - 1}{\epsilon_1 + 2}\right) + f_2 (M_2/d_2)\left(\frac{\epsilon_2 - 1}{\epsilon_2 + 2}\right)$$

$$= \frac{\epsilon - 1}{\epsilon + 2} \cdot \frac{f_1 M_1 + f_2 M_2}{d_{12}}$$

where P_i = molar polarization, f_i = mole fraction, M_i = molecular weight and d = density.

The final values obtained for γ_+ are 0.619 and 0.615 in the case of methanol–water and DMF–water respectively.

IR spectra were recorded on a Perkin–Elmer 437 spectrometer ($4000-300\ cm^{-1}$) using potassium bromide discs. The electronic spectra were measured with a prolabo UV-visible spectrometer using 1 cm matched quartz cells and at 25°C.

RESULTS

(i) Potentiometric results

Representative plots for the titration curves of BHP ligand in the absence and in the presence of divalent metal ions are shown in Fig. 1. Closely related plots were also obtained for either the same ligand in different solvents or for other ligands in 75% (v/v) dioxan–water solvent. In all cases, the

metal–ligand titration curves show the presence of an inflection at $a = 1$ (a = moles of base added per mole of ligand). This suggests that the ligands are only monoprotic through the dissociation of the hydrazo group hydrogen. The values of the acid dissociation constants, K^H were calculated as described previously[1] and are summarised in Table 2.

The titration curves of DAHP and BEHP ligands in the presence of copper(II) ions showed a distinct inflection at $m = 1$ (m = moles of base added per mole of metal ion) in addition to that at $m = 2$ to account for the stepwise formation of ML and ML_2 species. Such features were not observed with other cations where only one overlapping buffer region between $m = 0$ to $m = 2$ was observed. The calculation of the overall equilibrium constants were carried out using standard procedures based on the calculation of the average number of ligand bound per metal ion, $\bar{n}_L$ and the free ligand concentration, [L], then minimising the residuals in the equation,

$$\frac{\bar{n}_L}{(1 - \bar{n}_L)[L]} + \beta_{102} \frac{(\bar{n}_L - 2)[L]}{(1 - \bar{n}_L)} - \beta_{101} = 0$$

using a least squares method.

* Measurements were obtained in 75% dioxan-water solvent.

** Measurements were obtained in 75% DMF-water solvent.

The log of the formation constants of the divalent metal ion complexes with the different dyes are presented in Table 3(a). Values of $\log \beta_{102}$ for the bis chelates of Co, Zn, Cd and UO_2 ions with BEHP are not included because of the tendency of these species to hydrolyse in the region of its formation. For the same reason, only the values of $\log \beta_{101}$ are quoted in Table 3(b) for the lanthanide complexes with BHP in the different solvents.

(ii) *Spectral results*

The absorption characteristics of the free ligands resemble basically those of BHP[1]. The $\pi \rightarrow \pi^*$ transition shows a marked bathochromic shift accompanied by a decrease in the absorption intensity in the case of DAHP, whereas for the benzil derivative, the molar absorptivity is slightly enhanced compared to that of BAHP. A parallel behaviour was also observed for the trend in

* Values for the metal complexes are apparant and estimated for the 1:2 metal : ligand ratio except for UO_2-DAHP where the ratio is 1:1.

$n \to \pi^*$ transition. Table 4 summarises all the results obtained. At fixed ligand concentration, the absorbance was found to be pH dependent with a slight blue shift in the absorption maxima at high alkali concentration, $(-\log[H^+] = 12 - 14)$. The results were analysed for the calculation of the dissociation constant of BHP in 75% dioxan–water using the following equation[11],

$$A = A_L - \frac{[H^+](A - A_{HL})}{K^H}$$

where A, A_L and A_{HL} stands for the absorption of the mixture, anionic and neutral dye species respectively. The value of $\log K^H$ obtained was found to be 13.78 compared to 13.72 as obtained potentiometrically.

The UV spectral properties of the metal complexes are similar to that of the proton complex with a significant lowering in ϵ_{max} and a blue shift in λ_{max}(20 nm). In the visible region, the spectra of the complex solutions displayed an additional assymetric band as is shown in Fig. 2.

The solid ligands and their copper complexes were characterised by infrared spectroscopy. Important band groups and their assignments are summarised in Table 5.

(iii) Analytical studies

BHP was used as a reagent for the determination of copper(II) ions by means of three different ways.

In the first method, absorbances were recorded for Cu(II) solutions $(0.6$–$6.0 \mu g/cm^3)$ in the presence of sufficient excess of the reagent and at the wavelength 530 nm. The results adhere well to Beer–Lambert law with a standard deviation of 0.004. Alternatively, the purple coloured Cu–BHP (1:1) mixture was titrated spectrophotometrically at λ_{max} using standard EDTA solution as the titrant
Fig. 2. Electronic absorption spectra of M-BHP and M-DAHP Chelates in 75% dioxan-water at the optimum pH. (1) [Ni] = 8×10^{-5}M; [BHP] = 16×10^{-5}M. (2) [Co] = 8×10^{-5}M; [BHP] = 16×10^{-5}M. (3) [Cu] = 4×10^{-5}M; [BHP] = 8×10^{-5}M. (4) [Co] = 1×10^{-4}M; [DAHP] = 2×10^{-4}M. (5) [Cu] = 1×10^{-4}M; [DAHP] = 2×10^{-4}M. (6) [UO$_2$] = 1×10^{-4}M; [DAHP] = 1×10^{-4}M.

Table 5. Selected band groups in the IR spectra and their tentative assignments, cm^{-1}

Assignment	DAMP	BEHP	BHP	Cu-BEHP	Cu-BHP

				412 m	436 m

s = strong; m = medium; w = weak; b = broad.

and both the titrant and titrand were buffered to pH 8. Finally, when a few crystalls of the solid ligand were added to a warm solution of Cu(II) (0.02–0.10 M), a purple colour was obtained which turns bluish green at the equivalent point when titrating with a standard EDTA solution. In the latter case, BHP serves as indicator. The results obtained are in excellent agreement with those obtained following standard procedures.

All measurements were carried out in 75% dioxan–water solvent.

DISCUSSION

(i) Protonation equilibria

Among the various tautomeric forms of BAHP, tautomer **I** has been shown to adhere well with both spectral and potentiometric results.[1] Further evidence for this assignment is gained from the results reported here for the homologous species DAHP, BHP and BEHP. The presence of a strong ketocarbonyl stretching, $v(C = O)$ at 1630–1640 cm^{-1} and a broad band in the region of 3220–3250 cm^{-1} assigned to $v(N–H)$ suggests that the keto form of BHP and DAHP (structure **IV**) is the dominant one. This is supported by the absence of the bands characteristic of the OH group stretching frequency in the IR spectra of the two species.

A comparison of the pK^H value of BAHP with those obtained for DAHP, BEHP and BHP under similar experimental conditions, reflects at least partially, the differences in the basicity of the enolic OH group of the benzolylacetone segment in BAHP and the protonated pyridazine nitrogen in the other cases. The difference amounts to one log unit in the case of DAHP and 1.8 log units for BEHP and BHP species. The lower basicity of DAHP is accounted for by the stabilization of the anionic ligand by the coplanarity of the whole conjugated system. The non-coplanarity of the two phenyl groups as imposed by the stereochemistry of the benzil segment in BHP is also indicated from the relatively low molar absorptivity of this species.

It has been shown by Kole and Chaudhury[10] that protonation constants in mixed aqueous solvents decreases with, (a) increasing the dielectric constant of the solvent; (b) decreasing the extent of hydrogen bonding in water by the organic solvent and (c) increasing the proton solvation by the organic solvent. These effects are prominent at solvent contents greater than 60%. It has been indicated also[12] that dioxan molecules progressively breakdown the hydrogen bonded structure of water whereas, methanol can form hydrogen bonded associations with water. This effect in addition to the low dielectric constant of dioxan–water solvent compared to that of methanol–water or DMF-water would perhaps rationalise the relative pK^H values of BHP in the different solvents as is shown in Table 2.
Fig. 3. Log β_{ML} as a function of the atomic number Z for the various rare earth complexes. (A) Ln–BHP in 75% dioxan–water. (B) Ln–BHP in 75% methanol–water. (C) Ln–BHP in 75% DMF-water. (D) Ln–BAHP in 75% dioxan–water.

(ii) Complexation studies

The role of metal solvation is apparent in the comparison of the equilibrium constants, β_{101} for the different lanthanide-BHP chelates in the various solvents (see Table 3(b)). Although the order of increasing $1/\epsilon$ values of the media is,

dioxan–water > methanol–water $\simeq$ DMF–water

the values of β_{101} are markedly greater in methanol-water than in DMF-water. This is perhaps, due to the strong solvating power of methanol over DMF to the lanthanide ions which are hard acids.

The trend in the formation constants of Ln-BHP complexes reported here are much the same as reported previously for BAHP ligand (see Fig. 3). The major differences between both systems are related to the difference in basicities of the two ligands which determine the absolute magnitude of β_{101} values and also to the size of the chelate ring formed.

With azo ligands, the azo group can coordinate to lanthanide and actinide ions, particularly when additional complex stabilization is afforded by the presence of a second donor atom in a position favourable for chelation. Thus, in the isostructural PAR complexes [4-(2-pyridylazo)resorcinol], the uranyl ion was shown to coordinate to the pyridine nitrogen, the azo nitrogen farthest from the pyridine nitrogen, and the ortho phenolic group, forming a tridentate 1:1 chelate.[13] Based on similarity in ligand structure, it is expected that BHP and DAHP form complexes of a similar nature. However, a comparison of β_{101} values with those reported for PAR or PAN analogues[14] suggest that BHP and DAHP act as rather bidentate ligands. The complete disappearance of the carbonyl stretching band in the IR spectra of the solid UO$_2$-BHP and UO$_2$-DAHP complexes[15] is indicative of a chelation with the enolic form (Structure V).

$$Ar = C_6H_5$$
$$Ar' = C_6H_5 CH_2 ——$$
$$X = C_6H_5 \text{ (in BHP)}$$
$$= CH_3 \text{ (in DAHP)}$$

V
With transition elements, the relative stabilities of the 1:1 metal complexes are the same for the three ligands and are in agreement with the order found with other ligands, Cu(II) > Ni(II) > Co(II) > Zn(II) > Cd(II) except with BEHP where Ni(II) and Co(II) exchange places.

The copper(II) complexes were isolated from solution as the monohydrate 1:1 chelate, CuL(H$_2$O). Attempts to isolate the 1:2 chelates were unsuccessful. However, evidences are obtained from both potentiometric and spectral data for the presence of the 1:2 species in solution. The absence of the ketocarbonyl stretching, $v(C = O)$, and the observed shift in $v(C = N)$ and $v(N = N)$ in the IR spectra of Cu–BHP suggests the formation of a chelate of similar structure to that given above. The change in band position can be attributed to the shift of electron density when the ligand behaves as a bidentate N, O-donor.

The behaviour of BEHP appears curious at first. The ligand forms complexes with the transition elements of a comparable stability to those formed with BHP, BAHP and DAHP which suggest the participation of the available two donor centers (the azo and the pyridazine ring nitrogens) in coordination. If that is acceptable, then the only reason for the non-participation of the BHP/or DAHP pyridine nitrogens in bonding to metal ions is perhaps the preferable trans-arrangement of the vinyl and pyridazine moieties around the azo group which give no access of the simultaneous coordination of the three sites with the metallic centre.

The UV-visible spectra of the different complex systems show the presence of a complex band in the region of 440–580 nm. The intensity of this band is a function of both the molar ratio and the pH of the medium. With nickel and copper species, two overlapping exist in the pH region 3–6, whereas for cobalt complexes, the two absorption maxima are quite separate. Plots of the mole fraction (α_{ML} and α_{ML_2}) calculated from potentiometric data are also presented for the sake of comparison. Obviously, even in the absence of CoL or CoL$_2$ species or in the presence of insignificant concentrations of CuL or CuL$_2$ complexes, i.e. in moderately acidic media, the mixture of the metal and the ligand absorbs strongly. To account for this anomalously, the number of absorbing species in solution were determined by applying Coleman et al.[16] graphical method to the different data of BHP and DAHP complexes at several wavelengths and at the different relevant pH's. Typical plots at the overlapping regions are given in Fig. 5. The analysis revealed that only one absorbing species exists in moderately acidic region (ca. pH 3). Increasing the pH to 4(in the case of Cu and Ni complexes) or 5(in the case of Co chelates) two absorbing species were found as indicated by
Fig. 4. Absorption-pH and mole fraction-pH plots for (A) Co–BHP species at $\lambda = 580$ nm.
(B) Cu–BHP species at $\lambda = 540$ nm.
Fig. 5. Coleman *et al.* plots for the different BHP and DAHP chelates.

the linear plots shown in Fig. 5. Since the free ligands absorb far below this region of the spectrum, perhaps the only possible absorbing species in moderately acidic media is that formed between the metal ions and the acid ligands, MHL species. At very high acidities, protons compete with the metal ions for the available nitrogen donor sites and no complexes are formed, whereas in strong alkaline media, complex hydrolysis might account for the decrease in optical density.

By analogy, these bands are of a charge transfer origin. BHP and DAHP being a better π acceptor that BAHP, their charge transfer bands are expected at lower energy. Thus for the same metal ion, the order of increasing the energy of $d \rightarrow \pi$ transition is;

$$M(BAHP) > M(DAHP) > M(BHP).$$

Whereas, for the same ligand, the following order holds,

$$CoL > NiL \simeq CuL$$

which is the same order of metal reductibility.

The bands observed for Cu and Co chelates with BHP are quite broad and perhaps the $\pi \to d$ transitions in these cases are obscured and collapsed with those of the $d \to \pi$ origin. In general, when the metal ion was fixed, the energy of transition follows an order similar to that advanced in the previous paragraph.

For uranyl(VI) ion, an electron transfer takes place within the ion, from the oxygens of the uranyl group to the central uranium ion. This transfer involves much higher energy than that reported here (see Fig. 2). Coordination with ligands which are very prone to transfer electrons were found to cause the electron transfer bands to move further into the visible spectrum. Such an effect is brought about by the thiocyanate ion[17] and is likely to take place here with DAHP.

TRANSITION METAL COMPLEXES WITH 1-METHYL-4,4-DIMERCAPTOPIPERIDINE

H. BARRERA and F. TEIXIDOR*

Departament de Química Inorgànica, Universitat Autònoma de Barcelona, (Bellaterra),
Barcelona, Spain

Abstract—The syntheses of $Co(AH_2)_2X_2$ ($AH_2 = $ 1-methyl-4, 4-dimercaptopiperidine, X = Cl, Br, I, acetate, propanate, perchlorate, nitrate and sulphate), $M(AH_2)$ Cl_2 (M = Cd, Zn) are described. According to IR and UV-visible data it seems most probable that the amino*gem*-dithiol (AH_2) coordinates Co via both sulphur atoms, but Zn and Cd via one sulphur. A square pyramidal geometry about Co and a tetrahedral geometry about Zn and Cd are proposed. In no case has coordination via nitrogen been found. Strong X–H. . .N hydrogen bonds have been observed in most of these complexes.

Complexes containing mercaptoamines as ligands have been extensively studied.[1,2] However no complexes have been reported containing a *gem*-dithiol ligand, i.e. two thiol groups on the same carbon atom. This lack of research about these type of complexes may be due to the few *gem*-dithiols known, their general tendency to lose SH_2 and the tendency of sulphur to form bridges between two metals.

In an attempt to gain insight into the coordination chemistry of the dithiols we undertook a research using the readily synthesized 1-methyl-4,4-dimercaptopiperidine. The precipitating ability of the cation 1-methyl-4,4-dimercaptopiperidinium with halometallates of transition metal ions has been just recently reported.[3] It is interesting to mention the strong S–H. . .X hydrogen bonds detected in these salts. In the present paper we report on the coordinating ability of this ligand toward Co^{2+}, Zn^{2+} and Cd^{2+} ions.

EXPERIMENTAL

General

IR spectra were obtained on a Beckman IR-20A as KBr pellets. The IR spectral data are listed in Table 2. The UV-visible spectra were recorded on a Beckman, Acta III. Conductivity measurements were determined on a CDM-3 Radiometer Copenhaguen Conductivimeter in Dimethylform-

amide. The 1-methyl-4-piperidine (Fluka) was distilled before use. The preparation of 1-methyl-4,4-dimercaptopiperidine ($C_6NS_2H_{13}$) has been described previously.[4] All metallic salts were either commercially available or were synthesized according to Pascal's methods.[5] Solvents were used as received. The complexes were analyzed as follows: S as barium sulphate; Co, Zn and Cd as anthranilate; Cl as AgCl; C, H and N in a Perkin–Elmer 240 analyser. Results are given in Table 1.

Syntheses of complexes $Co(AH_2)_2X_2$ where X = Cl, Br, I, SCN, CH_3COO, CH_3CH_2COO

Throughout this paper the ligand $C_6NS_2H_{13}$ is symbolized as AH_2. The analytical formula and the analyses (calculated and observed) of the compounds are indicated in Table 1.

(*a*) $Co(AH_2)_2Cl_2$ *and* $Co(AH_2)_2X_2$ (X = Br, I, SCN). To a beaker containing $CoCl_2 \cdot 6H_2O$ (1.5 g) in methanol was added, with continuous stirring, 1-methyl-4,4-dimercaptopiperidine (2.3 g) in 60–100 cm^3 of methanol containing 5–10 cm^3 of acetic acid. A solid precipitated immediately and was collected by filtration and washed with methanol and ethyl ether. The dark green solid was dried under vacuum for 30 min. M.p. = 210°C(dec.).

With slight variations, compounds $Co(AH_2)_2Br_2$, $Co(AH_2)_2I_2$ and $Co(AH_2)_2(SCN)_2$ were prepared following the procedure for $Co(AH_2)_2Cl_2$. The salts used were $CoBr_2 \cdot 6H_2O$, $CoI_2 \cdot 2H_2O$ and $Co(SCN)_2 \cdot 4H_2O$, respectively. In this latter case butanoic acid was used instead of acetic acid.

(b) $Co(AH_2)_2(CH_3CO_2)_2$ and $Co(AH_2)_2(CH_3CH_2CO_2)$. The general features of these syntheses were as before. In particular $Co(CH_3CO_2)_2 \cdot 4H_2O$ was dissolved in acetic acid and $Co(CH_3CH_2CO_2)_2 \cdot 3H_2O$ in propionic acid. Isopropanol was used as the ligand solvent containing, in the former acetic acid and in the latter, propionic acid.

(c) $Co(AH_2)_2(ClO_4)_2$. Under vigorous stirring, Na $ClO_4(2.5\,g)$ were added to AH_3 Cl $(2\,g)$ in $120\,cm^3$ of ethanol. A precipitate of NaCl formed within minutes. When the precipitation was complete, NaOH$(0.2\,g)$ in ethanol was added and the suspension was filtered. Upon addition of $Co(ClO_4)_2 \cdot 6H_2O(2\,g)$ in ethanol to the filtrate, a dark green solid separated which was collected by filtration. The solid was washed three times with ethanol and dried thoroughly with dry-air.

(d) $Co(AH_2)_2(NO_3)_2$. The above procedure for $Co(AH_2)_2Cl_2$ was used to synthesize this compound. However butanoic acid was used instead of acetic acid. The solid was washed and dried as done in the ClO_4^- compound.

(e) $Co(AH_2)_2SO_4$. Equimolar amounts of a saturated solution of $NaHSO_4$ and $AH_2(2\,g)$, both in methanol, were mixed and, after standing for a while, filtered. To the filtrate, a recently prepared solution of $CoSO_4 \cdot 7H_2O$ was added. Immediately a green solid precipitated which was filtered, washed three times with methanol and dried at the vacuum line.

(f) $Zn(AH_2)Cl_2 \cdot 2H_2O$. In a beaker, were mixed two ethanolic solutions of $ZnCl_2$ $(0.6\,g)$ and AH_3 Cl $(1\,g)$, containing NaOH$(0.1\,g)$. Upon the mixing, a white solid separated which was filtered, washed with ethanol and ether and dried with dry air passing through the filter. Finally, the solid was dried at the vacuum line.

This compound is at first soluble in water but after a few minutes decomposes precipitating a solid.

(g) $Cd(AH_2)Cl_2 \cdot H_2O$. In a beaker were mixed two ethanolic solutions of $CdCl_2 \cdot 2,5H_2O$ $(1\,g)$, containing both of them a small amount of hydrogen chloride. Immediately a white solid separated which was filtered, washed with cold ethanol containing a small amount of hydrogen chloride and, finally, with ether.

The correct drying conditions for this compound have not been found. Its stoichiometry was determined by comparison of the atomic ratios of Cd, S and Cl.

It was proved that upon varying the drying conditions, the only variable element was sulphur, while the ratio Cl/Cd remained constant and averaged 1.99.

In order to know the ratio S/Cd all the solid resulting in one synthesis was placed wet in a 500 cm^3, round bottomed flask and treated with $120\,cm^3$ of Br_2–KBr[6] solution containing $CuCl_2(0.4\,g)$. Immediately the flask was tightly closed and thoroughly stirred for 1 hr. After cooling it at 0°C, concentrated $HNO_3(100\,cm^3)$ was carefully added. The resulting solution was gently heated for 1 hr and then evaporated to 50–60 cm^3. While continuing the heating, concentrated hydrochloric acid was added until no nitrogen dioxide vapours were apparent. The resulting solution was diluted to approx. 1 l. and SO_4^{2-} and Cd^{2+} analyzed from it.

RESULTS AND DISCUSSION

Cobalt complexes

The reaction of cobalt salts with 1-methyl-4,4-dimercaptopiperidine in ethanol, yields dark green solids whose stoichiometry has been determined to be $Co(AH_2)_2X_2$, where X = Cl, Br, I, SCN, acetate, propanate, ClO_4, NO_3 and $\frac{1}{2}SO_4$. All of the cobalt complexes discussed here gave very similar IR spectra (Table 2). Of these, it is important to note the strong absorptions at $\simeq 435\,cm^{-1}$ and $\simeq 2730\,cm^{-1}$ assigned to $\nu(M-S)$ and $\nu(N-H)$, respectively. This latter absorption exhibits an hypsochromic shift from $2710\,cm^{-1}$ (Cl) to $2750\,cm^{-1}$ (Br, I, SCN) attributed to hydrogen bond formation (N-H...Y). The frequency of the M-S absorption is high compared to other already reported $\nu(M-S)$ IR data. However, the presence of this band in all these spectra, independently of the X groups poses little doubt to its assignment. The IR spectral analysis of the X groups suggests that these are somehow coordinated. For instance, the $\nu(C-N)$ absorption band in $Co(AH_2)_2(SCN)_2$ occurs at $2090\,cm^{-1}$, while it is known to be at $2053\,cm^{-1}$ in KSCN.[7] In addition, the frequency separation between the asymmetric and symmetric modes of vibration of the OCO group in the acetate and propanoate complexes, $\Delta \simeq 160\,cm^{-1}$, suggest a monodentate coordination,[8,9] as it is thought of the sulphate and perchlorate complexes. However, the IR analysis of the nitrato compound suggest a non-coordinated nitrate group.

The 10^{-3}M conductivity values of these complexes $Co(AH_2)_2X_2$ in DMF at 25°C are indicated in Table 3. Comparison of them with accepted values for common types of electrolytes[10] suggest a molecular type of compound for the acetate and propanoate complexes but ionic for the others. However, excepting the perchlorate, which is on the lower side for 1:2 electrolytes, the iodide and thiocyanate complexes fall within the 1:1 type.

More structural information about these complexes is derived from the visible spectra, either in

Table 3. Conductivity values[a]

Complex	Assumed molecular weight	M
$Co(AH_2)_2I_2$	639	80
$Co(AH_2)_2(SCN)_2$	501	65
$Co(AH_2)_2(CH_3COO)_2 \cdot H_2O$	521	11
$Co(AH_2)_2(CH_3CH_2COO)_2$	531	12
$Co(AH_2)_2(ClO_4)_2$	584	130

(a) All conductivities were taken at 25°C and were calculated assuming a molecular weight given by the empirical formula.

the solid phase or in solution. A broad and symmetrical band, centered at 594 ± 1 nm, has been observed in all of the solid phase spectra of these complexes. This band shifted to 600 nm ($\epsilon = 2000$) when the spectra were recorded in DMF solution.

This visible spectral information clearly suggests the existence of a common chromophere in all of these $Co(AH_2)_2X_2$ complexes. Consequently, the X groups would not be coordinated to the cobalt and the conductivity and IR data would be explained by considering strong N–H...X hydrogen bonds as pointed out before. Besides, the high molar absorbance ($\epsilon \simeq 2000$, at 600 nm) can neither be explained by a centrosymmetric nor by a tetrahedral metal environment. We suggest that the square pyramidal geometry (Fig. 1) as exemplified by some dithiocarbamate complexes $Cu(R_2Dtc)_2$, $Cd(Et_2Dtc)_2$[11] could be consistent with the visible and IR data.

Zinc and cadmium complexes

The reaction of zinc and cadmium chlorides with 1-methyl-4, 4-dimercaptopiperidinium chloride in ethanol, yields white solids whose stoichiometry has been determined to be $Zn(AH_2)Cl_2 \cdot 2H_2O$ and $Cd(AH_2)Cl_2 \cdot H_2O$. The IR spectra of these solids

(Table 2) show, among others, absorptions at $2710\ cm^{-1}$, attributed to a N–H bond, and at the interval $255-325\ cm^{-1}$, attributed to terminal M–Cl[12] bonds in tetrahedrally coordinated complexes.[13]

Even though the M–S absorptions cannot be clearly identified in these IR spectra, we assume that the amino-dithiol moiety is coordinated to the metal by comparison with the IR spectra of $[AH_3]_2ZnCl_4$ and $[AH_3]CdCl_3$[3] salts, where 1-methyl-4, 4-dimercaptopiperidinium is the cation.

The amino-*gem*-dithiol-metal interaction takes place via sulphur of sulphurs, as is shown by the existence of an N–H band in the IR spectra of these complexes.

The existence of M-halogen bonds and the known tendency of the thiolate group to form bridges between metal atoms makes us believe that the structure of these Zn and Cd complexes may be as depicted in Fig. 2 with only one S atom of each ligand moiety binding the two metals. A structure like this has been observed by X-ray diffraction studies for $Zn(LH)Cl_2$,[2d] where LH is 1-methyl-4-mercaptopiperidine.
Fig. 1. Proposed structure for the $Co(AH_2)_2X_2$ complexes. A fifth coordination is obtained bonding the metal ion and one sulfur of a second $Co(AH_2)_2X_2$ moiety.
Fig. 2. Proposed structure for the $Zn(AH_2)Cl_2$ and $Cd(AH_2)Cl_2$ complexes.

CONCLUSION

The study of the Co, Zn and Cd complexes of 1-methyl-4,4-dimercaptopiperidine has permitted insight into the coordination behaviour of a *gem*-dithiol ligand. Attempts to get crystals suitable for an X-ray diffraction study have been unsuccessful. It is mostly due to the high insolubility in suitable solvents. As a consequence, the complete characterisation of the coordination is not yet known. However, it seems most probable, based on spectroscopic data that this ligand coordinates either via only one sulphur, bridging two metals, or via both sulphurs acting as a chelating agent.

TERNARY COMPLEXES OF MIXED N/O DONOR LIGANDS IN SOLUTION

P. RABINDRA REDDY* and M. HARILATHA REDDY

Department of Chemistry, Osmania University, Hyderabad 500 007, India

Abstract—The stability constants of the ternary Cu(II), Ni(II), Co(II), Mn(II), Mg, Ca and Zn complexes containing xanthosine and, as a second ligand, glycine have been determined in aqueous solution by potentiometric titration [$\mu = 0.10$ M(KNO$_3$), 35°C]. The stability constants of the binary system containing the above metal ions and xanthosine in a 1:2 ratio were also determined to compare the effect of the secondary ligand on a 1:1 metal–xanthosine system. The $\Delta \log K$ (defined as the difference in the overall: 1:1 stability constants and corresponding 1:1 binary complexes) values are more positive for 1:2 metal–xanthosine system than the 1:1:1 metal–xanthosine–glycine system. This difference in stability may be due to the "stacking" interaction in the 1:2 metal–xanthosine system.

Investigations of the stability of ternary complexes will help toward understanding the driving forces that lead to the formation of such complexes in biological systems. Although binary and ternary complexes of nucleotides in solution have received much attention during recent years.[1–11] very little is known about the nucleoside complexes. Because of the importance of nucleosides, which provide a link between purine and pyrimidine bases and nucleotides, in understanding the nature of metal nucleic acid interactions in biological systems, we have undertaken a programme to systematically investigate the interaction of various metal ions with nucleosides in solution. Mixed ligand complexes containing Cu(II) are relatively well investigated.[12,13] Much less is known about other metal ions, especially about those which are of basic biological importance like Mg, Ca or Zn. Therefore, in this paper we have carried out a detailed physicochemical studies on the interaction of Cu(II), Ni(II), Co(II), Mn(II), Mg, Ca and Zn with xanthosine and glycine in a 1:1:1 ratio to see how the stabilityof mixed ligand complexes varies with in a series of metal ions. We have also studied 1:2 metal–xanthosine complexes with a view to understand the effect of the same secondary ligand as compared to the different secondary ligand on 1:1 metal–xanthosine system.

The stability constants of the 1:1:1 ternary complexes of xanthosine are lower than those observed for 1:2 metal–xanthosine system, which

is expected on the basis of the stacking interaction in the latter. All measurements were made at 35° ± 0.1°C and 0.10 M(KNO$_3$) ionic strength.

EXPERIMENTAL AND CALCULATIONS

Xanthosine and glycine were obtained from Sigma Chemical Company (U.S.A). Transition and alkaline earth metal ions were of Analar Grade and were standardised volumetrically by titration with disodium salt of EDTA in the presence of a suitable indicator as outlined by Schwarzenbach.[14]

The experimental method employed consisted of a potentiometric titration of metal and xanthosine in a 1:2 ratio or metal ion, xanthosine and glycine in a 1:1:1 ratio at 35° ± 0.1°C with standard NaOH solution. The experimental conditions maintained were similar to those described in our previous work.[7]

The acid dissociation constants of xanthosine and glycine were calculated by the usual algebraic method. The stability constants of 1:2 metal–xanthosine complexes were determined by the help of the equations described earlier.[10]

In order to calculate the stability constants of the ternary complexes of Cu(II) and Ni(II) with xanthosine and glycine, in a 1:1:1 ratio, the following equations were used (omitting charges)

$$M + H_2L + HA \overset{K^{M}_{MHLA}}{\rightleftharpoons} MHLA + 2H^+ \quad (1)$$

together with the related equilibria

$$M + HL + A \rightleftharpoons MHLA \quad (2)$$

$$K_{MHLA}^{M} = \frac{T_M - [M]}{[M][HL][A]}. \quad (3)$$

However, for the ternary complexes of Co(II), Mn(II), Mg, Ca and Zn with xanthosine and glycine the following equations were used.

$$MA + H_2L \overset{K_{MHLA}^{MA}}{\rightleftharpoons} MHLA + H^+ \quad (4)$$

related equilibria

$$MA + GL \overset{K_{MHLA}^{MA}}{\rightleftharpoons} MHLA \quad (5)$$

$$K_{MHLA}^{MA} = \frac{T_M - [M]}{[MA][HL]} \quad (6)$$

where MA = 1:1 metal–glycine complex; H_2L = xanthosine; HA = glycine; T_M = total metal ion species present in solution; and [M] = concentration of the free metal ion.

The concentrations of various species involved in the above equations were obtained by setting up suitable material balanced equations and solving for the unknowns. The details were given in our earlier publications.[8]

RESULTS AND DISCUSSION

In Fig. 1(d) is given the mixed ligand titration curve of Cu(II)-xanthosine and glycine in a 1:1:1 ratio, which shows an inflection at $m = 2$ (where "m" is the moles of base added per mole of metal ion) indicating simultaneous formation of 1:1:1 mixed ligand complex in the buffer region between $m = 0$ and $m = 2$. Accordingly, it was assumed that a monoprotonated 1:1:1 complex is formed in this buffer region. The constant K_{MHLA}^{M} was calculated with the help of eqn (3). Similar titration curve was also obtained for Ni(II) and the constants thus calculated are given in Table 1.

Figure 1(c) gives the mixed ligand titration curve of Zn-xanthosine and glycine system in a 1:1:1 ratio. The constant K_{MHLA}^{MA} formed from 1:1 metal–galcine complex in the buffer region between $m = 1$ and $m = 2$ was calculated by eqn (6) and presented in Table 1.

Similar trends were obtained for Co(II), Mn(II), Mg and Ca. The constants for these systems are included in Table 1.
Fig. 1. Potentiometric titration curves for Cu(II) and Zn–xanthosine–glycine system in a 1:1:1 ratio at 35°C, $\mu = 0.10$ M(KNO$_3$). A = Free glycine; C = Zn–xanthosine–glycine; D = Cu(II)–xanthosine–glycine; m = moles of base added per mole of metal ion (for curves C & D); a = moles of base added per mole of ligand (for curves A & B). ---, Precipitation.

Table 1. Stability constants of complexes containing 1:1 and 1:2 ratios of metal ions and xanthosine, 1:1 ratio of metal ions with glycine and 1:1:1 ternary metal complexes of xanthosine with glycine. Temp. $= 35°C$; $\mu = 0.10 \ M(KNO_3)$

Xanthosine	pKa	= 5.56 $\pm$ 0.02
	pK$_{2a}$	= 9.90 $\pm$ 0.02

In Table 1 are also given the stability constants of binary (metal–xanthosine and metal–glycine) complexes and $\Delta \log K$ values, calculated as the difference in the overall 1:1:1 stability constants and 1:1 constants. Although the constants of Cu(II), Ni(II), Co(II), Mn(II) and Zn glycine systems are available in the literature, we have remeasured these constants as it is preferable to determine the binary and ternary complexes under the same conditions. Otherwise the experimental difference might show up in $\Delta \log K$ (Defined as the difference in the overall 1:1:1 stability constants and corresponding 1:1 binary complexes). However, our values agree well with those from literature. The stability constants of Mg and Ca glycine systems have been determined for the first time.

It is worthwhile here to mention briefly the theoretical value of $\Delta \log K$ and its origin. In a ternary system containing metal ion and two ligands (bidentate), H_2A and H_2L with significant difference in complexing capabilities, simple complex with one of the ligands is formed which has the more complexing tendency as compared to the other. However, if there is only small difference in the complexing tendencies between the two ligands the following type of complex will result.

$$M + A + L \rightleftharpoons MLA.$$
The reaction may proceed either of the following

equilibria

$$M + A \rightleftharpoons MA$$

$$MA + L \rightleftharpoons MAL$$

$$M + L \rightleftharpoons ML$$

$$ML + A \rightleftharpoons MLA.$$
In dilute solutions the possibility of having other species like hydroxo, polymeric, etc. can be ignored. Therefore, we have left with equilibrium constant which represent the overall or stepwise mixed ligand complex depending upon the system under investigation. The difference in stability between a binary complex and ternary complex is usually explained in terms of $\Delta \log K$.

$$\Delta \log K = \log K^{MA}_{ML} - \log K^M_{ML}$$

or

$$\log K^{ML}_{MLA} - \log K^M_{MA}.$$

Thus, if $\Delta \log K$ values are positive the ternary complexes are more stable than the corresponding binary complexes and if the values for $\Delta \log K$ are negative the binary complexes are more stable than the ternary complexes. However, the negative val-

ues for $\Delta \log K$ does not preclude the formation of ternary complexes. The stability of mixed ligand complex formation is also determined by the reproportionate constant from statistical consideration. Under these conditions when there is no interaction between MAL, MA$_2$ and ML$_2$, there is possibility of 50% formation of MAL, while binary complexes MA$_2$ and ML$_2$ are formed to the extent of only 25% each.

Thus in a mixed system, the probability of formation of mixed ligand complexes more than that of the binary complexes. A detailed discussion on this subject is found in an article by Sigel.[15]

It can be seen from the table that the ternary complexes are more stable than the binary complexes, resulting in the positive values of $\Delta \log K$ for all the metal ions studied. This is because the destabilization caused by ligand repulsion is smaller in a mixed ligand complex than in the binary complex. In the ternary systems, generally the reaction between the metal ion and the secondary ligands containing heteroaromatic nitrogen and oxygen donors result in the formation of more stable complexes than the ligands containing pure nitrogen and oxygen donor atoms. In this context, it is important and of interest to compare the $\Delta \log K$ values for 1:2 metal–xanation system with those of 1:1:1 metal–xanthosine N, N-tetramethylethylene diamine, α–α'-bipyridyl, 1, 10-phenanthroline and 5-sulphosalicyclic acid.[10] The $\Delta \log K$ values for the former are more positive than the latter cases. These results support the above observation. Similar observations were also made by Sigel.[16]

The above arguments can also be extended successfully to metal–xanthosine–glycine system. In this system there seems to be two types of interactions for the metal ions studied as is evident from the titration curves (Fig. 1c, d). The Cu(II) and Ni(II) form one type of complexes and Co(II), Mn(II), Mg, Ca and Zn form another type. Hence, we have chosen only the latter type for comparison with 1:2 metal–xanthosine system since in both the cases we have a similar type of complexes. The $\Delta \log K$ values of Co(II), Mn(II), Mg, Ca and Zn for 1:2 metal–xanthosine system are more positive than the corresponding $\Delta \log K$ values 1:1:1 metal–xanthosine–galcyine system, though in both the cases we have mixed N/O donor atoms in the secondary ligand. These differences in the stabilities are expected because of the fact that the glycine is an aliphatic ligand and therefore, cannot take part in stacking interaction with xanthosine in 1:1:1 ternary complex. On the other hand, xanthosine can take part in stacking interaction in 1:2 system. These results once again confirm out earlier observations[10] that, in the ternary complexes the extent of stacking interaction rather than the nature of the metal ion is more important in deciding the $\Delta \log K$ values.
Fig. 2. Possible (tentative) structure of Cu(II)–xanthosine-glycine system in solution. R = ribose.

It is important here to mention that it is a well established fact that purine and pyrimidine bases, nucleosides and nucleotides associate extensively in aqueous solution by a mechanism involving vertical stacking of bases. The divalent metal ions like Mg and Zn promote stacking by a factor of about 4 in nucleoside 5'-triphosphates.[17] Therefore, in the case of 1:2 xanthosine system also the stacking is expected to be promoted by divalent metal ions though to a lesser extent as compared to the nucleotides. Although we have an oxo group in xanthosine, we expect an alternating stacking arrangement with a partially overlapped orientation so that H-8 and H-1' can be both shielded to a similar extent. Here not only the steric hindrance of the ribosyl group is reduced but also the repulsion between the dipole moments of the adjacent bases expected in the straight stack is reduced. We could not compare the $\Delta \log K$ values for Cu(II) and Ni(II) systems as they form different types of complexes with xanthosine and glycine as explained above.

The $\Delta \log K$ value of Ni(II)–xanthosine–glycine complex is more positive than the Cu(II)–xanthosine–glycine complex indicating a more stable ternary complex of Ni(II). The instability of Cu(II)–xanthosine–glycine complex may be due to its low coordination number as compared to the Ni(II) complex.

Based on this we propose a possible (tentative) structure of Cu(II)–xanthosine–glycine complex in solution (Fig. 2).

BIS(INDENYL)TITANIUM(IV) AND ZIRCONIUM(IV) COMPLEXES OF MONOFUNCTIONAL BIDENTATE SALICYLIDIMINES

B. KHERA, A. K. SHARMA and N. K. KAUSHIK*
Department of Chemistry, University of Delhi, Delhi 7, India

Abstract—Dichlorobis(indenyl)-titanium(IV) and -zirconium(IV), $(C_9H_7)_2TiCl_2$ and $(C_9H_7)_2ZrCl_2$, react with bidentate Schiff bases such as salicylidene aniline, salicylidene-*o*-toluidine, salicylidene-*m*-toluidine and salicylidene-*p*-toluidine in a 1:1 molar ratio in refluxing tetrahydrofuran in the presence of triethylamine to yield complexes of the type $(C_9H_7)_2Ti(SB)Cl$ and $(C_9H_7)_2Zr(SB)Cl$, respectively where SB is the anion of the corresponding Schiff base, SBH. The new derivatives have been characterised on the basis of their elemental analyses, conductance measurements and spectral (IR, ^{1}H NMR and electronic) studies.

Schiff bases derived from the reaction of salicylaldehyde with primary amines represent a versatile series of ligands, the metal complexes of which have been widely studied.[1–3] Some Schiff base derivatives of bis(cyclopentadienyl)titanium(IV) and bis(cyclopentadienyl) zirconium(IV) with bidentate, terdentate and quadridentate Schiff bases are known.[4–7] Recently, we have reported[8,9] some reactions of dichloro bis(cyclopentadienyl)-titanium(IV) and bis(cyclopentadienyl) zirconium(IV) with N-aryl salicylidimines. However, reactions of bis(indenyl)-titanium(IV)- and bis(-indenyl)zirconium(IV)-dichlorides with Schiff bases have not been reported previously. The present work describes the reactions of bis(-indenyl)titanium(IV) and bis(indenyl)zirconium(IV) with bidentate Schiff bases derived from salicylaldehde and aniline, *o*-, *m*- or *p*-toluidine. The main interest in the preparation of such compounds is the attachment of Schiff base ligand to the titanium or zirconium atom in the presence of bulky idenyl groups, which due to some steric factors might have some effect on the structure of the complexes. However, various physico-chemical studies carried out for these complexes show the coordination to the central metal atom through nitrogen of azomethine group and oxygen of phenolic -OH group.

EXPERIMENTAL

Reagents and general techniques

All the reagents used were of analytical grade. Bis(indenyl)titanium(IV)dichloride and bis(indenyl)zirconium(IV)dichloride, $(C_9H_7)_2TiCl_2$ and $(C_9H_7)_2ZrCl_2$, were prepared by the reaction of indenyl thallium(I) and titanium tetrachloride or zirconium tetrachloride in 2:1 molar ratio in tetrahydrofuran. THF (Baker AR) was dried over sodium metal and then boiled under reflux until it gave a blue colouration with Ph_2CO. It was finally dried by distillation from $LiAlH_4$. *n*-Hexane (BDH) was dried by refluxing over sodium metal followed by distillation and triethylamine was dried as reported in the literature.[10] Nitrobenzene for conductance measurements was purified by the method described by Fay *et al.*[11] Titanium and zirconium were determined gravimetrically as their oxides and chlorine was estimated as silver chloride. Nitrogen was estimated by standard method as described by Vogel.[12]

Conductance measurements were made in nitrobenzene at 20 ± 0.05°C using a Systronic Digital Direct Reading Conductivity Meter Type 304. IR spectra were recorded in "KBr pellets" in the 4000–200 cm^{-1} region using a Perkin–Elmer 621 spectrophotometer. The proton NMR spectra were recorded at ambient temperature (20°C) at a sweep width of 900 Hz with a Perkin–Elmer R-32 spectrometer. Chemical shifts (δ, ppm) are expressed relative to an internal reference of TMS (1% by volume). Electronic spectra of the complexes in

acetone were recorded on Perkin–Elmer UV-visible spectrophotometer, Model554.

Preparation of Schiff bases

To an appropriate amine (6 mmole) in 60 cm³ of freshly distilled ethanol, salicylaldehyde (5 mmole) in 60 cm³ of freshly distilled ethanol was added dropwise with vigorous stirring. There was immediate precipitation of products but the mixture was refluxed for half an hour, then cooled in an ice bath and filtered. The product was recrystallised by addition of 40 cm³ of hot ethanol. The mixture was cooled in an ice bath, filtered, and washed with sodium-dried diethyl ether and the Schiff base was dried *in vacuo*. The yield was approx. 90%.

Preparation of the complexes

All operations were carried out under strictly anhydrous conditions. The Schiff base (4 mmole) was added to a solution of $(C_9H_7)_2TiCl_2$ or $(C_9H_7)_2ZrCl_2$, (4 mmole) in 40 cm³ of dry tetrahydrofuran. To this triethylamine, Et_3N (6 mmole) was added and the mixture was refluxed (68°C) for about 10–12 hr. Precipitated $Et_3N \cdot HCl$ was removed by filtration and the volume of the filtrate was reduced to *ca.* 30 cm³ by evaporating the solvent under reduced pressure at room temperature. The crystals of the product were obtained by adding about 75 cm³ of dry *n*-hexane.

RESULTS AND DISCUSSION

Dichloro-bis-(indenyl)titanium(IV) and dichloro-bis-(indenyl)zirconium(IV), react with bidentate Schiff bases in 1:1 molar ratio to yield complexes of the type $(C_9H_7)_2Ti(SB)Cl$ and $(C_9H_7)_2Zr(SB)Cl$, respectively according to the following equation:

$$(C_9H_7)_2MCl_2 + SBH + Et_3N \xrightarrow[68°C]{THF}$$
$$(C_9H_7)_2M(SB)Cl + Et_3N \cdot HCl$$
(M = Ti(IV) or Zr(IV); (SB)⁻ represents the anion of the corresponding bidentate Schiff base SBH).

All the Schiff base complexes crystallise as yellow to yellowish–brown crystals. They are highly soluble in common organic solvents, viz., benzene, THF, acetone, dichloromethane, nitrobenzene and chloroform. Electrical conductance measurements in nitrobenzene show them to be non-electrolytes and to be susceptible to hydrolysis. The analytical and physical data of the complexes are given in Table 1.

The assignments of characteristic IR frequencies for $(C_9H_7)_2M(SB)Cl$ complexes are listed in Table 2. Absorption bands indicating the presence of indenyl groups are found at *ca.* 3100 cm⁻¹ ν(C–H), 1450 cm⁻¹ ν(C–C), 1020 cm⁻¹ δ i.p. (C–H) and 815 cm⁻¹ δ o.p. (C–H). Appearance of these indenyl bands in the Schiff base derivatives indicate that electrons in these groups remain delocalised and π-bonded (η^5) to the metal.[13] Apart from this, the bands at *ca.* 355 and 440 cm⁻¹ may be assigned to ν(M–Cl) and metal-ring vibrations,[14] respectively.

A strong band at *ca.* 1625 cm⁻¹ is observed in the spectra of Schiff bases, which is characteristic of the azomethine (–HC=N–) group. Coordination of the nitrogen to the metal atom would, however, be expected to reduce the electron density in the

(m) = multiplet, (s) = singlet

azomethine link and thus lower the (C=N) frequency. In the Schiff base complexes, this band is very slightly shifted to the lower side in our studies (ca. 1600 cm^{-1}), showing the presence of coordination through the azomethine nitrogen.[4-7,15] A high intensity band at ca. 1275 cm^{-1} in the Schiff bases can be assigned to the phenolic C-O stretching.[4] In the complexes, the C-O stretching vibrations appear at 1310-1300 cm^{-1}. This shift to higher frequency indicates bonding of the ligand to the metal through oxygen. This is further supported by the disappearance of the broad v (O-H) band in the 3300-3150 cm^{-1} region in the complexes.

Bands at 560-540 cm^{-1} and 525-425 cm^{-1} can be tentatively assigned to M-O and M-N bands, however, specific assignments are difficult.[4]

The ^{1}H HMR spectra of the complexes were taken in deutero-chloroform. Chemical shifts for the protons in δ scale are listed in Table 2. The signal due to azomethine proton appears at ca. δ 8.60 ppm, showing a downfield shift as compared to the corresponding Schiff base ligand (δ 8.45 ppm) indicating its deshielding as a result of coordination through nitrogen of the azomethine group to metal. The signals due to indenyl protons overlap with that of aromatic proton signals of Schiff base and result in a complex multiplet in the range δ 6.58-7.70 ppm. The δ values of methyl protons in case of Schiff base complexes derived from salicylaldehyde and o-, m-, or p-toluidine occur at around δ 2.10 ppm.

The disappearance of the phenolic -OH proton signal in the Schiff base complexes indicates its deprotonation and having taken part in the bond formation to metal through oxygen.

The UV spectra of the complexes were recorded in chloroform. The bands appearing at ca. 250, 320 and 385 nm are due to the $\pi - \pi^*$ (benzoid), $\pi - \pi^*$ (azomethine) and $\eta - \pi^*$ (azomethine) electronic transitions, respectively. In the ligands (Schiff bases) the first two bands were observed at the same positions, whereas the third band was observed at ca. 425 nm. This hypsochromic shift in the Schiff base complexes may be due to the donation of the lone pair of electrons by the nitrogen of the azomethine group to the central metal atom.[5]

The visible spectra of the complexes in chloroform show a single band in the 24,800-24,300 cm^{-1} region. Absence of a d-d transition rules out the presence of an unpaired electron in the metal ion confirming the quadrivalent state of these metals.[16-18] On the basis of elemental analyses and spectral studies, the structure assigned to the $(C_9H_7)_2$M(SB)Cl complexes will involve the Schiff base bonding in the bidentate mode.

KINETICS AND MECHANISM OF SOME FAST ANATION REACTIONS OF A SERIES OF SUBSTITUTED dien COMPLEXES OF PALLADIUM(II). TEMPERATURE AND PRESSURE DEPENDENCIES IN WEAKLY ACIDIC AQUEOUS SOLUTION[1]

E. L. J. BREET†, R. van ELDIK* and H. KELM
Institute for Physical Chemistry, University of Frankfurt, Robert-Mayer-Str. 11,
6000 Frankfurt/Main, F.R.G.

Abstract—Anation reactions of the type $[Pd(L)(H_2O)]^{2+} + X^- \rightarrow [Pd(L)X]^+ + H_2O$ with L = 1, 4, 7-Et$_3$dien, 1, 1, 7, 7-Me$_4$dien and 1, 1, 4, 7, 7-Me$_5$dien and $X^- = Cl^-$, Br^-, I^- and N_3^- have been studied kinetically as a function of $[X^-]$, temperature and pressure (up to 1 kbar). Second-order anation rate constants decrease with an increase in the size of L, and are accompanied by an increase in $\Delta H^{\ne}$. For a given L the sequence $Cl^- < Br^- < I^- < N_3^-$ holds, and the values of $\Delta S^{\ne}$ and $\Delta V^{\ne}$ are consistent with an associative mechanism. The results are discussed with reference to similar anation reactions previously investigated.

During the past few years this laboratory has undertaken various studies on the kinetics and mechanism of substitution reactions of diethylenetriamine (dien) and substituted dien complexes of platinum(II) and palladium(II).[2-10] One of the aims of these studies was to determine the effect of steric hindrance on the rate and corresponding mechanism of substitution. The majority of these reactions are fast, so that with conventional kinetic techniques we were limited to the investigation of a few systems only. The recent addition of a high-pressure stopped-flow system[10] to our instrumentation, has allowed us to substantially expand the series of complexes previously investigated. We have now undertaken detailed kinetic studies of series of fast anation and substitution reactions of some dien and substituted dien complexes of palladium(II).

We planned to study anation reactions for all the complexes listed in Table 1, but some reactions are so fast that we could perform kinetic measurements for three complexes only, viz. [Pd(1,4,7-Et$_3$dien)(H$_2$O)]$^{2+}$, [Pd(1,1,7,7-Me$_4$dien)(H$_2$O)]$^{2+}$ and [Pd(1,1,4,7,7-Me$_5$dien)(H$_2$O)]$^{2+}$, in addition to those already investigated, viz. [Pd(1,1,4-Et$_3$-

dien)(H$_2$O)]$^{2+}$, [Pd(1,1,7,7-Et$_4$dien)(H$_2$O)]$^{2+}$ and [Pd(4-Me-1,1,7,7-Et$_4$dien)(H$_2$O)]$^{2+7,10}$. In this paper we report on the temperature and pressure dependencies of some anation reactions of these complexes in weakly acidic aqueous solution. A comparison between these results and the previously reported kinetic data permits some interesting mechanistic conclusions.

EXPERIMENTAL

A series of palladium(II) substituted dien complexes (Table 1) was prepared according to standard literature procedures.[11] The preparation of the complexes was simplified by isolating them as perchlorates. In a similar effort to simplify the tedious preparative procedure for the 1, 4, 7-Me$_3$dien complex we succeeded in isolating the species [Pd(1, 4, 7-Me$_3$dien)Cl$_2$]HCl, the details of which are reported elsewhere.[12] The complexes were subjected to chemical analysis,[13] the results of which are summarized in Table 1.

For the present study each complex was converted from the chloro into the aquo form by the addition of an equivalent amount of AgClO$_4$ to a hot solution of the complex and removal, on cooling, of the AgCl precipitate by filtration through a Sartorius membrane filter (0.1 μm pore size). The UV-visible spectral data presented in Table 2 for the chloro, aquo and hydroxo species (the latter two prepared in solution only), as well as for the species produced during anation by Cl^-,

*yields the same species in aqueous solution as the complex [Pd(1,4,7-Me$_3$*dien*)Cl]Cl prepared by the authors of ref. 11 (cf. ref. 12)

**differ somewhat from the data for the chloro species since the slight hydrolysis of these species in aqueous solution is excluded here by an excess of free chloride ion

Br⁻, I⁻, and N$_3$⁻, were obtained using a Perkin–Elmer 555 spectrophotometer. The acid dissociation constants of the aquo species reported in Table 3 were determined spectrophotometrically since deprotonation of the dien ligand led to complications at high pH in the normal titrimetric procedure. The method is based on the relation pH = pK + log{$(A_{aquo} - A)/(A - A_{hydroxo})$}, where A_{aquo} and $A_{hydroxo}$ are the absorbances of the aquo and hydroxo species respectively and A the absorbances at various pH during the titration. Solutions titrated were at an ionic strength of 0.1 mol dm^{-3}, adjusted with NaClO$_4$, so as to be in agreement with all subsequent kinetic experiments. All pH measurements were obtained using a Metrohm E520 pH meter.

Table 3. Acid dissociation pK values of substituted dien aquo complexes

Complex	pK
[Pd(dien)(H₂O)]²⁺	7.38 ± 0.01
[Pd(1,4,7-Me₃dien)(H₂O)]²⁺	7.05 ± 0.01
[Pd(1,4,7-Et₃dien)(H₂O)]²⁺	7.24 ± 0.01
[Pd(1,1,7,7-Me₄dien)(H₂O)]²⁺	7.54 ± 0.01
[Pd(1,1,4-Et₃dien)(H₂O)]²⁺	7.12 ± 0.01
[Pd(1,1,4,7,7-Me₅dien)(H₂O)]²⁺	7.29 ± 0.02

The kinetic experiments were performed on an Aminco stopped-flow system at ambient pressure and on the recently described[10] high-pressure stopped-flow system at pressures up to 1 kbar. The pseudo-first-order rate constants k_{obs} were determined in the usual way from six successive kinetic runs, a linearity standard of at least three half-lives being set for the corresponding plots. Chemicals of analytical reagent grade were used throughout the study and test solutions were prepared using doubly distilled water.

RESULTS AND DISCUSSION

The results of the chemical analysis of the synthesized complexes are in excellent agreement with the theoretically expected values as shown by the entries in Table 1. The measured UV-visible spectral data compare favourably with the available literature data according to Table 2. The pK values of all the aquo species in Table 3 fall within a narrow range of values as expected.

The anation reactions were studied at pH = 5 so that only aquo species were present in solution and no complication from the possible participation of hydroxo species could occur. These reactions were expected to exhibit, contrary to the two-term rate-law usually observed for substitution reactions of square planar complexes,[14] a first-order dependence on the entering ligand concentration. Thus k_{obs} was measured initially as a function of [X⁻] (X⁻ = entering ligand) at 25°C to confirm, as indicated in Table 4, that $k_{obs} = k_{anation}[X^-]$. In the subsequent measurements of the temperature and pressure dependencies of k_{obs} (Tables 4 and 5) only

one [X⁻] was considered. These measurements could, however, only be performed for the species [Pd(1,1,7,7-Me₄dien(H₂O)]²⁺ and [Pd(1,4,7,7-Me₅-dien)(H₂O)]²⁺ {and previously[10] for the species [Pd(1,1,4-Et₃dien)(H₂O)]²⁺}, since the anation reactions are so fast that for the species [Pd(1,4,7-Et₃dien)(H₂O)]²⁺ a single value of k_{obs} (Table 4) and for the species [Pd(1,4,7-Me₃dien)(H₂O)]²⁺ and [Pd(dien)(H₂O)]²⁺¹⁰ no data at all could be obtained despite the extremely low concentration and temperature conditions. This demonstrates the tremendous effect the steric hindrance, brought about by the dien ligand substituents, has on the anation rate.

The kinetic data presented in Tables 4 and 5 show some interesting tendencies. The value of $k_{anation}$ increases significantly with increasing nucleophilicity of the entering ligand according to the series Cl⁻ < Br⁻ < I⁻ < N₃⁻. The sequence is, with the exception of the azide ion (see further discussion), in agreement with the n_{Pt} values[15] usually observed for these ligands. The increase in $k_{anation}$ is accompanied by a decrease in the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ determined by application of the Eyring equation. Similarly the values of $\Delta V_{exp}^\ddagger$, calculated from the slopes of the linear plots of $\ln k_{obs}$ versus pressure, show a decrease along the quoted series and parallel the tendency in $\Delta S^\ddagger$ (Table 5). The significantly negative values of $\Delta S^\ddagger$ and $\Delta V_{exp}^\ddagger$ emphasize the associative nature of the anation process. In this respect it should be borne in mind that $\Delta V_{exp}^\ddagger$ is a composite quantity consisting of contributions from $\Delta V_{intr}^\ddagger$, due to changes in bond lengths and angles, and

* presented in non SI-units for direct comparison with available literature data

$\Delta V_{\text{solv.}}^{+}$, due to changes in solvation during the formation of the transition state. On the one hand it is reasonable to argue that $\Delta V_{\text{solv}}^{+}$ should be positive due to charge neutralization during the anation process and constant for the various entering ligands on account of their similar charge. On the other hand it is expected that $\Delta V_{\text{intr}}^{+}$ should be negative and should depend on the size of the entering ligands. It follows that $\Delta V_{\text{intr}}^{+}$ outweighs $\Delta V_{\text{solv}}^{+}$ to produce an overall negative value for $\Delta V_{\text{exp}}^{+}$ and that the trend in $\Delta V_{\text{exp}}^{+}$ can be ascribed to an increasing negative contribution from $\Delta V_{\text{intr}}^{+}$ along the series $Cl^- < Br^- < I^- < N_3^-$.

Alternatively, ion-pairing[16] may play a significant role during anation, resulting in a mechanism

$$[Pd(L)(H_2O)]^{2+} + X^- \overset{K}{\rightleftharpoons} \{Pd(L)(H_2O)^{2+} \cdot X^-\}$$
$$\swarrow k$$
$$Pd(L)X^+ + H_2O$$
for which $k_{\text{obs}} = kK[X^-]/(1 + K[X^-])$. The rate-law simplifies to $k_{\text{obs}} = kK[X^-]$ in our case where no appreciable curvature in the k_{obs} vs $[X^-]$ plots (Table 4) is observed. It follows that $k_{\text{anation}} = kK$ and $\Delta V_{\text{exp}}^{+} = \Delta \bar{V}(K) + \Delta V^+(k)$ with $\Delta \bar{V}(K)$ being expected positive due to charge neutralization during ion-pair formation. The significantly negative values of $\Delta V_{\text{exp}}^{+}$ (Table 5) suggest that $\Delta V^+(k)$ should be even more negative to outweigh the positive contribution from $\Delta \bar{V}(K)$ and thus confirm the associative character of the anation process.

Table 6 summarizes the present kinetic data obtained for anation by Cl^- with those previously measured for some other palladium(II) substituted dien complexes. The reactivity decreases in the order 1, 4, 7-Et$_3$dien > 1, 1, 7, 7-Me$_4$dien > 1, 1, 4-Et$_3$dien > 1, 1, 4, 7, 7-Me$_5$dien > 1, 1, 7, 7-Et$_4$dien > 4-Me-1, 1, 7, 7-Et$_4$dien and is accompanied by an increase in ΔH^+. This is ascribed to a corresponding increase in the extent of steric hindrance along the quoted series. The results illustrate the similarity in the steric behaviour of methyl and ethyl groups and the importance of the position of substitution (see 1, 4, 7-Et$_3$dien and 1, 1, 4-Et$_3$dien). The values of ΔS^+ and $\Delta V_{\text{exp}}^{+}$ are such that no definite tendency can be assigned. For instance, the more negative value of $\Delta V_{\text{exp}}^{+}$ for the anation of the species [Pd(4-Me-1,1,7, 7-Et$_4$dien)(H$_2$O)]$^{2+}$ is in agreement with le Noble's hypothesis[17] regarding more sterically hindered associative reactions having "later" or more product-like transition states, but it is in disagreement with the suggestion by the almost zero value

of ΔS^+ that the anation process is less associative (i.e. more dissociative). Moreover, the first and the last entry of $\Delta V_{\text{exp}}^{+}$ in Table 6 are almost the same, strongly emphasizing the prevailing associative process for the series of complexes quoted. The magnitude of $\Delta V_{\text{exp}}^{+}$ can once again be interpreted in terms of positive and negative contributions from $\Delta V_{\text{solv}}^{+}$ and $\Delta V_{\text{intr}}^{+}$, or $\Delta \bar{V}(K)$ and $\Delta V^+(k)$, respectively as discussed above.

Finally, a comparison of the results of this investigation with those reported for the anation of the species [Pt(dien)(H$_2$O)]$^{2+4,18}$ highlights an interesting difference. The order of reactivity $I^- > Br^- > N_3^- > Cl^-$ reported[4] for this species differs from the order of reactivity $N_3^- > I^- > Br^- > Cl^-$ found in the present study. The markedly higher nucleophilicity of the azide ion in the case of the palladium(II) systems has also been observed in other studies[4,5] and should be explained in terms of the inherent nature of the sterically hindered complexes. Unfortunately, the reactivity order for the extremely fast anation reactions of the corresponding species [Pd(dien)(H$_2$O)]$^{2+}$ cannot be determined to aid in the understanding of this feature.

Abstract—The effects of pH have been examined on the extraction of the title ions by complexing with LIX-64N in kerosene. The extent of metal extraction as a function of pH is: Cu(II) < Fe(III) < Ni(II) < Zn(II) < Co(II). Stripping of all metal ions but cobalt with sulphuric acid from loaded kerosene complexing solutions is easily accomplished. Oxidation of Co(II) to Co(III) in the organic phase prevents stripping of this metal ion.

Solvent extraction processes represent a technique of high significance in the hydrometallurgical field.[1-3] Extraction of metal ions into a water insoluble organic phase can only be effected if the metal ions are transferred as neutral species. Suitable to this purpose are acidic chelating extractants containing long chain alkyl groups to increase the lipophilicity of both complexes and ligands. To this class of ligands belong the substituted *ortho*-hydroxyoximes produced by General Mills Inc. and marketed as LIX reagents.[4-6] Since these reagents are known to be specific for copper extraction from acidic solutions,[6-8] most investigations have dealt with this metal and scarce information is available on the extraction of other metals. The present research partially fulfils these requirements, extending the solvent extraction process by the LIX-64N reagent to Cu(II), Ni(II), Co(II), Zn(II), and Fe(III) metal ions. Back extraction of some metal ions from kerosene solutions with sulphuric acid has also been studied.

EXPERIMENTAL

Apparatus

The extraction apparatus consists of a series of 100 cm³ round flasks magnetically stirred and immersed in a water bath set at 22°C. Metal analyses were performed on a Perkin–Elmer 380 atomic

absorption spectrophotometer. The pH measurements were taken on a Radiometer PHM28c pHmeter calibrated at pH 4.00 and pH 8.00 using buffer solutions.

Reagents

LIX-64N (General Mills Inc.) was used as a chelating extraction reagent and white kerosene (Fluka) as a diluent. Throughout a 10% (v/v) solution of this solvent (commercially available) was employed. $CuSO_4 \cdot 5H_2O$, $Fe_2(SO_4)_3 \cdot H_2O$, $NiSO_4 \cdot 7H_2O$, $ZnSO_4 \cdot 7H_2O$, and $CoSO_4 \cdot 7H_2O$ (Carlo Erba, Reagent grade) were dissolved in distilled water and used as 2.5×10^{-2} M solutions; a 8.33×10^{-3} M solution was however used for the iron salt, owing to its different stoichiometry. The pH of the aqueous phase was adjusted using concentrated solutions of sulphuric acid and sodium hydroxide. All solutions were adjusted to an ionic strength of 0.1 M with Na_2SO_4.

Extraction procedure

The distribution of the single metal ions between equal phase volumes (10.0 cm³) was examined at various hydrogen ion concentrations. 10.0 cm³ portions of each aqueous metal ion solution were adjusted at various pH using both H_2SO_4 and NaOH and added to 10.0 cm³ of 10% kerosene LIX-64N solution. Flasks were capped and mixtures magnetically stirred for 2 hr to reach equilibrium. The contents of each flask were then

---

*Author to whom correspondence should be addressed.

transferred to a separatory funnel and allowed to separate for *ca.* 1/2 hr. pH and metal concentration of the decanted aqueous layer were then determined. The metal ion contents in the organic phase were calculated as the difference between the starting aqueous soution concentration and the residual contents after equilibration. To achieve more accurate data concerning selective separations of couples of ions (e.g. Cu–Ni) the above procedure was slightly modified. The aqueous solutions were prepared mixing up two equal portions (10.0 cm^3) of the Cu and Ni solutions, each having the same concentration used for single experiments (i.e. 2.5×10^{-2} M) and the volume of the organic phase containing the chelating ligand was doubled. Thus, a constant LIX-64 N/metal ion ratio was always used.

Back extraction

The efficiency of aqueous sulphuric acid solutions in stripping the metal ions from loaded kerosene phases was determined by shaking equal volumes (10.0 cm^3) of kerosene solutions and sulphuric acid at various concentrations. After *ca.* 2 hr the mixtures were allowed to separate in a separatory funnel and the metal ion contents of the aqueous phases measured.

Loading capacity of LIX-64N

Since LIX-64N is a commercial solution of a mixture of an aromatic 2 - hydroxy - benzophenoneoxime (LIX-65N) and of an aliphatic α-hydroxyoxime (LIX-63) (the latter in small proportion, *ca.* 5%) in a high molecular weight hydrocarbon solvent,[9] the content of the active chelating ligand cannot be directly determined. The matter is also complicated by the existence of a *syn-anti* equilibrium, where the *syn* isomer is inactive. The loading capacity of the extractant solution was therefore chosen as active ligand concentration, the loading capacity being defined as the maximum amount of Cu(II) that a solution of the LIX reagent can accept when contacted with an infinite amount of a concentrated aqueous solution of Cu(II). This was experimentally determined by contacting successively 50 cm^3 of the LIX solution with several aqueous solutions of CuSO$_4$ 0.1 M at pH of *ca.* 6 (a value for which the extraction of Cu(II) is highest and the ligand cannot receive any more Cu(II) ions. See Fig. 1). The copper contained in the saturated organic phase was then stripped with five 20.0 cm^3 portions of 1 M H$_2$SO$_4$.

The molar amount of the active LIX reagent was considered to be twice the Cu(II) ion present in the stripped solution, since a complex of the type Cu(LIX)$_2$ is assumed to be formed in the kerosene

phase. On this basis the titre of the commercial LIX-64N stock solution was determined as 1.02 M.

RESULTS AND DISCUSSION

LIX-Reagents, which were introduced about twenty years ago by General Mills for the hydrometallurgical refining of copper, are in general high molecular weight hydroxyoximes. In particular, LIX-64N is a blending of 2 - hydroxy - 5 - nonylbenzophenone oxime (LIX-65N) and 5,8 - diethyl - 7 - hydroxydodecan - 6 - one oxime (LIX-63), the latter being the minor component (typical ratio 20:1 by weight).[4,9]
LIX-65N   LIX-63

Both reactants behave as acidic monoprotic ligands, HR, so that the extraction of divalent metal ions can be represented by the following equation:

$$M^{2+}_{(a)} + 2HR_{(o)} \rightleftharpoons MR_{2(o)} + 2H^+_{(a)} \qquad (1)$$

(where the subscripts (*a*) and (*o*) denote aqueous and organic phases, respectively). Previous studies showed that LIX-63 serves mainly to enhance the kinetics of extraction and has little or no effect on copper extraction, at least up to pH 4.[6,10]

Dependence of extraction ease on pH

Formation of uncharged metal complexes with LIX-64N reagent is largely dependent on the acid content of the aqueous phase, as can be seen from equilibrium (1). The distribution of a metal ion in an organic phase containing such reagents is therefore strictly controlled by the acidity of the solutions. Results from contacting equal volumes of kerosene and aqueous phases are shown in Fig. 1 as a plot of the percentage extraction vs the final pH of the aqueous phase.

Owing to the different charge (Fe^{3+} is likely to afford a complex of the type FeR$_3$), in order to get comparable data the iron concentration was chosen such that the amount of the chelating ligand was twice that stoichiometrically required, as for other divalent cations. Results of extraction from solutions containing single ions (Fig. 1) emphasize that all the metal ions investigated form stable complexes with LIX-64N in neutral or even acidic solutions. By properly choosing the pH ranges,
Fig. 1. Extraction of 2.5×10^{-2} M solutions of Cu(II), Ni(II), Co(II), Zn(II), and of a 1.67×10^{-2} M solution of Fe(III) with 0.1 M LIX-64N in kerosene; $a/o = 1$.

they can be selectively separated from each other. The extent of metal extraction as a function of pH, Cu(II) < Fe(III) < Ni(II) < Zn(II) < Co(II), is in strict agreement with the stability constants of the related salicylaldoxime complexes of these ions.[11] The most striking deviation is represented by Co(II), which although having been reported to have the same stability constant as Zn(II), is extracted at much higher pH values. The extraction of these ions by salicylaldoxime in benzene also compares well with the behaviour reported in Fig. 1 for the LIX-64N reagent.

The parallelism found for LIX-64N and salicylaldoxime is in agreement with the proposal of the same structure for the complexes obtained by both chelating ligands, which is quite an expected result. The structure below is thus proposed for the Cu(II) complex:[6,13]
The distribution plot of Cu(II) agrees also with that reported by Flett et al. for LIX-65N. To get more reliable data on selectivity, in one case an extraction study of an equimolecular mixture of two ions, namely Cu(II) and Ni(II), has been carried out. The results reported in Fig. 2 closely

resemble the corresponding curves of Fig. 1, thus confirming their reliability and showing that the extraction of copper is essentially unaffected by the presence of nickel, and vice versa.

The results and experimental conditions from this study prove of straight forward application to large scale commercial metal recovery processes. In
Fig. 2. Extraction of an aqueous equimolecular mixture of Cu(II) and Ni(II) (1.25×10^{-2} M) with 0.1 M LIX–64N in kerosene; $a/o = 1$.

fact, the ions studied undergo practically complete extraction in kerosene in a single run. Low solubility in water (reducing losses to a minimum) is also satisfied by kerosene, which thanks to its low volatility, can be used at quite high temperatures, a condition often required to speed up extraction in industrial applications. The ligand and metal complexes, also have low aqueous solubility in the pH range explored. At pH 1.8 the following data have been reported:[14]
	R=H	R = Ph$_3$(LIX-65N)	LIX-63	Cu(LIX-65N)$_2$
Solubility (10^6 M mol l/l)	6.8	1.0	15.5	0.13

A slight increase in solubility is expected for alkaline solutions of these ligands, where dissociation of the phenolic OH group takes place yielding ionic species of enhanced solubility in water. For instance, when R = H (see the structure above), the following behaviour was observed:[14]

pH	< 8	10.5	11.5	12.5
Solubility (10^6 M)	< 7	40	140	> 380

Although these values are expected not to be reached in a two phase system because of the favourable distribution of the chelating ligand in the organic phase[15,16] use of ligands of this type at higher pH values than those explored in this work is not advised. Moreover, precipitation of metal hydroxides in neutral to alkaline solutions can make the extraction more difficult.

BACK EXTRACTION (OR STRIPPING) OF METAL IONS FROM KEROSENE SOLUTIONS

For use in industrial applications, ease of recovery of metal from the organic phase and regeneration of the reagent for recycle are essential. This can be accomplished by stripping the kerosene solutions of the complexes with sulphuric acid, thus obtaining a concentrated aqueous solution of the metal ions and an organic phase containing the chelate reagent, which can be recycled. It should be pointed out that the metals requiring higher pH values in the extraction process require lower acid concentration in their back extraction from the organic phase. In this respect, nickel(II) and copper(II) (Fig. 3) have a regular behaviour whilst cobalt(II) is hardly stripped from the organic solutions.

Indeed, even concentrated sulphuric acid has no significant effect on the extracted cobalt complex. This fact may be attributed to the oxidation of Co(II) to Co(III) and the formation of stable
Fig. 3. Back extraction of 0.1 M LIX-64N kerosene solutions loaded with Cu(II), Ni(II) and Co(II) by sulphuric acid.

μ-peroxo-complexes in the organic phase.[17,18] The stripping process is favourable and complete for Cu(II) and Ni(II) under relatively mild conditions. By controlling the concentration of the sulphuric acid it is also possible to effect a further separation of the metal ions. When diluted acid is employed only nickel(II) is stripped, rejecting both copper(II) and cobalt(II) ions. Spot experiments carried out on Fe(III), and Zn(II) kerosene solutions indicate the reversibility for these systems.

CONCLUSIONS

Substituted salicylaldoximes, such as LIX-64N, proved to be highly selective copper(II), nickel(II), zinc(II), and iron(III) ions. The availability of the chelating extractants will both allow metal ion recovery from low grade solutions and separation in purification processes. The only drawback highlighted by this study is the irreversibility of cobalt(II) extraction.

Abstract—^{27}Al chemical shift data of polycrystalline LiAlO$_2$ polymorphs, obtained from high field measurements in combination with magic-angle spinning techniques, have been used for the determination of the Al coordination in the α-, β-, and γ-phase. The β-phase was shown to have only tetrahedrally coordinated Al atoms. In addition quadrupole coupling data have been derived from analysis of low field NMR spectra of ^{27}Al in order to characterize the symmetry of the Al sites. The NMR results are discussed with regard to the crystal structure of the phases.

^{27}Al nuclear magnetic resonance can provide structural information about the environment of the Al nuclei in polycrystalline and amorphous samples using either quadrupole coupling data or chemical shifts. In the first case the quadrupole moment (eQ) of the Al nucleus is used as a sensitive probe for the electric field gradient (EFG) at the nuclear site. The resulting quadrupole coupling constant e^2qQ/h (h is Planck's constant, and $eq = V_{zz}$) is a measure of the size of the electric field gradients, and the EFG tensor is characterized by the asymmetry parameter $\eta = (V_{xx} - V_{yy})/V_{zz}$ (V_{ii} denotes components of the EFG tensor in the principal coordinate system with $|V_{xx}| \leq |V_{yy}| \leq |V_{zz}|$).

In the other case the magnetic shielding of the aluminium by its electronic environment is investigated. As it has been shown recently,[1-3] the second way proves to be a convenient method for the identification of AlO$_4$ tetrahedra and AlO$_6$ octahedra. So in aluminates and aluminium oxides

AlO$_6$ groups provide shifts between 0 and 20 ppm, AlO$_4$ units give rise to lines between 60 and 80 ppm. Furthermore, in addition to their dependence on the special Al coordination, the chemical shifts were also shown to be dependent on the type of nuclei present in the second coordination sphere.[4] The determination of the ^{27}Al chemical shifts, usually complicated by the dominant quadrupolar broadening in solids, was facilitated at high magnetic fields in combination with magic-angle spinning technique (MAS) which greatly suppresses quadrupolar line broadening.[5,6] The quadrupole coupling data are usefully determined at low magnetic fields.

For a systematic NMR investigation both at high and low magnetic fields the three known polymorphs of LiAlO$_2$ were chosen which have different crystal structures with different kinds of Al coordination. In such a system, all phases have the same chemical composition, possible additional influences by various cations being eliminated.

In the trigonal α-LiAlO$_2$ the Li and Al atoms

have octahedral coordination,[7] in the tetragonal γ-phase (space group $P4_12_12$) both are tetrahedrally coordinated.[8] For the third modification, β-LiAlO$_2$, conflicting structures have been proposed. So Chang and Margrave[9] quote a monoclinic structure for the β-LiAlO$_2$, containing Li and Al atoms in mixed tetrahedral and octahedral coordination, whereas it is classified by Sachenko–Sakun *et al.*[10] and West[11] as orthorhombic and isostructural with β-LiGaO$_2$ (space group $Pna2_1$) with only tetrahedrally coordinated atoms.[12]

Quadrupole coupling data of LiAl$_5$O$_8$, a modified spinel form, have been reported by Stauss.[13]

EXPERIMENTAL

The low field ^{27}Al NMR measurements were carried out on a wide-line NMR spectrometer KRB 35 at frequencies of 4, 9 and 16 MHz. The first derivatives of the spectra were recorded. The high field measurements were carried out at the Friedrich–Schiller-University of Jena on a FKS 176 FT–NMR spectrometer supplemented with a 6.4 T superconducting magnet. The spectra were recorded at 70.4 MHz with static samples and in combination with the MAS-technique using a spinning rate of about 2.7 kHz. $\pi/6$ pulses of 1.6 μs duration were used. Up to 5000 FID's were accumulated with a repetition time of 0.5 s.

The chemical shifts, δ (ppm), measured relative to an external standard of aqueous AlCl$_3$ solution are denoted by a positive sign for low field shifts. The reproducibility of the chemical shift values was 1 ppm. The quadrupole coupling constants, the dipolar broadening, and asymmetry parameters were derived by a least-square fitting from the low field spectra, recorded at different magnetic fields, with an accuracy of 0.1 MHz, 0.5 kHz and 0.05, respectively.

The preparation of the samples is described elsewhere.[14]

RESULTS AND DISCUSSION

Figure 1 shows the derivative ^{27}Al NMR spectra of the three LiAlO$_2$ polymorphs recorded at low magnetic field (9 MHz, respectively 16 MHz) with conventional continuous wave technique. The corresponding spectra, recorded using pulsed NMR techniques, partially showed incorrect lineshapes due to the blocking of the receiver by the r.f. pulses. Therefore they were not suitable for the determination of the quadrupole parameters. The lineshape of the powder-pattern of the central (1/2, −1/2) spin transition perturbed by second-order quadrupole effects was computed according to
Fig. 1. ^{27}Al NMR spectra of the LiAlO$_2$ polymorphs obtained at 9 and 16 MHz. (——— experimental spectrum; ‐‐‐‐ computed lineshape; parameters are given in Table 1).

Narita *et al.*[15] The quadrupole coupling constant and asymmetry parameter were derived by a least-squares fitting.[16] Dipolar broadening was considered using a Gaussian convolution function with a peak-to-peak width of 2β of the derivative. The results are given in Table 1.

The corresponding high field spectra, shown in Fig. 2, illustrate the expected decrease of the quadrupolar broadening of the spectra with increasing magnetic fields. Therefore, at high fields correct lineshapes of the spectra could be obtained by pulsed NMR. The spectra, additionally narrowed by magic angle spinning of the samples, are also shown in Fig. 2. These MAS spectra allow an approximate determination of the chemical shifts. Considering the residual quadrupole shifts, the exact isotropic chemical shifts ($δ_{iso}$) can be determined using the quadrupole coupling parameters derived from the low field spectra (see Table 1). The value of $δ_{iso}$ can be determined either from the fitted high field spectra of the static sample or can be calculated directly adding a correction term[5,16]

$$δ_{corr} = 3 \times 10^4 \cdot \frac{1}{5}\left(1 + \frac{η^2}{3}\right)$$

$$\times \left(\frac{e^2qQ}{hν_0}\right)^2, \text{(ppm)} \qquad (1)$$

where $ν_0$ is the resonance frequency (MHz).

The chemical shifts $δ_{exp}$, experimentally obtained from the MAS spectra, the so-calculated correction

terms δ_{corr}, and the resulting exact isotropic chemical shifts δ_{iso} are also given in Table 1.

Chemical shifts

The chemical shifts of 17 and 82 ppm unambiguously reflect the octahedral Al coordination in the α-phase, and the tetrahedral Al coordination in the γ-phase of LiAlO$_2$, respectively. Likewise the chemical shift of 83 ppm in β-LiAlO$_2$ is a certain

evidence that the Al atoms in this phase are tetrahedrally coordinated. The comparison of the intensities of the NMR spectra of the various LiAlO$_2$ polymorphs showed comparable quantities. By this means it is checked that all of the Al nuclei are detected. Such an analysis is necessary since in some cases, mainly observed with 6-coordinated Al,[17] certain distorted Al–O structural groups could not be detected by NMR because of extreme line broadening. Thus it can be concluded that only tetrahedrally coordinated Al atoms exist in β-LiAlO$_2$. By this the NMR studies confirm the conclusions of Sachenko–Sakun et al.[10] and West[11] who classified the β-LiAlO$_2$ as orthorhombic with tetrahedral Al atoms only. A detailed discussion of this result in connection with the results of other methods is given elsewhere.[14]

As it can be seen from Figs. 1 and 2, the spectrum of β-LiAlO$_2$, compared to those of the other modifications, shows the smallest half-width of the resonance line indicating small distortions, i.e. minor electric field gradients, at the Al sites in this phase. This is also reflected in the quadrupole coupling constant of 1.8 MHz, compared to values of 2.8 and 3.2 MHz for the other phases. Corresponding to the small quadrupole coupling constant also a small, above-mentioned correction of the chemical shift value δ_{exp} results according to eqn (1). Whereas the experimentally found chemical shifts of γ- and β-LiAlO$_2$ actually differ more than 10 ppm, after the necessary correction only one common value of about 82 ppm results for both phases which approaches the value of Al(OH)$_4^-$ ions in alkaline solutions. Therefore the variation of δ_{exp} is to be assigned to residual quadrupole shifts and not to different magnetic shieldings of the Al nuclei. Thus the corrected ^{27}Al NMR chemical shifts seem to provide, apart from the direct coordination number, no information

about the further AlO_4 environment in this case. It has to be considered, however, that there are indeed different phases but the same kind of cations. So possible influences of the cations on the Al–O bonding and accordingly on the chemical shift are eliminated.

Quadrupole coupling parameters

Further information on the structure can be derived from the quadrupole coupling constant e^2qQ/h and the asymmetry parameter η. Whereas, as discussed above, the quadrupole coupling constant of β-$LiAlO_2$ distinctly contrasts, the asymmetry parameter in the different phases also point to different symmetries of the Al sites.

For the octahedrally coordinated Al in the α-phase an asymmetry parameter of 0.05 was derived which requires axial symmetry in the electric field gradients (zero asymmetry parameter). According to the trigonal structure of α-$LiAlO_2$[7] this axial field gradient can be assigned to a shortening of the AlO_6 octahedra along a threefold axis (along c-direction). The distortion of the octahedron is reflected in the two different interatomic O–O distances within the edges but not in the Al–O distance which is equal for all oxygen atoms (1.90 Å).[7] The two extremely different kinds of interatomic O–O distances of 2.80 and 2.58 Å are obviously the reason for the large quadrupole coupling constant of 3.2 MHz.

In the cases of the other two phases with tetrahedral Al coordination asymmetry parameters of 0.7 and 0.55, respectively, were obtained indicating nonaxial symmetry of the Al sites. This is in accordance with the structures of γ- and β-$LiAlO_2$ referring to the proposal of orthorhombic symmetry in β-$LiAlO_2$ as confirmed by our chemical shift data. In both structures there is no n-fold rotation axis with $n > 2$ for the AlO_x polyhedra hence $\eta \neq 0$ is required. Only in the case of the γ-$LiAlO_2$ (space group $P4_12_12$)[8] a twofold axis exists for the AlO_4 groups which requires $\eta \neq 0$, too.

Both structures consist of infinite three-dimensional arrays of AlO_4 and LiO_4 tetrahedra. Whereas in the case of the β-phase the tetrahedra have only vertices in common, in the γ-phase each AlO_4 tetrahedron shares one of its edges with another LiO_4 tetrahedron and each vertex of the tetrahedron is shared with two additional tetrahedra, one of each kind. Therefore in the latter case a significant distortion of the AlO_4 results which is reflected in a distinct decrease of one of

the O–Al–O bond angles to 101.7°, and correspondingly in a shortening of one of the six edges of the tetrahedron with an interatomic O–O distance of 2.737 Å compared with the average of the remaining five, nearly identical O–O distances of 2.900 Å.[8] This is apparently the reason for the great coupling constant of 3.2 MHz in the case of γ-$LiAlO_2$, whereas in the case of the β-$LiAlO_2$ the exclusive connection of the tetrahedra via vertices, having nearly equal O–O distances, explains the small quadrupole coupling constant of 1.8 MHz.

This illustrates that, although having a crystal structure with a higher symmetry, special structural groups can be subject to stronger distortions. So general conclusions concerning the electric field gradients at the Al sites in AlO_x polyhedra cannot be derived from the knowledge of the type of crystal structure but from a detailed analysis of the neighbouring atoms only.

NOTE

SYNTHESIS AND CHARACTERISATION OF ReOCl₃(DTO)₂ AND ReOCl₃(MBT)₂ COMPLEXES†

V. YATIRAJAM* and M. LAKSHMI KANTAM

Department of Chemistry, Kurukshetra University, Kurukshetra 132119, India

Abstract—New complexes of Re(V) with dithiooxamide and 2-mercaptobenzothiazole with the general formula $ReOCl_3L_2$, were prepared starting from potassium perrhenate. The compounds were characterised by chemical analysis, optical spectra and magnetic susceptibilities.

Many complexes of the general formula $ReOX_3L_2$ are known.[1] We report below the preparation of two new complexes of the type $ReOX_3L_2$ where X = Cl, and L is DTO† or MBT† by reacting the ligand with H_2ReOCl_5 in acetic acid. Complexes of these ligands with some transition metals[2,3] are known, but not with rhenium(V).

EXPERIMENTAL

Measurements and materials

Spectra were recorded on Beckman DU-2, Beckman IR-20, Brucker IFS 113 as applicable. Magnetic susceptibilities were determined by the Gouy method and conductivities on a Philips bridge PR 9500/90. Standard methods were used for determining the elements. The ligands were recrystallised from ethanol. Petroleum ether (60–80°) and other pure chemicals were used after thorough drying. Experiments were carried out in a glove box under dry nitrogen.

Preparations

$ReOCl_3(DTO)_2$—0.500 g of potassium perrhenate and 0.200 g of hydroquinone were dissolved in 16.7 cm³ of conc. HCl and vigorously shaken. The pure yellow solution of $ReOCl_5^{2-}$ ion[4] was then mixed with 46 cm³ of saturated magnesium chloride solution and extracted with 30 cm³ methyl ethyl ketone. The ketone layer was then mixed well with 15 cm³ each of acetic acid and acetic anhydride, while cooling under the tap. The cold solution was shaken with 30 cm³ petroleum ether. Two layers formed. The lower yellow layer was mixed with 10 cm³ each of acetic acid and acetic anhydride. After standing for 2 hr, the solution was shaken with (25 + 15) cm³ petroleum ether, the lower viscous yellow layer of H_2ReOCl_5 was diluted with 20 cm³ acetic acid–HCl.

To the above solution, 0.415 g DTO dissolved in 150 cm³ acetic acid–HCl, was added. An orange–brown precipitate formed immediately. It was filtered, washed with acetic acid–HCl followed by petroleum ether and

dried for 6 hr under vacuum over sodium hydroxide. Yield is 90%. The compound is somewhat soluble in acetone and only slightly soluble in nitromethane and acetonitrile.

$ReOCl_3(MBT)_2$—To an acetic acid solution of H_2ReOCl_5 obtained as above from 0.450 g potassium perrhenate and 0.170 g hydroquinone, was added 0.549 g MBT in 104 ml acetic acid–HCl and 13 cm³ acetic anhydride. The dark green precipitate was washed and dried as for the DTO complex. Yield is 75%. The compound is highly soluble in acetone but less so in dichloromethane, benzene and ethanol.

RESULTS AND DISCUSSION

Both the compounds analyse satisfactorily to the general formula $ReOCl_3L_2$.

$ReOCl_3(DTO)_2$ gave Re, 32.56(33.90); S, 22.30(23.30); Cl, 18.68(19.34)%.

$ReOCl_3(MBT)_2$ gave Re, 28.05(28.97); S, 19.56(19.93); Cl, 16.04(16.51).

Calculated values, in parentheses. The complexes show $\mu_{eff} = 0.50, 0.35$ B.M. at 292K respectively. The conductance (Ω^{-1} cm² mol⁻¹ at 292K) of the DTO complex is 62 in acetone and of the MBT complex, 21 in acetonitrile. The compounds are thus neutral molecules with but slight ionisation of chloride in the solvents. As Re(V) is normally 6-coordinated, the ligands must be present as monodentate neutral molecules in the complexes.

$ReOCl_3(DTO)_2$ shows IR absorption peaks (in cm⁻¹) at 3400m, sh, b, 3160s, sh, b, 1660m, sh, b, 1590m, b, 1485s, 1410w, 1308w, b, 1235w, 1010m, 985m, 790m, b, 680w, b, 600m, 333w, 311.2w, 284.4w, 194.3m, b. The assignments are made following Scott and Wagner[5] and Suzuki.[6] A decrease in the ν(C=S) and an increase in the ν(CN) and ν(NH), point to coordination of sulphur to the metal. Changes in the position and breadth of (NH) bands in the complex, point definitely to monodentate bonding of the ligand through the S atom and extensive participation of the H atoms of NH_2 in intramolecular and intermolecular hydrogen bonding with chlorine in the complex. The electronic spectrum of the complex

---

†DTO–Dithiooxamide, MBT–2-mercaptobenzothiazole.

*Author to whom correspondence should be addressed.

shows λ_{max} (in nm) at 330(10, 104) and 450(2965) while that of the ligand shows at 330(3140) and 490(22), the ϵ's are in parentheses.

ReOCl$_3$(MBT)$_2$ shows IR absorption peaks (cm^{-1}) at 3400m, b, 3005w, 1600w, 1580w, 1500s, 1432s, 1350m, 1315w, 1275m, 1012s, 975s, 858w, 327w, 292m, 260w, 235w, 217m, 189w. These show that hydrogen is present on N and that MBT is coordinated to Re(V) through S of the thioketo group. The electronic spectrum of the complex shows λ_{max} (in nm) at 340(7837) and 720(28) while the ligand[7] shows at 330(2253) only.

Both the complexes show two bands in their IR spectra assignable to v(ReCl). Hence, they are *cis*-isomers.[8]

TRANS-1,2-DITHIOOXALATE AS BRIDGING LIGAND—II†

THE X-RAY CRYSTAL STRUCTURE OF
μ-1,2-DITHIOOXALATO-BIS[BIS(TRIPHENYLPHOSPHINE)SILVER(I)]

Abstract—The X-ray structure of $(Ph_3P)_2Ag(SOC_2SO)Ag(PPh_3)_2$ shows this complex as the second authentic example containing a bridging *trans*-1,2-dithiooxalate ligand. The compound crystallizes in the monoclinic space group $P2_1/c$ with $a = 13.159(2)$, $b = 11.895(2)$, $c = 20.939(5)$ Å, $\beta = 101.35(2)°$ and $Z = 2$. The structure was solved by Patterson and Fourier methods for 5649 diffractometer data and refined to a final R value of 0.066 for 3545 observed reflections. The dimensions of the dithiooxalate bridge are compared with those of the corresponding *trans*-dithiooxalate in $(Ph_4As)_4[(O_2C_2S_2)_2In(SOC_2SO)In(S_2C_2O_2)_2]$. Differences between structures containing bridging *trans*-dithiooxalate or bridging *cis*-dithiooxalate, respectively, are discussed.

The classical sulphur ligand 1,2-dithiooxalate has been a subject of considerable recent interest, because the presence of four donor atoms in the dianion causes more than one possibility of coordination to the metal ions: 1,2-dithiooxalate is able to act as terminal SS- or OO-bonded ligand but also as bridging ligand between different or equal metal ions, respectively. X-ray structure analyses of compounds of the heterometallic type show that the thermodynamically favoured coordination is the *cis*-arrangement of the ligands whose sulphur donor atoms are bonded by the more thiophilic metal ion.[1] If the 1,2-dithiooxalate dianion acts as a quadridentate bridging ligand linking two equal metal ions a *trans*-arrangement of the ligand is expected.[2] Recently we reported on the synthesis and X-ray structure of the first authentic example containing such a planar *trans*-dithiooxalate bridge connecting two distorted InS_2O octahedra in the complex compound $(Ph_4As)_4[(O_2C_2S_2)_2In(SOC_2SO)In(S_2C_2O_2)_2]$.[3] In this paper we present a new synthesis and X-ray structure of the compound $(Ph_3P)_2Ag(SOC_2SO)Ag(PPh_3)_2$, first prepared by Coucouvanis and Piltingsrud in 1973,[2] containing a similar dithiooxalate bridge. The question was, which differences arise from the linking of different coordination spheres around the silver(I) ions and the indium(III) ions, respectively.

EXPERIMENTAL

Tris(triphenylphosphine)silver(I)chloride (1.86 g; 2 mmol) was dissolved in 25 cm³ pyridine. In this solution 495 mg (2.5 mmol) potassium 1,2-dithiooxalate were suspended with vigorous stirring. Careful addition of water in drops produced a transparent brown solution. After slow addition of more water the compound was deposited as yellow–brown crystals which were recrystallized by dissolving in 10 cm³ pyridine and slow addition of ethanol. The yield was nearly 100% referred to $(Ph_3P)_3AgCl$. The complex darkens from 140°C and melts at 167–170°C.

This synthesis is useful also in the case of the isomeric ligand 1,1-dithiooxalate,[4] producing a brown crystalline complex (m.p. 139–141°C), or for the reaction between $(Ph_3P)_2AuCl·O.5C_6H_6$ and 1,2-dithiooxalate causing a light-yellow product (m.p. 151°C).

Crystallography of $(Ph_3P)_2Ag(SOC_2SO)Ag(PPh_3)_2$

Crystals suitable for diffraction studies were grown from a concentrated pyridine solution of the complex covered with a layer of isopropanol and stored at 0°C over 24 hr. The investigated crystal had the shape of a thin plate with the dimensions $0.48 \times 0.32 \times 0.05$ mm.

Crystal data. $C_{74}H_{60}Ag_2O_2P_4S_2$, $M = 1384.94$, monoclinic, $a = 13.159(2)$, $b = 11.895(2)$, $c = 20.939(5)$ Å, $\beta = 101.35(2)°$, $U = 3213.4$ Å³; space group $P2_1/c$, $Z = 2$, $T = 293(1)K$, $D_c = 1.4319$ g·cm⁻³, $F(000) = 706$, $\mu(Mo–K_a) = 0.808$ mm⁻¹.

Data collection. CAD4 diffractometer, Mo–K_α radiation ($\lambda = 0.71069\text{Å}$, graphite monochromator), scan method $\omega - 2\theta$, measured reflections 15004 ($1° < \theta < 20°$ $\pm h$, $\pm k$, $\pm l$; $20° < \theta < 25°$ $+h$, $+k$, $\pm l$), 564 σ unique reflections, 3545 of them observed [$I > 29(I)$].

Structure solution and refinement

The structure was solved by heavy atom method using all 5649 unique diffractometer data. The Patterson map revealed the positions for Ag atoms. From the subsequent Fourier maps the residual non-hydrogen atoms were estimated. The refinement of all positions including the anisotropic temperature factors gave a final $R = \Sigma|\Delta F|/\Sigma|F_o| = 0.066$ and $R_w = [\Sigma w(\Delta F)^2/\Sigma w F_o^2]^{1/2} = 0.070$, respectively, with 4656 contributing reflections. The positions of the phenyl-hydrogen atoms were calculated and have been included as fixed atom contribution in the structure factor calculation. A table containing a complete summary of the data collection and refinement, tables of atomic co-ordinates, anisotropic thermal parameters and lists of F_o/F_c have been deposited with the Editor as supplementary material. Computer, programs and sources of scattering factor data are given in Ref. 3.

RESULTS AND DISCUSSION

The synthesis of the complex $(Ph_3P)_2Ag(SOC_2SO)Ag(PPh_3)_2$ in pyridine–water guarantees a complete reaction of the starting compound $(Ph_3P)_3AgCl$, if an excess of potassium dithiooxalate is used, and provides well formed crystals of the desired compound whereas the non-reacting dithiooxalate remains in solution. As shown in Fig. 1 the complex contains two silver(I) ions connected by a planar 1,2-dithiooxalate bridging ligand in *trans*-arrangement. Additionally each silver atom is coordinated to two phosphorus atoms of triphenylphosphine ligands. Thus, the central metal ions are surrounded by four donor atoms causing distorted tetrahedral AgP_2SO skeletons. As in the complex salt $(Ph_4As)_4[(O_2C_2S_2)_2In(SOC_2SO)In(S_2C_2O_2)_2]$ the bridging dithiooxalate ligand contains the inversion centre of the whole molecule. Some of the more important bond-lengths and angles are listed in Table 1 for comparison with the corresponding values of the indium compound. It is to be seen that the distances and angles in the *trans*-dithiooxalate ligands of both molecules show no difference greater than three times their estimated stan-

dard deviations. However, stronger deviations appear if the 1,2-dithiooxalate is bonded in *cis*-arrangement between different metal ions, e.g. aluminium(III) and silver(I) or iron(III) and silver(I), respectively,[1b] (see also Table 1). Whereas the C–C distances and the O–C–S angle are very similar in the four compared molecules, the C–O distances and the S–C–C angles are somewhat smaller and the C–S distances and O–C–C angles somewhat greater in the case of the *trans*-arrangement of the bridging ligands. The most surprising result is the similarity of the Ag–O and Ag–S distances in the structure under investigation. The last is typical for covalent silver(I)-sulphur bonding[5] and near the sum of covalent radii (2.57 Å), whilst the Ag–O distance is longer as that found in the Ag(I)-monothiocarbamate hexamer $[AgSOCN(C_3H_7)_2]_6$ having a threefold nonplanar AgS_2O-coordination (Ag–O 2.34–2.38 Å).[6] However, the distance is quite similar to the values in the two *bis*-complexes of silver(I) with 8-hydroxy–quinoline (Ag–O 2.451(4)–2.505(5) Å)[7] and pyridinecarboxylate-2(Ag–O 2.524(4) Å)[8] containing distorted tetrahedral AgO_2N_2 cores.

Because the In–O and In–S distances in the other structure with a *trans*-dithiooxalate bridge differ as expected, the equality found for Ag–O and Ag–S distances should be assumed to be a result of the different coordination geometry around the central metal ions: in the silver complex the bridging dithiooxalate links tetrahedra, in the indium complex, however, octahedra.

The Ag–S distance is considerably shorter in the complex containing the *trans*-dithiooxalate than those found in the two *cis*-dithiooxalate heterometallic compounds. Interestingly, the Ag–P_1 and Ag–P_2 bond lengths, which were found to be different, show a very similar behaviour in all three complexes compared.

NOTE

EPR DETECTION OF [Cu(*mnt*)X₂]²⁻†—A POSSIBLE HALOGENIDE STABILIZED INTERMEDIATE IN LIGAND EXCHANGE REACTIONS

J. STACH,* U. ABRAM, R. KIRMSE and W. DIETZSCH
Department of Chemistry, Karl-Marx-University, 7010 Leipzig, Liebigstr. 18, G.D.R.

and

VERA K. BELYAEVA and I. N. MAROV
Institute of Geochemistry and Analytical Chemistry, Academy of Sciences, Moscow, Vorob'evskoje chaussee 47a, U.S.S.R.

Abstract—During the reaction of $[Cu(mnt)_2]^{2-}$ with CuX_2 (X = Cl, Br) $[Cu(mnt)X_2]^{2-}$ species are formed and characterized EPR spectroscopically supporting a dissociative mechanism for ligand exchange reactions between $[Cu(mnt)_2]^{2-}$ and other Cu(II), Ni(II) and Pd(II) complexes which contain unsaturated dichalcogeno ligands.

In suitable solvents the reaction of $[Cu(mnt)_2]^{2-}$ with four-membered ring chelates of Cu(II), Ni(II) or Pd(II) containing unsaturated sulphur or selenium ligands (1) is characterized by quantitative formation of the mixed ligand complexes.[1,2]

$$[Cu(mnt)_2]^{2-} + ML_2 \rightarrow [Cu(mnt)L]^- + [M(mnt)L]^-$$
(1a)

$$[Cu(mnt)_2]^{2-} + [ML_2']^{2-} \rightarrow [Cu(mnt)L']^{2-}$$
$$+ [M(mnt)L']^{2-}$$
(1b)
Unfortunately, the reactions between the corresponding copper complexes are too fast to be followed by a conventional EPR experiment. However, ligand exchange reactions of $[Cu(mnt)_2]^{2-}$ with the more inert Ni(II) and Pd(II) species are slow enough to be easily followed by EPR. The increase of the reaction rate with the temperature and after adding of Cu^{2+} ions, and the decrease in presence of the noncoordinated ligands

observed by EPR for the system $[Cu(mnt)_2]^{2-} + [Pd(i\text{-}mns)_2]^{2-}$ ($i\text{-}mns = (CN)_2C = CSe_2^{2-}$) suggest a dissociative start mechanism of the exchange reaction as given by the eqns (2) and (3).[3]

$$[Cu(mnt)_2]^{2-} \rightarrow [Cu(mnt)]_s + mnt^{2-}$$
(2)

$$[Pd(i\text{-}mns)_2]^{2-} \rightarrow [Pd(i\text{-}mns)]_s + i\text{-}mns^{2-}.$$
(3)
The solvated mono-chelates $[Cu(mnt)]_s$ and $[Pd(i\text{-}mns)]_s$ appear to be the important species in the following chain reaction.

In this paper we report the EPR detection† of Cu(II) sulphur ligand mono-chelates stabilized by halogenide
$$M=Cu, Ni, Pd ; L = \text{(structure)} \quad - ; L' = \text{(structure)}$$

copper complexes are too fast to be followed by a conventional EPR experiment. However, ligand exchange reactions of $[Cu(mnt)_2]^{2-}$ with the more inert Ni(II) and Pd(II) species are slow enough to be easily followed by EPR. The increase of the reaction rate with the temperature and after adding of Cu^{2+} ions, and the decrease in presence of the noncoordinated ligands

ligands instead of solvent molecules, which are regarded as essential members in a dissociative ligand exchange mechanism: $[Cu(mnt)X_2]^{2-}(X = Cl, Br)$. Up to now only EPR spectra of CuLX and $[CuLX_2]^-$ chelates with L = dichalcogenocarbamate have been described by several authors.[4-13]

The $[Cu(mnt)X_2]^{2-}$ species could be obtained according to the reaction given in eqn (4).

[b]values from Ref. 8.
[c]values from Ref. 12.
Fig. 1. EPR spectrum of $[Cu(mnt)Cl_2]^{2-}$ at $T = 235$ K; solvent: acetonitrile; frequency: 9.51 GHz.

If tetra-n-butylammonium salts are not present during reaction (4) black scarcely soluble $Cu[Cu(mnt)_2]^{14,15}$ is deposited.

The room-temperature EPR spectrum of a solution containing $[Cu(mnt)Cl_2]^{2-}$ anions consists of the typical[63,65] Cu hyperfine structure (hfs) quartet. In the spectrum recorded at $T = 235$ K an additional hfs due to the interaction of the unpaired electron with $^{35,37}Cl$ nuclei ($^{35,37}Cl$, I = 3/2) can be observed. The copper hfs lines are split into seven $^{35,37}Cl$ ligand hfs components clearly resolved for the $m_I = +3/2$ copper hfs line as shown in Fig. 1 indicating the presence of two Cl atoms in the first coordination sphere.

The solution EPR spectrum observed for $[Cu(mnt)Br_2]^{2-}$ species at room temperature consists of a quartet of seven hfs lines arising from the interaction of the unpaired electron with $^{63,65}Cu$ and two $^{79,81}Br$ nuclei both having I = 3/2. Due to the values of the coupling constants a_0^{Cu} and a_0^{Br} the hfs lines are partially overlapped. The $^{63,65}Cu$ as well as the $^{79,81}Br$ isotopic splitting is not resolved because of the experimental line width. The assignment made is given in the stick spectrum of Fig. 2.

The g values and the hfs coupling constants derived from the spectra are given in Table 1. For comparison Table 1 contains also the EPR parameters found for

CuLX and $[CuLX_2]^-$ complexes (L = dithiocarbamate). $[Cu(mnt)X]^-$ species could not be observed during our investigations.

The isotropic $^{35,37}Cl$ and $^{79,81}Br$ hfs can be used to obtain an estimate of the halogen 3s and 4s contribution to the MO of the unpaired electron. The isotropic ligand hfs splitting is given by the familiar expression

$$a_0(X) = \frac{8\pi}{3} g_e g_N \beta_e \beta_N |\Psi(0)|^2 c_s^2$$

where c_s is the coefficient of the halogen 3(4)s orbital in the MO containing the unpaired electron. $|\Psi(0)|^2$ is the 3s(Cl), 4s(Br) electron density at the nucleus. The evaluation of c_s^2 is accomplished[16] by taking the ratio of the observed isotropic $^{35,37}Cl$ and $^{79,81}Br$ ligand hfs splitting, a_0^{obsd}, to that calculated for an unpaired electron residing in a Cl 3s ($a_0^{calc}(^{35}Cl) \sim 155, 0$ mT) and a Br 4s orbital ($a_0^{calc}(^{81}Br) \sim 780, 0$ mT):

$$c_s^2 = \frac{a_0^{obsd}}{a_0^{calc}}.$$

The values estimated are given in Table 1. The c_s^2 values derived are small for all complexes studied and suggest a distorted tetrahedral coordination geometry for the
Fig. 2. EPR spectrum of [Cu(mnt)Br$_2$]$^{2-}$ at room temperature in acetonitrile; frequency: 9.51 GHz.

CuS$_2$X$_2$ chromophores. This is also reflected by the isotropic copper hfs coupling which is noticeably reduced with respect to that observed for planar [Cu(mnt)$_2$]$^{2-}$.[17] For tetrahedrally distorted [Cu(mnt)$_2$]$^{2-}$ characterized by a dihedral angle of 47.4° between the planes of the ligands an isotropic copper hfs coupling of (−) 68.4 × 10^{-4} cm^{-1} has been found.[18] A quantitative analysis of the MO of the unpaired electron for [Cu(mnt)X$_2$]$^{2-}$ requires knowledge of the corresponding anisotropic hfs data. Unfortunately, the latter values could not be estimated because frozen solution spectra allowing their determination could not be obtained.

NOTE

ALUMINIUM TRIS(FLUOROSULPHATE)

SUKHJINDER SINGH and RAJENDAR D. VERMA*
Department of Chemistry, Panjab University, Chandigarh 160014, India

Abstract—Aluminium tris(fluorosulphate) is prepared by the reaction of aluminium tris(trifluoroacetate) and fluorosulphuric acid. The IR spectrum indicates a polymeric structure containing bridging bidentate fluorosulphate groups, giving hexacoordination around aluminium. Aluminium tris(fluorosulphate) forms coordination compounds with pyridine and bipyridyl.

Gallium,[1] indium[2] and thallium[2] tris-fluorosulphates are known. However, only a partially substituted fluorosulphate of aluminium,[3] and a 1:3 complex with MeCN,[4] $Al(SO_3F)\cdot3MeCN$ have been reported. Therefore, we have prepared and characterized aluminium tris(fluorosulphate).

The reaction between metal trifluoroacetates and fluorosulphuric acid has proved quite useful for obtaining fluorosulphates.[5,6] The reaction between aluminium tris(trifluoroacetate) and fluorosulphuric acid in a 1:3 molar ratio in sulphuryl chloride at 10°C yielded $Al(SO_3F)_3$ in a fast and clean reaction.

$$Al(O_2CCF_3)_3 + 3HSO_3F \rightarrow Al(SO_3F)_3 + 3CF_3CO_2H$$
$Al(SO_3F)_3$ is a very hygroscopic, white powder, stable for days in dry conditions, but is readily hydrolysed. It is insoluble in the usual non-coordinating organic solvents as well as in fluorosulphuric acid suggesting a polymeric nature.

$Al(SO_3F)_3$ reacts with mulling agents such as nujol and hexachlorobutadiene. Therefore, its IR spectrum was recorded as a thin film of the solid between silver chloride plates. The average value of two strong broad bands (1360 and 1180 cm^{-1}) lies around 1270 cm^{-1}, which is usually the value expected for bidentate bridging fluorosulphate groups as shown in $X_2Sn(SO_3F)_2$; X=Me,[7,8] Cl,[9] for which a structural determination has verified bridging fluorosulphate groups. Not only the stretching but also the deformation modes of the SO_3F group in $Al(SO_3F)_3$ compare well with the corresponding modes in tin(IV) derivatives.[7–9] The νS–F at 812 cm^{-1} as a strong band confirms the presence of only one type of fluorosulphate group. These assignments suggest that the aluminium in $Al(SO_3F)_3$, is octahedrally coordinated as expected.[10–12] Close resemblance of the IR spectrum of $Al(SO_3F)_3$ with that of $Ga(SO_3F)_3$[1] and $In(SO_3F)_3$[2] suggest a similar conformation of the SO_3F groups in these compounds.

The νS–O at 1420, 1290 and 1015 cm^{-1} indicate a monodentate[13] fluorosulphate group in $Al(SO_3F)_3\cdot3Py$. Thus, aluminium retains hexacoordination in this complex. The various νS–O values; 1410, 1375, 1280, 1180, 1080 and 1005 cm^{-1} and two values of νS–F; 850 and 830 cm^{-1} reveal the presence of both mono- and bidentate SO_3F groups in $Al(SO_3F)_3\cdot bipy$. The appearance of a weak band at 1235 cm^{-1} and shift of the bands at 1578, 601 and 403 cm^{-1} to 1610, 630 and 440 cm^{-1} in pyridine complex indicate the coordination of pyridine to aluminium.[14] A band which is not present in free bipyridyl, but has been found in several of its chelated complexes,[15] appears at 1335 cm^{-1} and a band at 990 cm^{-1} is intensified and shifts to 1020 cm^{-1} in $Al(SO_3F)_3\cdot bipy$ on coordination.

EXPERIMENTAL

Freshly distilled fluorosulphuric acid (1.8 g, 18 mmol) was transferred to a suspension of aluminium tris(trifluoroacetate) (2.196 g, 6 mmol) in 30 cm^3 of sulphuryl chloride, while the reaction vessel was immersed in liquid nitrogen. The temperature of the vessel was slowly allowed to rise to 0°C and the contents stirred magnetically for 6 hr at 10°C. The contents were filtered under dry N_2, repeatedly washed with sulphuryl chloride followed by tetrachloromethane. Finally, $Al(SO_3F)_3$ was obtained as a pure white powder in almost quantitative yield after removal of all volatiles under vacuum. Found: Al, 8.41; S, 29.85; F, 17.34; $Al(SO_3F)_3$ requires Al, 8.33; S, 29.63; F, 17.59%. IR (cm^{-1}): 1360sb, 1180sb, 1080s, 812vs, 645w, 609w, 542vs, 440w, 420mw.

Complexes $Al(SO_3F)_3\cdot3Py$ and $Al(SO_3F)_3\cdot bipy$ were prepared by stirring $Al(SO_3F)_3$ suspended in tetrachloromethane or benzene with the ligand in the required stoichiometric ratio or in excess for 20 hr under dry N_2 at room temperature, filtered, washed with the respective solvent and finally dried *in vacuo*. Found: Al, 4.19; S, 16.85; F, 10.44; C, 31.58; H, 2.56; N, 7.40; $Al(SO_3F)_3\cdot3Py$ requires Al, 4.81; S, 17.11; F, 10.16; C, 32.09; H, 2.67; N, 7.49%.

IR (cm^{-1}): 1610s, 1540m, 1525m, 1485m, 1465m,

NOTE

PREPARATION AND NMR SPECTRA DIAMINOTETRAARYLOXYCYCLOTRIPHOSPHAZENES

MEISETSU KAJIWARA* and YASUO KURACHI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, 464
Japan

Abstract—New diaminotetraaryloxycyclotriphosphazenes $N_3P_3(NH_2)_2(OR)_4$ were prepared by the reaction between $N_3P_3(NH_2)_2Cl_4$ and RONa in THF solvent and ^{31}P NMR data showed geminal compounds were formed.

Many organo derivatives of hexachlorocyclotriphosphazene have been synthesized[1] and proton or phosphorus NMR spectroscopy had been used for elucidating the structure of cyclophosphazene derivatives in solution. In this report the synthesis of new derivatives of hexachlorocyclotriphosphazene and their proton and phosphorus NMR spectra are described.

EXPERIMENTAL

$(NPCl_2)_3$ was prepared by the method of Kajiwara.[2] The melting point of $(NPCl_2)_3$ was 112° C.

$N_3P_3(NH_2)_2Cl_4$ was prepared by the method of Geral.[3]

$N_3P_3(NH_2)_2(OR)_4$ were synthesized by the reaction between $N_3P_3(NH_2)_2Cl_4$ and RONa in THF solvent. The aryloxy compound e.g. C_6H_5OH, HOC_6H_4F-p, HOC_6H_4Cl-p or $HOC_6H_4CH_3-p$ (0.08 mol) and 0.08 mol sodium, respectively, were placed in three-necked flask with 200 cm³ of THF. After the sodium had dissolved, 0.016 mol of $N_3P_3(NH_2)_2Cl_4$ (dissolved in 100 cm³ of THF) was added and the mixture was refluxed with stirring for two days. After work up involving stirring of solvent, extraction with ether followed by evaporation to dryness. The product was recrystallized from benzene.

Analysis

^1H–NMR spectra of the derivatives were measured with Niphon Denshi Model C 60 HL instrument, with tetramethylsilane or D. S. S as an internal standard. ^{31}PNMR specra of the derivatives was recorded on Niphon Denshi Model–60 type spectrometer using a sample tube (8 mm), chloroform solvent and H_3PO_4 as the reference at 24.3 MHz and 20° C.

RESULTS AND DISCUSSION

The results of chemical analysis and the yields are summarized in Table 1.

All of the derivatives are colourless crystalline solids soluble in organic solvents.

The NMR data of the compounds is summarized in Table 2. The chemical shifts of the proton in N–H can often provide a diagnostic test for geminal and non-genimal structure in cyclotriphosphazene derivatives with primary amino substituents.[4] The N–H resonances for the non-geminal compounds occurred at 4.1–4.4 ppm, whereas the geminal compounds displayed resonances at 3.1–3.8 ppm.[5] In the case of $N_3P_3(NH_2)_2(OR)_4$ compounds, δ N–H occurs at

$C_6H_4CH_3-p$	Calc	11.76	56.47	5.42	120–121	87
	Found	11.85	56.76	5.54		

Table 2. H^1 and ^{31}P NMR data for diaminotetraaryloxycyclotriphosphazenes

Compound	^1H-NMR (ppm)				^{31}P-NMR (ppm)		
	NH_2 (br)	OC_6H_5 (multiplets)	OC_6H_4	CH_3	ΓNH_2 (A)	P(OR) (B)	J_{AB}
$N_3P_3(NH_2)_2(OC_6H_5)_4$	2.3	7.3			-8.65	-16.50	1.48
$N_3P_3(NH_2)_2(OC_6H_4F-p)_4$	2.4		6.7-7.6		-8.75	-15.60	1.58
$N_3P_3(NH_2)_2(OC_6H_4Cl-p)_4$	2.4		7.0-7.4		-8.35	-15.5	1.52
$N_3P_3(NH_2)_2(OC_6H_4CH_3-p)_4$	2.3		7.0	1.3	-13.47	-16.87	0.73

2.3–2.4 ppm, so geminal compounds may be inferred. ^{31}P–NMR spectroscopy is used to confirm the geminal or non-geminal structure. The ^{31}P chemical shift of P–NH$_2$ in $N_3P_3(NH_2)_2Cl_4$[6] was recorded at -9.03 ppm and -18.3 ppm, respectively. It is found that the compound gives an AB$_2$ type spectrum and is the geminal structure. The ^{31}P NMR of the other compounds are summarized in Table 2.

It is assumed that ^{31}P chemical shifts and P–P coupling constants do not depend on electronegativity in the substituent groups. The ^{31}P chemical shifts and P–P coupling constants, for a large number of cyclophosphazene derivatives have been determined.[7] Also, it has been suggested that change in electronegativity, π–bonding, and bond angles influence ^{31}P chemical shifts.[8] In addition, the chemical shifts of a particular phosphorus atom may be affected by the substituents elsewhere on the ring. Finer[9] and Schuman[10] have proposed that coupling constants correlate with the electronegativity of substituents. As shown in Table 2, ^{31}P chemical shifts and coupling constants of the derivatives, except $N_3P_3(NH_2)_2(OC_6H_4CH_3-p)_4$, give similar values since electronegativity, π–bonding or bond angles within the substituents are similar. On the other hand, the $N_3P_3(NH_2)_2(OC_6H_4CH_3-p)_4$ P–P coupling constant is smaller than the other derivatives. This means that

factors such as stereochemistry of the substituent may also contribute to chemical shift or coupling constant.

FORMATION AND TRANSFORMATION OF ALKOXY-DERIVED BaGeO$_3$

OSAMU YAMAGUCHI,[*] MICHIHARU KI, TAKAYA NIIMI AND KIYOSHI SHIMIZU

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kyoto 602

Japan

Abstract——Beta-BaGeO$_3$, being high-temperature form, are formed metastably at 630-660 °C from an amorphous material prepared by the simultaneous hydrolysis of barium and germanium alkoxides. The transformation of BaGeO$_3$ can be summarized as follows; amorphous BaGeO$_3$

$$\xrightarrow[780-840°C]{} \alpha\text{-BaGeO}_3 \underset{1130-1150°C}{\overset{1180-1200°C}{\rightleftarrows}} \beta\text{-BaGeO}_3 \xrightarrow[1270°C]{} \text{melt.}$$

On cooling from the melt, β-BaGeO$_3$ can be retained at room temperature.
INTRODUCTION

Barium metagermanate, BaGeO$_3$, exists in at least two polymorphic modifications: a low-temperature α-form having a hexagonal pseudowollastonite-type structure and a high-temperature β-form having an orthorhombic pyroxene-type structure. There have been conflicting information in the literature concerning the formation and transformation of BaGeO$_3$. Roth[1] reported at first that α-BaGeO$_3$ changes to a different type of structure when heated with the addition of 1% Fe$_2$O$_3$. Liebau[2] showed that β-BaGeO$_3$ is formed by melting α-BaGeO$_3$ with the addition of 2% Fe$_2$O$_3$. Grebenshchikov et al.[3] reported that in the absence of mineralizers, α-BaGeO$_3$ remains unchanged at all temperatures, and β-BaGeO$_3$ is formed by the addition of BaSiO$_3$. Moreover, the transformation of BaGeO$_3$ in the presence of 2% Fe$_2$O$_3$ were studied by Grebenshchikov et al.[4] Reversible transformations of α- into β-BaGeO$_3$ and of β- into an undefined phase designated as the δ-form were observed at 1065 and 1160 °C, respectively. On the other hand, according to the results of Guha et al.,[5] β-BaGeO$_3$ is formed without addition of mineralizers, and in contrast to the Grebenshchikov et al. data[4] the transformations of α⇌δ and δ⇌β occur at 1100 and 1200 °C, respectively. However, no high-temperature X-ray analysis in the experiment of Guha et al.[5] was carried out for the identification of polymorphic modifications.

In the present study, it was found that β-BaGeO$_3$ is formed metastably at lower temperatures from an amorphous material prepared by the simultaneous hydrolysis of barium and germanium alkoxides. On the basis of this result, the transformation of BaGeO$_3$ was studied by thermal and high-temperature X-ray diffraction analysis.

EXPERIMENTAL

Germanium isopropoxide, Ge(OC$_3$H$_7$)$_4$, was a pure grade. Barium isopropoxide, Ba(OC$_3$H$_7$)$_2$, was synthesized by heating 99.9% barium metal in an excess of dehydrated 2-propanol for 5 h at 82 °C in a nitrogen atmosphere. The mixed alkoxides prepared in the mole ratio Ba^{2+}: Ge^{4+} =1:1 were refluxed for 20 h at the same conditions and then hydrolyzed by adding dropwise aqueous ammonia solution with stirring at 25 °C. After the termination of dropping, the resulting suspension was further stirred for 1 h at 20-25 °C. The hydrolysis product was separated from the suspension by centrifugation and dried at 80 °C under reduced pressure. The powder obtained is termed starting powder. Its average particle size, as determined by electron microscopy, was ca. 400 Å.

Thermal analyses (t.g., d.t.a.) were carried out in air at a rate of 10 °C min^{-1}. α-Alumina was used as a standard material in d.t.a. The specimens in the heating and cooling processes at a rate of 10 °C min^{-1} were identified by high-temperature X-ray diffractometry using nickel-filtered Cu-K$_\alpha$ radiation.

RESULTS AND DISCUSSION

Thermal analysis

Thermogravimetric examination of the starting powder showed a weight loss of 11.6% up to 360 °C, attributed to the loss of ammonia, surface-absorbed 2-propanol, absorbed water, and hydrated water.[6]

Figure 1(a) shows the d.t.a. curve of the starting powder in the heating process. Four peaks were observed at 630-660 °C, 780-840 °C, 1180-1200 °C, and 1270-1300 °C. They were sharp, so that the onset and end temperatures could be determined accurately. High-temperature X-ray diffraction analysis confirmed that the first exothermic peak (630-660 °C) is due to the crystallization of β-BaGeO$_3$ from an amorphous phase, and the second (780-840 °C) to the transformation of β- into α-BaGeO$_3$. The first and second endothermic peaks (1180-1200 °C and 1270-1300 °C) were found to be due to the transformation of α- into β-BaGeO$_3$ and the melting of β-BaGeO$_3$, respectively. In the cooling process from the melt, no peaks due to the transformation, except for the solidification, appeared in the d.t.a. curve. However, on cooling from the temperatures between 1200 and 1260 °C an exothermic peak was observed at 1130-1150 °C, corresponding to the transformation of β- into α-BaGeO$_3$ (Figure 1(b)).

X-Ray analysis

The starting powder was amorphous, no significant change in structure being recognized up to the temperature of the first exothermic peak (630-660 °C) in d.t.a. Pure BaGeO$_3$ derived from alkoxide showed the existence of two polymorphic modifications throughout the heating process; β-BaGeO$_3$ at 660-780 °C and 1200-1260 °C, and α-BaGeO$_3$ at 840-1180 °C. The third modification, δ-BaGeO$_3$, was not detected up to the melting temperature. In the present study, β-BaGeO$_3$ was crystallized metastably at 630-660 °C from an amorphous phase. The diffraction pattern of β-BaGeO$_3$ obtained by heating for 1 h at 700 °C was measured at room temperature using the standard X-ray diffractometer. The scanning speed of 1/4° min^{-1} of the goniometer was selected to satisfy the accuracy of d-spacing. Table 1 shows the observed values of d-spacing and relative intensity, in comparison with the Grebenshchikov *et al.* data.[4] Our powder pattern was more complex than that reported by them. All diffraction lines could be reasonably indexed by a orthorhombic unit cell[2] with a=4.59, b=5.70 and c=12.78 Å. The lattice parameters are little larger than those of β-BaGeO$_3$ (a=4.58, b=5.68 and c=12.76 Å)[2] formed by melting α-BaGeO$_3$ with the addition of 2% Fe$_2$O$_3$. On the other hand, the X-ray diffraction pattern of α-BaGeO$_3$ was identical with the reported one.[4] The reversible transformation of α-$\rightleftharpoons$ β-BaGeO$_3$ was observed at 1180-1200 °C and 1130-1150 °C. The X-ray diffraction pattern of β-BaGeO$_3$ observed at 1200-1260 °C was the same as that described above. Efforts to obtain β-BaGeO$_3$ at room temperature by rapid quenching from the temperatures between 1200 and 1260 °C failed to produce α-BaGeO$_3$ in the X-ray diffraction pattern. However, β-BaGeO$_3$ could be retained at room temperature on cooling from the melt, in agreement with the results of Liebau[2] and Guha *et al.*[5] From the thermal and X-ray data, the transformation of pure BaGeO$_3$ derived from alkoxide can be summarized as follows.

$$\text{Amorphous BaGeO}_3 \xrightarrow[630-660°C]{} \beta\text{-BaGeO}_3 \xrightarrow[780-840°C]{} \alpha\text{-BaGeO}_3 \underset{1130-1150°C}{\overset{1180-1200°C}{\rightleftharpoons}} \beta\text{-BaGeO}_3$$

DIAZA-CROWN-N,N-DIALKANOIC ACIDS COPPER(II) AND DICOPPER(II) COMPLEXES

R.A.Koliński[a] and J.Mroziński[b]

[a]Institute of Organic Chemistry, Polish Academy of Sciences, 01224 Warszawa,
[b]Institute of Chemistry, Wrocław University, 50383 Wrocław, Poland

Abstract—Twelve-, fifteen-, and eighteen-membered diaza-crown-N, N'-dialkanoic acids LH_2 and their inner salt copper(II) complexes CuL and dicopper complex $[CuL(3) . CuCl_2 . CH_3OH]_n$ were obtained. The complexes of 15- and 18-membered ligands contain Cu^{2+} ion inside the ring.

Relatively few synthetic inner salt complexes of macrocyclic ligands are known, due to the scarcity of suitable ligands. This suggested a study of diaza-crown-N,N-dialkanoic acids, the compounds containing a macrocycle and two aminoacid moieties. We now report the synthesis and the structure of some copper(II) inner complexes of these ligands.

Diaza-crown-N,N-dialkanoic acids were obtained by alkylation of aminogroups of 12-, 15-, and 18-membered diaza-crown ethers with ethyl bromoacetate or ethyl DL-2-bromopropionate, followed by hydrolysis of ester groups by refluxing an aqueous solution of the diester. The following diacids were obtained:
L(1)H_2, m=n=1, R=H, m.p.446–8 dec.,
L(2)H_2, m=1,n=2, R=H, m.p.446–8 dec.,
L(3)H_2, m=n=2, R=H, m.p.444–6 dec.[1],
L(4)H_2, m=n=2, R=CH$_3$, m.p.436–8 dec.,

L(4)H_2 has the meso-configuration.

Aminoacids L(1)H_2 – L(4)H_2 all contain zwitterionic structures as demonstrated by their ^{1}H NMR and IR spectra (νCO_2^- antisymmetric 1640 cm^{-1}).

The reaction of acids L(1)H_2 – L(4)H_2 with many copper(II) salts (chloride, bromide, perchlorate, acetate, etc.) in a 1 : 1 molar ratio in water or methanol produces CuL complexes. The absence of the anion(s) of the copper salt used in the reaction products confirms their inner salt structure. Reaction of acid L(3)H_2 with copper(II) chloride in a 1 : 2 molar ratio in methanol gives a dicopper complex $[CuL(3).CuCl_2.CH_3OH]_n$. Properties of the complexes are given in Table 1.

IR spectra of CuL complexes contain a very strong absorption band at 1640 cm^{-1} assigned to the antisymmetric νCO_2^- vibration. The assignment of the symmetric νCO_2^- band is difficult, because of its weak intensity and splitting especially in the spectra of centrosymmetric complexes. The frequency of the νCO_2^- band in complexes is the same as in the zwitterionic form of the parent aminoacids, which demonstrates their inner salt character and the unidentate coordination of the carboxylate groups $-C{\overset{O}{\underset{O-Cu}{}}}-$. The dicopper complex

^{g}CH$_3$OH: νOH 3490 cm^{-1},m,sharp.

has a single νCO_2^- band at 1570 cm^{-1}, which indicates a bridged coordination of the carboxylate groups $-C\overset{O-Cu-}{\underset{O-Cu-}{}}$. The presence of methanol is proved by the occurrence of the νOH band at 3490 cm^{-1} and by elemental analysis.

Electronic spectra of these complexes contain very broad $\underline{d}\rightarrow\underline{d}$ transition bands characteristic of tetragonally distorted $\underline{d}^9$ copper(II) complexes.

The effective magnetic moment values of CuL complexes lie appreciably above the spin-only value due to the mixing-in of some orbital angular momentum from the excited states $\underline{via}$ spin-orbit coupling.

EPR spectra of compounds CuL contain strong signals typical of rhombic symmetry with g_1, g_2, and g_3 components of the g tensor. Those of the dicopper complex indicate weak exchange interactions between the copper centres.

Starting from the known structure of ligands a variety of structures could be proposed for CuL complexes. The main structural features are: the metal ion inside the ring or outside the ring and the $\underline{cis}$ or $\underline{trans}$ (OONN or ONON, respectively) configuration of the coordination sphere and the carboxylate groups.

The Cu^{2+} cation (ionic radius r = 73 pm) is too large to get inside the 12-membered ring cavity (r = ca.60 pm). Taking into account the known structures of 12-membered ligands complexes[2] we propose the $\underline{cis}$ configuration for the CuL(1) complex with the Cu^{2+} cation located above the ring "plane". The point group of symmetry should be C_1 or C_2 depending on the ring conformation.

The Cu^{2+} cation fits very well into the 15-membered ring cavity (r = ca.80 pm). Therefore we propose the $\underline{trans}$ configuration for the CuL(2) complex with the Cu^{2+} cation inside the ring. The molecule is asymmetric because the ligand is asymmetric.

CuL(4-meso),m=1,R=CH$_3$
$\left[CuL(3), CuCl_2 \cdot CH_3OH\right]_n$

Complexes CuL(3) and CuL(4-_meso_) are _trans_ centrosymmetric molecules containing Cu^{2+} cation inside the ring, as shown by X-ray structure determination[3,4].

The structure of the dicopper complex was elucidated by X-ray analysis[5]. This shows a polymeric structure with an additional binding of the CO_2^- groups of the CuL(3) complex to the Cu^{2+} cation of the $CuCl_2$.

NOTE

REDUCTIVE NITROSYLATION OF TETRAOXOMETALLATES. PART VIII[1]. A VIRTUALLY SINGLE STEP SYNTHESIS OF AZIDO-NITROSYL DERIVATIVES OF CHROMIUM(I) DIRECTLY FROM CHROMATE IN AQUEOUS-AEROBIC MEDIA.

R. G. Bhattacharyya[*] and G. P. Bhattacharjee,

Department of Chemistry, Jadavpur University,

Calcutta 700 032, India.

Abstract — Azido-nitrosyl complexes and their derivatives of the types $[Cr(NO)(N_3)_5]^{3-}$ and $[Cr(NO)(N_3)_2(L-L)]$ [L-L = 2,2' bipyridine (bipy) and 1,10 phenanthroline (phen)] were synthesised directly from chromate ion using hydroxylamine hydrochloride, azide ion and hydroxyl ion and other appropriate ligands virtually in a single step process in an aqueous aerobic medium. The compounds are characterised by IR, molecular weight, molar conductance, magnetic susceptibility, esr and electronic spectral data.

Reductive nitrosylation of chromate ions using hydroxylamine and cyanide ions in an alkaline medium generating the $\{Cr(NO)\}^{2+}$ moiety has long been known[2]. Recently it has been shown[3] that such a reaction using hydroxylamine and thiocyanate ion can be achieved in a slightly acidic or near neutral medium, and it has now been realised that an excess of hydroxylamine hydrochloride is necessary for leading such reactions to completion[4,5]. It has been found that although hydroxylamine is the source of the nitrosyl group, use of another reducing anion (viz, cyanide, thiocyanate or oxalate ion) in conjunction with hydroxylamine is necessary for the progress of this type of reactions[6]. Such a reductive nitrosylation reaction using hydroxylamine and azide ion was unknown until very recently[1(b),7]. In fact, azido-nitrosyl complexes of metals are quite rare[1(b),7-9] owing to the mutual interaction of azide ion and nitric oxide producing dinitrogen and dinitrogen monoxide. Herein is described, for the first time, the reductive nitrosylation reaction of chromate ion using hydroxylamine hydrochloride and azide ion in an alkaline medium and generation of $\{Cr(NO)\}^{2+}$ moiety as is evident by synthesizing $[Cr(NO)(N_3)_5]^{3-}$ and $[Cr(NO)(N_3)_2(L-L)]$ directly from chromate ion in an aqueous aerobic medium.

EXPERIMENTAL

Preparation and characterization of the complexes : In a solution of NaOH (2 g in 25 cm^3 of H_2O) was dissolved K_2CrO_4 (0.5 g ; 2.6 mmol) and to this solution were added $NH_2OH.HCl$ (2.7 g ; 38.8 mmol) and NaN_3 (1.7 g ; 26.2 mmol) portionwise with constant stirring at 60-70° for 30 m. The deep red-violet solution (pH≈11) was cooled to room temperature and the pH of the

---

[*] Author for correspondence.

solution was lowered down to 6.5-7.0 with 6 M HCl. The clear solution (Solution A) was filtered out from any solid residue.

1. $[Cr(NO)(N_3)_2(bipy)]$:

The solution A was added to a hot aqueous (20 cm^3) solution of bipy (0.6 g ; 3.85 mmol) with stirring and the mixture was then cooled at 0° for 1 h and then again stirred at room temperature for another 1 h. The separated deep brown solid was filtered off, washed with water, ethanol and ether and dried over fused CaCl$_2$ at a reduced pressure. The substance was then extracted with anhydrous acetone and acetone was removed by evaporation. The dry mass was then crystallised from acetone-ether mixture as deep brown crystals. Yield : 0.54 g (65 %). M.P. 165°(d). Found : C, 37.5 ; H, 2.6 ; N, 39.0 ; Cr, 15.7 ; M.W. (DMF, Osmometric) 297. C$_{10}$H$_8$N$_9$OCr requires : C, 37.3 ; H, 2.5 ; N, 39.1 and Cr, 16.1 % . M.W. 322. IR : ν_{NN}2040(s), ν_{NO}1665(s), ν_{CrN}(NO) 610(w) and ν_{CrN}(bipy) 375(m),   400(sh) cm^{-1}. λ_{max} (in CH$_3$CN) 620 (ϵ_{max} = 50), 482 (60) and 370 (230) nm. μ_{eff} = 1.9 B.M.

2. $[Cr(NO)(N_3)_2(phen)]$:

The same method as described under (1) was followed using phen instead of bipy. Yield : 0.55 g (62 %). M.P. 177°(d). Found : C, 42.0 ; H, 2.2 ; N, 36.0 ; Cr, 14.7 ; M.W. 320. C$_{12}$H$_8$N$_9$OCr requires : C, 41.6 ; H, 2.3 ; N, 36.4 and Cr, 15.0 % . M.W. 346. IR : ν_{NN}2030(s), ν_{NO}1650(s), 1680(s) (1625 cm^{-1} (s) in CH$_3$CN solution). ν_{CrN}(NO) 615 (w) and ν_{CrN}(phen) 390(m), 415(sh) cm^{-1}. λ_{max}(CH$_3$CN) 616 (40), 502 (45) and 372 (270) nm. μ_{eff} = 2.0 B.M.

3. $(Ph_4P)_3[Cr(NO)(N_3)_5]$:

The solution A was added dropwise to a hot aqueous (25 cm^3) solution of (C$_6$H$_5$)$_4$ PBr (3.8 g ; 9.0 mmol) with stirring at the room temperature for 1 h. A chocolate brown precipitate was obtained which was filtered off, washed with water, ethanol, ether and dried over fused CaCl$_2$ at a reduced pressure. The compound was extracted with anhydrous acetone and the extract was evaporated to dryness. The dried mass was then crystallised from acetone-ether mixture when deep brown needles were obtained. Yield : 1.86 g (55 %). M.P. 190°(d). Found : C, 66.3 ; H, 4.2 ; N, 16.7 ; P, 6.9 ; Cr, 4.1. C$_{72}$H$_{60}$N$_{16}$P$_3$OCr requires : C, 66.0 ; H, 4.6 ; N, 17.1 ; P, 7.1 and Cr, 4.0 % . IR : ν_{NN} 2080(s), 2040(s), ν_{NO} 1660(s), ν_{CrN}(NO) 610(w) and ν_{CrN}(N$_3^-$) 365(w) cm^{-1}. λ_{max}(CH$_3$CN) 720 (20), 600 (105), 450 (350) and 342 (470) nm. μ_{eff} = 2.0 B.M.

RESULTS AND DISCUSSION

While in the case of thiocyanato-nitrosyl complexes the reductive nitrosylation of chromate ions becomes smooth and almost quantitative in an acidic or near neutral medium[4], the reaction being facile also in an alkaline medium[6], the same reaction with hydroxylamine and azide ions proceeds more effectively in an alkaline medium. The azido-nitrosyl chromium complexes prepared in the acidic medium are always impure and a purification by column chromatography is essential. However, irrespective of the reaction route the

yield of the azido-nitrosyl complexes are much lower than the analogous thiocyanato-nitrosyl complexes owing possibly to the intrinsic instability of the azido-nitrosyl complexes of metals and the instability of the azide ions in the reaction medium. However, the isolated complexes are quite stable as solid as well as in solution in organic solvents, unlike the corresponding rhenium complexes which are prone to decomposition in solution phase[7]. The isolation of the complexes is also rather easy and does not involve the separation of sticky solid as a crude reaction product as occurs in the cases of the analogous osmium complexes[1(b)].

The tetraphenylphosphonium salt is, as expected, found to be 3 : 1 electro-lyte (Λ_M = 380 ohm^{-1} cm^2 mol^{-1})[10]. Other complexes are non electrolytes and monomeric. Assuming the NO^+ formalism, the formal oxidation state of chromium in these complexes should be +1 (i.e. possessing $\{Cr(NO)\}^5$ moiety) which is manifested by their magnetic moment values (see experi-mental section) and esr spectra (g_{av} for all the complexes are 2.0). The esr spectra of the polycrystalline solid as well as of the acetonitrile solution of the complexes show only one line, the lack of ligand hyperfine coupling to the nitrosyl nitrogen atom as well as coupling to the spin active ^{53}Cr contrasting with the results found for some analogous com-plexes, viz., $[Cr(NO)(L_5)]^Z$ (Z = +2 for L = NH$_3$[11,12] or OH$_2$[12] ; Z = -3 for L = CN[12]) and paralleling some others, viz, $[Cr(NO)(CH_3CN)_5]$ (ref. 13), the thiocyanato-[3,4] and a few cyano-nitrosyl[12,14] derivatives. The local symmetry of the $[CrN(N_2)(N_2)]$ (in bipy and phen complexes) and $[CrN(N)_5]$ (the Ph$_4$P$^+$ salt) chromophores may approximate to C_{4v} and generate an M.O. configuration, $(e)^4$ $(b_2)^1$ (see ref. 15). So, the electronic transitions responsible for the three uv - vis bands in the L-L complexes may be desig-nated as $b_2 \longrightarrow e$ (π^* NO), $b_2 \longrightarrow b_1$ and $b_2 \longrightarrow a_1$. The hexaco-ordinated anionic complex, however, possesses an extra very weak band (brought out by Gaussian analysis from an weak inflection) at a quite low energy (720 nm) not observed in the pentacoordinated cases as well as in the analogous thiocyanato complex[4,6]. Whether this is due to $b_2 \longrightarrow e$ transition or due to any other transition is difficult to say. It may also be pointed out that the positions of the $d \longrightarrow \pi^*$ NO transitions in the present L-L series are comparable with the analogous thiocyanato complexes[4] which is quite natural when one compares the position of thio-cyanate and azide ions in the spectrochemical series.

NOTE

Synthesis, Reactions and Catalytic Activities of a Cationic
Acrylonitrile-Rhodium(I) Complex

T. Kwon, J.C. Woo and C.S. Chin*

Department of Chemistry, Sogang University, Mapo-gu, Sinsu-dong
Seoul 121, Korea

Abstract: Reaction of $RhCl(CO)(Ph_3P)_2$ (Ph_3P = triphenylphosphine) with $AgClO_4$ in acrylonitrile at $30°C$ produces a new cationic rhodium(I) complex, $[Rh(CH_2CHCN)(CO)(Ph_3P)_2]ClO_4$ (1) and AgCl. The ^1H-NMR and IR spectra of 1 suggest that acrylonitrile is coordinated to rhodium through the π-system of the vinyl group. The complex 1 reacts with molecular hydrogen to give a propionitrile-rhodium(I) complex, $[Rh(CH_3CH_2CN)(CO)(Ph_3P)_2]ClO_4$ (2) where the coordination of propionitrile through nitrogen is suggested by the ^1H-NMR and IR spectral data. The coordinated acrylonitrile in 1 is readily replaced with triphenylphosphine and propionitrile to give $[Rh(CO)(Ph_3P)_3]ClO_4$ and 2, respectively. The complex 1 is catalytically active for the hydrogenation and polymerization of acrylonitrile at $25°C$ under the atmospheric pressure of hydrogen.

The reaction of $IrCl(CO)(Ph_3P)_2$ with $AgClO_4$ in acrylonitrile produces AgCl precipitate and the clear yellow solution which is catalytically active for the polymerization of acrylonitrile under nitrogen at room temperature.[1] Subsequently, we have become interested in the reaction of the rhodium analog, $RhCl(CO)(Ph_3P)_2$ with $AgClO_4$ in acrylonitrile.

We wish to report the synthesis, reactions and catalytic activities of a new cationic rhodium(I) complex, $[Rh(CH_2CHCN)(CO)(Ph_3P)_2]ClO_4$ (1) which has been identified by elemental analyses, conductivity measurements, ^1H-NMR and IR spectral data. There have been a few other cationic acrylonitrile-rhodium(I) complexes reported (e.g., $[Rh(C_8H_{12})(CH_2CHCN)]ClO_4$, $[Rh(C_8H_{12})(CH_2CHCN)(Ph_3P)]ClO_4$) with their catalytic activities for the hydrogenation of olefins.[2]

The addition of $AgClO_4$ into the yellow solution of $RhCl(CO)(Ph_3P)_2$ in acrylonitrile under nitrogen immediately produced AgCl precipitate.[3] The yellow solution obtained by the removal of AgCl turned orange within one hour and eventually dark brown within three hours at $30°C$ under nitrogen. The addition of hexane to this dark brown solution resulted in brown solid of $[Rh(CH_2CHCN)(CO)(Ph_3P)_2]ClO_4$ (1) (eq. 1).[4] The complex 1 is stable in the solid state in air and in solution under nitrogen, and soluble in polar organic solvents (acrylonitrile, chloroform, dichloromethane) but insoluble in non polar solvents (benzene, hexane).

$$RhCl(CO)(Ph_3P)_2 + AgClO_4 + CH_2CHCN \longrightarrow$$
$$[Rh(CH_2CHCN)(CO)(Ph_3P)_2]ClO_4 + AgCl \qquad (1)$$
The molar conductance $(120\ ohm^{-1}cm^2mol^{-1})$ of $\underline{1}$ $(4.0 \times 10^{-5}\underline{M}$ in acrylonitrile) shows that the complex $\underline{1}$ is a 1:1 electrolyte.[5]

The formation of a π-bonding between acrylonitrile and rhodium is suggested by the IR spectrum of $\underline{1}$. The nitrile stretching frequency, ν_{CN} of acrylonitrile in $\underline{1}(2220\ cm^{-1}$, Nujol) is lower than that of free acrylonitrile $(2230\ cm^{-1})$. The decrease in ν_{CN} indicates that the acrylonitrile in $\underline{1}$ is coordinated to rhodium through the π-system of the vinyl group since it is well known that ν_{CN} of acrylonitrile increases upon coordination to a metal through nitrogen.[6] A very strong and broad absorption band at ca. $1100\ cm^{-1}$ (Nujol) attributable to the anionic tetrahedral ClO_4 group[7] supports that $\underline{1}$ is an ionic compound as confirmed by the conductivity data (see above). The ν_{CO} and ρ_{CH_2} (CH_2CHCN) in $\underline{1}$ appear at 1995 (very strong) and 950 (medium) cm^{-1} (Nujol), respectively.

The acrylonitrile hydrogens of $\underline{1}$ give rise to a multiplet at ca. δ = 5.75 ppm (vs. TMS, in $CDCl_3$) shifted upfield ca. 0.25 ppm from those (at ca. δ = 6.0 ppm) of free acrylonitrile. The multiplet due to the phenyl hydrogens of triphenylphosphine is seen at ca. δ = 7.5 ppm. The chemical shift of acrylonitrile in $\underline{1}$ and the ratio (10:1) of phenyl hydrogens to acrylonitrile hydrogens clearly suggest $Rh(CH_2CHCN)(Ph_3P)_2$ moiety in $\underline{1}$. The upfield shifts (0.25 ppm) observed for the acrylonitrile hydrogens in $\underline{1}$ are understood in terms of the increase in electron density at acrylonitrile due to its π-acceptor charactor through the π-system of the vinyl group as suggested by the IR data. The low oxidation state of rhodium in $\underline{1}$ probably facilitates the electron flow from the metal to the π-system of the vinyl group in the coordinated acrylonitrile. The hydrogens of acrylonitrile coordinated through nitrogen show downfield shifts relative to those of free acrylonitrile.[6,8] No complexes of coordinated acrylonitrile through the π-system of the nitrile group have been reported thus far.[6]

The complex $\underline{1}$ reacts with molecular hydrogen in chloroform at $25^\circ C$ to give the propionitrile-rhodium(I) complex, $[Rh(CH_3CH_2CN)(CO)(Ph_3P)_2]ClO_4$ $(\underline{2})$ (eq. 2).[9]

$$[Rh(CH_2CHCN)(CO)(Ph_3P)_2]ClO_4 \quad + \quad H_2 \quad \longrightarrow$$
$$[Rh(CH_3CH_2CN)(CO)(Ph_3P)_2]ClO_4 \tag{2}$$
The IR spectral data provide the information on the nature of the bonding between metal and nitrile. It is well established that the bonding of a nitrile to a transition metal through nitrogen increases ν_{CN} relative to ν_{CN} of the nitrile uncoordinated, whereas the bonding through the π-system of the $C{\equiv}N$ group is characterized by a decrease in ν_{CN}.[6] The ν_{CN} of propionitrile in $\underline{2}$ is seen at $2260\ cm^{-1}$ (Nujol) while that of free propionitrile is seen at $2248\ cm^{-1}$,[10] which suggests that the propionitrile in $\underline{2}$ is coordinated through nitrogen. The ν_{CO} $(1970\ cm^{-1}$, Nujol) observed for $\underline{2}$ is significantly lower than that (1995 cm^{-1}) for $\underline{1}$. This may be the reflection of stronger Rh-CO bond in $\underline{2}$ than in $\underline{1}$. The IR spectrum of $\underline{2}$ also shows a strong and broad band at $1100\ cm^{-1}$ (Nujol) suggesting the anionic tetrahedral ClO_4 group in $\underline{2}$ as seen for $\underline{1}$.[7]

The ^{1}H-NMR spectrum of $\underline{2}$ shows the methyl hydrogens of the coordinated propio-
nitrile at $\delta = 0.53$ ppm (triplet, vs. TMS, $CDCl_3$) and the methylene hydrogens at
$\delta = 1.97$ ppm (quartet), while free propionitrile shows those at $\delta = 1.22$ and $\delta = 2.38$
ppm, respectively. The moiety of $Rh(CH_3CH_2CN)(Ph_3P)_2$ is evident in $\underline{2}$ from the
chemical shifts of the hydrogens of propionitrile and the ratio of the phenyl hydro-
gens at ca. $\delta = 7.5$ ppm to the hydrogens of propionitrile. The methyl hydrogens
of propionitrile in $\underline{2}$ are shielded more upon coordination to rhodium(I) than the
methylene hydrogens (1.22 - 0.53 = 0.69 ppm and 2.38 - 1.97 = 0.41 ppm, respectively).
The hydrogens of saturated nitriles coordinated to d^6 transition metals (Ru(II), Rh
(III)) showed downfield shifts relative to those of the free nitriles,[8] while those
coordinated to d^8 transition metal (Ir(I)) showed upfield shifts.[11,12] The upfield
shifts observed for $\underline{2}$ may be due to the facile electron flow from the electron rich
rhodium(I) to propionitrile. The spin coupling between ^{103}Rh and the hydrogens of
coordinated propionitrile has not been observed.

Acrylonitrile in $\underline{1}$ is readily replaced by propionitrile or triphenylphosphine
to give $\underline{2}$ or $[Rh(CO)(Ph_3P)_3]ClO_4$[13] in chloroform under nitrogen at 25°C (eq. 3).

$$[Rh(CH_2CHCN)(CO)(Ph_3P)_2]ClO_4 \quad + \quad L \quad \longrightarrow$$

$$[Rh(CO)(Ph_3P)_2L]ClO_4 \quad + \quad CH_2CHCN \qquad (3)$$
$$L = CH_3CH_2CN, \quad Ph_3P$$

The reaction of $\underline{1}$ with molecular hydrogen to produce $\underline{2}$ (eq. 2) has prompted us
to investigate the catalytic activity of $\underline{1}$ for the hydrogenation of acrylonitrile.
It has been found that the acrylonitrile solution of $\underline{1}$ under hydrogen (P_{H_2} = 700 mmHg)
at 25°C catalytically produces propionitrile and polyacrylonitrile. For example,
a 10 ml of acrylonitrile solution of $\underline{1}$ (0.12 g, 0.15 mmole) under hydrogen (P_{H_2} = 700
mmHg) produces 7.5 mmoles of propionitrile and 0.12 g (ca. 2.3 mmoles of acryloni-
trile monomer) of insoluble beige polyacrylonitrile[14] for 100 hours at 25°C.

NOTE

HETEROPOLYBLUES: RELATIONSHIP BETWEEN METAL-OXYGEN-METAL BRIDGES AND
REDUCTION BEHAVIOUR OF OCTADECA(MOLYBDOTUNGSTO)DIPHOSPHATE ANIONS.

J.P. CIABRINI, R. CONTANT[*] AND J.M. FRUCHART.
Laboratoire de Physicochimie Inorganique, ERA 608, Université Pierre et
Marie Curie, Tours 54-55, 4, place Jussieu, 75230 Paris Cedex 05

Abstract: The reduction behaviour of $P_2W_{18-n}Mo_nO_{62}^{6-}$ anions that can undergo
one or two-electron reduction steps has been rationnalized by taking
Mo^V-O-Mo^V angle and its deformation ability into consideration.

INTRODUCTION

Among the numerous heteropolyanions known[1] to easily give heteropolyblues
by reduction $P_2Mo_{18}O_{62}^{6-}(P_2Mo_{18})$ and As_2Mo_{18} are the only two that undergo
two-electron reduction steps even in the absence of protonation process.
Garvey and Pope[2] explain this particular behaviour by the chirality of
P_2Mo_{18} owing to an intramolecular rearrangement of short and long $Mo-O-Mo$[3a]
bonds.

We have investigated the reduction processes of some $P_2W_{18-n}Mo_n$ and
$PW_{12-n}Mo_n$ polyanions that we recently prepared by stereospecific methods[4,5].
The Garvey and Pope interpretation was reconsidered by taking the influence
of the positions of molybdenum atoms on the reduction pattern into account.

EXPERIMENTAL

Preparation. $K_6P_2W_{15}Mo_3O_{62}$. To a mixture of molar hydrochloric acid(125 ml)
and molar sodium molybdate(15 ml) solutions were added $Na_{12}P_2W_{15}O_{56}$(20 g)
then, after dissolution, potassium chloride(25 g).The yellow precipitate
was filtered off and recrystallised from acidulous water(50 ml; pH 2).
Anal. Calcd for $K_6P_2W_{15}Mo_3O_{62}$,14 H_2O : K 5.11 ; Mo 6.28 ; P 1.35 ; W 60.1 ;
H_2O 5.49. Found: K 5.15 ; Mo 6.26 ; P 1.35 ; W 59.7 ; H_2O 5.50
All other compounds were prepared by previously published methods[4,5,6].
$Na_{12}P_2W_{15}O_{56}$ has been first erroneously described as $P_2W_{16}^{6-}$. Analytical
procedures were given previously[4].
Reduction. Phosphopolyanion solutions(5.10^{-3}mol.l^{-1}) were electrochemically
reduced at pH 1 to obtain two-electron blues and at suitable higher pH to
obtain four-electron blues. The polarogramms were recorded on Radiometer

PO4 polarograph with rotating glass-imbedded carbon rod electrode. The halfwave potentials depending on the nature and the concentration of the counterions, the measurements were made in molar Na^+ solutions.

RESULTS AND DISCUSSION

Halfwave potentials, measured under conditions where the reduced anions are not protonated, are given in table 1. α_1-$P_2W_{17}Mo$ that contains the molybdenum atom in an equatorial site is more reducible than P_2Mo_{18} as $PW_{11}Mo$ is more reducible than PMo_{12}. On the other hand when the molybdenum atom is in a "cap" M_3O_{13}, it is less reducible than P_2Mo_{18}. This agrees with Pope et al[7,8] proposal that P_2W_{18} is initially reduced at one one of the twelve equivalent equatorial tungsten atoms. Moreover it should be the same for P_2Mo_{18}. Indeed, all the $P_2W_{18-n}Mo_n$ compounds that contain equatorial molybdenum atoms are more reducible than P_2Mo_{18} while $P_2W_{15}Mo_3$ that contains molybdenum atoms only in a M_3O_{13} group is less reducible than P_2Mo_{18}.

Table 1. Half-wave potentials(V vs. S.C.E.)

Species	$E_{1/2}$ at pH 4.7		ΔE^a	$E_{1/2}$ at pH 13

PW_9Mo_3	+0.60	+0.26	0.34	-0.38	-0.98
PMo_{12}	+0.44	+0.27	0.17	-0.19	-0.38

[a] $\Delta E = E_{1/2}(0-I)-E_{1/2}(I-II)$ was calculated from $E_{3/4}-E_{1/4}$ for bielectronic waves. Then it is only an order of magnitude. [b] Arabic numerals in parenthesis refer to the positions of molybdenum atoms[9] (figure 1).
Figure 1. Idealized structure of a-$P_2W_{18}O_{62}$. a-$P_2Mo_{18}O_{62}$ has the same framework but the Mo-O-Mo bonds are alternatively short and long [3a].

Furthermore it appears that P_2Mo_{18} is not the only phosphopolyanion that undergoes two-electron reduction step; three other compounds studied here behave likewise. According to Garvey and Pope[2] interpretation, it is possible that in a group of molybdenum atoms the Mo-O-Mo bonds would be alternatively short and long but this effect should be the same in PMo_{12}[3b] and $P_2W_{15}Mo_3$ for which odd states of reduction were observed (table 1).

As the four anions that undergo two electron reductions contain at least a group of four corner-sharing MoO_6 octahedron, i.e. located in 4,9,10 and 15 positions, we assume that, in such a group, the stabilizing effect of antiferromagnetic spin pairing overcome the destabilizing effect of increasing charge. Indeed, if we consider, as usual, that electrons are introduced in metal atom d_{xy} orbitals perpendicular to the metal-terminal oxygen direction, the more d_{xy} orbitals overlap the more d electrons are strongly coupled. The largest overlap between d_{xy} orbitals and bridging oxygen 2p orbitals would occur for linear M-O-M bonds; this borderline case has been observed by Jeannin, Launay et al[10] on the $\left| W_4O_8Cl_8(H_2O)_4 \right|^{2-}$ anion where the two d electrons are strongly coupled in an antiferromagnetic way.

In P_2M_{18} compounds the M(4)-O-M(10) angle between the two PM_9 half-anion[3a] is 162°. As often as several molybdenum atoms are concerned the angle can open by rearrangement of short and long Mo-O-Mo bonds. Then ΔE(table 1) the difference between the first and second reduction potentials would decrease as the deformation ability of Mo(4)-O-Mo(10) bonds would increase (P_2Mo_{18} < $P_2W_{12}Mo_6$ < A-$P_2W_{13}Mo_5$ < $P_2W_{14}Mo_4$ < B-$P_2W_{13}Mo_5$ < P_2W_{18}). For instance, if we compare the two $P_2W_{13}Mo_5$ formally deriving from $P_2W_{12}Mo_6$ by replacing one molybdenum by one tungsten atom in position 16(A) or 15(B), the latter would more enhance the rigidity of the molybdenum group and then increase ΔE.

This interpretation, based on d_{xy} orbitals overlap and deformation ability of Mo-O-Mo bonds, can explain in the same way why P_2Mo_{18} and As_2Mo_{18} undergo second and third two-electron reduction steps[11] since they contain three groups of four corner-sharing MoO_6. For $P_2W_{18-n}Mo_n$(n = 4,5 or 6) compounds the first four electrons are introduced in the same group of molybdenum atoms, then the effect of increasing charge overcome the effect of spin pairing.

In PMo_{12} the splitting ΔE is about the same as in $P_2W_{15}Mo_3$ where the MoO_6 octahedrons are edge-shared but it is weaker than in PW_9Mo_3 where the MoO_6 are corner-shared with a theoretical Mo-O-Mo angle of 151°. Likewise $SiW_{12-n}Mo_n$ (n = 2 or 3)[9c] exhibit larger splittings[12] than $SiMo_{12}$ and even than SiW_{12}. All this agrees with the first two electrons introduced in the same M_3O_{13} group of XM_{12}, the two M^VO_6 octahedrons being then edge-shared.

The conclusion is that, for X_2M_{18} polyanions, the splitting of two-electron reduction steps into one-electron reduction steps varies with the M^V-O-M^V angle between the two XM_9 half-anions, If several MoO_6 octahedrons are corner shared the short and long Mo-O bonds can rearrange to favor angle opening and weaker splitting. Then the reduction behaviour of P_2Mo_{18} and As_2Mo_{18} is not an exception but merely a borderline case.

   J. C. S. Chem. Comm. 1979, 777.

9a In $P_2W_{15}Mo_3O_{62}^{6-}$ the three molybdenum atoms are in one M_3O_{13} "cap" as the

    vanadium atoms in the related compound $P_2W_{15}V^{IV}V^VO_{62}^{10-}$ (S. P. Harmalker and

    M. T. Pope, J. Am. Chem. Soc. 1981, 103, 7381). The lack of a M_3O_{13} group

    in $P_2W_{15}O_{56}^{12-}$ is confirmed by the formation of $Co_2P_4W_{30}O_{112}^{20-}$ and

    $Co_4(H_2O)_2P_4W_{30}O_{112}^{16-}$ complexes (J. P. Ciabrini, Thèse, Paris 1982).

9b The proposed structures of $P_2W_{18-n}Mo_n$(n = 4,5 or 6) have been confirmed by

    solving the X-ray structure of a tetramer of $P_2W_{12}^6$. It is formed by four

    entities P_2W_{12} identical with that we have

    proposed in $P_2W_{12}Mo_6^6$ (A. Tézé and R. Contant, to be published).

9c It is now established (F. Robert and A. Tézé, Acta Cryst. 1981, B37, 318)

    that molybdenum atoms in SiW_9Mo_3 and $SiW_{10}Mo_2$ (α and β isomers [12]) belong

    to different M_3O_{13} groups and that MoO_6 octahedrons are corner-shared. It

    should be the same in PW_9Mo_3.

NOTE

THE ^{1}H AND ^{2}H NMR SPECTRA OF HFeCo$_3$(CO)$_{12}$

G.E. Hawkes and E.W. Randall*

Department of Chemistry, Queen Mary College,
Mile End Road, London, El 4NS

S. Aime, R. Gobetto, D. Osella

Istituto di Chimica Generale ed Inorganica,
Universita di Torino, Corse Massimo d'Azeglio 48,
19125 Torino, Italy

Abstract - The detection of the ^{2}H resonance of

^{2}HFeCo$_3$(CO)$_{12}$ led to the detection of the broader

^{1}H resonance of the ^{1}H isotopomer. The shift is

-21.4 ppm.

In the past twenty years it has been widely demonstrated

that ^{1}H NMR spectroscopy is a simple, accurate and

effective method for the detection of a hydrido-ligand

in a metal complex.[1] Difficulties can arise in this method

however if the metal which is involved has a nucleus, M,

possessing an electric quadrupole moment. This is the

case if the nuclear magnetic spin quantum number, I, of

the metal has a value greater than ^{1}/2. Examples are

^{59}Co (I=^{7}/2) and ^{55}Mn (I=^{5}/2). Moderately rapid

relaxation of M caused by the electric quadrupole

relaxation mechanism, at a rate denoted $(T_{qM})^{-1}$, can then

broaden the hydrido ^{1}H resonance if M and H are scalar

spin coupled (J_{HM}). In the limit that the ^{1}H multiplet

has collapsed to a single broad Lorentzian line, the

1235

proton relaxation time T_2-H is given by [2]

$$(T_2\text{-H})^{-1} = I(I+1)4\pi^2 J_{HM}^2 T_{qM}/3$$

T_2-H can be so short that the ^{1}H resonance is very difficult to detect since the line is very broad. This has been the case for example with $HMCo_3(CO)_{12}$ [M=Fe,Ru,Os], so that the nature of the hydride ligand in solutions of these compounds has remained unknown.[3,4,5] Even in the case of the solids there was initial uncertainty concerning the bonding which was eventually elucidated by X ray and neutron diffraction studies of $HFeCo_3(CO)_9$ [$P(OCH_3)_3$].[6,7,8] These showed that the hydrido ligand occupied a μ_3-coordination site below the tricobalt face. Renewed attempts to detect the hydrido signal in the ^{1}H NMR spectra were unsuccessful. These employed low temperatures to increase the 'thermal decoupling' effect, on the presumption that broadening was because the collapse of multiplet structure was only partial.[9]

We report here a novel method for the measurement of the ^{1}H shift in these cases by the use of surrogate ^{2}H NMR spectra of a deuteriated sample.[10] A chloroform solution of $^2HFeCo_3(CO)_{12}$ gave a ^{2}H signal with a line-width of 35 Hz at 294 K. The technique works because the value of $^1J_{HM}$ for the ^{2}H isotopomer is smaller by a factor of 6.51 than the value in the ^{1}H isotopomer, and therefore the value of T_2-H is expected by equation 1 to be $(6.57)^2$, i.e., 42.38 times larger for the ^{2}H resonance

than for the ^{1}H resonance. Thus the contribution to the

^{2}H line-width from the H-metal interaction should be 42.38

times smaller for ^{2}H than for ^{1}H. A complication is that

since the ^{2}H nucleus possesses its own quadrupole moment,

the ^{2}H line-width might be dominated by this effect. The

fact that the width did not increase when the temperature

was raised to 333 K suggests that this is so. The value

of 35 Hz for the ^{2}H line-width however is still quite low

and if it was all attributed to the effect of the ^{59}Co

then the corresponding ^{1}H line-width would be

35 x 42.38 = 1483 Hz, a figure which should constitute

only an upper limit. Even a line of this width should be

detectable with high resolution instrumentation, however,

and it was indeed found by the use of a wide spectral

width (150 ppm) such as normally employed for example in

the detection of broad resonances of paramagnetic

complexes. At 302 K the width was measured as

approximately 550 Hz and the shift as ca. -21 ppm. The

line width decreased to 500 Hz at 292 K. The

corresponding ^{2}H line width is calculated as 13 Hz,

rather less than the value measured. The difference of

22 Hz must be due to the quadrupole relaxation of ^{2}H

itself. Use of a correlation time τ_c of 20 ps gives

the electric quadrupole coupling constant for ^{2}H as

150 kHz if axial asymmetry is assumed.

The hydrido shifts measured for ^{1}H and ^{2}H are the

same (within the rather large errors arising from the

large ^{1}H line-widths) as expected in the absence of

primary isotope effects on shieldings.[11] The value of
-21.4 ppm relative to TMS is surprisingly within the
normal region of absorption of μ_2-bridging
hydrides.[1,12] It is noticeably to high field of the
resonances for other μ_3-face bridging hydrides:[13,14]
$(\mu_3-H)_4 Re_4 (CO)_{12}$ at -5.1 ppm; $\left[(\mu_3-H)(IrLL'H_2)_3 \right]$
$\left[PF_6 \right]_2$ at -3.9 ppm. It is different also from the case
of $HFeCo_2 (CO)_9 CH$ which probably has a μ_3-hydride
structure although there is no report of a crystal
structure determination. For this compound the value
-9.81 ppm has been reported[15] and considerable
broadening of the hydrido resonance was ascribed to
the effect of the ^{59}Co nuclei.

Clearly the question now arises concerning what
is the range of shift values which μ_3-hydrido
resonances can have as the cluster types and the
metals vary.

The use of surrogate ^2H-spectra should
constitute an important method in studies of this
sort, and in more general investigations of hydrido
derivatives of cobalt, manganese and other
quadrupolar metals.

Abstract—Reaction of *trans*[Os(CO)$_2$(dppe)$_2$]$^{2+}$ with [KHB(OPr^i)$_3$] gives the formyl complex *trans*-[Os(CHO)(CO)(dppe)$_2$][SbF$_6$] which is thermally very stable; the crystal structure shows it to have *trans* stereochemistry and a long Os–C bond.

We have recently reported[1] the successful isolation of cationic formyl complexes of ruthenium from the action of monohydridic reducing agents on [Ru(CO)$_2$(P–P)$_2$]$^{2+}$

(P–P = Ph$_2$P(CH$_2$)$_n$PPh$_2$, n = 1, dppm; n = 2, dppe). Although these formyl complexes are sufficiently inert for isolation and characterisation, they decompose with half-lives of < 15 min in solution at room temperature.[2] We now report the isolation of an analogous osmium complex which is substantially more inert.

*Author to whom correspondence should be addressed.
Fig. 1. Solid state structure and atomic numbering scheme for the cation of *trans*-[Os(CHO)(CO)(dppe)$_2$][SbF$_6$]·CH$_2$Cl$_2$. C(1)–O(1), 1.181(11); Os–C(1), 2.155(28); Os–Ĉ(1)–O(1),130.7(27); C(2)–O(2), 1.096(35); Os–C(2), 1.983(32); Os–Ĉ(2)–O(2), 173.0(28); C(1)–Ôs–C(2), 172.1(11). Angles in °, lengths in Å.

Treatment of *trans*[Os(CO)₂(dppe)₂][SbF₆]₂, prepared from [OsCl₂(dppe)₂], CO and excess Ag[SbF₆], with excess [KHB(OPrⁱ)₃] leads to the formation of *trans*-[Os(CHO)(CO)(dppe)₂][SbF₆] which has been fully characterised spectroscopically.† The complex is very much more thermally stable than its ruthenium analogue. For example, only 60% conversion to *trans*-[OsCl(CO)(dppe)₂]⁺ is observed on refluxing *trans*-[Os(CHO)(CO)(dppe)₂][SbF₆] in CHCl₃ under N₂ atmosphere for 5 days, the remaining 40% being mostly unchanged formyl.

In view of the scarcity of information on the structures of transition metal formyls[3-5] in general and cationic formyls in particular, *trans*-[Os(CHO)(CO)(dppe)₂][SbF₆]·CH₂Cl₂ was studied by X-ray diffraction methods.‡ The structure of the cation (Fig. 1) shows the presence of mutually *trans* carbonyl

(NO)(PPh₃)] (1.225 Å)[4] but longer than that of [Rh-(CHO)(octaethylporphyrin)] (1.175 Å)[5] which is unusual in many ways, including its preparation[6] by insertion of CO into a rhodium hydrogen bond.

Metal formyl complexes are normally believed to have contributions to their structures from the two resonance forms shown in Fig. 2. We assume that the observed short C=O bond length arises from a lesser contribution from form II on account of the positive charge already present on the metal.

Consistent with this, the Os–C bond length (2.155 Å) is comparable with those observed for Os–C single bonds (2.15 Å)[7] but much longer than Os=C as found in [Os(PPh₃)₂(CO)₂(CC₆H₅Me)] (1.90 Å).[8] This contrasts with the M–C bond length of, e.g. [Re(C₅H₅)(CHO)(NO)(PPh₃)] which is closer to the value found for Re=C in carbene complexes.[4,9]
Fig. 2. Possible resonance forms for metal formyl complexes.

and formyl groups, the two being easily distinguished by an Os–Ĉ–O of 130.7° for the formyl ligand, similar to those reported for anionic (134°)[3] or neutral (130, 128°)[4,5] metal formyl complexes.

The formyl C=O bond length (1.181 Å) is somewhat shorter than those observed for [Et₄N][Fe(CHO)(CO)₃ (3,5-Me₂C₆H₃O)₃P] (1.195 Å)[3] and [Re(C₅H₅)(CHO)

INTERACTION OF ARYLDIAZONIUM SALTS WITH SOME SCHIFF-BASE COMPLEXES OF COBALT AND RUTHENIUM

NICHOLAS FARRELL*, MARIA N. DE OLIVEIRA BASTOS and ANTONIO A. NEVES

Departamento de Química, Universidade Federal de Minas Gerais, Belo Horizonte
MG 30.000, Brasil

Abstract—The interaction of aryldiazonium ions with some Schiff-base complexes of cobalt and ruthenium have been studied. With cobalt, one-electron oxidation of [Co(II)Salen] occurred; with [Co(I)Salen] the corresponding Co(III)-aryl complexes were isolated. In the case of ruthenium oxidation also occurs, [Ru(Salen)(CO)py] gave the corresponding monocation. The results, especially for ruthenium, are in contrast to the stabilisation of both nitrosyl and aryldiazonium adducts in analogous porphyrin complexes.

We have recently begun a study of the interaction of aryldiazonium ions with metal complexes of macrocycles and other quadridentate donor ligands and have reported on the preparation of aryldiazonium–ruthenium porphyrin species of the type [Ru(porphyrin)(N$_2$Ar)L]BF$_4$. To compare the effects of differing donor atoms in the equatorial plane we next studied the reactions of Schiff-base complexes† and this paper summarises our results on cobalt and ruthenium systems.

EXPERIMENTAL

All solvents were dried by usual methods and distilled under nitrogen. All reactions were carried out under a nitrogen atmosphere. The starting complexes of cobalt(II) were prepared by standard procedures[2,3] and the cobalt(I) Schiff base solutions generated *in situ* by the literature method.[4] Diphenyliodonium chloride was purchased from Aldrich Chemical Company Inc. and used without further purification.

IR spectra were recorded on a Perkin–Elmer 457 spectrometer for samples pressed in KBr discs. Visible spectra were recorded using a Cary-17 spectrophotometer. Elemental analyses were car-

ried out at the Centro de Tecnologia do Estado de Minas Gerais (CETEC), Belo Horizonte, Brasil.

N, N′-ethylenebis (salicylideneiminato) cobalt (III) tetrafluoroborate

To a stirred suspension of Co(Salen) (0.975 g, 0.003 mol) in CH$_2$Cl$_2$ (25 cm^3) was added a suspension of PhN$_2$BF$_4$ (0.58 g, 0.003 mol) in CH$_2$Cl$_2$ (25 cm^3). The mixture was stirred for 1 hr at reflux temperature during which time a red–brown solid precipitated. The solid was filtered off, washed with CH$_2$Cl$_2$ and recrystallised from acetone–ether to give a dark powder (yield, 45%). Found: C, 45.3; H, 3.92; N, 6.31. [C$_{16}$H$_{16}$N$_2$O$_3$BF$_4$Co] requires: C, 44.65; H, 3.72; N, 6.5%. Identical results were obtained using the *p*-NO$_2$ and *p*-OCH$_3$ salts and when acetone was used as solvent in place of dichloromethane. The iodo salt was prepared by metathesis with excess KI in acetone and compared with an authentic sample prepared by the literature method.[11]

Preparation of cobalt (III) Schiff-base aryl complexes

A stirred suspension of PhN$_2$BF$_4$ (0.192 g, 0.001 mol) in CH$_2$Cl$_2$ (15 cm^3) was added slowly to a filtered solution of [Co(I)Salen], (0.325 g, 0.001 mol) in THF (20 cm^3) at −10°C. The initial red–brown colour of the reaction mixture remained unaltered after 2 hr of stirring, when water (50 cm^3) was added to give a red–brown solid. This was filtered off and purified by chromatography on

†Abbreviations used in this paper: H$_2$Salen = N,N′-ethylenebis (salicylideneimine); H$_2$Acacen = N,N′-ethylenebis(acetylacetonediimine).

a neutral alumina column by elution in CH$_3$OH–CHCl$_3$ (1:3). The orange–red solid obtained upon evaporation was treated with pyridine to give the yellow–orange product (yield = 40%). Found: C, 55.5; H, 4.60; N, 6.70. Calc for [C$_{27}$H$_{24}$N$_3$O$_2$Co]; C, 55.95; H, 4.16; N, 6.99%. The IR spectrum of this product was identical with that of an authentic sample.[4] In a similar manner [Co(Acacen)Ph(H$_2$O)],[5] Found: C, 57.44; H, 6.54; N, 7.41. Calc for [C$_{18}$H$_{25}$N$_2$O$_3$Co]: C, 57.4; H, 6.64; N, 7.44; [Co(Salen)(p-NO$_2$Ph)py], CH$_3$OH. Found: C, 58.03; H, 4.80; N, 10.8% [C$_{28}$H$_{29}$N$_4$O$_5$Co] requires: C, 58.33; H, 5.03; N, 9.7%; [Co(Salen)(m-NO$_2$Ph)py]. Found: C, 61.06; H, 4.25; N, 10.1% [C$_{27}$N$_{25}$N$_4$O$_4$Co] requires: C, 61.6; H, 4.37; N, 10.65%, were prepared in 30–50% yields. Use of Ph$_2$I$^+$Cl$^-$ (0.316 g; 0.001 mol) in CH$_3$OH (10 cm^3) gave a red–brown solution with [Co(I)Salen] from which a red–brown solid was precipitated by addition of ether. This solid when recrystallised from pyridine gave the yellow–orange [Co(Salen) (Ph)py], identical with the authentic sample.[4]

Carbonylpyridine-N,N′ ethylenebis(salicylideneiminato)-ruthenium(II)

The complex [Ru(CO)Salen]$_2$, obtained as a precipitate from the reaction between Ru$_3$(CO)$_{12}$ and H$_2$Salen in refluxing toluene, was dissolved in pyridine and the solution heated under reflux for 16 hr, when the solvent was evaporated giving a yellow–green solid. Found: C, 54.6; H, 4.27; N, 8.53. Calc for [C$_{22}$H$_{21}$N$_3$O$_4$Ru]: C, 54.9; H, 4.31; N, 8.88%.

Carbonylpyridine N,N′ ethylenebis(salicylideneiminato)-ruthenium(III) tetrafluoroborate

The complex [Ru(Salen)(CO)py], (0.25 g; 0.503 mmol) was suspended in CHCl$_3$ (50 cm^3) and excess aryldiazonium salt added. The suspension was maintained under reflux for 16 hr, after which the cooled solution was filtered and concentrated to half-volume whereupon a green solid precipitated in 50% yield. Found: C, 43.80; H, 3.44; N, 7.09. Calc for [Ru(Salen)(CO)py]BF$_4$, 0.5 CHCl$_3$: C, 43.49; H, 3.46; N, 6.77%. A similar procedure using Et$_3$O$^+$BF$_4^-$ in place of ArN$_2^+$ BF$_4^-$ resulted in an identical product.

RESULTS AND DISCUSSION

Cobalt

The complexes studied were those of H$_2$Salen and H$_2$Acacen: The reactions of Co(II)Salen with p-XC$_6$H$_4$N$_2$BF$_4$, (X = H, NO$_2$, OCH$_3$), in either chloroform or acetone at room temperature all

gave the same product, characterised by IR spectroscopy and elemental analysis as the product of one-electron oxidation, [Co(III)(Salen)(H$_2$O)]BF$_4$. The formulation was confirmed by metathesis with I$^-$ and comparison of the IR spectrum with that of an authentic sample of [Co(Salen)I] formed by oxidation of [Co(II)Salen] with I$_2$.[4] A similar reaction occurs for [Co(II)acacen)(H$_2$O)$_2$]. This mode of reaction has been observed previously for aryldiazonium ions with [Cr(C$_6$Me$_6$)(CO)$_2$(PPh$_3$)] giving the corresponding monocation.[6]

In an attempt to prepare Co(III)-aryldiazenato complexes we next considered oxidative addition of Co(I) species. When C$_6$H$_5$N$_2$BF$_4$ in acetone was added to the green solution of Na[Co(I)Salen] in tetrahydrofuran[2] at room temperature the colour of the solution immediately changed to red–brown and upon work-up as described in the Experimental Section of σ-aryl complex [Co(Salen) (Ph)py] was obtained. Use of lower temperatures followed by precipitation with diethyl ether failed to isolate the presumed aryldiazenato intermediate. The use of aryldiazonium ions as arylating agents has been described previously for [IrCl(CO)(PPh$_3$)$_2$][7] and by Nesmeyanov's group with complexes such as [FePh(Cp)(CO)$_2$].[8] Extrusion of dinitrogen from isolated aryldiazenato complexes [Pt(N$_2$Ar)(PEt$_3$)$_3$]$^+$$^{(9)}$, and [RhCl$_2$(N$_2$Ar) (PPh$_3$)$_3$],[10] also gave the corresponding σ-aryl derivatives. Use of the diphenyliodonium salt, Ph$_2$I$^+$Cl$^-$, instead of PhN$_2^+$, also gave the σ-phenyl complex in good yield. With [Co(I)Acacen] the known[5] [Co(Acacen)(Ph)H$_2$O] was readily isolated.

To test the generality of this reaction and to study the effect of substituents on the phenyl ring in stabilizing the Co(III)-N$_2$Ar species the reactions of [Co(I)Salen] were investigated with XC$_6$H$_4$N$_2$BF$_4$ (X=p-NO$_2$, p-OCH$_3$ and m-NO$_2$). In the case of the p-NO$_2$ salt the initial red–violet colouration of the reaction mixture persisted for some time on warming to room temperature but the final product isolated was [Co(Salen) (p-NO$_2$C$_6$H$_4$)py] as dark crystals. Similarly the m-NO$_2$ salt gave a black crystalline solid with an IR spectrum very similar to the p-NO$_2$ derivative. An unusual reaction, however, occurred using p-CH$_3$OC$_6$H$_4$N$_2$BF$_4$. In this case the dark-brown solid which precipitated from the reaction mixture was identified by elemental analysis and IR spectrum to be [Co(III)Salen]BF$_4$, representing a formal two-electron oxidation. We have not as yet investigated the mechanism of this reaction but the observation agrees in general with the deactivating role of methoxy in nucleophilic aromatic substitution.

A formal two-electron oxidation occurs in the formation of the Ir(III)-tetrazene complex, $[Ir(CO)(PPh_3)_2(N_4Ar_2)]BF_4$ from $[Ir(Cl(CO)PPh_3)_2]$ and aryldiazonium ion in benzene/ethanol.[11] A mechanism involving attack of ArN_2^+ on an Ir(I)–N₂Ar moiety has been proposed;[12] a similar situation in the cobalt case could also account for the observed result.

The results outlined in the Scheme are in accord with the known chemistry of these cobalt complexes, but do underline again the utility of aryldiazonium and diphenyliodonium salts as phenylating agents in inorganic chemistry especially where the standard Grignard or aryllithium route is inaccessible and usually are made from the less reactive aryl halides.[13]

Initial results on dimethylglyoxime and porphyrin complexes of cobalt also indicate that this reactivity is in fact general. Thus reduction of $[CoCl(dmg)_2py]$ to Co(I) by $NaBH_4$, destruction of excess borohybride with acetone and reaction with $PhN_2^+BF_4$ gave the known[14] $[Co(dmg)_2Ph(py)]$. With Co(II)(TPP) in CH_2Cl_2 treatment with ArN_2^+ gave visible spectra indicative of oxidation, the Soret band moving from 412 to 435 nm. Attempts to prepare phenyl derivatives by reduction with Na/Hg in pyridine[15] and subsequent reaction with ArN_2^+ did not however give a pure product but instead a mixture of species with very similar R_f values.

$$Co(II)(L_4) \xrightarrow{\text{Na/Hg}} Na[Co(I)(L_4)]^-$$

$$\downarrow ArN_2^+ \qquad\qquad p\text{-}OCH_3C_6H_4N_2^+ \quad \downarrow ArN_2^+$$

$$[Co(III)(L_4)]^+ \xleftarrow{\qquad} Co(III)\text{-}Ar(L_4).$$
$$\xrightarrow{ArMgX}$$
Ruthenium

As the porphyrin species studied[1] were of the type $[Ru(porphyrin)(CO)L]$ we studied the synthesis of similar Schiff-base complexes using H_2Salen. The dimeric $[Ru(Salen)(CO)]_2$ has been prepared from $Ru_3(CO)_{12}$ and the base in DMF[16] while use of $[RuCl_2(PPh_3)_3]$ gives $[Ru(Salen)(PPh_3)_2]$ from which a number of derivatives may be prepared.[17,18]

We have found that use of the same solvent system as that used for porphyrins[19,20] gives a very clean and simple route to the dimer with yields of 80–85%. Thus upon reaction of H_2Salen with $Ru_3(CO)_{12}$ in refluxing toluene the yellow [Ru(Salen)(CO)]₂ precipitates upon formation. The complex isolated is analytically pure and may be used without further purification. Upon dissolution in solvents such as pyridine under reflux the yellow–green [Ru(Salen)(CO)py] is formed. The $v(CO)$ of this complex ($1930 \, cm^{-1}$) is comparable with that of such derivatives as $[Ru(pyr_2en)(CO)PPh_3]$ ($1940 \, cm^{-1}$).[17]

When $[Ru(Salen)(CO)py]$ was allowed to react with $C_6H_5N_2^+BF_4^-$ or $p\text{-}NO_2C_6H_4N_2^+BF_4^-$ in chloroform the initial yellow–green solution turned green and upon addition of ether a green solid was isolated. Elemental analysis and the IR spectrum [$v(CO) = 1950$, $v_{asym}(BF_4) = 1050 \, cm^{-1}$] were also indicative of one-electron oxidation of the Ru(II) centre to Ru(III). An identical product was obtained using $Et_3O^+BF_4^-$ which has also been shown to effect 1-e oxidation in inert metal complexes.[21] The IR bands attributable to the base move only slightly and are essentially identical to those reported for $[Ru(Salen)(CO)]_2$.

The assignment of 1-e oxidation is consistent with the chemistry observed previously but the very slight increase in $v(CO)$ is unusual. Very few carbonyl complexes with planar Schiff-base ligands are in fact known; the Fe(II)/Fe(III) complexes which might be expected to serve as comparison are not known because of lack of reactivity even at high pressures,[16] and points up an interesting difference with the phthalocyanine and porphyrin ligands where the carbonyl adducts are of course formed readily. The affinity of CO for Ru(II) is well documented; indeed oxidation of the corresponding ruthenium–carbonyl–porphyrin complexes results in cation radicals from oxidation of the macrocycle rather than the metal centre.[22] The low value of $v(CO)$ in the Salen species may be explained by a strong σ-donation to the Ru–CO bond. Further studies with different Schiff bases and oxidising agents are in progress to determine the generality of this point, as indeed very few Ru(III)-carbonyl complexes are known.

The analogy between the nitrosyl and aryldiazonium ions has been much discussed.[23] Reaction of NO with $Ru(Salen)(PPh_3)_2$ gives an oxobridged species; coordinated nitrite from oxidation of the nitrosyl group is also formed.[24] The results for Schiff-bases are in contrast to the stabilisation of both nitrosyl[25] and aryldiazonium adducts in the Ru-porphyrin series; consistent with the good σ-donor properties of the porphyrin ligand and the greater ease of oxidation of the Schiff bases. The use of metal–macrocycle complexes is becoming of increasing interest in the study of the coordination chemistry of small molecules, where donor atoms in the equatorial plane and physicochemical properties such as redox potentials, etc. can be systematically varied. The consistent differences found in this work encourage this approach.

Abstract—Dichlorotetrakis(dimethylsulphoxide)ruthenium(II) reacts with $AsPh_3$, $AsMePh_2$, $AsMe_2Ph$ and $SbPh_3$ in ethanolic hydrochloric acid solution to yield the complexes $RuCl_2(DMSO)_2(AsPh_3)_2$, $RuCl_2(DMSO) L_2$ (L = $AsMePh_2$, $AsMe_2Ph$, $SbPh_3$) respectively. The treatment of ruthenium(II) blue solution with $AsMePh_2$, $AsMe_2Ph$ and $SbPh_3$ in alcohol resulted in the formation of the complexes; $RuCl_2L_3$ (L = $AsMePh_2$, $AsMe_2Ph$ and $SbPh_3$), respectively.

The reaction of $RuCl_2(DMSO)_4$ with the bidentate ligands 1,2 bis(diphenylarsino)methane (DPAM), 1,2 bis(diphenylarsino)ethane (DPAE) and 1,2 bis(diphenylphosphino)methane (DPPM). 1,2 bis(diphenylphosphino)ethane (DPPE), in ethanol gave the complexes $RuCl_2(DPAM)_2$, $RuCl_2(DPAE)_2$, $RuCl_2(DPPM)_2$ $RuCl_2(DPPE)_2$, respectively. The complexes thus obtained undergo reaction with carbon monoxide, hydrogen, molecular nitrogen and nitric oxide to yield a variety of mixed ligand complexes.

During the last decade extensive research has been carried out on ruthenium(II) complexes of tertiary phosphines especially Wilkinsons's complex $RuCl_2(PPh_3)_3$.[1,2] In contrast to the tertiary phosphine complexes, there are very few reports on ruthenium(II) complexes with monotertiary arsines. Some of these complexes include $RuCl_2(AsMePh_2)_4$[3] and $RuCl_2(AsMe_2Ph)_4$[4] that were obtained by the interaction of $RuCl_3$ with $AsMePh_2$ or $AsMe_2Ph$, respectively. However, $RuCl_3$ is not a very good source of ruthenium(II) since reduction to the ruthenium(II) state by the less basic arsine ligands in high boiling solvents invariably results in the formation of either polymers or chlorobridged

dimers.[5] Thus, reaction of $RuCl_3$ with ethyl-diphenylarsine in the presence of acid yielded $Ru_2Cl_3(AsEtPh_2)_6Cl$ with triple chloro bridges.[6]

A number of ruthenium(II) complexes were reported with bidentate ligands. Thus interaction of ruthenium(III) halide with o-phenylene-bisdimethylarsine(diars) produces $RuX_2(diars)_2$.[7] Similar preparative method with the ditertiary phosphines, diphos, (1,2 bis(diphenylphosphino)ethane, 1,2 bis(diphenylphosphine)methane and o-phenylenebis(dimethylphosphine) gave $RuCl_2(diphos)_2$.[8] The diarsine complexes prepared by this method include *trans*-$RuCl_2(DPAE)_2$ and *trans*-$RuCl_2$ (DPAM)$_2$ (DPAE = 1,2 bis(diphenylarsino) ethane, DPAM = 1,2 bis(diphenylarsino) methane).[9]

In the present work attempts were made to prepare monomeric ruthenium(II) complexes with a variety of monodentate arsines and bidentate

*Present address: Central Salt & Marine Chemicals Research Institute, Bhavnagar 364 002, Gujarat, India.

phosphines and arsines. The complex RuCl$_2$ (DMSO)$_4$[10,11] was employed as a suitable starting material for the synthesis of Ru(II) complexes with mono and bidentate phosphines and arsines. The blue solution[12] prepared by the reduction of RuCl$_3$ with zinc amalgam was also employed successfully for the synthesis of Ru(II) complexes with monodentate ligands. The Ru(II) complexes thus obtained activate small molecules like H$_2$, N$_2$, CO and NO to yield a variety of mixed ligand complexes of mono or bidentate ligands with the small molecules.

EXPERIMENTAL

The ligands, triphenylstibine, 1,2-bis(diphenylphosphino)methane (DPPM),1,2-bis(diphenylarsino)methane (DPAM),1,2-bis(diphenylphosphino)ethane (DPPE),1,2-bis(diphenylarsino) ethane (DPAE) were obtained from Ventron Corp., U.S.A. Triphenylarsine was from Maybridge Chemical Co., U.K. The arsine ligands, methyldiphenylarsine and dimethylphenylarsine were prepared by reacting the respective methyliodoarsines with methylmagnesium bromide in dry ether. Methyliodoarsine and dimethyliodoarsine were prepared by standard methods.[13] The reaction products were purified by vacuum distillation. Hydrated ruthenium trichloride (RuCl$_3$·3H$_2$O) was purchased from Alfa Ventron, U.S.A. and also from Johnson Matthey (England). The complexes RuCl$_2$(DMSO)$_4$[10,11] and RuCl$_2$(PPh$_3$)$_3$[1,2] were synthesized by published procedures. All organic solvents and acids used were BDH Analar grade.

The gases used in this work, carbon monoxide and nitric oxide were prepared and purified by standard procedures. Pure molecular hydrogen was obtained by electrolysis of a 20% solution of sodium hydroxide in a U-tube fitted with nickel electrodes and the gas dried by passing through a calcium chloride tower. Nitrogen gas obtained commercially was freed from oxygen and moisture by passing through vanadium(II) sulphate and alkaline pyrogallol solutions and finally through ascarite. Vanadium(II) sulphate solution was prepared by reduction of vanadyl(IV) sulphate solution by passing the solution through a column filled with zinc amalgam. All the complexes reported in this work were prepared under purified nitrogen atmosphere using the Schlenk tube technique.

The elemental analysis of the elements carbon, hydrogen and chlorine was performed by the Microanalytical service, CSIRO Australia and Chemalytics Inc., Tempe, Arizona, U.S.A., IR spectra were recorded on a Beckman IR-12 spec-

trophotometer. The NMR spectra were recorded on Varian A-60 and HA-100 spectrometers. The electronic spectra were measured in methanol-chloroform or dichloromethane solvents using Cary Model-14 and Carl Zeise DMR-2 spectrometers. Conductance data were obtained in dimethylacetamide (DMA) solution using a systronic conductance bridge and a cell which had been calibrated with 0.1 M aqueous potassium chloride solution.

PREPARATIONS

(1) *Dichlorobis(dimethylsulphoxide)bis(triphenylarsine)ruthenium(II)*

A solution of 0.24 g (0.5 mmol) of RuCl$_2$(DMSO)$_4$ in 10 cm^3 of ethanol and 3 cm^3 of concentrated hydrochloric acid was refluxed for about 15 min. To the hot solution was added an ethanolic solution of triphenylarsine (0.612 g, 2 mmol) and refluxed for about 6 hr. The colour of the solution changed from orange to brown. The solution was evaporated to a small volume under reduced pressure and the orange brown complex was precipitated by dissolving in acetone and reprecipitating with ether. The same complex was also prepared by heating 0.24 g of RuCl$_2$(DMSO)$_4$ and excess of triphenyl arsine (1.530 g, 5 mmol) dissolved in a mixture of ethanol and hydrochloric acid (70 and 7 cm^3 respectively) in a sealed tube at 70°C for about 48 hr. At the end of the reaction period a green complex separated which was filtered and washed with methanol. The complex was recrystallised from dichloromethane and acetone.

(2) *Dichloro(dimethylsulphoxide)tris(diphenylmethylarsine)ruthenium(II)*

About 0.24 g (0.5 mmol) of RuCl$_2$(DMSO)$_4$ was dissolved in 10 cm^3 of ethanol and 3 cm^3 of concentrated hydrochloric acid was added and the solution refluxed for about 15 min. To the hot solution was added methyldiphenylarsine (0.9 gm, 3 mmol) in 20 cm^3 of ethanol and refluxed for about 6 hr. The colour of the solution changed from scarlet-red to brown. The solution was evaporated to a small volume and the chocolate brown complex was precipitated by the addition of petroleum ether and recrystallised from dichloromethane and ether.

(3) *Dichloro(dimethylsulphoxide)tris(dimethylphenylarsine)ruthenium(II)*

A solution of 0.24 g (0.5 mmol) of RuCl$_2$ (DMSO)$_4$ in 10 cm^3 of ethanol and 3 cm^3 of concentrated hydrochloric acid was refluxed for

about 15 min. To the hot solution was added a solution of dimethylphenylarsine (0.846 g, 3 mmol) and refluxed for about 6 hr. The solution was evaporated to a small volume and cooled to −25°C by keeping in dry ice. The orange complex was precipitated by the addition of petroleum ether (40–60 grade). The complex was recrystallised from dichloromethane and ether.

(4) Dichloro{dimethylsulphoxide}tris{triphenylstibine}ruthenium(II)

A mixture of $RuCl_2(DMSO)_4$ (0.24 g, 0.5 g, 0.5 mmol) and triphenylstibine (0.704 g, 2 mmol) in 30 cm³ of ethanol was refluxed for about 3 hr. The solution turned yellowish orange from brown. The pink powder separated was filtered and washed with methanol. The complex was re-crystallised either from alcohol or dichloromethane.

(5) Dichlorotris(methyldiphenylarsine)ruthenium-(II)

(6) Dichlorotris(dimethylphenylarsine)ruthenium-(II)

These complexes were prepared by the addition of 6 mmol of methyldiphenyl or dimethylphenylarsine to an alcoholic blue solution obtained by refluxing ruthenium trichloride (0.208 g, 1 mmol) with zinc amalgam for 30 min. Zinc was removed from the solution and 3–4 cm³ of hydrochloric acid added. The mixture was further refluxed in the presence of the appropriate ligand for 3–4 hr. For the methyldiphenylarsine complex, solvent was removed under vacuum and the brown complex precipitated by the addition of acetone and recrystallised from dichloromethane and ether. The dimethylphenyl arsine complex separated as yellow crystals was filtered, washed with acetone and methanol and recrystallised from alcohol.

(7) Dichlorotris(triphenylstibine)ruthenium(II)

Ruthenium trichloride (0.208 g, 1 mmol) was refluxed with zinc amalgam in alcohol for about 30 min. Zinc was removed and to the blue solution triphenylstibine (1.408 g, 4 mmol) in alcohol was added. The solution was refluxed for about $2\frac{1}{2}$ hr. A pink coloured solid separated which was filtered and washed with methanol. The complex was recrystallised from alcohol.

(8) Dichlorobis{1,2-bis(diphenylarsino)methane} ruthenium(II)

(9) Dichlorobis{1,2-bis(diphenylphosphino)methane}ruthenium(II)

To a solution of $RuCl_2(DMSO)_4$ (0.242 g, 0.5 mmol) in 10 cm³ of ethanol, was added a solution of the appropriate ligand (1 mmol) in 30 cm³ of ethanol. The mixture was refluxed for about 4 hr. Lemon yellow crystals in the case of $RuCl_2(DPPM)_2$ and orange crystals in case of $RuCl_2(DPAM)_2$ were filtered, washed with methanol and ether. The complexes were recrystallised from dichloromethane.

(10) Dichlorobis{1,2-bis(diphenylphosphino)ethane}ruthenium(II)

This complex was prepared by a method simpler than that of Chatt and Hayter.[8] 1,2 bis (diphenylphosphino)ethane (0.796 g, 2 mmol) in 20 cm³ of ethanol was added to a solution of $RuCl_2(DMSO)_4$ (0.242 g, 0.5 mmol) in 15 cm³ of ethanol and the solution refluxed for about 2 hr. The colour changed from dark orange to bright lemon-yellow. The lemon-yellow crystals separated were filtered and washed with methanol. The complex was recrystallised from dichloromethane.

(11) Dichlorobis{1,2-bis(diphenylarsino)ethane}-ruthenium(II)

This complex was earlier reported by Mague and Mitchener.[9] The complex was synthesized by a method simpler than earlier reported whereby the refluxing time was reduced and a good yield was obtained. The complex $RuCl_2(DMSO)_4$, (0.484 g, 1 mmol) was dissolved in 10 cm³ of ethanol and 1,2 bis(diphenylarsino)ethane (0.480 g, 1 mmol) in 30 cm³ of ethanol were refluxed for about 2 hr. Orange yellow crystals separated, which were filtered and washed with methanol. The complex was recrystallised from dichloromethane.

(12) Dichloro-dicarbonyl(dimethylsulphoxide)(triphenylarsine)ruthenium(II).

(13) Dichloro-dicarbonyl-bis(methyldiphenylarsine)ruthenium(II).

(14) Dichloro-dicarbonyl-bis(dimethylphenylarsine)ruthenium(II).

(15) Dichloro-dicarbonyl-bis(triphenylstibine)ruthenium(II).

(16) Dichloro-carbonyl-tris(triphenylstibine)ruthenium(II).

(17) Dichloro-dicarbonyl-bis{1,2-bis(diphenylarsino)methane}ruthenium(II).

(18) Dichloro-dicarbonyl-bis{1,2-bis(diphenylphosphino)methane}ruthenium(II)

(19) *Chloro-carbonyl-bis{1,2-bis(diphenylphos-Phino)ethane}ruthenium(II)chloride.*

(20) *Chloro-carbonyl-bis{1,2-bis(diphenylarsino)-ethane}ruthenium(II).*

In a general method of preparation of the carbonyls, about 0.02 mmol of the complex (1–4), (8–11) was dissolved in dry chloroform and a stream of carbon monoxide was passed through the solution until there was no further colour change. The solutions were concentrated to a small volume and the carbonyls (12–20) precipitated by the addition of petroleum ether, filtered and dried.

(21) *Hydrido-chloro-bis(dimethylsulphoxide)bis-(triphenylarsine)ruthenium(II).*

(22) *Hydrido-chloro-(dimethylsulphoxide)tris(methyldiphenylarsine)ruthenium(II).*

(23) *Hydrido-chloro-(dimethylsulphoxide)tris(dimethylphenylarsine)ruthenium(II).*

(24) *Hydrido-chloro-tris(methyldiphenylarsine)ruthenium(II).*

Molecular hydrogen was bubbled through a 0.02 m molar dimethylformamide solution of complexes (1)/(3), (5), for about 12 hr at 40°C. The dark brown hydrides were isolated by removing the solvent under vacuum and precipitation by petroleum ether.

(25) *Hydrido(dinitrogen)bis(dimethylsulphoxide)-bis(triphenylarsine)ruthenium(II)chloride*

(26) *Hydrido(dinitrogen)dimethylsulphoxide-tris-(methyldiphenylarsine)ruthenium(II)chloride.*

Molecular hydrogen was passed through a 0.02 m molar dimethylformamide solution of the complexes (1) and (2) and molecular nitrogen bubbled through the solution for about 24 hr. The mixed ligand hydrido-dinitrogen complexes were isoalted by removing the solvent under vacuum and addition of petroleum ether.

(27) *Dichloro-nitrosyl-(dimethylsulphoxide)bis(triphenylarsine)ruthenium(II).*

(28) *Dichloro-nitrosyl-(dimethylsulphoxide)bis(methyldiphenylarsine)ruthenium(II).*

(29) *Dichloro-nitrosyl-(dimethylsulphoxide)bis(dimethylphenylarsine)ruthenium(II).*

(30) *Dichloro-nitrosyl-(dimethylsulphoxide)bis(triphenylstibene)ruthenium(II).*

(31) *Dichloro-nitrosyl-tris(methyldiphenylarsine)-ruthenium(II).*

(32) *Dichloro-nitrosyl-bis(diphenylphosphinomethane)ruthenium(II).*

(33) *Dichloro-nitrosyl-bis(diphenylarsinoethane)-ruthenium(II).*

Nitric oxide was passed through a 0.02 mmol chloroform solution of complexes (1–5), (9) and (11) for about 24 hr until there was no further colour change. The solutions were concentrated to a small volume and the nitrosyls precipitated by the addition of petroleum ether.

RESULTS AND DISCUSSION

Tables 1 and 2 present the analytical data and the molar conductivities of the ruthenium(II) complexes with mono and bidentate tertiary arsines and phosphines. IR spectra of these complexes are given in Table 3. The NMR and electronic spectra of some of the complexes are given in Tables 4 and 5 respectively.

A brown complex (1) was obtained by the displacement of two molecules of coordinated DMSO by $AsPh_3$ from $RuCl_2(DMSO)_4$. X-Ray structure of the parent complex $RuCl_2(DMSO)_4$ had indicated two different types of coordination of DMSO groups; three DMSO groups are bonded through sulphur and one through oxygen to the metal ion[14] with *cis*-chlorides. When $RuCl_2(DMSO)_4$ reacts with triphenylarsine the weakly O-bonded DMSO group gets displaced first followed by one of the S-bonded DMSO groups to give the complex $RuCl_2(DMSO)_4(AsPh_3)_2$ with *cis*-chlorides. The νM-Cl is expected to give two bands. Although a sharp peak is obtained at $320\,cm^{-1}$ the other band must have been masked by the DMSO peak. The band at $1075\,cm^{-1}$ indicative of S-bonded DMSO was observed but no band appeared around $900\,cm^{-1}$ which could be attributed to O-bonded DMSO.[15] The metal–arsine and metal–sulphur absorptions overlap in the complex and the peak at $480\,cm^{-1}$ could not be assigned unequivocally to any of these vibrations. The complex is assigned a C_h geometry as shown in Fig. 1.

A green modification of complex (1) was obtained when $RuCl_2(DMSO)_4$ and triphenylarsine were refluxed in a sealed tube. The preparation in the sealed tube was attempted with an idea to completely displace dimethylsulphoxide by triphenylarsine in $RuCl_2(DMSO)_4$ complex. The green complex shows an IR spectrum identical to that of the brown complex.

Two geometrical isomers are possible for the complex $RuCl_2(DMSO)_2(AsPh_3)_2$, one with *cis* dispositions of DMSO, triphenylarsine and *cis* chlorides (Fig. 1) and the other with *cis* dispositions of DMSO, the chloride and *trans* disposition of triphenylarsine (Fig. 2).

Fig. 1.
Fig. 2.

The brown isomer will have a C_h symmetry while the green isomer will have a C_{2v} symmetry. The two isomers cannot be distinguished on the basis of IR spectra which indicate cis-chlorides in both the complexes. Dipole moment measurements gave almost identical values within experimental error of 1.18 Debye for the brown and 1.3 Debye for the green isomers, respectively. This is expected because both the compounds have cis-chlorides, and a cis or trans disposition of other less polar groups cannot make a significant difference in dipole moments. However, these two isomers were characterized on the basis of their NMR spectra. The NMR spectrum of the brown complex with non-equivalent sets of ligands exhibited two multiplets of equal intensity at 2.15τ and 2.65τ which may be assigned to the phenyl protons of cis-triphenylarsines. The methyl protons of cis-DMSO groups also appeared as two multiplets at 6.65τ and 7.75τ. The NMR spectrum of the brown compound thus supports a C_h symmetry for the complex.

In the NMR spectrum of the green isomer of (1) the phenyl protons of triphenylarsine exhibit a

single multiplet at 3.6τ and methyl protons of DMSO a multiplet at 8.8τ. This is in accord with a trans-deposition of the triphenylarsine and cis disposition of DMSO and chloride groups in the compound with a point group C_{2v}.

The electronic spectrum of the brown isomer of (1) gives charge transfer bands characteristic of the presence of both DMSO[16] and triphenylarsine[17a,b] in the coordination sphere of the metal ion. The electronic spectrum of DMSO gives absorption bands at 200 and 210 nm that can be assigned to the $\sigma - \sigma^*$ and $n - \pi^*$ transitions of the ligand,

respectively. The $n - \pi^*$ transition undergoes a red shift in the sulphur coordinated complex and is exhibited at 230 nm ($\epsilon 2.8 \times 10^4$) in the brown complex. The electronic spectrum of triphenylarsine shows absorption bands at 215 and 248 nm assigned to $\sigma - \sigma^*$ and $n - \pi^*$ transitions.

These bands are considerably red-shifted in the coordinated arsine at 250 and 270 nm, respectively with an increase in intensity. The absorption band at 290 nm in (1) appears to be a metal ligand (DMSO) charge transfer band. The transitions at 410 and 520 nm can be assigned to $d - d$ transi-

*C.T. = charge transfer bands.

tions in the complex corresponding to $1A_1 \to 1T_2$ and $1A_1 \to 1T_1$, respectively. The 10 Dq value calculated from these transitions comes to 20,518 cm⁻¹.

Carbonylation of complex (1) (brown isomer) resulted in the formation of the cis-dicarbonyl complex (13) by the displacement of a coordinated DMSO and triphenylarsine groups. The displacement is expected on the basis of the high trans-effect of DMSO and the arsine groups. The formation of the cis-dicarbonyl is indicated by the appearance of strong peak at 2010 cm⁻¹ accompanied by a peak of medium intensity at 1985 cm⁻¹ corresponding to the carbonyls trans to arsine and DMSO groups, respectively.

Hydrogenation of (1) (brown isomer) resulted in the formation of hydride (23) which exhibited a strong M–H peak around 1960 cm⁻¹. The hydride

is formed by the displacement of a coordinated chloride by hydride. The IR absorption bands corresponding to DMSO and triphenylarsine in complex (1) remain intact in the hydrido complex. On passing molecular nitrogen through the solution of the hydrido complex a hydrido-dinitrogen complex (26) is formed, as indicated by the total disappearance of metal-halogen band and the appearance of the characteristic dinitrogen peak around 2150 cm⁻¹; the hydrido peak was observed at 1940 cm⁻¹ in the complex. The hydrido and dinitrogen stretching frequency in this complex are similar to those observed in the complex $RuH_2(N_2)(PPh_3)_3$.[18]

Treatment of complex (1) with nitric oxide resulted in the formation of $RuCl_2(NO)(DMSO)$ (AsPh₃)₂ which showed a strong absorption band

characteristic of coordinated nitrosyl at 1850 cm^{-1}. The NO frequency in this complex could be compared to other ruthenium nitrosyl complexes where NO may be considered to be coordinated as NO^{+}[19].

Six coordinate complexes of the type RuCl$_2$-(DMSO)L$_3$, (L=AsMePh$_2$, AsMe$_2$Ph, SbPh$_3$)

Complexes (2–4) were obtained by the displacement of one weakly O-bonded and two S-bonded dimethylsulphoxide groups from RuCl$_2$(DMSO)$_4$ by the tertiary arsine or stibine. The remaining DMSO group is S-bonded in these complexes as confirmed by the presence of a strong band in the IR spectra of the complexes around 1075 cm^{-1} and the absence of bands around 900 cm^{-1} which could be assigned to O-bonded DMSO group. Since tertiary arsine and DMSO absorb in the region 400–500 cm^{-1}, the band at 480 cm^{-1} could not be assigned to either of these alone. The νM–Cl frequency in complexes (2–4) appear as a single peak at 324, 330 and 275 cm^{-1}, respectively, indicating a *trans* geometry of the coordinated chlorides. The complexes have very low dipole moments (0.77 and 1.15 Debye units for complexes 2 and 3, respectively) and are non-conducting in DMA (Table 1).

In complex (2) the phenyl protons of methyldiphenyl arsine merge and appear as a broad multiplet centered at 2.8τ. The methyl protons appear as two multiplets of 1:2 intensity at 8.3τ and 8.75τ, respectively and can be assigned to *meridional* arsines. The methyl protons of DMSO appeared at a lower field than the methyl protons of arsine (between 4.2τ and 6.5τ). The multiplets of methyl protons may be explained on the basis of a long range spin interaction of the methyl protons of DMSO with the methyl protons of arsine and vice versa.

The NMR spectrum of complex (3) is very well resolved as far as methyl protons are concerned, the phenyl protons again merge to give a broad multiplet centred at 2.55τ. The methyl protons of the *meridionally* disposed dimethylphenylarsine ligand are observed as two multiplets of 1:2 intensity at 8.13τ and 8.57τ. The methyl protons of DMSO are exhibited as multiplets centred at 6.69τ. The integration of NMR spectra are consistent with the proposed formulations.

The phenyl protons of triphenylstibine are well resolved (Table 3) in the NMR spectrum of complex (4) and appear as two multiplets at 1.75τ and 2.76τ in the ratio of 1:2. The methyl protons of DMSO appear at 6.5τ. The probable structure for

L = Asmeph$_2$, Asme$_2$ph, Sbph$_3$
Fig. 3.

these complexes is given in Fig. 3. The complexes have *meridional* disposition of arsine or stibine ligands with *trans* chlorides and conform to C$_{2v}$ symmetry.

The electronic spectra of complexes (2) and (4) (Table 4) show ligand-to-metal charge transfer bands due to DMSO and methyldiphenyl arsine or triphenylstibine. The absorption bands appear around the same region as in complex (1). Thus absorption at 230 nm could be assigned to ligand–metal charge-transfer in DMSO and bands at 246, 264 nm and 250, 272 nm in complexes (2) and (4) respectively may be assigned to ligand–metal charge-transfer in the arsine and stibine ligand, respectively. The absorption bands at 302 nm may be due to metal–ligand (DMSO) charge-transfer bands. The transitions around 400 and 500 nm can be assigned to d–d transition in the complex corresponding to 1A$_1$→1T$_2$ and 1A$_1$→1T$_1$ transitions, respectively. The 10 Dq value of complexes (2) and (4) calculated from these transitions are 21,067 and 20,861 cm^{-1}, respectively.

Cis-dicarbonyls (13–15) were obtained from complexes (2–4) by the displacement of DMSO and one of the arsine or stibine groups. The dicarbonyls were confirmed by the appearance of peaks around 2010 cm^{-1} and 2200 cm^{-1}, 1950 and 2010 cm^{-1}, 1980 cm^{-1} and 2040 cm^{-1} respectively in complexes (13–15).

Reaction of complexes (2) and (3) with molecular hydrogen yielded hydrido complexes (22) and (23) by the displacement of a coordinated chloride by a hydride. The hydrides Ru(H)Cl(DMSO)(AsMePh$_2$)$_3$ and Ru(H)Cl(DMSO)(AsMe$_2$Ph)$_3$ show strong absorption peaks around 1960 and 1920 cm^{-1} respectively. No hydride was obtained with complex (4) in accord with a much lower acidity of stibine as compared to arsine ligands. Treatment with nitrogen, of the hydrido complex (22) resulted in the formation of the hydrido-dinitrogen complex (26). The characteristic dinitrogen peak appeared at 2150 cm^{-1} and the hydrido

peak at 1960 cm^{-1}. The other hydrides failed to react with molecular nitrogen.

When nitric oxide was passed through complexes (2)–(4), nitrosyl complexes (28)–(30) were obtained. The NO stretching frequency appeared at 1810 and 1850 cm^{-1} respectively in complexes (28)–(30). Nitric oxide with high *trans*-effect prefers to be in a *trans* position to a ligand with a low *trans*-effect. Hence it could not occupy a position *trans* to DMSO. A position *trans* to tertiary arsine or stibine looks more feasible for the ligand which may be considered to be coordinated as NO$^+$ in these complexes.

Five coordinate complexes of the type RuCl$_2$L$_3$
(L = AsMePh$_2$, AsMe$_2$Ph *or* SbPh$_3$)

These three complexes (5)–(7) were obtained by the interaction of ruthenium blue solution with methyldiphenyl arsine, dimethylphenylarsine or triphenylstibene. Molecular weights of the these complexes in nitrobenzene indicated them to be monomers. The presence of two bands in νM–Cl region at 270, 330 cm^{-1} in complex (5) 235 and 315 cm^{-1} in complex (6) and 260 and 275 cm^{-1} in complex (7) (Table 3), shows two *cis* chlorides in these complexes. There are many bands in the region 425–490 cm^{-1} assigned to νM-L vibrations (L = As or Sb). The complexes are diamagnetic. Two structures may be considered for these complexes; a square pyramid with *cis* chlorides and two mutually *trans* and a *cis* arsine (Fig. 4a) and a trigonal bipyramid with two axial and one equatorial arsine (Fig. 4b). The two proposed structures cannot be distinguished on the basis of NMR since arsines have the same environment in both the structures. For both the structures one should observe in the NMR spectra two singlets of 1:2 intensity due to methyl protons of two arsine groups. Because of *cis* interactions with equatorial arsines, two multiplets of 1:2 intensity are observed at 8.3τ and 8.65τ in complex (5) and 8.75τ and 8.97τ in complex (6), respectively. Likewise, phenylprotons also appear as two multiplets at

2.5τ and 2.9τ and 3.9τ and 3.97τ, respectively. In a similar manner the NMR spectrum of complex (7) shows multiplets in a 1:2 ratio at 3.7τ and 4.1τ.

A square pyramidal arrangement of ligands with two *cis* chlorides and a *meridional* arrangement of ligands however seems to be a much better arrangement from a steric view point than the trigonal bipyramidal arrangement. Based on a square pyramidal arrangement of the ligands three spin-allowed transitions are possible, 1A$_1$→1A$_2$, 1A$_1$→1B$_2$, 1A$_1$→1E$_1$, the first transitions 1A$_1$→1A$_2$ should give the 10 Dq value approximately and it is 14,000 cm^{-1} in complex (5).

The electronic spectrum of complex (7) shows three d–d transitions at 770, 540, 434 nm which can be assigned to the transitions 1A$_1$→1A$_2$, 1A$_1$→1B$_2$ and 1A$_1$→1E$_1$ in a square pyramidal configuration as in complexes (5) and (6). The bands at 263, 298 and 303 nm are charge-transfer bands as in complexes (5) and (6). Based on the lowest energy transitions 1A$_1$→1A$_2$ the 10 Dq value in this complex is 12,987 cm^{-1}. Complex (7) reacted with carbon monoxide to yield a monocarbonyl (16) which exhibits a single strong band at 1950 cm^{-1}.

Complex (5) reacted with molecular hydrogen to yield a hydrido complex (24). As in the other hydrido complexes (21)–(24) complex (24) is formed by the displacement of a chloride from complex (5). The hydride exhibits a strong peak at 1920 cm^{-1}. Complexes (6) and (7) failed to react with molecular hydrogen.

Reaction of complex (5) with nitric oxide yielded the nitrosyl complex (31) which showed a strong band around 1910 cm^{-1} corresponding to a coordinated NO$^+$ in this complex.

Cis-RuCl$_2$(DPAM)$_2$

The complex was obtained from RuCl$_2$(DMSO)$_4$ by the displacement of all DMSO groups by the chelating agent. Mague and Mitchener[9] had prepared the complex *trans*-RuCl$_2$(DPAM)$_3$ by the interaction of hydrated ruthenium trichloride with excess of DPAM. In this complex, one of the

L=AsMePh$_2$, AsMe$_2$Ph, SbPh$_3$

(a)   (b)

Fig. 4.

DPAM was reported to be bidentate and the other two monodentate.[9] The complex reported in this work was thus obtained from a different route and is different in composition and structure from that reported by Mague and Mitchener.[9] The absence of DMSO peaks in the IR spectrum is an evidence of complete displacement of DMSO from RuCl$_2$(DMSO)$_4$. Thus the ligand DPAM seems to act as a bidentate ligand. The peaks at 330 and 485 cm^{-1} may be assigned to νM–As vibrations of the coordinated diarsine. The complexes with chelated DPAE or DPAM lack a centre of symmetry in the molecule and diarsine groups are coordinated as cis or trans and more than one νM–As stretching frequency are observed. The cis or trans geometry in these complexes is based mostly on the observed νM–Cl stretching frequency. The bands at 230 and 270 cm^{-1} in complex (8) may be associated with the M–Cl vibrations of the cis chlorides in the complex. The M–Cl frequencies are lower than complexes with trans-halogen since in this case the chlorides are trans to arsenic. A cis disposition of the two arsines in the complex is confirmed by the NMR spectrum which shows methylene protons as a doublet at 5.06τ. The doublet arises due to two non-equivalent methylene protons of a chelated diarsine group. The position of methylene resonance at 8.7τ is in accord with the bidentate coordination of DPAM. In the complex RuCl$_2$(DPAM)$_3$ the peaks due to the methylene protons of bidentate diarsine molecule were observed[9] at 5.17τ and those due to monodentate diarsine at 7.28τ. The arrangement of a chelated diarsine is thus in accord with the earlier observations.[9] There are two groups of phenyl protons one due to two mutually trans diarsine and another one due to two mutually cis diarsine groups. These two groups give rise to a complicated A$_2$B$_2$ pattern where many of the peaks overlap and appear as a broad multiplet centred at 3.5τ and many peaks in the 3.95–4.43τ region. Integration of phenyl and methylene protons however is in agreement with the proposed formulation of the complex. The probable structure for the complex is given in Fig. 5.
The electronic spectrum of RuCl$_2$(DPAM)$_2$ show ligand–metal charge-transfer bands at 245 and 270 nm (Table 5). The d–d transition in the complex was observed at 460 nm which can be assigned to the $1A_1 \rightarrow 1T_2$ transition.

Carbonylation of the complex yielded a dicarbonyl RuCl$_2$(CO)$_2$(DPAM)$_2$ (17). The IR spectrum of the dicarbonyl shows strong bands at 1935 and 2000 cm^{-1} associated with cis dicarbonyls. The dicarbonyls may be considered to have formed by

Fig. 5.

the opening of the DPAM chelate ring resulting in two molecules of DPAM acting as monodentate ligand. Mague and Mitchener[9] have prepared the compound RuCl$_2$(CO)$_2$(DPAM)$_2$ by the interaction of RuCl$_2$(DPAM)$_3$ with carbon monoxide. The configuration of the compound was proposed to be a mixture of (a) and (b) in Fig. 6.

The compound RuCl$_2$(CO)$_2$(L)$_2$ obtained in this investigation from cis-RuCl$_2$(DPAM)$_2$ is expected to have configuration 6(b) since carbonylation is expected to open the bidentate chelate rings of DPAM without any rearrangement of the halogens

(a)

(b)

L = DPAM

Fig. 6.

which is necessary in forming 6(a). The carbonyl frequencies of 2000 and 1930 cm^{-1} are in accord with a *cis* disposition of carbonyl groups to halogens.

Cis-RuCl$_2$(DPPM)$_2$

This complex is also prepared from RuCl$_2$(DMSO)$_4$ and diphos as other bidentate diphosphine or diarsine complexes. A complex of similar composition trans RuCl$_2$(DPPM)$_2$ was earlier reported by Chatt and Hayter[8] and later by Mague and Mitchener.[9] The former workers[8] prepared the complex directly from hydrated ruthenium trichloride and DPPM and the latter from red ruthenium carbonyl solution and DPPM. In this complex, the ligand is coordinated as a bidentate group. The procedure employed in this work for the preparation of RuCl$_2$(DPPM)$_2$ is more convenient than the earlier methods and gives the *cis* compound in a higher yield than the *trans* compound. As in the case of interaction of other chelated ligands with RuCl$_2$(DMSO)$_4$ interaction of DPPM with RuCl$_2$(DMSO)$_4$ results in complete displacement of DMSO by chelated phosphine as indicated by absence of peaks corresponding to coordinated DMSO in the IR spectrum of the complex.

The peaks at 420, 510, 545 cm^{-1} were assigned to vM–P vibrations of coordinated disphosphines (Table 3). The bands at 230, 275 cm^{-1} were indicative of a *cis* geometry for the chlorides.

The NMR spectrum of complex 9 exhibits peaks of equal intensity for methylene protons at 5.8τ and 8.7τ. This could be assigned to a bidentate and a monodentate phosphine ligand. On the basis of two modes of coordination for the complex, there are two structures possible for the complex. One is square pyramid (Fig. 7a) with two mutually *cis* phosphorus, a *trans* phosphorus and two mutually *cis* chlorides and the other one is a trigonal bipyramid (Fig. 7b) type of structure in which two phosphorus atoms (of two ligands) and a chloride are equitorial and a phosphorus and chlorine in axial position. In both the cases, there are two non-equivalent methylene groups due to the two modes of coordination of the ligand and two peaks due to methylene protons are expected in the NMR spectrum. Phenyl protons appear as a broad multiplet centered at 3.96τ. As in the case of other five coordinate complexes (5)–(7), the NMR as well as the electronic spectra of the complexes cannot decide between the two possibilities. On steric grounds the square pyramidal arrangement (7a) seems to be a better possibility than the trigonal bipyramid (7b).

(a)

(b)

Fig. 7.

On carbonylation of (9), a *cis*-dicarbonyl of RuCl$_2$(DPPM)$_2$ is formed which shows strong bands at 1960 and 2000 cm^{-1}. As in the case of (8), the dicarbonyl formation may involve the rupture of a bidentate chelate ring and as such has two monodentate ligands in *trans* disposition as that of RuCl$_2$(CO)$_2$(DPAM)$_2$. The carbonylation of RuCl$_2$(DPPM)$_2$ can be expected to be more facile on the basis of a square pyramidal configuration rather than a trigonal bipyramid (Fig. 8a). In the former case one of the carbons monoxide molecules can add to the vacant coordination position on the metal ion and the other opens up the chelated DPPM groups to form RuCl$_2$(CO)$_2$(DPPM)$_2$. A trigonalbipyramidal structure requires rearrangement of various groups. Mague and Mitchener[9] have reported a cationic monocarbonyl species [RuCl(CO)(DPPM)$_2$]Cl by the interaction of *trans*-RuCl$_2$(DPPM)$_2$ with carbon monoxide (Fig. 8b). In this case the displacement of a chloride seems to be easier than rupture of a DPPM group to form the carbonylated complexes. The formation of a dicarbonyl or monocarbonyl thus seems to depend very much on the geometry of the starting material.

Complex (9) reacted with nitric oxide to yield a nitrosyl complex RuCl$_2$(NO)(DPPM)$_2$ (32). The formation of a nitrosyl complex is confirmed by the appearance of a single band around 1825 cm^{-1}. A nitrosyl group gets added to the vacant coordi-
Fig. 8.

nation position on the metal ion to give a six coordinated species.

RuCl$_2$(DPPE)$_2$ and RuCl$_2$(DPAE)$_2$

These two complexes were prepared by the reaction of RuCl$_2$(DMSO)$_4$ with chelated phosphine or arsine. The complex RuCl$_2$(DPPE)$_2$ was previously obtained by Chatt and Hayter[8] by the direct reaction of hydrated ruthenium trichloride in ethanol with DPPE and the complex RuCl$_2$(DPAE)$_2$ was synthesized by Mague and Mitchener[9] by the reaction of Ru(CO)$_n$Cl$_3$ with DPAE. The method adopted in this work is different and more convenient than those of previous investigations[8,9] and gave a higher yield of the complexes. All the four DMSO groups from RuCl$_2$(DMSO)$_4$ are replaced by the bidentate chelating ligands to form RuCl$_2$L$_2$ (L = DPPE or DPAE). This is confirmed by the absence of peaks due to coordinated DMSO in the IR spectra of these complexes. The bands in the region 400–500 cm^{-1} may be assigned to the coordinated phosphorus or arsenic. The *trans* configuration of the complexes is confirmed by a single νM–Cl peak at 320 cm^{-1} in both the complexes.

The *trans* geometry of the chloride groups allow only *trans* disposition of the bidentate ligand. This fact is confirmed by the NMR spectra of the two complexes. The NMR spectrum of the complex RuCl$_2$(DPPE)$_2$ shows a multiplet at 4.1τ due to the

phenyl protons of the phosphine. The peaks due to the methylene protons are observed as multiplets at 7.26τ and 8.47τ in a ratio of 1:2. The methylene protons in the chelated ligand do not seem to be equivalent because in the five membered chelate ring methylene protons are expected to be above and below the plane containing the metal ion and the two phosphorus atoms. The configuration of the protons seems to be fixed in the ring since a flip-flop mechanism would give rise to a single methylene peak. The methylene triplet is expected because of the spin coupling of the protons by ^{31}P. In the NMR spectrum of the free ligand, the methylene protons are observed as one triplet at 8.07τ. This triplet arises due to splitting of equivalent methylene proton peak by the two phosphorus atoms. The NMR spectrum of complex RuCl$_2$(DPAE) shows a similar pattern to RuCl$_2$(DPPE). The only difference is that the methylene protons appear as two singlets since there is no splitting by arsenic. In the free ligand also there is a singlet due to equivalent methylene protons. The phenyl protons merge together and appear as a broad multiplet centered at 4.1τ in the complex. The integration of the phenyl and methylene protons in the two complexes is consistent with the proposed structures for these complexes (Fig. 9).

The electronic spectrum of RuCl$_2$(DPPE)$_2$ gave the ligand–metal charge-transfer bands at 240 and
E = As or P

Fig. 9.

250 nm (Table 5). The d–d transitions in the complex are observed at 372 and 440 nm which can be assigned to $1A_1 \rightarrow 1T_2$ and $1A_1 \rightarrow 1T_1$ transitions, respectively. The 10 Dq value calculated for the complex is 23,770 cm^{-1}. The electronic spectrum of RuCl$_2$(DPAE)$_2$ gave ligand–metal charge-transfer bands at 245 and 260 nm. These charge-transfer bands can be compared to the monoarsine (Table 5) complexes that give bands around 240–250 and 260–270 nm. These bands may be assigned in a manner similar to other spin paired octahedral complexes as (10). The 10 Dq value calculated for the complex is about 23,935 cm^{-1}. On comparing the 10 Dq value calculated for the chelating phosphine and arsine complexes to those of non-chelating arsine and DMSO complexes, it may readily be seen that chelation gives a much higher 10 Dq values (about 400 cm^{-1} more than non-chelated compounds). This indicates extra stability and much higher ligand field strength of the chelated ligands as compared to the monodentate ligands.

Carbonylation of complexes (10) and (11) yielded the monocarbonyls (19) and (20), respectively. These carbonyls can be considered to be cationic species obtained by the displacement of a coordinated chloride from the coordination sphere of the metal ion. The monocarbonyls (19) and (20) exhibit single sharp peaks at 1950 and 1925 cm^{-1}, respectively. The complexes are cationic as indicated by their conductivities in DMA (1:1 electrolyte). Displacement of carbon monoxide from Ru(CO)$_2$Cl$_n$ by DPAE gives rise to RuCl$_2$(DPAE)$_2$.[9] The coordination of DPAE or DPPE to the metal ion seems to be stronger than carbon monoxide since the chelating ligands can displace carbon monoxide from the coordination sphere of the metal ion. In the case of complexes (10) and (11) however a coordinated chloride is displaced in the presence of excess of carbon monoxide from the coordination sphere of the

metal ion to form cationic monocarbonyl species. These cationic carbonyl complexes are prepared for the first time and their formation seems to be a general phenomenon in the reactions of chelated phosphine or arsine complexes with carbon monoxide.

Complex RuCl$_2$(DPAE)$_2$ reacted with nitric oxide yielding a nitrosyl complex RuCl$_2$(NO)(DPAE)$_2$ (33). The nitrosyl group shows a band at 1825 cm^{-1} in the complex. The nitrosyl formation may involve the rupture of a bidentate chelate ring and as such may have bidentate and monodentate DPAE ligand and a seven coordinate geometry for ruthenium.

Abstract—Palladium(II) halide complexes with N-ethylimidazole (N–EtIm) and N-propylimidazole (N–PropIm) with general formulae $Pd(L)_2X_2$ and $Pd(L)_4X_2$ (X = Cl, Br, I) were prepared and characterized by spectroscopic methods and conductivity measurements. These complexes are diamagnetic and have square planar stereochemistry. The $Pd(L_2)X_2$ derivatives, are non-conductors, and have *trans*-structures except for the *cis*-$Pd(N–EtIm)_2Br_2$. The biological activity of water soluble Pd(II) compounds is also reported.

Imidazole is a heterocyclic penta-atomic ring isomer of pyrazole, with an aromatic character; the tautomeric nature of the imidazole is missing when the hydrogen of the imine atom is substituted with an alkyl group. The N-alkylimidazoles are basic substances which form salts with acids.

Imidazole is used as an analgesic, antipyretic and antiflammatory agent.[1] In previous papers we have characterized N-ethylimidazole and N-propyl-imidazole complexes with copper(II), nickel(II), cobalt(II)[2] and successively with zinc, cadmium and mercury(II) salts.[3]

Recently Reedijk *et al.* have prepared Pd(II) and Pt(II) complexes with imidazole and N-methylimidazole.[4]

The present paper reports the preparation and characterization of the complexes of general formula $Pd(L)_nX_2$ where L = N-ethylimidazole

(N–EtIm), N-propylimidazole (N–propIm) $n = 2$, 4; X = Cl, Br and I.

The aim of this work is to control different stoichiometrical formulas, to establish the stereochemistry of the isolated compounds and to evaluate their biological activity.

RESULTS AND DISCUSSION

The isolated metal complexes with analytical data and other physical properties are listed in Table 1, the far IR data in Table 2, the summarized electronic spectra are shown in Table 3 and the biological data are reported in Table 4.

The compounds, obtained by refluxing or by mixing from water the metal salt and the ligand, are of the $[Pd(L)_4]X_2$, and $Pd(L)_2X_2$ types. The $Pd(L)_2X_2$ non-conducting derivatives are insoluble in water, while the $[Pd(L)_4]X_2$ are generally soluble in water.

All the complexes are crystalline, diamagnetic, soluble in MeOH, DMF, $EtNO_2$ and MeCN.

	L = N–PropIm; X = Cl, Br, I		

N–PropIm in the near and mid IR spectra appear noticeably unchanged on passing from the spectra of the free ligands to those of the complexes.

Table 4. Inhibitory activity of the palladium(II) complexes

Complex	Inhibitory activity % (±2) 10^{-4}M
Pd(N–PropIm)$_2$Cl$_2$	41
[Pd(N–EtIm)$_4$]Br$_2$	16
[Pd(N–EtIm)$_4$]I$_2$	15
[Pd(N–PropIm)$_4$]Cl$_2$	20
[Pd(N–PropIm)$_4$]Br$_2$	32
[Pd(N–PropIm)$_4$]I$_2$	35

The medium absorption bands within the 3430–3400 cm^{-1}, v(OH) and 1670–1625 cm^{-1}, δ(HOH), ranges are present in [Pd(N–EtIm)$_4$]Cl$_2$·2H$_2$O.

The complex loses all the water at 110°C before its decomposition. From a detailed analysis of the IR spectrum, we have found that the rocking, twisting and wagging modes ascribable to coordinated water are absent, according to the literature data.[5]

The Pd(N–EtIm)$_2$Cl$_2$ and Pd(N–PropIm)$_2$Cl$_2$, non-conductors, in the far IR spectrum show respectively two bands at 334 and 326 cm^{-1} and a broad band in the 343–336 cm^{-1} assigned to v (Pd–Cl) terminal for cis-square planar compounds in C$_{2v}$ stereochemistry.[6,7]

In the far IR region the spectrum of the Pd(N–PropIm)$_2$Br$_2$ derivative shows a band whose position of the metal halogen stretching is diagnostic of terminal halides for trans-square planar compounds in D$_{2h}$ stereochemistry.[8]

The reflectance spectra of the $Pd(L)_2X_2$ compounds confirm the square planar geometry.[9] The band $v_1 = {}^1A_{1g} \rightarrow {}^1B_{1g}$ falls in the 26,450–25,000 cm^{-1} range and $\Delta_1 = v_1 + 3.5\,F_2$ in the 28,750–25,900 cm^{-1} range.[10]

The palladium(II) derivatives $[Pd(L)_4]X_2$ decompose in MeCN or EtNO$_2$, probably for rearrangement of the complexes. In the far IR spectra of these complexes the bands in the expected range for the $v(M-X)$ stretching vibrations are absent, so that the two halogens are outside the coordination sphere. The $[Pd(L)_4]X_2$ complexes, according to the electronic spectra (Table 3), are square planar.

The band in the 28,600–26,000 cm^{-1} range may be assumed to the $v_1 = {}^1A_{1g} \rightarrow {}^1B_{1g}$ transition and increases in the expected order: $Pd(L_2)X_2 < [Pd(L)_4]X_2$.

By assuming a value of $F_2 = 10\,F_4 = 600$ cm^{-1} for the Slater–Condon interelectronic repulsion parameters for these palladium(II) complexes,[8] it is possible to derive from the first spin allowed $d-d$ transition the values of Δ_1 by $\Delta_1 = v_1 + 3.5\,F_2$. The splitting parameter is in the 30,700–28,100 cm^{-1} range.

BIOLOGICAL ACTIVITY

In a previous paper[11] we have studied the inhibitory activity of the $M(L)_2X_2$ complexes (M = Pd(II), Pt(II); L = isox and its methyl and/or phenyl derivatives; X = Cl, Br) on the membrane bonded to Ca, Mg dependent ATP-ase.

The Pd(II) complexes have a higher effect than the Pt(II) compounds and the chloride derivatives show greater inhibitory activity than the bromide compounds.

Successively we have extended this study to the $M(L)_2X_2$ (L = BO and MeBO, where BO = benzoxazole; X = Cl, Br).[12] Also in this case for the complexes soluble in water, C_2H_5OH and CHCl$_3$ the inhibitory effect is similar to the isoxazole derivatives.

Recently we have isolated the $Pd(ox)(L)_n$ complexes (ox = oxalate, $n = 2,1$; L = above cited heterocyclic ligands).[13]

In the monomeric $Pd(ox)(L)_2$ (L=N–MeIm, N–EtIm and N–PropIm) the inhibitorial effect decreases in the order N–PropIm > N–EtIm > N–MeIm for the major length of the ligand chain.

In the dimeric $Pd(ox)(L)$ (L = isox, 3,5-diMeisox, 2-MeBO and 2,5-diMeBO) this activity increases with the steric hyndrance of the heterocyclic ligand and is generally higher than the $Pd(ox)(L)_2$ derivatives.

In Table 4 are listed the results of the inhibitory activity of the Pd(II) complexes 10^{-4} M in saline aqueous solution (NaCl, MgCl$_2$) on the Ca, Mg-dependent ATP-ase.

The N–PropIm complexes have inhibitory effect higher than the N–EtIm derivatives. This fact can be explained by the length of the N–PropIm chain that renders soluble the complex in the lipidic part of the enzyme.

$Pd(N–PropIm)_2Cl_2$ has as activity almost double that of $[Pd(N–PropIm)_4]Cl_2$, because in the first case the coordinated chlorides are replaced by the water molecules and successively by the thiolic groups.

The $[Pd(L)_4]X_2$ have activity that increases in the sequence I > Br > Cl; in fact the counteranion reduces its size and then its interaction in the same way.

The inhibitory activity values of these complexes are smaller than the $M(L)_2X_2$ (L = isox and its derivatives) compounds[11] because the imidazole ligands derivatives have stronger bonds with respect to the coordinate halides in the isoxazole complexes.

As far as the inhibitory mechanism the irreversible interaction of the imidazole derivatives complexes occurs with the sulphur anion of the thiol group of the enzyme that replaces the ligands in the square planar compounds.

EXPERIMENTAL

The N-ethylimidazole and N-propylimidazole purum were purchased from the BASF Company.

Starting materials

Palladium(II) salts were commercially available or were prepared according to the literature methods.

Preparation of the complexes

The complexes were prepared as in Ref. 11 or from water.

Analyses

Carbon, hydrogen and nitrogen have been determined with a Perkin–Elmer 240 elemental analyser.

IR spectra

The IR spectra have been recorded in the 4000–200 cm^{-1} range with Perkin–Elmer 325 and 180 spectrophotometers. The spectra in the 4000–450 cm^{-1} range were obtained using KBr discs, or Nujol mull; the far IR spectra in the 450–200 cm^{-1} with CsI discs for all compounds except to the iodide derivatives (450–100 cm^{-1}).

Electronic spectra

The electronic spectra were recorded with a Shimadzu MPS-50L spectrophotometer in the solid state in the 40,000–15,000 cm^{-1} range.

Conductivity measurements

These measurements were carried out with WTW LBR conductivity bridge at 25°C for 10^{-3} M solutions in MeOH and $EtNO_2$.

Biological analyses

The extraction method of the sarcoplasmatic reticulum (SR) containing Ca, Mg dependent ATP-ase, the ferment activity and the SH groups determination by amperometric titrations were published elsewhere.[11]

THE PRODUCTION OF $Cr(NH_3)_6^{3+}$ FROM THE ACID CATALYSED HYDROLYSIS OF $Cr(NH_3)_5(NCO)^{2+}$

DAVID YANG and DONALD A. HOUSE*

Department of Chemistry, University of Canterbury, Christchurch, New Zealand

Abstract—The rate of the reaction

$$Cr(NH_3)_5(NCO)^{2+} + H_3O^+ \longrightarrow Cr(NH_3)_6^{3+} + CO_2 + \text{other Cr(III) products}$$

has been investigated at 40–65°C with $[HClO_4]$ varying from 0.04 to 0.6 M ($\mu = 0.6\,M$, $NaClO_4$). The observed rate law has the form: $-d[Cr(NH_3)_5(NCO)^{2+}]/dt = k_{obs}[Cr(NH_3)_5(NCO)^{2+}]$ where $k_{obs} = a[H^+]^2\{1 + b[H^+]^2\}^{-1}$ and at 55.0°C, $a = 0.36\,M^{-1}s^{-2}$ and $b = 6.9 \times 10^{-3}\,M^{-1}s^{-1}$. The rate of loss of $Cr(NH_3)_5(NCO)^{2+}$ increases with increasing acidity to a limiting value (at $[H^+] \sim 0.5\,M$) but the yield of $Cr(NH_3)_6^{3+}$ decreases with increasing $[H^+]$ and increases with increasing temperature. In the kinetic studies the maximum yield of $Cr(NH_3)_6^{3+}$ was 35% but a synthetic procedure has been developed to give a 60% yield.

The major acid hydrolysis product of $M(NH_3)_5(NCO)^{2+}$ is $M(NH_3)_6^{3+}$ and the kinetics of this reaction have been measured for M = Co(III)[1,2] Ru(III)[3] and Rh(III).[3] At low acid concentrations ($< 0.1\,M$) the rate law $-d[M]/dt = k[M][H^+]$ is observed,[1–3] but at higher acidities, some deviation from this is found.

Recently, the synthesis of $Cr(NH_3)_5(NCO)^{2+}$ has been described,[4] and this too, hydrolyses in acid to give $Cr(NH_3)_6^{3+}$.[4] In our hands, however, the yield of hexammine from the reaction of $[Cr(NH_3)_5(NCO)](NO_3)_2$ in $HClO_4$ or HNO_3 was never greater than 20%. In this paper we describe kinetic data for the loss of $Cr(NH_3)_5(NCO)^{2+}$ in acid media and present conditions to produce a reasonable yield (60%) of $Cr(NH_3)_6^{3+}$.

EXPERIMENTAL

$[Cr(NH_3)_5(NCO)](NO_3)_2$ was prepared as described by Schmidtke and Schönherr.[4] The bright orange crystalline nitrate salt had visible absorption and IR spectral parameters similar to those

described in the literature. Cr Calc, 17.2% Cr Found, 17.1%.

Kinetic studies and product analysis

Solutions (6.6 mM) of $Cr(NH_3)_5(NCO)^{2+}$ were prepared by dissolving 100 mg of the nitrate salt (F.W. = 303) in water (20 cm³) and adding appropriate volumes of $HClO_4$ and $NaClO_4$ solutions to give 50 cm³ $\mu = 0.6\,M$, $[H^+] = 0.04 - 0.6\,M$. The rate of complex decomposition was measured spectrophotometrically (1 cm cells) at constant temperature either by repetitive scans or fixed wavelength (490 nm) techniques. No isosbestic points were maintained in the spectral scan envelope (700–300 nm), but satisfactory "infinity" readings (7–8 half-lives) were obtained.

Pseudo-first-order rate constants were calculated from the expression

$$kt = \ln \frac{A_0 - A_\infty}{A_t - A_\infty}$$

where A_0, A_t and A_∞ are the absorbances (490 nm) at time zero, time, t, and at the end of the reaction (> 7 half lives).

At the end of the reaction, the sample used for

―――――――――――――――――
*Author to whom correspondence should be addressed.

spectrophotometric analysis was returned to the bulk flask (which had been maintained at the appropriate temperature for the duration of the spectrophotometric measurements) and the solution was stored at $-5°C$ for at least 24 hr. During this time, all the $Cr(NH_3)_6^{3+}$ present crystallised as the perchlorate salt and $10 cm^3$ aliquots of the now pink coloured solution were removed for total Cr analysis.[5] The difference between the $[Cr]_{initial}$ $(6.6 mM)$ and the $[Cr]$ in the mother liquor allowed an estimate of the amount of $Cr(NH_3)_6^{3+}$ produced. The $[Cr]$ in the mother liquor of a control containing 100 mg of $[Cr(NH_3)_6](ClO_4)_3$ dissolved $50 cm^3$ of 0.04 M $HClO_4$, 0.56 M $NaClO_4$ was too small to be of any significance $(<0.1 mM)$.
Synthesis of $[Cr(NH_3)_6](ClO_4)_3$

A solution of $NaClO_4·H_2O$ (45 g) in water $(500 cm^3)$ with $5.0 cm^3$ of 60% $HClO_4$ added was heated to 85°C. 3 g of $[Cr(NH_3)_5NCO](NO_3)_2$ were rapidly added to the stirred solution and the temperature was maintained for exactly 6.0 min before rapid cooling in ice. After 24 hr at $-5°C$ the yellow crystalline product (2.7 g, 60%) was removed from the faintly pink coloured mother liquor by filtration, and washed successively with 2-propanol and ether, and air dried. Calc for $[Cr(NH_3)_6](ClO_4)_3$: Cr, 11.5%. Found: Cr, 11.5%.

Synthesis of cis-$[CrCl(NH_3)_4(OH_2)]Cl_2$

$[Cr(NH_3)_5(NCO)](NO_3)_2$ (2 g) was dissolved in HCl (6 M, $30 cm^3$) and warmed (40°C) until pink crystals deposited (20 min). The solution was cooled to room temperature, and the filtered product (1.5 g, 93%) washed with isopropanol and then ether and air dried. Calc for $[CrCl(NH_3)_4(OH_2)]Cl_2$: Cr, 21.3%. Found: Cr, 21.4%.

RESULTS AND DISCUSSION

Tables 1 and 2 list values for the pseudo-first-order rate constants (k_{obs}) for the loss of $Cr(NH_3)_5(NCO)^{2+}$ in acid conditions at various temperatures, together with yields of $Cr(NH_3)_6^{3+}$. Figure 1 shows a plot of k_{obs} vs $[H^+]$ at various temperatures. The non-linearity and limiting values at high $[H^+]$ suggest that the $[H^+]$ dependence on the reaction rate is unique for H^+ catalysed decompositions of $M(NH_3)_5(NCO)^{2+}$ complexes.[1-3] Activation energy plots for $\ln(k_{obs})$ vs $T(K)^{-1}$ at any particular $[H^+]$ are linear and Table 3 presents the calculated kinetic parameters, with a systematic trend to lower activation energies (and more negative activation entropies) with increasing acidity. The data in Table 2 indicate the decomposition reaction is characterised by a positive salt effect and linear plots of k_{obs}^{-1} vs $[H^+]^{-2}$ (Fig. 2) give slope (k_{lim}^{-1}) and intercept $([k_{lim}K]^{-1})$ (Table 4) for the reaction scheme:[2,3]

$$Cr(NH_3)_5(NCO)^{2+} + 2H^+ + H_2O \overset{K}{\rightleftharpoons}$$

$$Cr(NH_3)_5(NH_2C(OH)_2)^{4+} \qquad (1)$$

$$Cr(NH_3)_5(NH_2C(OH)_2)^{4+} \xrightarrow{k_{lim}} products \qquad (2)$$

where

$$k_{obs} = k_{lim}K[H^+]^2\{1 + K[H^+]^2\}^{-1}. \qquad (3)$$

Values of K (eqn 1) increase with increasing temperature and the associated thermodynamic parameters are given in Table 4.

The yield of $Cr(NH_3)_6^{3+}$ (Tables 1 and 2) increases with increasing temperature, and decreasing $[H^+]$ and is independent of ionic strength.

a̲ See footnote b̲, Table 1.

Although the maximum yield of $Cr(NH_3)_6{}^{3+}$ under the reaction conditions used was only 35%, we have extrapolated these trends to develop a synthetic procedure where yields of 60% of the hexaammine can routinely be obtained from the easily prepared $[Cr(NH_3)_5(NCO)](NO_3)_2$.

Unfortunately we have been unable to characterise the other Cr(III) complexes formed. Absorption spectra of the resulting pink solutions (after precipitation of $Cr(NH_3)_6{}^{3+}$) indicate a complex mixture of $Cr(NH_3)_x(OH_2)_{6-x}^{3+}$ ($x \neq 5$) but the ratio of the products ($x = 1$–4) could not be determined. We can exclude $Cr(NH_3)_5(OH_2)^{3+}$ as a product on three accounts:

(a) The $ClO_4{}^-$ salt of this complex is reasonably insoluble, but no $[Cr(NH_3)_5(OH_2)](ClO_4)_3$ was detected.

(b) Treatment of the pink solution with concentrated HCl did not produce any of the very HCl insoluble $[Cr(NH_3)_5Cl]Cl_2$.

(c) The major product of the reaction between $Cr(NH_3)_5(NCO)^{2+}$ and $6\,M$ HCl is cis-$[CrCl(NH_3)_4(OH_2)]Cl_2$.

Table 5 lists the reported visible absorption spectral parameters for various $Cr(NH_3)_x(OH_2)_{6-x}^{3+}$ species, together with selected data for the red $Cr(NH_3)_x(OH_2)_{6-x}^{3+}$ complex mixtures produced in the reaction between $Cr(NH_3)_5NCO^{2+}$ and H^+. Inspection of these data suggest that di- and tri-ammines are the most likely products and that,

like the production of $Cr(NH_3)_6^{3+}$, the product ratio depends on both $[H^+]$ and temperature. In addition, Table 5 also lists rate constants for the thermal rupture of successive Cr–NH$_3$ bonds in HClO$_4$ media.[6,8-10] If di- and tri-ammines are indeed produced, it is obvious that their rate of formation from the parent pentaammine must be strongly catalysed with respect to thermal Cr–NH$_3$ bond rupture. It has been observed previously,[11,12] that weakly acidic leaving groups (e.g. NO$_2^-$) can catalyse Cr–NH$_3$ bond rupture in acidic media and it is possible that the CO$_2$ produced in the acid

decomposition of $Cr(NH_3)_5(NCO)^{2+}$ behaves in a similar fashion.

CONCLUSION

Comparison of the data obtained here with those obtained for other $M(NH_3)_5(NCO)^{2+}$ systems is difficult because of different rate laws, but at a constant $[H^+]$ the order of reactivity is $Rh^3 > Co^{1,2} > Ru^3 \gg Cr$.

In the case of Rh, Co and Ru, there is good evidence[2,3] for an intermediate N-bonded carbamate complex and the mechanism proposed here

(eqns 1 and 2) incorporates such a protonated species for the Cr(III) system. It is possible that the rapid loss of NH_3 could be attributed to chelation of the carbamate (*cf.* oxalate)[13] and this could account for the isolation of *cis*-[$CrCl(NH_3)_4$ (OH_2)]Cl_2. Indeed $Cr(NH_3)_4\left(\begin{array}{c}/NH_2\\ \backslash O\end{array}\right\rangle C{=}O\,\Big)^{2+}$ or $Cr(NH_3)_4\left(\begin{array}{c}/O\backslash\\ \backslash O\end{array}\right\rangle C{-}NH_2\Big)^{2+}$ could also be included as potential components of the unknown red reaction products.

HYDROLYSIS OF CYANO(PYRROLYL-1)BORATES

JÓZSEF EMRI* and BÉLA GYÖRI
Department of Inorganic and Analytical Chemistry, Lajos Kossuth University, H-4010
Debrecen, Hungary

Abstract—The kinetics and mechanism of the hydrolysis of several cyano(pyrrolyl-1)borates in aqueous medium has been investigated. The hydrolysis of cyanophenyl(pyrrolyl-1)-borates, cyano(tripyrrolyl-1)borate and cyanohydro(pyrrolyl-1)borates proceeds via two kinds of reactions; (a) a special H^+ ion catalyzed reaction (A-1 mechanism) and (b) a H^+ ion concentration–independent process of S_N1 mechanism. In acidic medium the $[BH_2(NC_4H_4)CN]^-$ anion is reversibly protonated at the α-carbon of the pyrrolyl group and a product with composition $C_4H_5N \cdot BH_2CN$, stable towards hydrolysis is also formed.

In the H^+ ion catalyzed reaction the B–N bond very likely breaks, whereas upon the $[H^+]$ ion concentration–independent reaction a B–CN cleavage occurs. The presence of the cyano substituent significantly increases the hydrolytic stability of the B–N bond, whereas the pyrrolyl-1-substitution remarkably decreases the stability of the B–CN bonding.

In previous papers we have described the kinetics and mechanism of the hydrolysis of phenyl(pyrrolyl-1)borates[1] and hydro(pyrrolyl-1)-borates.[2] In this paper we wish to report on the study of the hydrolysis of several cyano(pyrrolyl-1)borates ($[BH_n(NC_4H_4)_{3-n}CN]^-$ and $[B(C_6H_5)_n(NC_4H_4)_{3-n}CN]^-$, where $n = 0, 1, 2$).

The kinetics and mechanism of the hydrolysis of the borates is significantly changed and modified by the presence of the cyano group. For example, the rate-constant of the hydrolysis of $[BH_3CN]^-$ anion[3] is about 10^8-fold lower than that of the BH_4^- anion.[4] Concomitant to the hydrolysis in D_2O such a rapid B–H isotopic exchange reaction takes place in the case of $[BH_3CN]^-$ that the $[BD_3CN]^-$ salts[3] can be isolated with good yields, whereas H-exchange of low degree has been observed upon hydrolysis of BH_4^- anion.[5] In this paper the effect of the cyano substituent on the kinetics and mechanism of the hydrolysis of (pyrrolyl-1)borates is described.

EXPERIMENTAL

The preparation of the borates utilized, $Na[B(C_6H_5)_2(NC_4H_4)CN]$, $Na[B(C_6H_5)(NC_4H_4)_2CN]$, $Na[B(NC_4H_4)_3CN] \cdot 1.5 \ C_4H_8O_2$, $K[BH_2(NC_4H_4)CN] \cdot C_4H_8O_2$ and $Na[BH(NC_4H_4)_2CN] \cdot 3 \ C_4H_8O_2$ have been described previously.[6,7]

The buffers used have been prepared in the usual manner using analytical grade chemicals from Reanal and Merck. The ionic strengths of the buffers was adjusted to $0.1 \ \text{mole/dm}^3$ or $1.0 \ \text{mole/dm}^3$ with NaCl. The pH values of the buffers was determined with a Radiometer model PHM-4 pH-meter. In the case of $K[BH_2(NC_4H_4)CN]$ at $[H^+] > 0.01$ mole/dm^3 the pH value was calculated on the basis of the HCl concentration, while at $[H^+] < 0.01$ mole/dm^3 the pH was measured, and the pH of a solution containing $0.010 \ \text{mole/dm}^3$ of HCl was acknowledged 2.00.

Kinetic measurements

The rate of hydrolysis of the cyano(pyrrolyl-1)-borates was followed by spectrophotometric (a) and complexometric (b) methods. The measurements were carried out at 25°C (or at 17.5 and 35°C) using samples thermostated to ± 0.1°C.

---

*Author to whom correspondence should be addressed.

(a) The concentration of the cyano(pyrrolyl-1)-borates in the buffer solutions was $2 \times 10^{-4} - 4 \times 10^{-4}$ mole/dm^3. The light absorption of the samples was determined using a Beckman Acta M–IV spectrophotometer at 250 nm (Na[B(C$_6$H$_5$)$_2$(NC$_4$H$_4$)CN]), 240 nm (Na[B(C$_6$H$_5$)(NC$_4$H$_4$)$_2$CN], Na[BH(NC$_4$H$_4$)$_2$CN] and Na[B(NC$_4$H$_4$)$_3$CN]) and 247 nm (K[BH$_2$-(NC$_4$H$_4$)CN]). The solid borate samples were dissolved in the buffer with rapid stirring and the change of absorption was followed for a period of 1–2 half-life time. The absorption of the hydrolysis products was measured when eight times the half-life of the reaction had elapsed.

(b) In neutral and alkaline media the progress of the hydrolysis was followed by measuring the free CN$^-$ ion concentration of the solution. For these experiments 0.02 mole/dm^3 solutions of the borates in the buffers were used. The free CN$^-$ ion concentration was determined by means of 0.1 mole/dm^3 AgNO$_3$ solution. For the determination of the end-point the I$^-$ ion indicator method was applied.

*Examination of the influence of acetic acid on the rate of hydrolysis*

The rate of the hydrolysis of Na[B(NC$_4$H$_4$)$_3$CN] at 25°C was measured in pH = 4.07 buffers with 0.1 ionic strength at different acetic acid concentrations (0.015, 0.15 and 0.35 mole/dm^3). The following values were obtained for the pseudo-first-order rate constants: 3.26×10^{-4}; 3.08×10^{-4} and 2.97×10^{-4} s^{-1}.
Determination of the activation parameters

The rate of hydrolysis was measured in pH = 5.36; 4.40; 3.90; 3.61 and 3.38 buffers and in the case of Na[B(NC$_4$H$_4$)$_3$CN] in pH = 3.90; 3.38; 2.43; 2.11 and 1.90 buffers at 17.5, 25.0 and 35.0°C. With the knowledge of the measured pseudo-first-order rate constants and the H$^+$ ion concentration, both the H$^+$ ion concentration-dependent and H$^+$ ion concentration-independent rate constants were determined. The actual [H$^+$] values were calculated from the measured pH values at 17.5, 25.0 and 35.0°C. The activation parameters were calculated in the usual manner from a plot of log k vs T^{-1} according to the Eyring equation using the determined values of the rate constants.

RESULTS AND DISCUSSION

The cyano(pyrrolyl-1)borates decompose slowly in aqueous acidic media, according to eqns (1) and (2) ($n = 0, 1, 2$):

$$[B(C_6H_5)_n(NC_4H_4)_{3-n}CN]^- + H^+ + (3-n)H_2O$$
$$= [B(C_6H_5)_n(OH)_{3-n}] + (3-n)C_4H_4NH + HCN \quad (1)$$

$$[BH_n(NC_4H_4)_{3-n}CN]^- + \cdot H^+ + 3H_2O$$
$$= B(OH)_3 + nH_2 + (3-n)C_4H_4NH + HCN. \quad (2)$$

In contrast with the hydrolysis of the other (pyrrolyl-1)-borates,[1,2] cyano(pyrrolyl-1)borates hydrolyse slowly also in strongly alkaline medium (0.1 mole/dm^3 NaOH) but pyrrole does not form upon the hydrolysis (Fig. 1). In neutral and alkaline medium this process takes place as shown by the following equations ($n = 0, 1, 2$):

$$[B(C_6H_5)_n(NC_4H_4)_{3-n}CN]^- + H_2O$$
$$= [B(C_6H_5)_n(NC_4H_4)_{3-n}OH]^- + HCN \quad (3)$$

$$[BH_n(NC_4H_4)_{3-n}CN]^- + (n+1)H_2O$$
$$= [B(NC_4H_4)_{3-n}(OH)_{n+1}]^- + nH_2 + HCN. \quad (4)$$

Since the spectrum of the borate significantly differs from that of the hydrolysis products in the range 220–270 nm, the rate of the hydrolysis of the cyano(pyrrolyl-1)borates can be readily followed by spectrophotometry. The measurement of the cyanide ion concentration is also a good method for determining the rate of hydrolysis in alkaline medium.
Fig. 1. The change of the spectrum of K[B(NC$_4$H$_4$)$_3$CN] ($c = 1.4 \cdot 10^{-4}$ mole/dm^3) upon hydrolysis in 0.1 mole/dm^3 NaOH solution: (a) before hydrolysis; (b) after hydrolysis; (c) after hydrolysis and adjustment of the pH first to acidic range (3–4) and then to the original value.

According to our studies the hydrolysis of cyano-(pyrrolyl-1)borates in aqueous buffers can be described as a kinetically pseudo-first-order reaction:

$$-\frac{d[B^-]}{dt} = k_1^{hydr}[B^-] \qquad (5)$$

where B^- denotes the cyano(pyrrolyl-1)borate and k_1^{hydr} is the pseudo-first-order rate constant. The measured k_1^{hydr} values of the cyano(pyrrolyl-1)-borates in aqueous buffers are summarized in Tables 1 and 3.

In acidic media the k_1^{hydr} values of the $[B(C_6H_5)_n(NC_4H_4)_{3-n}CN]^-$ anions ($n = 0, 1, 2$) and the $[BH(NC_4H_4)_2CN]^-$ anion varies linearly with the H^+ ion concentration (Table 1) and it can be expressed by the following equation:

$$k_1^{hydr} = k_H[H^+] + k_1 \qquad (6)$$

where k_H is the second-order rate constant of the acid-catalyzed process and k_1 is the first-order rate

constant of the H^+ ion concentration-independent reaction. The values of the k_H and k_1 rate constants, determined from the data given in Table 1, and also the ΔH^+ and ΔS^+ values, calculated from the k_H and k_1 constants are summarized in Table 2.

The rate-determining step in the H^+ ion-catalyzed hydrolysis of cyano(pyrrolyl-1)borates may be the cleavage of the B–CN or the B–N bond (in the case of borates containing B–H bond the cleavage of this bond may be also rate-determinant). We believe that in the reaction of the cyano(pyrrolyl-1)borate with H^+ ion the B–N bond is cleaved since the formation of pyrrole and the corresponding amine borane was observed in the reaction between cyano(pyrrolyl-1)borates and pyridine hydrochloride in non-aqueous solvents.[7,8]

On the contrary, the rate-determining step of the H^+ ion concentration-independent reaction can be only the cleavage of the B–CN bonding, as no formation of pyrrole can be observed in alkaline medium (Fig. 1), and also, the value of k_1^{hydr}, measured in alkaline medium, is equivalent with

that of k_1 determined for the process in acidic medium (Table 1), where the formation of pyrrole can be detected.

Studies with cyano(amino)borates ($[BH_2(NR_2)CN]^-$ anions), having analogous structure with that of the cyano(pyrrolyl-1)-borates, have shown that the rate-determining step of the hydrolysis is also the cleavage of the B–CN bond.[9]

According to the above experimental data, the hydrolysis of cyano(pyrrolyl-1)borates of type $[BR_n(NC_4H_4)_{3-n}CN]^-$ (where R = C_6H_5, $n = 1, 2$; R = H, $n = 0, 1$) can be described by the following equations:

$$[BR_n(NC_4H_4)_{3-n}CN]^- + H^+$$

$$\underset{k'_{-H}}{\overset{k_H}{\rightleftharpoons}} Br_n(HNC_4H_4)(NC_4H_4)_{2-n}CN \quad (7)$$

$$BR_n(HNC_4H_4)(NC_4H_4)_{2-n}CN$$

$$\overset{k_2}{\rightarrow} BR_n(NC_4H_4)_{2-n}CN + C_4H_4NH \quad (8)$$

$$B(C_6H_5)_n(NC_4H_4)_{2-n}CN + (3-n)H_2O$$

$$\overset{fast}{\longrightarrow} B(C_6H_5)_n(OH)_{3-n} + (2-n)C_4H_4NH + HCN$$
$$(9)$$

$$BH_n(NC_4H_4)_{2-n}CN + 3H_2O \overset{fast}{\longrightarrow} B(OH)_3 + nH_2$$

$$+ (2-n)C_4H_4NH + HCN \quad (10)$$

$$[BR_n(NC_4H_4)_{3-n}CN]^- \overset{k_1}{\rightarrow} BR_n(NC_4H_4)_{3-n} + CN^-$$
$$(11)$$

$$BR_n(NC_4H_4)_{3-n} + H_2O$$

$$\overset{fast}{\rightleftharpoons} [BR_n(NC_4H_4)_{3-n}OH]^- + H^+. \quad (12)$$

Since the borate is only weakly basic (i.e. $k'_{-H} \gg k'_H$), the Bodenstein principle can be applied for the reaction, namely, the concentration of $BR_n(HNC_4H_4)(NC_4H_4)_{2-n}CN$ remains small and quasi-constant all the time during the reaction.

At the same time—similarly to the reactions of phenyl(pyrrolyl-1)borates[1]—the reaction between the borate and the H$^+$ ion is a specific acid-catalyzed process (the rate of the hydrolysis is independent of the acid concentration), thus one can also assume that $k'_{-H} \gg k_2$.

As the hydrolysis takes place according to eqns (8) and (11) thus, the following expression can be given for the k_1^{hydr} value (eqn 5) on the basis of the

above considerations:

$$k_1^{hydr} = k_2 \frac{k'_H}{k'_{-H}} [H^+] + k_1. \qquad (13)$$

Equation (6), obtained from the experimental data, is practically identical with eqn (13), namely, the k_H value in eqn (6) is identical with the $k_2(k'_H/k'_{-H})$ value in eqn (13).

The hydrolysis involving the loss of CN^- ion (eqn 11) may be of S_N1 or S_N2-type process. However, the determined great ΔH^+ values and the small ΔS^+ values (Table 2) make the S_N1 mechanism more probable. This mechanism is also supported by the change of the k_1 values measured for $[B(NC_4H_4)_3CN]^-$ in dioxane–water mixtures (Fig. 2), since plotted $\log k_1$ vs $\log [H_2O]$ the slope is 5.7, whereas a value of about 2 would be eexpected if the process were of S_N2-type mechanism.[10]

Our studies have shown that the hydrolysis of $[BH_2(NC_4H_4)CN]^-$ under alkaline and weakly acidic conditions takes place similarly to that of the other cyano(pyrrolyl-1)-borates (Table 3).

Contrary to the results with the other cyano(pyrrolyl-1)-borates (Table 1) the k_1^{hydr} rate constant for $[BH_2(NC_4H_4)CN]^-$ approaches a constant value in more strongly acidic media (Table 3). Also, parallel with the relative decrease of the rate of the hydrolysis such a spectral change of the solution is observable which indicates the formation of a stable amine borane $(C_4H_5N \cdot BH_2CN)$ containing a pyrrolyl group protonated at the

7.9	c	$1.5 \cdot 10^{-6}$

α-position, arising from the reaction between $[BH_2(NC_4H_4)CN)]^-$ and the H^+ ion.[7] The formation of similar compounds, containing a-protonated pyrrolyl group, can be observed in more concentrated sulphuric acid solutions of $L \cdot BH(NC_4H_4)CN$-type amine boranes[8] $(L = amine)$ and of the $[BH(NC_4H_4)(CN)_2]^-$ anion.[11]

In the reaction of the $[BH_2(NC_4H_4)CN]^-$ anion with the H^+ ion first either the B–H or the B–N bond is cleaved. According to our results the cleavage of the B–N bond was more probable since neither hydrogen gas evolution was observed upon the reaction of the borate with acid in non-aqueous medium, nor could B–H exchange be detected upon hydrolysis in D_2O.[7] If the hydrolysis proceeds via the cleavage of the B–N bond, protonation at the N atom of the pyrrolyl group gives rise to hydrolysis. At the same time, protonation at the carbon atom results in a stable borane complex with composition $C_4H_5N \cdot BH_2CN$, since according to earlier results[12] the rate of the H-exchange at the N atom of the pyrrole derivatives is about 1000-fold greater than at either carbon atom. On the basis of these considerations the hydrolysis of the $[BH_2(NC_4H_4)CN]^-$ anion can be described by the following equations:

$$[BH_2(NC_4H_4)CN]^- + H^+ \overset{K_2}{\rightleftharpoons} C_4H_5N \cdot BH_2CN \qquad (14)$$

$$[BH_2(NC_4H_4)CN]^- + H^+ \underset{k_{-H}}{\overset{k_H}{\rightleftharpoons}} [BH_2(HNC_4H_4)CN]$$

$$\text{(15)}$$

$$[BH_2(HNC_4H_4)CN] \overset{k_2}{\rightarrow} BH_2CN + C_4H_4NH$$

$$\text{(16)}$$

$$[BH_2(NC_4H_4)CN]^- \overset{k_1}{\rightarrow} BH_2(NC_4H_4) + CN^-$$

$$\text{(17)}$$

$$BH_2CN + 3H_2O \overset{fast}{\rightarrow} B(OH)_3 + 2H_2 + HCN$$

$$\text{(18)}$$

$$BH_2(NC_4H_4) + OH^- \overset{fast}{\rightleftharpoons} [BH_2(NC_4H_4)OH]^-.$$

$$\text{(19)}$$

According to eqns (14)–(19), to the preceding results obtained from the hydrolysis studies with the other cyano-(pyrrolyl-1)borates, and also, taking into consideration the following relationship between the total concentration of the non-hydrolysed borate (C_B), the concentration of the borate (B^-) and the concentration of the pro-tonated product (HB):

$$C_B = [B^-] + [HB] = [B^-](1 + K_p[H^+]) \quad (20)$$

the k_1^{hydr} value can be given by eqn (21):

$$k_1^{hydr} = \frac{k_2 k_H/k_{-H}[H^+] + k_1}{1 + K_p[H^+]}. \quad (21)$$

After calculation of the k_1 values, the parameters of eqn (21) were determined by the method described earlier[2] using the data of Table 3. The resulting values are summarized in Table 4. The K_p value (80) obtained from the kinetic measurements is in good agreement with that ($K_p = 69$) determined by the spectrophotometric method.[7]

Comparing the k_H values of the phenyl(pyrrolyl-1)-borates[11] and the hydro(pyrrolyl-1)borates[2] with that of the corresponding cyano derivatives (Tables 3 and 4) it can be established that a H–CN or C_6H_5–CN substituent exchange in the molecule results in a 4–5 orders of magnitude decrease in the value of k_H, but in the case of $[BH_2(NC_4H_4)CN]^-$ a 7 orders of magnitude decrease was observed. Thus the hydrolytic stability of the $[BH_2(NC_4H_4)CN]^-$ anion is much larger than has been expected on the basis of the substituent effect. However, this extra-stability is in good accordance

Table 4. Rate constants (k_H, k_1) and protonation constant (K_p) of the hydrolysis of $KBH_2(NC_4H_4)CN$ at 25°C (ionic strength 1.0)

Rate constants (units)	Values
$k_2 \dfrac{k_H}{k_{-H}}$ (mole^{-1}·dm^3·s^{-1})	$(4.8 \pm 0.3) \cdot 10^{-3}$
k_1 (s^{-1})	$(1.6 \pm 0.1) \cdot 10^{-6}$
K_p (mole^{-1}·dm^3)	80 ± 6

with the results of the H-exchange studies in D_2O: in the case of the $[BH_2(NC_4H_4)CN]^-$ anion the pyrrolyl group can be entirely deuterated[7] whereas only partial deuteration can be observed with the other anions.[2,11] We believe that in the case of the hydrolysis of the cyano(pyrrolyl-1)borates a close connection exists between the alteration of the rate of the hydrolysis from the linear substituent-effect, and the degree of deuteration of the pyrrolyl group of the borate. Similar explanation can be given also for finding that the hydrolytic ability of the $[B(C_6H_5)_2(NC_4H_4)CN]^-$ anion is somewhat larger than that expected according to the linear substituent effect (Table 2).

Contrary to the other (pyrrolyl-1)borates[1,2] the hydrolysis of the cyano(pyrrolyl-1)borates involves a novel reaction—the hydrolytic loss of cyanide anion—which does not take place upon the hydrolysis of the BH_3CN^- ion, but does proceed in the case of amine boranes[9] ($[BH_2(NR_2)CN]^-$ anions). The data summarized in Tables 2 and 4 clearly show that the rate of the S_N1-type hydrolysis (k_1) of the cyano(pyrrolyl-1)-borates increases with the increasing number of the pyrrolyl groups of the molecule. A similar change is characteristic also for the Lewis-acid character of the (pyrrolyl-1)-boranes,[13] namely, the value of the k_1 constants (Tables 2 and 4) is primarily determined by the Lewis-acid character of the borane attached to the CN group.

PHOTOCHEMICAL PRODUCTION OF CHROMATE(VI) IONS FROM SOME CHROMIUM(III) COMPLEXES[1]

ADAM MARCHAJ and ZOFIA STASICKA*

Institute of Chemistry, Jagiellonian University, 30–060 Kraków, Poland

and (in part)

DETLEF REHOREK

Sektion Chemie, Karl-Marx-Universität, 7010 Leipzig, D.D.R.

Abstract—Complexes of the type $[Cr(CN)_{6-x}(OH)_x]^{3-}$ were found to produce the chromate(VI) ions upon exposure to UV radiation in alkaline medium. The quantum yields are reported and possible mechanism is discussed.

Chromium(III) complexes are generally known to undergo substitution and substitution-related photoreactions. Photoredox reactions of these compounds are apparently rare. Only in few cases such processes were reported and then reduction to chromium(II) species was concluded.[2-9]

The cyanide complex, $[Cr(CN)_6]^{3-}$, has received perhaps more detailed study than that of any other ligand and photosubstitution of the CN^- ligand was inferred as the only mode by all authors[5,10-17] except Fleischauer[4] who suggested also a redox behaviour from his flash experiments. Our previous study[18] has revealed that under special conditions photosubstitution has been accompanied by a redox process in the case of hexacyanochromate(III) and hydroxocyanochromates(III).

We now report details of the redox photodecomposition of chromium(III) complexes with CN^- and OH^- ligands.

RESULTS AND DISCUSSION

Spectral changes recorded upon exposure of aerated alkaline solutions of cyanochromates(III) were found to depend strongly on the energy of radiation. This is illustrated in Fig. 1(a) and 1(b) for $[Cr(CN)_6]^{3-}$ and $[Cr(CN)_5OH]^{3-}$, respectively. Other hydroxocyanochromates(III) could not be

studied photochemically due to their high thermal instability. However, similar photochemical behaviour was also detected in the case of the $[Cr(CN)_3(OH)_3]^{3-}$, the most stable member of this group. In all these systems exposure to radiation within LF bands (see Table 1) resulted only in absorption changes characteristic of substitution products (see Ref. 18), whereas irradiation within LMCT bands (Table 1) generated also another species absorbing at $26.8 \times 10^3 \, cm^{-1}$ and $36.6 \times 10^3 \, cm^{-1}$.

This new photochemical mode was observed not only in the case of cyanochromates(III) but also in highly alkaline solutions of other chromium(III) salts. These were characterized by two LF bands at $16.8 \times 10^3 \, cm^{-1}$ ($\epsilon = 29 \, dm^3 \, mole^{-1} \, cm^{-1}$) and $23.3 \times 10^3 \, cm^{-1}$ ($\epsilon = 30 \, dm^3 \, mole^{-1} \, cm^{-1}$) and a continuous increasing absorption towards higher wave numbers (Fig. 1c). Species prevailing in such a solution were as yet not fully defined, among others it was formulated earlier as $[CrO_2(H_2O)_n]^-$.[29] For the sake of convenience, the complexes studied here are formulated as $[Cr(CN)_{6-x}(OH)_x]^{3-}$, where $x = 0, 1, 3$ or 6.

Spectral characteristic of the product generated upon exposure to radiation from CT bands in all systems studied fitted that of the CrO_4^{2-} ions (see Fig. 1d). This conclusion was confirmed also by chemical analysis. The rate of the chromate(VI) production was found to depend on concentration of the OH^- ions and molecular oxygen in solution. However, considerable amounts of CrO_4^{2-} were

---

Fig. 1. Absorption changes observed in continuous photolysis of oxygenated alkaline (1 M KOH) solutions of: (a) $[Cr(CN)_6]^{3-}$ (10^{-2} M, $t_{irr} = 2$ min); (b) $[Cr(CN)_5OH]^{3-}$ (10^{-2} M, $t_{irr} = 5$ min); and (c) $[CrO_2(H_2O)_n]^-$ (10^{-3} M, $t_{irr} = 20$ min). Curves 1, in Figs. 1(a–c), refer to unirradiated solutions, curves 2—to solutions irradiated within LF bands ($\bar{\nu} \leqslant 32 \times 10^3$ cm^{-1}); and curves 3—to solutions irradiated within both, LF and CT, ranges (up to $\bar{\nu} \approx 37 \times 10^3$ cm^{-1}). In Fig. 1(d) the difference spectra, $(A_3 - A_2)$ from Fig. 1(a) (curve 1), Fig. 1(b) (curve 2) and Fig. 1(c) (curve 3) are compared with the spectrum of 10^{-4} M CrO_4^{2-} in 1 M KOH (curve 4).

observed also in aqueous unbuffered aerated solutions of $[Cr(CN)_6]^{3-}$ due to increase in pH in consequence of photoaquation. Some traces of Cr(VI) were also detected in de-aerated* alkaline solutions of $[Cr(CN)_{6-x}(OH)_x]^{3-}$.

Quantum yields of the CrO_4^{2-} production (Table 2) were found to depend strongly on the number of the CN^- ligands in the complex. The redox process at 265 nm was observed in the case of cyanochromates(III) to be accompanied by substitution. Its quantum yield could not be, determined however, with sufficient precision due to significant overlap of the product spectra with dominating absorption from the CrO_4^{2-} ions (see curves 3 in Figs. 1a, b). For hexacyanochromate(III) the substitution quantum yield under conditions quoted in Table 2 was roughly estimated as 0.06 ± 0.03.

Flash photolysis (time resolution 20 μs, detection within $14 < \bar{\nu} < 35 \times 10^3$ cm^{-1}) did not reveal any transient product preceding substitution in de-aerated as well as in aerated alkaline solutions of cyanochromates (see Fig. 2a). Since the experiments were carried out under conditions appropriate to detect transient absorption characteristic of hydrated electron (e.g. Ref. 31), its generation in the system seems to be improbable.

Chromate(VI) absorption was recorded not earlier than within seconds upon flashing of aerated samples (Figs. 2a and b) indicating that the CrO_4^{2-} ions are generated in secondary thermal processes at the expense of intermediates(I) absorbing weakly in the visible region, according to overall reaction

$$[Cr(CN)_{6-x}(OH)_x]^{3-} \xrightarrow{h\nu(CT)} \mathbf{I} \xrightarrow[OH^-, O_2]{kT}$$

$$CrO_4^{2-} + (6-x)CN^-. \tag{1}$$

The intermediate species, **I**, could be observed only upon flashing of the $[Cr(CN)_6]^{3-}$ complex in the

---

[d] based on SINDO/FEMP calculations [26,27]; the assignment of d – d bands is consistent with other reports [11,19, 21-23], whereas CTL$\rightarrow$M character of the more energetic transitions was suggested earlier by Schläfer et al [28], although Alexander and Gray [19], basing on SCCC MO method, assigned the band at 38.1x10^3 cm^{-1} to t_{2g} [M] $\longrightarrow t_{1u}$ π^* [L].

Table 2. Quantum yields of chromate(VI) production at 265 nm (1 M KOH, saturated with oxygen, T = 295 ± 0.5 K)

Complex	Concentration, [M]	Quantum yield, [mole Einstein^{-1}]
[Cr(CN)$_6$]$^{3-}$	2 x 10^{-3}	0.057 ± 0.002
[Cr(CN)$_5$OH]$^{3-}$	2 x 10^{-3}	0.025 ± 0.002
[CrO$_2$(H$_2$O)$_n$]$^-$	1 x 10^{-2}	0.007 ± 0.002

presence of an excess of the CN^- ions. Then, a short-lived absorption with a maximum at $\sim 30.5 \times 10^3$ cm^{-1} was recorded (Fig. 2c) that fitted into that characteristic of the [Cr(CN)$_6$]$^{4-}$ complex in solution.[25,30] Rapid decay of the [Cr(CN)$_6$]$^{4-}$ absorption when the [OH$^-$]/[CN$^-$] ratio in solution is higher than 5[25] would be responsible for the lack of any transient absorption in our experiments carried out in absence of the excess CN^-.

These results have led us to believe that CT photochemistry of the [Cr(CN)$_{6-x}$(OH)$_x$]$^{3-}$ complexes proceeds through photoreduction pathway.

This conclusion is consistent with the LMCT character of the transitions (see Table 1) and is

supported by the quantum yield values (Table 2) corresponding with the reported earlier[25] tendency of the chromium(III) complexes to be reduced to the Cr(II) ones in alkaline medium.

Subsequent fate of chromium(II) species generated photochemically would depend on the presence of oxygen in the system. In aerated solution, chromium(III) complexes should be rapidly regenerated. However, chromium(II) compounds are known[32] to be oxidized by molecular oxygen not only to chromium(III) but also to chromium(VI) with presumable generation of O_2^- and/or O_2^{2-} ions. The latter are used to oxidize Cr(III) compounds in alkaline medium to the CrO_4^{2-} ions for analytical purposes. Hydrogen peroxide was
Fig. 2. Absorption changes recorded upon flashing of: (a) $[Cr(CN)_6]^{3-}$ (2×10^{-4} M) in oxygenated 0.01 M NaOH: curves 1 and 2—difference spectra $(A_t - A_o)$, recorded at delay times, t, between 20 μs and 0.2 s (curve 1) and at 200 s (curve 2), curve 3—difference spectrum $(A_{200s} - A_{20\mu s})$; (b) $[CrO_2(H_2O)_n]^-$ (2×10^{-3} M) in oxygenated 1 M NaOH: curves 1–4—difference spectra $(A_t - A_o)$ for t between 20 μs and 1 s (no changes), 22, 120 and 600 s, respectively; (c) $[Cr(CN)_6]^{3-}$ (2×10^{-4} M) in de-aerated 0.02 M NaOH and 0.05 M KCN curve 1 (left scale)—difference spectrum $(A_{10\mu s} - A_{300\mu s})$, curve 2 (right scale)—spectrum of the $[Cr(CN)_6]^{4-}$ complex according to Ref. 25.

reported[30] also to produce chromate(VI) from alkaline cyanochromates(II). We have found that the $[Cr(CN)_{6-x}(OH)_x]^{3-}$ complexes are transformed to the CrO_4^{2-} ions by an excess of H_2O_2 at room temperature (with the exception of $[Cr(CN)_6]^{3-}$ that needs to be heated).

Thus, reductive properties of generated photochemically chromium(II) species would be responsible for chromium(VI) production in secondary thermal processes.

On the other hand, chromium(II) complexes were reported[25] to catalyze substitution of hexacyanochromate(III) in aqueous alkaline cyanide media. Thus, the substitution proceeding upon exposure of the $[Cr(CN)_6]^{3-}$ complex to CT radiation would be a consequence of the catalytic properties of chromium(II) species generated photochemically, although population of the $^4T_{2g}$ level could not be excluded as well.

The photoreduction pathway should be accompanied by generation of ligand or/and sol-

vent radical. In aqueous solution of the $[Cr(CN)_{6-x}(OH)_x]^{3-}$ complexes, where $x \neq 6$, these could be the $\cdot CN$ and $\cdot OH$ radicals, whereas for $x = 6$, the only one possible would be $\cdot OH$.

Unfortunately, due to the high concentration of OH^- ions and relatively high radiation energy necessary for the redox process to proceed, our scavenging experiments did not lead to unequivocal detection of any radical in aqueous solution.

On the other hand, use of ESR spin trapping technique in methanolic solution of $K_3[Cr(CN)_6]$/crown ether has revealed that photochemical decay of the $[Cr(CN)_6]^{3-}$ signal ($g = 1.992$, 43.3 G linewidth) was accompanied by generation of spin adducts of the $\cdot OCH_3$ and $\cdot CH_2OH$ radicals (Table 3). This would be consistent with the intermolecular pathway

$$[Cr(CN)_6]^{3-} \xrightarrow{\frac{h\nu(CT)}{CH_3OH}} [Cr(CN)_6]^{4-} + \cdot OCH_3 + H^+ \quad (2)$$

Table 3. Hyperfine splitting constants of spin adducts (in mT) generated in photolyzed solutions of $K_3[Cr(CN)_6]$/18-crown-6

Radical	Spin trap	Solvent	a_N	a_H	
$\cdot OCH_3$	DMPO	CH_3OH / NaOH	1.36 ± 0.02	0.76 ± 0.02	/1H/
$\cdot CH_2OH$	DMPO	CH_3OH / NaOH	1.60 ± 0.02	2.27 ± 0.02	/1H/
$\cdot CH_2OH$	ND	CH_3OH / CH_2Cl_2 (5 : 1 v/v)	1.37 ± 0.02	0.79 ± 0.02	/2H/

Abbreviations : DMPO = 5,5-dimethylpyrroline-1-oxide;   ND = nitrosodurene.

followed by

$$\cdot OCH_3 + CH_3OH \longrightarrow \cdot CH_2OH + CH_3OH \quad (3)$$
although the $\cdot OCH_3$ radical production in a secondary thermal process cannot be excluded, as well. Besides the $\cdot OCH_3$ and $\cdot CH_2OH$ radicals, other signals were also detected which could be assigned to radicals generated from spin trap and crown ether in reaction with reducing or oxidizing species.

The results obtained in methanolic medium as well as those from aqueous solutions induced us to postulate that CT photochemistry of the $[Cr(CN)_{6-x}(OH)_x]^{3-}$ complexes proceeds through intermolecular reduction

$$[Cr(CN)_{6-x}(OH)_x]^{3-} \xrightarrow[\text{SH}]{hv(CT)}$$

$$[Cr(CN)_{6-x}(OH)_x]^{4-} + \cdot S + H^+ \quad (4)$$
where $SH = H_2O$ or CH_3OH. Secondary thermal reactions of the chromium(II) complexes would be responsible for the chromate(VI) production in aerated alkaline solutions and (at least in part) for aquation accompanying the redox process.

EXPERIMENTAL

Materials. Cyano- and hydroxo-cyano-chromates(III) were prepared according to the methods described earlier.[18] The $[CrO_2(H_2O)_n]^-$ complex was obtained in solution from chromium potassium alum, $KCr(SO_4)_2 \cdot 12H_2O$, using an excess of KOH or NaOH. The solution was irradiated not before stopping its spectral changes. Alkalis were purified from carbonates, other chemicals were best available commercial reagents without further purification. For flash experiments water was purified adequately to observe the absorption of hydrated electron.

Apparatus and procedure. Techniques used for flash and continuous irradiations were described elsewhere.[18,33]

ESR spectra were recorded at room temperature using a JEOL JES-3BQ spectrometer. Irradiations were performed directly within the ESR cavity by a 200-W high pressure mercury lamp (HBO 200, Narva, Berlin). The light $\bar{v} < 28 \times 10^3 cm^{-1}$ was cut off by means of 1 cm of saturated $NiSO_4$ solution and 2 mm of the Schott glass UG 5.

Abstract—Solubilities and the solvolytic behaviour of various inorganic compounds, Lewis acids and bases in fused monobromoacetic acid at $60 \pm 0.5°C$ are discussed. Ionic compounds are fairly soluble, iodides and thiocyanates being comparatively more soluble than chlorides and bromides. Tetraalkyl ammonium halides are highly soluble in this solvent. Conductometric and spectroscopic studies of various Lewis acids and bases in fused monobromoacetic acid indicate their solvolytic behaviour and their subsequent ionization. The solvolyses products $BBr_3 \cdot CH_2BrCOOH$ and $SbCl_5 \cdot CH_2BrCOOH$ have been observed to be the strongest Bronsted acids. Auto-ionization of this solvent has been supported by acid/base titrations.

Very little is known about fused monobromoacetic acid as solvent compared to acetic acid,[1] monochloroacetic acid,[2–5] sulphuric acid,[6] disulphuric acid,[7] or fluorosulphuric acid.[8] Earlier work on the solubility of substances in monobromoacetic acid is very limited. It has a convenient working range (6 b.p. 208°C, m.p. 48.5°C, dipole moment 2.90 at 35°C and specific conductance value $1.35 \times 10^{-3} ohm^{-1} cm^{-1}$). From freezing point, viscosity and density data of the mixture of $SnBr_4$ and $CH_2BrCOOH$ it has been reported[9] that there is no interaction between these two components. However in the case of $SbBr_3$–$CH_2BrCOOH$ system some chemical interaction has been proposed (*loc. cit.*). This is unreasonable since $SnBr_4$ is a stronger

acceptor than $SbBr_3$. Although monobromoacetic acid is moderately acidic in nature, very few adducts with nitrogen and oxygen donor molecules are known,[10,11] which seems surprising. A quantitative method for the estimation of organic tertiary bases has been established,[12] but no attempt has yet been made to isolate their addition compounds with monobromoacetic acid or to characterize them. Therefore, in view of the very favourable properties of fused monobromoacetic acid an attempt has been made to study it as a non-aqueous solvent. In this paper, we report the results of a study of the solubilities of various compounds, Lewis acids and bases and their solvolytic behaviour in fused monobromoacetic acid.

EXPERIMENTAL

Monobromoacetic acid was prepared and purified by the method reported earlier.[13] The best

available commercial A.R. grade samples were used for solubility determinations. Lewis acids used were either commercially available or were prepared in the laboratory by standard methods. Organic tertiary bases were purified by distillation over potassium hydroxide pellets before use.

Quantitative determination of the solubilities of various solutes were made by taking a known amount of the salt and monobromoacetic acid in a small stoppered flask. Monobromoacetic acid was added in such an amount that there was always an excess of the solid undissolved. Each experiment was carried out in a dry box flushed continuously with dry nitrogen. The flasks were closed tightly, spring retainers on the standard taper stoppers. These flasks were rotated continuously in a thermostat maintained at $60 \pm 0.5°C$ for about 38 hr; to ensure that the equilibrium was established. After this the contents were filtered quickly in the dry box. Careful estimation of the cations by standard methods allowed the solubility of the substance in grams per 100 g of the solvent to be determined. From the qualitative study of the solubilities, the substances were extremely low

solubilities have been considered to be insoluble, while others which are soluble to an extent of either less than 5% or 5–10% have been termed as sparingly soluble and fairly soluble respectively. The colour of the saturated solution at equilibrium and the thermal changes during the dissolution have been observed as shown in Table 1.

Solvates of Lewis acids and bases were prepared by taking excess of monobromoacetic acid dissolved in hot benzene in a flask and adding Lewis acid or base in small amounts with constant shaking of the solution till a solvate separated. It was then quickly filtered in a dry atmosphere, washed with anhydrous hot benzene to remove the excess of monobromoacetic acid, finally washed with anhydrous methylene chloride and then dried under vacuum. In the case of the boron tribromide solvate, both the compounds were mixed in equimolar amounts in liquid SO_2 and then the solution was slowly restored to room temperature and a white solid was obtained on evaporating the solvent. In certain cases the bases form solvates which are separated as a second liquid phase. Excess of the solvents were decanted and the last traces of the solvent

were removed under vacuum. After keeping the liquid solvates for a couple of days, needle shaped compounds separate. All these compounds have been characterized by elemental analysis and are reported in Table 2.

The conductance measurements in mono-bromoacetic acid were made in a specially designed cell with a y-shaped jacket and a cell constant of 0.678 cm^{-1} kept in a thermostat at $60 \pm 0.5°C$. The solutions were prepared directly in a conductance cell. The conductance was measured using a precision conductivity bridge (Phillips PR-9500). The infrared spectra of various solvates were recorded using a Perkin–Elmer Model 337 spectrophotometer either as neat liquids or as Nujol mulls.

RESULTS AND DISCUSSION

Fused monobromoacetic acid has a comparatively high dipole moment and low dielectric constant compared to acetic and monochloroacetic acids, which helps in the dissolution of various ionic compounds. The solubility of various solutes in monobromoacetic acid has been checked at $60 \pm 0.5°C$ and their values are given in Table 1. It has been noted that the chlorides of Mn, Ba, Pb,

Ni, Co and Cu, etc. are insoluble in it. Iodides and thiocyanates of these elements are more soluble. Anhydrous chlorides of Li, Na, K, NH_4, Ca, Sr are also insoluble. The low dielectric constant of monobromoacetic acid accounts for its being a poor solvent for these ionic compounds. Non-metals like S, Se, Te, phosphorus and the oxides of iron, chromium, aluminium, copper and lead are also insoluble. It is interesting to note that the anhydrous acetates of Na, K, Li and Cs are fairly soluble while those of Ca, Mg, Ba, Sr, Zn, Cd are insoluble. Tetramethyl ammonium chloride and bromide are highly soluble. When these compounds are added in excess, corresponding mono-bromoacetates separated out. Lewis acids and bases are fairly soluble in monobromoacetic acid. Chlorides of Zn, Ca, Mg form solvates of composition $MCl_2 \cdot 2CH_2BrCOOH$ when dissolved in monobromoacetic acid. Phosphorous and arsenic halides are miscible with monobromoacetic acid in all proportions without the separation of any compound. However, antimony and bismuth trichlorides form solids of composition $MCl_3 \cdot CH_2BrCOOH[M = Sb, Bi]$. Selenium and tellurium tetrachlorides undergo reduction when

In brackets ( ) the values are given for % Nitrogen in the base;   D = Decomposed

heated with monobromoacetic acid but $FeCl_3$ and $AlCl_3$ are highly soluble in it. Tetrahalides of tin and titanium, and pentahalides of antimony and phosphorus are completely miscible with mono-bromoacetic acid in all proportions. The substances which are soluble are generally Lewis acids and give coloured solutions probably due to the formation of solvates or complexes and which has been shown conductometrically in this solvent. Qualitative tests show that the solubilities of most of the solutes increase with rise in temperature. Only strong Lewis acids form adducts with mono-bromoacetic acid.

Organic tertiary bases (Table 1) are highly soluble in monobromoacetic acid. Varying amounts of heat are produced when these two compounds are mixed. Solid compounds of bases with fused monobromoacetic acid have been isolated from their solutions in carbon tetrachloride. Mono-bromoacetates of alkali metals are highly soluble in monobromoacetic acid, while monobromoacetates of alkaline earth metals are only sparingly soluble.
The auto-ionization of fused monobromoacetic acid has already been suggested as;

$$2CH_2BrCOOH \rightleftharpoons CH_2BrCOOH_2^+ + CH_2BrCOO^-. \tag{1}$$
According to the solvent system concept, those solutes which directly or indirectly produce the cations characteristic of the auto-ionization of the solvent shall be acids of the system and the solutes which produce directly or indirectly the anions characteristic of the auto-ionization of the solvent shall be the bases of the system.

Lewis acids are fairly soluble in fused mono-bromoacetic acid and form highly conducting solutions. The breaks in their conductance composition curves (Fig. 1) have been observed at the molar ratios of Lewis acid: solvent of 1:1 and 1:2 and which corresponds to the solvate formation. The

high conductance of solutions containing these solvates may be supported by the ionization of these adducts as;

$$MX_3 + CH_2BrCOOH \rightarrow MX_3 \cdot CH_2BrCOOH$$
$$\updownarrow$$
$$H^+(\text{solvated}) + (MX_3 \cdot CH_2BrCOO)^-$$

(where $X = Cl, Br., M = Al, B$)

$$SnX_4 + 2CH_2BrCOOH \rightarrow SnX_4 \cdot 2CH_2BrCOOH$$
$$\updownarrow$$
$$H^+(\text{solvated}) + (SnX_4 \cdot 2CH_2BrCOO)^-$$

$$SbCl_5 + CH_2BrCOOH \rightarrow SbCl_5 \cdot CH_2BrCOOH$$
$$\updownarrow$$
$$H^+(\text{solvated}) + (SbCl_5 \cdot CH_2BrCOO)^-.$$

The nature of these solutions and the formation of these adducts has been further supported by isolating these solvates as shown in Table 2. Only very strong acceptor molecules form solvates with monobromoacetic acid. Except $SnCl_4$ and $SnBr_4$ which form solvates in this solvent in a 1:2 mole ratio all other metal halides form solvates in 1:1 mole ratios and show that monobromoacetic acid acts as a mono-dentate ligand in these solvates. All these compounds are moisture sensitive, have high melting points and are insoluble in polar solvents, but are soluble in various aprotic solvents. Molar conductance values of the milimolar solutions show them to be quite ionic in nature.

There are some references to solvates of Lewis acids with various aprotic solvents and molar conductance values of milimolar solutions show them to be quite ionic in nature.

There are some references to solvates of Lewis acids with various carboxylic acids but IR

Table 3. Shift of carbonyl stretching frequency in fused monobromoacetic acid on complex formation

Compound	Observed Carbonyl frequency (cm^{-1})	$\Delta\nu$ cm^{-1}	Compound	Observed Carbonyl frequency (cm^{-1})	$\Delta\nu$ cm^{-1}
$CH_2BrCOOH$	1720	–	$CH_2BrCOOH \cdot SbCl_5$	1640	80
$CH_2BrCOOH \cdot TiCl_4$	1650	70	$CH_2BrCOOH \cdot SnCl_4$	1672	48
$CH_2BrCOOH \cdot SnBr_4$	1654	66	$CH_2BrCOOH \cdot AlCl_3$	1664	56
$CH_2BrCOOH \cdot AlBr_3$	1660	60	$CH_2BrCOOH \cdot FeCl_3$	1678	62
$CH_2BrCOOH \cdot SbCl_3$	1675	45	$CH_2BrCOOH \cdot BBr_3$	1645	75
Fig. 1. Conductance composition curves of Lewis acids in CH_2Br–COOH at $60°C \pm 0.5°C$.

spectral evidence in support of their formation are very limited.[14,15] Monobromoacetic acid has a sharp intense band at 1720 cm^{-1} which may be attributed to carbonyl stretching mode.[16] A broad absorption band at 3430 cm^{-1} may be assigned to hydrogen bonded hydroxyl group. Pure carboxylic acids are known to have peaks near 1400 and 1300 cm^{-1} which arise from O–C vibrations but coupled with –OH vibrations in-plane bending vibrations.[17] It is therefore not possible to study the O–C vibrations of these adducts as has been described in the case of the adducts of the esters.[18] Changes in the frequency due to carbonyl group of the ligand on adduct formation have been noted.

On adduct formation with Lewis acids the absorption band due to –OH group of the monobromoacetic acid becomes very sharp. In the case of very weak acceptors like ferric chloride and antimony trichloride, the stretching frequency for the –OH group for the various adducts is at the same position as has been reported for the –OH group of the monomeric acid. It is quite resonable to assume that in these adducts the intermolecular hydrogen bonded structure of the ligand is ruptured. On adduct formation the withdrawal of

electrons from the carbonyl oxygen weakens the hydrogen bond and strengthens the adjacent –OH bond.

The carbonyl stretching frequency in the cases of aldehydes,[19] ketones,[20] amides[21] and esters[18] are lowered on complex formation with various acceptor molecules. With the withdrawal of electrons from the carbonyl group, the double bond character of the carbonyl group is reduced and the carbonyl frequency is lowered, accompanied by a corresponding increase in the O–C stretching mode. But if the ethereal oxygen is to be the donor site, a reverse effect would be expected. The present studies show that there is decrease in the $v(C=O)$ frequency of the ligand on adduct formation and thus the carbonyl oxygen of monobromoacetic acid is the donor site. If the lowering of the (C=O) stretching mode is a measure of the acceptor strength of the Lewis acids, then from Table 3 it is quite clear that the order of their acceptor strength is;
$$SbCl_5 > BBr_3 > TiCl_4 > SnBr_4 > AlBr_3 > AlCl_3$$

$$> SnCl_4 > SbCl_3 > FeCl_3.$$

The adduct $BBr_3.CH_2BrCOOH$ when dissolved in fused monobromoacetic acid forms further solvate;

$$BBr_3 \cdot CH_2BrCOOH + CH_2BrCOOH$$
$$\updownarrow$$
$$CH_2BrCOOH_2^+ + (CH_2BrCOOBBr_3)^-.$$
This behaviour has been supported by its molar conductance value, infra-red spectral measurements of the solid and also from its behaviour in solutions. Boron tribromide and aluminium trihalide adducts with monobromoacetic acid give absorption bands at 525, 540, 520 and 540 cm^{-1} respectively. The bands at 540 cm^{-1} are analogous to the degenerate ν_4(M–Cl) bending mode in MCl_4[20,21][M = B, Al]. These bands may be assigned to the change in the local symmetry from T_d to C_{3v} for the boron and aluminium. In these compounds a strong absorption band is also observed at 1100 cm^{-1} which may be due to a M–Br stretching mode analogous to ν_4 but this is coupled with the M–O stretching mode which also occurs in the same region.[22] In the case of the $SbCl_5.CH_2BrCOOH$ compound, a new band, not present in the ligand appears at 412 cm^{-1} which may be attributed to the Sb–O stretching mode.[23] The absorption bands at 342 cm^{-1} and 630 cm^{-1} may be attributed to Sb–Cl stretching modes in an octahedral environment of the metal.[24] Antimony, therefore, has achieved an octahedral environment by combining with the carbonyl-oxygen of the monobromoacetic acid as;

$$SbCl_5 \cdot CH_2BrCOOH + CH_2BrCOOH$$
$$\rightleftharpoons CH_2BrCOOH_2^+ + (SbCl_5.CH_2BrCOO)^-.$$
In the case of adducts of the tetrachlorides of tin and titanium, the metal–oxygen stretching modes are observed at 390 cm^{-1} and 460 cm^{-1} respectively. These stretching modes are observed at the same region as has been reported in literature.[25,26] The metal–chlorine stretching mode is observed at 380 cm^{-1} with a shoulder at 362 cm^{-1}. A sharp absorption band at 295 cm^{-1} may also be assigned to Sn–Cl stretching mode. As the Sn–O stretching mode of the spectrum is simpler than Sn–Cl stretching mode, the ligands are probably disposed at *trans*-positions to each other.[27] It is therefore probable that the tetrachlorides of tin and titanium acquire a co-ordination number of six by combining with two molecules of mono-bromoacetic acid with *trans*-disposition of the ligands.

Table 2 show that a large number of bases form solvates with monobromoacetic acid. Their solution behaviour in bromoacetic acid has been shown by IR spectral studies where only the principal spectra of these complexes are discussed. It has been noted that during complexation the bands of the pure compounds undergo the same changes and in the same order as reported for pyridinium chloride[28] complexes of acetyl chloride and pyridine.[29]

Bases are known to form complexes with Lewis acids where the nitrogen atom of the tertiary bases donates electrons to the vacant orbital of the central metal atom. Their IR spectra have been changed on donation. Here we discuss the formation of pyridinium, picolinium, quinolinium ions in monobromoacetic acid and their formation has been supported by their IR spectra when compared with the reported IR spectra of pyridine chloride.

Table 4 show the various bands obtained in case of pyridine, quinoline, picoline and piperidine and their assignment is according to Wimsprest and Bersten.[30] The C–H stretching mode of pyridine shifts to lower region on its adduct formation with monobromoacetic acid. The lowering of this band has been assigned to the co-ordination of pyridine through the nitrogen atom. Presently this band is found as a broad band at 2730 cm^{-1}. In pure pyridine, this band is observed at 3002 cm^{-1}. A broad absorption band at 2942 cm^{-1} is assigned to the –CH$_2$ group of monobromoacetic acid. The strong absorption bands at 1580, 1570, 1480 and 1440 cm^{-1} in pyridine are due to the C⸺C and C⸺N symmetric and antisymmetric stretching vibrations. Evidently the donation of electrons by the nitrogen of pyridine will increase the double bond character of the C⸺C and C⸺N bands owing to the reduced electron density on the nitrogen. New bands are found in the adduct C$_5$H$_5$N·CH$_2$BrCOOH at 1620, 1605, 1505, 1482 cm^{-1} are nearly at the same position as those of the pyridinium ion (*loc. cit.*). Two strong bands in the adduct at 1383 and 1320 cm^{-1} are at the same position as those of pyridinium ions. Pyridine has a very weak band at 1375 cm^{-1} which is intensified and shifts a little in the pyridinium ion complex. A new absorption peak is observed at 1435 cm^{-1} in the compound may be assigned to the N–H stretching frequency. The absorption peaks

at 1250, 1204 and 1165 cm^{-1} are due to the C–H in-plane deformation bands of pyridine which are present at 1222, 1150 and 1075 cm^{-1} in the free base. The shift to higher frequency is based on the withdrawal of electron density from the C–H bond. The next three bands at 1050, 1025 and 1002 cm^{-1} found in the adduct are at the same position as in pyridinium ion. These bands arise from the deformation of the pyridine ring. They appear at 1035 and 995 cm^{-1} on complex formation. Strong bands at 890 cm^{-1} in the spectrum of the complex is present in pyridine at 885 cm^{-1} as a weak band. Two bands at 751 and 680 cm^{-1} in the complex are in the same position as in (PyH)$^+$Cl$^-$ (755, 682 cm^{-1}) while pure pyridine absorbs at 785 and 705 cm^{-1}. Similar spectral changes have been observed in complexes with other tertiary organic bases as shown in Table 4. Thus all the changes in the spectra correspond to the formation of the protonated N cations as;

$$C_5H_5N + CH_2BrCOOH \rightleftharpoons C_5H_5N \cdot CH_2BrCOOH$$
$$+ \updownarrow$$
$$C_5H_5N\overset{+}{H} + CH_2BrCOO^-$$
Similarly the adducts of monobromoacetic acid with 2, 2'-bi-pyridyl and 1, 10-phenanthroline have been prepared and characterized by their elemental analysis (Table 2). Both these compounds are susceptible to the hydrolytic attack but are quite
Table 5. IR spectra (cm^{-1}) of the adducts of 2, 2'-bipyridine and 1, 10-phenanthroline with monobromoacetic acid

stable in a dry atmosphere. Molar conductance values of their milimolar solutions indicate them to be ionic. The infra-red spectra of these compounds have also been tabulated in Table 5 along with the fundamental vibrations of the pure ligand. All the spectral changes as shown in Table 5 suggest that 2, 2′-bipyridinium ion is formed on complex formation with monobromoacetic acid.

From the above studies, it is evident that the adducts of acids and bases with fused monobromoacetic acid are ionic in nature and it is reasonable to assume that ions are formed when these solvates are dissolved in fused monobromoacetic acid and both behave as solvo acids and solvo bases producing ions specific to the auto-ionization of the solvent. It is therefore of interest to carry out acid/base titrations in fused monobromoacetic acid conductometerically and visually. Crystal violet, malachite green and benzanthrone have been used to detect the end points in the case of visual titrations. Change in colour of the indicators near the end points are very sharp. The results are reproducible and the indicators can

act reversibly. Figure 2 illustrates the conductometric titration curves of boron tribromide adduct with monobromoacetic acid and various bases. Acid/base neutralization reactions may be suggested as;

$$CH_2BrCOOH_2^+ + K^+ + CH_2BrCOO^-$$
$$+ (BBr_3 \cdot CH_2BrCOO)^-$$
$$\downarrow$$
$$K^+ + 2CH_2BrCOOH + (BBr_3 \cdot CH_2BrCOO)^-.$$

Similarly in case of SbCl$_5$, the reaction may be suggested as;

$$(SbCl_5 \cdot CH_2BrCOO)^- + C_5H_5NH^+$$
$$+ CH_2BrCOO^- + CH_2BrCOOH_2^+$$
$$\rightarrow (SbCl_5 \cdot CH_2BrCOO)^- + C_5H_5NH^+$$
$$+ 2CH_2BrCOOH$$

Decrease in the conductance of the solution upon addition of the acid solution is due to the
Fig. 2. Conductometric titrations between BBr$_3$CH$_2$BrCOOH and bases in fused monobromoacetic acid at 60°C ± 0.5°C.

removal of CH_2BrCOO^- ions. After the molar ratio acid:base of 1:1, when there is complete removal of CH_2BrCOO^- ions further addition of $CH_2BrCOOH_2^+$ ions causes an increase in the conductance of the solution. The presence of only one break in the conductance composition curve shows that $SbCl_5 \cdot CH_2BrCOOH$ and $BBr_3 \cdot CH_2BrCOOH$ behave as monobasic acids.

In the case of stannic chloride and titanium tetrachloride adducts, there are two breaks in the conductance-composition curves corresponding to the molar ratio acid:base of 1:1 and 1:2 confirming the dibasic character of these adducts which ionize as;

$$MX_4 \cdot 2CH_2BrCOOH + CH_2BrCOOH$$

$$\rightarrow CH_2BrCOOH_2^+$$

$$+ (MX_4 \cdot CH_2BrCOOH \cdot CH_2BrCOO)^-$$
and subsequently ionize as:

$$(MX_4 \cdot CH_2BrCOOH \cdot CH_2BrCOO)^-$$

$$+ CH_2BrCOOH$$

$$\downarrow$$

$$CH_2BrCOOH_2^+ + [MX_4(CH_2BrCOO)_2]^{2-}.$$
All these studies support the ionic behaviour of monobromoacetic acid and suggest its mode of ionizations as:

$$2CH_2BrCOOH \rightleftharpoons CH_2BrCOOH_2^+ + CH_2BrCOO^-.$$

SPECTRAL INTENSITY ANALYSIS OF THE Sm^{3+}-POCl$_3$-ZrCl$_4$ SYSTEM

K. BUKIETYŃSKA* and B. RADOMSKA

Institute of Chemistry, University of Wroclaw, 50-383 Wroclaw, Poland

Abstract—The solution absorption spectra of the Sm^{3+}-POCl$_3$-ZrCl$_4$ system were recorded within the 40,000-4000 cm^{-1} range. A number of absorption bands in solution in the near-IR region were considered taking advantage of the optical transparency of the solvent. It was proved that only in this case the Judd–Ofelt parameters Ω_λ are physically significant and can be determined with relatively good accuracy.

Spectral intensity data for the Sm^{3+} ion are scarce. Application of the Judd–Ofelt equations[1,2] to the analysis of the intensity of f–f transitions leads usually to high errors in the evaluated Ω_2 parameter, the error being sometimes one order higher than the Ω_2 values.[3–5] A satisfactory set of intensity parameters of Sm^{3+} has been reported only for the Sm^{3+}–DClO$_4$, Sm^{3+}–TBP solutions and the Sm^{3+}–KNO$_3$–LiNO$_3$ eutectic.[6–8] We have studied the Sm^{3+} ion spectra in POCl$_3$–ZrCl$_4$ solutions. The large transparent range (down to 4000 cm^{-1}) in the near-IR region for this aprotic solvent made it possible to observe $4f$–$4f$ transitions, which in protic solvents are very difficult to measure because of the existence of relatively strong and broad absorption bands in this region due to the overtones of OH, NH and other similar groups. This holds particularly for the Sm^{3+} ion because relatively intense absorption bands (with the hypersensitive one: $^4F_{1/2} \leftarrow {}^6H_{3/2} \approx 6400$ cm^{-1}) occur in this region.

EXPERIMENTAL

Freshly precipitated samarium carbonate, prepared from Sm$_2$O$_3$ (Merck 99.9%), was dissolved in a solution containing 60% of trifluoroacetic acid (Reachim). The excess carbonate was filtered off; after evaporation samarium trifluoroacetate crystallized. The product was dried under vacuum over P$_2$O$_5$ at 330 K for about 150 hr,[9,10] then it was monitored by IR spectroscopy and analysed.

We further used ZrCl$_4$ (Merck zur Synthese 99%) and POCl$_3$ (Merck), freshly distilled in a stream of dry nitrogen. Sm(CF$_3$COO)$_3$–

POCl$_3$–ZrCl$_4$ solutions were prepared by dissolving Sm(CF$_3$COO)$_3$ in the POCl$_3$–ZrCl$_4$ mixture under dry nitrogen atmosphere as described by Brecher and French.[11] The solutions were slightly heated for 10 hr to remove the volatile impurities. The concentration of Sm^{3+} ions was determined as follows: samples of the solution were evaporated to dryness and then treated with warm HClO$_4$. The insoluble residue (with Zr) was filtered off and the amount of samarium was determined gravimetrically as oxalate. The Sm^{3+}:Zr^{4+} molar ratio could be calculated from the amount of ZrCl$_4$ and Sm(CF$_3$COO)$_3$ used in the preparation.

Absorption spectra were recorded over the 40,000-4000 cm^{-1} region with a Cary 14 spectrophotometer, with POCl$_3$ as standard.

RESULTS AND DISCUSSION

The experimental oscillator strengths were calculated by graphical integration of the absorption bands (with correction for the base line) using an appropriate programme. From the experimental oscillator strengths, the Ω_Ω parameters were calculated using the least-squares method from the equation:[1,2,12]

$$P = x \frac{8\pi^2 mc}{3h} \sigma \sum_{\lambda=2,4,6} \frac{\Omega_\lambda (f^n \psi J \| U^{(\lambda)} \| f^n \psi' J')^2}{2J+1}$$

where P = the oscillator strength of the transition, x = Lorentz field correction for the refractivity of the medium, σ = the wavenumber (in cm^{-1}), J, J' = the total quantum numbers of the initial and final states respectively, $(f^n \psi J \| U^{(\lambda)} \| f^n \psi' J')^2 = U(\lambda)$ = the squares of the matrix elements of the unit tensor operator.[13] The root-mean square deviation (rms) were determined from the differences

between the experimental oscillator strengths and those calculated from the evaluated set of Ω_λ parameters.

In all the investigated spectra of Sm^{3+} ions in $POCl_3$–$ZrCl_4$ solutions (similarly to those of Dy^{3+} in $POCl_3$–$ZrCl_4$), a rise of the spectral base line is observed in the UV region down to 24,000 cm^{-1}. This fact makes accurate measurements in this spectral region very difficult. The changes in the base line cause the variations of the oscillator strength values from one solution to another. It is difficult to decide what effect is responsible for this phenomenon. However the application of $POCl_3$ as solvent made it possible to determine with good accuracy the oscillator strength values for the bands within the near-IR region (transitions to the $^6H_{13/2}$; $^6F_{1/2}$, $^6H_{15/2}$, $^6F_{3/2}$; $^6F_{5/2}$; $^6F_{7/2}$ and $^6F_{9/2}$ levels). It is possible to leave out the UV part of the spectrum since a sufficient set of oscillator strengths is available in this case.

Experimental oscillator strengths values and those calculated from the Judd–Offelt equation for the Sm^{3+}–$POCl_3$–$ZrCl_4$ solutions with different Sm^{3+} concentrations are presented in the Table 1. The rms deviations of the oscillator strengths and evaluated sets of the intensity parameters are also included. The evaluated sets of the Ω_λ parameters reproduce relatively well the experimental set of the oscillator strengths values. The advantage of using the aprotic solvent in the investigation of the spectral intensity of the Sm^{3+} ion consist in the fact

that, aside from the relatively intense bands in the near IR, most of the 4f–4f transitions of the Sm^{3+} ion give rise to the rather weak absorption bands. For the transitions at wave number higher than 7500 cm^{-1}, the U(2) matrix element values are small (they do not exceed 0.022) and the total of all the U(2) values for about 100 transitions within the 7500–48,300 cm^{-1} spectral range is over 30 times smaller than that for the five transitions within the 4200–7500 cm^{-1} energy range. Moreover, the interpretation of the Sm^{3+} spectrum becomes complicated by the high density of the energy levels in the visible –UV regions. There it is necessary to assign arbitrarily the centres of gravity for a rather large number of states for each of the complex band envelopes observed up 20,000 cm^{-1}.[8] Thus, those observables are of little value in the fitting procedure and the omission of this group of bands seems to be quite reasonable.

We found that if the transitions with higher U(2) and U(4) matrix elements values transitions: $^6F_{5/2} \leftarrow {}^6H_{5/2}$ and $^6F_{3/2}\,{}^6H_{15/2}\,{}^6F_{1/2} \leftarrow {}^6H_{5/2}$ are included in the set of absorption bands used for the calculations, the values of the Ω_λ parameters for the Sm^{3+}–$POCl_3$–$ZrCl_4$ solutions are insensitive to variations of the fitting procedure. This was proved by repeating the fitting procedure with omission of one or two absorption bands. If however the $^6F_{5/2} \leftarrow {}^6H_{5/2}$ and/or $^6F_{3/2}\,{}^6H_{15/2}\,{}^6F_{1/2} \leftarrow {}^6H_{5/2}$ transitions were excluded from the considered absorption bands, the values of the Ω_2 and Ω_4 parameters

varied significantly and were determined with a low accuracy (if the $^6F_{3/2}\,^6H_{15/2}\,^6F_{1/2} \leftarrow\,^6H_{5/2}$ transitions were excluded then $\Omega_2 = 58.5 \pm 18.6$). This means that when those important transitions are omitted, the Ω_2 and Ω_4 parameter values will become simply fitting parameters with no physical meaning.

From these results we are led to conclude definitely that a reasonable set of Ω_λ parameters can be evaluated for the Sm^{3+} ion (similarly as for the Dy^{3+}[14]) only if the near-IR region is available to measurements. To avoid the danger of evaluation of Ω_λ values devoid of physical meaning for the Sm^{3+} ion it is always necessary to consider transitions in the near-IR region.

STERIC EFFECTS IN THE COMPLEXATION KINETICS OF COPPER(II) WITH *RAC*-5,5,7,12,12,14-HEXAMETHYL-1,4,8,11-TETRAAZACYCLOTETRADECANE IN BASIC AQUEOUS MEDIA

FU-TANG CHEN, CHUNG-SHIN LEE and CHUNG-SUN CHUNG*

Republic of China

Abstract—Copper(II) reacts with *rac*-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraaza-cyclotetradecane (tet-b) in strongly basic aqueous media to give [Cu(tet-b) (OH) (blue)]$^+$ which contains trigonal bipyramidally co-ordinated Cu^{2+} with the tet-b ligand in its most stable, folded form. The kinetics of formation of this blue complex have been studied at $25.0° \pm 0.1°C$ using the stopped-flow technique. Second-bond formation is proposed as the rate-determining step for tet-b reaction with $Cu(OH)_3^-$ and $Cu(OH)_4^{2-}$. Possible mechanisms for the reaction and the steric effects resulting from the methyl groups on the alkyl backbone of the macrocyclic ligand are considered.

In order to account for the remarkable kinetic effects of ligand cyclization upon complex formation rate constants, a number of papers have dealt with various aspects of the kinetics of incorporation of metal ions into macrocyclic ligands.[1-10] As recently demonstrated,[5] the comparative behaviour of the closely correlated open-chain and cyclic ligands indicates that ligand cyclization itself has only a relatively small influence upon the complex formation rate-constants. Instead, the more significant kinetic effects arise from the substitution at the nitrogen donor atoms of the open-chain ligands or on the alkyl backbone of the cyclic compounds.[5]

In the current investigation, we have attempted to study the steric effects resulting from alkyl substitutions on the alkyl backbone of the macrocyclic ligand in complexation reaction. To accomplish this we have studied the kinetics of copper (II) reacting with unprotonated *rac*-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane (tet-b, see Chart 1) in strong NaOH solutions.

Under these conditions the copper is present as a mixture of soluble hydroxide species,[5-11] and the ligand is essentially unprotonated.[12] Thus the reaction studied may therefore be represented by the formulation in eqn (1).

$$Cu(OH)_x^{2-x} + \text{tet-b} \xrightarrow{k_{obsd}}$$

$$[Cu(\text{tet-b})(OH)(\text{blue})]^+ + (x-1)OH^- \quad (1)$$
In marked contrast to the reactions of 1,4,8,11-tetraazacyclotetradecane (cyclam, see Chart 1) and *meso*-5,12-dimethyl-1,4,8,11-tetraazacyclotetradecane (Me$_2$cyclam, see Chart 1), tet-b reacts with copper(II) in basic aqueous media to give initially a blue 5-coordinate complex [Cu(tet-b)(OH)(blue)]$^+$ with the ligand in its most stable, folded form.[13] This kinetically controlled blue product is readily converted to the more thermodynamically stable red isomers, and the kinetics of this blue-to-red interconversion has recently been reported.[14,15]

EXPERIMENTAL

Reagents. The macrocyclic ligand tet-b was prepared by using the procedure described by Hay, Lawrance, and Curtis;[16] m.p. 102–105° (lit. m.p. 97–105°[17]). Found: C, 64.47; H, 12.64; N, 18.34. Calc. for $C_{16}H_{36}N_4 \cdot H_2O$: C, 63.53; H, 12.66; N, 18.52%. The ligand stock solutions were standardized by spectrophotometric mole ratio plots with standard Cu(II) solution.

The salt $Cu(ClO_4)_2 \cdot 6H_2O$ was recrystallized twice from water and standardized by titration with ethylenediaminetetraacetate. $NaNO_3$ was recrystallized twice before use. A saturated solution of sodium hydroxide (reagent grade) was prepared to precipitate sodium carbonate. A sample of this was diluted with freshly boiled, distilled, deionized water and stored in a Nalgene Teflon bottle. It was standardized against weighed amounts of potassium hydrogen phthalate.

Kinetic measurements. The reactions were monitored at 270 and 670 nm using a Union Giken RA-401 stopped-flow spectrophotometer. The temperature was maintained at $25.0° \pm 0.1°C$. Ionic strength was controlled at 1.0 mol dm^{-3} by using $NaNO_3$. The rate constants were obtained by a linear least-squares fit of the data by using the IBM 1130 computer.

RESULTS

In the $[OH^-]$ range of the measurements the ligand is essentially unprotonated, while the copper(II) is present as $Cu(OH)_3^-$ and $Cu(OH)_4^{2-}$.[5] The reactions were studies as a function of NaOH concentration at $25.0° \pm 0.1°C$ in an attempt to resolve the individual rate contributions of $Cu(OH)_3^-$ and $Cu(OH)_4^{2-}$. Studies were carried out under pseudo-first-order conditions by using at least a tenfold excess of ligand or copper(II) ion. The observed pseudo-first-order rate constants are given in Table 1. Plots of k'_{obsd} vs [tet-b] and k'_{obsd} vs $[Cu(OH)_x^{2-x}]$ give straight lines as shown in Figs. 1 and 2 respectively. The reaction was found to be first order with respect to each reactant and to proceed to completion according to the rate expression in eqn (2). The second-order rate constants are given in Table 1.

$$d[Cu(tet\text{-}b)(OH)(blue)^+]/dt = k_{obsd}$$
$$[Cu(OH)_x^{2-x}]_T[tet\text{-}b] \qquad (2)$$

As shown in Table 1, values of k'_{obsd} decreased as $[OH^-]$ increased. The rate of formation can be represented by eqn (3). Here L is tet-b.

$$\text{Rate} = k_{obsd}[Cu(OH)_x^{2-x}]_T[L] = k^L_{Cu(OH)_3}$$
$$\times [Cu(OH)_3^-][L] + k^L_{Cu(OH)_4}$$
$$\times [Cu(OH)_4^{2-}][L]. \qquad (3)$$

DISCUSSION

As shown in Table 2, the resolved rate constants decrease with increasing methyl substitutions on the alkyl backbone of the cyclic ligands, and the difference increases dramatically for the highly substituted ligands, tet-b and tet-a. This trend indicates that the reactions exhibit a significant degree of association with the incoming nucleophile at the point of the rate-determining step.

The position of the rate-determining step is an important consideration in comparing the reactivities of closely related multidentate ligands with metal ions. The kinetics of Cu(II) reacting with a series of open-chain and cyclic polyamines have been studied by Lin *et al.*[5] For the reactions of cyclam and Me$_2$cyclam, Jahn-Teller (tetragonal) inversion following the first copper–nitrogen bond

formation is proposed as the rate-determining step with $Cu(OH)_3^-$, while second copper–nitrogen bond formation is proposed as the rate-determining step with $Cu(OH)_4^{2-}$.[5]

In the reaction of tet-b, the formation of Cu–N(1) or Cu–N(8) bond is expected to be faster than the formation of Cu–N(4) or Cu–N(11) bond on steric grounds. Accordingly, the first-coordinate-bond formation with N(1) or N(8) is expected to represent the predominant reaction route for the $Cu(OH)_x^{2-x}$ reaction with tet-b. The second-bond formation is the formation of Cu–N(4) or Cu–N(11) bond. As pointed out by Turan and Rorabacher,[19] alkyl substitution at sites three or more atoms removed from the donor atom undergoing coordinate-bond formation has little effect upon the ligand reactivity. Therefore, only·

one of the six methyl groups on the alkyl backbone of tet-b has significant effect upon the ligand reactivity at the point of first coordinate-bond formation. If Jahn–Teller inversion following the first-bond formation were the rate-determining step for the $Cu(OH)_x^{2-x}$ reaction with tet-b, the observed difference of the resolved rate constants between tet-b and cyclam should be mainly attributable to the steric effect of a C-substituted methyl group. The small ratios $k^{tet-b}_{Cu(OH)_3}/k^{cyclam}_{Cu(OH)_3}$ and $k^{tet-b}_{Cu(OH)_4}/k^{cyclam}_{Cu(OH)_4}$ strongly suggest that the first coordinate-bond formation may not be the rate-determining step for the tet-b reaction with $Cu(OH)_3^-$ or $Cu(OH)_4^{2-}$.

It is extremely unlikely for copper(II) to maintain a coordination number of 7 with three amine groups of tet-b and three OH^- groups. The fact that $Cu(OH)_4^{2-}$ appears as a reactant indicates that the rate-determining step occurs prior to the third coordinate-bond formation.[5] Furthermore, chelate effect and the stable copper–amine bonds also suggest that the rate-determining step occurs prior to the third-bond formation.[20] Thus these kinetic results lead to the postulate that second-bond formation is the rate-determining step for tet-b reacting with $Cu(OH)_3^-$ and $Cu(OH)_4^{2-}$.

It is interesting to note that first-bond formation is the rate-determining for the $Cu(OH)_3^-$ reaction

with cyclam or Me$_2$cyclam, while the second-order formation is the rate-determining for the $Cu(OH)_3^-$ reaction with tet-b. This sterically induced shift in the rate-determining step can readily be explained by the reaction mechanism proposed by Rorabacher and Margerum shown in Fig. 4.[5] As discussed previously, the second-bond formation is the formation of Cu–N(4) or Cu–N(11) bond, and the large steric effects resulting from the methyl groups on tet-b related to the crowding of coordinated water molecules and the high-energy barrier to internal rotation are expected to retard the formation of the second Cu–N bond (k_{2a}) and to accelerate the reelongation of the Cu–N bond (k_{-1b}). This would greatly improve the chances that $k_{-1b} > k_{2a}$, resulting in a shift of the rate-determining step to the point of second-bond formation. Similar sterically induced shift in the rate-determining step for Ni(II)–diamine reactions has been reported.[19]

Another interesting aspect of this study is the geometry of the product. In marked contrast to the reactions of $Cu(OH)_x^{2-x}$ with cyclam and Me$_2$cyclam,[21] $Cu(OH)_x^{2-x}$ reacts with tet-b to form initially a blue complex. This blue complex has been neutralized and isolated as [Cu(tet-b)]$_2$Cl(ClO$_4$)$_3$ which contains 5-coordinate (trigonal-bipyramidal) copper and with the tet-b ligand in its

Fig. 4. Detailed mechanism proposed by Rorabacher and Margerum (Ref. 5) for $Cu(OH)_3^-$ (or $Cu(OH)_4^{2-}$) reacting with a tetraamine macrocyclic ligand showing sequential bonding and Jahn–Teller inversion steps.

most stable, folded form.[13] Chloride ion, which occupies one of the positions in the trigonal plane, dissociates from the copper in dilute solution but the electronic spectral characteristics of the complex in aqueous solution are similar to those of the crystals.[22] The blue complex is the kinetically controlled product, and is readily converted to the more thermodynamically stable red isomer in basic solution. The thermodynamics and kinetics of this blue-to-red interconversion have recently been reported.[14,23]

Assuming an initial coordination number of six for $Cu(OH)_x^{2-x}$ the coordination number of the blue product indicates that at some point in this reaction the formation of a copper–nitrogen bond has caused the loss of two coordinated water molecules. As pointed out by Margerum,[21] it is energetically more favourable if the multiple desolvation step occurs after the coordination of several strong donor groups. In order to relieve the steric congestion attributable to the methyl groups and to avoid multiple desolvation occurring prior to the rate-determining step, this highly substituted macrocyclic ligand folds in the complexation reaction with $Cu(OH)_x^{2-x}$, resulting in the formation of the blue species.

In addition to the reaction of $Cu(OH)_x^{2-x}$ with tet-b, unstable blue intermediates were also observed in the reactions of copper(II) with highly substituted macrocyclic tetraamines such as *meso*-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotet radecane, *rac*-5,7,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane, *meso*-5,7,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane, and 5,7,12,14-tetraethyl-5,12-dimethyl-1,4,8,11-tetra-azacyclotetradecane.[24] Similar to the reaction of tet-b, some degree of ligand twisting or folding may be necessary to avoid multiple desolvation occurring prior to the rate-determining step. The formation of the blue species is a consequence of the folding or twisting of the macro-cyclic ligand. The kinetics of the blue-to-red interconversions of copper(II) complexes of these ligands have recently been reported.[24-26] It is interesting that such blue intermediates were not observed for the $Cu(OH)_x^{2-x}$ reaction with the less sterically hindered ligands such as cyclam and $Me_2cyclam$.[21]

In conclusion, the steric effects attributable to the substituted methyl groups on tet-b retard the forward steps and accelerate the backward steps of the complexation reaction of tet-b with copper(II), resulting in a shift of the rate-determining step to the point of second-bond formation, and a folding of the macrocyclic ligand.

Abstract—Synthesis of two Ni(II) complexes with furfural S-methylthiosemicarbazone (HL) of the formula $[Ni(HL)_2(H_2O)_2](ClO_4)_2$ (**A**) and $[Ni(HL)_2(ClO_4)_2]$ (**B**) are reported. Compound **A** was obtained from an ethanolic solution of $Ni(ClO_4)_2 \cdot 6H_2O$ and HL, whilst compound **B** was produced by heating compound **A** to 378 K. An X-ray analysis of the complex **A** showed that it has a *trans*(H_2O)-*trans*(HL) octahedral configuration in which HL behaves as a bidentate (NN) ligand. On the basis of the IR and electronic spectra as well as the magnetism, it was found that the compound **B** has also an octahedral configuration in which, HL and ClO_4 groups, are coordinated.

The synthesis and structural investigations of a considerable number of complexes of transition metals with S-methylthiosemicarbazide[1,2] and different S-methylthiosemicarbazones[3–9] have been recently reported. It has been established that S-methylthiosemicarbazide[1,2] and acetone S-methylthiosemicarbazone[3] behave as bidentate (NN) ligands. On the other hand, the products obtained by a condensation reaction of S-methylthiosemicarbazide with salicyladehyde[4–7] and 8-quinolinaldehyde[8,9] behave as tridentate (NNO) and (NNN) ligands, respectively. Studying further these complexes of 3d elements with S-methylthiosemicarbazones we report here the syntheses, IR and electronic spectra of two Ni(II) complexes with the new furfural S-methylthiosemicarbazone $[Ni(HL)_2(H_2O)_2](ClO_4)_2$ and $[Ni(HL)_2(ClO_4)_2]$ as well as the crystal structure analysis of the first complex, where HL = furfural S-methylthiosemicarbazone†:
EXPERIMENTAL

Elemental analysis. For the elemental analysis the air-dry substance was used. Nickel was determined as bis(dimethylglyoximato)-nickel(II) after decomposing the complex by heating with 5.0 cm³ of conc. HNO_3 and 3–4 drops of conc. H_2SO_4. Nitrogen was determined as N_2 according to Dumas' method; carbon and hydrogen were determined by combustion into CO_2 and H_2O, respectively.

Magnetic susceptibility measurements. Magnetic susceptibility was measured at 300 K according to the Faraday method using $Hg[Co(NCS)_4]$ as calibrant; diamagnetic corrections were made by employing Pascal's constants.[10]

IR and electronic spectra. IR spectra were recorded with Carl–Zeiss model Specord IR 75 in KBr. Electronic spectra were measured in reflection mode on monochromator SPM-2 (Zeiss–Jena) using a reflection cell of the type R-45/0. Samples were prepared to comply with the

†This ligand can be coordinated as a monoanion (L⁻) resulting from deprotonation of the NH₂-group (unpublished results).

hypothesis of theory.[11] MgO powder was used as a white standard.

Preparation of ligand. The ligand, furfural S-methylthiosemicarbazone was obtained by heating with refluxing the ethanolic solution of the stoichiometric amounts of S-methylthiosemicarbazide hydrogen iodide,[12] furfural and $Na_2CO_3 \cdot 10H_2O$. After completing the reaction (3 hr) the solution was filtered and its amount reduced to a small volume by heating with warm air. The yellowish crystals of the ligand, formed at room temperature, were filtered out and washed with ethanol and ether. Yield: 60%.

Preparation of complexes. $[Ni(HL)_2(H_2O)_2]$ $(ClO_4)_2$. A mixture consisting of 0.6 g of $Ni(ClO_4)_2 \cdot 6H_2O$ and 0.5 g of furfural S-methylthiosemicarbazone was dissolved by heating in 4.0 cm³ of ethanol and left at room temperature for about 50 hr. The resulting green–grey crystals were filtered off and washed with ethanol and ether. Yield: 0.6 g. Found: Ni, 8.76; C, 26.06; H, 3.17; N, 13.01; H_2O, 5.42; Calc. for $[Ni(HL)_2(H_2O)_2](ClO_4)_2$: Ni, 8.89; C, 25.47; H, 3.36; N, 12.73; H_2O, 5.45%; $\mu_{eff} = 3.18$ B.M. (300 K).

$[Ni(HL)_2(ClO_4)_2]$. Heating the powdered crystals of $[Ni(HL)_2(H_2O)_2](ClO_4)_2$ at 378 K produced the anhydrous complex $[Ni(HL)_2(ClO_4)_2]$. This transformation was accompanied by a change of colour from green–grey into yellow–green. The new compound is air stable. Found: Ni, 9.39; C, 27.08; H, 2.82; N, 13.61; Calc. for $[Ni(HL)_2(ClO_4)_2]$: Ni, 9.41; C, 26.94; H, 2.91; N, 13.46; $\mu_{eff} = 3.29$ B.M. (300 K).

Crystal structure analysis of $[Ni(HL)_2$ $(H_2O)_2](ClO_4)_2$. Crystal data of the complex are: $NiC_{14}H_{22}N_6O_{12}S_2Cl_2$, $M_r = 660.04$, triclinic $P\bar{1}$, $a = 7.938(2)$, $b = 12.039(3)$, $c = 7.807(2)$ Å,

solved by direct methods using MULTAN and refined by full-matrix least-squares techniques. All non-hydrogen atoms were refined with anisotropic thermal parameters; H atoms were kept with fixed values for both positional and isotropic thermal parameters. The positions of all H atoms were located from a difference map. The least-squares refinement converged to a final $R = 0.062$. The ESD of an observation of unit weight was $S = 5.63$ for the observed reflections. The correction for extinction was applied with the refined value of $g = 0.35624 \times 10^{-7}$. Atomic scattering factors including the corrections for anomalous dispersion were taken from International Tables for X-ray Crystallography. Final atomic coordinates, thermal parameters and list of F_o/F_c values have been deposited with the Editor as supplementary material; copies are available on request. Bond distances and angles are given in Table 1.

RESULTS AND DISCUSSION

Descriptions of the crystal structure. As shown by Fig. 1 the lattice consists of discrete complex cations $[Ni(HL)_2(H_2O)_2]^{2+}$ and ClO_4^- bound together by hydrogen bonds. However, the Ni(II) is screened completely from the anions. Ni(II), situated at a centre of symmetry, is surrounded pseudo-octahedrally by four N and two O atoms. The four nitrogen atoms: N(1), N(1), N(3) and N(3) form a plane around Ni with a mean Ni....N distance of 2.112(5) Å, which is in a good agreement with those found in high-spin Ni(II) complexes with four coplanar N donors.[13] The apical positions of the octahedron are occupied by two water molecules at a distance of 2.119(5) Å from Ni(II). Each water molecule maintains two hydrogen bonds with the ClO_4^- ions

$\alpha = 99.34(2)$, $\beta = 110.44(2)$, $\gamma = 105.74(2)°$; $V = 645.0(7)$ Å³, $D_c = 1.70$ g cm⁻³, $D_o = 1.75$ g cm⁻³, $Z = 1$, $\mu_{(MoK_\alpha)} = 11.8$ cm⁻¹, $F(000) = 338$.

X-Ray diffraction data and accurate cell dimensions were measured on an automated Enraf–Nonius CAD–4 diffractometer using graphite monochromated MoK_α radiation and the ω-2θ scan mode. Of the 2286 unique reflections recorded with $2\theta < 50°$, 1818 were regarded as observed $I > 4\sigma(I)$. No absorption correction was applied. The intensity statistics suggested the centrosymmetric space group $P\bar{1}$. The structure was

These infinite chains are formed along the [100] direction. They are crosslinked by a third hydrogen bond built up between N(2)–H(N2) bonds pointing outward from the complexes and O(1) atoms of the anions.

Fig. 1. A perspective view of the crystal lattice showing the coordination polyhedron around Ni(II) sitting at a centre of symmetry and some of the symmetry equivalent ClO_4^- tetrahedra. Atomic numbering is given with molecular fragments at (x, y, z). Bare numbers are for carbon atoms unless indicated otherwise. The numbering of H atoms is omitted. Symmetry equivalent atoms are labelled as follows: *, $= \bar{x}, \bar{y}, \bar{z}$; ** $= 1 - x, \bar{y}, \bar{z}$; *** $1 - x, \bar{y}, 1 - z$.

vigorous thermal motion of the ClO_4 tetrahedra the mean Cl–O bond length (1.363(4) Å) should be significantly shorter than that which is expected theoretically (1.45 Å)[14] and observed at low temperature. In accordance with the positions of H atoms around N(1) and N(2) inferred from difference Fourier synthesis the C(1)–N(1) double bond (1.265(5) Å) together with the low S–C(1)–N(2) angle (111.2(5)°) suggest that the new furfural S-methylthiosemicarbazone ligand predominantly assumes the *imido* form. No such localized C(1) = N(1) double bond has been found in other transition metal complexes with different S-methylthiosemicarbazone ligands.[3,6,7,9]

The thiosemicarbazide moiety together with C(3) and C(4) atoms lie roughly in the same plane (0.9744X + 0.1509Y − 0.1669Z = − 0.0966). The maximum deviation (0.18 Å) from this plane is shown by N(2). The furan ring is practically planar, the maximum displacement from the best plane (0.7281X + 0.5221Y − 0.4441Z = − 1.2517) is about 0.02 Å. The dihedral angle between these two least squares planes is 36.1(4)°. The two symmetry related ($\bar{1}$) ligands are bound together by a pair of weak hydrogen bond formed between the N(1)–H(N1) moiety and the ether oxygen O(8) of the symmetry related furan ring and vice versa.

$$H \ldots O = 2.37(1), \quad N \ldots O = 3.00(1) \text{ Å}$$

$$NH \ldots = 127(1)°.$$

Magnetic and spectral data. Both compounds are paramagnetic and their effective magnetic moments (3.18 B.M. for $[Ni(HL)_2(H_2O)_2](ClO_4)_2$ and 3.29 B.M. for $[Ni(HL)_2(ClO_4)_2]$) are within the limits characteristic for hexacoordinated Ni(II).[15] These values are in agreement with the unequivocally determined octahedral configuration for $[Ni(HL)_2(H_2O)_2](ClO_4)_2$ and with the supposed structure (based on the spectroscopic data) for $[Ni(HL)_2(ClO_4)_2]$. In Fig. 2 the fragments of the IR spectra for both complexes are depicted. It can be seen for $[Ni(HL)_2(H_2O)_2](ClO_4)_2$ in the region of 1150–1080 cm^{-1} there is a considerably wide very intense triplet band which can be assigned to the v_3 vibrations of ClO_4 group. It is known from the literature[15,16] that the ionically bonded perchlorate has around 1100 cm^{-1} a characteristic wide band of strong intensity which often shows tendency for splitting. The last is more pronounced in complexes which is the consequence of deformation of T_d symmetry of ClO_4 group, which is, on the other hand, caused by its coordination or, by presence of hydrogen bonds. With respect to the unequivocally determined ionic character of ClO_4 group in the complexes, the structure of $v_3(ClO_4)$ band is doubt-

Fig. 2. Fragments IR spectra of:——$[Ni(HL)_2(H_2O)_2]$ $(ClO_4)_2$;---$[Ni(HL)_2(ClO_4)_2]$.

lessly, a consequence of the identified hydrogen bonds of these groups and atoms.

In contrast to this the $v_3(ClO_4)$ band in the IR spectrum of $[Ni(HL)_2(ClO_4)_2]$ is split into one band of very strong intensity at 1115 cm^{-1} on the one hand, and two somewhat weaker bands at 1150 and 1065 cm^{-1}, on the other hand. This is most probably due to the effect of coordination of the perchlorate group. In this way the paramagnetism of the compound can be also explained and supports the postulated octahedral configuration consisting of the two molecules of the bidentate furfural S-methylthiosemicarbazone and two ClO_4 groups.

It can be expected that the octahedral structure of this complex would be expected to be more tetragonally deformed compared to the starting aquo-complex; the same is indicated by the higher value of its magnetic moment.

The diffusion-reflection spectra are shown in Fig. 3. The reflectance spectra indicate unequivocally, the identical type of coordination of the central ion. Their array and the number of absorption maxima indicate the octahedral coordination of Ni(II). The Ni(II) ion involves the system $3d^8$ system. The first three maxima (1, 2, 3) can be attributed to the energy levels on a diagram of the Tanabe-Sugano type,[17] with the symmetry corresponding to the octahedral crystal field (Table 2).
Fig. 3. Reflection spectrum of: —— $[Ni(HL)_2(H_2O)_2](ClO_4)_2$; – – – $[Ni(HL)_2(ClO_4)_2]$.

Table 2. Electronic spectral data

Complex	Transitions $[cm^{-1} \cdot 10^3]$			cm^{-1}	
	$^3A_{2g} \rightarrow {}^3T_{2g}(F)$	$^3A_{2g} \rightarrow {}^3T_{1g}(F)$	$^3A_{2g} \rightarrow {}^3T_{1g}(P)$	Dq	B
$[Ni(HL)_2(H_2O)_2](ClO_4)_2$	9.8	16.0	22.5	980	910
$[Ni(HL)_2(ClO_4)_2]$	9.6	15.8	22.5	960	950

The parameters of crystal field strength (Dq) and Racah parameters (B) were determined using a pair of equations derived from the theory of the crystal field,[18] are shown in Table 2.

The small difference in the values of the energy levels and other parameters, are probably due to difference in the strength of the ligand field of H_2O molecules and ClO_4 group.

It can be supposed that the band at 30,700 cm^{-1} (IL) results from a transition of the intraligand character since it was also detected in the spectrum of the free ligand of similar type.[19]

POTENTIOMETRIC DETERMINATION OF THE STABILITY CONSTANTS OF A MODEL (Na$^+$ + K$^+$)ATPase COMPLEX

GRAHAM E. JACKSON* and MARK J. KELLY

Department of Inorganic Chemistry, University of Cape Town, Rondebosch 7700, South Africa

Abstract—Formation constants for the binary and ternary Mn(II)–nitrilotriacetic acid (NTA) and adenosine triphosphate (ATP) which model the action of (Na$^+$ + K$^+$)ATPase have been determined at 25°C and $I = 150$ mmole dm^{-3} NaCl. The results are interpreted in terms of the known stabilities of the enzyme complexes and it is concluded that metal–ion chelation of ATP alone is not enough for hydrolysis to occur. A substantial stabilisation of the ternary complex occurs, possibly through bridging sodium ions.

An important facet in the normal functioning of a biological cell is the maintenance of a Na and K concentration gradient across the cell membrane. As the cell membrtane is permeable to these ions via a passive transport mechanism, the cell requires an energy dependent, active transport mechanism to maintain the ionic balance against the concentration gradient. It is believed that the active transport mechanism, the so-called sodium pump, involves Na$^+$ and K$^+$ activated adenosinetriphosphatase,[1,2] a membrane bound metaloenzyme.

Grisham and Mildvan[1] have proposed a mechanism for the action of (Na$^+$ + K$^+$)ATPase. An essential part of this proposal is coordination of manganese(II) to the enzyme and subsequent coordination of ATP to form a ternary complex. Using nuclear magnetic resonance techniques one tight binding site for manganese(II) with a dissociation constant, K_D, of 0.88 μM has been found.[1] Kinetic studies have given an activator constant K_A of the same value, thus identifying the single tight manganese(II) binding site as the active site of the enzyme.[3]

Dissociation constants for ternary Mn(II)–(Na$^+$ + K$^+$)ATPase–phosphate and methylphosphonate[1] complexes have also been determined. However, because of the rapidity of ATP hydro-

lysis no ternary ATP complex has been studied. In an attempt then, to throw more light onto the role of the metal-ion in the sodium pump mechanism, the stability constants of ternary Mn(II)–model (Na$^+$ + K$^+$)ATPase–ATP have been determined. In choosing a simple molecule as a model for the enzyme cognizance was taken of the known strength of Mn-enzyme binding. This dictated the use of a multidentate mixed nitrogen, oxygen donor ligand, e.g. nitrilotriacetic acid (NTA).

RESULTS AND DISCUSSION

Protonation constants were determined for ATP and found to agree with the literature (Table 1). Formation curves (Fig. 1) for the Mn(II)–ATP system at different total metal and ligand concentrations were non-superimposable indicating the presence of protonated and/or hydroxo species. Final MINIQUAD[4] refinement resulted in the model given in Table 1. While the agreement between the experimental and theoretical formation curves is acceptable, at higher pH values there are reproducible systematic deviations. The low "crystallographic" R factor indicates the basic correctness of the model while the high χ^2 suggests the existence of further minor species. The introduction of hydroxo species did not result in a significant[5] improvement in the model and hence were discarded. The final results are in good agreement with the literature considering the different experimental conditions.

Fig. 1. Metal complex formation curves for the Mn(II)–ATP system at 25°C and $I = 150$ mmol dm^{-3} NaCl. The symbols represent different combinations of total ligand and total metal concentrations. The full lines represent corresponding theoretical curves obtained using the constants given in Table 1.

A similar set of experiments was carried out using NTA instead of ATP. In this case the formation curves were all superimposable indicating simple stepwise, mononuclear complex formation. MINIQUAD refinement resulted in a model and constants (Table 1) in very good agreement with the literature.

Potentiometric data from titrations of manganese(II), NTA and ATP with base were used to refine constants for the ternary system. Conditions were varied so as to maximise the formation of ternary species and minimise the formation of binary metal complexes. Again the final model (Table 1), as exemplified by the very low R value, is in good agreement with the experimental data. The high value for χ^2 may be a result of inadequately defining the binary Mn(II)–ATP system.

In order to compare the formation constants of our model system with results obtained for the native enzyme system it is necessary to calculate the association constants for the various interactions of a pH of 7.4. This can be done using the appropriate equations, e.g.
$$Mn + ATP \rightleftarrows MnATP$$

$$K_a = \frac{[MnATP]}{[Mn][ATP]}$$

where [ATP] = total concentration of uncomplexed ATP. In this way K_a, for the model system, is calculated to be 2.07 log units. This does not compare well with association constants of 5.32 and 5.14 log units for complexation of inorganic phosphate and methylphosphate respectively, to the Mn–ATPase complex.[1] However the stability of these latter two complexes is far greater than ATP with Mn(II) on its own (log $K_a = 4.7$). Since the presence of a bulky ligand (the $Na^+ + K^+$)ATPase protein molecule) on the metal centre is expected to destabilize any subsequent chelation (as shown by the model system) there must be a very substantial interaction between ATP and the protein in the ternary $(Na^+ + K^+)$ATPase–Mn(II)–ATP complex, i.e. coordination to the Mn(II) alone cannot account for the stability of the complex. Grisham and Mildvan[1] have postulated the existence of bridging sodium ions between the phosphate residues of ATP and the protein. However it is difficult to envisage such an electrostatic interaction stabilizing the complex by a factor of 10^4.

Of special interest is the amount of ternary complex formed at physiological pH. To this end a species distribution diagram (Fig. 2) was constructed. This shows that at no time is an appreciable amount of the Mn(II)–ATP complex formed. Rather initial coordination is to NTA followed, at higher pH, by formation of the ternary Mn(II)–NTA–ATP complex. An essential feature of the proposed Grisham and Mildvan[1] sodium pump mechanism is the deprotonation of the ternary complex upon migration to the outer surface of the cell membrane. In our model system this
Fig. 2. Species distribution diagram for the ternary Mn(II)/NTA/ATP system. Total concentrations of Mn(II), NTA and ATP are: 3.3×10^{-3}, 3.3×10^{-3}, 7.9×10^{-3} mol cm^{-3} respectively. Using the notation (IIII) to represent species $ATP^{4-} \cdot NTA^{3-} \cdot Mn^{2+} \cdot H^+$: 1 = (1000), 2 = (0010), 3 = (1010), 4 = (1011), 5 = (1012), 6 = (1001), 7 = (1002), 8 = (0101), 9 = (0102), 10 = (0103), 11 = (0110), 12 = (1110) and 13 = (1111).

deprotonation does take place but at a physiologically unrealistic pH of 6.5. Even so the duplication of this feature is encouraging.

In conclusion, although our simple model of $(Na^+ + K^+)$ATPase is not in good quantitative agreement with the enzyme system, it does duplicate several of the essential features, viz. (i) coordination of ATP to the metal–ion, (ii) increased stability due to interaction with the protein and (iii) deprotonation of the complex at higher pH.

EXPERIMENTAL

Stock solutions of nitrilotriacetic acid (Merck) and manganese(II) chloride were standardised by a Gran[6] plot and compleximetric (EDTA) titration respectively. ATP (Merck) being unstable, was weighed directly into the titration vessel. All solutions were prepared using degassed, glass distilled water.

Potentiometric titrations were carried out as described in Ref. 7, all studies being performed at $25.00° + 0.05°C$ and $I = 150$ mmol dm^{-3} in NaCl. The electrode system was calibrated using the MAGEC[8] approach. Protonation curves for the ligands were obtained at different total ligand concentrations while metal complex formation curves were obtained at different metal:ligand ratios and for different total ligand and total metal concentrations. All titrations were repeated at least twice to check the reproducibility of the system. The data was treated to MINIQUAD[4] least squares analysis and the resulting "best" set of constants checked using the PSEUDOPLOT[9] approach.

THIOCYANATO ADDUCTS OF CHROMIUM(II) CARBOXYLATES AND THE MOLECULAR STRUCTURE OF TETRAETHYL-AMMONIUM TETRA-μ-PROPIONATODIISOTHIO-CYANATODICHROMATE(II)

PETER D. FORD, LESLIE F. LARKWORTHY,* DAVID C. POVEY
and ANDREW J. ROBERTS
Department of Chemistry, University of Surrey, Guildford GU2 5XH, England

Abstract—X-Ray crystallographic studies on $[NEt_4]_2[Cr_2[(O_2CC_2H_5)_4(NCS)_2]$ show that the Cr–Cr separation (2.467 Å) in the dinuclear anion is one of the longest known. The thiocyanato groups are N-bonded, and the results emphasize the known sensitivity of the quadruple Cr–Cr bond to the nature of the axial ligands. The compound crystallises in the tetragonal space group $P4/mnc$ with two molecules per unit cell, the dimensions of which are $a = b = 9.785(1)$, $c = 21.186(2)$ Å. Magnetic investigations from room to liquid nitrogen temperature on the tetra-μ-propionato complex and on $[NMe_4]_2$ $[Cr_2(O_2CCH_3)_4(NCS)_2]$ show that both complexes have been obtained free from paramagnetic chromium(III) impurities. Their weak paramagnetic susceptibilities (χ_{Cr} is approx. 200×10^{-6} cm^3 mol^{-1} at 295 K and 50×10^{-6} cm^3 mol^{-1} at 90 K) are inherent, and are ascribed to temperature independent paramagnetism at low temperature plus paramagnetism arising from slight population of the triplet state ($2J \simeq 700$ cm^{-1}, $g = 2$, $N\alpha = 50 \times 10^{-6}$ cm^3 mol^{-1}) at higher temperatures.

The preparation of the first dichromium carboxylato complex with axially bonded anions, $[NEt_4]_2[Cr_2(O_2CCH_3)_4(NCS)_2]$, was recently reported.[1] From its reflectance spectrum and a correlation[2] between the band frequencies and Cr–Cr separations in known compounds, it was suggested[1] that the Cr–Cr separation in this compound should be among the longest known. Single crystal investigations have now shown that this is true for the analogous compound $[NEt_4]_2$ $[Cr_2(O_2CCH_2CH_3)_4(NCS)_2]$.

RESULTS AND DISCUSSION

Structure of the dinuclear anions

The carboxylato-bridged dinuclear structure of the anions in $[NEt_4]_2[Cr_2(O_2CCH_2CH_3)_4(NCS)_2]$ is represented in Fig. 1. The anions have $4/m$ symmetry, with the linear N-bonded thiocyanato ligands along the four fold axis defined with the Cr–Cr bond. Coordination of thiocyanate through nitrogen increases the N–C bond length (1.168 Å,

Table 1) and decreases the C–S bond length (1.614 Å) compared with the free ion values (1.149 and 1.689 Å).[3] This is the usual effect of coordination through nitrogen. All Cr–O bond lengths

are equal (2.019 Å), and very close to the average value (2.018 Å) in $[Cr_2(O_2CCH_3)_4(OH_2)_2]^4$. The Cr–O bonds of the CrO_4 units are bent towards the Cr–Cr bond (Cr'–Cr–O = 86.5°) presumably because the Cr–Cr bond length (2.467 Å) is greater than can be accommodated without distortion by the bite of the carboxylato ligands.

Extensive crystallographic investigations[5] have emphasized how the length of the Cr–Cr bond is primarily dependent upon whether axial ligands are present. Axial ligands donate electron density into the $d_{z^2} - d_{z^2}\sigma^*$ antibonding orbital and so lengthen the bond, the effect being greater with more strongly donating (basic) ligands. The nature of the bridging ligands is secondary, but the Cr–Cr bond is longer when weakly donating bridges are present.

Tetra-μ-carboxylato dichromium(II) complexes show a range of Cr–Cr bond distances from 2.28 Å in $[Cr_2(O_2CC_{14}H_9)_4(DME)_2]$ (DME = 1,2-dimethoxyethane) to 2.54 Å in $[Cr_2(O_2CCF_3)_4(Et_2O)_2]$, and in all cases axial ligands are present. Excluding the trifluoroacetate complex, which is exceptional in the weak donor nature of the bridge, the thiocyanato complex has the longest Cr–Cr bond.

N-bonded thiocyanate is usually considered a σ-donor, with a weaker ligand field than ammonia or pyridine, and, as isothiocyanic acid is a strong acid[3], NCS^- is a weak base. Nevertheless, since the Cr-Cr bond in the thiocyanato adduct is longer than in the pyridine (2.369 Å) and pyrazine (2.342 Å) adducts of chromium(II) acetate[5], NCS^- has greater donor strength than these amines towards the Cr–Cr bond. This may be because the charge and weak π-donor ability of NCS^- offset its lower basicity.

The Cr-Cr bond is considerably shorter than the Cu–Cu bond (2.643 Å)[6] in the analogous copper(II) dimer, $[NMe_4]_2[Cu_2(O_2CCH_3)_4(NCS)_2]$, and the Cr–N bond (2.249 Å) is somewhat longer than the Cu–N bond (2.08 Å), but in other respects the two structures have similar geometry.

Magnetic investigations

Owing to the difficulty in preventing oxidation, it has been uncertain whether the weak paramagnetism of chromium(II) acetate samples is inherent or arises from traces of chromium(III) impurities. The magnetic behaviour over a temperature range of one sample of chromium(II) acetate monohydrate[7a] could be reproduced by assuming strong interactions in a dinuclear structure $\{2J = 1250°(869\,cm^{-1})\}$, and 0.3% Cr^{3+} impurity ($\mu_{eff} = 3.87$ B.M., independent of T). Similar behaviour was found[1] for $[NMe_4]_2[Cr_2(O_2CCH_3)_4(NCS)_2]$. On the other hand, unpublished magnetic susceptibility measurements on $[Cr_2(O_2CCH_3)_4(OH_2)_2]$ are said[2] to show that the ground state consists of filled shells, and the weak paramagnetism of $[Cr_2(O_2CCH_3)_4(NH_3)_2]$ was ascribed[8] to temperature independent paramagnetism. Since molecular orbital calculations suggest[9] that the highest filled level lies some $5000\,cm^{-1}$ below the first excited level, population of the triplet state is expected to be insignificant at room temperature, and quadruply bonded Cr_2^{4+} species should be diamagnetic or at the most exhibit some temperature independent paramagnetism.

Samples of $[NMe_4]_2[Cr_2(O_2CCH_3)_4(NCS)_2]$ and $[NEt_4]_2[Cr_2(O_2CCH_2CH_3)_4(NCS)_2]$, after correction for the diamagnetism of the ligands, gave small positive values of χ_{Cr} which decreased as the tem-

perature was lowered (Table 2). There is no increase in χ_{Cr} at low temperatures in contrast to the behaviour of the acetate, $[Cr_2(O_2CCH_3)_4(OH_2)_2]^{7a}$, the new stearate (see Experimental), and the earlier preparation[1] of $[NEt_4]_2[Cr_2(O_2CCH_3)_4(NCS)_2]$, which all showed increases in χ_{Cr} at low temperatures due to small amounts of chromium(III) impurities. The data for $[NMe_4]_2[Cr_2(O_2CCH_3)_4(NCS)_2]$ and $[NEt_4]_2[Cr_2(O_2CCH_2CH_3)_4(NCS)_2]$ can be approximately reproduced over the available temperature range by substitution of $J = 375 \, cm^{-1}$ (NMe$_4$ salt), $J = 320 \, cm^{-1}$ (NEt$_4$ salt), $g = 2$ and $N\alpha = 50 \times 10^{-6} \, cm^3 \, mol^{-1}$ in the expression

$$\chi_{Cr} = \frac{Ng^2\beta^2}{kT}\left[\frac{1}{3+x^2}\right] + N\alpha$$

where $x = \exp(J/kT)$, to which the full expression[7b] for antiferromagnetic interaction in a binuclear chromium(II) complex ($S = 1$ or 2) reduces when J is large. Errors are large[7a] in measurements on weakly paramagnetic compounds but in these preparations paramagnetic impurities have been avoided so that the weak paramagnetism must be inherent. The singlet–triplet separation ($2J$) is of the order of $700 \, cm^{-1}$ which is inconsistent with the molecular orbital calculations[9] and the tentative assignment[2] of the $\delta \to \delta^*$ transition to a weak band at approx. $16000 \, cm^{-1}$.

Spectroscopic investigations

The IR spectra of the complexes contain absorption bands (Table 3) characteristic[3] of N-bonded NCS^- groups in agreement with the crystal structure determination.

A detailed analysis[2] of the low temperature polarised single-crystal absorption spectrum of $[Cr_2(O_2CCH_3)_4(OH_2)_2]$ has shown that there are dominant absorption bands at approx. $21000 \, cm^{-1}$ (Band I) and approx. $30,000 \, cm^{-1}$ (Band II). Band I has been assigned to the $\delta \to \pi^*$ transition of the binuclear system intensified by vibronic coupling, and band II to charge transfer from a non-bonding π-orbital of the carboxylate ligand to the π^* metal orbital. The energies of bands I and II in a limited series of quadruply bonded dichromium complexes comprising the carbonate $[NH_4]_4[Cr_2(CO_3)_4(OH_2)_2] \cdot H_2O$ (Cr–Cr = 2.214 Å[10] and some carboxylato complexes {of which $[Cr_2(O_2CH)_4(C_5H_5N)_2]^{11}$ showed the longest Cr–Cr separation (2.408 Å)} have been found [2] to decrease linearly with increasing Cr–Cr separation. Bands I and II in the powder reflectance spectra of the thiocyanate adducts (Table 3) are at lower frequencies than any in the above series in agreement with the greater Cr–Cr separation (2.467 Å).

The diffuse reflectance spectra of Cs_4 $[Cr_2(SO_4)_4(OH_2)_2] \cdot 2H_2O^{12}$, $[Cr_2(O_2CCH_3)_4(NH_3)_2]^8$ $[Cr_2(stearate)_4(OH_2)_2]$ are included in Table 3. From the frequencies the Cr–Cr separation

would be expected to decrease in the order given, with the separation in the amine being approx. 2.5 Å commensurate with the high basicity of ammonia. The stearate is likely to have as short a Cr–Cr bond as the carbonate complex. Unfortunately, crystallographic data are not available for these three complexes.

EXPERIMENTAL

In the preparation[1] of [NEt$_4$]$_2$[Cr$_2$(O$_2$CCH$_3$)$_4$(NCS)$_2$], chromium(II) acetate monohydrate was extracted into a hot ethanolic solution of tetraethylammonium thiocyanate. The thiocyanate solution was obtained by mixing equimolar solutions of tetraethylammonium chloride and potassium thiocyanate in ethanol, followed by centrifugation to remove the precipitated chloride. This procedure was satisfactory with the acetate, but the corresponding propionate was not obtained pure. In the present work the tetraethylammonium and tetramethylammonium thiocyanates were first isolated.

To prepare [NMe$_4$]NCS equimolar amounts of the alkylammonium bromide (10.00 g) and potassium thiocyanate (6.31 g) were refluxed in absolute ethanol (150 cm^3). Potassium bromide was filtered off from the hot solution using a fine filter paper, the solution reduced to half volume, allowed to cool to room temperature, and residual KBr filtered off. Crystalline tetramethylammonium

thiocyanate was obtained by cooling the filtrate overnight in a refrigerator. It was twice recrystallised from a minimum of absolute ethanol. In the preparation of tetraethylammonium thiocyanate, the crude product was obtained by the slow addition of dried ether to the ethanolic solution. The hygroscopic thiocyanate was recrystallised from a minimum volume of a 5:2:3 mixture of ethanol, acetone and ether.

The monohydrates of chromium(II) acetate and chromium(II) propionate crystallised when a solution of chromium(II) bromide obtained from hydrobromic acid and the metal was filtered into a solution containing the sodium carboxylate in small excess. Previously,[13] spectroscopically pure chromium has been used in the preparation of chromium(II) salts, but the less expensive electrolytically produced metal (99.5%) supplied by BDH Chemicals Limited has been found satisfactory.

Preparation of ditetramethylammonium tetra-μ-acetatodiisothiocyanatodichromate (II)

Chromium(II) acetate monohydrate (1.54 g) was extracted by boiling ethanol (125 cm^3) containing an equimolar amount of tetramethylammonium thiocyanate (1.07 g). The suspension was refluxed for about 30 m, and, as the thiocyanato complex proved to be almost insoluble in ethanol, it was filtered off and dissolved in boiling, dry methanol (150 cm^3). On cooling, violet crystals appeared.

These were filtered off, washed with cold ethanol, and dried by continuous pumping for 2 hr. Yield = 55%. Found: C, 35.8; H, 6.00; N, 9.13. $C_9H_{18}N_2O_4SCr$ requires C, 35.8; H, 6.00; N, 9.27%.

Preparation of ditetraethylammonium tetra-μ-propionatodiisothiocyanatodichromate (II)

Chromium(II) propionate monohydrate (1.22 g) was extracted by boiling ethanol (100 cm³) containing an equimolar amount (0.75 g) of tetraethylammonium thiocyanate, and the solution refluxed for 1 hr. Violet crystals were obtained on slow cooling. The crystals were filtered off and dried as above. Since the complex oxidises only slowly, it was possible to select a crystal suitable for X-ray investigation in air and seal it under nitrogen in a Lindemann capillary to prevent long term oxidation. Yield = 65%. Found: C, 46.8; H, 7.98; N, 7.27. $C_{15}H_{30}N_2O_4SCr$ requires C, 46.6; H, 7.82; N, 7.25%.

Preparation of tetra-μ-stearatodichromium (II) dihydrate

To prepare the stearate $[Cr_2(O_2C(CH_2)_{16}CH_3)_4(OH_2)_2]$, sodium stearate was extracted with boiling water into a solution of chromium(II) bromide prepared as for the acetate and propionate. The orange product was filtered off, washed with cold water and dried as above. The insolubility of the stearato complex in common solvents frustrated attempts to prepare a thiocyanate adduct. Yield = 60%. Found: C, 68.45; H, 11.1. $C_{36}H_{72}O_5Cr$ requires C, 67.9; H, 11.4%.

The IR spectrum contained a broad water absorption at 3400 cm⁻¹. The sample was contaminated with approx. 2% of chromium(III) impurity since its magnetic behaviour paralleled that of the earlier preparation[1] of $[NEt_4]_2[Cr_2(O_2CCH_3)_4(NCS)_2]$, but with values of χ_{Cr} approximately twice as large ($\mu_{eff} = 0.9$ B.M. at 294 K and 0.6 B.M. at 90 K).

Physical measurements

Magnetic measurements were carried out from room to liquid nitrogen temperature by the Gouy method. Because of their very weak paramagnetism, about 1.2 g of the samples was packed into wide bore (5 mm) quartz tubes, and since traces of oxidation can markedly affect the magnetic results this was done in all-glass apparatus within an inert atmosphere box. The box, fitted with a re-circulatory gas purification system, was manufactured by Faircrest Engineering Ltd., Croydon.

Electronic spectra were recorded on a Beckman Acta MIV recording spectrophotometer provided

with a diffuse reflectance attachment. A lithium fluoride reference was used and the samples were sealed under nitrogen. Infrared spectra of nujol mulls were recorded on a Perkin–Elmer 577 spectrophotometer.

CRYSTALLOGRAPHIC STUDIES

Crystal data

$[C_{14}H_{20}N_2O_8Cr_2S_2][(C_2H_5)_4N]_2$, M = 768.97, tetragonal, $a = b = 9.785(1)$, $c = 21.186(2)$ Å, $U = 2028.5$ Å space group $P4/mnc$, $Z = 2$, $D_c = 1.26$ g. cm⁻³, D_m not measured, F(000) = 816, $\mu(Mo-K_\alpha = 6.3$ cm⁻¹.

Data collection

Enraf Nonius CAD4 diffractometer, Mo–K_α radiation. ($\lambda = 0.71069$ Å, graphite monochromator), crystal sealed under nitrogen in a Lindemann glass capillary, $\theta/2\theta$ scan mode, $1.0° \leqslant \theta \leqslant 25.5°$, 1905 data measured as orthorhombic, reduced to 1001 unique reflexions, 541 observed [$I \geqslant 2.50\,\sigma(I)$]; uncorrected for absorption but corrected for crystal decay during measurement (intensity of reference reflexion dropped by 17%).

Structure solution and refinement

The structure was solved by the heavy atom method and refined by full matrix least squares to a final conventional R-factor of 0.046 [weighting scheme used: $W = 1/[\sigma^2(F_0) + 0.04\,F_0^2]$. Non-hydrogen atoms were assigned anisotropic thermal parameters and all hydrogen atoms from the tetraethylammonium cation were located from a difference map and included in the refinement with isotropic thermal parameters. The positioning of the terminal carbon atom C(4) has proved extremely difficult. Electron density maps persistently located this atom off the mirror plane (*xyo*) thus producing a sec-butyrate although microanalyses do not support this. We are forced to conclude that this atom is disordered and a fixed occupancy of 0.5 has been assigned. The C(3)–C(4) bond length is very short and as such must be regarded as artificial although attempts to fix the C(4) atom at a more reasonable position resulted in a large increase in its thermal parameters. Its refined position is, therefore, one which produces a minimum in the R-factor.

VAPOUR PHASE CHEMISTRY OF
OXOVANADIUM IV β-DIKETONATES

D. A. JOHNSON and A. B. WAUGH*

Chemical Technology Division, Australian Atomic Energy Commission, Lucas Heights
Research Laboratories, Lucas Heights, Sydney 2232, Australia

Abstract—A series of fluorinated and one non-fluorinated β-diketonate complexes of oxovanadium IV have been prepared, their gas phase IR spectra examined, vapour pressures determined and their vapour phase thermal decomposition investigated. Decomposition of the fluorinated complexes occurred according to the overall reaction scheme $VO(\beta\text{-diket})_2 \rightarrow VOF_2 + $ Furanone. The furanones $C_5HF_5O_2$, $C_5H_4F_2O_2$ and $C_8H_{10}F_2O_2$ were isolated and identified. The non-fluorinated complex gave the parent diketone and a vanadium oxide as its principal products.

While there are abundant structural[1-5] and spectral data[1,2,5-8] available for vanadyl β-diketonates as solids and in solution, little information is available on their thermal properties. The only vapour phase chemistry reported[9-12] relates to the gas chromatography of these complexes.

This study was undertaken as a prelude to later investigations[13] into IR laser irradiation of vanadyl β-diketonates. For these investigations it was necessary to know the vapour pressures, vanadyl absorption frequencies and the products from vapour phase thermal decomposition. Some known compounds[6,11] and others not previously reported were prepared and characterized. Gas phase IR spectra and vapour pressures were measured and vapour phase thermal decompositions investigated.

EXPERIMENTAL

Preparation of metal complexes

Complexes of the following β-diketonates were prepared; hexafluoroacetylacetone (HHFA), trifluoroacetylacetone (HTFA), pivaloyl trifluoroacetone (HPTA) and dipivaloyl methane (HDPM).

$VO(HFA)_2$, $VO(TFA)_2$, $VO(DPM)_2$ and VO-

*Author to whom correspondence should be addressed. Present address: CSIRO, Division of Energy Chemistry Lucas Heights Research Laboratories, Private Mail Bag 7, Sutherland, NSW 2232, Australia.

$(PTA)_2$ were prepared by a modified procedure of Selbin *et al.*[6] in which vanadyl sulphate was maintained in excess of the diketone. Weakly coordinated water associated with these complexes was removed under vacuum.

An extraction method was used to prepare the complex $VO(HFA)_2TMP$. A chloroform solution of 0.8 mmole HHFA and 0.4 mmole of trimethyl phosphate was shaken with 0.4 mmole of $VOSO_4$ in distilled water. The chloroform layer was separated, washed, dried and then evaporated with dry nitrogen. $VO(HFA)_2py$ was prepared by the addition of a stoichiometric amount of pyridine to a chloroform solution of $VO(HFA)_2$, followed by removal of the solvent.

The complexes were purified by vacuum sublimation and then by sublimation in a flow tube apparatus with a dry nitrogen carrier gas at reduced pressure. Results of elemental analyses are shown in Table 1.

IR spectra and vapour pressure determinations

Gas phase spectra of the purified complexes were measured using a Perkin–Elmer 225 spectrophotometer. The compound was contained in an evacuated heatable 10 cm cell fitted with NaCl windows. Condensation of compounds on the windows was prevented by having a side arm on the cell at a lower temperature than the windows.

A calibrated flow of nitrogen carrier gas was employed to determine the vapour pressures of the complexes by the mass transport method.

* Oxygen was not analysed in the presence of fluorine

Vapour phase thermal decompositions

Samples of the complex were volatilized and carried through a heated zone at 460°C with an average residence time of 0.5 s. The volatile decomposition products were collected in a U-tube at 77 K. Capillary chromatography was used to determine the number of volatile products formed. Purification of products was achieved using a 2 m 10% cetyl phosphate on celite column. The components were analysed by mass spectrometry using an A.E.I. MS3 and their gas phase IR spectra determined. Non-volatile components remaining in the decomposition tube were washed out with water, acidified and analysed for vanadium and fluorine.

RESULTS AND DISCUSSION

IR *spectra of complexes*

In the range 1100–900 cm^{-1}, two absorption bands were observed for all compounds. The very intense band in each instance is the V=O stretch and the very weak, broad band in the 950–960 cm^{-1} range is a ligand absorption. A very weak band in this region has also been observed by the authors for the compound Cu(HFA)$_2$, and by others[14] for the compound U(HFA)$_4$.

The frequencies of the vanadyl stretch for the complexes in the gaseous state at 160°C are listed in Table 2. Full width half maximum height measurements determined from expanded scale spectra were approx. 9 cm^{-1} for all complexes.

Vapour pressure data

The vapour pressure equations and enthalpies of vaporization have been calculated and are summarized in Table 3. Generally speaking, the vanadyl β-diketonates are considerably more volatile than their uranyl analogues.[15,16]

Analysis of thermal decomposition products

Mass spectral analysis of the volatile decomposition products revealed, with one exception, only two products from each complex and the unaltered neutral ligand. In each instance, these products were a trace amount of the parent β-diketone and the remainder, a compound with a

molecular weight 20 amu less than that of the β-diketone.

The principal products from VO(TFA)$_2$ and VO(PTA)$_2$ decompositions display similarities in the IR spectra and in the mass spectral breakdown pattern to the product from VO(HFA)$_2$TMP, VO-(HFA)$_2$py and VO(HFA)$_2$ decompositions.

These HFA complexes give rise to a product identical to that observed in the thermal[17] and laser induced[18] decompositions of UO$_2$(HFA)$_2$L and to one of the products of the UV photolysis of HHFA.[19] This compound has been identified as the furanone C$_5$HF$_5$O$_2$ with a molecular weight 20 amu less than the parent diketone. However, in agreement with Ekstrom et al.[17] we have observed (Table 4) differences in the mass spectrum reported by Bassett and Whittle.[19] We also observe a different gas phase molar extinction coefficient for this furanone. A sample purified by gas chromatography indicated $\epsilon_{247nm} = 6070$ L mol^{-1}cm^{-1}, compared to $\epsilon_{247nm} = 3000$ L mole^{-1} cm^{-1} found by Bassett and Whittle.

Fragmentation of the molecular ion C$_5$HF$_5$O$_2$$^+$ (Fig. 1) occurs via two routes.[17] The first involves loss of a neutral COF$_2$ fragment followed by loss of CO and subsequent breakdown. A second route involves loss of F before losses of COF$_2$ and CO.

The mass spectrum of the VO(TFA)$_2$ decomposition product has a parent ion m/e 134. Its fragmentation, with loss of a neutral COF$_2$ followed by loss of CO (Fig. 2), is similar to that observed for C$_5$HF$_5$O$_2$.

The spectrum of the product from VO(PTA)$_2$ indicates one breakdown pattern (Fig. 3) of the ion m/e 176 (mw of HPTA is 196) which parallels the second route for C$_5$HF$_5$O$_2$. In this instance, however, a methyl group is removed before the COF$_2$ and CO fragmentations.

The IR spectra of products from VO(TFA)$_2$ and VO(PTA)$_2$ decompositions display absorptions (Table 5) near the 1786 and 1684 cm^{-1} bands of the furanone C$_5$HF$_5$O$_2$. These bands have been assigned[17,19] as C=O and C=C absorptions respectively. Likewise each compound has an absorption near the 1163 cm^{-1} band of C$_5$HF$_5$O$_2$. Brown and Morgan[20] suggest that absorptions in this range may be due to the stretching vibrations of an isolated CF$_2$ group.

The presence of carbonyl and ethylenic groups in the spectra, the existence of an ion 20 amu less than the parent β-diketone and the similarities in the mass spectral breakdown pattern indicate that these compounds are analogues of the furanone.

The latter has been shown[17] to be formed from a

uranyl HFA complex by loss of a fluoride ion to the central metal atom from the coordinated ligand, and the residue of the ligand cyclizing to form an ether linkage.

By analogy with the stoichiometry of the uranyl system, the co-decomposition product of a furanone from a vanadyl β-diketonate decomposition should be VOF_2. Analyses for V and F on the aqueous washes from VO(HFA)$_2$, VO(HFA)$_2$TMP and VO(TFA)$_2$ decompositions were variable. This was possibly due to secondary reactions and reaction with the glass decomposition tube. The aqueous solutions were blue due to vanadyl ion, as confirmed by polarography. Later work on laser decomposition of VO(PTA)$_2$[13] indicated a V:F ratio of 1:1.9 in the aqueous wash.

In view of the spectral evidence and the presence of vanadyl fluoride as a co-decomposition product, the thermal decomposition of fluorinated vanadyl β-diketonates parallels the decomposition of fluorinated uranyl β-diketonates, VO(β-diket)$_2$L$\rightarrow$VOF$_2$ + L + Furanone. The following structures are proposed for the two new furanones formed from the complexes VO(TFA)$_2$ and VO(PTA)$_2$

The mode of decomposition of VO(DPM)$_2$

differs from the mode of decomposition in which a furanone and VOF_2 are formed. HDPM is the principal product, with lesser amounts of CO and 2-methylpropene as confirmed by mass spectrometry. A further thirty compounds were detected by capillary chromatography on a 50 m OV–101 glass column. A black non-volatile residue, which may be VO or VO_2, remained in the decomposition tube.

A different decomposition route is evident for β-diketonates in which the ligand is purely hydrocarbon. The absence of atoms or groups capable of leaving as negative ions, such as F^- in the case of fully and partly fluorinated ligands, is undoubtedly significant with respect to the mode of decomposition.

EQUILIBRIUM AND STRUCTURAL STUDIES OF SILICON(IV) AND ALUMINIUM(III) IN AQUEOUS SOLUTION—10. A POTENTIOMETRIC STUDY OF ALUMINIUM(III) PYROCATECHOLATES AND ALUMINIUM(III) HYDROXO PYROCATECHOLATES IN 0.6 M Na(Cl)

LARS-OLOF ÖHMAN* and STAFFAN SJÖBERG
Dept. of Inorganic Chemistry, University of Umeå, S-901 87 Umeå, Sweden

Abstract—Equilibria between aluminium(III), pyrocatechol (1,2-dihydroxybenzene, H_2L) and OH^- were studied in 0.6 M Na(Cl) medium at 25°C. The measurements were performed as emf titrations (glass electrode) within the limits $1.5 \leq -\log[H^+] \leq 9$; $0.0005 \leq B \leq 0.015$ M; $0.006 \leq C \leq 0.03$ M and $2 \leq C/B \leq 30$ (B and C stand for the total concentrations of aluminium(III) and pyrocatechol respectively). All data can be explained with a main series of complexes: AlL^+, $\log \beta_{-2,1,1} = -6.337 \pm 0.005$; AlL_2^-, $\log \beta_{-4,1,2} = -15.44 \pm 0.017$ and AlL_3^{3-}, $\log \beta_{-6,1,3} = -28.62 \pm 0.024$ together with two minor species: $Al(OH)L_2^{2-}$, $\log \beta_{-5,1,2} = -23.45 \pm 0.079$ and $Al_3(OH)_3L_3$, $\log \beta_{-9,3,3} = -29.91 \pm 0.066$. Of the two, the latter probably is a type of average composition complex principally occurring at low C/B quotients. The first acidity constant for pyrocatechol as determined in separate experiments is $\log \beta_{-1,0,1} = -9.198 \pm 0.001$. The standard deviations given are $3\sigma(\log \beta p,q,r)$. Data were analyzed with the least squares computer program LETAGROPVRID. In a model calculation using kaolinite as solid phase, we compared the complexation ability of this system with that of the system $Al^{3+}-OH^-$-salicylic acid, reported earlier in this series.

During the last decades, precipitation (rain, snow) has become increasingly acidic due to the extensive use of sulphur containing fossil fuels. In areas of poorly buffered bedrocks, i.e. non-carbonate bedrocks, this phenomenon has resulted in elevated amounts of Al(III) being leached into streams and lakes. Although Al(III) has been regarded earlier as quite non-toxic, recent findings reveal that the elevated aluminium concentrations could cause severe damage to fish and other biota.[1] It is, however, important to realize that all aluminium leached into the environment does not solely occur as free Al^{3+}-ion and hydroxo complexes. Due to the ubiquitous occurrence of complex forming compounds (mainly of an organic origin) some of the aluminium occurs as complex bound and this influences the speciation, total solubility and toxicity of Al(III) in natural waters. Furthermore, the occurrence of octahedrally coordinated aluminium in nearly neutral and slightly alkaline solution has

been shown to be of vital importance for the formation of clay minerals at low temperatures.[2]

In a current project at this department, we are systematically investigating the ability of Al(III) to form complexes with ligand classes occurring in natural waters, with special reference to the formation of mixed hydroxo complexes. In a preceding paper of this series,[3] we investigated the complex formation between Al^{3+} and salicylic acid (2-hydroxy-benzoic acid) and found, in a comparison with the system Al^{3+}-OH^--gallic acid[4,5] (3,4,5-trihydroxy-benzoic acid) that the Al-o-hydroxybenzoate complexes dominate at low $-\log h$ ($h = [H^+]$), whereas the o-diphenolic complexes dominate in nearly neutral and alkaline solution. However, due to the eventual influence of the substituting groups on gallic acid we also pointed out the necessity to perform this comparison with the unsubstituted o-diphenol, pyrocatechol (1,2-dihydroxybenzene, H_2L). The complex formation between Al^{3+} and pyrocatechol has been the subject of a number of investigations,[6-9] all of which indicate the formation

---

*Author to whom correspondence should be addressed.

of three mononuclear complexes AlL^+, AlL_2^- and AlL_3^{3-}. Yet, when the formation constants for these species are compared, it is found that the authors have reported constants differing by powers of ten. A critical perusal of these papers show that all these investigations are based on relatively few experimental data with small variations in Al^{3+}/pyrocatechol-quotient and total concentrations. Furthermore, in none of these papers has any unbiased search for complex model been applied. Therefore we have found it valuable for the user of formation constants and quite necessary for our comparison to perform a careful and unbiased investigation of this system.

EXPERIMENTAL

Chemicals and analysis. Pyrocatechol (1,2-dihydroxybenzene) (Merck *p. a.*) was sublimed before use. Stock solutions were prepared by dissolving $C_6H_4(OH)_2$ in standardized HCl and the content checked potentiometrically. The titrated amount was in full agreement (within 0.1%) with that expected from weighing. After preparation, the solution was used within a few days to avoid effects from the slow oxidation which occurs in acidic solution. Stock solutions of sodium chloride and aluminium chloride as well as the dilute hydrochloric acid and sodium hydroxide solutions were prepared and standardized as described earlier.[4]

Apparatus. The automatic system for precise EMF titrations, the thermostat and the electrodes were described earlier.[4] In order to protect neutral and alkaline solutions from oxygen, we have taken the same precautions as in Part 1 of this series.[4]
METHOD

The present investigation has been carried out as a series of potentiometric titrations at 25°C in a constant ionic medium of 0.6 M Na(Cl). The titration procedures, calibrations and the assumptions made in connection with the use of the glass electrode were the same as described earlier.[4]

The first acidity constant of pyrocatechol was determined in separate titrations within the concentration range 0.005–0.04 M and $-\log h \lesssim 9$. No attempts were made to evaluate the second acidity constant.

The three-component titrations were performed at constant C/B-ratios (B and C stand for the total concentration of aluminium(III) and pyrocatechol respectively) in the $-\log h$ range 1.5–9. The total concentration of H^+, H, calculated over the zero level H_2O, Al^{3+} and $C_6H_4(OH)_2$, was varied by means of burette additions of solutions containing H^+ or OH^-. The more advantageous method of

adding OH^- coulometrically, permitting titrations at constant B and C, was not applicable in this system as some unknown side reaction took place together with the H^+ reduction. B and C were varied within the limits $0.0005 \leq B \leq 0.015$ M and $0.006 \leq C \leq 0.03$ M covering the C/B ratios: 30, 15, 10, 7.5, 6, 4 and 2. At $C/B = 4$ and 2, the available $-\log h$ range was restricted to an upper limit due to extremely slow attainment of equilibrium. (The potentials were found to be still drifting after 12 hr without any visible precip-. itation.) To test reproducibility and reversibility of equilibria, both forward (increasing $-\log h$) and backward (decreasing $-\log h$) (see *Special precautions* in Ref. 4) titrations were performed.

Data treatment. The total complexation behaviour of a system producing or consuming OH^- can suitably be illustrated by the function $Z_c(-\log h)$, i.e. the average number of OH^- reacted per ligand. A plot of this kind is given in Fig. 1 where the appearance of the curves reflect the binary (eqns 1 and 2) as well as the ternary complexes (eqn 3) in the system, forming as follows:

$$C_6H_4(OH)_2 \Leftrightarrow C_6H_4O(OH)^- + H^+ \quad \beta_{-1,0,1} \quad (1)$$

$$p\,H^+ + q\,Al^{3+} \Leftrightarrow H_pAl_q^{p+3q} \quad \beta_{p,q,0} \quad (2)$$

$$p\,H^+ + q\,Al^{3+} + r(C_6H_4(OH)_2) \Leftrightarrow H_pAl_q$$
$$(C_6H_4(OH)_2)_r^{p+3q}; \quad \beta_{p,q,r}. \quad (3)$$

For determining the first acidity constant of pyrocatechol (eqn 1) we will make use of results obtained in separate experiments. The hydrolysis of Al^{3+} (eqn 2) has been studied earlier in this series.[10,11] These studies have given evidence for the following main species and corresponding equilibrium constants: $AlOH^{2+}$; $\log \beta_{-1,1,0} = -5.52$, $Al_3(OH)_4^{5+}$; $\log \beta_{-4,3,0} = -13.57$, $Al_{13}O_4(OH)_{24}^{7+}$; $\log \beta_{-32,13,0} = -109.2$ and $Al(OH)_4^-$; $\log \beta_{-4,1,0} = -23.46$.

In the analysis of the three-component data, the results in these two-component subsystems are assumed as correct and all effects above this level are treated as being caused by ternary complex formation. The object of computation is then to determine sets of *pqr*-triplets and corresponding equilibrium constants that "best" fit the experimental data. In this evaluation the least-squares computer program LETAGROPVRID[12] (version ETITR[13,14]) was applied. As best model or models we consider those giving the lowest error squares sum $U = \Sigma[(H_{calc} - H_{exp})/C]^2$. The LETAGROP calculations also give standard deviations $\sigma(Z_c)$, $\sigma(\beta p, q, r)$ and $3\sigma(\log \beta_{p,q,r})$ which are defined according to Sillén.[15,16] The computations were performed on a CD CYBER 730 computer.
Fig. 1. A part of the experimental data plotted as curves $Z_c(-\log h) = (h - H - k_w h^{-1})/C$ for C/B ratios 2, 4, 6, 10, 15, 30 and ∞. Here k_w stands for the ionic product of water and H for the total concentration of protons, calculated over the zero level H_2O, Al^{3+}, $C_6H_4(OH)_2$. All symbols denote initial concentrations. The full curves have been calculated using the set of proposed constants in Table 1.

DATA, CALCULATIONS AND RESULTS

The data used to evaluate the first acidity constant of pyrocatechol comprises 6 titrations with 98 experimental points. The analysis ended at $\sigma(Z_c) = 0.002$ giving $\log(\beta_{-1,0,1} \pm 3\sigma) = -9.198 \pm 0.001$. The analysis of three-component data, comprising 19 titrations with 308 experimental points, was started by preparing the Bjerrum plot $\bar{n}(\log[L^{2-}])$. This plot is given in Fig. 2 in which the shape of the curves attests that the main complexes in the system are AlL^+, AlL_2^- and AlL_3^{3-}. (L^{2-} denotes the pyrocatecholate dianion $C_6H_4O_2^{2-}$). However, a comparison of the experimental curves with the theoretical ones, reveals that some systematic deviations remain at low C/B-quotients. Formation constants for the main species AlL^+, AlL_2^- and AlL_3^{3-} were evaluated by means of a LETAGROP calculation at high (10–30) quotients. This calculation ended at $\sigma(Z_c) = 0.003$ and the equilibrium constants obtained were $\log\beta_{-2,1,1} = -6.34 \pm 0.01$; $\log\beta_{-4,1,2} = -15.44 \pm 0.02$ and $\log\beta_{-6,1,3} = -28.62 \pm 0.03$.

When these equilibria were applied to the titrations at lower quotients and the residuals $\Delta = (H_{calc} - H_{exp})/C$ were plotted as a function of $-\log h$, two well-separated residual peaks divided at $-\log h \approx 6$ appeared. As these residual curves

showed a close resemblance to the analogous curves obtained in the system H^+-Al^{3+}-1,2-dihydroxynaphthalene-4-sulphonate[11] we decided to use the same approach, i.e. to try the simple hypothesis that each peak could be explained by a single complex $H_pAl_q(H_2L)_r^{p+3q}$. The strategy was thereby to find that pqr-combination with corresponding equilibrium constant which gives the lowest error squares sum $U = \Sigma[(H_{calc} - H_{exp})/C]^2$. The result of the first search, performed on the "acid" peak $(-\log h \lesssim 6)$, is given in Fig. 3 and it is seen that the complex $H_{-9}Al_3(H_2L)_3$ with $\log\beta_{-9,3,3} = -29.94 \pm 0.08$ gives the closest fit to the experimental data. In the same manner, the "alkaline" peak is best explained with the complex $H_{-5}Al(H_2L)_2^{2-}$; $\log\beta_{-5,1,2} = -23.46 \pm 0.08$ (Fig. 4).

In a final calculation the equilibrium constants for these species as well as those for the main species were varied on the whole data set. This calculation ended at $\sigma(Z_c) = 0.003$ and the final equilibrium constants are given in Table 1. With this final model, no systematic deviations remained. In order to visualize the amounts of the different species, the computer program SOLGASWATER[17] equipped with plotting procedures has been used to calculate some distribution diagrams. These are presented in Fig. 5.
Fig. 2. Experimental data plotted as curves $\bar{n}(\log[L^{2-}]) = \bar{n}(\log[C_6H_4(O)_2^{2-}])$. In the calculation, an arbitrary value of $\log k_2 = -13.0$ for the second acidity constant of pyrocatechol has been used. The chosen value affects the scale on the x-axis but not the shape of the $\bar{n}$ curves. The full curve has been calculated assuming the formation of AlL^+, AlL_2^- and AlL_3^{3-} and it is seen that minor systematic deviations remain with this model.

Fig. 3. Results of the first pqr-analysis concerning the "acid" $(-\log h \lesssim 6)$ peak. The diagrams give the error squares sums $U_{Z_c}(pr)_q \times 10^{-1}$ assuming one new complex. In the calculations, aluminium hydrolysis and the species $(-2, 1, 1)^+$, $(-4, 1, 2)^-$ and $(-6, 1, 3)^{3-}$ have been assumed to be known. The calculations are based on 212 points giving $U_{Z_c}(00)_0 = 1128 \times 10^1$.

Fig. 4. Result of the second pqr-analysis on the "alkaline" $(-\log h \gtrsim 6)$ peak. The complex $H_{-9}Al_3(H_2L)_3$ has, in addition to those complexes mentioned in the first pqr-analysis (some of them marked with a star in the left diagram), been assumed to be known and the diagrams give $U_{Z_c}(pr)_q \times 10^{-1}$ assuming one new complex. The calculations are based on 101 points giving $U_{Z_c}(00)_0 = 505 \times 10^1$.

Table 1. Binary and ternary complexes in the three-component system Al^{3+}-OH^--pyrocatechol. The formation constants are related according to the reaction $pH^+ + qAl^{3+} + rH_2L \Leftrightarrow H_pAl_q(H_2L)_r^{p+3q}$, where H_2L stands for pyrocatechol

No. of titr./ no. of points	p	q	r	Tentative formula	$lg(\beta_{pqr} \pm 3\sigma)$

	-5	1	2	$Al(OH)L_2^{2-}$	-23.45 ± 0.079

DISCUSSION

The present study has given evidence for the existence of a main series of complexes $(-2, 1, 1)^+$, $(-4, 1, 2)^-$ and $(-6, 1, 3)^{3-}$. As these complexes are most probably chelates between the aluminium(III) ion and the two *ortho*-coordinated phenolic groups on pyrocatechol (H_2L), the complexes could be written as AlL^+, AlL_2^- and AlL_3^{3-}. In addition to these major complexes, two hydrolyzed species, $(-9, 3, 3)$ and $(-5, 1, 2)^{2-}$, are formed, mainly at relatively low C/B-quotients (Fig. 5). These species could be written as $Al_3(OH)_3L_3$ and $Al(OH)L_2^{2-}$ respectively. In the evaluation of data, we pointed out the resemblance between this system and the H^+-Al^{3+}-1,2-dihydroxynaphthalene-4-sulphonate system.[11] A comparison of the results shows that while the more acidic deviations are best explained with a mononuclear species $(-3, 1, 1)$ in the dihydroxynaphthalenic system, the best fit in the present system is obtained assuming a trinuclear species $(-9, 3, 3)$. The present study was performed at higher total concentrations, which favours the formation of species with higher nuclearities. From this fact and also because a tendency of dimerization of $(-3, 1, 1)$ to $(-6, 2, 2)$ was indicated in the dihydroxynaphthalenic system, it is assumed that the $(-9, 3, 3)$ species actually is a polymerization product of $Al(OH)L$, i.e. $[Al(OH)L]_3$. Therefore the composition $(-9, 3, 3)$ should be regarded as average numbers and several degrees of polymerization probably exist in these solutions. This could also give an explanation to the very slow attainment of equilibria recorded at low C/B-quotients.

As for the more alkaline hydrolyzed species, the complex $(-5, 1, 2)$ $[= Al(OH)L_2]$ is the one that best fits in both systems. Furthermore, by com-

Fig. 5. Distribution diagrams $F_i(\log h)_{B,C}$. F_i is defined as the ratio between aluminium(III) in a species and total aluminium(III). The calculations have been performed using the computer program SOLGASWATER with equilibrium constants given in Table 1.
Fig. 6. Diagram showing predominating Al-species. In the calculations kaolinite was equilibrated with solutions of different compositions. The dissolution of kaolinite also yields small amounts of gibbsite, $Al(OH)_3$. Formation constants for kaolinite, amorphous SiO_2 and gibbsite are according to Helgeson.[18]

Fig. 7. The solubility of kaolinite, S_{Al}, with $C = 0$, 30 and 100 μM respectively.

paring the acidity constants obtained by writing the formation of this species as $AlL_2 + H_2O \Leftrightarrow Al(OH)L_2 + H^+$ (-8.01 and -8.04 for the phenolic and naphthalenic system respectively) the near resemblance between the systems is emphasized.

Besides the reservations made concerning the species ($-9, 3, 3$), we consider that the complexes are well established because of the low standard deviations of the equilibrium constants (Table 1).

Fig. 8. Diagram showing the sum of distribution coefficients, ΣF_i, for Al-pyrocatecholates (Al–P), Al-salicylates (Al–S), Al-hydrolysis (Al–OH) as well as $F_{Al^{3+}}$. The total concentration of pyrocatechol is equal to that for salicylic acid (30 μM) and kaolinite is the stable solid phase.

Thus, a comparison can be made between the ability of the *o*-hydroxy-benzoate and the *o*-diphenolic group to form complexes with aluminium(III). For this purpose, a number of SOL-GASWATER model calculations have been performed. In the first of these, the clay mineral kaolinite, $Al_2(OH)_4Si_2O_5$, was equilibrated with solutions of different pyrocatechol(C) contents. The results are presented as a predominance area diagram in Fig. 6. As can be seen AlL^+, AlL_2^-, $Al(OH)L_2^{2-}$ and AlL_3^{3-} are all predominating within specified ranges. This implies that the solubility of kaolinite increases in the presence of pyrocatechol within a rather broad $-\log h$ range, especially in neutral or slightly alkaline solutions (see Fig. 7). A comparison between the present and the corresponding salicylate system[3] reveals that the two ligands have different complexing abilities. In the salicylate system complexation is significant in slightly acidic solutions ($4 \leq -\log h \lesssim 6$), while pyrocatechol is "active" in more alkaline solutions. This behaviour is illustrated in Fig. 8, which is the result of a calculation where kaolinite was equilibrated with equal amounts of each ligand (30 μM). This figure also shows the importance of pure Al-hydrolysis with $-\log h \gtrsim 5.5$.

THE REACTION OF METHYLBORYLENE WITH CYCLOHEXENE AND SOME OTHER OLEFINIC COMPOUNDS

Utrecht, The Netherlands

Abstract—Some potential methylborylene-generating systems were investigated, using cyclohexene as the trapping agent. Methylborylene, generated by the system $2C_8K/MeBBr_2$, reacts with cyclohexene to yield 2-methyl-2-boratricyclo-[7.4.0.0^{3,8}]-tridecane (MBTT) **Ia**. In the course of the work an isomer of MBTT was synthesized along a completely different route and compared with **Ia**. With the system $2C_8K/MeBBr_2$, only cyclic olefins were converted to analogues of MBTT. An acyclic olefin and a conjugated diene yielded only haloboration products. Possible mechanisms leading to the formation of MBTT **Ia** are discussed.

In 1976, in a preliminary publication,[1] we reported the generation of the carbene-like species methylborylene (MeB:) and its reaction with cyclohexene, to form a product which was tentatively identified as the methyl-bridged dimer of 7 - methyl - 7 - borabicyclo[4.1.0]heptane, a borirane derivative. More extensive investigations have shown this structural assignment to be incorrect. In this paper we wish to report our findings in full, and to revise our earlier assignment.

Since 1976, only one other publication has appeared on the reaction of a carbene–analogous borylene with an olefinic system. In 1977 Ramsey and Anjo[2] presented indirect evidence for the addition of a borylene to cyclohexene. Upon irradiation of tris-1-naphthylboron in cyclohexene and treatment of the reaction mixture with a basic dilute aqueous solution of hydrogen peroxide, they obtained (among other products) *cis*-1,2-cyclohexanediol, indicating cycloaddition of 1-naphthylborylene to the double bond. The presumed intermediate borirane derivative was not isolated.

We explored methylboron dibromide as a methylborylene-generating source, according to

$$2M + MeBBr_2 \rightarrow MeB: + 2MBr \ (M = metal).$$

As a reductor lithium metal proved to be unreactive towards $MeBBr_2$, but the very strongly reducing liquid alloy NaK_5 produced methylborylene, as was established by GC/MS investigation of the mixture obtained upon reaction of NaK_5 and $MeBBr_2$ in cyclohexene.[1] However, this system appeared to be highly unreliable: TWO REACTIONS OUT OF FIVE WENT OUT OF CONTROL AND ENDED IN EXPLOSIONS. In the search for other reducing systems, sodium naphthalide and bisbenzenechromium were investigated. Both reacted exothermally but smoothly with $MeBBr_2$. In the simultaneous presence of cyclohexene a complex mixture was obtained in both cases. However, the products obtained upon reaction with NaK_5 could not be detected by GC/MS.

The ideally suited reductor was found in the intercalate potassium–graphite compound C_8K.[3–8] In order to follow the course of the reactions between C_8K, $MeBBr_2$ and cyclohexene by means of ^1H NMR, the reactions were carried out in benzene, using the following stoichiometry:

It appeared that a reaction occurred only at reflux temperature, as indicated by the

potassium–graphite turning black. ¹H NMR showed the intensity of the olefinic signal to diminish strongly. After the intensity of the olefinic signal had become constant, the reaction mixture was worked up by filtering off all solid material and removing the benzene from the filtrate by distillation. No compounds boiling between 100–180° proved to be present in the residue. According to ¹H NMR and GC/MS the residue consisted of two main components: unused MeBBr₂ and the unknown boron compound. It proved impossible to separate these components by vacuum distillation; for the mixture a boiling range of 80–90°/0.6 Torr was observed. In a subsequent experiment the excess MeBBr₂ was removed by titrating the filtrate with a solution of ethyllithium in benzene, thus converting the MeBBr₂ to Et₂MeB. Following the conversion of all MeBBr₂, further addition of EtLi results in quaternization of both boron compounds present (and other secondary reactions, *vide infra*), so the "equivalence point" should not be exceeded. As an (external) indicator for this titration aqueous silver nitrate was used.

Once the MeBBr₂ had been converted, it proved possible to obtain the unknown compound almost pure by vacuum distillation (b.p. 60–62°/0.2 Torr). The distillate was a colourless, extremely air- and moisture-sensitive liquid, with a musty, disagreeable and persistent odour. The distillates of several runs were investigated by ¹H NMR, ¹³C NMR, GC/MS and molecular weight determination. The unknown compound was identified as 2 - methyl - 2 - boratricyclo[7.4.0.0³,⁸]tridecane, MBTT (Ia), with the stereochemical configuration as shown below.
The ¹H NMR spectra of Ia (recorded in benzene or benzene-d6) showed two broad multiplets lying between δ 1.25 and 1.60 ppm and between δ 1.60 and 2.00 ppm, respectively (the cyclohexyl protons). At δ 0.87 ppm a sharp triplet was observed (J = 1.5 Hz), which on closer inspection proved to have a more complicated structure: the methyl group on boron. The ratio of the cyclohexyl vs the methyl protons was, for the purest fractions, 20 : 3.

The ¹³C NMR spectra of Ia were recorded in toluene-d8, both at ambient temperature and at − 60°, as carbon atoms bound to boron can hardly (if at all) be observed at ambient temperature due to the quadrupole moment of the boron nuclei. The resonances from the broadband decoupled spectra are given in Table 1 (shifts in ppm

Table 1. ¹³C NMR data of **Ia**, **II** and **VII** (shifts in ppm downfield, relative to TMS)

downfield, relative to TMS). A number of the resonances could not be assigned individually. The assignments are consistent with the C–H couplings observed in gated and off-resonance decoupled spectra, and with the differences in the spectra recorded at ambient temperature and at − 60°, respectively.

A molecular weight determination was performed by ebulliometry in benzene, using decalin as a reference. A figure was obtained of 195 ± 5 (Calc. 190). According to GC/MS investigations even the purest fractions carried minor impurities. Biphenyl was always present. Further, the treatment of the filtrate with ethyllithium gives rise to the formation of dodecahydro–biphenylene (tricyclo[6.4.0.0²,⁷]dodecane, **III**) which was decidedly not present in the original reaction mixture, as was proven by GC/MS.
The stereochemical configuration of **III** was not established. Over various runs, the absolute quantities of biphenyl and **III** varied, as well as their relative ratio.

The mass spectrum of MBTT **Ia** is given in Fig. 1.

The isotope peak at m/e 189 has an intensity of 25% of that of the parent peak at m/e 190, as can be expected for a molecule containing one boron atom (¹⁰B: ¹¹B = 1 : 4). Further mass spectrometric investigations revealed that the fragment at m/e 108 ([C₇H₁₃B]⁺) is formed in the fragmentation of the molecular ion (m/e 190).

In chemical ionization MS experiments, using ammonia, the "parent peak" was found at m/e 206

Fig. 1. Mass spectrum of MBTT **Ia**.

([M + NH$_2$]$^+$); using methane, the parent (and base) peak was found at m/e 189 ([M–H]$^+$), with its isotope peak at m/e 188.

In the fore-run of the distillations in some experiments two oxygen-containing boron compounds were found and identified by ^{1}H NMR and GC/MS: 7 - methyl - 7 - bora - 8 - oxabicyclo[4.2.0]octane (**IV**) and 7,9 - dimethyl - 7,9-dibora - 8 - oxabicyclo[4.3.0]nonane (**V**). The mass spectra of **IV** and **V** are shown in Figs. 2 and 3, respectively.

The occurrence of compounds **IV** and **V** is due to traces of water, originally present in the graphite used for the synthesis of the batch of C$_8$K used. It is quite difficult to free graphite from all traces of water.
It should be noted that in the GC/MS investigations no trace of compound **VI**, 2,9 - dimethyl - 2,9 - diboratricyclo[8.4.0^{3,8}]tetradecane, the formal dimer of the borirane derivative **VIII**, could be detected (see the corresponding reaction of methylborylene with acetylenes[10,13]).

For MBTT several stereoisomers can be envisaged (depending on the way in which it had been formed, *vide infra*). It was decided to synthesize MBTT along a route yielding one isomer of known configuration. The following synthesis was carried out.

Starting from the fact that hydroboration al-

Fig. 2. Mass spectrum of 7-methyl-7-bora-8-oxabicyclo[4.2.0]octane (**IV**).
Fig. 3. Mass spectrum of 7,9-dimethyl-7,9-dibora-8-oxabicyclo[4.3.0]nonane (V).

ways takes place *cis*, the configuration of II could be assigned unambiguously.

MBTT II was characterized by ^{13}C NMR (both at ambient temperature and at − 60°, with broadband and gated decoupling; solvent toluene-d8) and by GC/MS. The ^{13}C NMR resonance signals of II (which could only be assigned partially) are given in Table 1. The resonance signals of VII, di-$\Delta^{1,1'}$-cyclohexene, are given as well. It is seen from Table 1 that Ia and II are different isomers of MBTT. The mass spectrum of II was identical to that of Ia.

Finally, in order to explore the scope of the reaction of the system 2C$_8$K/MeBBr$_2$ with cyclohexene, comparable reactions were carried out with cyclopentene, cycloheptene, 2,3-dimethyl-butene-2 and 2,3-dimethylbutadiene-1,3. The reaction mixtures were investigated by GC/MS. The two cyclic olefins reacted in a way fully analogous to that observed with cyclohexene. Allowing for the mass difference of minus or plus one methylene unit, the mass spectra of the compounds formed were similar to that of MBTT.

With the acyclic olefin and the conjugated diene fast haloboration was observed, followed by secondary reactions with C$_8$K. Very complex mixtures of boron and bromine containing products were obtained, without a trace of the compounds expected. No further attempts were made to identify individual components of these mixtures.

STRUCTURE AND MECHANISM OF FORMATION OF MBTT Ia

One obvious proposal for the mechanism of formation of MBTT Ia is to assume a sequence of haloboration steps, followed by reaction with C$_8$K:
There are, however, observations that render this mechanism less likely. In an earlier communication on borylene chemistry,[10] we reported the following experiment. Cyclohexene was refluxed with an equimolar amount of MeBBr$_2$ in benzene for 6 days. By means of ^{1}H NMR the intensity of the olefinic signal was observed to decrease, albeit very slowly. After this reaction period all remaining cyclohexene and MeBBr$_2$ were removed *in vacuo*. The boron- and bromine containing residue, upon treatment with C$_8$K, failed to yield even a trace of MBTT, as was established by GC/MS. In a private communication,[11] Prof. Eisch stated that the haloboration of olefins give the *cis*-adducts as the kinetic products, which, upon standing, tend to isomerize to the thermodynamically more stable *trans*-adducts. Our experiments with 2,3-dimethyl-butene-2 and 2,3-di-methylbutadiene-1,3, which compounds proved to be much more susceptible to haloboration than the cyclic olefins, show that, even when C$_8$K is present from the start (and so can react with the primary *cis*-haloboration product), no compounds corresponding to MBTT Ia are formed. Further, the prolonged treatment of cyclohexene with MeBBr$_2$ (which should lead to the *trans*-adduct) failed, upon reaction with C$_8$K, to

yield MBTT **Ia**. Therefore, in our opinion, a mechanism involving haloboration can be ruled out.

We prefer an alternative mechanism, in which the formation of MBTT **Ia** takes place as follows:
The first step is the *cis*-cycloaddition of methylborylene (generated by the system $2C_8K/MeBBr_2$) to cyclohexene, resulting in the formation of 7 - methyl - 7 - borabicyclo[4.1.0]heptane (**VIII**), a borirane derivative. This molecule then reacts with a second molecule of cyclohexene in a symmetry-allowed $[_\pi2_s + _\sigma2_a]$ cycloaddition reaction in which a B–C bond is broken to MBTT **Ia** or **Ib**.

Recently, the occurrence of a similar $[_\pi2_s + _\sigma2_a]$ cycloaddition of tetracyanoethylene to cyclopropanone acetals has been established by Verhoeven *et al.*[12]

In principle, the reaction of **VII** with a molecule of cyclohexene by a $[_\pi2_s + _\sigma2_a]$ cycloaddition can lead to various products:
In view of the steric requirements of the cyclohexane ring, inversion at the C atom (pathways A and B) appears highly improbable; there are, however, no impediments to inversion at the boron atom (pathways C and D). Of the latter two mechanisms pathway C appears more favourable on grounds of less steric hindrance in the approach of the reactants. Here, it should be noted that in some reactions a slight amount of a second isomer of · MBTT (or its homologues in the cases of cyclopentene and cycloheptene) appeared to have formed. In the GC/MS investigations two peaks

with nearly the same retention times were visible in the gas chromatogram (one large, the other small), having almost identical mass spectra. In our opinion, the main product of the reaction of the system $2C_8K/MeBBr_2$ with cyclohexene is **Ia**; **Ib** may be formed in small amounts.

EXPERIMENTAL

All experiments were carried out in an atmosphere of dry, oxygen-free nitrogen. Ethyllithium was synthesized under argon. Solvents were purified and stored under nitrogen. Liquids were handled with syringes. ^1H NMR spectra were recorded using Varian EM390, HA-100, T60 and EM360 spectrometers (Utrecht) and a Bruker WH 90 FT spectrometer (Chemical Laboratory of the Free University, Amsterdam). ^{13}C NMR spectra were recorded on Varian XL100/15 and CFT-20 spectrometers by Dr. T. Spoormaker and Messrs. D. Seykens, A. V. E. George and R. Janssen (Utrecht) and on a Bruker WM 250 spectrometer by Drs. O. S. Akkerman and F. J. J. de Kanter (Amsterdam).

GC/MS investigations were carried out on a Finnigan 3100D Mass Spectrometer with 6110 Data System and Finnigan 9500 Gas Chromatograph by Miss E. Ch. Th. Gevers, Mrs. G. G. Versluis-de Haan and Mrs. C. M. Bijlsma-Kreuger at the Institute for Organic Chemistry TNO at Utrecht, and on a Kratos MS 80 Mass Spectrometer with Data General Nova 3 Data System and Carlo Elba/Kratos Gas Chromatograph by Mr. C. Versluis and Mrs. A. van der Kerk-van Hoof at the Laboratory for Analytical Chemistry of The State University at Utrecht. Elementary analyses of the products obtained could not be brought to consistency due to their extreme air- and moisture sensitivity.

Molecular weights were determined by ebulliometry using a Gallenkamp MW 125, modified for operation in a nitrogen atmosphere.

Tetramethyltin was kindly provided by the Institute for Organic Chemistry TNO at Utrecht.

Syntheses of starting compounds

$MeBBr_2$ was synthesized by literature procedures,[14,15] starting from Me_4Sn and BBr_3.

Cyclohexene was purified by distilling it twice from P_2O_5.

Sodium naphthalide,[16] bisbenzenechromium,[17,18] C_8K[6], 1,1' - dihydroxy - 1,1' - dicyclohexyl,[19] di-$\Delta^{1.1'}$-cyclohexene[19] ethyllithium[20,21] were synthesized according to literature procedures.

Reaction of $MeBBr_2$ *with* NaK_5 *in cyclohexene*

To 15 cm³ of cyclohexene were added 5.56 g

(25 mmoles) of NaK$_5$. To this stirred liquid–liquid suspension 8.80 g (47 mmoles) of MeBBr$_2$ were added slowly. In the course of 45 min the temperature rose to 60° and the mixture turned into a grey–black suspension. After 24 hr stirring all solid material was filtered off and a clear deep-red filtrate was obtained. This solution was investigated by GC/MS[1]. The solid material left after filtration is extremely reactive; it should be destroyed with a 20–30% solution of tertiary butyl alcohol in liquid paraffin.

Synthesis of 2-methyl-2-boratricyclo(7.4.0.0^{3,8}]-tridecane (MBTT Ia)

In a typical run 20.00 g (148 mmoles) of C$_8$K were suspended in a mixture of 5.98 g (73 mmoles) of cyclohexene and 70 cm^3 of benzene. The mixture was heated to reflux and 13.74 g (74 mmoles) of MeBBr$_2$ were added dropwise in the course of 60 min with continuous stirring. In the course of 1 hr the potassium–graphite turned black. Refluxing and stirring were continued for 24 hr, whereupon the mixture was cooled to room temperature and stirred for 2 more days. Next, all solid material was filtered off. A clear brown solution was obtained. A solution of ethyllithium in benzene was added in small portions from a syringe to the brown filtrate, with stirring. After addition of each quantity of EtLi/benzene, stirring was stopped to let the lithium bromide settle, so it would not interfere with the bromide test. A few drops of the supernatant were brought in ten drops of distilled water in a small test tube. The mixture was shaken for half a minute to ensure complete hydrolysis of any MeBBr$_2$ present. Then a few drops of an aqueous solution of silver nitrate were added to the contents of the test tube. When MeBBr$_2$ was still present in the filtrate, a yellowish–white precipitate of silver bromide, soluble in concentrated aqueous ammonia, was formed; when only compounds R$_3$B were present, a greyish precipitate was formed which did not dissolve upon addition of concentrated aqueous ammonia, but turned black instead. After all MeBBr$_2$ had been removed from the filtrate, the lithium bromide was filtered off and all benzene and Et$_2$MeB were removed *in vacuo*. The residue was subjected to vacuum distillation. Three fractions were collected; the major fraction (b.p. 60–62°/0.2 Torr) proved to be almost pure MBTT Ia.

Synthesis of 2-methyl-2-boratricyclo[7.4.0.0^{3,8}]tridecane (MBTT II)

For the synthesis of methylboron dihydride, MeBBr$_2$ was reacted with LiAlH$_4$. A direct reaction

in ether or THF was impossible, as (organo) boron halides avidly cleave ethers. However, the following indirect route proved to be quite satisfactory.

To a suspension of 3.00 g (79 mmoles) of LiAlH$_4$ in light paraffin oil were added 29.30 g (158 mmoles) of MeBBr$_2$. No reaction occurred. Next, the reaction vessel was cooled in ice and connected to a cold trap (cooled at − 60°) provided with 45 cm^3 of THF, and 25 cm^3 of ether were added slowly, with stirring, to the LiAlH$_4$/MeBBr$_2$ mixture. An exothermic reaction ensued, and a gas (methylboron dihydride) was seen to evolve. After all Et$_2$O had been added, the contents of the cold trap were thawed. According to ^{1}H NMR, the yield of MeBH$_2$ was *ca.* 30% (47 mmoles). The THF solution was transferred into a dropping funnel. A second dropping funnel contained a solution of 7.63 g (47 mmoles) of di-$\Delta^{1,1'}$-cyclohexene (VII) in 45 cm^3 of THF. A three-necked, round-bottom flask containing 50 cm^3 of THF was equipped with both funnels. The two reactants were slowly added, at an equal rate. In this fashion, neither reactant was much in excess, thus minimizing the amount of unwanted side-products. The reaction of the MeBH$_2$.THF complex with VII was exothermic and instantaneous. After the reactants had been added, the reaction mixture was warmed to 50° for 45 min. Thereupon, all volatile components were removed *in vacuo* and the residue, a clear, colourless liquid, was investigated by GC/MS and ^{13}C NMR. It proved to be reasonably pure (better than 90%) MBTT II.

Reaction between cyclohexene and MeBBr$_2$; treatment of the reaction product with C$_8$K

In 10 cm^3 of benzene were brought 1.92 g (10 mmoles) of MeBBr$_2$ and 0.79 g (9.6 mmoles) of cyclohexene. The mixture was refluxed for 6 days. In the course of this time the reaction mixture took on a deep purple–blue colour. The reaction was followed with ^{1}H NMR; the olefinic signal was observed to diminish slowly to about 25% of its initial value. After cooling the mixture to room temperature all volatile components were removed *in vacuo*. The residue was diluted with benzene and added to 1.10 g (7 mmoles) of C$_8$K. This mixture was refluxed for 24 hr (with stirring) and stirred for another 36 hr at room temperature. The potassium–graphite slowly turned black. After this time, all solid material was filtered off. Inspection of the filtrate by GC/MS showed no MBTT to be present.

The product of the reaction between MeBBr$_2$ and cyclohexene was shown, by flame tests, to contain both boron and bromine. It fumed heavily on contact with air and smelled ghastly.

Reactions of the system $2C_8K/MeBBr_2$ *with cyclopentene, cycloheptene, 2,3-dimethylbutene-2 and 2,3-dimethylbutadiene-1,3.*

These reactions were carried out analogously to the reaction of the system $2C_8K/MeBBr_2$ with cyclohexene. After filtering off all solid material the filtrates were investigated by GLC and GC/MS.

Abstract—The reactivity of borane carbonyl (BH_3CO) and its isoelectronic counterpart the acetylium cation (CH_3CO^+) are compared resulting in the formulation of (carbonyl)trihydroborate anions, $BH_3C(O)X^-$, which are isoelectronic and isostructural with organic carbonyls. By analogy with the ease of reduction of organic carbonyl compounds by hydroborate, the relative stability towards self-reduction-oxidation (hydride transfer from boron to carbonyl carbon) in $BH_3C(O)X^-$ is proposed. The postulated order, with increasing stability is $BH_3C(O)Cl^- < BH_3C(O)H^- < BH_3C(O)R^- < BH_3C(O)OR^- < BH_3C(O)NR_2^- < BH_3C(O)O^{2-}$. Experimental results of this study together with known chemistry are shown to be consistent with the proposed order. Further, it is suggested that a similar predictive scheme may be applicable to the chemistry of the amine-carboxyboranes (boron analogues of α-amino acids) and their derivatives.

The reactions of borane carbonyl (BH_3CO) with potassium hydroxide in alcohol and with amines have resulted in the preparation of a number of trihydroborate containing species including $BH_3CO_2^{2-}$,[2a,b] $BH_3CO_2R^{-2c-4}$ (R = C_2H_5, CH_3, H) and $BH_3C(O)NR_2^-$.[5] The reactions were viewed as being analogous to carbon dioxide reactions with the BH_3 group as the isoelectronic analogue of oxygen.

A number of considerations presented below suggest that it may also be fruitful to compare the chemistry of BH_3CO with another of its iso-electronic species, the acetylium cation, CH_3CO^+. Equations (1) and (2) demonstrate the analogy where X^- may be a number of different substituents including OH, OR and NR_2.

$$CH_3CO^+ + X^- \rightarrow CH_3\overset{\displaystyle O}{\overset{\displaystyle \|}{C}}X^- \qquad (1)$$

$$BH_3CO + X^- \rightarrow BH_3\overset{\displaystyle O}{\overset{\displaystyle \|}{C}}X^-. \qquad (2)$$

Further, use of this analogy readily lends itself to a simple predictive scheme for the relative stability of $BH_3C(O)X^-$ anions towards internal reduction

of carbonyl by the hydroborate moiety based on how an analogous organic carbonyl function is reduced by tetrahydroborate (BH_4^-).

THE BORANE CARBONYL/ACETYLIUM ION ANALOGY

Interest in analogies between BH_3CO and CH_3CO^+ was prompted by our ^{11}B and ^{13}C chemical shift correlations in isolectronic tetracoordinate boron and carbon compounds.[6–9] If one proceeds a step further and compares the physical and chemical characteristics of borane carbonyl with its isoelectronic carbon containing counterpart, numerous similarities are observed. Structural studies show that the skeletal framework of borane carbonyl[10–13] and the acetylium cation[14] have linear geometries. Physical studies have shown that borane carbonyl exists as a monomer and is involved in an equilibrium of the type where CO is a product:[15]

$$BH_3CO \rightleftharpoons CO + \tfrac{1}{2}B_2H_6. \qquad (3)$$
Similarly, acylium ions have been shown to be involved in the following equilibrium:[16]

$$RCO^+ \rightleftharpoons CO + R^+. \qquad (4)$$
Trialkylborane carbonyls, BR_3CO, have not been isolated but have been suggested as intermediates in reactions.[17] Acylium ions of the type CR_3CO^+ where a relatively stable tertiary carbenium ion, R_3C^+, can be generated are more unstable than R_2CHCO^+ or RCH_2CO^+. This similar order of stability (toward loss of CO), $BH_3CO > BR_3CO$ and $CH_3CO^+ > CR_3CO^+$, suggests an examination

of the chemistry of BH_3CO in terms of its analogue, CH_3CO^+.

A comparison is further prompted by MO calculations on $[CH_3CO]^+$ and BH_3CO. The carbonyl carbon in $[CH_3CO]^+$ is strongly positive[14,18] and should be quite susceptible to nucleophilic attack. Likewise, molecular orbital calculations show that the carbonyl carbon in borane carbonyl is strongly positive[19] and would also be expected to be strongly susceptible to nucleophilic attack. Just as we would expect $[CH_3CO]^+$ to react with a wide variety of nucleophiles, X^-, to form the well-known carbonyl compounds shown in Table 1, a similar reactivity for BH_3CO with nucleophiles X^- would result in a series of borane carbonyl anions (Table 1) which are counterparts to the organic carbonyls. Also, the known reactions of borane carbonyl with amines and base may be depicted as shown in eqns (6) and (8), and are thus comparable to the expected reaction of CH_3CO^+ with the same substrates [eqns (5) and (7)].
$$CH_3CO^+ \xrightarrow{HNR_2} CH_3C(O)NR_2H^+ \xrightarrow{HNR_2}$$

$$CH_3C(O)NR_2 + R_2NH_2^+ \qquad (5)$$

$$BH_3CO \xrightarrow{HNR_2} BH_3C(O)NR_2H \xrightarrow{HNR_2}$$

$$BH_3C(O)NR_2^- + R_2NH_2^+ \qquad (6)$$

$$CH_3CO^+ \xrightarrow{KOH} CH_3CO_2H \xrightarrow{KOH} K^+CH_3CO_2^- \qquad (7)$$

$$BH_3CO \xrightarrow{KOH} K^+BH_3CO_2H^- \xrightarrow{KOH} K_2^+BH_3CO_2^{2-}. \qquad (8)$$

PREDICTIVE SCHEME FOR BORANE CARBONYL ANION STABILITY

In contrast to the well-known organic carbonyl compounds, Table 1 lists a number of presently unknown borane carbonyl anions. While the absence of some of these species suggests a number of preparative possibilities, there are, however, some general considerations pertinent to the relative stability of the anions which may be proposed. The borane carbonyl anions contain both the hydroborate moiety with its well-known reducing capability and a carbonyl group susceptible to reduction. It is well known that the ease of reduction of organic functional groups by tetrahydroborate varies generally in the order:[20]

$$RCCl > RCH > RCR > RCOR > RCNR_2, \quad RCO^-$$

ready reduction at room temperature	decreasing reactivity	no reduction
Thus, acyl halides and aldehydes are readily reduced at room temperature whereas amides and carboxylates are not reduced. Based on the above observations and using the BH_3 internal moiety as the reducing agent of the carbonyl, the relative stability of borane carbonyl anions may be postulated as

$$BH_3CCl^- < BH_3CH^- < BH_3CR^- < BH_3COR^- < BH_3CNR_2^-, BH_3CO^{2-}$$
$BH_3C(O)Cl^-$ is then predicted to be the species most easily able to undergo self-reduction-oxidation and $BH_3CO_2^-$ would be predicted to be the most stable. The carboxylato-, carboxamido-, and alkoxycarbonyl-hydroborate derivatives are well characterized[1-5] and their isolation and stability are consistent with this prediction. For instance, the potassium and sodium salts of the carboxylatotrihydroborate anion ($BH_3CO_2^-$) are stable to decomposition up to 400°C with the ^{11}B and ^{1}H NMR of the anion suggesting that CO_2^- is comparable to hydride in electron-donating ability.[2a] It is evident that in this anion the hydroborate and carbonyl species are capable of coexisting.

The borane carbonyl anions in Table 1 not characterized to date were the acid chloride, aldehyde and ketone analogues. Subsequently, investigations concerning the nature of these borane carbonyl anions and related species were undertaken and pertinent literature results studied in view of the above prediction.

RESULTS AND DISCUSSION

Studies involving the postulated $BH_3C(O)Cl^-$

The attempted preparation of the anion $BH_3C(O)Cl^-$ was based on the reaction of borane carbonyl and a stoichiometric quantity of tetraethylammonium chloride in chloroform at low temperature. Rapid absorption of borane carbonyl, accompanied by solubilization of tetraethylammonium chloride, occurs around 0°C when the system is warmed from −196°C. Repetition (three times in 30 min) of this warming/freezing (liq N_2) process to facilitate dissolution of the BH_3CO, followed by stirring at −78°C overnight, produced only trimethylboroxine and the recovered tetraethylammonium chloride. No CO is detected. The overall reaction may be given as

$$3BH_3CO \xrightarrow[CHCl_3]{(C_2H_5)_4NCl} (CH_3BO)_3 \qquad (9)$$
The same products are obtained even when the reaction was carried out as quickly as possible (ca. 20 min. for complete absorption of BH_3CO) in the event that the anion, $H_3BC(O)Cl^-$, could be isolated as the kinetic product of this reaction. These results may be rationalized by the following proposed mechanism:

(i) $\quad BH_3CO + Cl^- \rightarrow BH_3C(O)Cl^-$
$\quad\quad\quad$ (rate determining) $\qquad (10)$

(ii) $3BH_3C(O)Cl^- \rightarrow (CH_3BO)_3 + 3Cl^-$ (fast) (11)
Assuming the above mechanism to be applicable, the absorption of BH_3CO into solution should proceed with only a catalytic quantity of Cl^-. This is the observed result with again, only tri-

methylboroxine and tetraethylammonium chloride catalyst being recovered after a 30 min. reaction period.

Our inability to isolate a stable $BH_3C(O)Cl^-$ anion is consistent with its position in our stability series since this anion would be expected to be the most unstable toward internal reduction of the carbonyl by the hydroborate moiety. Just as tetrahydroborate reacts rapidly with acetyl chloride by a nucleophilic attack on the carbonyl carbon to give the reduced product, $H_3BC(O)Cl^-$ would be expected to undergo rapid internal reduction to give trimethylboroxine.
The observation that BH_3CO is rapidly absorbed into a solution containing chloride along with the observed[15] value of $K = 2.8 \times 10^4$ for the system $\frac{1}{2}B_2H_6 + CO \rightleftharpoons H_3BCO$, suggested that a mixture of B_2H_6 and CO should be absorbed into a chloride solution at room temperature since as H_3BCO is formed it should be rapidly and irreversibly removed by reaction with chloride.

In accord with this, when a mixture of B_2H_6 and CO (in a 1:2 mole ratio) is allowed to stand at room temperature above a stirred $CHCl_3$ solution of tetraethylammonium chloride, the reactants are consumed in a period of 30 hr. Only trimethylboroxine is produced and the tetraethylammonium chloride recovered. By contrast, when a similar experiment is carried out, but the chloride omitted, there is only a slight drop in total pressure in the system due to formation of a small equilibrium concentration of BH_3CO.

Using a THF/B_2H_6 solution containing tetraethylammonium chloride, CO at less than one atm. pressure is readily absorbed into the solution with the reaction complete in 1 day. Only trimethylboroxine is produced and the chloride salt recovered. Even when the mostly insoluble NaCl salt is used, the reaction still proceeds slowly and is about 30% complete (based upon CO uptake) after $2\frac{1}{2}$ days. In the complete absence of a chloride salt, CO is not absorbed into a THF/B_2H_6 solution except to form a small equilibrium quantity of BH_3CO. Brown and Rathke[21] have also reported that CO is not absorbed into THF-borane.

Additional results using a mixed solvent system of THF and glyme showed that over a 15 hr period 2 moles of CO per mole of B_2H_6 (at a total pressure less than 1 atm.) are absorbed into a stirred solution of tetraethylammonium chloride at room temperature. Only trimethylboroxine and tetraethylammonium chloride were recovered. In contrast to when THF is used, CO *is* absorbed into a glyme/B_2H_6 solution with BH_3CO being formed in yields as high as 98% depending upon reaction conditions.[22,23] The BH_3CO can be isolated as long as chloride is not present.
The foregoing results are in accord with the proposed mechanism:

(i) $\frac{1}{2}B_2H_6 + CO \underset{k_2}{\overset{k_1}{\rightleftharpoons}} BH_3CO$ (12)

(ii) $BH_3CO + Cl^- \rightarrow BH_3C(O)Cl^-$ (13)

(iii) $3BH_3C(O)Cl^- \rightarrow (CH_3BO)_3 + 3Cl^-.$ (14)

In this mechanism, step (i) (or k_1) controls the rate; steps (ii) and (iii) are fast and irreversible. Although step (i) is written to involve only the reaction of B_2H_6 and CO it is, no doubt, a reaction involving solvent.[24,25] Since the H_3BCO may be recovered from B_2H_6/glyme solutions (in the absence of chloride) it seems valid that the formation of the H_3BCO is still the rate-determining step. In the same reaction ($B_2H_6 + CO$) in $CHCl_3$, however, diborane is not absorbed to any great extent by a $(C_2H_5)_4NCl/CHCl_3$ solution and borane carbonyl is probably formed according to step (i) even though some H_3BCl^- ions may be present in solution.

Studies involving the postulated formyltrihydroborate anion, $H_3BC(O)H^-$

A mechanism may also be put forth which is consistent with the observation by Brown and Rathke[21] that at atmospheric pressure within a few hours two moles of carbon monoxide per mole of diborane are absorbed into a solution of diborane in THF containing a catalytic quantity of sodium tetrahydroborate with trimethylboroxine being the only product. The reaction pathway we propose is:

(i) $\frac{1}{2}B_2H_6 + CO \rightleftharpoons H_3BCO$ (15)

(ii) $H_3BCO + BH_4^- \rightarrow H_3B\overset{\displaystyle O}{\overset{\|}{C}}\text{-H-}BH_3^-$ (16)

$\qquad\qquad\qquad\text{or } H_3BC\overset{\displaystyle H}{=}OBH_3^-$

(iii) $3H_3B\overset{\displaystyle O}{\overset{\|}{C}}\text{-H-}BH_3^-$

$\qquad\text{or } \xrightarrow{\qquad\qquad} (CH_3BO)_3 + 3BH_4^-.$ (17)

$\qquad H$
$3H_3BC = OBH_3^-$

Just as aldehydes are very rapidly reduced by hydroborates, the rapid self-reduction-oxidation of the anion $H_3BC(O)H^-$ is not unexpected and is completely consistent with our prediction of stability of borane carbonyl anions. Coordination of BH_3 to the carbonyl oxygen (ii) would make the carbonyl carbon even more susceptible to nucleo-

philic attack and reduction. Although Brown and Rathke had assumed the presence of the tetrahydroborate anion was necessary for the reduction to occur, our work shows that merely the presence of an anion such as Cl^- in solution is sufficient to cause the indicated reactions. Even in the presence of catalytic amounts of sodium chloride in a solution of diborane and tetrahydrofuran, about 30% of the CO over the solution is absorbed, based upon the reaction of 2 moles of carbon monoxide per mole of diborane, in a period of 60 hr. Since CO will not react with a tetrahydrofuran–borane solution except to give a small equilibrium concentration of BH_3CO, the chloride, which must be in very low concentration because of the low solutilbity of sodium chloride in THF, is catalyzing the reaction.

Studies involving the postulated $H_3BC(O)R^-$

From their studies of the reaction between equimolar quantities of phenyllithium and borane carbonyl, Carter and Moyé established the existence of a 1:1 adduct which was a white solid soluble in ether at low temperatures.[26] ^{11}B NMR measurements show at low temperature a 1:3:3:1 quartet with a B–H coupling constant of 104 Hz (chemical shift not reported). As the temperature increased the quartet diminished and other unidentified species appeared giving weak peaks at lower field. Further decomposition occurred upon warming. The process was not reversible as cooling the mixture did not give the original quartet. The postulated structure for $C_6H_5Li \cdot H_3BCO$ was $Li^+[H_3BC(O)C_6H_5^-]$ and it was further suggested on the basis of infrared and deuteration studies that the decomposition involved an internal hydride shift from the hydroborate to the carbonyl carbon. Both the stability of the lithium salt and the internal reduction process are completely consistent with an unstable intermediate in accordance with our predictive scheme.

Studies involving borane carbonyl and simple bases

The results described above and the predicted stability scheme for the borane carbonyl anions suggest that reactions between borane carbonyl and simple bases [such as oxides (O^{2-}), alkoxides (OR^-), amides (NR_2^-) and acetates ($CH_3CO_2^-$)] in suitable solvents should give the corresponding borane carbonyl anions. Indeed, Malone and Parry[2b] showed that the reaction between moist calcium oxide and borane carbonyl gives a product with an IR spectrum consistent with that of calcium (carboxylato)trihydroborate (CaH_3BCO_2). They also isolated a solid from the reaction of borane carbonyl and sodium methoxide in methanol and diethyl ether which gave characteristic

B–H and C=O IR absorptions. The fact that this solid hydrolyzes in base solution to $Na_2BH_3CO_2$ strongly indicates the solid to be the methoxycarbonyl derivative $Na^+[BH_3CO_2CH_3^-]$. Our ^{11}B NMR results show for the borane carbonyl acetate anion reaction product in tetrahydrofuran a 1:3:3:1 quartet ($\delta = -33.5$ ppm) indicating the product to be the (acetoxycarbonyl)trihydroborate anion, $BH_3C(O)-OC(O)CH_3^-$. The quartet observed is not due to free borane carbonyl since a sharp 1:3:3:1 quartet is obtained for BH_3CO neat and in various solvents (neat, $\delta = -48.5$ ppm;[26] acetone, $\delta = -45$ ppm; methanol and diethyl ether, $\delta = -48.5$ ppm).

Reductions with $K_2BH_3CO_2$

The foregoing results support the hypothesis that trends in the stability of $H_3BC(O)X^-$ anions towards internal reduction of carbonyl by the BH_3 moiety may be related to the ease of hydroborate reduction of the analogous $CH_3C(O)X$ species. To gain an appreciation for the reducing power of the borane moiety in $BH_3C(O)X^-$, a study was carried out of the reducing characteristics of $BH_3CO_2^{2-}$ towards some typical organic carbonyl compounds.[27] It was found that the reducing behaviour of potassium(carboxylato)trihydroborate in methanol at ambient temperature was generally comparable to that of potassium tetrahydroborate in water although slower. As examples, benzaldehyde and m-nitrobenzaldehyde were reduced to the alcohol in 48 hr and 30 min respectively and butyric acid, benzamide, and butyronitrile were stable to reduction even after 2 weeks. It may be concluded that the reducing power of the BH_3 moiety in $H_3BCO_2^{2-}$ is roughly comparable to BH_4^-. Although differences in the substituent X in $H_3BC(O)X^-$ could be expected to influence the reducing ability of the borane group toward carbonyl, major differences are not likely. Moreover, while the effect on the reducing ability of the hydroborate moiety by an X substituent may be small, the effect of X on the carbonyl reactivity to which it is directly attached would be expected to vary considerably. Consequently, the change in internal reduction susceptibility of the carbonyl as predicted by our stability scheme is not surprising and reflects the general change of electron density at the CO carbon as X is varied. The same effect is responsible for the variations in reducibility of the organic carbonyls by tetrahydroborate.[20] While an intermolecular reduction process involving attack of one $H_3BC(O)X^-$ on the carbonyl of another is possible, an intramolecular process is thought to be more likely because of the negative charge on both species. The effect on carbonyl reactivity by neighboring groups has also been

studied by Angelici with reactions between transition metal carbonyl complexes and amines or alkoxides to form carboxamido or carboalkoxy derivaties:[28]

$$L_nMCO^+ + 2RNH_2 \rightarrow L_nMC(O)NHR + RNH_3^+.$$

By decreasing the number of CH_3 groups in the arene, L, the electron density at the carbonyl carbon atom was reduced and the reaction as written proceeded more favourably. A rather good correlation was found between CO force constants, which reflect the electron density at the carbonyl carbon, and the reactivity: CO complexes with force constants greater than 17.2 mdyn/Å readily formed carboxamido complexes; those with force constants between 16 and 17 gave mixtures (the reactions were reversible), whereas those below 16.0 showed no evidence for carboxamido formation. According to this correlation, the value of the CO force constant for H_3BCO (17.98,[29] 17.94[30]) allows one to predict that the carboxamido derivative would be isolable as is the case.

CONCLUSION

The foregoing study has presented a general picture of the reactivity of borane carbonyl and has offered a simple predictive scheme for the stability of the resultant species. Information gained here on the relative stability of $H_3BC(O)X^{n-}$ species may be particularly applicable in exploring the chemistry of derivatives in which the boron has varying substituents. One example is the derivative chemistry of the novel class of compounds, the boron analogues of amino acids, $R_3NB(R')HCO_2H$.[31] The tendency toward self-reduction-oxidation in $R_3NB(R')HC(O)X$ may depend upon the nature of X and vary in a like manner as shown in our predictive scheme. Preliminary studies are consistent with this since $Me_3NBH_2CO_2H$, $Me_3NBH_2C(O)N(H)C_2H_5$, and $Me_3NBH_2C(O)OR$[31] are stable compounds, whereas attempts to prepare $Me_3NBH_2C(O)Cl$ were unsuccessful and the B–H linkage was lost.[32]

EXPERIMENTAL

General techniques

Standard vacuum line techniques were used for air-sensitive compounds. Infrared data were obtained from Perkin–Elmer Model 237B or 257 instruments as nujol mulls or potassium bromide pellets. Varian A-60 and Varian HA-100 spectrometers were used for proton (60 MHz; TMS, std) and [11]B (32.1 MHz; $BF_3 \cdot OEt_2$, std) NMR data respectively.

Solvents were dried by standard methods. Di-

borane was either obtained commercially (Callery Chemical Co.) or synthesized by published procedures.[33] Borane carbonyl was synthesized as reported in the literature.[5,15] $K_2BH_3CO_2$ was also prepared as reported.[2] Tetraethylammonium chloride was dried in a drying pistol for 36 hr, stored in an evacuated flask and transferred under nitrogen. Tetra-*n*-butylphosphonium acetate was obtained from Alpha-Inorganics and used without further purification.

Borane carbonyl absorption into a chloroform solution of $(C_2H_5)_4NCl$

A 5 mmol sample of H_3BCO was condensed at $-196°C$ onto a frozen solution of $(C_2H_5)_4NCl$ (5.1 mmol) in 20 cm^3 $CHCl_3$. Slow warming of the mixture resulted in a pressure increase until the $(C_2H_5)_4NCl$ solubilized, *ca* 0°C, at which point the pressure decreased rapidly. This procedure was repeated three times in a 30 min period after which the mixture was stirred at $-78°C$ overnight. Non-condensible gas was not present as indicated by a pressure check after freezing to $-196°C$. The mixture was warmed and the volatiles removed leaving a white solid shown by IR to be pure $(C_2H_5)_4NCl$. The volatile (in addition to solvent) was shown to be $(CH_3BO)_3$, ($\delta CH_3 = 0.39$ ppm).

The above procedure was also carried out on a 6.8 mmol sample of H_3BCO with 5.1 mmol $(C_2H_5)_4NCl$ in 20 cm^3 $CHCl_3$. The warming–cooling process was performed three times within 20 min with the same observations as previously noted. Removal of volatiles gave identical products as before. Use of a catalytic amount of $(C_2H_5)_4NCl$ with 5 mmol H_3BCO in 5 cm^3 THF and a reaction time of 30 min (warmed and cooled three times) gave only $(C_2H_5)_4NCl$ (IR) and $(CH_3BO)_3$ (NMR).

The system B_2H_6 and CO in the absence of $(C_2H_5)_4NCl$

6.85 mmol of B_2H_6 and 20 mmol of CO were allowed to stand above pure chloroform at room temperature. The pressure in the system dropped slightly from an initial value of 621 mm (21°C) to 615 mm (20°C) after 12 hr.

Attempted reaction of diborane with tetraethylammonium chloride

B_2H_6 (3.16 mmol), condensed onto a solution of $(C_2H_5)_4NCl$ (6.65 mmol) in 50 cm^3 $CHCl_3$, showed no pressure change above the solution after 12 hr at room temperature.

Reaction of diborane and carbon monoxide with tetraethylammonium chloride as a catalyst

In 1,2-dimethoxyethane (Glyme) and THF·B_2H_6

(7.69 mmol) was admitted at room temperature into a flask containing 0.44 mmol $(C_2H_5)_4NCl$ slurried in 8 cm^3 of glyme. The $(C_2H_5)_4NCl$ dissolved immediately and 3 cm^3. THF was condensed in after which the solution was allowed to warm to room temperature. After admitting 21.8 mmol of CO (initial total pressure in system, 512 mm) a pressure decrease of 40 mm occurred and a white precipitate formed. After stirring the solution for 15 hr at room temperature the CO was measured and it was found that 16.1 mmol was absorbed giving a $CO:B_2H_6$ mole ratio of $16.1:7.7 = 2.08$. Addition of more CO did not result in further absorption. Hydrolysis of the entire reaction mixture with 6N HCl did not give evolution of hydrogen.

In tetrahydrofuran. A 6 mmol sample of B_2H_6 was condensed into a flask containing a small unweighed sample of $(C_2H_5)_4NCl$. Addition of a large excess of CO (at less than 1 atm. pressure) and monitoring the CO absorption which ceased after 1 day resulted in recovery of only pure $(C_2H_5)_4NCl$ (IR) and $(CH_3BO)_3$ (NMR).

In chloroform. A similar procedure was used utilizing B_2H_6 (6.37 mmol) and $(C_2H_5)_4NCl$ (8.92 mmol). The B_2H_6 is not completely absorbed into the CHCl$_3$ solution leaving considerable pressure in the system above the vapor pressure of CHCl$_3$. Admittance of 13.3 mmol of CO (at less than 1 atm.) into the system and standing at room temperature resulted in a slow absorption of the gases into solution which eventually ceased after 30 hr. Distillation through traps held at $-78°$ and $-196°C$ did not yield any recovered B_2H_6. Pure $(C_2H_5)_4NCl$ (IR) remained in the flask.

Absorption of carbon monoxide into a solution of tetrahydrofuran and diborane with sodium chloride as a catalyst.

A 4.2 mmol sample of carbon monoxide was absorbed after 60 hr into a system containing 19.7 mmol CO, 7.29 mmol B_2H_6, 15 cm^3 THF and 1.4 mmol of NaCl (very little of which was soluble in the solution).

Reduction studies using $K_2H_3BCO_2$

Essentially the same procedure was utilized in the reaction of $K_2H_3BCO_2$ and each of the following organic compounds: benzaldehyde, *m*-nitrobenzaldehyde, butyric acid, benzamide and butyronitrile. The reaction using benzaldehyde is given as an example. (GC or NMR was used for analysis if TLC was inappropriate.)

A 0.2 mmol sample of benzaldehyde was allowed to react with 0.1 mmol of potassium (carboxylato)trihydroborate in 4 cm^3 of methanol with

stirring. The sample was analyzed every 30 min for 2 hours using TLC (1:1 CHCl$_3$:CH$_3$OH) and again after 24 hr. R_f values from the reaction mixture were compared to known samples of pure benzaldehyde and benzyl alcohol.

^{11}B *NMR study of the reactions between n-*$Bu_4P^+OC(O)Me^-$ *with* BH_3CO

7 mmol of n-$Bu_4P^+OC(O)Me^-$ were dissolved in 15–20 ml of dry THF at room temperature in a flask on the vacuum line. A 6 mmole quantity of BH_3CO was added at $-196°C$ and the flask allowed to warm slowly to $0°C$. The ^{11}B NMR of the solution exhibited a $1:3:3:1$ quartet, $\delta = -33.5$ ppm from $BF_3 \cdot Et_2O$.

SOME COMPLEXES OF NICKEL (II) WITH MORPHOLINE

JOSÉ PALAZÓN, JOSÉ GÁLVEZ, GABRIEL GARCÍA and GREGORIO LÓPEZ*

Department of Inorganic Chemistry, University of Murcia, Murcia, Spain

Abstract—The compounds NiX_2M_x[M = morpholine; X = C_6F_5 (x = 2), $NO_3(x = 3)$, Br(x = 2 or 3), and I(x = 4)] have been prepared and investigated. Magnetic and spectral studies have been carried out to determine the mode of coordination and stereochemistry of the complexes. Except for $NiBr_2M_3$, which appears to contain bridging morpholine, in all other compounds the neutral ligand acts as a monodentate N-donor group.

For the elements of the nickel group, a number of complexes containing 1,4-dioxan have been recently prepared.[1-3] This investigation has been now extended to morpholine (M), a related six membered heterocyclic ligand containing two donor sites (O and N atoms). The nitrogen atom is usually the donor in nickel[4-6] and palladium complexes[7] with morpholine, but the ligand has been found to act as a bridging group in some cases.[8]

This paper reports on the preparation of the nickel complexes NiX_2M_x, where X = C_6F_5, NO_3, Br, and I. Magnetic and spectral studies have been carried out to determine the mode of coordination and stereochemistry of the complexes.

EXPERIMENTAL

Materials

Morpholine and 2,2-dimethoxypropane were obtained from May and Baker Ltd. and Fluka, respectively, and used as such. Nickel salts were commercial products. Diethyl ether and tetrahydrofuran were distilled over sodium in the presence of benzophenone.

Analyses

The C, H, N analyses were performed with a Perkin–Elmer 240 C microanalyzer. Nickel was determined by titration with EDTA.[9]

Physical measurements

IR spectra were recorded in the 4000–250 cm^{-1} range on a Nicolet MX-1 spectrophotometer as Nujol or Fluorolube mulls. The diffuse reflectance

spectra were recorded as Nujol mulls in the 5000–30000 cm^{-1} range on a Beckman DK-2A spectrophotometer. The mulls were smeared between two glass plates on filter paper and run against a reference consisting of similar plates containing Nujol only. Thermal decomposition studies were carried out in nitrogen on a Netzsch STA-429 thermobalance. Magnetic susceptibilities were measured by the Faraday method using a Bruker B-15 magnetic balance (magnetic field, 7 kG) calibrated with Co[Hg(SCN)$_4$].[10] Conductivities were measured with a Philips PW 9501/01 conductimeter.

Preparation of the complexes

$Ni(NO_3)_2M_3$. Ni(NO$_3$).6H$_2$O (1 g; 3.4 mmol) was refluxed in 2,2-dimethoxypropane (8 cm^3) for 1 hr. After cooling the resulting yellowish green solution, 8 cm^3 of morpholine were added and the colour of the solution turned to deep green. Addition of diethyl ether (20 cm^3) resulted in the formation of a sticky product, which was transformed into a green powder by stirring for 48 hr in the same solvent. The solid was filtered under nitrogen and dried under vacuum. Yield, 84%. The compound is hygroscopic and was kept in a P$_4$O$_{10}$ desiccator.

$NiBr_2M_3$. As NiBr$_2$.3H$_2$O (1 g; 3.7 mmol) was refluxed in 2, 2-dimethoxypropane (8 cm^3) for 1 hr, a brownish–yellow suspension was formed, which turned green on cooling. Addition of morpholine (8 cm^3) to the reaction mixture changed again from green to yellow. After stirring for 4 hr, the precipitate was filtered off, washed with diethyl ether, and dried under vacuum. Yield, 75%. The very hygroscopic brownish–yellow product was kept in a P$_4$O$_{10}$ desiccator.

$NiBr_2M_2$. This blue compound was formed sim

ply when $NiBr_2M_3$ was heated at 130°C under nitrogen atmosphere. Yield, 100%. It is hygroscopic.

NiI_2M_4. Anhydrous NiI_2 (1 g; 3.2 mmol; prepared by heating the hydrated salt at 140°C) was stirred in morpholine/2, 2-dimethoxypropane (10 cm³/3 cm³) for 12 hr. The reaction mixture, initially dark brown, changed to green and the resulting solid was filtered off, washed with diethyl ether, and dried under vacuum. Yield, 72%.

$Ni(C_6F_5)_2M_2$. The working up for the preparation of this compound was different from the others. The experimental procedure followed in the preparation of a tetrahydrofuran-dioxane solution containing "$Ni(C_6F_5)_2$" was adapted from Ref. 1. A freshly prepared and filtered solution of C_6F_5MgBr (1.145 mmol) in THF (15 cm³) was added to a suspension of anhydrous $NiBr_2$ (100 mg; 0.458 mmol) in THF (5 cm³). After refluxing for 2 hr, 10 cm³ of dioxane were added, to precipitate the magnesium salts as dioxane adducts. After standing in the cold overnight, the solid was filtered off and the resulting orange solution was then treated with 0.5 cm³ of morpholine and the colour immediately changed to yellow. The solution was stirred for 30 min at room temperature, then concentrated under vacuum. Addition of hexane afforded a golden yellow solid, which was recovered by filtration and recrystallized from $CHCl_3$/hexane. Yield, 70%.

RESULTS AND DISCUSSION

The organocomplex $Ni(C_6F_5)_2M_2$ was prepared by addition of morpholine to a recently prepared tetrahydrofuran-dioxane solution containing "$Ni(C_6F_5)_2$"[1]:

$$\text{"Ni(C}_6\text{F}_5)_2\text{" in THF-dioxane} \xrightarrow{+M} \text{Ni(C}_6\text{F}_5)_2\text{M}_2.$$
All other nickel compounds were prepared by addition of morpholine to the respective hydrated or anhydrous nickel salts in the presence of the dehydrating agent 2,2-dimethoxypropane, where the substitution reaction takes place. The analytical data and some physical properties of the nickel compounds are collected in Table 1.

The IR spectrum of the yellow organocompound, $Ni(C_6F_5)_2M_2$, shows the characteristic absorptions of the C_6F_5 group[11] at *ca.* 1630 m, 1500 vs, 1050 vs, and 780 s cm^{-1}. The diamagnetism and electronic spectrum (Table 2) are compatible with a square planar geometry for this species. Moreover, the infrared band observed at 781 cm^{-1} has been used for structural elucidation. As in previous cases[2,12] the number of infrared bands observed for the X-sensitive mode has been correlated with the symmetry of the C–M–C skeleton on the basis that in complexes containing $M–C_6F_5$ bonds this mode has mainly $v(M–C)$ character.[12] Accordingly, we assign the *trans* configuration to $Ni(C_6F_5)_2M_2$, since its spectrum shows a single band in the 800–750 cm^{-1} range (D_{2h} symmetry).

The stoichiometry, magnetic moment, and electronic spectral data (Table 2) are all compatible with an octahedral geometry for the green compound NiI_2M_4.[13] Thus its electronic spectrum shows three bands at 8700, 15,060 and 25,640 cm^{-1}, which can be assigned to the transitions from the ground state $^3A_{2g}(F)$ to the excited states $^3T_{2g}(F)(v_1)$, $^3T_{1g}(F)(v_2)$ and $^3T_{1g}(P)(v_3)$, respectively. From the corresponding Tanabe-Sugano diagram and with $v_2/v_1 = 1.73$, $Dq/B = 1.04$ is obtained. Hence for NiI_2M_4 $10 Dq = 8,700$ cm^{-1}, $B = 870$ cm^{-1} and $\beta = 0.84$. Moreover, the v_3 transition is predicted to be at 25,750 cm^{-1} a value which is in good agreement with the experimental one (25,640 cm^{-1}).

Table 1. Colours, melting points, and analytical data of nickel compounds

NiI_2M_4	3.19	8,700; 15,060; 25,640

[a]At 15 °C; diamagnetic corrections were made. [b]In acetone solution.

The compounds $NiBr_2M_3$ and $Ni(NO_3)_2M_3$ are very hygroscopic and in water give pale green solutions. Their electronic spectra show three bands (Table 2) which can be interpreted assuming pseudooctahedral geometries for both compounds. However, the internal consistency of the spectral data is not so good as that observed for the above-mentioned iodocomplex, and any intent to derive values for the ligand field parameters would be meaningless. The assignation of hexacoordinate nickel in $NiBr_2M_3$ requires that either Br or morpholine acts as bridging ligand and, in fact, there is infrared spectral evidence (see below) that some morpholine is O-bonded to nickel. A similar situation should be present in $Ni(NO_3)_2M_3$, but since no O-bonded morpholine is evidenced by the IR spectrum, coordinated nitrate groups should be here within the coordination sphere of the metal atom. In fact, its infrared spectrum shows the absorptions typical of coordinated NO_3 groups:[14] 1490 vs, 1420 vs, 1300 sh and 805 m. The structural situation could be similar to that observed for $Ni(NO_3)_2(3\text{-pic})_3$,[15] where it was assumed that one nitrate group acts as a unidentate and the other as a bidentate ligand. The conductivity of $Ni(NO_3)_2M_3$ in $10^{-3}M$ acetone solution ($\Lambda_M = 18 \text{ cm}^2\Omega^{-1}\text{mol}^{-1}$) also supports[16] the assigned structure.

The paramegnetism of the deep blue $NiBr_2M_2$ definitely rules out the presence of square planar arrangement about the divalent nickel ion. The electronic spectrum of this complex shows two single bands at 8700 and 11,365 cm^{-1}, and a third double band with absorption maxima at 15,875 and 17,240 cm^{-1}. This result and the similarity of the spectrum with those observed for pseudotetrahedral complexes of the type NiL_2X_2 (both

shape and frequencies are nearly identical to those reported for $Ni(Me_4tn)Br_2)$[17] lead us to assign a pseudotetrahedral structure to this compound. On this basis, the band at 8700 cm^{-1} is assigned to one of the three compounds of the v_1 transition, $^3T_1(F) \rightarrow ^3T_2(F)$, the band at 11,365 cm^{-1} as the $v_2{}^3T_1(F) \rightarrow ^3A_2(F)$, and the bands at 15,875 and 17,240 cm^{-1}, which are not resolved, as $v_3{}^3T_1(F) \rightarrow ^3T_1(P)$. The abnormally high position of the component of v_1 could be taken as indicative of a large distortion of the T_d symmetry.[18] The low magnetic moment (3.02 BM) found for this compound also supports the presence of such a distortion.

The characteristic infrared bands of morpholine in these complexes are collected in Table 3. For comparison, bands of the free ligand are also shown. Since the N-hydrogen (and lone pair) can be equatorial or axial, free morpholine can obviously exist as two conformers,[19] but the most probable conformation adopted by coordinated morpholine should be the axial one. In free axial morpholine, the N–H stretching vibration occurs at 3298 cm^{-1}; on complexation this band is shifted to lower frequencies and sometimes it is split due to solid state effects.[20,21] In good agreement, this vibration appears at ca. 100 cm^{-1} lower in the spectra of the nickel complexes (except for $Ni(C_6F_5)_2M_2$). In free morpholine the fundamentals v_{13} and v_{31} (at 1097 and 1225 cm^{-1}, respectively) have the largest contributions from C–N stretch whereas v_{14} and v_{32} (at 1031 and 1201 cm^{-1}, respectively) are predominantly C–O stretch. On this basis, we assign the bands at ca. 1225 and 1100 cm^{-1} as derived from the fundamentals v_{31} and v_{13} of morpholine, respectively. In the 1100–1040 cm^{-1} range one or two bands (or

Values in parentheses are from the equatorial conformer.[19] Except for Ni(C$_6$F$_5$)$_2$M$_2$, an additional band is observed in the 1600–1550 cm^{-1} range. However, the fundamental ν_{33}, at 1141 cm^{-1} in free morpholine, is not observed in the spectra of nickel compounds.

shoulders) are observed, which can be derived from ν_{13}, since the C–N vibration will be affected by the nitrogen to nickel bonding. Except for NiBr$_2$M$_3$, the C–O stretching modes are observed in the spectra of the nickel complexes at nearly the same frequency as in free morpholine, indicating that the neutral ligand acts here as unidentate N-donor ligand. However, in NiBr$_2$M$_3$ the C–O stretching modes appear as double bands (1195, 1175 cm^{-1} and 1035, 1025 cm^{-1}, respectively), which can be attributed to the presence of both unidentate and bidentate morpholine. These results are compatible with those obtained from the corresponding analytical and electronic spectral data.

KINETICS AND SALT EFFECTS OF THE REDUCTION OF OCTACYANOMOLYBDATE(V) AND OCTACYANOTUNGSTATE(V) BY SULPHITE IONS

CHARLES R. DENNIS, STEPHEN S. BASSON and JOHANN G. LEIPOLDT*

Department of Chemistry, University of the Orange Free State,
Bloemfontein 9300, Republic of South Africa

Abstract—The kinetics of the reduction of octacyanomolybdate(V) and octacyanotungstate(V) by sulphite ions has been studied over a wide pH range. The reaction is catalysed by alkali metal ions. The rate law is found to be of the form:

$$R = \left(\frac{a[A^+] + b[H^+]}{c + [H^+]}\right)[M(CN)_8{}^{3-}][SO_3{}^{2-}].$$

The third order rate constants at $[OH^-] = 0.05$ mol dm^{-3} for the reduction of $Mo(CN)_8{}^{3-}$ and $W(CN)_8{}^{3-}$ were determined as 6.2×10^3 dm^6 mol^{-2} s^{-1} and 22.3 dm^6 mol^{-2} s^{-1} respectively at 298 K for $A^+ = Na^+$ while K_a for the hydrogen sulphite ion was determined as 2.4×10^{-8} mol dm^{-3}. It was established that the reaction proceeds via an outer-sphere mechanism. An explanation for the alkali metal ion catalysis is proposed.

The reaction between hexacyanoferrate(III) and sulphite ions has been the subject of various publications. Both inner- and outer-sphere mechanisms have been proposed. An inner-sphere mechanism[1] via a $Fe(CN)_5SO_3{}^{4-}$ intermediate was proposed but later studies[2] with labelled ^{14}CN-ions disproved the existence of such a species. Brown and Higginson[3] also prefered an inner-sphere mechanism because the hexacyanoferrate(III) ion is a mild oxidant. Other studies[4,5] suggested a mechanism where a complex, $[Fe(CN)_5\cdot(CN\cdot SO_3)]^{5-}$, is formed between the hexacyanoferrate(III) and sulphite ions, in which the sulphito group is bonded directly to a cyano ligand. This was described as a compromise between an inner- and outer-sphere mechanism. A reinvestigation[6] has shown that the SO_3^- product radical ion of the rate determining step also formed a similar intermediate in the subsequent reduction of $Fe(CN)_6{}^{3-}$ ions.

The $Fe(CN)_6{}^{3-} - SO_3{}^{2-}$ reaction, with first order dependences on hexacyanoferrate(III) and sulphite ion concentrations respectively is retarded by addition of product $Fe(CN)_6{}^{4-}$ ions[7] whilst $[OH^-]$ had no significant effect on the reaction rate for the concentration range between 0.26 and 0.60 mol dm^{-3}. These results led to a proposed radical and complex forming reaction mechanism in which observed alkali metal ion catalytic effects were not provided for. The kinetics of the reduction of octacyanomolybdate(V) and octacyanotungstate(V) by sulphite ions were investigated in order to compare the kinetics of these reactions with that of $Fe(CN)_6{}^{3-}$ with $SO_3{}^{2-}$, as well as to clarify the alkali metal ion catalysis.

EXPERIMENTAL

$Cs_3Mo(CN)_8\cdot 2H_2O$ and $Cs_3W(CN)_8\cdot 2H_2O$ were prepared by literature methods[8–10] and were used as primary standards after recrystallization. Analytical grade sodium sulphite was used as source of sulphite ions and was standardized by an iodimetric method. All other reagents were of analytical grade and redistilled water was used throughout. The desired buffer solutions at constant ionic strength for the kinetic measurements at a pH between 5 and 9 were prepared by mixing suitable volumes of 0.067 mole dm^{-3} Na_2HPO_4 and 0.20 mole dm^{-3} NaH_2PO_4. An Orion pH-meter (model 701) was used for pH measurements.

The sulphite ion concentrations in the reaction mixtures were at least ten-fold in excess to the

*Author to whom correspondence should be addressed.

concentration of the complex cyanide to ensure pseudo-first-order reaction conditions. Sodium ethylenediaminetetraacetate was added to each reaction mixture to suppress catalysis by metal ion impurities. The reaction progress for the reduction of the $Mo(CN)_8^{3-}$ was followed by measuring the decrease in $[Mo(CN)_8^{3-}]$ at 390 nm using a Durrum D-110 stopped-flow spectrophotometer while the reduction of $W(CN)_8^{3-}$ was followed by measuring the decrease in $[W(CN)_8^{3-}]$ at 357 nm using a Pye Unicam SP 1700 spectrophotometer. In both cases the temperature was controlled to within 0.1 K.

The stoichiometry of both reactions was determined volumetrically by oxidation of the products $M(CN)_8^{4-}$ (M = Mo, W), with standard Ce(IV) solutions using N-phenylanthranilic acid as indicator.

RESULTS AND DISCUSSION

The stoichiometry determinations confirmed the overall reaction in alkaline medium to be:

$$2M(CN)_8^{3-} + SO_3^{2-} \rightarrow 2M(CN)_8^{4-} + SO_4^{2-}. \tag{1}$$
The pseudo-first-order plots of $\log[M(CN)_8^{3-}]$ vs time were linear for at least two half lives. The kinetic results show that the reactions are also first order with respect to $[SO_3^{2-}]$ while the concentration of the product, $[M(CN)_8^{4-}]$, had practically no effect on the reaction rate. Both reactions show first order dependence with respect to the alkali metal ion concentration. The effect of the different alkali metal ions on the rate of the reaction between $W(CN)_8^{3-}$ and SO_3^{2-} at $[OH^-] = 0.05$ mole dm^{-3} are shown in Fig. 1. It was also found that the reaction rate is independent of $[OH^-]$ for pH > 9.0 and dependent on $[OH^-]$ for pH < 9.0. The effect of the pH on the reaction rate for the reaction between $Mo(CN)_8^{3-}$ and SO_3^{2-} in the presence of sodium ions is shown in Fig. 2. The third order rate constants for the various alkali metal ions for the reduction of $Mo(CN)_8^{3-}$ and $W(CN)_8^{3-}$ at high pH are shown in Fig. 3.

The fact that a plot of the first order rate constant against alkali metal ion concentration is linear with a zero intercept (Fig. 1) show a very strong alkali metal ion catalysis. To show that this effect is not due to the variation of the ionic strength, the alkali metal ion concentration was varied at constant ionic strength using KCl, K_2SO_4 and $K_3Co(CN)_6$ as electrolytes (Table 1). These results clearly show the alkali metal ion catalysis.

The observed dependence of k_{obs} on the pH (Fig. 2) as well as the first-order dependence in each of alkali metal (A^+), sulphite and $M(CN)_8^{3-}$ ion

Fig. 1. A plot of k_{obs} vs alkali metal ion concentration for the $W(CN)_8^{3-}$ reaction $[W(CN)_8^{3-}] = 5 \times 10^{-4}$, $[SO_3^{2-}] = 5 \times 10^{-3}$, $[OH^-] = 0.05$, $[EDTA] = 1 \times 10^{-5}$ mol dm^{-3}, T = 293 K.
Fig. 2. A plot of k_{obs} vs pH for the $Mo(CN)_8{}^{3-}$ reaction. $[Mo(CN)_8{}^{3-}] = 5 \times 10^{-4}$, $[SO_3{}^{2-}] = 5 \times 10^{-3}$, $[Na^+] = 0.1$, $[EDTA] = 1 \times 10^{-5}$ mol dm^{-3}, T = 298 K.

Fig. 3. A plot of the rate constant vs polarisability of the alkali metal cations. $[OH^-] = 0.05$ mol dm^{-3}; T = 298 K. $[EDTA] = 1 \times 10^{-5}$ mol dm^{-3}. ●, $Mo(CN)_8{}^{3-}$ reaction; ■, $W(CN)_8{}^{3-}$ reaction.
Table 1. Experimental third order rate constants at constant ionic strength with different electrolytes for the $Mo(CN)_8^{3-}$ reaction. $[OH^-] = 0.05 \, mol \, dm^{-3}$, $T = 298 \, K$. $[EDTA] = 1 \times 10^{-5} \, mol \, dm^{-3}$

Electrolyte	$I = 0,3 \, mol \, dm^{-3}$		$I = 0,6 \, mol \, dm^{-3}$	
	$[K^+]$	$k_{obs} \times 10^{-4}$ $dm^6 \, mol^{-2} s^{-1}$	$[K^+]$	$k_{obs} \times 10^{-4}$ $dm^6 \, mol^{-2} s^{-1}$
KCl	0,30	1,27	0,60	1,28
K_2SO_4	0,20	1,27	0,40	1,28
$K_3Co(CN)_6$	0,15	1,28	0,30	1,28

concentrations show the rate law to be

$$\frac{-d \, [M(CN)_8^{3-}]}{dt} = \left(\frac{a[A^+] + b[H^+]}{c + [H^+]} \right)$$
$$\times [M(CN)_8^{3-}][SO_3^{2-}] \quad (2)$$

The following equilibria exist in solution:

$$HSO_3^- \overset{K_1}{\rightleftharpoons} H^+ + SO_3^{2-} \quad (3)$$

$$A^+ + M(CN)_8^{3-} \overset{K_2}{\rightleftharpoons} AM(CN)_8^{2-} \quad (4)$$

$$A^+ + SO_3^{2-} \overset{K_3}{\rightleftharpoons} ASO_3^- \quad (5)$$

Equilibrium 3 explains the observed hydrogen ion dependence. The increase in the reaction rate with increase of pH (see Fig. 2) shows that the SO_3^{2-} ion is much more reactive than the HSO_3^- ion. The lower reactivity of the HSO_3^- ion may be explained as follow: Connick[11] has shown that the following equilibria exist in aqueous solution

$$:SO_3^{2-} + H^+ \rightleftharpoons H:SO_3^- \rightleftharpoons HO\overset{..}{S}O_2^-$$
$$\qquad\qquad\qquad\quad \mathbf{I} \qquad\qquad \mathbf{II}$$
I is the dominant form while isomer **II** is present in only a small amount. Both isomers **I** and **II** will be unreactive; in **I** the lone pair is tied up by the H^+ ion while in **II** electron density will be withdrawn from the sulphur atom by the H^+ ion.
Equilibria 4 and 5 represent the outer-sphere ion-pair formation reactions. The association constants, K_2, for a few cations with $Mo(CN)_8^{3-}$ and $W(CN)_8^{3-}$ were determined with specific-ion electrodes, see Table 2. These values are of the same magnitude as found for cyanocomplexes (3:1 electrolytes) determined by conductivity measurements[12].

The association constant K_3 is not known. It is however expected to be lower than the value for SO_4^{2-} with K^+ ions (approx. $3 \, dm^3 \, mol^{-1}$). The
formal charge on the sulphur atom in $:SO_3^{2-}$ is $+1$ and -1 at each oxygen atom while in the case of SO_4^{2-} the formal charge on the sulphur atom is zero and $-\frac{1}{2}$ on each oxygen atom. A cation paired to SO_4^{2-} gets thus less nett repulsion from the nearby sulphur atom than in SO_3^{2-}. Apart from this, it is expected (as in the case of HSO_3^-) that ASO_3^- will be less reactive than SO_3^{2-}.

It is clear from the above discussion that reactions 4 and 5 cannot explain the strictly first order dependence (see Fig. 1) of the reaction in the alkali metal ion concentration range employed.

The experimental results may be explained by the following reaction mechanism:

$$HSO_3^- \overset{K_1}{\rightleftharpoons} H^+ + SO_3^{2-} \quad (3)$$

$$A^+ + M(CN)_8^{3-} \overset{K_2'}{\rightleftharpoons} [(CN)_7MCN:A]^{2-} \quad (6)$$

$$[(CN)_7MCN:A]^{2-} + SO_3^{2-}$$
$$\overset{K_4}{\rightleftharpoons} [(CN)_7MCN:A:SO_3]^{4-} \quad (7)$$

$$[(CN)_7MCN:A:SO_3]^{4-} \overset{k_1}{\rightarrow} SO_3^-$$
$$+ M(CN)_8^{4-} + A^+ \quad (8)$$

Table 2. Association constants for alkali metal ions with complex cyanide ions. $T = 298 \, K$; $I = 0.1 \, mol \, dm^{-3}$

Cation	Anion	$K_{ass} \, (dm^3 \, mol^{-1})$
K^+	$Fe(CN)_6^{3-}$	$4,8 \pm 1$
K^+	$W(CN)_8^{3-}$	$9,6 \pm 3$
Na^+	$W(CN)_8^{3-}$	$13,5 \pm 6$
Na^+	$Mo(CN)_8^{3-}$	$10,0 \pm 2$
Cs^+	$Mo(CN)_8^{3-}$	$9,5 \pm 3$
Cs^+	$W(CN)_8^{3-}$	$7,9 \pm 2$

$$HSO_3^- + M(CN)_8^{3-} \overset{K_5}{\rightleftharpoons} [(CN)_7MCN:H:SO_3]^{4-} \quad (9)$$

$$[(CN)_7MCN:H:SO_3]^{4-} \overset{k_2}{\rightarrow} SO_3^-$$

$$+ M(CN)_8^{4-} + H^+ \quad (10)$$

$$SO_3^- + M(CN)_8^{3-} \overset{k_3}{\rightarrow} SO_4^{2-} + M(CN)_8^{4-}$$

$$(11) \quad \text{fast}$$

Reactions 6–8 represent the contact ion-pair formation between complex cyanide and alkali metal ions, bridging of the lone pair on SO_3^{2-} with the cation part of the contact ion-pair and the slow rate determining step respectively. K_2', the contact ion-pair formation constant, is expected to be much smaller than K_2 (reaction 4) since A^+ is more specifically bonded to the nitrogen lone pair of a cyanide ligand in contrast to the outer-sphere ion association of equilibrium 4.

Reactions 9 and 10 explain the slow observed reaction rate in acidic solution, see Fig. 3. The hydrogen bond formation between HSO_3^- and $M(CN)_8^{3-}$ (reaction 9) explains the absence of any alkali metal ion catalysis in acidic solution. Such a hydrogen bond formation was also proposed for the solid state in the crystal structure determination of $H_4W(CN)_8 \cdot 4HCl \cdot 12H_2O$[13] and tetrakis(pyridinium - 2 - carboxylicacid)octacyanomolybdate(IV)[14].

The rate law according to the proposed mechanism is given by

$$\frac{-d[M(CN)_8^{3-}]}{dt} = \left(\frac{k_1 K_1 K_2' K_4[A^+] + k_2 K_5[H^+]}{K_1 + [H^+]} \right)$$

$$\times [SO_3^{2-}]_T[M(CN)_8^{3-}]. \quad (12)$$

This corresponds to the experimental results (eqn 2) with $a = k_1 K_1 K_2' K_4$, $b = k_2 K_5$ and $c = K_1$.

The value of K_1 for reaction 3 was calculated from a least squares fit of the data in Fig. 2 to eqn (12). The calculated value of $pK_1 = 7.62$ at $I = 0.1 \text{ mol dm}^{-3}$ is in very good agreement with the value given by Meites[15] and Dick[16] of 7.64 at $I = 0.1 \text{ mol dm}^{-3}$.

Futher evidence for the proposed mechanism is the increase in the reaction rate from Li^+ to Cs^+, see Fig. 3. The same phenomena as well as strictly first order dependence on the alkali metal ion concentrations were also observed for the reactions of $Mo(CN)_8^{3-}$ and/or $W(CN)_8^{3-}$ with I^{-}[17,18], As (III)[19,20], $Se(IV)$[21], $Te(IV)$[22] and thiourea.[23] The large increase in the reaction rates from Li^+ to Cs^+ may be due to the greater effectivity of the

Fig. 4. A plot of $\log k_{obs}$ vs reduction potential $(A^+ = Na^+)$.

larger alkali metal ion as a charge buffer (and thus stabilization of the proposed intermediate $[(CN)_7MCN:A:SO_3]^{4-}$) and a bridge for electron transfer. Another evidence for this view on the catalytic effect of the alkali metal ions where they serve as an electron bridge is the linear relationship between the experimental rate constants and the polarizability[24] of the cations, (see Fig. 3).

The Marcus cross-relation (eqns (13)–(15)) predicts a type of linear behaviour with gradient 8.46 where k_{12} is the cross-reaction rate constant, k_{11} and k_{22} are the self exchange rate constants for the couples and K_{12} is the equilibrium constant:

$$k_{12} = (k_{11}k_{22}k_{12}f)^{1/2} \quad (13)$$

$$\log K = \frac{n(\Delta E^\circ)}{0.0591} \quad (14)$$

$$\log k_{12} = 0.5(\log k_{11} + \log k_{22} + \log f)$$

$$+ 8.46 \, n(\Delta E^\circ). \quad (15)$$

A plot of $\log k_{obs}$ $(A^+ = Na^+$ and $[OH^-] = 0.05 \text{ mol dm}^{-3})$ for the oxidation of the sulphite ions by $Mo(CN)_8^{3-}$, $W(CN)_8^{3-}$ and $Fe(CN)_6^{3-}$ (last value from Swinehart[7]) vs E° of the oxidizing agents[25](Fig. 4) is linear with a gradient of 9.2 V^{-1}. This is in very good agreement with the theoretical value and show that the Marcus theory is valid for those oxidations. This result also support the outer-sphere reaction mechanism proposed for the $Fe(CN)_6^{3-}$-sulphite reaction.[7]

A VARIABLE TEMPERATURE ¹H NMR STUDY OF STEREOCHEMICAL NON-RIGIDITY IN GROUP VI METAL PENTACARBONYL COMPLEXES OF 1,3,5,7-TETRATHIAN; [M(CO)₅(SCH₂SCH₂SCH₂SCH₂)] (M = Cr OR W)

E. W. ABEL, G. D. KING, K. G. ORRELL* and V. ŠIK

Department of Chemistry, University of Exeter, Exeter EX4 4QD, England

Abstract—Stereochemical non-rigidity in the complexes [M(CO)₅(SCH₂SCH₂SCH₂SCH₂)] (M = Cr or W) has been studied by dynamic nuclear magnetic resonance spectroscopy. In the temperature range *ca.* −100 to 120°C two intramolecular processes were observed, namely pyramidal atomic inversion about sulphur atoms, and a commutation of the M(CO)₅ moiety between coordination sites on different sulphur atoms. Accurate energy barriers for both processes have been obtained by detailed computer simulations of the static and the dynamic spectra. The magnitudes of ΔG^+ (298.15 K) are compared with those reported for related complexes. The exact nature of the M(CO)₅ shift cannot be unambiguously assigned from the observed spectral line-shape changes. Two possible mechanisms are proposed and discussed.

Dynamic NMR studies[1] have cast considerable light upon fluxional processes, and in recent years we have shown[2–8] that coordination complexes of the general formula [M(CO)₅L] (M = Cr, Mo or W; L = a sulphur or selenium containing ligand) can undergo a remarkable variety of *intra-molecular* rearrangements. To date, such fluxions include pyramidal atomic inversions,[2–5] 1,2-metal shifts,[4,5] 1,3-metal shifts,[2,7,8] and 6-membered ring reversals.[2,8] Accurate energy barriers for all of these processes have been obtained utilising well developed spectral line-shape analysis techniques.[9] During the course of these investigations it has become evident that the magnitude of ΔG^+ (298.15 K) for such processes is dependent upon several factors such as the nature of the metal centre, the ligand atom and the stereochemistry of the ligand.

We have recently reported[8] the results of investigations into the stereochemical non-rigidity of Group VI metal pentacarbonyl complexes of substituted and unsubstituted 1,3,5-trithian. At temperatures above ambient a commutation of the M(CO)₅ group, via a series of 1,3-shifts, over all possible sulphur coordination sites was observed. It was postulated that the magnitude of the ΔG^+

(298.15 K) parameter for such a process is largely dependent on the skeletal flexibility of the ligand. In an attempt to corroborate this we have investigated the M(CO)₅ complexes of the larger, more flexible, eight membered ring ligand 1,3,5,7-tetrathian, SCH₂SCH₂SCH₂SCH₂. Variable temperature ¹H NMR studies of the complexes [M(CO)₅(SCH₂SCH₂SCH₂SCH₂)] (M = Cr or W) exhibit pyramidal atomic inversions about ligand sulphur atoms, and at temperatures well above ambient, a commutation of the M(CO)₅ group among coordination sites of different sulphur atoms occurs. The precise energy barriers obtained for both processes are compared with those for the corresponding trithian complexes.

EXPERIMENTAL

Materials and preparations

Metal hexacarbonyls were obtained commercially, and purified by sublimation (50°C/0.005 mmHg). 1,3,5,7-tetrathian was prepared and purified using literature procedures.[10,11] The complexes [M(CO)₅(SCH₂SCH₂SCH₂SCH₂)] (M = Cr or W) have been previously reported.[12,13] All reactions and manipulations were performed under an atmosphere of nitrogen, using freshly distilled, nitrogen purged solvents. Analytical data are reported in Table 1.

Spectra

These were obtained as described in detail in a previous publication.[8]

Line shape analyses

These were carried out using modified versions[14] of the original DNMR3 program of Kleier and Binsch.[15,16] Variable temperature experimental spectra and computer simulated spectra were compared visually until "best-fits" were obtained. The rate constants so obtained were used with the sample temperatures, to obtain the Arrhenius and Eyring activation parameters for the fluxional processes, using a least squares fitting technique. Errors quoted for the free energy of activation (ΔG^+) were calculated from the standard deviation term $|\sigma(\Delta H^+) - T\sigma(\Delta S^+)|$ as prescribed by Binsch and Kessler.[9]

RESULTS

^{1}H NMR studies

The two complexes [M(CO)$_5$(SCH$_2$SCH$_2$SCH$_2$SCH$_2$)] (M = Cr or W) showed essentially similar spectral changes at temperatures both above and below ambient. The chromium complex is taken as typical.

Low temperature studies

At ambient temperature the 100 MHz ^{1}H NMR spectrum of [Cr(CO)$_5$(SCH$_2$SCH$_2$SCH$_2$SCH$_2$)] in CD$_2$Cl$_2$/CS$_2$ (70:30, v:v) shows two singlets, intensity ratio 1:1. The four methylene protons adjacent to the coordinated sulphur atom are closest to the influence of the metallic group and are therefore assigned to the singlet at higher frequency. Cooling to below −100°C caused this signal to resolve into an AB quartet (see Fig. 1). Concurrently, the other (lower frequency) singlet was observed to broaden significantly. These spectral changes are consistent with the cessation of pyramidal atomic inversion of the coordinated sulphur atom.

Crystallographic studies have established[17] the boat-chair arrangement to be the conformation of the molecule of 1,3,5,7-tetrathian. It is not unreasonable to assume that the boat-chair structure is retained in solutions of the Cr(CO)$_5$ complexes. This results essentially in two different molecules depending upon whether the Cr(CO)$_5$ moiety is an axial or equatorial substituent to the ligand ring as illustrated in Fig. 2. Two fluxional processes can interchange these conformations. The effects of the sulphur atom inversions and the ring reversals
Scheme 1.
Fig. 1. Experimental and computer simulated low temperature spectra of [Cr(CO)₅(SCH₂SCH₂SCH₂SCH₂)] showing the effects of pyramidal sulphur inversion; L = free ligand, M = methylene protons attached to C(2) and C(3).

upon the methylene protons closest to the metal coordinated sulphur are illustrated in Fig. 3. If both processes were slow on the NMR time scale the spectrum for these four protons would consist of two AB quartet patterns in an intensity ratio

corresponding to the relative populations of the two different molecules (I + III) and (II + IV). It has already been noted[18] however, that ring reversal in uncomplexed 1,3,5,7-tetrathian is rapid even at −170°C. Further, it has been shown that coor-
Fig. 3. The effect of ring reversal (R.R.) and pyramidal sulphur inversion (S.I.) on the environments of the four methylene protons adjacent to the coordinated sulphur atom in $[M(CO)_5(\overline{SCH_2SCH_2SCH_2SCH_2})]$ (M = Cr or W).

dination of such rings to metal moieties has no appreciable influence on ring reversal barriers.[19] Thus at *ca.* −100°C there would be rapid equilibration of conformers (I) and (II) with (IV) and (III) respectively. The single AB quartet observed is therefore the ring-reversal-averaged result of the two quartets possibly expected.

Ideally, similar spectral changes should be observed for the methylene protons on C(2) and C(3). However, their greater distance from the metal centre very considerably reduces the chemical shift difference between the equatorial and axial protons, and consequently their ambient temperature singlet broadens, but without any well defined splitting.

The full dynamic nuclear spin problem for the "metal-adjacent" protons is outlined in Fig. 3., but due to the absence of ^4J(H–C–S–C–H) coupling and rapid ring reversal this simplifies to an $AB \rightleftharpoons BA$ exchange problem. The experimental and computed spectra are shown alongside in Fig. 1. The static parameters used in the band shape fittings are listed in Table 2. The coordinated sulphur atom inversion energies are given in Table

3, where they are compared with those of the corresponding 1,3,5-trithian complexes.

High temperature studies

At ambient temperature the ^1H NMR spectrum of $[Cr(CO)_5(\overline{SCH_2SCH_2SCH_2SCH_2})]$ consists of two singlets of equal intensity from the four equilibrated "metal-adjacent" protons and the four equilibrated "metal-remote" protons. On increasing the temperature these two singlets collapse to a single band (*ca.* 105 and 120°C respectively for the chromium and tungsten complexes), which does not exchange with the sharp proton resonance of added free ligand. This spectral collapse is completely reversible on temperature drop. At temperatures higher than those quoted above the ligand resonance commences broadening with the onset of *inter*-molecular ligand–metal exchange processes.

The coalescence of these two separate resonances is consistent with an *intra*-molecular equilibration of all of the ligand methylene environments. As in the cases of the analogous complexes of 1,3,5-trithian and β-2,4,6-trimethyl-1,3,5-

a   Calculated for T = 298.15K.

trithian,[8] this is believed to be a consequence of the M(CO)$_5$ group commuting between the coordination sites of the different sulphur atoms. In the trithians[8] only 1,3-shifts are possible, and the post-shift metal destinations are exactly equivalent. However, the "additional" sulphur atom present in the 1,3,5,7-tetrathian means that in addition to two 1,3-shift movements, there is a possible 1,5-movement. These possibilities, along with their effects upon the chemical and magnetic environments of all methylene protons, are illustrated in Fig. 4.

Although the full dynamic nuclear spin problem initially appears quite complex, the lack of ^4J(H–C–S–C–H) couplings permits simplification to that shown in Scheme 1(a). This can be further reduced to Scheme 1(b), where $k(T) = k(1,3) + k(1,5)$. It is immediately apparent that there is no possibility of positively deducing

whether a 1,3 or 1,5 or a combination of both types of shift is occurring, since the same nuclear spin averaging would occur in all cases. Further, the inherent simplicity of the ^{1}H NMR spectrum renders ineffective homonuclear double resonance (saturation transfer) techniques, which elsewhere[9] have been so effective in resolving some such ambiguities.

Whilst we are unable to define the exact nature of the intra-molecular rearrangement that occurs in the complexes [M(CO)$_5$(SCH$_2$SCH$_2$SCH$_2$SCH$_2$)] at high temperature, we favour the idea that 1,3-shifts are the predominant and possibly exclusive mechanism, vide infra. The Arrhenius and Eyring parameters for the intra-molecular metal shifts are listed in Table 3, where they are compared with those for the corresponding shifts in trithian complexes. Static parameters used in the band shape fittings are noted in Table 4.
Fig. 4. Diagrammatic representation of 1,3- and 1,5-metal shifts in the complexes [M(CO)₅(SCH₂SCH₂SCH₂SCH₂)] (M = Cr or W) together with their respective effects on the nuclear magnetic spin system of the ligand methylene protons.

DISCUSSION

Energy data of the fluxional processes

Of the activation parameters for fluxional processes, ΔG^+ has been recognised as least susceptible to systematic errors of temperature and rate constant.[9] We therefore, as previously,[2,4,6,8] base our discussions of the relative ease of the fluxional processes upon the ΔG^+ (298.15 K) values listed in Table 3. The *intra*-molecular nature of these rearrangements, is indicated by the absence of exchange with added free ligand. Further confirmation from the numerical values of $\log_{10} A$ and ΔS^+ close to 13 and zero respectively for all cases is notable in Table 3.

1. Pyramidal sulphur inversion

A comparison of ΔG^+ values reveals coordinated sulphur inversion energies for the complexes $[M(CO)_5(\overline{SCH_2SCH_2SCH_2SCH_2})]$ to have a small but finite dependence upon the nature of the Group VI metal, that for chromium being *ca.* 3 kJ mol^{-1} less than for tungsten. This is in line with previous observations in Group VI metal carbonyl complexes. Such a trend we believe to be the result of two main factors.[21,22] Increasing electron withdrawal from an inverting centre leads to increased inversion barriers.[23] With electronegativities of chromium and tungsten being 1.56 and 1.40 respectively,[24] we would expect the chromium complex to have the larger ΔG^+ for inversion, the reverse of what is observed. However, $(p-d)\pi$ interaction of lone pairs of electrons on the inverting sulphur atom with the metal leads to a lowering of the inversion barrier,[21] and this effect has been postulated as an explanation for the different inversion barriers of dialkylsulphides in Pd(II) and Pt(II) complexes.[14,25,26] For sulphur inversion, the $(3p-3d)\pi$ conjugation in the chromium complex will be a considerably more effective overlap than the $(3p-5d)\pi$ conjugation in the tungsten analogue.

The relative magnitudes of the electronegativity and conjugation effects will control the magnitude of ΔG^+ for the inversion process, and in these complexes, with ΔG^+ in the order W > Cr, the conjugation effect apparently overrides the electronegativity influence.

When an inverting atom is incorporated into a ring, the energy barrier increases with reduction in ring size as the "angle-strain" in the transition state becomes greater.[22] The CSC ground state bond angles for the 8- and 6-membered rings $\overline{SCH_2SCH_2SCH_2SCH_2}$ and $\overline{SCH_2SCH_2SCH_2}$ are 102.6°[17] and 98.9°[27] respectively. Both of these should ideally become 120° in the transition state of the inversion process, and easier access of the 8-membered ring to the transition state is highlighted by a difference of *ca.* 10 kJ mol^{-1} in the ΔG^+ values in Table 3 for the 8- and 6-membered rings. Indeed ΔG^+ values for the metal pentacarbonyl complexes of the very flexible 1,3,5,7-tetrathian are very comparable to those of the acyclic complexes[28] $[M(CO)_5(CH_3SCH_2SCH_2SCH_3)]$ ($\Delta G^+ = 42.5$ and 41.6 kJ mol^{-1} for W and Cr respectively), in which "angle-strain" would be virtually zero.

2. Metal group commutations

As already noted, the very simple line-shape changes that occur in the high temperature spectra of the complexes $[M(CO)_5(\overline{SCH_2SCH_2SCH_2SCH_2})]$ (M = Cr or W) do not allow us to discern the precise nature of the $M(CO)_5$ commutation. The 1,3,5,7-tetrathian has much greater flexibility than the 1,3,5-trithian. Whereas the 6-membered ring has an observable slowing of its chair–chair ring reversal (^{1}H NMR coalescence temperature of only $-33°C$)[29] there is no observable slowing of any ring conformational process in the tetrathian ligand down to $-170°C$.[18] A comparison of energies for $M(CO)_5$ commutations (Table 3) shows ΔG^+ values to be significantly greater (*ca.* 5 kJ mol^{-1}) for complexes of 1,3,5,7-tetrathian than those of 1,3,5-trithian. We have previously proposed[8] that ΔG^+ values for 1,3-metal shifts are largely dependent upon the skeletal flexibility of the ligand system. Once again the high flexibility of the 8 membered ring bears comparison with the very flexible acyclic analogues. Thus ΔG^+ for the proposed 1,3-shift in $[W(CO)_5(\overline{SCH_2SCH_2SCH_2SCH_2})]$ is 83.5 kJ mol^{-1} compared with 84.6 kJ mol^{-1} for the 1,3-shift in the acyclic complex $[W(CO)_5(CH_3SCH_2SCH_3)]$.[6]

In a previous study[8] we found that ΔG^+ for a 1,3-shift in complexes of 1,3-dithian (a two-sulphur heterocycle) was much greater than that in 1,3,5-trithian (a three-sulphur heterocycle). As both these ligands have similar flexibilities, it would appear that perhaps a statistical factor associated with the reduced probability (in 1,3-dithian) of access to a suitably placed sulphur atom for the 1,3-shift is in evidence. Therefore, on purely statistical grounds a 1,3-shift in the tetrathian complexes would be favoured over a 1,5-shift. However, there are also the relative distances involved in these two types of commutation to be considered. It is pertinent to note that in the complexes of 1,4-dithian, a two-sulphur heterocycle with an almost identical skeletal flexibility[30] to that of 1,3-dithian, a 1,4-shift was not observed

at any temperature.[31] This would initially imply that any 1,5-shift would be even less likely. However, with highly flexible 8-membered ligand rings, certain conformations may bring sulphur atoms within sufficiently close proximity for 1,5-metal shifts to be feasible. In other words, very high ligand flexibility and 1,5-metal shifts may be to some extent mutually compatible.

It therefore remains an open question as to whether 1,3-, 1,5- or both types of shifts are operating in these tetrathian complexes. However, since the measured activation energies follow the energy trends of clearly identified 1,3-shifts in other complexes, it would seem most likely that, in these 8-membered ligand ring complexes, a 1,3-sulphur-metal commutation is the dominant fluxion.

SYNTHESIS AND CHARACTERIZATION OF URANIUM (VI) CHLORIDE FLUORIDES

Willard H. Beattie and William B. Maier II

Chemistry Division

University of California, Los Alamos National Laboratory

P. O. Box 1663, Los Alamos, New Mexico 87545

Abstract—Uranium (VI) chloride fluorides were synthesized by the reaction of liquid HCl and solid UF_6 between -80 and -114°C. These dark red compounds are unstable above -40 to -60°C. The simplest formulas derived from compositional analysis are UF_5Cl and UF_4Cl_2.

INTRODUCTION

Compounds of the type MF_5Cl, where M is sulfur,[1] selenium,[2] tellurium,[3] tungsten,[4] or rhenium[5] have been synthesized, and the existence of UF_5Cl has been postulated.[6] In addition, UF_4Cl_2 has been made by photolysis of UF_4 and Cl_2 in an Ar matrix.[7] We report here the preparation, and quantitative analysis, of mixtures of UF_5Cl, UF_4Cl_2, and UF_3Cl_3.

These compounds were first observed during solubility studies of UF_6 in low-temperature solvents[8,9] when a red product formed from solid UF_6 in liquid HCl at -80 to -114°C. The red product was very soluble in HCl; the solution was bright red at low concentrations and opaque at high concentrations. The solubility of UF_6 in HCl was not measurable in the presence of the reaction product, but it was <0.01$\underline{M}$ from the estimated weight of the undissolved solid UF_6.

Attempts to synthesize uranium (VI) compounds of the type $UF_{6-n}Cl_n$, where $1 \leq n \leq 5$, at room temperature have been unsuccessful. If UF_6 is mixed with BCl_3, $TiCl_4$ or $AlCl_3$ and warmed to ambient room temperature, the only U(VI) compound reported is UCl_6.[10] It is interesting to note that Michallet et al[11] observed intense red color when UF_6 was mixed with cold liquid or solid $TiCl_4$ at temperature as low as ~80 K, but they attributed the color to a complex, $UF_6 \cdot 2TiCl_4$.

We have examined the reaction of UF_6 with several chlorinators. Well-controlled preparations can be arranged by dissolving both the UF_6 and either BCl_3 or $TiCl_4$ in a cold liquid solvent, such as $CFCl_3$, Xe, Kr, or $SiCl_4$. When the chlorinator is HCl dissolved in liquid Xe, the order of mixing is important: if UF_6 is first dissolved, the red color fails to develop upon addition of HCl; if HCl is first dissolved, the UF_6 initially deposits in the cell as a solid and a red solution results. Cl_2, CCl_4, and $SiCl_4$ do not react rapidly with UF_6 at T ≤ 25°C. UF_6 reacts when mixed with $SOCl_2$, $POCl_3$, and PCl_3, but the reaction stops with ponderable solid UF_6 and chlorinator remaining, and the UF_6 is probably reacting only with impurities in these three chlorinators.

The most successful preparative technique involving neat HCl and solid UF_6 is described here. The reactions that occur in this synthesis are

$$UF_6 \text{ (s)} + HCl \rightarrow UF_5Cl + HF \tag{1}$$

$$UF_5Cl + HCl \rightarrow UF_4Cl_2 + HF \tag{2}$$

$$UF_4Cl_2 + HCl \rightarrow UF_3Cl_3 + HF, \text{ etc.} \tag{3}$$

Identification of the $UF_{6-n}Cl_n$ species has been accomplished by combining several techniques. Nuclear magnetic resonance spectroscopy gives evidence that there are no unpaired electrons in the soluble compounds produced by low-temperature reaction between UF_6 and liquid HCl, and we infer that these compounds are hexavalent uranium species. NMR also suggests that the reaction between UF_6 and liquid HCl mostly produces species with $n \leq 3$ in our studies.[12] Wavenumbers calculated[13] for $UF_{6-n}Cl_n$ from a simple force-field model and from force constants estimated from UF_6, UCl_6, and UF_5Cl spectra are in good agreement with wavenumbers of observed infrared absorption features.[8] Changes produced in the infrared spectra of $UF_{6-n}Cl_n$ mixtures by photolysis, by thermal decomposition, and by dissolution in various inert solvents have been used to help identify the different $UF_{6-n}Cl_n$ species. Changes in infrared spectra during reaction between UF_6 and either BCl_3 or $TiCl_4$ indicate that chlorination normally proceeds sequentially; i.e., UF_5Cl forms first, then UF_4Cl_2, etc. $UF_{6-n}Cl_n$ species have been identified for all values of $0 \leq n \leq 6$ in other studies,[14] but for the studies reported here, compounds with more than three chlorine atoms were not detected.

EXPERIMENTAL

The UF_6, obtained from the Oak Ridge Gaseous Diffusion Plant, was treated to reduce HF to <0.01%. The HCl, Airco electronic grade 99.99% pure, was used without further purification.

The preparation was carried out in either a borosilicate glass or a Kel-F reflux apparatus, which allowed the HCl to react with the solid UF_6 in one vessel and the product to collect in another. The borosilicate glass apparatus, shown in Fig. 1, and the Kel-F apparatus are similar, and no other materials were used except that the Kel-F apparatus also has a Monel diaphragm valve and a Teflon coated stir bar. The reflux apparatus was held in a clear glass dewar flask with the upper tubes protruding through an 8-cm-thick Styrofoam cover. The temperature was controlled by varying the flow of a stream of cold N_2 gas through the inner part of the dewar flask. Voltage from the thermocouple in the reaction vessel was monitored by an automatic temperature controller that controlled the N_2 flow.

The procedure is as follows. The apparatus is evacuated, and UF_6 is sublimed from a calibrated volume at known temperature and pressure into the reaction vessel. Then 10 to 15 mℓ of HCl ($\geq$ 100-fold molar excess) is condensed over the UF_6 at -80 to -114°C until the liquid levels reaches the top of the spill tube and fills about half of the sample vessel. The sample vessel is heated electrically to 10 to 40°C above the reaction vessel, so that the HCl vaporizes and recondenses in the reaction vessel. This condensation causes more liquid to spill over into the sample vessel. The reflux rate is typically 0.1 to 0.5 mℓ/min. The red solute is continually removed from the reaction vessel and concentrated in the sample vessel. The high-mass density of the solid UF_6 particles prevents them from rising to the level of the spill tube, even with vigorous stirring. Typically, it takes 8 to 16 hours for the solid UF_6 to disappear completely and for the red color of the solution to vanish from the reaction vessel for a typical UF_6 fill of 2 to 4 mmoles. The HCl is then removed (without boiling or bumping) by lowering the temperature to $\lesssim$-127°C and by pumping on the frozen mixture. When most of the HCl has been pumped away, the solid remaining in the sample vessel is held at -80°C and pumping is continued for $\leq$16 hours to remove traces of HCl. The final pressure obtained is 10^{-2} to 10^{-3} Pa (10^{-4} to 10^{-5} torr). After removal of the HCl, the samples collected at -80°C were dark-red porous lumps.
Figure 1. Borosilicate glass apparatus for preparation of uranium chloride fluorides. The interior of the dewar is cooled by cold N_2 vapor. A solution of uranium chloride fluorides in liquid HCl spills from the reaction vessel into the sample vessel. The HCl is evaporated and then recondensed in the return tube.

Samples of the solid red material were obtained by immersing the sample vessel in liquid N_2 and by sealing the neck, if glass, or by clamping off the tube, if Kel-F, under vacuum. The sealed sample vessel was allowed to warm to room temperature with attendant thermal decomposition. Quantitative analysis of uranium, fluorine, and chlorine, and semiquantitative spectrochemical analysis for metals were done on the solid phase. In some experiments, mass spectrometric analyses were done on the gases evolved during thermal decomposition of the sample.[15] The residue in the reaction vessel and connecting tubes was collected in water, and the amount of uranium was determined.

The gases existing in the cold reflux apparatus after preparation were sometimes quantitatively analyzed by mass spectrometry.

RESULTS AND DISCUSSION

A gas sample collected from a sample prepared at -120°C in the glass apparatus, before pumping off the HCl, contained no F_2, Cl_2, ClF, ClF_3, or SiF_4, but did contain HF, which is consistent with reactions (1) and (2). A gas sample collected at -80°C from a sample prepared in the glass apparatus contained Cl_2, SiF_4, and traces of HF. The decrease in HF concentration and the increase in SiF_4 concentration indicate that the HF found in samples collected at -80°C (compared with those collected at -120°C) reacted with the glass. The principle reaction with glass is given by

$$4HF + SiO_2 \rightarrow SiF_4 + 2H_2O \quad . \tag{4}$$

Samples prepared in the Kel-F apparatus had small green patches, identified as UF_4, that formed at the top of the HCl liquid phase before it was pumped off. Samples prepared in glass had similar green patches. The UF_4 was probably produced by a reduction of the uranium by the HCl gas phase, e.g.,

$$UF_5Cl + HCl(g) \rightarrow UF_4(s) + HF + Cl_2 \quad , \tag{5}$$

as suggested by the Cl_2 found in samples collected at -80°C. Reaction 4 is similar to the reported reduction of UF_6 to UF_5 by gaseous HBr.[16]

Thermal decomposition of the product, which occurs at temperatures between -60 and -40°C, is observed as a gradual change from dark red to brown, accompanied by evolution of Cl_2, some residual HCl, and traces of HF. Thermal decomposition of samples prepared in borosilicate glass evolved SiF_4 and a small amount of BF_3 in addition to the above named compounds. The brown solid did not dissolve when it was recooled and fresh liquid HCl was added. These observations indicate that the brown product probably consists of U(V) compounds, and therefore the initial thermal decomposition reactions are believed to be
$$UF_5Cl \rightarrow UF_5 + 1/2 \ Cl_2 \quad , \tag{6}$$

$$UF_4Cl_2 \rightarrow UF_4Cl + 1/2 \ Cl_2 \quad , \tag{7}$$

and

$$UF_3Cl_3 \rightarrow UF_3Cl_2 + \tfrac{1}{2} \ Cl_2 \quad . \tag{8}$$

On continued warming, samples prepared in glass slowly changed from brown to olive green and the pressure increased. The green solid is soluble in ~7$\underline{M}$ HNO_3—but not in H_2O—and contains no chloride ion (by $AgNO_3$ test). The observed stability, color, absence of chlorine and insolubility serves to identify the green solid as UF_4.

Quantitative chemical analyses of the chlorine, fluorine, and uranium in two particular samples, I and II, were carried out.[17] The fluorine analysis was carried out in two steps, which distinguished the F in U(IV) compounds from that in U(V) compounds.

In step 1, the sample was reacted with excess water, and the resulting fluorine and chlorine were determined. In step 2, the fluorine in the remaining solids was determined by pyrohydrolysis. The reactions of some uranium fluorides and chloride fluorides with excess water in step 1 are

$$UF_6 + 2H_2O \rightarrow UO_2F_2 + 4HF \quad , \tag{9}$$

$$2UF_5 + 2H_2O \rightarrow UF_4 + UO_2F_2 + 4HF \quad, \tag{10}$$

$$2UF_4Cl + 2H_2O \rightarrow UF_4 + UO_2F_2 + 2HF + 2HCl \quad, \tag{11}$$

$$2UF_3Cl_2 + 2H_2O \rightarrow UF_4 + UO_2F_2 + 4HCl \quad, \tag{12}$$

$$UF_4 + H_2O \rightarrow \text{no reaction} \quad. \tag{13}$$

UF_5Cl and UF_4Cl_2 are not included here because they decompose above -40 to -60°C. These reactions indicate that the fluorine released (as HF) in step 1 should be 4 moles per mole of UF_6, 2 per UF_5, 1 per UF_4Cl, and none per UF_3Cl_2 or UF_4; the remaining fluorine released from the solid UF_4 and UO_2F_2 in step 2 should be 2 moles per mole of UF_6, 3 per UF_5, 3 per UF_4Cl, 3 per UF_3Cl_2, and 4 per UF_4. The relative amounts in steps 1 and 2 provide internal checks on the consistency of the analysis.

Sample I was prepared in the glass apparatus. After preparation, this sample was maintained at -80°C and pumped for 7 days to remove HCl and other volatile components. The sample vessel was sealed, warmed to ambient room temperature for 5 hours, weighed, and broken into water for analysis. The gases in the bulb were included in the analysis. The residue in the other tubes and reaction vessel was rinsed out and weighed. The results are given in Table I.

TABLE I

ANALYSIS OF SAMPLE I

(Prepared in Glass Apparatus)

	Mass (mg)	Amount (mmoles)
Sample collected	521.4	1.313[a]
Residue of U[b]	33	0.108[b]
U	312.5 ± 0.4	1.313
Cl	35.5 ± 0.1	1.001
F	120.0 ± 6.0	6.315
Sum U + Cl + F	468.0	

[a]See text for composition.

[b]Assumed to be $UF_4 + UO_2F_2$.

If it is assumed that Sample I contains a mixture of UF_4 and compounds of the type $UF_{6-x}Cl_x$ we may set up three linear equations, in which the sums of the number of moles of each of the elements U, F, and Cl in these compounds are set equal to the analyzed amounts in Table I. A general solution gives 0.281 m moles UF_4 and the remaining compounds are composed of 1.029 m moles U, 5.179 m moles F, and 1.001 m moles Cl. These remainders have the approximate stochiometric ratio of UF_5Cl, and a mixture of 2.4 mole % UF_6, 76.2 mole %, UF_5Cl, and 21.4 mole % UF_4 corresponds exactly to the analysis of the whole sample.

Samples prepared in glass turned green when warmed to ambient temperature. This may be explained as follows. The products of Reaction (4) remain in the apparatus during preparation. The SiF_4 is removed during the pumping out of HCl, but the solid H_2O remains with the red solid. During thermal decomposition, a second release of SiF_4 and a little BF_3 occurs at

-40 to -30°C, where the vapor pressure of H_2O reaches 13 to 40 Pa (0.1 to 0.3 torr). (The mass of the SiO_2 removed from the glass is considered in this treatment, but not the mass of B_2O_3, because the number of moles of BF_3 is less than 10% of the number of moles of SiF_4.) Since the sample vessel is sealed, the following reaction may be expected.

$$2UF_5Cl + 2H_2O \rightarrow UO_2F_2 + UF_4 + Cl_2 + 4HF \quad . \tag{14}$$

The products, UF_4, Cl_2, and traces of HF, which were identified in similar unsealed preparations, are consistent with this hypothesis.

The material balance of Sample I was checked as follows. On warming the samples, Reactions (4) and (14) form a chain reaction that ends when the UF_5Cl is completely reacted. During the decomposition of the sample the quantity of SiO_2 removed from the glass is equal to half of the amount of HF formed in Reaction (1); this, in turn, is equal to half of the amount of $UF_5Cl + UF_4$. This loss from the glass erroneously adds 0.641 m moles, 39.4 mg, to the measured sample mass because the sample mass was obtained as a difference between the full sample container and the residual glass. An additional error in the measured sample mass is caused by the solid H_2O formed by the sum of Reactions (1) and (4) at the reaction temperature; the amount of H_2O is also equal to half of the amount of $UF_5Cl + UF_4$, and its mass is 11.5 mg. If the sum of these masses is added to the sum of U + Cl + F, one obtains 517.9 mg, in excellent agreement with the 521.4-mg sample mass.

Sample II was prepared in the Kel-F apparatus. The sample was pumped for 16 hours at -80°C, then sealed and thermally decomposed by warming it to ambient room temperature. The gases evolved during thermal decomposition were quantitatively analyzed mass-spectrometrically. The results are given in Table II. The amount of fluorine-containing gases evolved was insignificant. The HCl probably was evolved by desorption and deocclusion, and the trace of BrCl probably was introduced as an impurity of HBr in the HCl. The brown solid was analyzed after the green solid, along with some adhering brown solid, was mechanically separated from the sample, and results are given in Table II.

Since no chlorine was found in Step 2, there are no stable, non-volatile chlorine-containing compounds in the residue of Step 1; thus, it contains no U(IV) chloride fluorides, and the brown solid consists only of U(V) and U(VI) compounds. If we assume that the brown solid is a mixture of n_0, n_1, n_2, and n_3 m moles respectively of UF_6, UF_5, UF_4Cl, and UF_3Cl_2 (decomposition products of UF_6, UF_5Cl, UF_4Cl_2, and UF_3Cl_3 respectively), we have from Table II

$$n_0 + n_1 + n_2 + n_3 = 0.4996 \text{ m moles U}$$
$$n_2 + 2n_3 = 0.0592 \text{ m moles Cl}$$
$$6n_0 + 5n_1 + 4n_2 + 3n_3 = 2.4266 \text{ m moles F.}$$

Combining these equations gives $n_0 = 0.0122$, and from the second equation we deduce that $0.0296 < n_2 + n_3 < 0.0592$, and $n_3 < 0.0296$. It follows that $0.428 < n_1 < 0.458$.

Additional validation of these results are obtained from the individual results of Steps 1 and 2, from which we may write the respective equations

$$4n_0 + 2n_1 + n_2 = 0.9526 \text{ m moles F}$$
$$2n_0 + 3n_1 + 3n_2 + 3n_3 = 1.474 \text{ m moles F.}$$

Combining these equations with the $n_0 = 0.122$ gives $n_1 - n_3 = 0.421$, and therefore $0.421 < n_1 < 0.451$, which is in substantial agreement with the above inequality for n_1. The difference

TABLE II

ANALYSIS OF SAMPLE II

(Prepared in Kel-F Apparatus)

	Mass (mg)	Amount (mmoles)
UF_6 fill	173.9	0.731
Gas evolved during thermal decomposition		
Cl_2		0.34 ± 0.05
HCl		0.085 ± 0.01

Sample collected	175.3	
U	118.9 ± 0.1	0.4996
Cl[a]	2.10 ± 0.02	0.0592
Cl[b]	0	0
F[a]	18.1 ± 0.2	0.9526
F[b]	28.0 ± 0.3	1.474
F(total)	46.1 ± 0.5	2.427
Sum U + Cl + F	167.1 ± 0.6	

[a]Reaction with moist air (step 1).

[b]Pyrohydrolysis (step 2).

between the mass of sample collected and the sum U + Cl + F may be partly due to bits of Kel-F eroded from the container by the stirrer.

These data indicate that the mixture that decomposed into the brown solid was composed of 2 mole% UF_6, 86 to 92 mole % of UF_5Cl, and 6 to 12 mole% (UF_4Cl_2 + UF_3Cl_3), with < 6 mole% UF_3Cl_3.

One mole of Cl is evolved during thermal decomposition per mole of U(VI) chloride fluoride by equations (6) to (8); since the evolved Cl equals 0.68 ± 0.10 mmoles, the combined UF_6 + UF_4 is approximately 0.051 mmoles, or 7.0 mole %. The UF_6 fraction of the brown solid (from which UF_4 was separated) was 2.4 mole %; therefore we estimate the UF_4 content of the total sample to be only ~3.6 mole %.

Solubility tests of UF_5Cl, made in the apparatus used for sample preparation, indicate that UF_5Cl is soluble in liquid HCl, $COCl_2$, and Cl_2. Decomposition occurred rapidly upon contact with the precooled solvents, CCl_4 CS_2, $CHCl_3$, CH_3COCH_3, and CH_3OH, at temperatures near the higher of either the freezing points of the solvents or -80°C. The red solid rapidly turned green upon contact with room temperature air.

Reaction (1) will go to completion only if UF_5Cl is continually removed from the reaction vessel. Early attempts to prepare the red compound by stirring solid UF_6 with liquid HCl in a single vessel without refluxing resulted in an incomplete reaction with only ~1/4 of the UF_6 reacting in 16 hours. In the sample vessel the back reaction is prevented by the limit of solubility of UF_5Cl, and the low concentration of HF, due to distillation; e.g., if

the sample vessel is 20°C warmer than the reaction vessel, the vapor pressure of HF would be increased by a factor of 6 to 9, and the concentration decreased by a similar factor.

CONCLUSIONS

The uranium chloride fluorides UF_5Cl and UF_4Cl_2 can be prepared by a reaction between solid UF_6 and liquid HCl. Compositional analyses of two particular samples were consistent with about 2 mole% UF_6, 76 mole% UF_5Cl and 21 mole% UF_4 in sample I, and 2 mole% UF_6, 86 to 92 mole% UF_5Cl, 6 to 12 mole% UF_4Cl_2 + UF_3Cl_3, and < 6 mole% UF_3Cl_3 in sample II. These uranium (VI) chloride fluorides are thermally unstable, and decompose to U(V) compounds at temperatures > -40 to -60°C.

Studies of Amidino-Complexes of Copper(I) and (II). Carboxylate Analogues

Melvyn Kilner* and Antoni Pietrzykowski

Department of Chemistry, The University of Durham, South Road, Durham City, DH1 3LE

Lithioamidines $\{R'N(Li)C(R)NR'; R = H, CH_3, C_6H_5; R' = C_6H_5, p\text{-}CH_3C_6H_4\}$ react with anhydrous copper(II) chloride to form $[Cu\{R'NC(R)NR'\}_2]_n$ complexes, and with anhydrous copper(I) chloride to form $[Cu\{R'NC(R)NR'\}]_m$. The copper(II) complexes are diamagnetic, purple solids, which are air stable in the solid state but very air reactive in solution. Experimental data are consistent with a dimeric or more highly associated structure, and an X-ray structural determination shows $[Cu\{C_6H_5NC(C_6H_5)NC_6H_5\}_2]_2$ to be dimeric with four bridging amidino-groups and a short Cu–Cu distance (2.46Å). The copper(I) complexes are pale yellow solids, which in solution are subject to rapid aerial oxidation, especially in the presence of free amidines, and disproportionation to $[Cu\{R'NC(R)NR'\}_2]_n$ and copper metal. Differences in properties are noted between acetamidino-, benzamidino- and formamidino-complexes, the last complexes of copper(I) being most stable towards disproportionation. $Cu\{C_6H_5NC(CH_3)\text{-}NC_6H_5\}_2$ reacts with pyridine (Py) to form the copper(I) derivative $Cu\{C_6H_5NC\text{-}(CH_3)NC_6H_5\}.2Py$ and with carbon disulphide to form $Cu\{C_6H_5NC(CH_3)NC_6H_5\}_2.CS_2$ which is reduced to form $Cu\{C_6H_5NC(CH_3)NC_6H_5\}.CS_2$.

THE isoelectronic relationship between allyl, amidino, triazeno and carboxylato-groups has been noted previously,[1,2] together with the differences in the mode of bonding to transition metals. The metal assumes a position out of the plane of η^3-allyl groups,[3] whereas for bidentate carboxylato-groups the metal adopts a position in, or close to, the ligand skeletal plane.[4] Amidino-groups have been shown to exhibit structural features similar to those of carboxylato-groups,[5] and also in common with the latter, have a high propensity to bridge between two identical[5-8] or different transition metals.[9,10] For example, amidines and carboxylic acids both react with chromium and molybdenum hexa-carbonyls to produce M_2L_4 complexes, and for M = molybdenum the structures of the complexes in the solid state are closely related, both consisting of a quadruple bonded Mo_2 unit bridged symmetrically by four ligand groups.[5] The ability of the amidino-group to encourage metal-metal interactions in binuclear complexes has been studied for other metals, and here we report studies involving copper. Attempts have been made to promote direct copper-copper bonding in complexes analogous to the copper(II) carboxylates.[4,11]

Previous studies of both copper(I) and (II) carboxylates have been extensive,[12] but only limited attention has been paid to amidino-copper complexes. In 1956 copper(II) acetate was treated with N,N'-diarylformamidines in refluxing ethanol to yield the copper(I) complexes $[Cu(RNCHNR)]_n$,[13] reactions which occur only for formamidines. Relevant also to the present work are complexes of the iso-electronic triazeno-group. The crystal structure of 1,3-dimethyltriazenocopper(I)[7] consists of a tetramer based on a diamond Cu_4 unit with single amidino-groups bridging alternate sides of the Cu_4 plane. The 1,3-diphenyltriazeno-complex, in contrast, has a dimeric structure with two triazeno-groups bridging the metals.[6]

Interestingly dimer-tetramer equilibria have been established for related formamidino-complexes.[14] Also bis-1,3-diphenyltriazenocopper(II),[15] unlike the

corresponding copper(II) acetate, is diamagnetic and thought to have a similar dinuclear structure with four bridging triazeno-groups. We report here our studies of related acetamidino-, benzamidino-, and formamidino-complexes of both copper(I) and copper(II), together with some attempted ligand addition reactions.

RESULTS AND DISCUSSION

A. Bis-amidinocopper(II) Complexes

These complexes have been synthesised from anhydrous copper(II) chloride and lithio-amidines in monoglyme solution as purple solids (see Table 1) which are recrystallised from dichloromethane using Soxhlet extraction. The reaction started below ambient temperature, but was allowed to continue for 18 h. to reach completion. The product slowly precipitated. There was no evidence for an intermediate amidinochloro-complex, $Cu(Am)Cl$. Yields of the microcrystalline materials, which melted in the range 160-220° with decomposition, were 50-70%. Though the solids are air stable over many months, rapid decomposition occurs in solution in the presence of air. The solutions become cloudy and deposit a brown solid whilst changing to a brown-green colour. At best the materials are only sparingly soluble in organic solvents, a property which restricted structural studies of the complexes. Benzamidino- and formamidino-complexes have a marginally better solubility than acetamidino-complexes, and the best solvents were found to be chloro-carbons (CH_2Cl_2, $CHCl_3$).

Molecular weight measurements by cryoscopy in benzene were undertaken on $Cu\{C_6H_5NC-(C_6H_5)NC_6H_5\}_2$, but the level of solubility made the results subject to large errors. Because of the high relative molecular mass (RMM) and low concentration of solutions small variations in temperatures correspond to large differences in RMM values. Never-the-less the values of 985, 892 and 708   which compare with values of 606 for the monomer and 1212 for the dimer raise the question of monomer $\rightleftharpoons$ dimer or monomer   oligomer or polymer equilibria occurring in solution, though no data from other sources support such a process. Interestingly Vrieze et al.[14] report dimer $\rightleftharpoons$ tetramer equilibria for a series of formamidino-copper(I) complexes, though the formation of a monomer intermediate is un-likely in this process which requires only the cleavage of one metal-nitrogen bond of the dimer. Magnetic measurements of the solid amidino-copper(II) complexes, $Cu\{C_6H_5NC(CH_3)-NC_6H_5\}_2$ and $Cu\{C_6H_5NC(C_6H_5)NC_6H_5\}_2$ using a Gouy balance show the complexes to be diamagnetic, and mass spectral studies of the complexes show the presence of Cu_2 species. Every complex exhibits peaks arising from $[Cu_2(Am)_2]^+$ as the highest $^m/e$ fragment in the spectrum implying association of $Cu(Am)_2$ units in the vapour state and possibly in the solid state. A typical breakdown pattern for $Cu\{C_6H_5NC(CH_3)NPh\}_2$ is illustrated in Figure 1. Source temperatures used were slightly lower than the melting points of the complexes at which they tend to decompose (according to thermal gravimetric analysis studies). $[Am]^+$ peaks are the most intense in the spectra, though the peaks due to $[Cu_2Am_2]^+$ are the most intense peaks for a copper containing species). $[CuAm_2]^+$, $[Cu_2Am]^+$ and $[CuAm]^+$ fragments are also commonly observed. Loss of RCN ($R = CH_3$, C_6H_5) from $[Cu_2\{R'NC(R)-NR'\}_2]^+$ is well documented as an important fragmentation step, though it is less important for formamidino-complexes.

Infrared spectroscopic data (Table 2) consist of absorptions at 1568-1463 and 1263-1231 cm.$^{-1}$ characteristic of delocalised amidino-complexes[16] but from such data it is not possible to differentiate between bridging and chelate bonding. Use of ^{1}H n.m.r. spectroscopy for structural studies was limited by the low solubility of the complexes in suitable solvents, though a spectrum was recorded for $Cu\{p-CH_3C_6H_4NC(CH_3)N-p-CH_3C_6H_4\}_2$

which was consistent with symmetrical bridging or bidentate amidino-groups. It must how-
ever be noted that p-tolyl groups have been shown by one of the authors to be insensitive
to different bonding situations occurring at the two nitrogen atoms in such groups.[16]
Furthermore the sharp signals provide further evidence for a diamagnetic complex. The
diamagnetism of the complex, its low solubility in organic solvents and the m.s. data
are consistent with a dimeric (I) or more highly associated complex (II), but not with a
monomeric complex.

    For one of the complexes, $Cu\{C_6H_5NC(C_6H_5)NC_6H_5\}_2$, suitable crystals for an X-ray
crystallographic study were produced which would allow the problem of a dimeric or an
oligomeric/polymeric structure in the solid state to be resolved. The crystal structure
determined by Halfpenny,[17] shows a dimeric structure (I) with four bridging amidino-
groups. The structure is closely related to that of $Mo_2\{C_6H_5NC(C_6H_5)NC_6H_5\}_4$ and is the
same as that proposed for the isoelectronic triazenocopper(II) complexes. The copper-
copper distance of 2.46Å is consistent with direct bonding between the coppers, and
represents a Cu-Cu single bond.

    A thermal gravimetric study of the complexes under a nitrogen atmosphere produced
the thermograms shown in Figure 2. The benzamidino-complexes and $[Cu_2(DPTAA)_4]$ contained
monoglyme of crystallisation, and the initial mass losses for these complexes correspond
to the loss of solvent. The curves for the two benzamidino-complexes appear very
similar, but assessment of the % mass loss data indicate different modes of decomposition.
Three stages occur for each of the benzamidino- and acetamidino-complexes, though the mass
loss data show no close relationship between the corresponding stages for each complex.
Loss of complete amidino-groups was not a recognisable process, but fragmentation of
amidino-groups was common with losses of [PhNCPh], $[CH_3C_6H_4NC(CH_3)N]$ and [PhNCNPh] being
typical. The final residue results after a lower mass loss than that expected for
formation of copper metal, but in all cases the data is not consistent with a
characterisable material.

B. Amidino-Copper(I) Complexes

    Copper(I) complexes were synthesised by the reaction of lithioamidines with anhydrous
copper(I) chloride in monoglyme as pale yellow, diamagnetic solids in ca. 50-70% yield
(see Table 1). Attempts were made to synthesise acetamidine and benzamidino-complexes
from copper(II) acetate by the method of Bradley and Wright[13] but without success. The
N,N'-diphenylformamidinocopper(I) complexes are apparently stable to disproportionation in
solution whereas the acetamidino- and benzamidino-complex are labile. The copper(I)
complexes are non-volatile and have higher melting points than their copper(II) counter-
parts, together with a higher solubility in organic solvents. Amidinocopper(I) complexes
readily oxidise in air to the copper(II) complexes, particularly in solution, where the
process is noticeably accelerated by the presence of the free amidine. In the solid state,
N,N'-diphenylacetamidinocopper(I), on exposure to air develops a bluish-green/red colour
on the surface. In solution disproportionation also occurs with deposition of the metal
and development of the purple colour characteristic of the copper(II) complexes. This
reaction prevented purification of the complexes by recrystallisation methods. Stability
of the solutions towards disproportionation in the order acetamidino < benzamidino <<
formamidino-complexes, and solutions of the last complexes showed virtually no signs of
reaction. Interestingly a detailed study of the dimer-dimer and dimer-tetramer equilibria
by ^{1}H and [13]C n.m.r. methods has been reported by Vrieze et al.[14] for a series of
formamidinocopper(I) complexes, with no reference being made to disproportionation in
solution. Indeed solutions of these complexes appear remarkably stable compared with

solutions of benzamidino- and acetamidino-complexes, though it is conceivable that some
of the minor changes i.e. broadening and weak new signals, could arise from copper(II)
derivatives.

The mass spectra of the copper(I) complexes are very similar to those of the
copper(II) complexes, with $[Cu_2Am_2]^+$ ions being the highest ^{m}/e value ions detected.
$[CuAm_2]^+$ ions are detected for all the complexes. The fragmentation pattern follows
closely that shown in Figure 1 for $Cu\{C_6H_5NC(CH_3)NC_6H_5\}_2$. The $[Cu_2Am_2]^+$ ion may
represent the parent ion for the complex, and indeed for $[Cu(C_6H_5NNNC_6H_5)]_2^6$ a dinuclear
complex has been established. However the ion may also represent a thermolysis product
of a tetranuclear complex, as established for $[Cu(CH_3NNNCH_3)]_4$.[7] Infrared spectra are
strikingly similar to those of copper(II) complexes and n.m.r. spectra provided little
structural information which was reliable because of low solubility and disproportiona-
tion in suitable solvents.

Thermograms for the copper(I) complexes are given in Figure 3. The benzamidino-
complexes decompose in one stage, whereas for the acetamidino-complexes decomposition
occurs in a two stage process. A thermogram, intermediate between these two types, with
a merging together of the two stages is exhibited by the formamidino-complex. All the
complexes decompose to form a residue, which contains, in addition to copper, a small
percentage of carbon, hydrogen and/or nitrogen, though in the case of the N,N'-diphenyl-
benzamidino-complex the % loss in weight corresponds most closely to a residue of copper
metal. The intermediate stages in the decomposition of the acetamidino-complexes
correspond closely to the loss of three amidino-groups from a Cu_4Am_4 unit (where Am =
R'NC(CH_3)NR', R' = C_6H_5, $\underline{p}$-$CH_3C_6H_4$). Though these complexes were too unstable towards
disproportionation in solution (to Cu(O) and Cu(II)) to allow relative molecular mass
measurements by using colligative properties, this feature in the thermogram possibly
provides some evidence for tetramers in the solid state, as found for the isoelectronic
N,N'-dimethyltriazino-complex.[7]

C. Reactions of $Cu\{C_6H_5NC(CH_3)NC_6H_5\}_2$ with Pyridine and Carbon Disulphide

Pyridine reacts with the bis-amidinocopper(II) complex in monoglyme over 4d to
produce a brown powder thought to be $Cu\{C_6H_5NC(CH_3)NC_6H_5\}.2C_5H_5N$ on the basis of
elemental analysis. This reduction of a copper(II) complex to a copper(I) complex is a
process achieved by many ligands, including phosphines and phosphites, and for example
triphenylphosphine reacts with hydrated copper(II) chloride in ethanol to produce
$(Ph_3P)_3CuCl$ or $[PPh_3CuCl]_4$ depending on the molar ratios of the reactants.[18]

With carbon disulphide attempts were made to accomplish insertion into a copper-
nitrogen bond. The purple solution of the copper(II) complex dissolved in carbon
disulphide became brown over ½ h. and deposited a brown solid which though impure showed
characteristics of an addition compound. Analytical data suggested the formulation
$Cu\{C_6H_5NC(CH_3)NC_6H_5\}_2.CS_2$. Recrystallisation of the material from toluene/hexane
mixtures led to a decrease in carbon, hydrogen and nitrogen content, but an increase in
copper and sulphur contents, the data being consistent with reduction to the copper(I)
complex, $Cu\{C_6H_5NC(CH_3)NC_6H_5\}.CS_2$.

Distinct differences occur between the reactions of this bis-amidinocopper(II)
complex and the corresponding carboxylato-complex with neutral ligands, and may reflect
the weak coordinating properties of ligands trans- to the second metal in the dinuclear
unit, or reflect the steric properties of the N-substituents associated with four

Figure 2. Thermograms for Bis-amidinocopper(II) Complexes.

Figure 3. Thermograms for Amidinocopper(I) Complexes.

amidino-groups. It is well established that complexes containing strong metal-metal interactions tend to form weak bonds _trans_ to the metal-metal bond.[19] For metal-metal bonded amidino-complexes pyridine and triphenylphosphine failed to form adducts of the type $Cu_2Am_4L_2$, whereas for the acetato-complex water, dioxane, pyridines and anilines give $Cu_2(OCOCH_3)_4L_2$ derivatives.[20]

EXPERIMENTAL

    Anhydrous copper(I) and copper(II) chlorides, triphenylphosphine, pyridine, N,N'-diphenylacetamidine and -formamidine, acetamidinium hydrochloride and benzamidinium hydrochloride were obtained from commercial sources and used without further purification. N,N'-Diphenylbenzamidine, N,N'-di-_p_-tolylbenzamidine, N,N'-dimethylbenzamidine and N,N'-di-_p_-tolylacetamidine were prepared by standard methods.[21] n-Butyllithium, ca. 1.23M in hexane, was used as supplied without purification. Hydrocarbon solvents and diethylether were dried over extruded sodium, and monoglyme was freshly distilled from sodium hydride prior to use. Chlorocarbon solvents and carbon disulphide were dried over molecular sieves. All solvents were de-gassed under reduced pressure, stored under nitrogen, and transferred by syringe against a counter flow of nitrogen. All reactions were performed with rigorous exclusion of air.

    I.r. spectra in the range 4000-400 cm.$^{-1}$ were recorded with a Perkin-Elmer 457 spectrophotometer, and ^{1}H n.m.r. spectra at 90 MHz with a Bruker HX90E spectrophotometer. Mass spectra were obtained with an A.E.I. MS9 instrument at 70 eV and an accelerating potential of 8 kV. Samples were inserted directly into the ion source at temperatures between 80°-220°C. Thermogravimetric studies were undertaken using a Stanton Redcroft TG750 balance.

    Carbon, hydrogen and nitrogen contents of the complexes were determined with a Perkin-Elmer 240 Elemental Analyser, and copper by atomic absorption spectroscopy using a Perkin-Elmer 403 spectrometer. Sulphur content was obtained by combustion of the complex in oxygen to sulphate, followed by the volumetric determination of sulphate using a standard barium perchlorate solution. Phosphorus content was determined by combustion of the sample in air, followed by volumetric determination of phosphate.

Preparation of Bis(N,N'-diphenylacetamidino)copper(II), $Cu\{C_6H_5NC(CH_3)NC_6H_5\}_2$.-

n-Butyllithium (5.9 ml; 1.23M in hexane) was added to a frozen solution of N,N'-diphenylacetamidine (1.54 g, 7.31 mmol) in monoglyme (40 ml), and the mixture allowed to warm slowly to ambient temperature and stand for ½ h. The resulting inhomogeneous product mixture was then transferred onto a frozen suspension of anhydrous copper(II) chloride (0.49 g, 3.65 mmol) in monoglyme (40 ml), and the reaction mixture stirred at ambient temperature for 18 h. After filtering the resulting mixture, the purple residue was washed with hexane (2 x 10 ml), dried _in vacuo_ and recrystallised from hot dichloromethane using a modified Soxhlet extraction method. A purple microcrystalline solid, $Cu\{C_6H_5NC(CH_3)NC_6H_5\}_2$ (m 165° dec, 61% yield) was obtained, which could be stored in the solid state in air over many months without noticeable change. The complex in solution remains unchanged when stored under nitrogen over many days, but rapid changes occur in the presence of air.

M.s. The highest mass fragment observed gave peaks at ^{m}/e 548, 546, 544 corresponding to $[Cu_2Am_2]^+$ and arising from ^{63}Cu and ^{65}Cu (69 and 31% abundancies respectively).

Preparation of other Bis-amidinocopper(II) Complexes.- The method described above was used generally to prepare the following complexes as purple solids typically in 50-70%

yields.

Bis(N,N'-di-p-tolylacetamidino)copper(II), m. 220° dec.

M.s. The highest mass fragment was observed at ^{m}/e 602 and 600 corresponding to $[Cu_2Am_2]^+$.

^{1}H n.m.r., δ(CDCl$_3$): 2.84(8H), 7.69(6H), 7.91(3H) p.p.m.

Bis(N,N'-di-p-tolylbenzamidino)copper(II), m. 175° dec.

M.s. The highest mass fragment was observed at ^{m}/e 726 and 724 corresponding to $[Cu_2Am_2]^+$.

Bis(N,N'-diphenylbenzamidino)copper(II), m. 180° dec. M 985, 892, 708 by cryoscopy in benzene (monomer requires 606, dimer 1212).

M.s. The highest mass fragment was observed at ^{m}/e 670 and 668 corresponding to $[Cu_2Am_2]^+$.

Bis(N,N'-diphenylformamidino)copper(II), m. 160° dec.
M.s. The highest mass fragment was observed at ^{m}/e 518 and 516 corresponding to $[Cu_2Am_2]^+$.

Preparation of N,N'-Di-p-tolylacetamidinocopper(I), Cu{p-CH$_3$C$_6$H$_4$NC(CH$_3$)N-p-CH$_3$C$_6$H$_4$}.-

n-Butyllithium (2.70 ml, 1.84M in hexane) was added to a frozen solution of N,N'-di-p-tolylacetamidine (0.89 g, 4.14 mmol) in monoglyme (25 ml), and the mixture allowed to warm slowly to ambient temperature. After ½ h. the resulting reagent was syringed onto a frozen mixture of anhydrous copper(I) chloride (0.41 g, 4.14 mmol) and monoglyme (30 ml), and the mixture allowed to warm to ambient temperature. After stirring for 12 h., the pale yellow precipitate was separated by filtration, washed with hexane (2 x 10 ml), and dried in vacuo. Soxhlet extraction using dichloromethane yielded pale yellow micro-crystalline N,N'-di-p-tolylacetamidinocopper(I), m. 220° dec.

M.s. The highest mass fragment was observed at ^{m}/e 602 and 600 corresponding to $[Cu_2Am_2]^+$.

Preparation of other Amidinocopper(I) Complexes.- The method described above was used generally to prepare the following complexes as yellow solids typically in 50-70% yields.

N,N'-Diphenylformamidinocopper(I), m. 270° dec.

M.s. The highest mass fragment was observed at ^{m}/e 518 and 516 corresponding to $[Cu_2Am_2]^+$.

N,N'-Di-p-tolylbenzamidinocopper(I), m. 210° dec.

M.s. The highest mass fragment was observed at ^{m}/e 726 and 724 corresponding to $[Cu_2Am_2]^+$.

N,N'-Diphenylbenzamidinocopper(I), m. 260° dec.

M.s. The highest mass fragment was observed at ^{m}/e 670 and 668 corresponding to $[Cu_2Am_2]^+$.

N,N'-Diphenylacetamidinocopper(I), m. 210° dec

M.s. The highest mass fragment was observed at ^{m}/e 532 and 530, corresponding to $[Cu_2Am_2]^+$.

Reaction of Bis(N,N'-diphenylacetamidino)copper(II) with Pyridine.- A suspension of the complex (0.38 g, 0.8 mmol) in monoglyme (15 ml) was stirred with pyridine (0.063 g, 0.8 mmol) for 4d at ambient temperature. The brown precipitate of the product, Cu{C_6H_5NC-(CH_3)NC$_6$H$_5$}$_2$·2C$_6$H$_5$N, was separated by filtration, washed with monoglyme and dried _in vacuo_. Found: C, 67.1; H, 5.81; N, 13.0; Cu, 14.8: $C_{24}H_{23}N_4$Cu requires C, 66.9; H, 5.38;' N, 13.0; Cu, 14.7%.

Reaction of Bis(N,N'-diphenylacetamidino)copper(II) with Carbon Disulphide.- The complex was stirred in carbon disulphide for 24 h., the initial purple solution turning brown over ½ h. After filtration the solvent was removed _in vacuo_ to produce a brown solid. Found: C, 59.8; H, 4.90; N, 10.4; Cu, 12.4; S, 12.0: Cu(DPAA)$_2$·CS$_2$ requires C, 62.4; H, 4.69; N, 10.0; Cu, 11.4; S, 11.5%. After recrystallisation from toluene/hexane mixtures, found C, 49.7; H, 4.31; N, 8.42; Cu, 17.7; S, 17.6: Cu(DPAA)·CS$_2$ requires C, 51.6; H, 3.75; N, 8.03; Cu, 18.2; S, 18.4%.

Abstract—The emission intensity at 517 nm from $Pt_2(pop)_4^{4-}$ (pop = $P_2O_5H_2^{2-}$) is quenched by the addition of sulphur dioxide. The sulphur dioxide coordinates at the axial platinum(II) sites by a η^1-SO_2 bond. This coordination is supported by ^{31}P NMR and Raman spectroscopy of aqueous solutions. The electronic spectrum of a sulphur dioxide saturated solution of $Pt_2(pop)_4^{4-}$ shows an absorption at 428.5 nm ($\epsilon = 4.1 \times 10^4$). From the decrease in the chromophore for uncomplexed $Pt_2(pop)_4^{4-}$ the equilibrium constant for SO_2 binding is estimated to be $1.74 \, M^2 l^{-2}$. The effect of adding different quenchers to aqueous solutions of $Pt_2(pop)_4^{4-}$ is discussed. The compound $Pt_2(pop)_4^{4-}$ will undergo 2-electron reduction with chromous ion.

The complex $K_4[Pt_2(pop)_4] \cdot 2H_2O$ (pop = $P_2O_5H_2^{2-}$) was discovered because of its intense emission at 514 nm in aqueous solution.[1] This emission is sufficiently strong that the luminescence can be used as the basis for the quantitative determination of trace platinum.[2] Following the discovery of the complex $Pt_2(pop)_4^{4-}$, a number of articles have been published describing the structure, spectroscopy, and reaction chemistry of this binuclear complex.[3–7] Spectroscopic studies on $Pt_2(pop)_4^{4-}$ have assigned the fluorescence ($\lambda_{max} = 407$ nm) and phosphorescence ($\lambda_{max} = 517$ nm) emissions to the respective transitions $^1A_{2u} \rightarrow ^1A_{1g}$ and $^3A_{2u} \rightarrow ^1A_{1g}$. Single crystal measurements show the 367 nm absorption band polarized parallel to the Pt–Pt axis, and the 452 nm absorption band polarized perpendicular.[5] When the synthesis of these pop complexes is carried out at higher temperatures, further ligand condensation occurs and a higher homologue platinum(II) complex is formed which has an emission band at 650 nm.[8] Recently an article has been published showing that in aqueous solutions of $Pt(CN)_4^{2-}$, it is the presence of higher oligomers which cause the emission band to be observed at 525 nm. This emission is quenched by added nitrite ion or oxygen,[9,10] and these recent results of the cyanide complexes are of

significance to our observations on the effects of adding different excited state quenchers to aqueous solutions of $Pt_2(pop)_4^{4-}$.

RESULTS AND DISCUSSION

The emission intensity from concentrated aqueous solutions of $Pt(CN)_4^{2-}$ is efficiently quenched by added oxygen. For the complex $Pt_2(pop)_4^{4-}$, however, the presence of added oxygen in aqueous solutions causes only partial quenching of the phosphorescence since such solutions exhibit emission at 517 nm for several hours even under such experimental conditions.[2] Evidence from ^{31}P NMR spectroscopy confirms that the final quenched solution contains the monomeric complex $[Pt\{OP(OH)_2\}_4H_2]$, which has been formed by hydrolytic cleavage of the pop ligand.[11] The difference in quenching efficiency of dissolved oxygen toward $Pt_2(pop)_4^{4-}$ and $Pt(CN)_4^{2-}$ is possibly a consequence of the sterically crowded hydrophilic ligands in $Pt_2(pop)_4^{4-}$. These hydrophilic P-bonded $P_2O_5H_2^{2-}$ ligating groups will undergo hydrogen bonding of the peripheral hydroxyl groups to water, resulting in the molecule creating a hydration sphere cage about the ligand surface. Such a hydration cage can therefore effectively prevent dissolved oxygen molecules from penetrating sufficiently close to the platinum(II) ions to efficiently quench the 514 nm emission from the metal centred excited state.

Addition of Cl_2, Br_2, I_2, CH_3I and NO_2 causes immediate loss of emission intensity. These compounds undergo an oxidative addition reaction to form binuclear platinum(III) complexes $[Pt_2(pop)_4XY]^{4-}$ ($X = CH_3$, $Y = I$, $X = Y = Cl$, Br, I, NO_2) which now have the filled $d\sigma$ level (rather than $d\sigma^*$) as the HOMO.[7] More significantly, rapid emission quenching is caused by the addition of sulphur dioxide to an aqueous solution of $Pt_2(pop)_4^{4-}$. This quenching is reversible since either dilution or passage of nitrogen gas through the solution causes the 514 emission intensity of $Pt_2(pop)_4^{4-}$ to be recovered (equation 1). The yellow solution which results from the quenching addition of SO_2 retains

$$Pt_2(pop)_4^{4-} + 2SO_2 \rightarrow Pt_2(pop)_4(SO_2)_2^{4-} \qquad (1)$$
platinum in the divalent binuclear state of $Pt_2(pop)_4^{4-}$. The solution structure of this adduct shows a second-order pattern in the ^{31}P NMR spectrum centred at δ 65.01 [$^1J(PtP) = 3043$ Hz]. This chemical shift position is close to that found for $Pt_2(pop)_4^{4-}$, and $^1J(PtP)$ is in the 3000 Hz range for Pt(II)–Pt(II) complexes, rather than in the 2000 Hz range for Pt(III)–Pt(III) compounds.[11] The observation of a single ^{31}P NMR line confirms that substitution has occurred in an axial position. The Raman spectrum of the quenched SO_2 solution shows a band at 111 cm^{-1} which is principally due to ν(Pt–Pt).[6] This frequency represents a shift of 5 cm^{-1} from the position of the same stretch in pure $Pt_2(pop)_4$.[4–6] Since the value of $^1J(PtP)$ in the ^{31}P NMR spectrum indicates little difference in bonding for the $Pt_2(pop)_4^{4-}$ ion between the free and the SO_2 quenched state, it is likely that this shift to lower energy in ν(Pt–Pt) in the presence of SO_2 is due to mass rather than bonding effects. The aqueous solution Raman spectrum of $Pt_2(pop)_4^{4-}$ in the presence of SO_2 also shows an absorption at 220 cm^{-1}, along with a shoulder at 250 cm^{-1}. This band at 220 cm^{-1} is in the expected region for S bonded to platinum(II), and is likely due to ν(Pt–S) in $Pt_2(pop)_4(SO_2)_2^{4-}$. The high energy region of the Raman spectrum of an SO_2 saturated aqueous solution shows a strong broad band at 1112 cm^{-1}, along with a sharp band at 1148 cm^{-1}. The band at 1112 cm^{-1} is due to the symmetric S–O stretch of the coordinated SO_2 molecule, and the band at 1148 cm^{-1} is the symmetric stretch for the free dissolved SO_2 in solution.[12] A recent compilation of vibrational data on metal complexed SO_2 has correlated the position of ν(SO) with its geometric coordination mode. Since our observed Raman band for the symmetric SO stretch is at 1112 cm^{-1} this identifies the compound as a η^1–SO_2 complex.[13] In a recent article[14] investigating the complexation of sulphite ion to the axial positions in $[Rh_2(OCOCH_3)_4]$, the bands due to the symmetric SO stretch are found at 1000 cm^{-1} and 933 cm^{-1}. Since these bands are much lower in energy than our 1112 cm^{-1} band, we can assume that sulphur dioxide and not sulphite ion is bonded to platinum(II) in the $Pt_2(pop)_4^{4-}$ ion. We believe that this complex $Pt_2(pop)_4(SO_2)_2^{4-}$ represents the first example of an SO_2 adduct with platinum in its divalent state.

Significant changes are also observed in the electronic

Fig. 1. Electronic spectrum of an aqueous solution of $Pt_2(pop)_4^{4-}$ saturated with sulphur dioxide.

spectrum of $Pt_2(pop)_4^{4-}$ upon addition of SO_2 to an aqueous solution of the complex. The most noticeable change is the decrease in intensity of the 367 nm absorption band ($^1A_{1g} \rightarrow {}^1A_{2u}$). Since this transition results from electron transfer between metal centred orbitals,[4,5] its observed intensity change is further supportive of the premise that the binding of SO_2 to $Pt_2(pop)_4^{4-}$ is by coordination to platinum(II), rather than by association with the peripheral hydroxylic groups of the pop ligand. In Fig. 1 we show the experimental electronic spectral data obtained on saturating a $2.81(5) \times 10^{-5}$ M solution of $Pt_2(pop)_4^{4-}$ with sulphur dioxide. It is apparent from these data that a new chromophore at 428.5 nm replaces the absorption at 367 nm. Assuming a concentration of 1.64 M for aqueous SO_2 at 20°C,[15] and subtracting the absorbance at 367 nm due to the tail from the SO_2 chromophore,[16,17] we find an equilibrium constant (at 20°C) of 1.74 M^{2}l^{-2} for the formation of $Pt_2(pop)_4(SO_2)_2^{4-}$ (eqn 1). From this derived concentration of 1.7×10^{-5} M for $Pt_2(pop)_4(SO_2)_2^{4-}$, we obtain a value of 4.1×10^4 for the extinction coefficient of the absorption band at 428.5 nm due to the SO_2 adduct. From this value of ϵ it is apparent that this band is due to a charge transfer transition. The band may be a Pt(II)$\rightarrow$$SO_2$ MLCT transition,[18] but since the extinction coefficient is very close to that of the $^1A_{2u} \leftarrow {}^1A_{1g}$ transition in $Pt_2(pop)_4^{4-}$, it is probably this same transition red shifted in the SO_2 adduct. From the solution equilibrium constant for SO_2 binding it is apparent that the solutions contains significant quantities of uncomplexed
Fig. 2. Raman spectrum of the NO_2 modes in $Pt_2(pop)_4(NO_2)_2{}^{4-}$.

$Pt_2(pop)_4{}^{4-}$, yet the emission from this ion is completely quenched. From earlier studies it is known that SO_2 can be an excited state quencher for anthracene at rates approaching diffusion control,[19,20] and it is probable that such quenching of $Pt_2(pop)_4{}^{4-}$ by SO_2 is occurring in this case.

For structural purposes it is informative to compare the Raman spectrum of this SO_2 adduct of $Pt_2(pop)_4{}^{4-}$ with that of the binuclear platinum(III) complex $Pt_2(pop)_4(NO_2)_2{}^{4-}$. This compound with doubly N-bonded nitro ligands[21] shows $v(Pt–Pt)$ at $151\ cm^{-1}$ and $v(Pt–N)$ at $267\ cm^{-1}$. The high energy region of the solution Raman spectrum shows strong absorption bands at $820\ cm^{-1}$ and $1320\ cm^{-1}$ for the symmetric NO_2 bend and stretch respectively (Fig. 2). These bands are in the correct region for an N-bonded nitro complex.[22] By comparison these symmetric bands in uncoordinated nitrite ion are found at 829 and $1325\ cm^{-1}$.[23] This small shift from free nitrite ion, along with the low energy of the $v(Pt–N)$ band, indicates that the nitro ligand is weakly bonded. Thus the NO_2 and SO_2 ligands bind respectively to binuclear platinum(III) and platinum(II) by weak coordination through the central N or S atom.

Addition of chromous ion to $Pt_2(pop)_4{}^{4-}$ results in quenching of the emission at 514 nm. Addition of $Cr(H_2O)_6{}^{2+}$ to a solution of $Pt_2(pop)_4{}^{4-}$ sealed under oxygen free conditions results in evolution of hydrogen and a decrease in the absorption band due to $Pt_2(pop)_4{}^{4-}$ at 367 nm. The hydrogen evolution is probably caused by chromous reduction of water induced by pH lowering in the solution upon addition of $Pt_2(pop)_4{}^{4-}$. Concomitantly with the decrease in intensity of the 367 nm band, three new bands at 373 nm ($\epsilon = 9.6 \times 10^3$), 413 nm ($\epsilon = 1.0 \times 10^4$), and 459 nm ($\epsilon = 1.3 \times 10^4$) appear in the spectrum (Fig. 3). Quantitative spectrophotometric titration of $Pt_2(pop)_4{}^{4-}$ with chromous ion under carefully controlled oxygen free conditions shows a stoichiometry of 1:2 for formation of $Cr(H_2O)_6{}^{3+}$. Thus $Pt_2(pop)_4{}^{4-}$ undergoes a 2-electron reduction

$$Pt_2(pop)_4{}^{4-} + 2Cr^{2+} \rightarrow Pt_2(pop)_4{}^{6-} + 2Cr^{3+} \qquad (2)$$

with chromous ion (eqn 2). Assuming these electrons enter the $A_{2u}(6p_z)$ LUMO state of $Pt_2(pop)_4{}^{4-}$, the appearance of new absorbances in the electronic spectrum is due to transitions into the higher manifold of states from this new ground state.[4,5] Changes in the aqueous solution Raman spectrum of $Pt_2(pop)_4{}^{4-}$ are also ob-

Fig. 3. Electronic spectrum of an aqueous solution of $Pt_2(pop)_4{}^{4-}$ with added excess $Cr(H_2O)_6{}^{2+}$.

served upon addition of chromous ion. The observation of Stokes and anti-Stokes lines at 106 cm^{-1} represents a 10 cm^{-1} lowering of frequency from v(Pt–Pt) in Pt$_2$(pop)$_4^{4-}$, indicative of the electrons being transferred into the metal centred molecular orbitals.[6] Assuming no change in hydration at the axial position, we tentatively conclude that the platinum (6p_z) orbital has some small antibonding character with respect to intermetallic bonding.

Addition of compounds other than SO$_2$ and 1,1-bis(2-sulphoethyl)-4,4'-bipyridinum inner salt[5] will cause emission quenching of Pt$_2$(pop)$_4^{4-}$. Thus addition to Pt$_2$(pop)$_4^{4-}$ of hydroquinone, pyrogallol and carbon disulphide causes a loss of phosphorescence in solution, and the appearance of a Raman band (Pt–Pt) in the 113–114 cm^{-1} region. Addition of simple alcohols, glycols or oxalic acid does not result in emission quenching.

EXPERIMENTAL

The complex K$_4$[Pt$_2$(pop)$_4$]·2H$_2$O was prepared by published procedures.[1,3,5,24] Electronic spectra were measured on a Cary 219 spectrophotometer as aqueous solutions in 1 cm quartz cells. Raman spectra were measured on a Ramanor instrument using an argon ion 554 Control laser. Samples were prepared as aqueous solutions. ^{31}P NMR spectra were measured on a Nicolet wide bore spectrometer operating at 80.98 MHz. Chemical shifts are referenced to high frequency of 85% H$_3$PO$_4$.

Chromous ion reductions were carried out under oxygen free conditions in a Vacuum Atmosphere drybox. Spectral intensity data were obtained on a Bausch and Lamb Model 20 visible spectrophotometer operating in the drybox. Solutions of chromous ion were prepared by the zinc amalgam reduction of chromium trioxide. Quantitative estimations of the reduction reaction were made by measuring the intensity increase of the 417 nm chromium(III) chromophore.

NOTE

A ^{35}Cl NUCLEAR QUADRUPOLE RESONANCE STUDY OF NH$_4$ICl$_4$·H$_2$O

K. B. DILLON* and J. LINCOLN

Chemistry Department, University of Durham, South Road, Durham DH1 3LE, England

Abstract—The "missing" fourth ^{35}Cl NQR frequency postulated for NH$_4$ICl$_4$·H$_2$O at room temperature has been observed. Four signals were also found for this compound at 195K, but the results at 77K were less clear-cut, with either five or (probably) six resonances detected. The occurrence of a phase transition between 77 and 195K seems likely. A structure is suggested for the ICl$_4$$^-$ ion at room temperature from the relationship found previously between NQR frequency and bond length in tetrachloroiodates.

Several ^{35}Cl NQR frequences have been reported for salts containing the ICl$_4$$^-$ ion,[1,2] and although the spread of frequencies for this ion in any one compound may be large (>13 MHz for form I SCl$_3$$^+ICl_4$$^-$ at 77K[2]), reflecting distortion of the anion from D$_{4h}$ symmetry, the average frequency is remarkably constant.[1] Thus for fourteen sets of data at room temperature the average frequency is 22.337 (ESD 0.090) MHz.[1] The only apparent exception was NH$_4$ICl$_4$·H$_2$O, for which three signals at 27.96, 24.68 and 19.98 (average 24.21) MHz at room temperature have been observed.[3] It was suggested by Dillon and Waddington from comparison with the results for KICl$_4$·H$_2$O[4] that a fourth line at lower frequency might not have been detected for NH$_4$ICl$_4$·H$_2$O, and its frequency was predicted as 16.7 ± 0.4 MHz.[1] We have now observed this "missing" resonance, and also report ^{35}Cl NQR data for the compound at 195 and 77K.

NH$_4$ICl$_4$·H$_2$O was prepared in a similar way to the literature method.[3] NH$_4$Cl was treated with iodine in concentrated aqueous HCl, and the product (NH$_4$ICl$_2$) then chlorinated *in situ*. Nitrogen was blown over the solution to reduce the volume, and orange crystals were precipitated. These were filtered off and dried by suction. ^{35}Cl NQR spectra were recorded as described previously.[5]

At room temperature four equally intense ^{35}Cl NQR signals were observed for the title compound, at 27.960, 24.675, 19.930 and 17.190 MHz. The first three values are in very good agreement with the previous report,[3] and the fourth resonance is the "missing" frequency. It lies just outside the predicted range of 16.7 ± 0.4 MHz, but the average frequency at room temperature of 22.439 MHz is still very close to the average over fourteen sets of data.[1] Four signals were also found at 195K, at 28.025, 24.850, 19.995 and 17.455 MHz (average 22.581 MHz); a weaker resonance at 19.575 MHz was assigned to the ^{37}Cl counterpart of the signal at

24.850 MHz (calculated[6] ^{37}Cl frequency 19.585 MHz). The whole frequency range was not scanned, but just the areas where signals might reasonably be expected by comparison with the room temperature results, hence the other ^{37}Cl signals were not investigated.

The data at 77K were more ambiguous; the two signals at highest frequency occurred at 28.060 and 25.105 MHz, but the lowest frequency signal was split into two components, at 17.827 and 17.743 MHz. The intermediate signal was probably also split, with frequencies measured at 19.953 and 19.850 MHz, but the possibility of overlap with the ^{37}Cl resonance corresponding to the ^{35}Cl signal at 25.105 MHz (calculated[6] value 19.786 MHz) cannot be entirely discounted. The results suggest strongly that a phase transition occurs between 77 and 195K. The average frequency at 77K, on the assumption that both lower frequency signals are split, is 22.713 MHz, in excellent agreement with the average value from sixteen sets of data at this temperature of 22.634 (ESD 0.130) MHz.[1]

The results also indicate that NH$_4$ICl$_4$·H$_2$O may be isostructural at room temperature with KICl$_4$·H$_2$O, the crystal structure of which has been determined;[7] it shows four different I–Cl bond lengths of 2.42, 2.47, 2.53 and 2.60 (ESD 0.01)Å. From the relationship found previously between ^{35}Cl NQR frequency and bond length at room temperature,[1] the ICl$_4$$^-$ ion in NH$_4$ICl$_4$·H$_2$O may be similarly distorted, with bond lengths of 2.43, 2.47$_5$, 2.54$_5$ and 2.58$_5$ (± 0.01)Å and the longest bond *trans* to the shortest one, as in KICl$_4$·H$_2$O.

The observation of the fourth signal, and the close similarity of the average frequency for the ICl$_4$$^-$ ion in NH$_4$ICl$_4$·H$_2$O to literature values both at room temperature and 77K,[1] lend some confidence to predictions of NQR frequencies based on these averages for other tetrachloroiodates where not all the resonances may have been detected. More crystal structure deter-

minations are required before the relationship[1] between bond length and NQR frequency can be confirmed, but deductions of structure and distortion from D_{4h} symmetry derived from NQR measurements may be particularly useful where the compounds cannot readily be obtained in crystalline form.

NOTE

THE WEISS CONSTANT: A PROBE FOR THE MOLECULAR PACKING OF MONOMERIC COPPER(II) COMPLEXES?

M. R. SUNDBERG*, R. UGGLA, T. BÖÖK† and I. KALKKU‡

University of Helsinki, Department of Inorganic Chemistry, SF-00100 Helsinki, Finland

Abstract—Magnetic properties of the complexes $Cu(pn)_2WO_4 \cdot 1.8H_2O$, $Cu(pn)_2I_2$, $Cu(pn)_2Br_2 \cdot 1.6H_2O$ and $Cu(pn)_2Cr_2O_7$ (pn = 1,2-diaminopropane) have been studied by ESR, magnetic balance (Gouy method) and PA techniques. Curie constants C were obtained from ESR spectra, temperature independent paramagnetism $N\alpha$ from PA spectra, and Weiss constants θ from magnetic susceptibility data. Isotropic factors r were calculated, describing reduction of the orbital angular momentum and the spin–orbit coupling constant from their free-ion values. From the measured crystal g values we conclude that there is axial elongation in all the coordination polyhedra, corresponding to the ground state $d_{x^2-y^2}$. The different line shapes in the ESR spectra depend on the alignment of the pseudo-tetragonal axes, induced by the counterion. The counterions have a clear effect on both the magnetic parameters and the reduction factors. The alignment of the pseudo-tetragonal axes is also reflected in the value of the Weiss constant. A correlation is proposed between the Weiss constant and molecular packing.

ESR has been proved effective for investigating the bonding and stereochemistry in copper(II) complexes.[1] In many cases the stereochemistry can be concluded from the line shape of the ESR spectrum and the calculated g factors.[2] Because of the symmetry of the pn molecule the ESR spectrum will exhibit three g values, corresponding to the symmetry D_{2h}, unless there is more than one set of crystallographically equivalent coordination polyhedra, in which case the number of g values may be less. The lineshape of the spectrum will vary owing to interaction of the copper(II) ions.[2]

Monomeric copper(II) complexes usually obey the Curie–Weiss law

$$\chi_M^{corr} = \frac{C}{T - \theta} + N\alpha \qquad (1)$$

where χ_M^{corr} is the diamagnetically corrected molar susceptibility. The Curie constant C can be defined as[3]

$$C = Ng_{iso}^2\mu_B^2/4k. \qquad (2)$$

The Weiss constant θ represents the splitting of the ground state levels in zero-field.[4] The term due to the temperature independent paramagnetism $N\alpha$ can be calculated from the expression[5]

$$N\alpha = 4N\mu_B^2/\Delta E \qquad (3)$$

where ΔE is the energy difference between the ground state and the excited state.

The calculated effective magnetic moment for mononuclear copper(II) complexes is given by the spin-only value $\mu_{s.o.}$ of 1.73 B.M. The experimental values lie appreciably above this value, owing to mixing-in of some orbital angular momentum from the excited state via spin–orbit coupling[2]

$$\mu_{eff} = \left(1 - \frac{2r^2\lambda}{\Delta E}\right)\mu_{s.o.}. \qquad (4)$$

The parameter r describes the reduction of the orbital angular momentum and the spin–orbit coupling constant from their free-ion values to their values in the actual copper(II) complex. It is influenced by such factors as covalent bonding and electron delocalization from the ligand atom to the copper(II) ion.

According to an earlier study the compounds $Cu(pn)_2I_2$, $Cu(pn)_2Cr_2O_7$ and $Cu(pn)_2Br_2 \times 1.6H_2O$ are mononuclear and centrosymmetric.[6] Of the fourth compound, $Cu(pn)_2WO_4 \times 1.8H_2O$, only the cell dimensions are known.[7] The purpose of the present study was to

*Author to whom correspondence should be addressed.

‡Present address: Helsingin Suomalainen Yhteiskoulu, SF-00300 Helsinki, Finland.

investigate the influence of the counterion on the magnetic parameters and to gather data for elucidation of the possible correlation between structural and magnetic properties.

EXPERIMENTAL

The preparation and analysis of the compounds have been reported earlier.[7-10] The ESR spectra of the powdered samples were obtained at room temperature with a Varian E3 spectrometer. The external magnetic field was 3240 G (1 G = 1 × 10^{-4} T) and scan range ± 500 G. 2,2,6,6-Tetramethylpiperidin-1-oxyl was used as calibrant with 2.0055 as splitting factor.[11] The microwave frequency was 9245 MHz and it was measured with a Hewlett–Packard 5245 L electronic counter equipped with a 5255 A frequency converter.

The magnetic susceptibilities were obtained with a Newport Variable-Temperature Gouy Balance. The measurements were carried out in the temperature range 93–303 K in a nitrogen atmosphere. Copper(II) sulphate pentahydrate served as standard.[12] Diamagnetic corrections were applied using Pascal's constants.[13] The effective magnetic moments were calculated with the usual equation $\mu_{eff} = 2.83\sqrt{(\chi_M^{corr} - N\alpha)T}$. The Weiss constants were calculated using standard least squares fit.

The PA spectra of the powdered samples were obtained at room temperature with an EDT OAS 400 spectrometer.

RESULTS AND DISCUSSION

The ESR spectra are shown in Fig. 1 and the corresponding g values in Table 1. Because of the asymmetry of the ligand the symmetry around copper(II) in the CuN$_4$ plane is rhombic. Thus the ESR spectrum will have three g values, providing that the pseudo-tetragonal axes are aligned. Cu(pn)$_2$WO$_4$ × 1.8H$_2$O ex-

Table 1. The observed g values

Compound	g_1	$g_\parallel$	g_2	$g_3(g_\perp)$	g_{iso}
Cu(pn)$_2$WO$_4$·1.8H$_2$O	2.050		2.062	2.174	2.095
Cu(pn)$_2$I$_2$		2.196		2.050	2.099
Cu(pn)$_2$Br$_2$·1.6H$_2$O	2.137		2.049		2.078
Cu(pn)$_2$Cr$_2$O$_7$					2.063

hibits a typical spectrum of this kind. If the rhombic distortion is very small the powder technique will not be sufficiently sensitive to resolve the two planar components. This is the case for Cu(pn)$_2$I$_2$ where the space group is triclinic and the pseudo-tetragonal axes must be parallel.[10] This type of line-shape will also be generated by complexes exhibiting a slight misalignment of the pseudo-tetragonal axes. As the misalignment of the axes proceeds further, the spectrum will begin to look like that of Cu(pn)$_2$Br$_2$ × 1.6H$_2$O. The ultimate misalignment generates an isotropic spectrum, as is approximately the case for Cu(pn)$_2$Cr$_2$O$_7$. The angle between the pseudo-tetragonal axes can be calculated as 59° from the known structure of the complex. Although the obtained g values are not molecular but crystal ones, there is one common feature for all compounds: the lowest g value is almost constant at 2.05. The variation of the counterion causes changes in the packing of the molecules, which are reflected in the different line shapes of the ESR spectra. Because the lowest g values are all > 2.04, the complexes must be axially elongated and have the ground state $d_{x^2-y^2}$.[2]

The calculated magnetic susceptibilities and magnetic moments are shown in Table 2. The values obtained are typical of mononuclear copper(II) complexes. To calculate the Weiss constants, the respective Curie constants and $N\alpha$ values were obtained from eqns (2) and (3). The

Table 3. ΔE values obtained from PA spectra with the calculated magnetic parameters and reduction factors. The r value for $Cu(pn)_2Cr_2O_7$ is unreasonable since the maximum possible value for r is 1.00. The error arises from the uncertainty of the location of the d–d transition due to charge transitions of dichromate ions. Accordingly the corresponding $N\alpha$ value has been calculated by giving the value 60×10^{-6} to Cu(II) and 74×10^{-6} to Cr(VI)

	ν_{max}/nm	μ_{eff}	C	θ	r	$N\alpha \cdot 10^6$

[a] very broad

required g_{iso} and ΔE values are listed in Tables 1 and 3, respectively, and the magnetic parameters together with the calculated reduction factors (eqn 4) are shown in Table 3. From the results we can readily see that the counterion has a marked influence on the magnetic parameters. There also seems to be a correlation between the covalency of the Cu–L bond and the magnetic properties.

The Weiss constants obtained display a general correlation with the ESR results describing the misalignment (or alignment) of the pseudo-tetragonal axes. The negative values indicate antiferromagnetic interactions in which the magnetic moments (or spins) of the individual centres tend to align themselves antiparallel to one another. In ferromagnetic systems the opposite is true.

Our results encourage us to believe that a mathematical correlation could be established between the Weiss constant and the copper–copper distance and the angle between the magnetic axes.

THE REPORTED ION Fe₃S₂(NO)₅⁻: A RE-INVESTIGATION

ANTHONY R. BUTLER, CHRISTOPHER GLIDEWELL,* ANDREW R. HYDE
and JOSEPH McGINNIS

Chemistry Department, University of St. Andrews, St. Andrews, Fife KY16 9ST, Scotland

Abstract—Salts reported to contain the iron–sulphur cluster nitrosyl anion $Fe_3S_2(NO)_5^-$ are shown to be identical with those containing the well-known anion $Fe_4S_3(NO)_7^-$.

The anions $Fe_4S_3(NO)_7^-$ and $Fe_2S_2(NO)_4^{-2}$, which occur in the black and red Roussin salts,[1] are structurally related to the 4-Fe and 2-Fe iron–sulphur clusters of natural occurrence. The reported synthesis[2] of a third such anion $Fe_3S_2(NO)_5^-$ is therefore of considerable chemical interest, as the number of naturally occurring 3-Fe species is small: in addition, the salts of this anion are reported to have a number of interesting spectroscopic properties, which would repay further study.

We report here that all our attempts to repeat the preparation of salts of the 3-Fe anion $Fe_3S_2(NO)_5^-$ using the published procedure[2] yield instead the corresponding salts of the known and very stable 4-Fe anion $Fe_4S_3(NO)_7^-$.

---

*Author to whom correspondence should be addressed.

Upon following the literature method, we have repeatedly obtained black crystals, as reported, of the ammonium, sodium, and potassium salts, and additionally of the tetraphenylarsonium salt also. As judged by their electronic spectra (Table 1) these salts all contain the same chromophore: these spectra moreover are indistinguishable from those of the corresponding salts of $Fe_4S_3(NO)_7^-$. Using the tetraphenylarsonium salt as the preferred analysable form, microanalysis (Table 1) demonstrated clearly that this salt was $Ph_4As^+Fe_4S_3(NO)_7^-$, rather than $Ph_4As^+Fe_3S_2(NO)_5^-$, and hence that all the salts contained the anion $Fe_4S_3(NO)_7^-$, rather than the reported anion $Fe_3S_2(NO)_5^-$.

One plausible formulation of the anion $Fe_3S_2(NO)_5^-$ can be derived, by loss of NO^+, from the as yet unknown $Fe_3S_2(NO)_6$ (I), formally derived from the isoelectronic $Fe_3S_2(CO)_9$ (II), of known structure.[3] We

have recently attempted the preparation of (I) by nitrosylation of (II), where the Fe_3S_2 group is already present.[4] No 3-Fe compound was obtained, but instead the sole product from a variety of procedures was the 4-Fe anion $Fe_4S_3(NO)_7{}^-$, in yields up to 80%. When very mild conditions were used, in an attempt to prevent molecular reorganisation, no nitrosylation occurred, and (II) was recovered unchanged. Thus, even when the Fe_3S_2 core is pre-formed, the only stable nitrosyl derivative is $Fe_4S_3(NO)_7{}^-$, entirely consistent with our failure to isolate any salt of the $Fe_3S_2(NO)_5{}^-$ ion.

I   II
Although the anion $Fe_3S_2(NO)_5{}^-$ is an even-electron ion, it is reported[2] to give ESR spectra under a wide variety of conditions: the five-line spectrum in aqueous alkali bears a remarkable similarity to that reported[5] for the species $Fe(NO)_2{}^+$, obtained by reaction of Fe(II) salts with nitric oxide in alkaline solution. We find, in contrast, that the prepared product yields no ESR spectrum in neutral solution, but in alkaline solutions gives a spectrum characterized by coupling to a single ^{14}N nucleus, with $A_N = 5$ G. The reported spectrum[2] is hard to understand: any fragmentation, in solution, of an iron–sulphur cluster nitrosyl to yield $Fe(NO)^{x+}$ or $Fe(NO)_2{}^+$ ions must also yield S^{2-} (or SH^-), and it has been clearly demonstrated[5] that in the presence of sulphide ions, the sole paramagnetic iron nitrosyl species which can be detected by ESR contains one nitrogen atom, not two. This is consistent with our own observations, but not with those reported for the supposed $Fe_3S_2(NO)_5{}^-$ ion, and we conclude that whatever the reported ESR spectrum[1] may represent, it is not the fragmentation product of an iron–sulphur cluster nitrosyl derivative.

Finally we note that the formula weight of the supposed salt $K[Fe_3S_2(NO)_5]$ was reported to have been established by a mass spectral determination of $m/z = 420$ for M^+, corresponding closely to the ion-pair cation $[KFe_3S_2(NO)_5]^+$ (for which $m/z = 421$): we remark merely that we are unable to confirm this.

THE TRANSITION-METAL ASSISTED SYNTHESIS OF THE *ANTI*-OCTADECABORATE ANION [B$_{18}$H$_{21}$]$^-$ FROM THE *NIDO*-DODECAHYDRONONABORATE ANION [B$_9$H$_{12}$]$^-$

J. BOULD, N. N. GREENWOOD* and J. D. KENNEDY
Department of Inorganic and Structural Chemistry, The University of Leeds, Leeds LS2 9JT,
England

Abstract—When heated under reflux in CH$_2$Cl$_2$ solution with [Os(CO)$_3$Cl$_2$]$_2$, two *nido*-[B$_9$H$_{12}$]$^-$ units edge-fuse to form *anti*-[B$_{18}$H$_{21}$]$^-$.

Recent reports have described the use of metal centres in promoting the conjunction of both borane and carborane clusters to produce *conjuncto* linked species, i.e. those joined by one straightforward two-electron, two-centre boron–boron σ-bond. Thus the reaction of *nido*-B$_5$H$_9$ with catalytic amounts of PtBr$_2$ results in a dehydrodimerisation reaction giving [1,2-(B$_5$H$_8$)$_2$] in 92% yield[1] and the reaction of *nido*-[2,3-Me$_2$C$_2$B$_4$H$_5$]$^-$ with HgCl$_2$ yields [μ,μ'-(Me$_2$C$_2$B$_4$H$_5$)$_2$Hg] which, upon heating at 180°C, gives the *conjuncto* *nido*-carborane [5,5'-(Me$_2$C$_2$B$_4$H$_5$)$_2$)].[2] Similarly, organometallic complexes such as [(RR'C$_2$)Co$_2$(CO)$_6$] and [Ir(CO)Cl(PPh$_3$)$_2$] have been used to catalyze the addition of various alkynes to small carboranes with the formation of two-electron two-centre σ-bonded linkages.[3]

We now wish to report the first example of the use of a transition metal complex to promote the fusion of two nonaborate clusters to form a higher boron hydride cluster in which two smaller sub-clusters are linked by two common boron centres, i.e by a common polyhedral edge rather than by an intercluster *conjuncto* B–B σ-bond.

During attempts to synthesize novel polyhedral osmaboranes,[4] we have found that the reaction of [NEt$_4$] [*nido*-B$_9$H$_{12}$] (84 mg, 0.3 mmol) with [Os(CO)$_3$Cl$_2$]$_2$ (50 mg, 0.3 mmol) in refluxing CH$_2$Cl$_2$ under nitrogen (5 hr) produces a mixture which, when separated by preparative tlc (mobile phase CH$_2$Cl$_2$/MeCN, 96:4; stationary phase silica gel Fluka Type G.F. 254), gives a 20% yield (11 mg, R$_f$0.3) of [NEt$_4$][*anti*-B$_{18}$H$_{21}$] (see Fig. 1).

The product was readily identified by comparison with an authentic sample using ^{11}B NMR spectroscopy. Other compounds were present in small amounts which require

further identification although most appear to be various ionic and neutral derivatives of both the *syn* and *anti* isomers of [B$_{18}$H$_{22}$] (for the definition of *syn* and *anti* see Ref. 5).

Unfortunately the osmium complex is not catalytic in action and doubling the borane to metal ratio did not increase the yield of [B$_{18}$H$_{21}$]$^-$. This indicates that the osmium probably forms an intermediate metallaborane complex which subsequently reacts further to give the product. In this it may have some parallels to the bis(carboranyl)mercury(II) complex mentioned above which eliminates elemental mercury to form a B–B σ-linked carborane when heated. Further work is planned to find the ultimate fate of the osmium complex in the reaction reported here.

The fusion of an *arachno*-nonaborane cluster has been described previously where [B$_9$H$_{13}$(OBu$_2$)] is heated at 140°C to give the *syn* isomer of [B$_{18}$H$_{22}$] in 34% yield,[6] and the reaction reported here therefore offers a useful, if ostensibly expensive, route to the *anti*-isomer since the anion readily yields neutral *anti*-[B$_{18}$H$_{22}$] upon acidification.[7] In the general case it also demonstrates the potential of transition metal centres for promoting fusions of this and other related cluster types.

In this context it is of interest to note the recent report of the fusion of the nine-vertex compound *arachno*-[(PMe$_2$Ph)$_2$PtB$_8$H$_{12}$] in refluxing toluene to give a seventeen-vertex metallaborane [7-(PMe$_2$Ph){7-

Fig. 1.

---

*Author to whom correspondence should be addressed.

$PtB_{16}H_{18}$-9'-(PMe_2Ph)}].[8] This is a further indication that transition metal centres may be able to play an increasingly important role in the fusion of nine-vertex or indeed other sized borane and metallaborane clusters to form novel macropolyhedral species.

BOOK REVIEW

The Origin of ,the Chemical Elements and the Oklo Phenomenon. P. K. Kuroda. 1982. 24 figs., 48 tabs. XI, 165 pages. 485 g Cloth DM 92.–; US $ 36.80. Berlin–Heidelberg–New York: Springer-Verlag ISBN 3–540–11679–6.

The origin of the world, the meaning of life, and all that sort of thing, have excited man's imagination from time immemorial[1] to the present day.[2] Speculation on these topics has spawned a vast literature of mythology, Friga who spun the clouds, Pele whose hair came from volcanoes and so on, whose chief characteristic has been its logical and reasonable unreasonableness. The reader has only to suspend his disbelief and all will be made clear. Has much changed now that the age of enlightenment has dawned, given rise to reason, and reached a pinnacle of achievement in our present scientific era? Do we not still tell stories fantastic, but now expressed in millibarns and megayears yet still fantastic speculation n'ertheless? The present book by Professor Kuroda is a valiant attempt to see what order, based on scientific facts, can be established in the heady bizarre and truly metaphysical world when there was no world. In general, he is concerned with the origin of the elements and in particular to rationalise the specific isotopic abundancies that can be observed both on earth and in the heavens— well those bits of the heavens that come our way like meteorites and samples of lunar rock—in terms of intricate patterns of nuclear reactions. It is, however, difficult to tell a clear and coherent story since the quality of theoretical speculation is inversely proportional to the possibility of experimental verification. Nowhere is this more clearly seen than in the field of cosmological nucleogenesis. Furthermore, much of this book deals rather too extensively with the minutae of specific problems: an overall picture fails to emerge. Thus such diverse topics as xenonology (a study truly of strange things!), the extinction of the dinosaurs and Nature's own do-it-herself nuclear reactor at Oklo, all find some place in this monograph.

—Fait de tout pour faire un monde . . .

From: J. Effel, *La Création du Monde*. La Livre de Poche, Paris (1974).

Despite these short comings this is an interesting and fascinating book which gives a timely review of the literature of nucleogenesis and which enables the author to put his own considerable achievements and considered opinions into a broader perspective. A personal book then, but one which can be read with profit by anyone interested in the beginnings of it all.
