1. INTRODUCTION

Chromium was recognized as an essential trace element in 1955.[1] Rats fed a chromium deficient diet developed an impaired tolerance for intravenous glucose, which could be reversed by an insulin potentiating factor present in brewer's yeast, meat and various other foods. The insulin potentiating factor was found to be a complex of chromium(III)[2] and such substances have been termed Glucose Tolerance Factor(s) (GTFs). Chromium was demonstrated to be essential for humans in 1975.[3]

Chromium has a number of other biological effects, including carcinogenicity[4] and a variety of allergic responses;[5] these are mainly induced by chromium(VI). Chromium is also implicated in protein synthesis and lipid metabolism.[6]

There have been a number of reviews of chromium biochemistry including an extensive article by Mertz,[7] a review of the nutritional role of chromium[8] and several shorter articles mainly concerned with GTF.[9–12] This review will deal solely with those aspects of chromium biochemistry and chemistry relevant to glucose tolerance and discuss both the evidence for and possible structure of GTF, and relevant aspects of the chemistry of chromium(III).

2. CHROMIUM AS A BIOLOGICALLY ESSENTIAL ELEMENT

Rats fed a Tolura yeast ration developed a progressive impairment of intravenous glucose tolerance,[1] although this diet was deficient in a number of known essential dietary components, none of these reversed the condition. Brewer's yeast was found to be particularly effective in preventing the syndrome[2] and the unidentified nutritional factor was termed GTF. Purified fractions[13] were capable of both preventing and curing the condition with a single oral dose of 100 mg/100 g of body weight. GTF was found to contain chromium(III) and to become very unstable as the purity increased.

GTF deficient rats were treated with 47 elements[14] of which only chromium(III) restored glucose tolerance. Samples isolated from yeast were much more active than simple substances such as $CrCl_3$ and rather stable complexes such as the tris-acetoacetonate were found to be quite ineffective. Similar effects were found when complexes were incorporated into the diet,[15] or injected intravenously.[16] When injected the optimal dose was much lower at 0.25 mg/100 g of body weight (a neutral solution of chrome alum). As might be expected absorption has an enormous effect on the availability of chromium(III), the kinetic inertness and facile hydrolysis of chromium complexes are probably problems.

The work outlined above rapidly established chromium(III) to be an essential element closely involved with glucose tolerance. It is surprising that, in the period since it's original identification, nothing approaching an exact molecular structure for GTF has emerged. We shall now outline the methods available for the testing, isolation and synthesis of GTF.

3. TESTING OF THE GLUCOSE TOLERANCE FACTOR (GTF)

There is a problem in interpreting studies of chromium(III) complexes which relate to GTF. *In vivo* activity can only be demonstrated by expensive experiments on large numbers of chromium deficient animals. *In vitro* studies are cheaper and more reproducible, but may not actually be related to the *in vivo* mode-of-action of GTF. The vast majority of assay systems involve the potentiation of insulin activity by GTF in isolated fat cells. Mertz has described GTF/chromium(III) as a "true potentiator of the action of the hormone (insulin)".[17] Both insulin and GTF are required in, the *in vivo* and *in vitro* systems to produce maximal effects. The effect of chromium is hence unique and quite distinct from the "insulin mimetic" behaviour of many other metal ions. There is a close relationship between the effects of chromium deficiency *in vivo* and the *in vitro* assays, but there is no hard evidence that the *in vitro* tests are relevant to the mode-of-action of GTF and/or chromium *in vivo*.

The effect of trivalent chromium on glucose uptake by rat epididymal fat tissue was investigated.[15] Four 100 mg pieces of tissue could be obtained from each rat, one of these was used as a control. Tissue samples were then incubated for 2 hr with the chromium complex, glucose and insulin; the absorption of glucose was then determined by chemical or radiochemical assay of that remaining in the medium. The increase in the rate of uptake on the addition of chrome alum varied between + 5% and + 70%, and was particularly marked at low insulin concentrations.

In related studies CO_2 production from isolated epididymal adipose tissue has been measured in the presence of either chromium complexes or purified GTF.[18,19] In this method dose response curves (rate of metabolism vs. insulin concentration) are plotted, chromium(III) complexes and GTF produce steeper dose response curves than insulin alone. This clearly demonstrates that insulin activity is being enhanced, rather than the simple addition of two isolated effects. The effect of purified GTF in this system was much greater than that of any of the synthetic complexes.

A microbiological assay for GTF has been developed,[20] the growth of Flavobacterium rhenanum being linearly dependent on the GTF concentration. Activity was expressed as a regression value (the slope of a plot of growth vs GTF concentration). A linear relationship was obtained between the values obtained by this method and bioassay values obtained from the rat epididymal fat assay.[18]

Quite recently a new assay system has been reported,[21] this allows up to seventy-five assays to be performed using the fat cells of a single rat. Adipocytes were prepared from the epididymal fat pads of chromium(III) deficient rats by the method of Rodbell.[22] Small quantities of these cells were then incubated with the material to be tested and radio-labelled glucose. Carbon dioxide production after 30 min incubation was then measured by trapping the gas in hyamine and

scintillation counting. Typical results are illustrated in Fig. 1, insulin potentiation being measured as the ratio of the carbon dioxide production at a fixed insulin level in the presence and absence of the chromium complex.

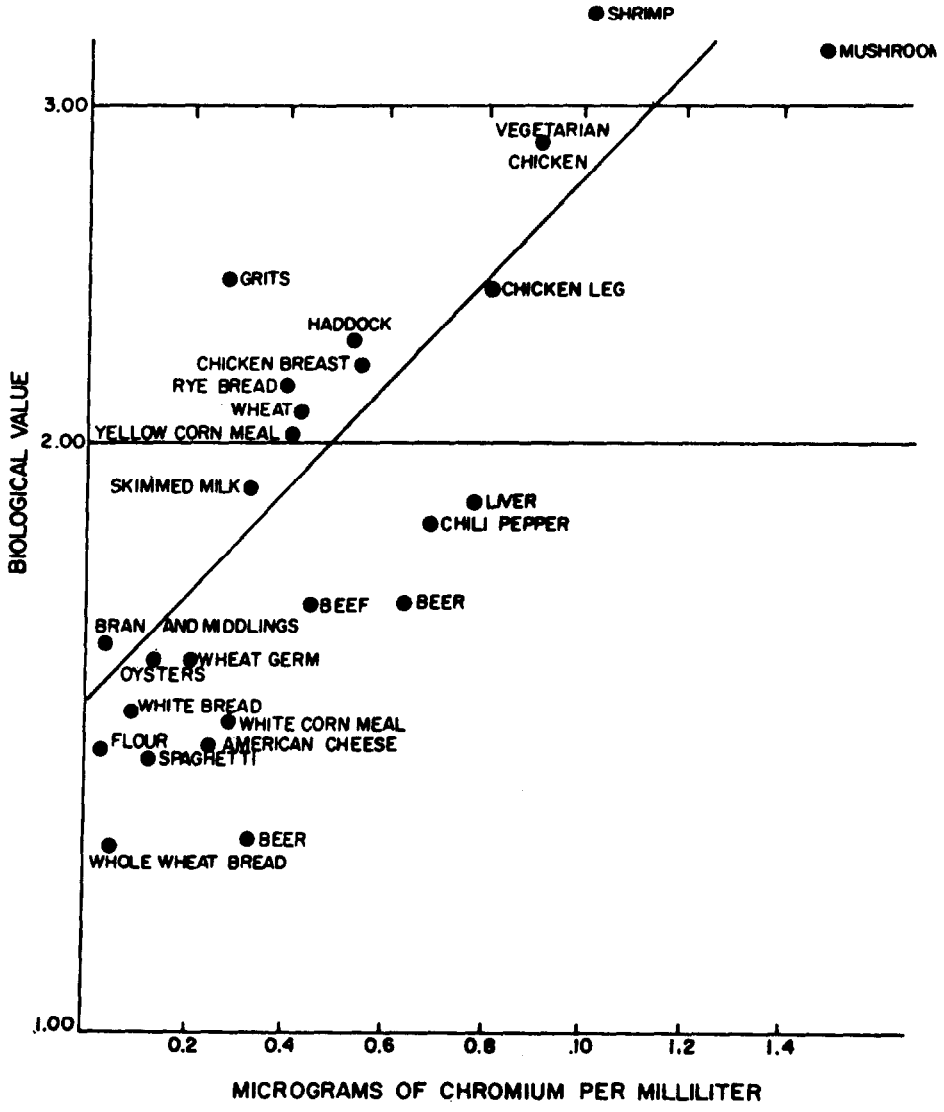
4. ISOLATION AND PURIFICATION OF THE GLUCOSE TOLERANCE FACTOR (GTF)

As mentioned in the introduction highly purified GTF fractions are unstable, the reasons for this are not clear. A number of procedures for the isolation and purification of GTF have appeared. The vast majority of such substances are obtained from yeasts and in particular Brewer's yeast. In this section we shall describe some of the more recent and reliable isolation and purification procedures for GTF(s).

In 1973 Toepfer *et al.* determined the chromium content of a number of food stuffs.[23] Total chromium and alcohol extractable chromium were determined, a significant relationship was found between alcohol extractable chromium and biological activity (as determined by the rat epididymal tissue assay[18]). This is illustrated in Fig. 2. An alcoholic extraction is often the first step in the isolation of GTF.

A partial purification of GTF from brewer's yeast, involving, alcoholic extraction and chromatography on activated charcoal has been described.[24] An increase in the specific activity of GTF of eighty fold was observed. This sample was used to study the binding of GTF to insulin. A sample of ^{51}Cr labelled GTF has been prepared from brewer's yeast grown in a medium containing isotopically labelled chromium.[25] The complex was isolated by extraction with butanol followed by chromatography on Sephadex G-25 and ion exchange chromatography. The ion exchange results suggested that the GTF was a single anionic species. Gel permeation chromatography results pointed to a reversible aggregation of GTF in buffers of low ionic strength. A preliminary amino acid analysis indicated the involvement of leucine or isoleucine, proline, valine, alanine, serine and either glutamic or aspartic acid. This complex was shown to be more readily retained, than simple salts by rats. However it was not tested for GTF activity and has a rather different amino acid composition from other GTF(s). In a related study a number of isotopically labelled chromium(III) complexes, which did not bind to insulin, were isolated.[26]

A detailed procedure for the extraction of GTF from Saccharomyces carlsbergenis has been reported.[27] The extraction procedure was broadly similar to that described above and involved ethanolic extraction, hydrolysis, and ion exchange chromatography. In this work nicotinic acid (I) was detected in the complex both by its characteristic UV and mass spectra. Glycine, glutamic acid and cysteine together with trace amounts of other amino acids were found in the purified sample of GTF. This is probably the most refined GTF yet isolated. Although IR spectra were recorded for this sample no detailed spectroscopic studies were undertaken which is unfortunate as studies of the ligand field spectra might help to suggest likely structures.



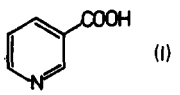


Fig. 2. Relationship between alcohol extractable chromium and biological activity. After Toepfer Ref. 19. Reproduced with permission.

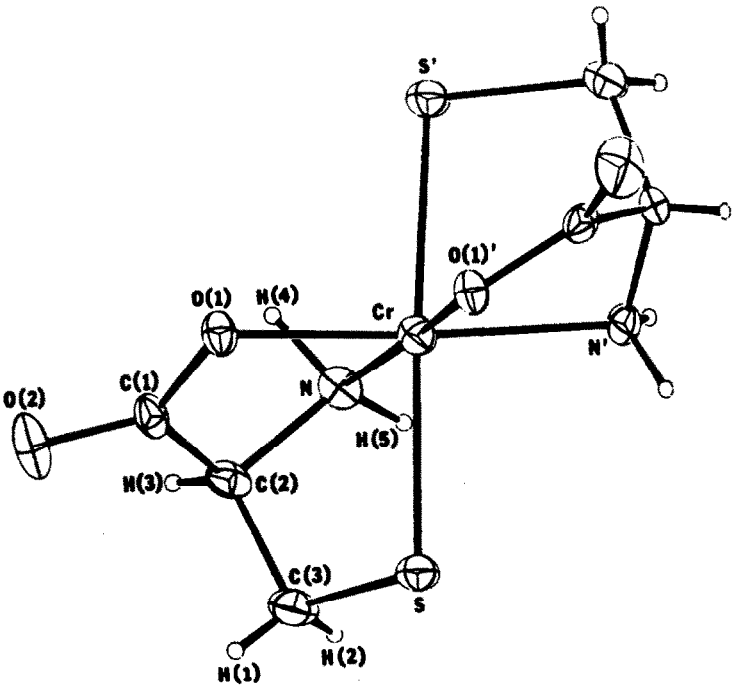
(I)

The isolation of GTF from a yeast extract (Merck) has been described.[28] The procedure involved stirring the extract with 1 : 1 butanol/water, dialysis (3500 molecular weight cut off), and ion-exchange chromatography on DAE-11 cellulose (Cl^-) and Dowex 50W × 8 (H^+). The compound isolated had similar properties to that described by Mertz[27] although no analytical results are provided. The lack of details is unfortunate, a procedure utilizing yeast extracts would eliminate the necessity of cultivating large quantities of yeast to obtain GTF. The extract enhanced carbon dioxide production by several yeast strains investigated, no effect could be observed in experiments on cell free extracts.



Recently the crystallization of a GTF has been reported,[29] the substance isolated by the Mertz method[27] was further purified by ion-exchange chromatography. Two purple chromium(III) containing fractions were obtained, one of these was successfully crystallized from alcohol/water. A complex of chromium(III) with tryptophan has been isolated from yeasts[30] the authors of this paper suggest that complexes of this ligand may be important in an understanding of GTF.

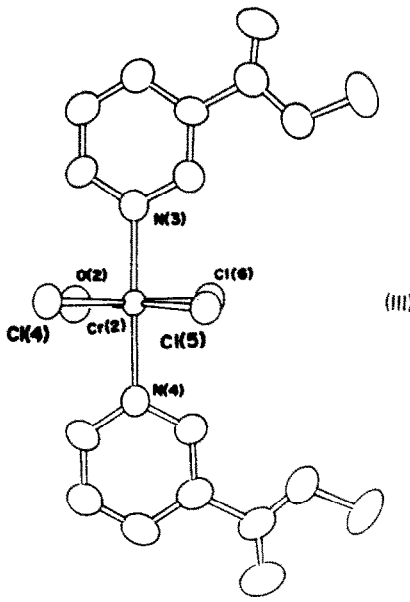
Finally it has been suggested that chromium(III) may not be an essential component of GTF.[30a,30b] A very thorough chromatographic purification of GTF from Brewer's yeast led to the separation of the Mertz "GTF" into several fractions, including biologically active fractions which contained no chromium(III). However these complexes were tested by monitoring their effect on yeast metabolism, hence the results do not preclude the biological activity of chromium(III) in mammalian systems.

Nicotinic acid is present in the more active GTF preparations isolated from yeasts. The coordination chemistry of this ligand is particularly relevant to glucose tolerance and the presence of this substance is apparently essential for the maximal activity of complexes in *in vitro* tests. The instability of highly purified GTF fractions has frequently been commented on.[7-9] This may be because the substance is stabilized by a protein *in vivo*.

5. SYNTHESIS OF THE GLUCOSE TOLERANCE FACTOR (GTF)

The synthesis and characterization of materials showing biological activity similar to that of GTF isolated from yeast is a logical objective of workers in this area. As already mentioned Mertz found aquo- and similar complexes of chromium to be more active than chelates with strong ligands. An exception to this was an unspecified cysteine complex[31] prepared by C. L. Rollinson which showed marked, but erratic, behaviour in GTF tests. Further investigation of this observation would be interesting, particularly as the crystal structure of a cysteine complex is now known[32] (II).

(II)



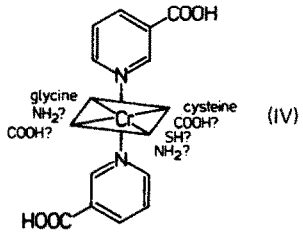
A complex with considerable activity in *in vitro* tests has been synthesised.[27] The preparation involved reacting chromium(III) acetate in 80% alcohol with two equivalents of nicotinic acid followed by the addition of one equivalent, in turn, of glycine, glutamic acid and cysteine. A complex containing nicotinic acid was isolated from the reaction mixture by ion exchange chromatography. The physical properties and biological activity of this complex were very similar to those of GTF isolated from yeast.[27] Although this material is probably a mixture, it should be further investigated as it is one of the most potent synthetic materials as yet obtained.

Anderson *et al* have reported a complex of glutathione/nicotinic acid and chromium(III) to be particularly active in their *in vitro* assay.[21] The complex was described as being purified by *hplc*, however we cannot find the details of the preparation in earlier work from this group.[33,34] This is unfortunate as this is also a species of quite remarkable biological activity.

A ternary complex of nicotinic acid and pyridoxylidene has been prepared. Nicotinic acid is coordinated via the pyridine nitrogen, the biodistribution of this complex was similar to that of GTF.[35] A recent review of the metal ion complexes of glutathione[36] fails to mention the possible

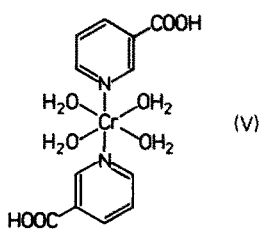
importance of a glutathione/chromium complex in glucose tolerance, the section on chromium concentrates on chromium(VI) chemistry.

The lack of serious synthetic work on GTF is surprising. Recently a number of studies of chromium(III)/nicotinic acid chemistry have appeared, but none of the following work appears to be of any direct relevance to GTF as isolated from yeasts.



(III)

GTF has been suggested[10] to contain *trans*-nicotinic acid groups, the structure[37] of *trans*-bis(methylnicotinate) aquatrichlorochromium(III) is shown below (III). The Cr–N bond distance is 2.094 Å, which is similar to nitrogen bond lengths in other chromium(III) complexes. The structure of a tri-nuclear chromium(III)/nicotinic acid complex has been reported.[38] The nicotinic acid molecules bridge the chromium atoms via carboxylate oxygens. The structure of this complex is quite different from that proposed for GTF.



The thermodynamics of the binding of nicotinic acid and its derivatives to di-aqua[N,N′-ethylenebis (salicylideneaminato)] chromium(III) chloride have been investigated.[39] The binding of nicotinic acid to this (labile) complex was not particularly favourable ($K = 7.3$), No suggestions as to the reasons for the apparently essential nature of nicotinic acid in GTF could be made on the basis of this work. Various cobalt(III) complexes of nicotinic acid have been synthesised.[40] A detailed study of the kinetics of ligand substitution in labile chromium(III) Schiff's base complexes has appeared. In these labile complexes a dissociative interchange I_d mechanism was suggested for substitution reactions.[41]

6. STRUCTURE OF THE GLUCOSE TOLERANCE FACTOR (GTF)

The lack of structural information in the papers cited above means that any suggested structure for GTF must be highly speculative. Mertz has suggested[10] that two trans nicotinic acids are coordinated to chromium as illustrated below (IV). The first coordination sphere is completed by the various amino acids involved. Although there is little evidence to support this suggestion it has

(IV)

(V)

attracted support and influenced other workers.[37] One product of the reaction of nicotinic acid and chromium(III) (mole ratio 3 : 1, pH 3.2) has been suggested to be tetra-aquo *trans*-bisnicotinate complex[10] (V). This substance showed some biological activity but no spectral or other characterization was reported. It would be surprising if chloro ligands were not coordinated in this complex.

The view that N-bonded *trans*-nicotinic acids are involved in GTF has recently been challenged,[41a] an O-bonded nicotinic acid complex has been shown to have some biological activity. The biological significance of chromium(III) was suggested to relate to the ability of the relatively hard chromium(III) centre to form stable complexes with the carboxylate group of nicotinic acid. The crucial grouping recognized by the biological system would hence involve the nitrogen of the O-coordinated nicotinic acid.

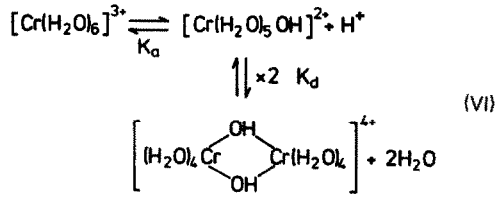
7. INSULIN

The one unequivocal action of the hormone insulin is its ability to facilitate the transport of glucose across the plasma membranes of muscle and fat cells. There are numerous reviews of the effect and mechanism of action of this hormone.[42] Insulin is believed to exert its primary action (i.e. interact with the receptor) at the membrane of the target cell.

The work of Cuatrecasas[43] demonstrates this elegantly. In the isolated adipocyte model, isotopically labelled insulin covalently bound to Sepharose beads (which are larger than the isolated fat cells), is capable of exerting its full hormonal activity. The association of insulin with its receptor is a simple bimolecular process (dissociation constant 5×10^{-11}). Isotopically labelled insulin could be displaced from the receptor by native insulin but not by oxidised or reduced insulin. This kind of work is of obvious relevance to the mode-of-action of GTF. Detailed studies of GTF or chromium/cell/insulin interactions of the kind described[43] for insulin/cell systems will be needed for a full understanding of the mode-of-action of GTF *in vitro*.

8. CHROMIUM(III) CHEMISTRY

The coordination chemistry of chromium(III) was first investigated by Pfeiffer forming a logical extension to Werner's studies of cobalt(III) complexes. A number of the properties of chromium(III) are rather different from the majority of essential trace elements. Most essential metals are (with the exception of cobalt(III) in vitamin B_{12}) kinetically labile in ligand substitution reactions, chromium(III) complexes are usually fairly inert in ligand substitution reactions. The hydrolysis of chromium(III) is particularly facile and leads to the formation of a number of very stable hydroxy-species. These factors combine to make studies of the thermodynamic stability of chromium(III) quite difficult and consequently rare. In marked contrast the redox stability of the plus three oxidation state ($E^{\ominus} = -0.41$) for chromium(III)/(II) (in aqueous solution),[44a] allows complex formation reactions to be studied; this is quite different from the cobalt(III) system ($E^{\ominus} = +1.84$).[44b] We shall now consider in detail some of the properties of chromium(III) relevant to the chemistry of GTF.



8.1 *Kinetics of substitution reactions*

Chromium(III) has the electronic configuration d^3, crystal (or ligand) field activation energy calculations suggest that such complexes would be kinetically inert.[45] In general this is borne out in practice, the half-life for the exchange of water at the hexaquo-complex is 384 hr (20°C).[46]

Substitution at chromium(III) centres has received a considerable amount of attention[47] because of the possibility of A or I_a.[47] Many chromium(III) formation reactions involve a rate law:[47]

$$k_{obs} = k_i K_{os}[L]/1 + K_{os}[L] \tag{1}$$

k_i is the interchange rate constant, K_{os} is the outer sphere complexation constant and L is the ligand.

(VI)

Such studies are usually held to be carried out under sufficiently acidic conditions that the monohydroxy species of chromium(III) may be ignored. On balance the evidence in the literature seems to favour an associative interchange mechanism (I_a via a tight ion pair derived from the hexaquospecies. The literature reveals some anomalies; in a series of classic papers Hamm *et al.* studied the formation of chromium(III) complexes with dicarboxylic and hydroxy-acids.[48–50] Their kinetic results, (most notably the reaction was zero order in ligand) were originally interpreted in terms of a strictly dissociative process. Basolo and Pearson[51] later suggested that a saturated ion pairing mechanism, (for which eqn (1) becomes $k_{obs} = k_i$) provides a more plausible explanation for Hamm's observations. In marked contrast for the reactions of malonate[52] and oxalate[53] with chromium(III), Banerjea and Chaudhuri found a dependence of reaction rate on ligand concentration. The conditions used in the latter studies were considerably more acidic than those used by Hamm. Complications of rate constants[54] and activation parameters[55,56] for chromium(III) reactions are available, but as exemplified above the situation is far from simple.

The reactions of amino acids with chromium(III) are of relevance to the formation of GTF and absorption of chromium. The reaction with glycine has been studied on several occasions[57,58] and most recently in our laboratory.[59] In the pH range 3.0–3.8 ($I = 0.4$, $NaClO_4$) we have found the reaction to obey the rate law $k_{obs} = k + k'[H]^{-1}$ and be zero order in ligand concentration. The reaction scheme shown in Fig. 3 accounts for our observations, and involves associative interchange within a tight outer-sphere complex for the aquo-species, and a more loosely bound outer-sphere complex for the mono-hydroxy chromium(III) species. In earlier studies of the reactions of chromium(III) with glycine the pH of the reaction was not adequately controlled.

Under certain circumstances ligand substitution in chromium can be rapid and it seems possible that this might provide a mechanism by which chromium(III) could interact with cells/insulin. The ligands involved in GTF are unlikely to promote such lability in adjacent coordination sites. This kind of chemistry is usually associated with rigid (often π-acceptor) ligands which give rise to tetragonal stereochemistries. The rapid rate of reaction of nicotinic acid with chromium(III) Schiff's base complexes has already been mentioned.[41] Other systems in which ligand substitution reactions are rapid include: porphyrin complexes[60–62] and $[Cr(EDTA)H_2O]$[63–65].

8.2 *Thermodynamic studies*

Compared to the majority of transition metals there have been very few studies of the equilibrium between common ligands and chromium(III).[66] There are two major problems involved in measuring equilibrium constants for chromium(III) systems. The kinetic inertness of the

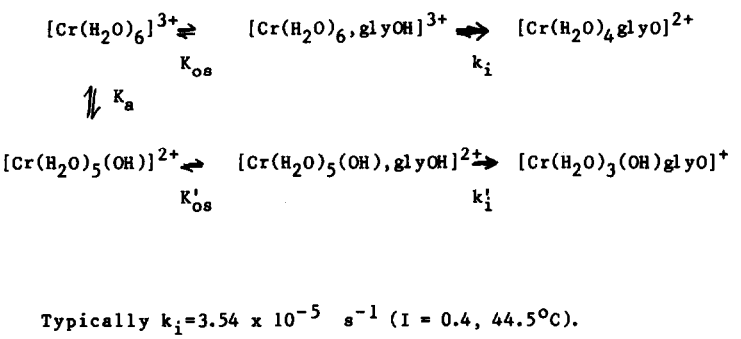


Fig. 3. Scheme for the reaction of chromium(III) and glycine.

hexaquo-complex means that a lengthy equilibration of ligand and metal is required. Secondly the hexaquo complex hydrolyses readily[67a](VI) ($pK_1 = 4.29$ and $K_D = 3.3$, 1M $NaClO_4$, 25°C[67b]) and often effectively irreversibly at higher temperatures. The species formed on the hydrolysis of chromium(III) have recently been studied in some detail.[67b]

Santappa *et al.* have recently studied[68] complexation by a variety of amino acids including aspartic[71] and glutamic acids. Their results together with those of related studies are summarised in Table 1.

Table 1. Typical equilibrium constants*

LIGAND	K_1	K_2	NOTES
L-aspartic acid	12.15	8.98	50°C [68]

glycine	7.60	–	40°C, [59] 0.4M $NaClO_4$

* $\log_{10}$ values in 0.1 $NaClO_4$, except reference [59]

8.3 *Synthetic studies*

In this section we shall concentrate on complexes of chromium(III) with those ligands (mainly amino acids) believed to be involved in GTF. In general it has not been realized that these complexes are related to GTF and hence they have not been tested for GTF behaviour.

The preparation of the tris complexes of chromium(III) with the anions of glycine and alanine has been reported on several occasions.[72-79] The isomeric purity of these complexes was first seriously considered by Gillard *et al.*[72] Red insoluble complexes of L-alanine and glycine were found to be *D-β(fac)* and *β(fac)* isomers respectively and were isomorphous with their cobalt(III) analogues. The preparation of the purple *α(mer)* isomer had been claimed by Israily[77] though later workers[72,78] were unable to repeat this preparation. Recently a novel preparation of the *α(mer)* isomer has been reported[78] and characterization by luminescence spectroscopy suggested as a reliable method of judging isomeric purity. The formation of dihydroxy-bridged dimers is a characteristic feature of chromium(III) chemistry and complexes of the kind $[Cr_2(gly)_4(OH)_2]$ originally discovered by Ley[76] have frequently been synthesized.[72,80,81]

There have been a number of synthetic studies of other chromium(III)/amino acid systems.[82-84] In this series of papers a novel solid state synthetic method was developed. Solid hexaammine chromium(III) nitrate was heated with the amino acid, good yields being obtained by this method. Various basic and other amino acids were studied and in all cases *β-(fac)* isomers were obtained.

The complexes of sulphur containing amino acids have been studied and crystal structures for L-cysteine[32] and D-penicillamine[85] complexes determined. The methionine complex of chromium(III) has also been prepared,[86] the red complex has the formula $[Cr(met)_3]$ and is presumably a *β-(fac)* isomer.

The synthesis of aspartic acid complexes has been reported on several occasions,[87,88] in the latter paper three isomers were isolated. Serine complexes have been prepared.[89] Two isomers of

bis(L-histidinato)chromium(III) have been prepared,[90] together with a μ-hydroxy species. Electronic spectra were interpreted with the aid of angular overlap calculations.

Mixed amino acid complexes have been prepared involving aspartic acid and histidine,[91] structures were assigned by comparing CD and other spectra to the related cobalt(III) complexes. In general amino nitrogens were not found trans to each other. Other relevant complexes which have been prepared include mixed amino acid/nitrilotriacetates,[92] a complex of chromium(III) pentammine and glycine[93] and a series of complexes with pyridine carboxylic acids.[94]

Glutathione complexes of chromium(III) have recently been prepared in our laboratory.[95] In these species the chromium is coordinated by both the glycine residue {N,O} and the sulphur of the cysteine components of glutathione. A bis-glutathione complex and mixed complexes with cysteine, glycine and glutamic acid have been prepared. These complexes are being tested for GTF behaviour.

9. MODE-OF-ACTION OF THE GLUCOSE TOLERANCE FACTOR (GTF)

Mertz has listed[7] the following as possible mechanisms by which GTF might act.

1. Chromium may form a complex with insulin in the blood or pancreas.
2. Chromium might inhibit tissue insulinase.
3. The initial binding of insulin to tissue might be enhanced by chromium(III).
4. Chromium could act as a co-factor for a membrane carrier involved in glucose transport.
5. Chromium could act as a catalyst in the initial reaction between insulin and a specific membrane receptor site(s).

There have been remarkably few studies which provide any evidence as to the mode-of-action of GTF, or even the feasibility of Mertz's suggestions outlined above. In order for GTF to effect glucose metabolism it must undergo some specific interaction with the system responsible for glucose uptake and/or metabolism. *In vivo* and *in vitro* results suggest that the most likely mechanism is direct enhancement of insulin activity. The first two of Mertz's suggestions can hence be considered unlikely.

The suggestion that the binding of insulin to receptors is enhanced by chromium has been studied, effectively testing suggestion five above. The binding of insulin to epididymal tissue was only enhanced by about 20%.[96] The formation of a stable GTF/insulin complex has been demonstrated,[19] acylation of the α and ϵ amino groups of insulin inhibited complex formation. The binding constant was not estimated. The synthetic complex of nicotinic acid and glutathione with chromium(III) prepared by Anderson[33,34] binds very strongly to insulin.

A polarographic study of the interactions between chromium/insulin/mitochondria has been reported.[97] A polarographic wave for insulin was attributed to reduction of the disulphide linkage. In the presence of insulin the polarographic wave for the reduction of chromium(III) (1M KCl, pH 7.4, 10^{-4} M Cr(III) of unspecified source) was shifted, indicating complex formation. Three insulin molecules were associated with each chromium(III) and the apparent instability constant was estimated as $10^{-14.5}$ (presumably an overall constant for dissociation of the tris complex). There were also changes in the polarograms of mitochondria and mitrochondria/insulin mixtures in the presence of chromium(III). Insulin reacts with mitochondria by the formation of sulphydryl-disulphide linkages and this reaction is enhanced by the presence of chromium(III). There are suggestions that insulin reacts with its receptor via sulphide linkages.[98,99] The above work supports the suggestion that a possible role for chromium(III) is to facilitate disulphide bond formation by forming an intermediate ternary complex.

The above studies produce no clear suggestion for the mode-of-action of GTF. Obviously the lack of a detailed knowledge of the molecular structure of the factor hampers such work. Perhaps the most attractive hypothesis is that chromium has its own receptor site and that binding to this site potentiates the activity of insulin at a second site (viz. 4 above).

There are a number of features of chromium(III) chemistry which need to be considered.

1. The interaction appears to be rapid, labile substitution positions might be involved. However as pointed out above the ligands involved in GTF are unlikely to promote this kind of chemistry.
2. Nicotinic acid appears to be a near essential component of GTF; unlike other monocarboxylic acid substituted pyridines, nicotinic acid is not capable of acting as an electron transporting bridging ligand in inner-sphere electron transfer reactions.[100] The nature of the coordination of nicotinate in GTF will be crucial to understanding GTF. In a complex containing N-coordinated nicotinate the carboxylate group could be involved in hydrogen bonding to receptor sites.

3. Sulphur containing amino acids also appear to be required and the mode of co-ordination is unknown. If cysteine were coordinated in glycine like mode there would be a free sulphydryl group available for reaction with either insulin or the receptor. The reactivity of such groups in coordinated cysteine has not been investigated.

4. As a consequence of its high charge, ion-pairing is often significant in the reactions of chromium(III).[101] This seems unlikely to be important in GTF as negatively charged ligands are involved in the complex.

The properties of chromium(III) provide no obvious clues as to why this element has evolved a biochemistry so closely related to glucose tolerance. There must be some, as yet, unelucidated explanation for this specific requirement of higher animals for chromium(III).

10. CONCLUSIONS

Chromium deficiency in man and higher animals results in an impairment of intravenous glucose tolerance and diabetes like symptoms. It seems likely that chromium(III) metabolism is abnormal in certain forms of the diabetic condition. We shall now summarise a number of particularly relevant observations.

In a strain of mice with a genetic form of diabetes, glucose tolerance was restored by dosing with purified GTF. In contrast the administration of "inorganic" chromium was ineffective.[102] This work suggests that the ability to absorb chromium and/or synthesise GTF is responsible for the diabetic condition of these animals.

Tissue chromium levels have been shown to decrease with age.[103] This seems particularly relevant to the pregnancy and senile onset forms of diabetes. The heavy demand placed on the mothers body store of chromium(III) has been demonstrated in the laboratory rat; old breeder rats showed impaired glucose tolerance which could be reversed by dosing with chromium.[104] In contrast a recent study[105] of thirty-six pregnant women (including diabetics) found no evidence for abnormal chromium metabolism in gestational diabetes. Mertz has shown[106] that in pregnant rats GTF may be transported across the placenta.

A very limited number of clinical trials involving diabetics have been reported, the results have been summarized by Anderson[8,107] and others.[7] In several cases a favorable response to chromium(III) administration was observed; at present the results are too limited for any conclusions to be drawn. There seems to be some commercial interest in such therapy, a chromium(III) complex of oxobutanol has been patented[108,109] as a dietary supplement and/or therapeutic agent. Chromium metabolism is often disrupted in diabetics, chromium(III) levels in the urine of diabetics are double those in normal subjects.[110]

In conclusion one important aspect of the biochemistry of chromium is its ability to potentiate glucose tolerance. The mechanism by which glucose tolerance is improved is unknown, but seems likely to involve the potentiation of insulin activity by a chromium(III) complex termed GTF. The structure of the complex active in higher animals is unknown. A complex with remarkable biological activity in both *in vivo* and *in vitro* systems has been isolated from Brewer's yeast. GTF isolated from yeasts often contains nicotinic acid and either glutathione or its constituent amino acids. Both GTF and synthetic analogues of GTF have as yet been poorly characterized and there is scope for much more work. Perhaps the most interesting and reliable observation is that complexes which are effective in potentiating the activity of insulin, in *in vitro* models, contain nicotinic acid.

The coordination chemistry of chromium(III) is of crucial importance in glucose tolerance and possibly diabetes. It is surprising that the complexes involved have not been characterized in the 25 yr or so since they were first suggested to exist. This review does not present a comprehensive survey of the biological literature relating to chromium(III) and glucose tolerance, the interested reader is referred to the detailed and excellent articles by Mertz[7,10] and Anderson.[8,107]

ON THE HYDROLYSIS OF THE TITANIUM(IV) ION IN CHLORIDE MEDIA

LIBERATO CIAVATTA,* DIEGO FERRI and GIUSEPPE RICCIO
Dipartimento di Chimica dell'Università, Via Mezzocannone, 4, 80134 Napoli, Italy

(*Received* 14 *December* 1983; *accepted* 17 *February* 1984)

Abstract—Determinations of the [Ti(IV)]/[Ti(III) ratio in solutions of titanium(IV) chloride equilibrated with $H_2(g)$, at 25°C in 3 M (Na)Cl ionic medium, have indicated the predominance of the $Ti(OH)_2^{2+}$ species in the concentration ranges $0.5 \leq [H^+] \leq 2$ M and $1.5 \times 10^{-3} \leq [Ti(IV)] \leq 0.05$ M. From the equilibrium data the reduction potential has been evaluated

$$Ti(OH)_2^{2+} + 2\,H^+ + e \rightleftharpoons Ti^{3+} + 2H_2O,\ E_{oH} = (7.7 \pm 0.6) \times 10^{-3}\ V.$$

The acidification reactions of $Ti(OH)_2^{2+}$ were also studied in 12 M(Li)Cl medium at 25°C by measuring the redox potential of the Ti(IV)/Ti(III) couple as a function of $[H^+]$. The potentiometric data in the acidity range $0.3 \leq [H^+] \leq 12$ M have been explained by assuming

$$Ti^{4+} + e \rightleftharpoons Ti^{3+},\ E_o = 0.202 \pm 0.002\ V$$

$$Ti^{4+} + H_2O \leftrightharpoons TiOH^{3+} + H^+,\ \log K_{a1} = 0.3 \pm 0.01$$

$$Ti^{4+} + 2H_2O \leftrightharpoons Ti(OH)_2^{2+} + 2H^+,\ \log K_{a1}K_{a2} = 1.38 \pm 0.05.$$

NOTATION

- B total titanium concentration
- B_3 titanium(III) concentration
- B_4 titanium(IV) concentration
- E_0 standard potential of $Ti^{4+} + e \rightleftharpoons Ti^{3+}$
- E_{oH} standard potential of $Ti(OH)_2^{2+} + 2H^+ + e \rightleftharpoons Ti^{3+} + 2H_2O$
- $f(i)$ activity coefficient of the "i" species
- H analytical concentration excess of H^+ assuming as zero level Ti^{4+} and H_2O
- h equilibrium concentration of H^+
- K equilibrium constant for $H^+ + Cl^- \leftrightharpoons HCl$
- K_{an} equilibrium constant for $Ti(OH)_{n-1}^{5-n} + H_2O \rightleftharpoons Ti(OH)_n^{4-n} + H^+$
- $K_{p,q}$ equilibrium constant for reaction (7)
- R B_3/B in solutions equilibrated with hydrogen gas

Concentrations and equilibrium constants are expressed on the molar scale, M, moles/dm^3.

The hydrolysis of the titanium(IV) ion has been studied by a number of investigators but as yet some uncertainties remain on the nature of the protolysis products. Beukenkamp and Herrington,[1] from cation exchange determinations, found that the charge per Ti(IV) atom varies from 1.4 to 1.7 in $HClO_4$ at acidities up to 1.5M. They assumed the equilibrium

$$Ti(OH)_2^{2+} + H_2O \leftrightharpoons Ti(OH)_3^+ + H^+ \qquad (1)$$

with a constant of about $10^{-0.3}$.

Nabivanets,[2] Liberti and Vicedomini,[3] and Magon *et al.*[4] studied the distribution of Ti(IV) to cation exchange resins in the range 0.1–1 M $HClO_4$. On the basis of the distribution decrease with the second power of the acid concentration these authors postulated the presence of $Ti(OH)_2^{2+}$ even though the data are consistent with any doubly charged species as $Ti_2(OH)_6^{2+}$ or $Ti(OH)ClO_4^{2+}$. Nabivanets[2] estimated for equilibrium (1) a constant of $10^{-1.3}$ and also determined that two moles of H^+ are released per mole of Ti(IV) extracted from HCl–$HClO_4$ solutions. Therefore he assumed the presence of $Ti(OH)_2^{2+}$. However his data can be equally well explained by $Ti(OH)Cl^{2+}$ or $TiCl_2^{2+}$ or $Ti(OH)ClO_4^{2+}$.

*Author to whom correspondence should be addressed.

Babko *et al*,[5] and Liberti *et al.*[6] measured the solubility of hydrous TiO_2 in dilute HCl and $HClO_4$, respectively, and interpreted the solubility decrease up to 10^{-2} M H^+ by assuming $Ti(OH)_2^{2+}$. On the other hand Babko *et al.*[5] as well as Nabivanets and Lukachina[7] suggested that the constant solubility, $\sim 10^{-5.5}$ M, in the acidity range from 10^{-7} to 10^{-3} M indicated the formation of $Ti(OH)_4$. From their data Baes and Mesmer[8] estimated for

$$Ti(OH)_2^{2+} + 2H_2O \leftrightharpoons Ti(OH)_4 + 2H^+ \qquad (2)$$

an equilibrium constant of 10^{-5}.

More recently, Einaga,[9] using a glass electrode, has measured at 25°C the hydrogen ion concentration of several titanium(IV) chloride solutions. The [Ti(IV)] ranged from 0.019 to 0.048 molal, the acidity was varied between $10^{-1.1}$ and $10^{-0.7}$ molal and all the solutions were made to contain 2 molal Cl^- by adding NaCl. The accuracy of his measurements was limited by the slow attainment of equilibrium. Einaga explained the data assuming TiO^{2+} as the central group and the reaction

$$8\ TiO^{2+} + 12H_2O \leftrightharpoons (TiO)_8(OH)_{12}^{4+} + 12H^+$$

with a constant (molal scale) of $10^{-1.68}$.

CHOICE OF THE EXPERIMENTAL CONDITIONS AND METHOD OF INVESTIGATION

In this work the redox potential of the Ti(IV)/Ti(III) couple was measured in chloride media of different acidity. The choice of chloride as a solvent salt instead of perchlorate, the favourite of equilibrium analysis chemists for the least complexing tendency of ClO_4^-, was imposed by the appreciable rate at which ClO_4^- is reduced by Ti(III).

Measurements with a glass electrode were not made because at the acidities in question, $h \geq 0.3$ M, the differences $h - H$, even if evaluated from accurate e.m.f. data (0.1 mV), become too uncertain to bear significant information on the nature of the hydrolytic species. At any rate, since the ratio B/H never exceeded 0.05, we could easily find with good approximation expressions $h = h(H, B)$, as shown in the section "Treatment of the data and results".

The interpretation of the potentiometric data is somewhat simplified by the fact that the hydrolysis of the titanium(III) ion, according to Pâris and Gregoire[10] and to Krentzien and Brito,[11] is practically suppressed in our solutions, therefore the $[Ti^{3+}]$ value may always be set equal to B_3.

In the initial stage of the investigation we adopted a 3 M (Na)Cl medium, a level of concentration most often used in studies of the hydrolysis of metal ions.[8] Subsequently, in order to extend the acidity interval, the experiments were carried out in 12 M (Li)Cl. Lithium chloride has a high solubility; additionally its solutions exhibit osmotic coefficients nearly identical to those of HCl.[12] This means that in HCl–LiCl mixtures of constant $[Cl^-]$ the water activity remains essentially unchanged. This is a prerequisite for the constant ionic medium method. The most serious difficulty for the choice of the optimal experimental conditions was represented by the oxidation of the Ti^{3+} ion by water. The reaction is much suppressed by increasing the Cl^- concentration and by decreasing the acidity. It becomes practically negligible at $h < 5$ M in 12 M (Li)Cl. In more acidic solutions the Ti^{3+} oxidation caused drifts in the potentials of platinum electrodes which, however, did not exceed 3×10^{-7} V/s, corresponding to changes in $[Ti^{3+}]$ of about 10^{-9} M/s, in the most unfavourable case; 12 M H^+, 10^{-4} M Ti^{3+}, 2×10^{-3} M Ti(IV). In addition to platinum, which catalyzes the oxidation of Ti^{3+}, gold and mercury electrodes were tested. These did not prove to be inert in our highly complexing media. Therefore the exact B_3 values in the most acidic solutions were determined by analysing samples of the test solution.

On the other hand, the oxidation by water of Ti^{3+} occurs readily in 3 M (Na)Cl media so that rapidly changing potentials were observed with Pt or Hg or Au electrodes. However, good and reproducible determinations could be obtained of B_4/B_3 ratios in titanium solutions equilibrated with hydrogen gas which are equivalent to potentiometric measurements with the Ti(IV)–Ti(III) half-cell. Solutions of Ti(IV) were equilibrated with H_2(g) at 1 atm in presence of finely divided palladium. Then the excess of dissolved H_2 was determined by analysing the Ti(III) content through oxidation with $K_2Cr_2O_7$. In spite of tedious and time-consuming manipulations the "batch" method produces data as accurate as the potentiometric ones provided, as presently, that the B_4/B_3 ratio is not too far from unity.

The test solutions were prepared, just before an experiment initiated, by dilution of stock solutions stored at 4°C. As indicated by the sluggish formation, within a few months, of a precipitate of Ti(IV) hydroxide or oxychloride, the measurements at $h \leq 1$ M were made in supersaturated solutions. Since the amount of solid phase was negligible during the experiment, the results still give a true picture of the equilibria in clear solutions. The coincidence within the limits of experi-

mental error of data obtained by increasing or decreasing B_3 was taken as a criterion for the attainment of real equilibrium in the homogeneous phase.

The potentiometric measurements in 12 M (Li)Cl

Each experiment started by placing a solution of general composition: B M $TiCl_4$, H M HCl, 0.03 M AgCl, $(12 - H - 4B)$ M LiCl, in the cathode compartment of the electrolysis circuit

$$- \quad \text{Pt/TS/12 M LiCl/Ag} \quad + \qquad \text{(C)}$$
$$\text{constant-current supply}$$

and, each ensuing step of electrolysis involved the introduction of a few micromoles of electrons in the test solution, TS, the e.m.f. of cell (R)

$$- \text{RE/TS/Pt} + \qquad \text{(R)}$$

in which

$$\text{RE} = \text{Ag/}10^{-2}\text{M AgCl, 12 M LiCl/12 M LiCl}$$

and

$$\text{TS} = B_4 \text{ M } TiCl_4,\ B_3 \text{ M } TiCl_3,\ 0.03 \text{ M AgCl},\ H \text{ M HCl},\ (12\text{–}H\text{–}4B + B_3)\text{M LiCl},$$

was determined.

The silver(I) in TS served as depolarizer. Silver metal is deposited on the Pt gauze cathode and, due to the appreciable overpotential of the H^+ discharge on silver, no significant amount of current is used to reduce H^+. Silver reacts with Ti(IV) rapidly and quantitatively in solutions where $h < 5$ M and essentially the electrons introduced into TS, except a small amount used to reduce oxidizing impurities, only produce Ti^{3+}. The effect of trace amounts of impurities, mostly oxygen still remaining in TS purged with N_2(g), was accounted for by means of Gran's[13] diagrams, constructed using the data at low levels of B_3. In more acidic solutions the yield of Ti^{3+} decreased with h and was about 90% in 12 M HCl. The actual Ti(III) concentration was ascertained by analysing samples of TS with $K_2Cr_2O_7$.

The e.m.f. of cell (R) can be written at 25°C in V

$$E_R = E_0 + 0.05916 \log \frac{[Ti^{4+}] f(Ti^{4+})}{[Ti^{3+}] f(Ti^{3+})} + E_j - E_{RE} \quad (3)$$

where E_j denotes the liquid junction potential arising at the boundary between TS and 12 M LiCl, and E_{RE} stands for the potential of the reference electrode. The standard states are so defined that f(i)$\rightarrow$1 as the composition of TS tends to 12 M LiCl.

The potential of the reference half-cell, E_{RE}, was determined by measuring the e.m.f. of cell (Q)

$$-\text{RE/}10^{-2}\text{M HCl, 11.99 M LiCl/}H_2\text{(g)/Pt} + \text{(Q)}.$$

In accordance with our definitions, E_Q, the e.m.f. of cell (Q), may be written with good approximation

$$E_Q - 0.05916 \log((10^{-2} - [HCl])/p_{H_2}^{1/2}) = -E_{RE} \quad (4)$$

In eqn (4) $p_{H_2} = p_{atm} - p_{H_2O} - p_{HCl}$. The water vapour pressure was estimated from the osmotic coefficients listed by Robinson and Stokes,[12] while p_{HCl} was obtained by interpolation of data published by Scarano *et al.*[14] The concentration of associated hydrochloric acid was calculated by assuming for $H^+ + Cl^- \rightleftharpoons HCl$ a constant of $10^{-2.32}$. This was deduced as described in "Treatment of the data and results".

In order to determine the liquid junction potential, E_j, and to detect possible changes in E_{RE} the e.m.f. of cell (S)

$$- \text{RE/}10^{-2}\text{M AgCl, } H \text{ M HCl,}$$
$$(12 - H) \text{ M LiCl/Ag} + \qquad \text{(S)}$$

was measured after each series of experiments at the same H level. The e.m.f. of cell (S) is equal to

$$E_S = 0.05916 \log f(Ag^+) + E_j. \quad (5)$$

By subtracting from eqn (3), eqns (4) and (5) and the analytically determined quantity 0.05916 log (B_4/B_3) we may calculate for each point at the same H the function (6)

$$E_0^*(B_4, H) = E_0 + 0.05916 \log \frac{[Ti^{4+}]}{B_4} + 0.05916 \log \frac{f(Ti^{4+})}{f(Ti^{3+}) f(Ag^+)}. \quad (6)$$

The data $E_0^*(B_4, H)$ form the basis of the following calculations. For the correct interpretation of the data some assumptions must be made on the variation of the activity coefficients due to the replacement of Li^+ by H^+. We postulated that no appreciable variation occurs. The validity of this hypothesis was corroborated by confronting the results of the potentiometric work with spectrophotometric measurements in the UV region.

MATERIALS AND ANALYSIS

A series of 0.8 M *titanium(IV) chloride* solutions in 8 M HCl was prepared and analysed as described previously.[15] The solutions were stored at 4°C in a refrigerator in order to freeze reactions leading to precipitation of hydroxides and to minimize HCl losses by volatilization. As periodical analyses indicated, the acid concentration decreased by less than 0.3% in 6 months.

For the determination of the *actual titanium(III) concentration* samples of 10 or 20 cm^3, withdrawn under a nitrogen atmosphere, were added to an excess of deoxygenated $K_2Cr_2O_7$ solution. The oxidation of Ti(III) by Cr(VI) was found to proceed to completion almost instantaneously. The remaining Cr(VI) was treated with NaI and the I_3^- formed was titrated amperometrically with $Na_2S_2O_3$. By this procedure micromolar amounts of I_3^- could be analysed with an uncertainty of $\pm 0.5\%$.

Lithium chloride was made from Li_2CO_3 and HCl Merck of p.a. quality products. First, a 6 M solution was prepared with a small Li_2CO_3 excess. The slightly alkaline solution after boiling was left to stand for a week and then the precipitate of FeOOH and $SiO_2(H_2O)_x$ was filtered off. The acidity was adjusted to 10^{-3} M and the solution was heated to displace CO_2 and to concentrate it further. No Fe(III) and SO_4^{2-} ions could be detected in 14 M stock solutions.

The LiCl concentration was determined by Mohr's method. The low HCl concentration was estimated by coulometric acid-base titrations using a glass electrode as indicator.

Hydrochloric acid p.a. Merck, ~ 38%, was standardized against $KHCO_3$ with an accuracy of 0.1%. The acid concentration was checked periodically to account for losses by volatilization.

Sodium chloride. Baker was dried at 110°C for 2 hr before use.

Silver chloride was precipitated from HCl and $AgNO_3$ p.a. products and was dried at 110°C.

Palladium black, saturated with hydrogen gas, was prepared by cathodic reduction on a large platinum net from $PdCl_2$ in 1 M HCl solution.

Hydrogen as well as *nitrogen*, from commercial cylinders, were passed through activated copper to remove traces of oxygen, then presaturated with the ionic medium and finally led through a sintered glass disc of porosity G4 into the test solution.

EXPERIMENTAL

The e.m.f. measurements were performed at 25.00 ± 0.05°C in a paraffin oil thermostat. The cell arrangement was similar to that described by Forsling *et al.*[16] The Ag, AgCl electrodes, prepared according to Brown,[17] were soaked in 12 M LiCl for 2 days before use. Platinum gauze electrodes were boiled in 1:1 HNO_3 and ignited in alcohol flame. When two Pt electrodes were immersed in the same test solution, they agreed always to within 2×10^{-5} V. For the measurements with cell(Q) palladium coated Pt electrodes were employed. The e.m.f. values of cells(R), (Q) and (S) were measured with a precision of 10^{-5} V using a Dynamco Ltd 2022 digital voltmeter.

Prior to each experiment with cell(R) a stream of purified and presaturated nitrogen gas was led for 1/2 hr through the test solution to purge it of dissolved oxygen. By prolonged scrabbling of the test solutions we have not been able to avoid losses of HCl even when three or four wash bottles had been used. This effect was more pronounced at low acidities when the high viscosity of the solutions makes the attainment of the gas–liquid equilibrium slower. Throughout the measurements the solution was protected by atmospheric contamination by keeping the TS in a six-necked vessel fitted with high vacuum ground glass stoppers. The slight overpressure which develops by temporary temperature rise during electrolysis may cause extrusion of HCl gas if the vessel is not hermetically closed. The small decrease of H, for the removal of HCl by the H_2 flow during the measurements with cell(Q), was accounted for by analysis of the solutions soon after the E_Q value was recorded. The coulometric circuit(C) consisted of a 4 cm^2 platinum net which served as the cathode and a platinum gauze coated with a thick layer of silver which formed the anode. The bridge solution and the anode compartment were placed in a half-cell vessel of the "Wilhelm" type.[16] As the constant-current source a Metrohm E 211 A coulometer was employed. The accuracy and constancy of the current was checked by passing it through a standard resistor and by measuring the resulting potential. The current levels between 0.3 and 3 mA were found to be constant and accurate to within $\pm 0.05\%$. The electrolysis was carried out in steps of no more than 10 μF to minimize temperature increase in the system.

Two identical platinum electrodes, 1 cm long wires, immersed in solution stirred at a constant speed, were employed for the amperometric detection of iodine. The electrodes were connected through a Keithley 168 Autoranging D.D.M. microammeter at a sensitivity of 10^{-7} A, to a source of 0.1 V.

The spectrophotometric measurements were carried out at 25 ± 1°C with an Optika CF4 spectrophotometer using quartz cuvettes. The reference consisted of HCl–LiCl solutions of concentrations

identical to those in the test solutions. The whole absorption spectrum between 200 and 350 nm was recorded but only the absorbancies at 208 nm were used for the calculations. The estimated error in the absorbance is $\pm 5 \times 10^{-3}$.

TREATMENT OF THE DATA AND RESULTS

The excess solubility of $H_2(g)$ *in* 3 M (Na)Cl

In Table 1 the determinations of the ratios [Ti(IV)]/[Ti(III)] in solutions equilibrated with hydrogen gas are summarized in the form of $R(B, H, p_{H_2})$ data.

By assuming that we may set activities equal to molar concentrations[18] and that Ti(IV) species of the most general composition, $Ti_p(OH)_q^{4p-q}$, are present, the equilibrium may be represented by

$$Ti_p(OH)_p^{4p-q} + (p/2)H_2(g) + (q-p)H^+ \quad (7)$$

with equilibrium constant

$$K_{p,q} = [Ti^{3+}]^p[Ti_p(OH)_q^{4p-q}]^{-1} h^{p-q} p_{H_2}^{-p/2}$$

thus

$$R = \frac{B_3}{B_3 + B_4} = \frac{1}{1 + \sum pK_{p,q}^{-1} B_3^{p-1} h^{p-q} p_{H_2}^{-p/2}}. \quad (8)$$

Inspection of Table 1 indicates that, at constant p_{H_2} and h; $\sim H$, R is independent of $B_3(= BR)$, hence, according to (8), $p = 1$. To find q a single species was assumed to predominate and the quantities

$$h = H + qB - (q-1)BR \quad (9)$$

and

$$\log K_{1,q} = \log \frac{R}{1-R} - (q-1)\log h - \frac{1}{2}\log p_{H_2} \quad (10)$$

were calculated for each point with a series of q; 0, 1, 2, 3 and 4. Table 1 shows that no systematic trend of $\log K_{1,q}$ was found with $q = 2$, whereas the deviations for $q \neq 2$ by far exceeded the experimental error. We may thus conclude that in the experimental conditions of Table 1 the predominating Ti(IV) species is the dihydroxotitanium(IV) ion, $Ti(OH)_2^{2+}$.

From the average value of $\log K_{1,2} = 0.13 \pm 0.01$ we calculated for the reduction half-cell

$$Ti(OH)_2^{2+} + 2H^+ + e \rightleftharpoons Ti^{3+} + 2H_2O$$

the standard potential

$$E_{oH} = (7.7 \pm 0.6) \times 10^{-3}\ V.$$

The protolytic equilibria in 12 M (Li)Cl

The $E_0^*(B_4, H)$ data, which form the basis of the following calculations, are given in Table 2.

At each of the H values studied, the E_0^* function proved to remain constant as the Ti(IV) concentration was stepwise decreased within the limits indicated in Table 2. This observation indicates that only mononuclear hydrolysis products are formed. Hence, taking into account the results in 3 M (Na)Cl medium and assuming the constancy of the activity coefficients, we can write from eqn (6)

$$E_0^* = E_0 - 0.05916 \log (1 + K_{a1}h^{-1} + K_{a1}K_{a2}h^{-2}). \quad (11)$$

To evaluate E_0 and the K_{an} values the experimental data recalculated in the form $E_0^*(\log (H - [HCl] + 2B)$ were compared with the normalized[19] form of (11), $Y(\log u)$, where

$$Y = E_0^* - E_0 = -0.05916 \log(1 + Lu + u^2) \quad (12)$$

2.02	12.10	193.6±0.5	1-2

$$\log u = \frac{1}{2}\log K_{a1}K_{a2} - \log h \qquad (13)$$

$$\log L = \frac{1}{2}(\log K_{a1} - \log K_{a2}). \qquad (14)$$

For the construction of the experimental plot we introduced the approximation

$$h \sim H - [\mathrm{HCl}] + 2B \qquad (15)$$

which provides reasonable values for h. In fact, since B never exceeded 1% of H, h must be very close to $H - [\mathrm{HCl}]$. The inequality $h > H - [\mathrm{HCl}]$ yields for h the lower limit, while, in accordance with the findings in 3 M (Na)Cl, the upper limit is represented by $h \leq H - [\mathrm{HCl}] + 2B$. We evaluate from the data of Table 2 that the higher and lower h values differ by no more than 0.005 log units. This uncertainty is obviously negligible with respect to other sources of experimental error encountered in the present study.

The extent of association of HCl in LiCl–HCl mixtures was calculated by means of

$$\log K = -2.32 - 0.019\,H. \qquad (16)$$

Equation (16) presumes that, in LiCl–HCl mixtures of 12 M Cl^-, log K varies linearly with H between the values −2.32, valid in 12 M LiCl, and −2.55, relevant to 12 M HCl. The constants were deduced from HCl vapour pressure data, following the approach suggested by Robinson and Bates.[20] For the calculations we employed; density of 12 M LiCl = 1.2543 g/cm^3 (Ref. 21), density of 12 M HCl = 1.179 g/cm^3 (Ref. 22), p_{HCl} in 12 M HCl = 206 torr, value interpolated on the linear plot log p_{HCl} vs log (molality) constructed from data tabulated in International Critical Tables,[23] p_{HCl} in 12 M LiCl = 29.42 × total HCl concentration, torr/M, as evaluated from the study by Scarano *et al.*[14]

An acceptable agreement, within the limits of experimental error, could be found throughout the L range between 0.2 and 0.6, however $L = 0.4$ yielded the best fit. By reading off the differences $E_0^* - Y$ and log $(H - [\mathrm{HCl}] + 2B) - \log u$ in the position of the closest coincidence we computed in accordance with the definitions (12–14)

$$E_0 = 0.202 \pm 0.002\ \mathrm{V} \qquad (17)$$

$$\log K_{a1} = 0.3 \pm 0.1 \qquad (18)$$

$$\log K_{a1}K_{a2} = 1.38 \pm 0.05 \qquad (15)$$

The fit between the model curve and the experimental data is illustrated in Fig. 1.

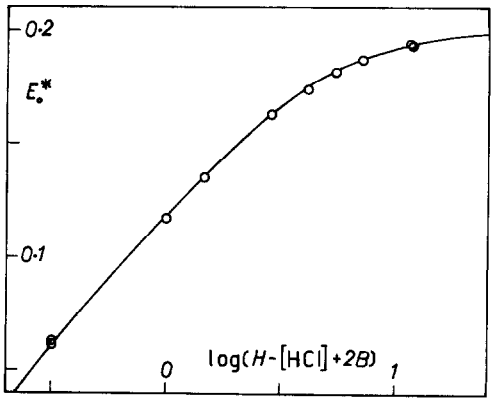

Fig. 1. The conditional standard potential, E_0^*, as a function of log $(H - [\mathrm{HCl}] + 2B)$. The curve has been calculated with the constants given in eqns (17–19).

The calculations hitherto presented are based on the assumption that the activity coefficient quotient in (6) and those included in the K_{an} expressions remain constant when the medium ion Li^+ is substituted by H^+. To get an idea of the plausibility of this hypothesis, the variations with H of the absorbance at 208 nm were interpreted in terms of the K_{an} given above. The measurements of ϵ_M, the absorbance per unit path length (cm) and unit concentration (M), were combined with the analytical data, H and $B = B_4$, and the K_{an} values to construct the function

$$F = \log \epsilon_M + \log (1 + K_{a1}(H - [\mathrm{HCl}] + 2B)^{-1} + k_{a1}K_{a2}(H - [\mathrm{HCl}] + 2B)^{-2}). \qquad (20)$$

Then the graph $F(\log (H - [\mathrm{HCl}] + 2B))$ was confronted with the family of model functions, ϕ (log v), where

$$\phi = F - \log \epsilon(\mathrm{Ti}^{4+}) = \log (1 + \rho v + v^2)$$

$$\log v^2 = \log K_{a1}K_{a2} - 2\log h + \log \epsilon(\mathrm{Ti(OH)_2^{2+}}) - \log \epsilon(\mathrm{Ti}^{4+})$$

$$\log \rho^2 = \log (K_{a1}/K_{a2}) + 2\log \epsilon(\mathrm{TiOH}^{3+}) - \log (\epsilon(\mathrm{Ti}^{4+})\epsilon(\mathrm{Ti(OH)_2}^{2+})).$$

The best agreement, as illustrated in Fig. 2, was found with $\rho = 0.375$. We also derived by translation of the coordinates the values of the molar absorptivities; $\epsilon(\mathrm{Ti}^{4+}) = (5.75 \pm 0.56) \times 10^3$, $\epsilon(\mathrm{TiOH}^{3+}) = (4 \pm 2) \times 10^3$ and $\epsilon(\mathrm{Ti(OH)_2}^{2+}) = (3.2 \pm 0.1) \times 10^3$.

We may thus conclude that the spectrophotometric measurements are satisfactorily explained by assuming the magnitude of K_{a1} and K_{a2} given in (18) and (19) indicating that the activity coefficient

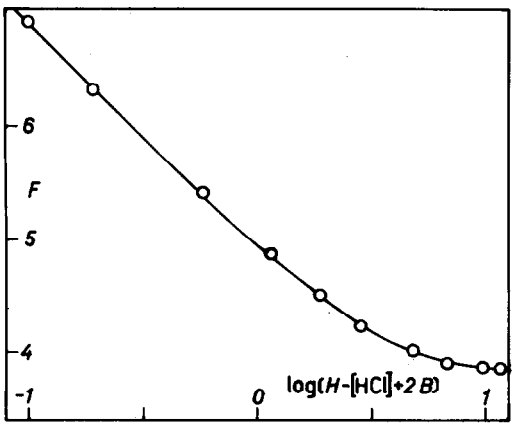

Fig. 2. Spectrophotometric measurements at 208 nm. F, eqn (20), as a function of log $(H - [HCl] + 2B)$. The curve has been calculated with the K_{an} values of eqns (18) and (19) and with the molar absorptivities given in the text.

quotients remain approximately constant when Li^+ is replaced by H^+.

DISCUSSION

We may regard as the most important result of this work the conclusion that in chloride solutions of $h \geq 0.3$ M the Ti^{4+}, $Ti(OH)^{3+}$ and $Ti(OH)_2^{2+}$ species are formed in detectable amounts. The species may contain a number of water molecules and chloride ions which, however, cannot be deduced from equilibrium analysis methods applied in a constant ionic medium.

Evidence for $TiCl_6^{2-}$ and for $TiO_2Cl_4^{4-}$ in concentrated, ≥ 12 M, hydrochloric acid solutions has been obtained from Raman studies. Rumpf[24] assigned three frequences to $TiCl_6^{2-}$. However, Davies and Long[25] have recently reinvestigated the spectra of solutions of molar $Cl^-/Ti(IV)$ ratios 7.3 and 10.6 and have found four reasonably strong lines instead of three, as expected for $TiCl_6^{2-}$ on the basis of octahedral symmetry. These authors in addition to or instead of $TiCl_6^{2-}$ suggested an oxyhalide complex with a highly symmetric structure, as *trans*-$TiO_2Cl_4^{4-}$, on the basis of the relatively low number of Raman lines.

By assuming that the constants in eqns (18) and (19) are valid under the experimental conditions of Davies and Long, ~ 11 M H^+ and ~ 1.6 ÷ 2.7 M Ti(IV), almost 75% of the metal is present as Ti^{4+}, i.e. $TiCl_6^{2-}$, while the remaining 25% is in the form of $Ti(OH)^{3+}$ and $Ti(OH)_2^{2+}$. In reality the *trans*-$TiO_2Cl_4^{4-}$ species suggested by Davies and Long is a mixture of $Ti(OH)^{3+}$ and $Ti(OH)_2^{2+}$ which in a less schematic fashion may be written, respectively, $Ti(OH)(H_2O)Cl_4^-$ and $Ti(OH)_2Cl_4^{2-}$. We may thus infer that the titanium species present in 12 M Cl^- solutions are anionic chloride complexes.

The last conclusion seems in contrast with that of a previous work[15] concerning the investigation of Ti(IV)-F^- complexes in 3 M (Na)Cl media. Then the presence of chloride complexes of Ti(IV) was excluded from the small influence on the equilibrium constants caused by the replacement of Cl^- with ClO_4^-. Evidently, as the fluoride[15] also the chloride complex formation is accomplished within a narrow free-ligand concentration leaving small room for intermediate steps. A magnitude of 10^{-3} for the constant of $Ti(OH)_2^{2+} + 4Cl^- \leftrightharpoons Ti(OH)_2Cl_4^{2-}$ would suffice to have only 7% of Ti(IV) in the form of $Ti(OH)_2Cl_4^{2-}$ at 3 M Cl^-, whereas practically all the metal, 95%, complexed in 12 M Cl^-.

(*Received*: 25 *July* 1983; *accepted after revision* 17 *February* 1984)

Abstract—Some hitherto unknown complexes of thiosemicarbazide (Htsc) and antimony(III) halides have been synthesized in 1,4-dioxane. The elemental analyses have indicated that these compounds are of the type $Sb(CH_5N_3S)Cl_3$ and $Sb(CH_5N_3S)X_3.C_4H_8O_2$, where X = Br or I. The electronic and vibration spectral analyses have shown that Htsc acts as a bidentate ligand in these complexes, linking through sulphur and "the hydrazine terminal nitrogen" to Sb(III).

Only a few papers have been published on the subject of the synthesis and structure of thiosemicarbazide (Htsc) complexes and an examination of their optical and magnetic properties, and most of them describe the complexes of the transition metal ions.[1–3] Crystallographic studies[1] have shown that Htsc acts as a bidentate ligand with metal ions such as: Cu(II), Ni(II), Co(II), Zn(II) and Fe(III) to form various complexes. Htsc is in the *cis* configuration in such complexes[4] and forms a stable pentagonal chelate ring. In Ag(I) and Hg(II) complexes, e.g. $Ag(Htsc)Cl$,[5,1] $Hg(Htsc)_2Cl_2$ and $Hg(Htsc)_2Br_2$[6] Htsc acts as a monodentate ligand in the *trans* configuration, i.e. the same as the free Htsc molecule. As for the Htsc complexes of the metal ions of the main groups of periodic system, only the complex of Bi(III) is known. This complex $(BiCl_3)_3.4Htsc$ was synthesized by Battaglia *et al.* and the authors have also studied its structure. They showed that it contains an unusual $[Bi_4Cl_{10}(Htsc)_6]^{2+}$ cation.

In the present work are presented the results of the studies of Htsc complexes of Sb(III) as the representative of the main group V of the periodic system. It is well known that Sb(III) ions hydrolize strongly in aqueous solution[8] and that, on the other hand, thiosemicarbazide undergoes protolysis in a strongly acid medium.[9] Because these two processes interfere with complex formation in aqueous solution, we undertook an attempt to synthesize some new Sb(III) complexes of Htsc in a non-aqueous medium.

EXPERIMENTAL

The following chemicals were used: Htsc (p.a.) and $SbCl_3$ (p.a.), both produced by Reachim; $SbBr_3$ (p.a.), produced by Ferak–Berlin; SbI_3, prepared according to[10] and recrystallized from a CCl_4 solution; 1,4–dioxane ($C_4H_8O_2$), purified free from peroxides[11] and distilled before use, and methanol (p.a.), both produced by POCh – Gliwice (Poland).

Electronic spectra were obtained on spectrophotometer Specord, Carl Zeiss Jena in 1 cm quartz cells. IR spectra were obtained on spectrophotometer Specord IR-71, Carl Zeiss Jena, using KBr tablets.

Preparation of $Sb(CH_5N_3S)Cl_3$

0.0025 mole (0.57 g) of $SbCl_3$ was dissolved in 25 cm^3 of 1,4-dioxane. 0.005 mole of Htsc dissolved in 50 cm^3 of 1,4-dioxane was added to the warm solution. The mixture was heated to 50°C under a reflux condenser. The pale yellow solution was left to cool. A white precipitate was obtained which was filtered off, washed with 1,4-dioxane and air-dried first and then dried over P_2O_5 under vacuum (0.79 g of precipitate was obtained; *ca.* 100% yield).

*Author to whom correspondence should be addresesed.

An analogous compound was obtained when methylene chloride with a 5% addition of ethyl alcohol was used as the solvent, but because of the low solubility of Htsc in it, a solution of 0.0025 mole (0.23 g) of Htsc in 200 cm^3 of the solvent was used.

Preparation of $Sb(CH_5N_3S)Br_3.C_4H_8O_2$ *and* $Sb(CH_5N_3S)I_3.C_4H_8O_2$

0.01 mole of SbX_3 (X = Br, I) was dissolved in 100 cm^3 of 1,4-dioxane and simultaneously gently heated. When hot, this solution was added to the previously prepared solution of 0.02 mole (1.8 g) of Htsc in 200 cm^3 of dioxane. The mixture was kept at 50°C for 1 hr and then left at room temperature to crystallize. After 48 hr the precipitate was filtered off, washed by 1,4-dioxane and air-dried first and then dried over P_2O_5 under vacuum. The yield was 95% for $SbBr_3$ and 97% for SbI_3.

RESULTS AND DISCUSSION

Composition and properties of the complexes

In Table 1 there are given the physical properties and elemental analyses of the prepared complexes.

Electronic spectra

The characteristic absorption bands of these complexes in methanol solutions are listed in Table 2. These data indicate that the short-wave band at 204 nm of the ligand Htsc does not, in general, undergo any change when the ligand is bonded to SbX_3, and that the intensity of this band increases as X changes from Cl to I. This region comprises also the characteristic bands of the SbX_3 solutions. Interference of these bands with the absorption band of the ligand may be the reason for the increase in absorption at 204 nm. The other band of thiosemicarbazide at 241 nm undergoes a "blue shift" on complexing in the Cl or Br complexes, but it cannot be observed when X = I because of the intense band due to SbI_3. The intensity decreases on passing from the ligand to the chloro-complex, then increases with the bromo-derivative. Dioxane present in two of the complexes does not absorb in this region.

In the longer wave region a new band of variable intensity occurs at 267 nm, which is not observed in the Htsc spectrum nor in the spectra of the solutions of SbX_3. Because of its position in the longer wave region than the intramolecular Htsc bands and because of its high intensity observed for all the complexes, the new band formed at 267 nm can be attributed to the charge-transfer transition L→M. The curves labelled "mixtures" in Figs. 1(4), 2(4) and 3(4) were obtained after mixing a solution of SbX_3 with solutions of Htsc, and the curves of the complexes (Figs. 1(3), 2(3) and 3(3)) were obtained after dissolving the previously prepared precipitates.

Methanol solutions of the discussed complexes are not stable. After 48 hr there began to precipitate orange deposits of Sb_2S_3 in the solutions if the concentration is $\sim 1.10^{-3}$ mole/dm^3.

IR spectra

Characteristic absorption frequencies of Htsc and its complexes of Sb(III) halides are presented in Table 3. Assignment of the bands was based on

the works of Mashima[12] and Adejumobi.[13] In the NH_2 stretching vibration region of the ligand only irregular and not so characteristic changes were observed in the presence of SbX_3. Moreover, CH vibrations are observed in this region.

The $-NH_2$ bending vibrations region (1640 and 1620 cm^{-1} for Htsc), show practically, no change in the complex if its position and intensity are regarded. In this region (1500–1300 cm^{-1}) in the spectrum of Htsc there are observed two characteristic frequencies, which have been attributed to a composite $\nu_{(CN)} + \nu_{(C=S)} + \nu_{(NH_2)}$ vibration at 1480 and 1315 cm^{-1}. When the complex is formed, these bands undergo a 40 cm^{-1} shift to the lower frequencies (the band at 1480 cm^{-1}) and a 70 cm^{-1} shift to the higher frequencies. Similar effects were observed in the complexes: $Ni(Htsc)_2(NO_3)_2$, $Cu(Htsc)_2(NO_3)_2$ and $Zn(Htsc)Cl_2$,[13] in which Htsc

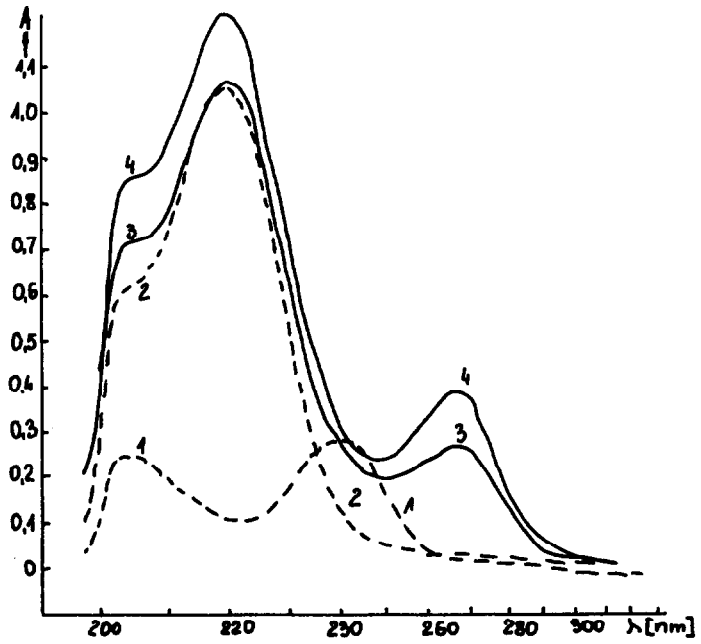

Fig. 3. Electronic spectra in methanol solutions. (1) $2.5.10^{-5}$ mole/dm^3 Htsc. (2) $2.5.10^{-5}$ mole/dm^3 SbI_3. (3) $2.5.10^{-5}$ mole/dm^3 $Sb(Htsc)I_3.C_4H_8O_2$. (4) Mixture: $2.5.10^{-5}$ mole/dm^3 Htsc + $2.5.10^{-5}$ mole/dm^3 SbI_3.

acts as a bidentate ligand, linking through sulphur and the nitrogen atom to the metal ion. Contrary to this, in $HgCl_2(Htsc)_2$ and $HgBr_2(Htsc)_2$ complexes, in which only linking through the sulphur atom occurs,[14] no significant changes in the bands at 1480 and 1315 cm^{-1} were observed.

The two intense bands at 1000 and 800 cm^{-1} in the Htsc spectrum (the second one is attributed mainly to C=S stretching) undergo significant changes in complexes of Sb(III)halides. The 1125–680 cm^{-1} region of $Sb(Htsc)Cl_3$ complexes is almost "blank" and there occurs only a very weak band at 1000 cm^{-1}. Shift of the band at 800 down to 680 cm^{-1} with a considerable decrease in its intensity confirms that the linking occurs through sulphur and the hydrazine nitrogen atom. In the case of complexes in which there is linking via sulphur only, the $\nu_{(C-S)}$ vibration at 800 cm^{-1} is reduced by about 30 cm^{-1}.[6] In the case of Htsc complexes of $SbBr_3$ and SbI_3 there appear sharp and quite intense bands at 860, 890, 1080 and 1040 cm^{-1}. They are the result of the coordination

(*Received* 8 *August* 1983; *accepted after revision* 17 *February* 1984)

Abstract—It has been established that the reaction of metallocyclopentadienyl mercurials with an excess of elemental lanthanides Ln(Ln = Sm, Eu, Yb) in tetrahydrofuran yields substituted cyclopentadienyl derivatives of the metals.

Among the first reported organic derivatives of divalent lanthanides were the bis-cyclopentadienyl derivatives (Cp_2Ln; Ln = Sm, Eu, Yb),[1–3] as well as aryl and alkyl derivatives of the type RLnI(R = ar., alk.; Ln = Sm, Eu, Yb)[4].

Previously, to synthesize divalent cyclopentadienyl derivatives of samarium, europium and ytterbium, we resorted to the following reaction.[5]

$$(C_5H_5)_2Hg + m\,Ln/Hg \longrightarrow (C_5H_5)_2Ln\cdot(THF)_n$$

Ln = Sm, Eu, Yb; $m = 4(5)$; $n = 1$–2.

EXPERIMENTAL

Literature methods were used to prepare $(C_5H_5FeC_5H_4)_2Hg$[6] (1) and $[(OC)_3MnC_5H_4]_2Hg$[7](5). Other chemicals were purchased.

All solvents were dried over $LiAlH_4$ and under an atmosphere of nitrogen prior to use. All reactions were carried out at room temperature in purified solvents under an atmosphere of nitrogen unless it is stated otherwise.

^{1}H NMR spectra were recorded on Bruker WP-200 SY(200.13 MHz) spectrometers and were referenced to internal TMS in C_4D_8O. The IR spectra for (2)–(4) and (6)–(8) were measured on a Perkin–Elmer 580 spectrometer in a CaF_2 cell. The X-Ray fluorescence analyses were made on a VRA-2 spectrometer on the complexes in the form of a tablet.

SYNTHESIS OF BIS-FERROCENYL (LANTHANIDE) DERIVATIVES

Bis-ferrocenyl samarium (2). Addition of (0.75 g, 5 mmol) elemental samarium as powder to solution of (1) (0.57 g, 1 mmol) in 50 cm^3 THF. The resulting red solution was stirred at room temperature for 120 hr, filtered (canulla), and THF evaporated to dryness under vacuum. The oily residue was washed with C_6H_6(3 × 10 cm^3) and then extracted with tetrahydrofuran (25 cm^3) filtered, concentrated to *ca.* 10 cm^3 and cooled to −13°C to give deep orange crystals. Yield, 0.06 g, 12%; m.p. 340° (dec.). ^{1}H NMR: $\delta(FeC_5H_5)$:4.280 ppm, $\delta(FeC_5H_4)$:4.305 ppm. IR (Nujol mull)cm^{-1}: 405 m, 478 m, 498 m, 592 vw, 614 w, 722 vw, 798 s, 815 s, 838 vw, 877 m, 890 vw, 995s, 1015s, 1028s, 1064s, 1095m, 1100s, 1141s, 1154s, 1185w, 1219vw. 1250s, 1300 m, 1350w, 1366m, 1375m, 1405m. 1460s, 1515w, 1585vw, 2680vw, 2720s, 2850s, 2920s, 3064m, 3090m.

Similarly, bis-ferrocenyl europium(3) and bis-ferrocenyl ytterbium (4) from (1) and elemental europium(ytterbium).: (3) – ^{1}H NMR: $\delta(FeC_5H_5)$: 4.268 ppm, $\delta(FeC_5H_4)$: 4.318 ppm.; IR(Nujul mull)cm^{-1}: 408m, 475m, 488w, 592w, 610w, 718vw, 792s, 815s, 830w, 855vw, 880m, 890w, 998s, 1010s, 1042m, 1090m, 1105s, 1140s, 1155s, 1194w, 1220vw, 1250s, 1304s, 2682vw, 2720s, 2850s, 2918s, 2922vw, 3062m, 3082m.

(4)-^{1}H NMR: $\delta(FeC_5H_5)$: 4.264 ppm, $\delta(FeC_5H_4)$: 4.151 and 4.458 ppm ($H_{\alpha,\beta}$). IR(Nujol mull)cm^{-1}: 402m, 478m, 590vw, 515w, 725vw, 795s, 815s, 836s, 846w, 880m, 892vw, 995m, 1020s, 1030s, 1040m, 1092m, 1100s, 1140s, 1154s, 1585w, 2682vw, 2720s, 2850s, 2920s, 3060m, 3085m.

SYNTHESIS OF BIS-CYCLOPENTADIENYLMANGANESETRICARBONYL (LANTHANIDE) DERIVATIVES

Bis-cyclopentadienylmanganesetricarbonyl samarium-tetrahydrofuranate (6). Addition of (0.75 g, 5 mmol) elemental samarium as powder to a solution of (5) (0.6 g, 1 mmol) in 25 cm^3 THF. The reaction mixture was stirred at room temperature for 5 hr. After the reaction stopped the yellow solution was decanted and concentrated to *ca.* 5 cm^3 and addition 50 cm^3 *n*-hexane to solution and cooled to −13°C, to give yellow crystals. Yield, 0.46 g, 74%; m.p. 120° (dec). ^{1}H NMR: $\delta(MnC_5H_4)$: 5.185 ppm. IR(Nujol mull)cm^{-1}: ν(C≡O): 1720w, 1780m, 1918s, 2015s; (THF): 1724w, 1768m, 1925s, 2010s.

Similarly, bis-cyclopentadienylmanganesetricarbonyl europium-bis-tetrahydrofuranate(7) and bis-cyclopentadienylmanganese ytterbiumtetrahydrofuranate(8) from (5) elemental europium-(ytterbium). (7)-^{1}H NMR: $\delta(MnC_5H_4)$: 5.208 ppm, IR(THF)cm^{-1}: ν(C≡O): 1724w, 1772m, 1925s, 2012s. (8)-^{1}H NMR: $\delta(MnC_5H_4)$: 5.226 and 4.916 ppm ($H_{\alpha,\beta}$). IR(THF) cm^{-1}: ν(C≡O): 1740w, 1790m, 1942s, 2025s.

RESULTS AND DISCUSSION

Carrying on with the research in this field, the reaction has been extended to π-cyclopentadienyl organometallic derivatives of mercury which have been examined using, by way of example, the reaction between bis-ferrocenyl mercury and bis-cyclopentadienylmanganesetricarbonyl mercury with samarium, europium and ytterbium. It has turned out that bis-ferrocenyl mercury (1) reacts with elemental and amalgamated lanthanides in THF very slowly:

$$\underset{(1)}{[(C_5H_5)Fe(C_5H_4)]_2Hg} + m\,Ln/Hg \longrightarrow \underset{(2)\text{–}(4)}{Ln[(H_4C_5)Fe(C_5H_5)]_2}$$

Ln = Sm(2), Eu(3), Yb(4); m = 4(5).

Moreover, a prolonged heating or boiling of the reaction mixture produced a sparingly soluble compound consisting of Fe, Hg and corresponding lanthanide which were identified by X-ray fluorescence spectroscopy.

However, at room temperature the reaction between bis-cyclopentadienylmanganesetricarbonyl mercury (5) and elemental lanthanides in THF proceeds with, the formation in high yield of the divalent derivatives:

$$\underset{(5)}{[(OC)_3Mn(C_5H_4)]_2Hg} + mLn \longrightarrow \underset{(6)\text{–}(8)}{Ln[(H_4C_5)Mn(CO)_3]]_2\cdot(THF)_n}$$

Ln = Sm(6), Eu(7), Yb(8); m = 4(5); n = 1–2.

Tables 1 and 2 contain the products of reactions.

Likewise, as this was mentioned in the literature,[4,8] the iodides of ferrocene and cyclopentadienylmanganesetricarbonyls react with Sm, Eu and Yb forming divalent derivatives of ferrocene and cyclopentadienylmanganesetricarbonyls of the

The yield of ferrocene (cyclopentadienylmanganesetricarbonyl) lanthanides was determined in terms of that of the trimethylsilyl (acyl, benzoyl) derivatives of ferrocene and cyclopentadienylmanganesetricarbonyls. The structure of compounds obtained has been proved by the data acquired with the aid of elemental analysis (Table 2), IR and PMR spectroscopy (shown in the Experimental).

Cu(II) COMPLEXES OF N-PROPYL-2-PICOLINAMINE N-OXIDE

GÖZEN ERTEM† and DOUGLAS X. WEST*
Department of Chemistry, Illinois State University, Normal, IL 61761, U.S.A.

(*Received* 7 *December* 1983; *accepted* 17 *February* 1984)

Abstract—Cu(II) complexes have been prepared with N-propyl-2-picolinamine N-oxide (PA) employing the perchlorate, tetrafluoroborate, nitrate, chloride and bromide salts. The following unique solids have been isolated and characterized: $Cu(PA)_2X_2$ ($X = ClO_4^-$, BF_4^- and NO_3^-) and $Cu(PA)X_2$ ($X = Cl^-$, Br^-). Characterization has been accomplished primarily by IR, electronic and ESR measurements of the solid state since considerable alteration of the complexes occurs on dissolution. PA bonds as a bidentate ligand via its N-oxide oxygen and amine nitrogen in all of the complexes. Anion coordination occurs in the halogen complexes and the nitrate ions appear to be bound to Cu(II) as monodentate ligands in $Cu(PA)_2(NO_3)_2$. In addition, there appears to be a rhombic distortion of the CuO_2N_2 chromophore of the perchlorate and tetrafluoroborate solids which is probably due to the steric requirements of the propyl substituents.

A study of the Cu(II) complexes of N-alkyl-[1] and N,N-dialkyl-2-picolinamine N-oxides[2] using the percholate, tetrafluoroborate, nitrate, chloride and bromide salts as starting materials has been carried out in our laboratories. To date we have reported on the N-methyl, N-ethyl, N-isopropyl and N-tert-butyl- complexes among the N-alkyl derivatives (MA, EA, IPA and TBA, respectively). In addition, a parallel study of the Cu(II) complexes of 2-alkyl- and 2-dialkylaminopyridine N-oxides[3] is in progress. Consequently, we are able to compare the potential 5- and 6-membered bidentate rings (i.e. N-oxide oxygen and amine nitrogen functioning as donor atoms) of the two series as well as observe any steric effects caused by increasing the size of the alkyl substituent(s) bonded to the amine nitrogen. In this latter series we noticed several differences between the complexes formed with the propyl derivative compared to the isopropyl derivative.[3] Therefore, we now report the preparation and characterization of five Cu(II) complexes of the title ligand as well as a comparison of the spectral properties to those of the previously isolated Cu(II) complexes of both series of ligands.

EXPERIMENTAL

N-propyl-2-picolinamine N-oxide(PA) was prepared in the same manner as the previous members of this series.[1] The Cu(II) complexes were also prepared as described previously and the instrumentation employed has been described.[1,4]

RESULTS AND DISCUSSION

The compounds isolated in this study are shown in Table 1. Compounds of identical stoichiometry have been isolated with each of the other N-alkyl-2-picolinamine N-oxides.[1] The colors of the solids isolated here are identical to those isolated with EA, but are not similar to IPA since its nitrate, chloride and bromide solids were blue, bright green and dull olive, respectively.[1] Like the other series[1] the perchlorate and tetrafluoroborate solids yield 1:2 electrolytes, the nitrate a 1:1 electrolyte and the halide complexes both are non-electrolytes.[5] Therefore, the two halide compounds might again be expected to be 4-coordinate with the two halogen atoms and a bidentate PA ligand bonding to Cu(II). The perchlorate and tetrafluoroborate solids can probably be considered planar with small interaction between the Cu(II) and the polyatomic anion and similar to the $Cu(MA)_2(ClO_4)_2$. Pavkovic *et al.*[6] have determined the crystal structure of this complex. For the nitrate complex to be a 1:1 electrolyte in solution either there is one coordinated nitrate and one ionic nitrate or two

weakly coordinated nitrates with one dissociated in solution while the other remains coordinated, or associated electrostatically to the Cu(II) center. Our spectral studies of the previous members of the series[1] suggested the latter to be the case.

Assignments of the important IR bands which aid in the understanding of the Cu(II)-ligand bonding are presented in Table 2. The ν_{NH} of PA is found at somewhat higher energy than IPA and TBA and at much greater energy than MA and EA,[1] and this is an indication that the larger alkyl groups reduce the extent of hydrogen bonding. This hydrogen bonding is intramolecular in contrast to the 2-alkylaminopyridine N-oxides which have intermolecular hydrogen bonding.[7] In the complexes the ν_{NH} band is shifted to lower energy indicating coordination by the amine function. However, the shift for the perchlorate and tetrafluoroborate solids is significantly less than for the rest of the compounds in this study. This same trend occurred in the previously studied compounds[1] and suggests a lack of hydrogen bonding to the tetrahedral polyatomic anions, but significant bonding to the weakly coordinated nitrate ions. Possibly, the lower energies of ν_{NH} in the halo complexes is because the ligand is bound very strongly due to the weaker donor ability of the halogen atoms.

The ν_{NO} is shifted to lower energy in the complexes compared to its position in the ligand's spectrum confirming the coordination of the N-oxide oxygen in the complexes. Consistent with reduced hydrogen bonding of the ligand, ν_{NO} is at higher energy than for other ligands of the series.[1] This band is also at higher energy in the complexes since the magnitude of the shift on complexation is the same. The higher NO bond order is probably due to factors other than weaker CuO bonding since ν_{CuO} in these complexes is little changed from previous studies.[1] Other spectroscopic studies (*vide infra*) show differences in the stereochemistry of these complexes which could account for this difference. Although some increase in the energy of δ_{NO} upon complexation has been observed previously, the greatest increase occurs with the present PA complexes. A metal ion effect similar to

that of hydrogen bonding[8] as well as the formation of a chelate ring[9] contribute to this increase in energy.

We have tentatively assigned bands at 1055 and 953 cm^{-1} to the antisymmetric and symmetric CNC bending modes of the propylamino groups, respectively. The energies are similar to the analogous bands in the other members of the series[1] for which our assignment was based on the studies of Katritzky and Jones.[10] Upon complexation these bands are both shifted to lower energy further substantiating coordination by the amine function.

In the 300–400 cm^{-1} spectral region each of the complexes has at least two bands. We have assigned the higher energy band to ν_{CuO} fully realizing that bands in this portion of the spectrum are most often combination bands. This is within the 376–421 cm^{-1} range proposed[11] for ν_{MOPy} and identical to our previous assignments[1] although the TBA complexes were at somewhat higher energy (i.e. 400–420 cm^{-1}). Assignment of the lower energy band to ν_{CuN} is consistent with our previous assignments[1] as well as those of others.[12]

It is of interest to note that ν_{CuO} for the 2-alkylaminopyridine N-oxide complexes[3] are generally found at energies near or above 400 cm^{-1} when these ligands are bound as monodentate ligands via the N-oxide oxygen. However, the Cu(II) complexes of 2-dialkylaminopyridine N-oxides[13] in which the ligand functions as a bidentate group, generally have ν_{Cu-O} at energies substantially below 400 cm^{-1}.

Although not shown in Table 2, the IR spectrum of $Cu(PA)_2(ClO_4)_2$ has $\nu_3(ClO_4)$ = 1080 *s,b* and $\nu_4(ClO_4)$ = 630*s* as well as a very weak band at 941 cm^{-1} assignable to $\nu_1(ClO_4)$. The latter band is IR inactive for purely tetrahedral perchlorate and its appearance, along with the lack of splitting of ν_3 and ν_4, suggests non-coordinated, but hydrogen bonded, perchlorate ions. Similarly, the spectrum of $Cu(PA)_2(BF_4)_2$ possesses a strong band at 1060 cm^{-1} and a band of medium intensity at 530 cm^{-1} assignable to ν_3 and ν_4 of BF_4^-, respectively. Based on this assignment there is no indication of coordination of the terafluoroborate ion.

Lever *et al.*[14] suggest that coordinated and ionic nitrate can be distinguished by inspection of the $\nu_1 + \nu_4$ region (i.e. 1700–1800 cm^{-1}) of the spectrum. Weak bands are found at 1785 and 1774 cm^{-1} and the difference of 11 cm^{-1} is within the range of 5–26 cm^{-1} that has been postulated for monodentate nitrate ligand.[14] Since no other bands are observed in this region, it is likely that both nitrates are weakly bound as monodentate ligands. A weak band at 280 cm^{-1} is possibly assignable to ν_{Cu-O} of coordinated nitrato group in agreement with the findings of other workers.[15]

As is shown in Table 2 the chloride and bromide solids both have two bands assigned to copper–halogen stretching frequencies which would be consistent with the cis arrangement expected for the $Cu(PA)X_2$ centers. Additionally, both solids have these bands in energy ranges that would be consistent with terminal rather than bridging halogens.[16] The Br/Cl ratio of the average energies is 0.74 which is consistent with the two compounds having similar structures.[17] Compared to the previous compounds of this series,[1] the average energies of the two bands are generally lower suggesting a steric effect.

We have omitted from Table 3 the intraligand bands in that they provide little information about the bonding of the complexes. Additionally, there

Table 3. Charge transfer (L→M) and *d–d* electronic transitions (kK) for the Cu(II) complexes of N-propyl-2-picolinamine N-oxide (PA)

	Solid State		Solution (CH_3CN)	
Compound	L ⟶ M	d-d	L ⟶ M	d-d

$Cu(PA)Br_2$	27.78sh 23.58sh 18.52(Br⟶Cu)	16.13	23.26sh	15.63

is a charge transfer band (*ca.* 31 kK) which we have not included. All of the complexes show a second charge transfer band at *ca.* 26 kK and this has been assigned to an O→Cu(II) transition in agreement with other Cu(II) complexes of substituted pyridine N-oxides.[18] In addition, the two halide solids have at least one additional band at somewhat lower energy than 26 kK due to halogen-to-copper (II) transitions. Accurate assignment of the energies of these bands is difficult because they are shoulders on the higher energy bands mentioned above. However, the Cl→Cu(II) band is generally found in the 20.5–22.5 kK range while the transfer from Br is found at somewhat lower energy. The intensity of the band at 18.52 kK in the solid spectrum of $Cu(PA)Br_2$ suggests it to also be Br→Cu(II) as was suggested for $Cu(MA)Br_2$ and $Cu(EA)Br_2$.[1]

Finally, before discussing the individual compounds it should be noted that there is definitely a change in the nature of the coordination spheres upon dissolution in CH_3CN. There is a loss of the two *d–d* peaks of the reflectance spectra for each of the solids derived from salts of polyatomic anions. This is consistent with a square planar to tetragonally distorted octahedral change in the Cu(II) coordination[19] and is likely achieved by axial bonding of the solvent molecules. In addition, the loss of spectral detail in the compounds of the polyatomic anions is accompanied by a shift to lower energy of the *d–d* band in the halide complexes which also suggests the bonding of additional ligands or possibly, a distortion to a more tetrahedral structure. The remainder of this report will concentrate on the individual compounds including the *d–d* transitions of Table 3 as well as the ESR parameters in Table 4. The IR and other information already discussed will be included only when it is pertinent to the proposed stereochemistry of the compounds.

$Cu(PA)_2(ClO_4)_2$. The *d–d* maximum of the main band, which is generally assigned to transitions to $d_{x^2-y^2}$ from both d_{xz}, d_{yz} and d_{z^2}, at 17.48 kK is consistent with an essentially square planar CuO_2N_2 chromophore.[20] However, since the analogous IPA complex had this band at 18.18 kK and the tetrafluoroborate salt of this study has the band at 17.69 kK, a very weak interaction with the perchlorate anion(s) is not ruled out. Other possibilities are tetrahedral or rhombic distortions of the CuO_2N_2 chromophore. As is shown in Fig. 1 we were unable to accurately assign the lowest magnetic field *g*-value in the powder spectra of either the perchlorate or tetrafluoroborate salt of PA. This is probably due to a rhombic distortion and we have assigned the two other *g*-values as shown in Fig. 1. With the IPA complexes of these two anions the *d–d* band was higher than for the corresponding EA complexes. This higher energy was considered to be due to stronger planar bonding because of the greater steric hindrance of the larger IPA groups preventing interaction of the tetrahedral counter ions with copper in the axial positions. Since the *d–d* bands for PA complexes are even lower than the corresponding EA complexes (e.g. $\nu_{dd} = 17.95$ kK for $Cu(EA)_2(ClO_4)_2$),[1b] the cause of the apparent rhombic distortion is a steric effect of a different nature. We suggest for these complexes that either repulsion between two propyl groups of a Cu(II) center or between Cu(II) centers is more important than repulsion between the propyl groups and the anions. A single crystal X-ray study of either $Cu(PA)_2(ClO_4)_2$ or $Cu(PA)_2(BF_4)_2$ as well as a study of the complexes

with the various N-butyl-2-picolinamine N-oxides, which is presently being carried out in our laboratories, should help to confirm our suggestion.

The appearance of the shoulder in the solid reflectance spectrum is indicative of primarily planar bonding[21] rather than the tetragonally distorted octahedral Cu(II) complexes which generally display a single, broad *d–d* band. As is shown in Table 3 dissolution of the complexes in acetonitrile yields spectra with a broad *d–d* band envelope indicating considerable interaction between the solvent and the Cu(II) center with the likely explanation that the CuO_2N_2 chromophore adds solvent molecules in the axial positions. The ESR spectrum of a frozen acetonitrile solution shows a resolved, axial $d_{x^2-y^2}$ ground state spectrum with $g_\parallel = 2.247$, $g_\perp = 2.059$ and $A_\parallel = 166$ G which again suggests axial bonding of the solvent molecules because of the loss of the rhombic spectrum of the solid. Warming this solution, which was frozen immediately upon preparation, gave $g_0 = 2.122$ and $A_0 = 65$ G and, since g_{av} is also equal to 2.122, there is no altering of the nature of the copper (II) site upon freezing. Therefore, we can calculate $A_\perp = 14.5$ G using $A_0 = [(2A_\perp + A_\parallel)3]$. If the solution is allowed to stand for periods of more than an hour, features appear in the frozen solution spectrum which are due to other Cu(II) species and suggest that some substitution for the ligands by solvent molecules occurs.

$Cu(PA)_2(BF_4)_2$. Other than the fact that the tetrafluoroborate salts always have a slightly higher energy maxima for both the main *d–d* band and the low energy shoulder than the corresponding perchlorate solid in this series of complexes, there is little difference between the two solids. Often the $g_\parallel$ value of the powder ESR spectrum is slightly lower and both these differences probably arise from the somewhat poorer donor ability of a fluorine atom compared to an oxygen atom.

$Cu(PA)_2(NO_3)_2$. The IR results indicated that both nitrate ligands were bound in a monodentate fashion to the copper center while the molar conductivity value was indicative of a 1:1 electrolyte. The solid state *d–d* bands are lower in energy than for the previous two solids which can also be indicative of bonding of the anion. Further a typical $d_{x^2-y^2}$ powder ESR spectrum was obtained with $g_\parallel$ in a range more consistent with a tetragonal CuO_2N_2 chromophore[22] than a square planar one.[20]

The same apparent contradiction between the molar conductivity and infrared results was found for $Cu(IPA)_2(NO_3)_2$ and the remaining spectral data for these two solids is virtually identical. We suggest that dissolution does involve dissociation of both nitrate ions from the copper center since the solution *d–d* band is essentially the same as that found for the perchlorate and tetrafluoroborate solutions. The lower conductivity must be a result of some ion pairing probably involving hydrogen bonding, which is not possible with the larger anions. Therefore, both $Cu(PA)_2(NO_3)_2$ and $Cu(IPA)_2(NO_3)_2$ can be considered to be tetragonally elongated octahedral complexes with the nitrate ions weakly coordinated in the axial positions. It is interesting to note that both $Cu(MA)_2(NO_3)_2$ and $Cu(TBA)_2(NO_3)_2$ had "reversed" ESR powder spectra which was suggested to be caused by the presence of inequivalent sites in the unit cell[23] with adjacent copper centers misaligned by 90°[24] for the former[1a] and a compressed octahedron for the latter.[1d] Both of these compounds have molar conductivities that are less than expected for 1:2 electrolytes as well.

$Cu(PA)Cl_2 \cdot H_2O$. Consistent with a broad and weak band centered at 3450 cm^{-1} assignable to a hydrate rather than coordinated water,[25] is an endothermic DSC peak at 124° which is accompanied by a weight loss of 5.2% (Calc. 5.7%). The IR spectrum supports a monomeric $Cu(NO)Cl_2$ chromophore, but the dominance of the intraligand and charge transfer bands in the electronic spectrum makes it difficult to assign the *d–d* bands. The solution electronic and ESR spectra both indicate a substantial change of species (only with methanol were we able to get a sufficiently concentrated solution for the ESR measurement). The powder ESR spectrum has an extremely high value for $g_\perp$, particularly when the rather low value for $g_\parallel$ is considered. Additionally, there is another feature present in the powder spectrum at 77 K (Fig. 2) suggesting either a mixture of monomers or a monomer and a dimer. A third possibility is a cationic species and an anionic species such as $Cu(PA)_2^{2+}$ and $CuCl_4^{2-}$ or $Cu(PA)_2Cl^+$ and $CuCl_3^-$ but the non-electrolytic character in

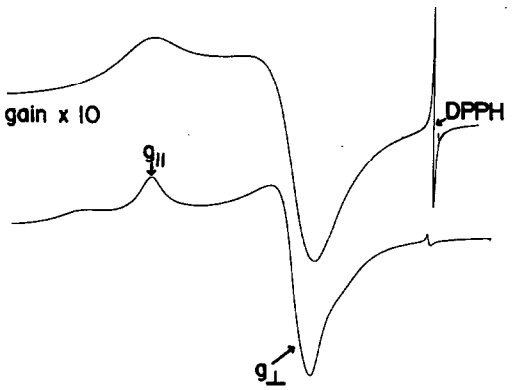

Fig. 2. Powder ESR spectra of $Cu(PA)Cl_2H_2O$ at room temperature (upper) and 77 K (lower).

CH_3CN argues against this possibility. The dominant species, however, is more than likely the 4-coordinate $Cu(PA)Cl_2$ species because the relatively simple IR spectrum is supportive of this structure and a single Cu(II) center.

$Cu(PA)Br_2$. Like $Cu(PA)Br_2$, both $Cu(MA)Br_2$ and $Cu(EA)Br_2$ were violet[1] but $Cu(IPA)Br_2$ and $Cu(TBA)Br_2$ were olive green. The violet color arises from a strong band in the 18 kK region of the visible spectrum. The weak bands at lower energy extending into the near IR are assignable to *d–d* transitions of a tetrahedrally distorted 4-coordinate species. Both $Cu(MA)Br_2$ and $Cu(EA)Br_2$ had rhombic ESR spectra as solids while $Cu(IPA)Br_2$ had an axial spectrum with $g_\parallel = 2.235$, $g_\perp = 2.048$ and $g_{av} = 2.110$. $Cu(PA)Br_2$ has a similar value for g_{av} to the rest of this series but a considerably lower $g_\parallel$ and higher $g_\perp$. This probably is indicative of more covalent bonding of the bromo ligands and the resultant low energy Br→Cu(II) band giving the violet color to $Cu(PA)Br_2$. Recall that $Cu(IPA)Br_2$ is olive green.

In conclusion, PA bonds exclusively as a bidentate ligand via the N-oxide oxygen and the amine nitrogen. While minor differences occur in the spectral properties of the PA complexes when compared to the complexes of MA and EA, these complexes are considerably different from those of IPA. Examples of the differences are the following: a rhombic distortion of the PA complexes with a considerably lower *d–d* band maximum for the perchlorate and tetrafluoroborate salts, the color differences of the nitrate and halogen salts of the two ligands, and the apparent greater covalency of the PA complexes derived from the halogen salts. As indicated earlier we are proceeding to a study of the various N-butyl-2-picolinamine N-oxides to compare with the TBA already reported on[1d] as well as the remainder of the series.[1,2]

CIRCULARLY POLARIZED LUMINESCENCE STUDIES OF THE ADDUCTS FORMED WITH MIXED-LIGAND Eu(III) β-DIKETONE COMPLEXES AND DIMETHYL SULFOXIDE OR N,N-DIMETHYL FORMAMIDE

HARRY G. BRITTAIN* and C. K. CHAN
Chemistry Department, Seton Hall University, South Orange, NJ 07079, U.S.A.

(*Received* 17 *January* 1984; *accepted* 2 *March* 1984)

Abstract—The adducts formed by $Eu(DK)_2(CDK)$ and $Eu(DK)(CDK)_2$ [DK = achiral β-diketone ligand, and CDK = chiral β-diketone ligand] with either dimethyl sulfoxide (DMSO) or N,N-dimethyl formamide (DMF) have been studied by means of circularly polarized luminescence spectroscopy. While extremely strong stereoselective effects had been observed in earlier studies involving $Eu(CDK)_3$ adducts, analagous phenomena were found to be much smaller in the mixed-ligand compounds. These observations imply that steric interactions involving bulky camphorato ligands are significantly greater than those involving the achiral (and planar) β-diketone ligands.

The determination of enantiomeric purities via NMR spectroscopy involves the use of lanthanide derivatives of chiral β-diketones, many of which are derived from bornan-2-one:

R = $-CF_3$, TFAC
= $-C_3F_7$, HFBC

Applications for the Pr(III) and Eu(III) *tris*-derivatives of TFAC and HFBC have been widespread.[1] In many cases, the lanthanide induced shifts appear to increase in a linear manner as the lanthanide complex is added, but this is not always the case. For instance, the magnitude of the paramagnetic induced shifts has been shown to depend on the stoichiometry of the adduct complex.[2] These dependences are undoubtedly associated with the stereochemical equilibria of the adduct complexes, and any theoretical analysis of induced shifts requires detailed knowledge regarding the adduct in question.

Such information is available from chiroptical studies on the chiral lanthanide compounds, and it has been found that circularly polarized luminescence (CPL) spectroscopy is ideally suited for the stereochemical investigations.[3,4] When either $Eu(TFAC)_3$ [TFAC = (+)-trifluoroacetylcamphor] or $Eu(HFBC)_3$ (HFBC = (+)-3-heptafluoropropylbutyrylcamphor] is dissolved in a non-coordinating solvent, no optical activity can be observed. However, when one forms the adduct complex, strong optical activity is often obtained.[5,6] Similar observations can be made for Tb(III) complexes.[7] This behavior has been studied in detail for sulfoxides, sulfones, and phosphate esters,[8] as well as formamide and acetamide derivatives.[9] Similar results have been noted with Eu(III) derivatives of other chiral β-diketonates.[10]

As a means to study these stereoselective phenomena we have synthesized a series of mixed-ligand Eu(III) complexes containing both chiral and achiral β-diketone ligands, and have reported the chiroptical properties of these in non-coordinating solvents.[11] Compounds having the general formulae $Eu(DK)_2(CDK)$ and $Eu(DK)(CDK)_2$ were prepared, where DK signifies an achiral β-diketone ligand and CDK signifies an inherently chiral β-diketone ligand. It had been noted earlier that adduct formation with the

*Author to whom correspondence should be addressed.

$(EuCDK)_3$ compounds was usually accompanied by the generation of intense optical activity within the Eu(III) emission bands, even though the substrates used to generate the adducts were not chiral. The strongest stereoselective effects were noted in the DMSO adducts,[5,6,8] and the analagous DMF adducts yielded only slightly weaker effects.[5,6,9] Since these effects were thought to result from steric interactions among the bulky camphorato ligands, it was deemed important to observe whether any stereoselectivity could be observed in the DMSO and DMF adducts formed by $Eu(DK)_2(CDK)$ and $Eu(DK)(CDK)_2$. Such studies constitute the present report.

EXPERIMENTAL

The $Eu(DK)_2(CDK)$ and $Eu(DK)(CDK)_2$ compounds used in the present work were prepared as described[11] with the analysis and characterization of these being described therein. In the present work, we shall focus on the compounds where DK = TTFA [4,4,4-trifluoro-1-(2-thienyl)butane-1,3-dionate], DPM [2,2,6,6-tetramethylheptane-3,5-dione], BZAC [benzoylacetone], or DBM [dibenzoylmethane]. As in the earlier works, we will consider only CDK = TFAC or HFBC. The ligands used to prepare the mixed-ligand compounds were used as received from Aldrich. Dimethyl formamide (DMF) and dimethyl sulfoxide (DMSO) were obtained as spectroquality solvents, and were used as received. Stock solutions of each material made up in spectrograde $CHCl_3$, and titrations were carried out in which the substrates were added to $CHCl_3$ solutions of the Eu(III) chelates. These titration procedures have been adequately summarized in our earlier work.[7-10] All measurements were thus performed in $CHCl_3$ solution at room temperature.

All CPL and TL (total luminescence) measurements were obtained on apparatus constructed in our laboratory. In most cases, the 365 nm output of a 200 W Hg–Xe arc lamp was used to excite the complexes. This wavelength was selected by a combination of a 0.1 m grating monochromator and UV-transmitting filters. Measurements of the TL and CPL spectra were carried out simultaneously within the $^5D_0 \rightarrow {}^7F_J$ (J = 0, 1, 2) band systems associated with the Eu(III) ion. The emission was analyzed by a 0.5 m grating monochromator at 5 Å resolution, and it was determined that further increases in resolving power did not yield any significant improvement in the spectral features.

The chiroptical measurements produce two quantities normally measured in arbitrary units. The total luminescence (TL), defined by:

$$I = I_L + I_R \tag{1}$$

and the circularly polarized luminescence, defined by:

$$\Delta I = I_L - I_R. \tag{2}$$

In eqns (1) and (2), I_L and I_R represent the emitted intensities of left- and right-circularly polarized light, respectively. One may remove the unit dependence associated with I and ΔI by taking the ratio of these, and this quantity is termed the luminescence dissymmetry factor:[3]

$$g_{lum} = \Delta I/(1/2)I \tag{3}$$

The g_{lum} factor has theoretical as well as experimental significance in that it may be related to the rotational strength of the transition.[3]

RESULTS AND DISCUSSION

In non-coordinating solvents, one may speak of an $Eu(DK)_3$ compound, but in coordinating solvents one deals with adduct complexes. Upon interaction with a substrate, S, the formation of 1:1 adducts:

$$Eu(DK)_3 + S \rightleftharpoons Eu(DK)_3(S) \tag{4}$$

and 1:2 adducts:

$$Eu(DK)_3 + 2S \rightleftharpoons Eu(DK)_3(S)_2 \tag{5}$$

may be observed. When the substrate is optically active, then chirality may be observed in the f–f emission bands of the Eu(III) ion.[4]

The phenomena associated with the $Eu(CDK)_3$ complexes are more complicated. Since the CDK ligands are inherently chiral, preparation of the $Eu(CDK)_3$ compound results in the formation of four diastereomers. In $CHCl_3$ solution one would anticipate that these would be formed in roughly equivalent amounts, since these compounds are exceedingly labile. The analogous diastereomers of inert transition metal complexes have been resolved,[12,13] and it has been found that the chirality of the Δ isomers is essentially equal in magnitude and opposite in sign to that of the Λ isomers. Thus, in a solution containing equal amounts of the various stereoisomers, one should not be able to observe any optical activity. This has been found to be the case,[5,6] indicating that in non-coordinating solvents the camphorato ligands do not sterically crowd each other. Upon formation of

the adduct complexes:

$$Eu(CDK)_3 + S \rightleftharpoons Eu(CDK)_3(S) \quad (6)$$

$$Eu(CDK)_3 + 2S \rightleftharpoons Eu(CDK)_3(S)_2 \quad (7)$$

one would anticipate that the bulky camphorato ligands would be forced to interact more in the adduct complexes, and the complexes ought to adopt the configurations of lower energy. This process would effectively constitute a partial resolution, and should result in the observation of optical activity within the f–f bands. Such predictions have been verified.[5–10]

The rather low absorptivities of the Eu(III) f–f transitions make the measurement of circular dichroism difficult, but fortunately one may also study f–f optical activity by means of CPL spectroscopy. Excitation of Eu(III) β-diketone complexes by near-UV radiation can result in the observation of strong luminescence in the red region of the spectrum. This emission consists of a series of well-resolved transitions from the excited $^5D_0$ level to the ^7F_J levels of the ground state. We shall henceforth label the spectroscopic transitions by their defining J quantum numbers, and have observed the 0–0 (580 nm), 0–1 (595 nm), and 0–2 (615 nm) bands during the course of our work. CPL within the 0–0 transition is not permitted,[3] but strong CPL was normally observed within the 0–1 and 0–2 transitions.

$Eu(DK)_2(CDK)$ series

In non-coordinating solvents, reasonably strong CPL spectra were obtained for $Eu(DPM)_2(HFBC)$, $Eu(BZAC)_2(HFBC)$, $Eu(DBM)_2(HFBC)$, and $Eu(TTFA)_2(HFBC)$,[11] and the CPL spectra were not found to vary greatly with the identity of the DK ligand. This behavior stands in sharp contrast to that noted for $Eu(TFAC)_3$ or $Eu(HFBC)_3$, where *no* CPL can be obtained in non-coordinating solvents for the reasons just mentioned. With only one chiral ligand present per Eu(III) ion, one would predict that only the vicinal effect would contribute to the metal ion optical activity. This effect represents the chirality resulting when dissymmetry is induced at the Eu(III) ion by the presence of an asymmetric carbon on one of the β-diketone ligands. In the absence of adduct formation, one would not expect to observe significant configurational effects (chirality resulting from the dissymmetric placement of chelate

rings about a metal ion). It should be noted that the $Eu(DK)_2(TFAC)$ compounds could not be studied as the emission intensity of these was too weak to permit the observation of CPL.

The alterations in photophysical parameters upon adduct formation were found to vary somewhat as the DK ligands were varied. When DK = DBM or DPM, it was found that the TL intensities increased only slightly upon formation of the adduct complexes. At the same time, no change was observed in the CPL lineshapes and the intensities of these (as measured by the dissymmetry factors) increased slightly. On the other hand, when DK = BZAC it was found that both the TL and CPL intensities underwent significant decreases upon formation of the DMSO or DMF adducts. As before, the CPL lineshape did not change. The dissymmetry factors obtained for the free complexes and the adducts may be found in Table 1.

Very different behavior was observed in the case of DK = TTFA. A considerable increase in the TL intensity was noted when forming the DMF or DMSO adducts. With DMF, the optical activity was found to increase somewhat, but there was no change in the CPL lineshape. However, when forming the DMSO adduct, a considerable change was observable in the CPL spectrum. Examples of these changes have been provided in Figs. 1 and 2.

The CPL spectra associated with the DMSO adduct appear to consist of a superposition of the DMF lineshapes and the lineshapes of a new

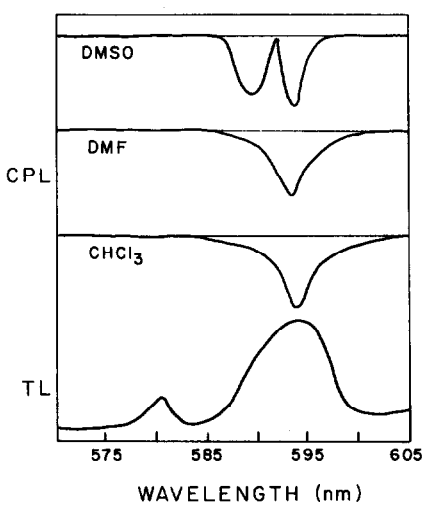

Fig. 1. Circularly polarized luminescence spectra obtained for $Eu(TTFA)_2(HFBC)$ dissolved in $CHCl_3$, and for its DMF and DMSO adducts. species. It appears that upon addition of sufficient amounts of DMSO or DMF 1:2 Eu $(CDK)_3$/substrate adducts form.[14] The two substrates could bind *cis* or *trans* to each other depending on the overall steric requirements of the Eu(III) complex, and it is entirely possible that equal amounts of these coexist in the DMSO adduct. The other adducts apparently exhibit much more of a stereochemical preference, and consequently the CPL spectra indicate the presence of only one compound.

$Eu(DK)(CDK)_2$ series

When two chiral β-diketone ligands are bound by a single lanthanide ion, one would expect that a combination of vicinal and configurational effects would play a role in determining the chirality at the metal ion. Depending on the steric requirements of the compounds, a variety of possibilities might result. In non-coordinating solvents, the dissymmetry factors of the $Eu(DK)(CDK)_2$ compounds happened to be smaller than those of the analagous $Eu(DK)_2(CDK)$ compounds, and when DK = BZAC the CPL lineshapes were actually opposite to those of the other complexes.[11] These observations all indicate that the chirality of the $Eu(DK)(CDK)_2$ compounds cannot be taken as a simple summation of two vicinal effects, and indicate that the observed optical activity contains a strong configurational contribution. However, these configurational effects were found to be considerably smaller than those noted in the

DMSO or DMF adducts of $Eu(CDK)_3$ complexes.[5,6]

Formation of the DMF or DMSO adducts of $Eu(DBM)(TFAC)_2$ led to a doubling of the TL intensities, and a marked decrease in the CPL intensities. For the $Eu(DPM)(TFAC)_2$ or $Eu(TTFA)(TFAC)_2$ compounds, formation of the DMSO adducts also led to sizable increases in the TL intensities, but to a total disappearance of the CPL spectra. These results indicate that significant stereochemical alterations can accompany the formation of the adduct complexes in the $Eu(DK)(CDK)_2$ series.

The $Eu(BZAC)(TFAC)_2$ compound was unique in that its CPL spectra were found to be opposite in sign to those of the rest of the $Eu(DK)(TFAC)_2$ series. The DMF adduct of this compound exhibited behavior quite like that of $Eu(DBM)(TFAC)_2$, but formation of the DMSO adduct led to an inversion of the CPL spectra. These effects have been illustrated in Fig. 3 and 4. This latter phenomenon suggests that the decrease in CPL intensities noted with DK = DBM, DPM, or TTFA is associated with formation of significant amounts of adducts whose CPL sign patterns are opposite to those of the parent compounds.

The dissymmetry factors corresponding to the entire series where CDK = TFAC have been collected in Table 2.

The trends observed with the $Eu(DK)(HFBC)_2$ compounds were found to be quite different from

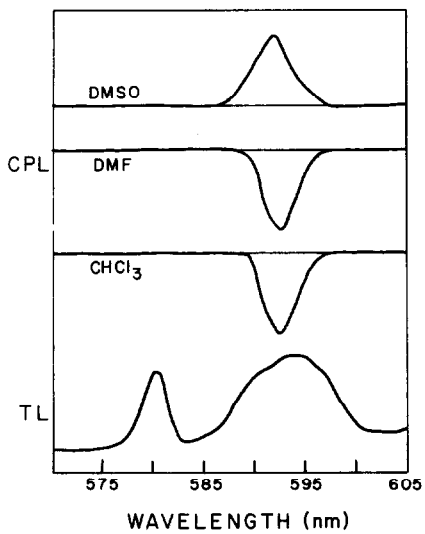

Fig. 3. Circularly polarized luminescence spectra obtained for $Eu(BZAC)(TFAC)_2$ dissolved in $CHCl_3$, and for its DMF and DMSO adducts. those found for the $Eu(DK)(TFAC)_2$ complexes. With the $Eu(BZAC)(HFBC)_2$, $Eu(DBM)(HFBC)_2$, and $Eu(DPM)(HFBC)_2$ compounds, formation of the DMSO or DMF adducts led to very small changes in the TL intensities. The CPL intensities were found to undergo only small decreases upon formation of the adduct complexes, and the luminescence dissymmetry factors obtained when CDK = HFBC are found in Table 3. Even though the CPL lineshapes obtained for DK = DBM were opposite to those found for DK = BZAC or DPM, the presence of a general trend indicates similar behavior. The decrease in CPL intensity probably reflects the formation of small amounts of a stereoisomer whose chirality is opposite to that of the parent complexes.

The CPL spectrum of $Eu(TTFA)(HFBC)_2$ dissolved in $CHCl_3$ does not resemble that of any of the other $Eu(DK)(HFBC)_2$ complexes, and in fact appears to represent the contributions made by two emitting species. This situation would thus be very much like that seen earlier for $Eu(TTFA)_2(HFBC)$, although the wavelength maxima of the CPL bands were observed to be very different in the two systems.

Formation of the DMF or DMSO adducts of $Eu(TTFA)(HFBC)_2$ led to large enhancements in the TL intensities. While formation of the DMF adduct led to reductions in the CPL intensities, the two CPL peaks were not found to decrease by the same amount. Such an observation would be con-

sistent with the existence of two species in solution, each of which experienced differing perturbations upon adduct formation. Formation of the DMSO adduct led to rather dramatic changes in the CPL spectra, as has been shown in Figs. 5 and 6. Once again it was found that the process of adduct formation affected each CPL peak in a different manner: the band at lower wavelength was scarcely affected, but the peak at higher wavelength was replaced by a band of opposite sign.

The dissymmetry factors corresponding to the compounds having CDK = HFBC have been collected in Table 3.

CONCLUSIONS

That formation of adduct complexes can greatly affect the stereochemistry of Eu(III) β-diketone compounds has been amply demonstrated. In addition, it has been shown that multiple emitting species are capable of coexisting in solution under a given set of conditions. The particular distribution of these is dictated by the nature of the β-diketone ligands, and by the steric requirements of the substrates.

A determination of the wavelengths associated with the CPL maxima within the 0–1 transitions proved illuminating. For each of the $Eu(DK)_2(CDK)$ or $Eu(DK)(CDK)_2$ compounds (either the free complex or the adduct), CPL maxima were only observed at three wavelengths (as indicated in the tables). The CPL observed at each maximum could be either positive or negative in sign, depending on the particular complex and substrate in question. It was often observed that formation of the adduct complex diminished the observed optical activity of several of the Eu(III) complexes. We may interpret this result to imply that the process of adduct formation could result in the stabilization of the other epimer, and that these could coexist under those conditions. This explanation would in turn explain the variability observed in the dissymmetry factors obtained with the $Eu(DK)_2(HFBC)$ compounds, even though here the chirality of the complex was due only to the presence of a single vicinal effect. In most cases only a single conformation did predominate, but varying amounts of the other enantiomer were also present. The degree of stereoselectivity would naturally be dictated by the particular nature of the β-diketone ligand. Similar arguments could be advanced to explain the variabilities found in the chiralities of the $Eu(DK)(CDK)_2$ compounds.

It has been found that $Eu(DK)_3(S)_2$ adducts generally adopt the coordination polyhedron of a square antiprism.[15] Within this constraint, three structures are possible for the adduct complexes, and these have been illustrated elsewhere.[10] The presence of differing β-diketone ligands (most of which are not symmetrical) within these polyhedra will lead to the production of a large number of diastereomers. However, it is probably true that

the chiroptical properties at the Eu(III) ion are determined primarily by the dissymmetric placement of the ligands (configurational effects). In that case, it should ultimately be possible to identify each of the three basic square antiprisms as leading to a particular CPL lineshape. Each of these conformations would in turn be capable of existing as either of its two epimers, and the stereoisomer populations consequently determine the magnitude of any observed optical activity.

It was noted in the earlier work[5,6,8,9] that stereoselective effects observed in $Eu(CDK)_3$ complexes were much greater in DMSO adducts relative to those obtained in DMF adducts. This trend has continued in the mixed-ligand complexes. In any situation where the conformational equilibria could be altered, such alterations were found to be induced by the DMSO solvent. DMF adducts generally resembled the free compounds quite closely. These trends indicate that the DMSO substrate is more sterically demanding than is the DMF substrate.

A final note concerns the degree of stereoselectivity in the mixed-ligand complexes relative to that observed in the $Eu(CDK)_3$ compounds. Extremely large stereoselective effects were observed in the DMSO and DMF adducts of the $Eu(CDK)_3$ compounds, and this effect was attributed to the existence of large steric interactions among the CDK ligands upon adduct formation. Replacement of one CDK ligand by a DK ligand greatly reduces the magnitude of these effects, and replacement of another CDK ligand by a DK ligand essentially reduces the stereoselective effects to nothing. These trends imply that the achiral DK ligands possess considerably smaller steric requirements than do the bulky CDK ligands. Consequently, the compounds containing higher amounts of DK ligands would more readily form adducts with bulky substrates than would Eu(III) compounds having higher amounts of CDK ligands.

IONIC EQUILIBRIA IN FERRIC SULFATE–SULFURIC ACID SOLUTIONS

C. K. LEE and L. L. TAVLARIDES*
Department of Chemical Engineering and Materials Science, Syracuse University, Syracuse, NY 13210, U.S.A.

(*Received* 5 *January* 1984; *accepted* 2 *March* 1984)

Abstract—The ionic equilibria of ferric sulfate–sulfuric acid aqueous solution are modeled mathematically, taking into account the effect of ionic strength. Results of this analysis indicate that ion interactions can significantly change the ionic concentration of the solutions which could lead to errors in the evaluation of data on iron(III) extraction kinetics or equilibrium.

Equilibrium and kinetic studies of iron(III) extraction by organic chelating agents have been widely investigated[1–7] because of the practical importance of these reactions in the hydrometallurgical field. In the extraction of metals such as copper, uranium, cobalt, and nickel from their leach solutions, iron(III) is typically present as an impurity. Therefore, to properly analyze selective nonferrous metal extraction, it is necessary to model the iron(III) speciation in the aqueous phase. Various investigators have assumed that only the ferric ion (Fe^{3+}) is extracted during iron(III) extraction,[5,7] such as iron(III) nitrate extraction by 8-hydroxy quinoline. However, other researchers[1,4,6] suggest that both Fe^{3+} and $FeOH^{2+}$ are simultaneously extracted by the organic reagent, such as oximes and tri-*n*-butylacetohydroxamic acid. Thus, regardless of which iron species is extracted, it is necessary to have an accurate estimate of the reactive species concentration in the aqueous phase in order to develop an accurate equilibrium and/or kinetic model for the two-phase extraction system.

In a recent work, Freeman and Tavlarides[8] developed a model for estimating the equilibrated ionic species concentration in the copper sulfate–sulfuric acid system. This model considers the coupling of the copper sulfate ion-pair dissociation and the bisulfate ion dissociation in aqueous solution. The analysis includes the effects of ionic strength and temperature. These results have been successfully applied to model the chemical equilibrium of the copper(II)-sulfate/β-alkenyl-8-hydroxy quinoline extraction system.[9] For iron(III) extracted by an organic chelating agent, few published works consider the ionic equilibria in the aqueous phase. Typically, the reactant in the aqueous phase is obtained by assuming complete dissociation of the iron salt in solution. The concentration of the ferric ion is then regarded as either equal or proportional to the $[Fe]^T$. Indeed, iron(III) exists as at least seven species in the acid sulfate system. Dousma *et al.*[10] presented an equilibrium model for the iron(III) system which considered the influence of sulfate ions on the formation of iron oxides. The model, however, does not properly account for the variation of the stability constant as a function of ionic strength. The purpose of this work is to present a comprehensive model for the ferric sulfate–sulfuric acid aqueous phase ionic equilibria in which the effect of ionic strength is considered. The model employs a straightforward mathematical calculation to predict the concentrations of ionic species.

AQUEOUS IONIC EQUILIBRIA

Models for the ferric sulfate dissociation and its related ionic species equilibria can be developed from the information available in the literature. There are many ionic equilibrium relationships that may be used to depict the speciation in the iron(III) acid sulfate solution. However, the work by Dousma *et al.*[10] indicates that only some of the equilibria need to be considered. The pertinent reactions for the aqueous phase equilibria of ferric sulfate–sulfuric acid solution can be represented by the following nine equations.

*Author to whom correspondence should be addressed.

$$Fe_2(SO_4)_3 \overset{k_1}{\rightleftharpoons} 2Fe^{3+} + 3SO_4^{2-} \quad (1)$$

$$HSO_4^- \overset{k_2}{\rightleftharpoons} H^+ + SO_4^{2-} \quad (2)$$

$$Fe^{3+} + SO_4^{2-} \overset{k_3}{\rightleftharpoons} FeSO_4^+ \quad (3)$$

$$Fe^{3+} + HSO_4^- \overset{k_4}{\rightleftharpoons} FeHSO_4^{2+} \quad (4)$$

$$Fe^{3+} + 2SO_4^{2-} \overset{k_5}{\rightleftharpoons} Fe(SO_4)_2^- \quad (5)$$

$$Fe^{3+} + H_2O \overset{k_6}{\rightleftharpoons} FeOH^{2+} + H^+ \quad (6)$$

$$2FeOH^{2+} \overset{k_7}{\rightleftharpoons} Fe(OH)_2Fe^{4+} \quad (7)$$

$$Fe^{3+} + 2H_2O \overset{k_8}{\rightleftharpoons} Fe(OH)_2^+ + 2H^+ \quad (8)$$

$$H_2O \overset{k_9}{\rightleftharpoons} H^+ + OH^-. \quad (9)$$

Of these nine reactions, the first is assumed to dissociate completely into Fe^{3+} and SO_4^{2-} in the aqueous solution because of the strong electrolytic behavior of ferric sulfate. Therefore, only eight equilibrium relations need to be considered. Concentrations of the ferric ion, hydrogen ion, and other ionic species are estimated by modeling the aqueous phase mathematically. In addition to the equilibria expressed in eqns (2)–(9), the mass balances of the total sulfur and iron concentrations, and the electroneutrality of the solution are also considered. Accordingly, the following set of eleven nonlinear algebraic equations can be obtained:

HSO_4^- *dissociation*

$$k_2 = \frac{[HSO_4^-]}{[H^+][SO_4^{2-}]}. \quad (10)$$

$FeSO_4^+$ *formation*

$$k_3 = \frac{[FeSO_4^+]}{[Fe^{3+}][SO_4^{2-}]}. \quad (11)$$

$FeHSO_4^{2+}$ *formation*

$$k_4 = \frac{[FeHSO_4^{2+}]}{[Fe^{3+}][HSO_4^-]}. \quad (12)$$

$Fe(SO_4)_2^-$ *formation*

$$k_5 = \frac{[Fe(SO_4)_2^-]}{[Fe^{3+}][SO_4^{2-}]^2} \quad (13)$$

$FeOH^{2+}$ *formation*

$$k_6 = \frac{[FeOH^{2+}][H^+]}{[Fe^{3+}]}. \quad (14)$$

$Fe(OH)_2Fe^{4+}$ *formation*

$$k_7 = \frac{[Fe(OH)_2Fe^{4+}]}{[FeOH^{2+}]^2}. \quad (15)$$

$Fe(OH)_2^+$ *formation*

$$k_8 = \frac{[Fe(OH)_2^+][H^+]^2}{[Fe^{3+}]}. \quad (16)$$

H_2O *dissociation*

$$k_9 = [H^+][OH^-]. \quad (17)$$

Sulfate balance

$$[S]^T = [SO_4^{2-}] + [HSO_4^-] + [FeSO_4^+] + [FeHSO_4^{2+}] + 2[Fe(SO_4)_2^-]. \quad (18)$$

Iron balance

$$[Fe]^T = [Fe^{3+}] + [FeSO_4^+] + [FeHSO_4^{2+}] + [Fe(SO_4)_2^-] + [FeOH^{2+}] + 2[Fe(OH)_2Fe^{4+}] + [Fe(OH)_2^+]. \quad (19)$$

Electroneutrality

$$[H^+] + 3[Fe^{3+}] + [FeSO_4^+] + 2[FeHSO_4^{2+}] + 2[FeOH^{2+}] + 4[Fe(OH)_2Fe^{4+}] + [Fe(OH)_2^+] = 2[SO_4^{2-}] + [HSO_4^-] + [Fe(SO_4)_2^-] + [OH^-]. \quad (20)$$

Equations (10)–(20) can be combined with the ionic strength relationship

$$I = \frac{1}{2}\sum_{j=1}^{n} (z_j)^2 C_j \quad (21)$$

for constant values of k_i, $i = 2,9$, to obtain four nonlinear algebraic equations:

$$[Fe]^T - [S]^T - [Fe^{3+}] + [SO_4^{2-}] + k_2[H^+][SO_4^{2-}] + k_5[Fe^{3+}][SO_4^{2-}]^2 - k_6[Fe^{3+}]/[H^+] - 2k_7k_6^2[Fe^{3+}]^2/[H^+]^2 - k_8[Fe^{3+}]/[H^+]^2 = 0 \quad (22)$$

$$2[Fe]^T + [H^+] - 2[SO_4^{2-}] - k_2[H^+][SO_4^{2-}] + [Fe^{3+}] - k_3[SO_4^{2-}][Fe^{3+}] - 3k_5[Fe^{3+}][SO_4^{2-}]^2 - k_8[Fe^{3+}]/[H^+]^2 - k_9/[H^+] = 0 \quad (23)$$

$$[S]^T - [SO_4^{2-}] - k_2[H^+] - k_3[Fe^{3+}][SO_4^{2-}] - k_2k_4[H^+][SO_4^{2-}][Fe^{3+}] - 2k_5[Fe^{3+}][SO_4^{2-}]^2 = 0 \quad (24)$$

$$I - \frac{1}{2}([H^+] + 4[SO_4^{2-}] + k_2[H^+][SO_4^{2-}] + 9[Fe^{3+}] + k_3[SO_4^{2-}][Fe^{3+}] + 4k_2k_4[H^+][SO_4^{2-}][Fe^{3+}] + k_5[Fe^{3+}][SO_4^{2-}]^2 + 4k_6[SO_4^{2-}]/[H^+] + 16k_7k_6^2[SO_4^{2-}]^2/[H^+]^2 + k_8[Fe^{3+}]/[H^+] + k_9/[H^+]) = 0. \quad (25)$$

The dependence of the stability constants k_2–k_9 on ionic strength is included in this formulation. The correlations[11–18] for stability constants applied here for model computations at 25°C are

$$k_2 = (1/0.0104)\exp\{-5.29\sqrt{I}/(1 + 0.56\sqrt{I})\} \quad (26)$$

$$\log k_3 = 4.04 - 6\sqrt{I}/(1 + 1.7\sqrt{I}) + 0.233I \quad (27)$$

$$k_4 = 6 - 1.36(I - 1.2) \quad (28)$$

$$\log k_5 = \log k_3 + 1.34 - 2\sqrt{I}/(1 + 1.9\sqrt{I}) - 0.077I \quad (29)$$

$$\log(k_6/6.5 \times 10^{-3}) = -2.04\sqrt{I}/(1 + 2.5\sqrt{I}) + 0.01I \quad (30)$$

$$\log k_7 = 1.46 + 4.08\sqrt{I}/(1 + 2.1\sqrt{I}) + 0.075I \quad (31)$$

$$k_8 = 7 \times 10^{-8} + 1.4 \times 10^{-7}I \quad (32)$$

$$k_9 = 10^{-14}. \quad (33)$$

These stability constants, which are dependent on ionic strengths, are substituted into eqns (22)–(25) to solve for the independent variables $[H^+]$, $[SO_4^{2-}]$, $[Fe^{3+}]$, and the ionic strength I. The Secant method [19] is employed here. The roots of the equations must be positive and the resulting values for concentrations must be physically meaningful. Otherwise, the initial approximated values of the roots must be adjusted to obtain the proper set of roots.

RESULTS AND DISCUSSION

The results of computation presented here for ferric sulfate–sulfuric acid solutions are a general case based on assumed values for the total iron and total sulfur concentrations.

Figure 1 shows the concentration profiles of iron ionic species in the aqueous phase as a function of total sulfur concentration at a constant total iron concentration 0.003M. It can be noted here that $FeSO_4^+$ is the dominant iron species existing in the aqueous phase. The concentration of other sulfate-bearing iron species is lower than that of $FeSO_4^+$. At high total sulfur concentration ($\sim 10^{-1}$mol/dm^3), the concentration of $FeOH^{2+}$ is much lower than that of Fe^{3+}. However, at low sulfur concentration ($\sim 10^{-3}$mol/dm^3), the concentration of these two iron species are of the same magnitude. The concentration of $FeOH^{2+}$ becomes larger than that of Fe^{3+} below a certain low-level concentration of sulfur ($< 7 \times 10^{-3}$mol/dm^3). The concentrations of other hydroxy-bearing iron species, $Fe(OH)_4Fe^{4+}$, and $Fe(OH)_2^+$, are at least an order of magnitude lower than that of Fe^{3+}. These concentrations are decreased precipitously as the sulfur concentration increases. The composition of Fe^{3+} in the solution is about 2–7% of the total iron concentration. Further, the Fe^{3+} concentration is not linearly related to the total iron present in the solution.

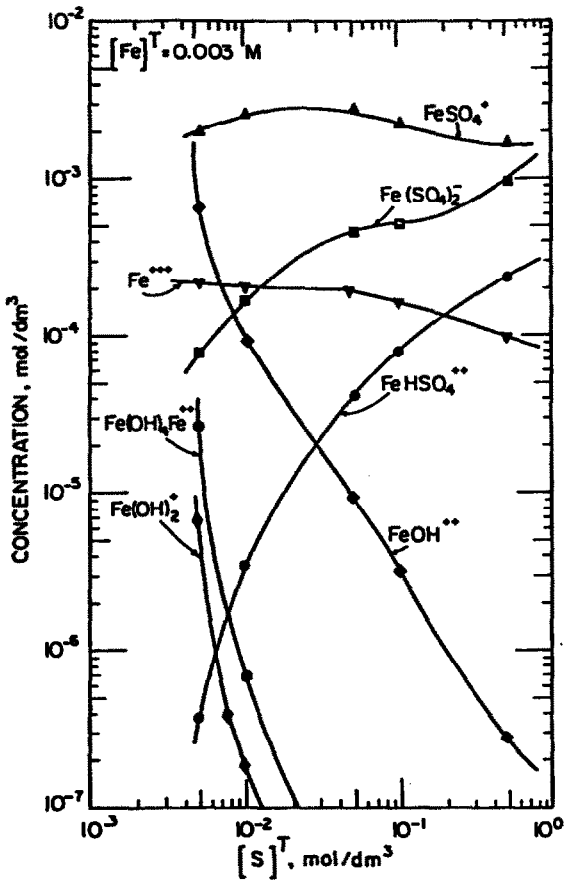

Fig. 1. Concentration profiles of various iron ionic species as a function of total sulfur concentration at a constant total iron concentration of 0.003 mol/dm^3.

Figure 2 shows the dependence of hydrogen ion on the total sulfur and total iron concentration. The H^+ concentration changes rapidly with total sulfur concentration, especially as the ratio of $[Fe]^T$ to $[S]^T$ approaches 2/3, the value of the stoichiometric coefficient of ferric sulfate compound. If the ratio of $[Fe]^T$ to $[S]^T$ equals 2/3, it indicates that there is no additional sulfuric acid added into the solution and the solution is expected to contain a low concentration of H^+. The similar phenomenon can be seen from the plot of $[H^+]$ as a function of $[Fe]^T$ in the same figure. At low iron concentration the $[H^+]$ does not change significantly. This may be because the acidity associated with iron at low iron concentrations may not change the acidity of the solution, in which the sulfur concentration (and the corresponding hydrogen ion concentration) is already high. Figure 3 shows the concentration profiles of various ionic species with total sulfur concentration at a constant total iron concentration of 0.1M. The profiles show trends similar to that in Figs. 1 and 2, although the iron concentration here is several orders of magnitude higher. Figure 4 shows the variation of Fe^{3+} and $FeOH^{2+}$

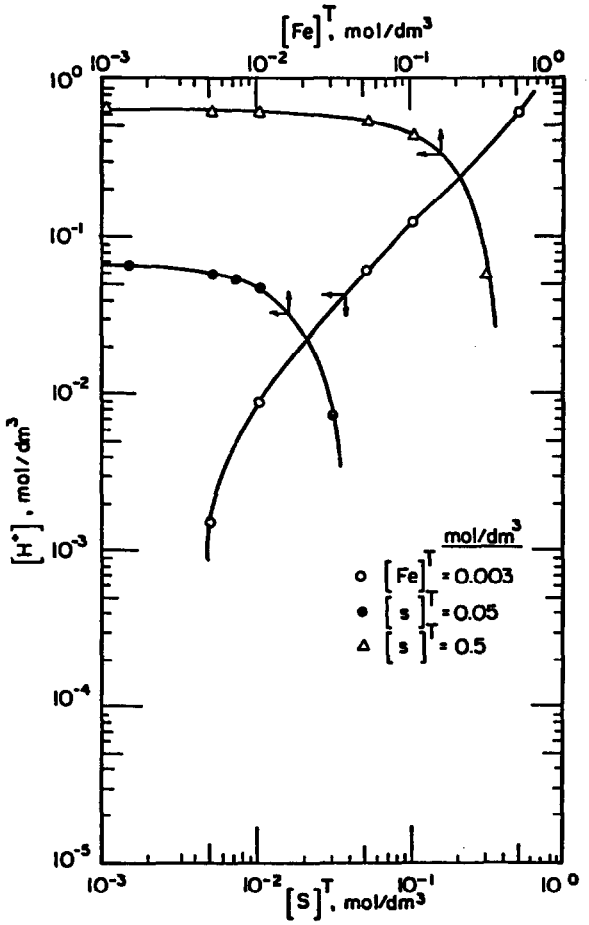

Fig. 2. Effects of total sulfur and total iron concentration on the hydrogen ion concentration profile.

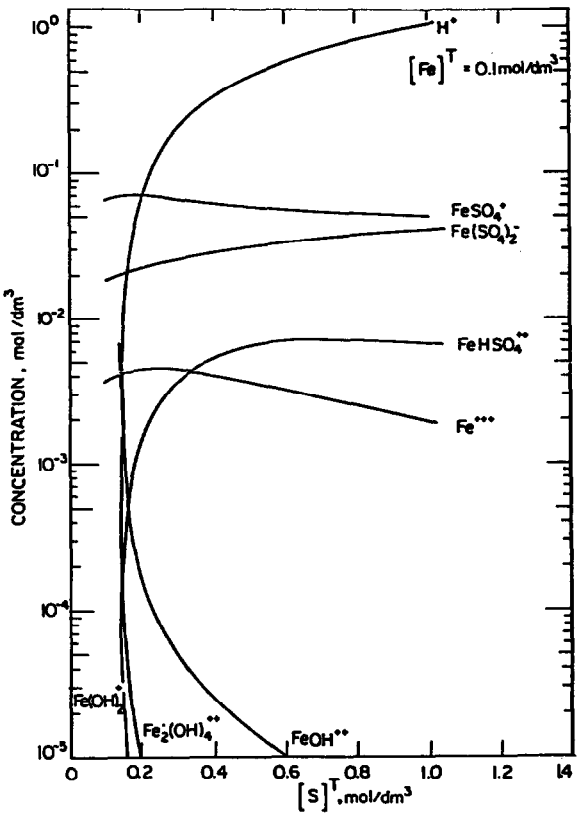

Fig. 3. Concentration profiles of various iron ionic species as a function of total sulfur concentration at a constant total iron concentration of 0.1 mol/dm³.

concentration as a function of total iron concentration at two levels of total sulfur concentration. One can see from Fig. 4 that the concentrations of both Fe^{3+} and $FeOH^{2+}$ increase rapidly with total iron content. In addition, at low iron concentration ($< 10^{-2}$mol/dm³), the concentration of Fe^{3+} is an order of magnitude higher than that of $FeOH^{2+}$.

Accordingly, these results clearly show the nonlinear dependence of Fe^{3+}, $FeOH^{2+}$, and other ionic species on the total iron concentration. Thus, to properly model metal ion extraction kinetics[20] or two-phase metal ion distribution data[21] that are based on knowing the concentration of Fe^{3+} or $FeOH^{2+}$ ions, aqueous phase equilibrium modeling as shown here is necessary for proper estimation of metal ion concentrations. One, therefore, cannot assume that concentrations of Fe^{3+} and $FeOH^{2+}$ in the aqueous phase are linearly related to total iron concentration in analysis of equilibrium or kinetic data in the liquid–liquid, two-phase extraction system.

CONCLUSION

A chemical equilibrium model is developed to predict metal speciation and concentrations in the iron(III) sulfate system. The relations are highly nonlinear and give rise to a wide range of concen-

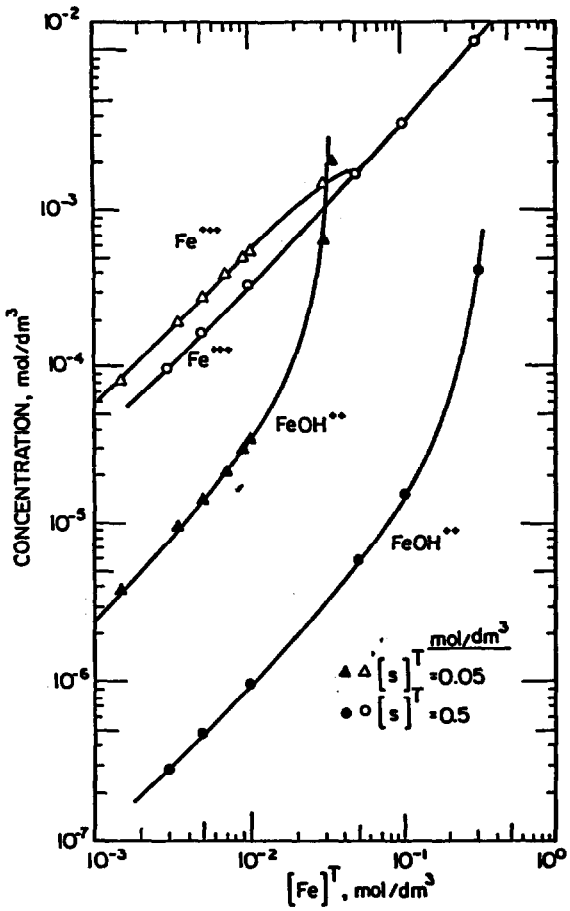

Fig. 4. Dependence of Fe^{3+} and $FeOH^{2+}$ concentrations on the total iron concentration at two levels of total sulfur concentration.

trations of the iron complexes over realistic concentration ranges.

Iron(III) extraction equilibrium and kinetics investigations in which the hydrogen ion, the ferric ion, and $FeOH^{2+}$ ion are considered important variables should include the effects of ionic interactions. Nonlinear dependence of Fe^{3+} and $FeOH^{2+}$ concentrations in the ferric sulfate–sulfuric acid solutions indicates that the consideration of ionic equilibria is necessary to obtain an accurate equilibrium model or chemical kinetic model for the two-phase extraction system.

The analysis above is readily employed to yield calculated values for the concentration of each species in ferric sulfate–sulfuric acid solution.

The temperature dependence of the ionic equilibria can be included if temperature dependence of the equilibrium constants can be obtained. This dependence can be estimated by the Van't Hoff equation if the enthalpy change for each reaction is available.

SOLUBILITY EQUILIBRIA OF SOLID SOLUTIONS OF HYDROXYL- AND CHLOR-APATITE OF ARSENIC

T. S. B. NARASARAJU, P. LAHIRI,* P. R. YADAV and U. S. RAI*
Department of Chemistry, Banaras Hindu University, Varanasi-221005, India

(*Received* 30 *January* 1984; *accepted* 2 *March* 1984)

Abstract—The solubility equilibria of arsenic hydroxylapatite, $Ca_{10}(AsO_4)_6(OH)_2$, chlorapatite, $Ca_{10}(AsO_4)_6(Cl)_2$, and their nine solid solutions were investigated at 37°C in the pH range, 4.6 to 7.8, in buffered systems through microanalytical determination of calcium, arsenic and chloride in their saturated solution. Stoichiometric dissolution of the samples was proved by the constancy of the ionic products of the apatite phase in the saturated solution.

Arsenic hydroxylapatite [AsHA], $Ca_{10}(AsO_4)_6(OH)_2$, which is an isomorph of calcium hydroxylapatite, $Ca_{10}(PO_4)_6(OH)_2$, is obtained by incorporation of arsenic in the human-skeletal system through $PO_4^{3-} \rightleftharpoons AsO_4^{3-}$ exchange.[1] The presence of a large excess of chloride ions in the body fluids enables the formation of another isomorph arsenic chlorapatite [AsClA], $Ca_{10}(AsO_4)_6(Cl)_2$, at the bone/body fluid interface. While partial replacement of OH^- by Cl^- in AsHA results in the formation of a series of solid solutions of hydroxyl- and chlor-apatite of arsenic complete replacement results in the formation of arsenic chlorapatite. The formation of AsHA and AsClA at the bone/body fluid interface leads to a disturbance in the calcium and phosphorus metabolism through a shift in the calcification and resorption equilibrium. Explanation and possible elimination of such pathological conditions can be provided by investigations on the solubility of AsHA, AsClA and their solid solutions under a simulated biological condition. The present work was undertaken to investigate the dependence of the solubility product of such samples on their chloride content which is significant from the biological point of view.

EXPERIMENTAL

While AsHA was obtained by a wet method[2,3] the AsClA and its solid solutions with AsHA were prepared by an appropriate solid state reaction[4,5] using AsHA and $CaCl_2$ as starting materials. The homogeneity of the samples were confirmed through chemical, X-ray, electronmicroscopic, infrared and thermal analyses as reported earlier.[5] The solubility product of each sample was investigated at the biologically significant temperature of 37°C by analyses of its saturated solution at a few chosen pH values in the range 4.70–7.38 in buffered systems, the final pH of each system being measured using a digital pH meter (pH 5651, E CIL). The experimental details for the equilibration of the samples to prepare their saturated solutions and to separate them from the likely colloidal component were reported earlier[6–8]. Microanalytical methods were used to determine the ingredients present in the saturated solution. Calcium was determined complexometrically[9,10] while arsenic and chloride were estimated spectrophotometrically[11–13], separate aliquots being taken each time.

RESULTS AND DISCUSSION

A few representative sets of results on the determination of the solubility product of AsHA, AsClA and nine of their solid solutions are included in Table 1. The hydroxyl ion concentration of each sample at a given pH was incorporated in column (6) of the table. The experimentally determined concentrations of calcium, arsenic and chloride are given in columns (3)–(5). In order to scrutinize stoichiometric dissolution of the samples the g · atom ratios, Ca/As are reported in column (8) of the table. From the total arsenic content, given in column (7) of the table and pH of the saturated solution, concentration of H_3AsO_4, $H_2AsO_4^-$, $HAsO_4^{2-}$ and AsO_4^{3-} were evaluated using the three

dissociation constants[14] of H_3AsO_4; $K_1 = 4.0 \times 10^{-3}$, $K_2 = 1.0 \times 10^{-7}$ and $K_3 = 3.2 \times 10^{-12}$ and pKw = 13.54. The concentrations of H_3AsO_4, $H_2AsO_4^-$ and $HAsO_4^{2-}$ are eliminated from the table as they are not used in the expression of the solubility product of apatitic phase. However, the concentrations of AsO_4^{3-}, needed to calculate the ionic product of the samples are reported in column (7) while the values of $pK_{ip}(-\log K_{ip})$ and their average are given in columns (9) and (10) respectively.

The buffer combination of desired pH maintained at a molarity of 0.165 with respect to sodium nitrate in order to keep the ionic strength constant was used as the medium of dissolution. To overcome the inaccuracy involved in the evaluation of the activity coefficients of the dissolved ionic species of these systems, La Mer[15] suggested that an aqueous solution of 0.165 M sodium chloride, a solvent of biological importance may be considered as a standard solvent of reference in which all the activity coefficients may be assigned the value of unity. Since the use of sodium chloride is not permissible in these systems sodium nitrate was used and the ionic product of the samples evaluated were taken as the solubility product.

The results included in the present table established that the solubilities of AsHA, AsClA and their solid solutions increased with increasing hydrogen ion concentration of the medium of dissolution. It can be attributed that a saturated aqueous solution of AsHA exhibits the following equilibrium:

$$Ca_{10}(AsO_4)_6(OH)_2 \rightleftharpoons 10Ca^{2+} + 6AsO_4^{3-} + 2OH^- . \quad (1)$$

The presence of AsO_4^{3-} ion in an aqueous media as a product of dissolution further establishes the following equilibria which are all pH dependent.

$$AsO_4^{3-} + H_3O^+ \rightleftharpoons HAsO_4^{2-} + H_2O \quad (2)$$

$$HAsO_4^{2-} + H_3O^+ \rightleftharpoons H_2AsO_4^- + H_2O \quad (3)$$

$$H_2AsO_4^- + H_3O^+ \rightleftharpoons H_3AsO_4 + H_2O \quad (4)$$

The OH^- ion of eqn (1) on the other hand participates in an additional pH dependent equilibrium characteristic of all aqueous media as shown below:

$$H_3O^+ + OH^- \rightleftharpoons 2H_2O. \quad (5)$$

A shift from left to right occurs in all the above equilibria when H_3O^+ ion concentration is increased. All these equilibria are collectively responsible for influencing equilibrium (1). But eqn (2) shows the presence of AsO_4^{3-} ion which being

a direct participant is naturally more dominant in influencing the equilibrium represented by eqn (1).

An additional enhancement of the solubility of apatite could be justified on the basis of eqn (5) which accounts for the removal of OH^- ion, a product of dissolution. The marked pH dependence of the solubilities of AsHA and its solid solutions with AsClA can thus be accounted for. Analogous to the equilibria operative in the case of AsHA as mentioned above, a saturated solution of AsClA is characterized by the following equilibrium in addition to those given in eqns (2)–(4).

$$Ca_{10}(AsO_4)_6(Cl)_2 \rightleftharpoons 10Ca^{2+} + 6AsO_4^{3-} + 2Cl^-. \quad (6)$$

It is evident that the role of equilibrium (5) being absent, the equilibrium (6) is controlled by equilibria (2)–(4). The above arguments are substantiated by the observed fact that the calculated proportion of AsO_4^{3-} ions of the saturated solution

given in column (7) of the table of all samples decreased with an increase in the hydrogen ion concentration of the medium of dissolution. The marked pH dependence of the solubilities of AsHA and its solid solution with AsClA can thus be accounted for.

Another significant finding of the present investigations has been that the solubilities of the samples were found to decrease with an increase in the proportion of their Cl^- content, the experimental conditions being the same. A three-pronged explanation to account for the lower solubility of AsClA over that of AsHA and for a systematic diminution of solubilities of the solid solutions with increasing chloride content may be suggested. The first is based on the thermoanalytical approach that the free energy of dissolution of an ionic crystal is dependent on ionic replacement and the lattice energy. The thermodynamical derivation which represents the dependence of the decrease in the free energy of dissolution of a solute on the radius of the anion replaced is given below:

$$\Delta^0_{G_{soln}} = \{(164Z^2 + m)/(r_+ + 0.85) - (164Z^2 - n)/(r_- + 0.1)\} + \{332Z^2/R_0 + \left(1 - \frac{1}{n_B}\right) - 8.03(m+n)\}(\text{k cal/mole}).$$

It involves the dependence of ΔG^0 solution on the replacement of an anion of the solute by another of a different ionic radius as the cations are the same in both solutes. The average change in the solubility of an ionic component depends exclusively on the relative variation in $\Delta G^0_{hydration}$ and $\Delta G^0_{lattice}$ term as shown above by the first and second terms for sparingly soluble salts like apatites. This is justified by the fact that the alterations in hydration energies[16] for the pair of ions involved (Cl^- and OH^- ions) in the replacement investigated are of very small magnitude. It is evident from the above expression that decrease in solubility increases when the change brought about by ionic replacement is more in lattice energy than in the hydration energy. The lattice energy of AsHA is lower than the chloride substituted product could be proved by noting their decomposition temperature from thermoanalytical studies.[13] The higher stability of AsClA over AsHA can be attributed to a more compact packing of ions in the lattice of Cl^- substituted apatites than that of AsHA. This in turn, is due to the spherical symmetry of Cl^- ions unlike that of OH^-. The observed decrease in the solubility of apatites with an increase in the chloride content of samples can thus be accounted for on the basis of the accompanying increase in the lattice energies.

The second explanation for the low solubilities of AsClA and solid solutions is based on the concept of ionic equilibria prevalent in these systems and on the divergence in the extent of dissociation of water and hydrochloric acid. The extent to which the ionic equilibrium of water (eqn 5) is affected, diminished as one goes from AsHA to AsClA due to depletion in the supply of OH^- ions accompanying dissolution. The equilibrium (5) remains unaffected as Cl^- ions produced due to dissolution of AsClA forms a highly dissociated hydrochloric acid.

The third explanation which can be applied exclusively to the lower solubilities of the solid solutions over that of AsHA is based on structural consideration as was shown by Young *et al.*[17] According to them ions such as F^-, Cl^- and OH^- or a combination of them exist in apatites in columns or linear chains coincident with their six-fold screw axis. It was established[18,19] through infrared spectral studies that the OH^- and Cl^- ions constituting the lattice of a solid solution of AsHA and AsClA are mutually linked up through hydrogen bonding. The hindrance caused to the diffusion of the OH^- ions through the column mentioned above can be a factor in reducing the solubility of chloride containing solutes since the columns offer themselves as the most vulnerable points[20,21] for the diffusion of the ions located in them into the medium of dissolution. A constant value for the solubility product of apatites at a given temperature and the agreement of ratios of measured concentrations of the dissolved species with the corresponding ratios of the solute could prove that the apatites exhibit stoichiometric dissolution.

(*Received* 25 *January* 1984; *accepted* 2 *March* 1984)

Abstract—The extraction of Cu(II) with 1-phenyl-3-methyl-4-acyl-5-pyrazolone (HA), in different organic solvents has been studied. The extraction mechanism of Cu(II) and the composition of the extracted species has been determined. Cu(II) was extracted as CuA_2, or in the presence of TOPO, as CuA_2TOPO. The extraction constants do not change regularly with increasing the length of acyl chain in the 1-phenyl-3-methyl-4-acyl-5-pyrazolone derivatives. The effect of the temperature on the extraction of Cu(II) has also been investigated.

Metal extraction from aqueous solution with 1 - phenyl - 3 - methyl - 4 - benzoyl - 5 - pyrazolone (PMBP) has been studied extensively.[1–9] PMBP is an excellent complexing agent of metals due to the great reactivity of its –CO group and stability of its complex. The extraction of Cu(II) by PMBP from aqueous solution has also been reported in a previous paper by Mirza[10] and Zolotov *et al.*[11] Recently 1 - aryl - 3 - methyl - 4 - aroyl - 5 - pyrazolone has been introduced for extraction of La(III) and Ba(II) by Umetani *et al.*[12] Furthermore, Tochiyama *et al.*[13] developed a method for the extraction of lanthanides, using a mixture of 1 - phenyl - 3 - methyl - 4 - octanoyl - 5 - pyrazolone and TOPO. However, there has been little systematic study of the extraction of metal ions utilizing the 1 - phenyl - 3 - methyl - 4 - acyl - 5 - pyrazolone derivatives. Thus, the acyl derivatives of the type $(C_{10}H_9N_2O)$-$(C_nH_{2n+1}CO)$ (n = 2–10) were synthesized systematically by our laboratory and the solvent extraction of various metal ions by these derivatives has been investigated. Compared to other β-diketones such as TTA and AA, these derivatives have a lower pKa value. Therefore, it was hoped that these derivatives might prove to be more attractive as ligands for the extraction of metals. The present work was undertaken in order to investigate the extraction equilibria of Cu(II) at 25°C utilizing these derivatives in different organic solvents and the dependence of the extraction constants on the number of carbon atoms in the acyl chain.

Data on the extraction of metal ions with PMBP at various temperatures are very scarce. Therefore, the temperature dependence of the extraction constant was also measured in the range of 6–37°C for the extraction of Cu(II) by PMBP diluted with MIBK.

EXPERIMENTAL

Reagents. 1 - phenyl - 3 - methyl - 4 - acyl - 5 - pyrazolone was synthesized as described[14] and purified by several recrystallizations from methanol, and elemental analysis was done for these reagents as shown in Table 1. Here the reagents are represented by C_N in which N means the number of carbon atoms involved in the acyl chain. The solution of Cu was prepared by dissolution of 1.00 g Cu metal (99.99%) in nitric acid solution, and 10 ppm Cu(II) solution was used for the extraction studies. All other chemicals were of analytical grade.

C_{11} : $C_{21}H_{30}N_2O_2$; PMBP : $C_{17}H_{14}N_2O_2$

b) Calculated values are given in parentheses .

Procedure. Equal volumes (10 cm^3) of the aqueous (10 ppm Cu) and organic (0.01M PMBP or any other reagents) phases were shaken mechanically in a 50 cm^3 glass-stopped centrifuge tube for about 30 min at 25°C. The aqueous pH was controlled by the addition of perchloric acid, while the ionic strength was kept at 0.1 M with sodium perchlorate. After centrifugation, the copper in the aqueous phase was determined by atomic absorption. The amount of copper extracted into the organic phase was obtained from the difference between the aqueous copper concentration before and after the equilibration. The pH of the aqueous phase was also measured after the extraction in all experiments.

RESULTS AND DISCUSSION

The solvent extraction behaviour of Cu(II) can be understood by the variation of distribution ratio D as a function of the aqueous phase acidity and as a function of the extractant concentration. For the extraction of Cu(II), plot of log D vs log [reagent concentration] at constant ionic strength and pH are in all cases linear with slope 2 indicating that the complexes formed are CuA_2. The experimental data obtained for the extraction of Cu(II) by C_8-benzene and PMBP–MIBK solutions are given in Fig. 1. The total concentrations of the reagent are plotted instead of the equilibrium concentrations, as these magnitudes are directly proportional. The plots of log D vs pH also gave straight lines of slope near 2, indicating that 2 moles of hydrogen ions are released during the formation of the extracted species. The results of experiments are presented in Fig. 2, for 0.01M C_8 in chloroform, benzene and MIBK. These plots were in all other 4-acyl derivatives [HA] straight lines with a slope of 2. Thus, the extraction process may be represented by the equation

$$Cu^{2+} + 2HA \rightleftharpoons CuA_2 + 2H^+$$

$$K_{ex} = [CuA_2]_{org}[H^+]^2_{aq}/[Cu^{2+}]_{aq}[HA]^2_{org}$$

hence

$$\log K_{ex} = \log D - 2pH + 2\log [HA]:$$

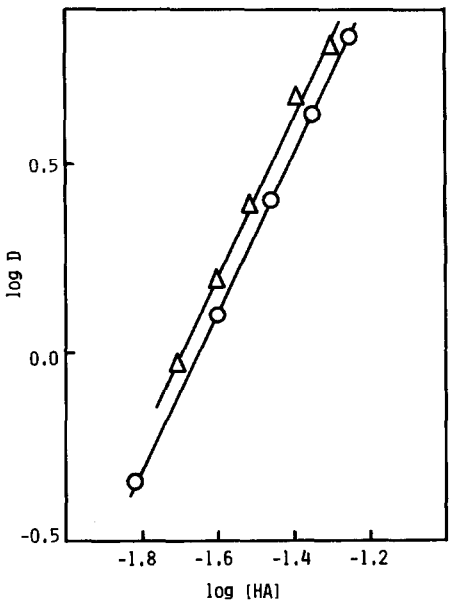

Fig. 1. Variation of distribution ratio for Cu(II) as a function of PMBP and C_8 concentration at constant pH. –△–, C_8 in benzene, pH = 1.54: –○–, PMBP in MIBK, pH = 1.07.

where HA represents the ligand, A its anion and K_{ex} is the extraction constant for copper complex. The index *org* and *aq* denote organic and aqueous phase respectively, and D is the distribution ratio of Cu(II).

The values of log K_{ex} have been calculated for all the systems as shown in Fig. 3. The extraction does not change regularly with increasing the length of acyl chain in the extractant. As can be seen from Fig. 3, the log K_{ex} values between C_3 and C_{11} were constant in MIBK, benzene and chloroform systems, respectively. When benzene was used as organic solvent for the extraction of Cu(II) with PMBP, the value of log K_{ex} is 0.55 and is about 0.2 for 4-acyl derivatives. On the other hand, the values[15] of log K_{ex} for $Cu(TTA)_2$ and $Cu(AA)_2$ complexes in benzene were −1.32 and −3.93 respectively. Thus, these 4-acyl derivatives and PMBP have a larger extraction constant for Cu(II) than TTA and AA. This effect is certainly due to the large acid dissociation constant of 4-acyl derivatives compared to the other β-diketones. The values of pKa for 4-acyl derivatives and PMBP were measured in 10% (v/v) dioxane–water at 25°C, which were given in Table 1. It is apparent from the results that the increase in number of methylene groups in these derivatives did not have an important influence on the acid dissociation.

A comparison of log K_{ex} value shows that Cu(II)

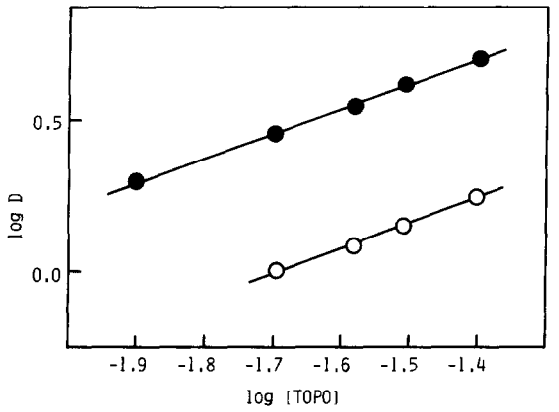

Fig. 5. Variation of distribution ratio for Cu(II) as a function of TOPO concentration (PMBP = 0.01M). —●—, pH = 1.55; —○—, pH = 1.34.

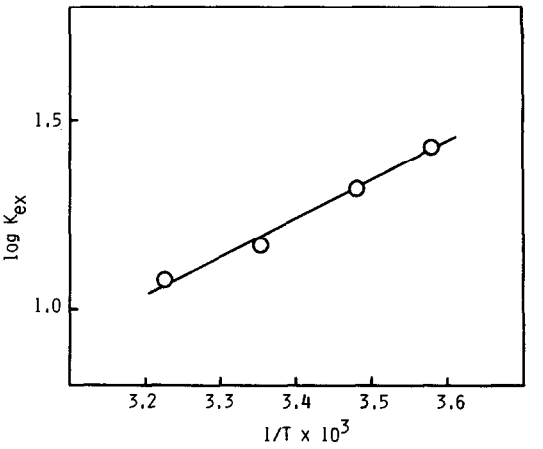

Fig. 7. Variation of extraction constant for Cu(II) as a function of temperature.

is better extracted by MIBK-4-acyl derivative systems than benzene and chloroform. However, when benzene or chloroform were used as organic solvents the value of log K_{ex}, showed no marked difference. The higher extractibility of the Cu(II) complexes in the MIBK-4-acyl derivative systems, as represented by K_{ex} values, may be due to the difference in the distribution coefficient of the Cu(II) complexes or synergistic effect by MIBK. Furthermore, the small difference of the K_{ex} values between the PMBP and other 4-acyl derivatives is certainly due to the difference in the acid dissociation constant of these extractants. It appears that PMBP is a better extractant of Cu(II) than other 4-acyl derivatives in the same experimental conditions.

The effect of the addition of trioctyl phosphine oxide (TOPO) to the organic phase has also been studied. When TOPO is added to the PMBP-benzene solution, the synergistic effect is observed, i.e. an enhancement of the distribution ratio of Cu(II). In order to find the extraction mechanism, the influence of various factors upon the distribution ratio was investigated. The plots of log D vs pH of the aqueous phase in the presence and the absence of TOPO gave straight lines with a slope of 2, respectively, as shown in Fig. 4. The slope 2 for the linear region of these curves indicates that two molecules of PMBP are involved in the extracted species of Cu(II).

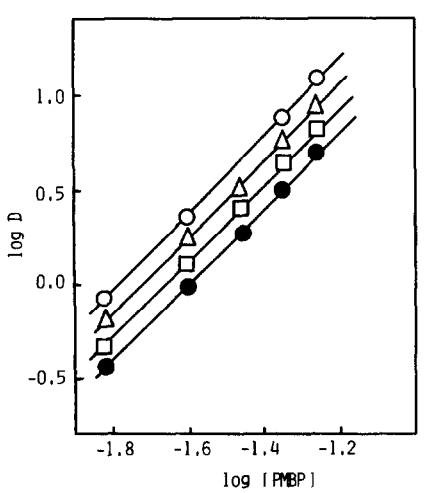

Fig. 6. Variation of distribution ratio for Cu(II) as a function of PMBP concentration in MIBK at constant temperature and pH (1.06) —○—, 6°C; —△—, 14.5°C; —□—, 25°C; —●—, 37°C.

The influence of TOPO concentration on the distribution ratio of Cu(II) at constant pH of aqueous phase and constant PMBP concentration was studied. The results obtained are presented in Fig. 5. The slope near 1 of curves indicating that only one TOPO molecule is associated with the extracted species of Cu(II). The overall reaction mechanism of the synergistic extraction can be written as follows:

$$Cu^{2+} + 2HPMBP + TOPO \rightleftharpoons [Cu(PMBP)_2TOPO] + 2H^+.$$

The extraction of Cu(II) with various concentrations of PMBP in MIBK at temperature between 6 and 37°C gave the results in Fig. 6. The values of the extraction constant increase monotonously with a decrease in the temperature. A plot of log K_{ex} against 1/T gave a straight line as shown in Fig. 7. The value of the enthalpy change, ΔH of -19.3 kJ/mol was calculated from the slope.

SELENIUM DIBROMIDE AND DICHLORIDE IN ACETONITRILE

JOHN MILNE
Ottawa-Carleton Institute for Research and Graduate Studies in Chemistry, University of Ottawa Campus, Ottawa, Canada, K1N 9B4

(*Received* 31 *January* 1984; *accepted* 2 *March* 1984)

Abstract—The nature of 2/1 Cl/Se and Br/Se stoichiometric mixtures in acetonitrile has been studied by UV-visible and Raman spectroscopy. For both mixtures the selenium dihalide has been shown to be the predominant species in solution, although there are other species present in equilibrium with the dihalide, according to

$$3SeCl_2 = Se_2Cl_2 + SeCl_4$$

$$2SeBr_2 = Se_2Br_2 + Br_2$$

as demonstrated by both techniques. The Raman spectra of $SeCl_2$ and $SeBr_2$ are given. Force constant calculations show that the bonds in the dihalides are the strongest SeCl and SeBr bonds known.

Diorganyl selenium compounds are well-known in the chemical literature but little work has been carried out on the dihalides, which are only known in the gas phase, or in the case of selenium bromide, in solution. Attempts to isolate the solids (or liquids) leads to disproportionation producing elemental selenium, diselenium dihalide and the tetrahalide.[1,2] In non-aqueous solutions, selenium tetrabromide yields $SeBr_2$, Br_2 and Se_2Br_2.[3,4] However, $SeCl_4$ remains intact as the monomer in solution.[5] The Raman spectrum of $SeCl_2$ has been recorded at 350°C,[6] but that of $SeBr_2$ has not yet been published. Selenium dichloride has been shown to exist in concentrated HCl[7] but its existance in non-aqueous solvents has not yet been studied. Selenium difluoride has been studied by matrix isolation[8] and force constants have been calculated. It was considered of interest to study the equilibria involving selenium dichloride and dibromide in acetonitrile by UV-visible spectrophotometry, establish their Raman spectra and determine the stretching force constants for these interesting molecules for comparison with the force constants of the related seleninyl halides.[9]

EXPERIMENTAL

Materials

Acetonitrile (MeCN) and nitromethane ($MeNO_2$) were purified by refluxing over P_2O_5 for one hour and distilling (respective B. P. 81–82°C and 100–1°C). Selenium (Baker AR) was ground before use. Bromine (Baker AR) was distilled (boiling point 59°C). Selenium tetrabromide and selenium tetrachloride were prepared according to standard methods.[10,11]

Procedures

Solutions of selenium tetrahalide, selenium dihalide and diselenium dihalide in acetonitrile were made up by weight from appropriate stoichiometric ratios of selenium and selenium tetrahalide. Spectrophotometric measurements were made with a Varian DMS 90 UV-visible spectrophotometer using 1 mm path-length quartz cells. Raman spectra were recorded using a Jobin-Yvon monochromator in conjunction with PAR photon counting. The spectra were excited with a Spectra Physics krypton ion laser operating at 647.1 nm. All spectra were recorded at 25°C.

RESULTS AND DISCUSSION

UV-visible spectrophotometry

The spectra of a 1.2×10^{-3} mol l^{-1} solution of Se_2Cl_2 and 6.2×10^{-4} mol l^{-1} solution of $SeCl_4$ in MeCN are given in Fig. 1 (traces A and B respectively). Selenium tetrachloride exhibits a shoulder at 255 nm and a peak at 225 nm while diselenium dichloride shows a shoulder at 340 nm and peaks at 295 and 245 nm. The spectrum of a solution with Se-Cl stoichiometry corresponding to that of $SeCl_2$ ($c_{Se} = 3.1 \times 10^{-3}$ mol l^{-1}) is also shown in Fig. 1 (trace D); this spectrum has bands

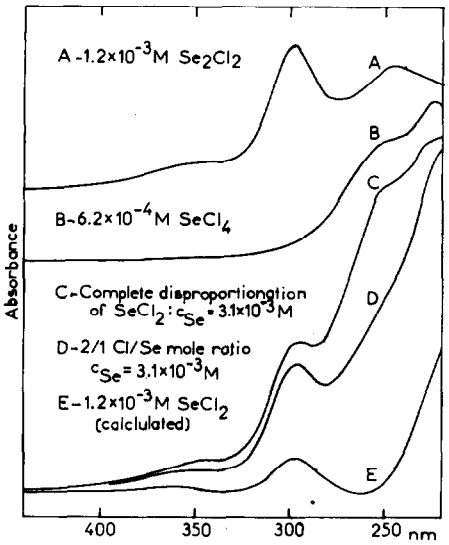

Fig. 1. UV-visible spectra of selenium chlorides in MeCN.

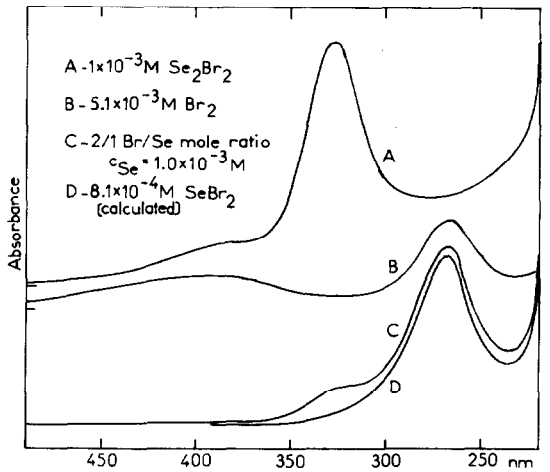

Fig. 2. UV-visible spectra of selenium bromides in MeCN.

corresponding to those of $SeCl_4$ and Se_2Cl_2 suggesting that $SeCl_2$ is completely disproportionated in MeCN according to

$$3SeCl_2 \overset{K_{disp}}{\rightleftharpoons} Se_2Cl_2 + SeCl_4. \quad (1)$$

However, calculation of the spectrum for complete disproportionation of $SeCl_2$ in this solution ($[Se_2Cl_2] = [SeCl_4] = 1.0 \times 10^{-3}$ mol l^{-1}) gives the trace designated as C in Fig. 1. Complete disproportionation does not account for the observed spectrum and some $SeCl_2$ must be present. By assuming various concentrations of Se_2Cl_2 ($[Se_2Cl_2] = [SeCl_4]$) and using the spectra of these species, the spectrum of $SeCl_2$ may be generated by difference from the observed spectrum for 2/1 mole ratio Cl/Se stoichiometry (trace D). The lowest concentration of $SeCl_2$ producing a spectrum which is positive across the measured range of wavelength (220–500 nm) is 1.2×10^{-3} mol l^{-1}; this corresponds to a disproportionation constant K_{disp} ($K_{disp} = [Se_2Cl_2][SeCl_4]/[SeCl_2]^3$) of 2.1×10^2 $mol^{-1}l$. The $SeCl_2$ spectrum generated is given in Fig. 1 (trace E). The concentration of $SeCl_2$ must however be regarded as a minimum, and K_{disp} is smaller than 2.1×10^2 $mol^{-1}l$ as is indicated by the Raman spectra discussed below. At this concentration, even with this minimum amount of $SeCl_2$ present the $SeCl_2$ represents 0.45 mole fraction of all the selenium species whereas Se_2Cl_2 and $SeCl_4$ represent 0.225 mole fraction each.

Selenium tetrabromide is known to decompose in non-aqueous solvents to $SeBr_2$, Se_2Br_2 and Br_2.[3,4] The spectrum of a solution in MeCN, corresponding to the stoichiometry for $SeBr_2$, $c_{SeBr_2} = 1 \times 10^{-3}$ mol l^{-1}, is given in Fig. 2 (trace C). The spectra of Se_2Br_2, 1.0×10^{-3} mol l^{-1} (trace A) and Br_2, 5.1×10^{-3} mol l^{-1} (trace B) are given in the same figure The spectrum corresponding to $SeBr_2$ has a shoulder at 327 nm corresponding to the principal peak in the spectrum of Se_2Br_2, but the intensity of the peak at 268 nm is far too great to be accounted for by Br_2 alone, which has a peak near this wavelength. The strong peak at 268 nm is due to $SeBr_2$; as in carbon tetrachloride,[3] $SeBr_2$ represents the major constituent in solutions of 2 : 1 Br/Se stoichiometry. Selenium dibromide absorbs weakly at 390 nm, whereas both Br_2 and Se_2Br_2 absorb strongly.[3] The absorbance at this wavelength may be used to evaluate the equilibrium constant for the reaction

$$2SeBr_2 \overset{K_d}{\rightleftharpoons} Se_2Br_2 + Br_2. \quad (2)$$

Using the extinction coefficients at 390 nm for Br_2 and Se_2Br_2 (146 and 920 $cm^{-1}mol^{-1}$ respectively), the concentrations of Br_2 and Se_2Br_2 may be evaluated ($[Br_2] = [Se_2Br_2] = 0.94 \times 10^{-4}$ mol l^{-1}); the concentration of $SeBr_2$ may be determined from the difference ($[SeBr_2] = 8.1 \times 10^{-4}$ mol l^{-1}). The equilibrium constant, K_d, for this reaction is 1.4×10^{-2}. The spectrum of $SeBr_2$ (trace D in Fig. 2) is determined by subtracting the spectra of Br_2 and Se_2Br_2 from trace C in Fig. 2. The equilibrium constant, K_d, is smaller than that observed for the same equilibrium in carbon tetrachloride, indicating a relatively greater stability for $SeBr_2$ in MeCN. This probably results from the greater basicity of MeCN relative to that of carbon tetrachloride, producing stronger solvation.

Raman spectroscopy

The Raman spectrum of Se_2Cl_2 in MeCN, listed in Table 1, is very similar to that reported by Kiefer[12] for Se_2Cl_2. The strongest band at 369 cm^{-1} in coincident with an MeCN band; for purposes of identification of Se_2Cl_2 in solution, the band at 138 cm^{-1}, which is also quite strong, can be used. The spectrum of $SeCl_4$ in MeCN exhibits an band at 258 cm^{-1} and additional stronger bands which lie under the solvent peak at 370 cm^{-1}. In nitromethane ($MeNO_2$), which has no bands in this region, $SeCl_4$ bands are observed at 357 and 392 cm^{-1}. In neither case is a band observed at 545 cm^{-1} where elemental chlorine exhibits a peak.[6] Unlike $SeBr_4$, or $SeCl_4$ in the gas phase at 350°C,[6] $SeCl_4$ is stable in these solvents. The spectrum of a solution in MeCN with a 2/1 Cl/Se stoichiometry, which is listed in Table 1, is clearly not consistent with that expected for a mixture of $SeCl_4$ and Se_2Cl_2. A strong peak is observed at 412 cm^{-1}, an additional peak at 381 cm^{-1} is partly masked by the solvent band at 370 cm^{-1} and a third band is observed at 165 cm^{-1}. The only peak observed which can be attributed to either of the disproportionation products is that at 135 cm^{-1} due to Se_2Cl_2. There must therefore also be a small contribution to the peak at 381 cm^{-1} from Se_2Cl_2 (369 cm^{-1}) as well as that from the solvent. The spectrum of $SeCl_2$ in acetonitrile agrees well with that observed by Ozin and Van der Voet for $SeCl_2$ in the gas phase at 350°C.[6] It should be noted that the predominance of $SeCl_2$ in these solutions, where concentrations are several times greater than those solutions studied by UV-visible spectrophotometry, indicates that K_d is smaller than the estimate determined above on the basis of the UV-visible spectra.

The spectra of selenium bromides in acetonitrile solutions, which are red in color, are very difficult to obtain due to absorption of the laser exciting line. No spectra could be obtained using argon ion laser excitation. However, by utilizing the krypton ion laser line at 647.1 nm and by using solutions relatively dilute for Raman spectroscopy in solution (~ 0.3 mol l^{-1}), it was possible to obtain reasonable spectra of solutions with 2/1 Br/Se stoichiometry. The spectra show no bands due to Br_2 (304 cm^{-1} for MeCN solution) or for Se_2Br_2 (strongest band at 254 cm^{-1})[12] as expected from the equilibrium constant determined above, which indicates a $SeBr_2$ concentration nearly 9 times greater than that of Se_2Br_2 ($[Se_2Br_2] = [Br_2]$). Apparently the concentration of these dissociation products is too low for observation. Polarization measurements on the spectrum of $SeBr_2$ indicates that the band at 266 cm^{-1} is the symmetric SeBr stretching mode, which lies below the antisymmetric stretching mode at 290 cm^{-1}, observed in the infrared spectrum of non-aqueous solutions of $SeBr_2$.[4]

Force constants

The three bands observed in the Raman spectra for $SeCl_2$ and $SeBr_2$ can be used to calculate force constants for these molecules with a quite reasonable degree of accuracy. The General Valence Force Field equations given by Siebert[13] may be used, assuming the stretch-bend interaction con-

stant to be negligible. The vibrational assignment, bond angle ($\angle$(XSeX))[8,14] and calculated force constants are given in Table 2. The set of force constants for SeF_2, based upon the matrix isolation spectra of Willner,[8] assuming the stretch-bend interaction constant, g, to be zero, are also given in Table 2. The effect on the SeF stretching force constant of ignoring g is small;[8] in general, for purposes of comparing stretching force constants, the calculations are acceptable. As expected, the stretching force constants decrease with increasing halogen atomic weight, reflecting a decrease in SeX bond strength. The remarkable feature of these SeX bond stretching force constants is their magnitude. In the case of the chlorides and bromides they are the largest SeX force constants measured. In the case of SeF_2 only the equatorial SeF bonds in SeF_4 are stronger. In all cases the stretching constants are greater than those of the analogous seleninyl halides. The replacement of a non-bonded electron pair in SeX_2 molecules by a doubly-bonded oxygen

rather than strengthening the SeX bonds, as expected on the basis of the resultant electron withdrawal from selenium, in fact causes a weakening of these bonds. In the case of $SeCl_2$ and $SeOCl_2$, this weakening of the bond is also reflected in SeCl bond lengths, 2.18 and 2.20 Å respectively.[15,16] It is interesting to note in this connection that the doubly-bonded oxygen repels neighbouring SeCl bond pairs in the $SeOCl_3^-$ anion more strongly than does the non-bonded electron pair.[17]

MOLYBDENUM CARBONYL COMPLEXES OF BINUCLEATING PYRIDINE-BASED LIGANDS

JOSEPH A. CONNOR,* E. JOYCE JAMES and COLIN OVERTON
Chemical Laboratory, University of Kent, Canterbury, Kent CT2 7NH, England

(*Received* 1 *February* 1984; *accepted* 2 *March* 1984)

Abstract—Reaction of $[Mo(CO)_4(diene)]$ with 4,4′-bipyridine (44′B), *trans*-1,2-bis(2-pyridyl)ethene (2-bpe) and *trans*-1,2-*bis*(4-pyridyl)-ethene (4-bpe) gives polymeric $[Mo(CO)_4(44'B)]_n$, mononuclear *cis*-$[Mo(CO)_4(2\text{-bpe})_2]$ and binuclear $[Mo(CO)_4(4\text{-bpe})]_2$ respectively. Reaction of the same ligands with $[Mo(CO)_4(bpy)]$ (bpy is 2,2′-bipyridine) produces the bridged binuclear complexes $[\{Mo(CO)_3(bpy)\}_2(44'B)]$ and $[\{Mo(CO)_3(bpy)\}_2(4\text{-bpe})]$. Products are characterised by microanalysis and spectroscopy (IR, ^1H NMR, UV/vis). Reduction of $[\{Mo(CO)_3(bpy)\}_2(44'B)]$ produces an anion in which the unpaired electron is localised on the chelating bpy ligand.

Complexes in which there is electronic interaction through a conjugated bridging ligand between two metal atoms in different formal oxidation states are the objects of attention as models for electron transfer reactions.[1] A rich variety of such models incorporating later members of the *d*-transition series iron, cobalt, ruthenium and rhodium, have been described, but relatively few compounds containing earlier members of the series have been prepared.[2] We report the results of investigations of the reaction of the molybdenum(0) complexes *cis*-$[Mo(CO)_4L_2]$ (L_2 is bicyclo-[2.2.1]-hepta-2,4-diene, or 2,2′-bipyridine) with potentially binucleating ligands 4,4′-bipyridine (44′B), *trans*-1,2-bis(2-pyridyl)ethene (2-bpe) and *trans*-1,2-bis(4-pyridyl)ethene (4-bpe). Our observations emphasize the influence of both steric constraints and chelation in defining the substitution products and suggest that the interaction between the metal atoms in these binuclear products is only weak.

RESULTS

Substitution in hexacarbonylmolybdenum. Reaction between hexacarbonylmolybdenum and 44′B in refluxing toluene produced a bright red insoluble precipitate which was shown to be the polymer $[Mo(CO)_4(44'B)]_n$ rather than the molecular binuclear complex $[Mo_2(CO)_{10}(\mu^2\text{-}44'B)]$. Attempts to prepare this molecular binuclear complex by halide substitution[3] in $[Mo(CO)_5Br]^-$ with 44′B in the presence of $AgBF_4$ were similarly unsuccessful. Reaction between equimolar quantities of $[Mo(CO)_5(THF)]$ and 44′B in dichloromethane gave an orange product characterised as $[Mo(CO)_5(44'B)]$ by microanalysis and IR spectra: reaction of this rather poorly-soluble material with further $[Mo(CO)_5(THF)]$(1 mol) produced insoluble red material which was shown to be $[Mo(CO)_4(44'B)]_n$ from analysis and IR spectra. Reaction between $Mo(CO)_6$ and 2-bpe in toluene at reflux temperature gives orange $[Mo(CO)_4(2\text{-bpe})_2]$.

Substitution in (*bicyclo*[2.2.1]-*hepta*-2,4-*diene*) *tetracarbonylmolybdenum*, [*Mo*(*CO*)$_4$(*NBD*)]. This complex is known[4] to react under mild conditions with 2,2′bipyridine (bpy) to substitute the diene and form the mononuclear complex *cis*-$[Mo(CO)_4(bpy)]$. With 44′B, the product of the substitution reaction is the red polymer $[Mo(CO)_4(44'B)]_n$. Introduction of an olefinic link in the substituting ligand as in 4-bpe leads to a dark red binuclear complex $[Mo(CO)_4(4\text{-bpe})]_2$, on reaction with $[Mo(CO)_4(NBD)]$ in THF, rather than either $[Mo(CO)_4(4\text{-bpe})_2]$ or a polymer. A simple change in ligand geometry between 4-bpe and 2-bpe results in the formation of a yellow-orange mononuclear $[Mo(CO)_4(2\text{-bpe})_2]$, in which one donor nitrogen atom on each ligand is not coordinated, rather than $[Mo(CO)_4(2\text{-bpe})]_2$.

Substitution in (2,2′-*bipyridine*)*tetracarbonyl-molybdenum*, [*Mo*(*CO*)$_4$(*bpy*)]. This complex reacts with bpy at high temperature (refluxing tetralin or 1-methylnaphthalene) to form[5] *cis*-$[Mo(CO)_2(bpy)_2]$. With 44′B as nucleophile, substitution

*Author to whom correspondence should be addressed.

proceeds under much milder conditions in refluxing acetonitrile solution to form the black, binuclear, air-stable complex [{Mo(CO)$_3$(bpy)}$_2$(44′B)]. This complex is rather poorly soluble in most solvents at room temperature. The analogous complex of 4,4′-di(*t*-butyl)-2,2′-bipyridine, L_R, namely [{Mo(CO)$_3L_R$}$_2$(44′B)] prepared from *cis*-[Mo(CO)$_4L_R$], is fairly soluble in common organic solvents and can be crystallised from chloroform. The reaction of [Mo(CO)$_4$(bpy)] with 4-bpe in refluxing acetonitrile gave the purple–black, binuclear air-stable complex [{Mo(CO)$_3$(bpy)}$_2$(4-bpe)]. Surprisingly, there was no net reaction between [Mo(CO)$_4$(bpy)] and 2-bpe under similar conditions (refluxing acetonitrile): only unchanged starting materials were recovered.

Spectroscopic measurements

IR spectra in the region 2100–1600 cm^{-1} both in the solid state and in solution are consistent with *cis*-disubstitution in [Mo(CO)$_4$(2-bpe)$_2$] and [Mo(CO)$_4$(4-bpe)]$_2$, and with *fac*-geometry in [{Mo(CO)$_3$(bpy)}$_2$L] (L = 44′B, 4-bpe) (Table 1). The presence of a second metal atom in the binuclear systems exerts no significant influence on the frequency of the ν(CO) absorptions. The position of the lowest energy MLCT band in the visible region of the electronic spectrum (Table 1) demonstrates the effect of extending the chromophore in the binuclear complexes by comparing [Mo(CO)$_4$(bpy)](431 nm) with [{Mo(CO)$_3$(bpy)}$_2$(44′B)] (489 nm) and [{Mo(CO)$_3$(bpy)}$_2$(4-bpe)] (580 nm).

In the ^{1}H NMR spectra, the coordination shifts of the binucleating ligands 44′B and 4-bpe are generally small (*ca.* 0.1 ppm) and rather insensitive to changes occurring at the metal atom (Table 2); however, there are significant shifts in the resonances of the spectator bpy ligands which, with the exception of H6, generally move to lower field.

Reduction reactions

Reduction of [{Mo(CO)$_3$(bpy)}$_2$(44′B)] with potassium amalgam in dimethoxyethane solution gives a red-purple solution. The ESR spectrum of this solution is very similar to that of the bpy radical anion with g_{av} 2.005 and a signal width of 25G. Reduction of [{Mo(CO)$_3L_R$}$_2$(44′B)] (which is more soluble in dimethoxyethane) produced a red-purple solution. The ESR spectrum of this solution is qualitatively different to the foregoing and very similar to that of the L_R radical anion with g_{av} 2.006 (28G). These spectra were quite distinct from the spectrum of the 44′B radical anion produced under similar conditions. These experiments strongly suggest that the unpaired electron density is largely localised on the bpy (or L_R) ligand rather than on the 44′B ligand in these complexes. There is no evidence for molybdenum hyperfine interaction in these spectra.

DISCUSSION

Our lack of success in preparing either [Mo(CO)$_4$(44′B)$_2$] or [Mo$_2$(CO)$_{10}$(44′B)] by apparently obvious and straightforward methods stands in contrast to the ease with which [Mo(CO)$_4$(2-bpe)$_2$] was prepared. The lability of [Mo$_2$(CO)$_{10}$(pyrazine)] in solution has been described.[6] The influence of the ethene link, both in imposing stereochemistry and restricting reactivity by steric factors is evident from a comparison of results reported here. Thus, whereas bpy provides a chelate complex *cis*-[Mo(CO)$_4$(bpy)], 2-bpe forms a di-substituted mononuclear complex *cis*-[Mo(CO)$_4$(2-bpe)$_2$], and whereas 44′B forms polymeric [Mo(CO)$_4$(44′B)]$_n$, 4-bpe will form a bi-

nuclear complex $[Mo(CO)_4(4\text{-bpe})]_2$. The contrast between the complexes $[Mo(CO)_4(2\text{-bpe})_2]$ and $[Mo(CO)_4(4\text{-bpe})]_2$ emphasizes the importance of the mutual disposition of the donor functions in these ligands which is underlined by the formation of $[\{Mo(CO)_3(bpy)\}_2(4\text{-bpe})]$ in comparison with the apparent inability of 2-bpe to form an analogous bridged binuclear complex.

NMR studies suggest that the binucleating ligands 44'B and 4-bpe do not undergo much net change when coordinated as bridging ligands, whereas the chelating bpy or L_R ligands in the same complexes do experience change as a result of the introduction of either 44'B or 4-bpe. These observations are emphasized by the results of the one-electron reduction of the complexes $[\{Mo(CO)_3(bpy)\}_2(44'B)]$ and $[\{Mo(CO)_3(L_R)\}_2(44'B)]$ in which the chelating (bpy or L_R) ligand is reduced rather than the bridging (44'B) ligand. These observations are in contrast to those[7] on the one-electron reduction of $[Mo_2(CO)_8(bpym)]$ (bpym is 2,2'-bipyrimidine) in which the binucleating, bridging ligand is reduced. Later experiments on $[Mo_2(CO)_8(bpym)]$ have shown that electrochemical reduction in THF is reversible ($E_{\frac{1}{2}} = -0.67, -1.51$ V vs S.C.E.). The one-electron reduction product ($E_{\frac{1}{2}} = -0.67$ V) shows a complex 5-line ESR signal (g_{av} 2.0022) consistent with localisation of the unpaired electron density on molybdenum. Electrochemical studies on $[\{Mo(CO)_3(bpy)\}_2(44'B)]$ in acetonitrile solution indicate that both oxidation ($E_{\frac{1}{2}} = +0.3$ V) and reduction ($E_{\frac{1}{2}} = -1.62, -1.88$) are reversible.

EXPERIMENTAL

All preparations were carried out in an atmosphere of oxygen-free dry dinitrogen. Solvents were dried, deaerated and distilled under nitrogen immediately prior to use. IR spectra were recorded in solution using 1.0 mm path length solution cells and as mulls with Nujol and hexachlorobutadiene on PE 257 or 625 spectrometers. UV and visible spectra were recorded on a Unicam SP 800 spectrometer. NMR spectra were recorded on either Brucker WP 80 or Jeol PS 100 spectrometers using Fourier transform techniques. ESR spectra were recorded on a Varian E 112 spectrometer operating at 9.238 GHz.

Microanalyses were carried out by Mr. M. Hart at Manchester and Mr. A. Fassam at Canterbury. Molybdenum hexacarbonyl was purchased from Pressure Chemical, Pittsburg, and 4,4'-bipyridyl, 2-bpe and 4-bpe were purchased from Aldrich. The complex $[Mo(CO)_4(\eta^2, \eta^2\text{-}C_7H_8)]$ was prepared,

using freshly distilled bicyclo[2.2.1]hepta-2,4-diene, according to the literature.[8]

Preparation of (4,4′-bipyridine)tetracarbonylmolybdenum polymer

Freshly sublimed hexacarbonylmolybdenum (1.00 g, 3.78 mmol) and 4,4′-bipyridine (0.29g, 1.85 mmol) were heated together in toluene at reflux for 6h under anaerobic conditions. On cooling the mixture, a bright red precipitate was isolated by filtration from the yellow mother liquor and extracted with warm petroleum ether (60–80°C boiling fraction) (5 × 50 cm^3). The red powder was dried in a vacuum to yield 0.59 g of material (43% yield based on Mo). Found: C, 45.5; H, 2.1; Mo, 27.5; N, 7.6. Calc. for $(C_{14}H_8MoN_2O_4)_n$: C, 46.1; H, 2.2; Mo, 26.4; N, 7.7%.

Preparation of (4,4-bipyridine)pentacarbonylmolybdenum

(a) A mixture of $Et_4N[Mo(CO)_5Br]$ (0.446 g, 1 mmol)[9] and 4,4′-bipyridine (0.156 g, 1 mmol) in dichloromethane (30 cm^3) was treated with $AgBF_4$ (0.19 g, 1 mmol) and stirred rapidly. Filtration after 15 minutes was followed by concentration by distillation under reduced pressure to give a red solid which did not redissolve. Found C, 45.3; H, 2.3; N, 7.4.

(b) A solution of 4,4′-bipyridine (0.31 g, 2 mmol) in dichloromethane was added to $[Mo(CO)_5(THF)]$ (*ca.* 0.6 g based on presumed quantitative conversion of 0.53 g $Mo(CO)_6$ in THF) at room temperature. An orange solid which precipitated from the mixture was isolated by filtration. This solid appears to be photosensitive and is converted by the action of direct sunlight to the red solid complex $[Mo(CO)_4(44'B)]_n$ already mentioned. The orange solid was analysed: Found: C, 45.8; H, 2.3; N, 7.0. Calc. for $C_{15}H_8MoN_2O_5$: C, 45.9; H, 2.0; N, 7.1%.

Preparation of tetracarbonyl bis(1,2-bis(2-*pyridyl*)*ethene*)*molybdenum*

Solid *cis*-$[Mo(CO)_4(\eta^2,\eta^2\text{-}C_7H_8)]$ (0.78 g, 2.6 mmol) and solid 2-bpe (0.94 g, 5.2 mmol) were placed in a Schlenk tube and tetrahydrofuran (30 cm^3) was added. The mixture was stirred for 18 hr (overnight). The orange–red reaction mixture was evaporated to dryness under reduced pressure and the residue was extracted with dichloromethane, filtered and then carefully placed beneath a layer of petroleum ether (40–60°C boiling fraction). The solution was stored at 278K and after six days the crystalline material was isolated by filtration. The orange crystals were washed with petrol. Yield 1.1 g, 75%. Found: C, 58.7; H, 3.3; N, 10.1. Calc. for $C_{28}H_{20}MoN_4O_4$: C, 58.7; H, 3.5; N, 9.8%.

Preparation of tetracarbonyl(1,2-bis(4-*pyridyl*)*ethene*)*molybdenum dimer*

Solid 4-bpe (0.81 g, 4.4 mmol) was added portionwise to a stirred solution of $[Mo(CO)_4(\eta^2,\eta^2\text{-}C_7H_8)]$ (0.67 g, 2.2 mmol) in THF (30 cm^3). The colour of the mixture turned deep red immediately. The reaction mixture was stirred at room temperature overnight, concentrated under reduced pressure. The residue was extracted with dichloromethane and the extract solution was placed beneath a layer of petroleum ether. Red-brown crystals were isolated by filtration after four days, washed with petroleum ether and dried under vacuum. Yield 0.55 g, 65%. Found: C, 48.9; H, 2.6; N, 7.3. Calc. for $C_{14}H_{10}MoN_2O_4$: C, 49.2; H, 2.5; N, 7.2%.

Preparation of μ^2-(4,4′-*bipyridine*)bis{(2,2′-*bipyridine*)*tricarbonylmolybdenum*}

Solid 4,4′-bipyridine (0.214 g, 1.37 mmol) was added to a solution of $[Mo(CO)_4(bpy)]$ (1.00 g, 2.75 mmol) in acetonitrile (30 cm^3) and the mixture was heated at reflux for 12 hr, during which time the colour changed from red to black. A black solid precipitated from the solution on cooling. The solid was isolated by filtration, washed with chloroform (5 × 15 cm^3) until the washings were no longer red, then once with petrol and then dried under vacuum. Yield: 0.828 g, 73%. Found: C, 51.8; H, 2.7; Mo, 23.7; N, 9.9. Calc. for $C_{36}H_{24}Mo_2N_6O_6$: C, 52.2; H, 2.9; Mo, 23.2; N, 10.1%. Using a similar procedure with (4,4′ - di(tert - butyl) - 2,2′ - bipyridine)tetracarbonylmolybdenum gave well-formed purple-black crystals of $[\{Mo(CO)_3L_R\}_2(44'B)]$. Yield 59%. Found: C, 58.6; H, 5.6; Mo, 18.2; N, 7.6. Calc. for $C_{52}H_{56}Mo_2N_6O_6$: C, 59.3; H, 5.3; Mo, 18.2; N, 7.6%. Using 4-bpe with $[Mo(CO)_4(bpy)]$ in a similar sequence produced $[\{Mo(CO)_3(bpy)\}_2(4abpe)]$ as a purple–black solid. Yield 82%. Found: C, 52.7; H, 3.1; N, 9.8. Calc. for $C_{38}H_{26}Mo_2N_6O_6$: C, 53.4; H, 3.1; N, 9.8%.

ON THE CHELATION OF STANNATE (IV), ANTIMONATE(V) AND TELLURATE(VI) ANIONS WITH CYCLIC AND ACYCLIC HEXOLS

JOLOCAM MBABAZI
Department of Chemistry, Makerere University, P.O. Box 7062, Kampala, Uganda

(*Received* 5 *May* 1983; *accepted after revision* 2 *March* 1984)

Abstract—Conductimetric, potentiometric and titrimetric studies of aqueous telluric acid at pH 4.8–11.0 in the presence of acyclic hexols show that whereas only 1 : 1 complexes are formed at low pH, 1 : 3 polyol-tellurates exist only in strongly alkaline media. The 1 : 2 chelates behave as transient intermediates. Cyclohexols exclusively form 1 : 1 complexes with stannate(IV), antimonate(V) and tellurate(VI) oxyanions, even at extreme pH conditions.

The stability of polyol-tellurate complexes,[1] like that of the periodate analogues,[1,2] increases with pH. As a result, apart from the expected 1 : 1 polyol-tellurates,[3,4] complexes of other stoichiometries might exist at high pH. Part of this investigation was to put this possibility to experimental test, using cyclic and acyclic hexols, and falls in line with recent studies[5–7] on related systems. The extension of this work to stannate and antimonate hexahydroxyanions was prompted by their isostructural and isoelectronic nature with telluric acid.[8–11] Although it had earlier been reported that complexes are formed between polyols and antimonic acid in aqueous solution,[12] the evidence was inconclusive about their stoichiometries, presumably due to the appreciable degree of aggregation of antimonate ions in acidic aqueous media.[13] Polyol-antimonates of known structure are however mentioned elsewhere in the literature,[14,15] but the materials and experimental conditions used are different from those employed in the present study. Electrophoretic migration of polyols in aqueous sodium stannate[16] is evidence that similar complexes are formed, but to what extent is yet to be fully established. The present work endeavours to fill portions of this gap.

EXPERIMENTAL

A Wayne–Kerr Universal bridge and a dip cell (const. = 1.37 cm^{-1}) were used for electrolytic conductance studies. The experimental techniques used were similar to those earlier described under telluric acid,[6] except for stannate and antimonate solutions to which potentiometric and indicator titrations did not apply. Studies on stannate and antimonate anions were carried out using sodium stannate, $Na_2Sn(OH)_6$, and potassium antimonate, $KSb(OH)_6 \cdot \frac{1}{2}H_2O$, respectively. Stock solutions (0.010 M) of potassium antimonate were prepared as described in Ref. 12; their pH was raised using solid potassium hydroxide, and lowered using dilute hydrochloric acid. That of stannate solutions was raised using solid sodium hydroxide, and the pH readings taken on these solutions using a glass electrode were corrected for the sodium error.

RESULTS

(1) *Telluric acid*

Addition of sufficient dulcitol, as shown by pH titration studies, increased the acidity of telluric acid. This effect, a well-known phenomenon,[3,6] is indicative of complex formation. In such titrations, it may be shown that the pH of the solution at half-neutralisation, $(pH)_{\frac{1}{2}}$, is numerically equal to the pKa value of the weak acid. A plot of $(pH)_{\frac{1}{2}}$ showed a discontinuity at a 1 : 1 dulcitol-tellurate mole ratio. The acidity of the mixtures did not appear to increase further after ~2 : 1 polyol-tellurate mole ratio. A similar investigation with other acyclic hexols mannitol, sorbitol, allitol and altritol, and their cyclic counterparts *allo*, *epi*, *cis*, *muco*, *meso* and *neo*inositol gave similar results, but the decrease in pH of telluric acid solutions caused by the presence of equimolar quantities of polyol was in the order : dulcitol > mannitol, allitol > altritol, sorbitol > cyclohexols. The acidity of telluric acid was little affected by *scyllo*inositol. Titration of telluric acid to a phenol-

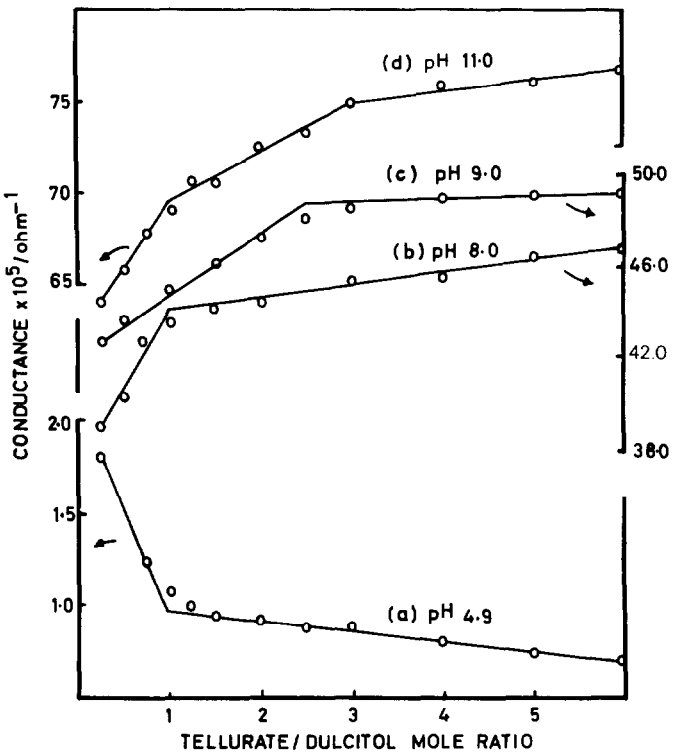

Fig. 1. Conductances of telluric acid (0.010 M) at various *initial* pH, after addition of dulcitol, at 25°C.

phthalein endpoint in the presence of the alditols showed evidence for only 1 : 1 complexes when the titres were plotted against the polyol-tellurate mole ratio. The cyclitols, however, gave poor endpoints.

When the conductance measurements at constant tellurate concentrations were plotted against the tellurate-polyol mole ratio (Fig. 1) according to the method of Yoe and Jones,[17] formation of only a 1 : 1 complex of dulcitol was indicated in the pH range 4.8–8. At pH > 10 a 1 : 3 dulcitol-tellurate complex was indicated. In the intermediate pH range the plots gave curves with discontinuities lying between tellurate-polyol mole ratios 2 and 3. The corresponding pH measurements (Fig. 2) gave

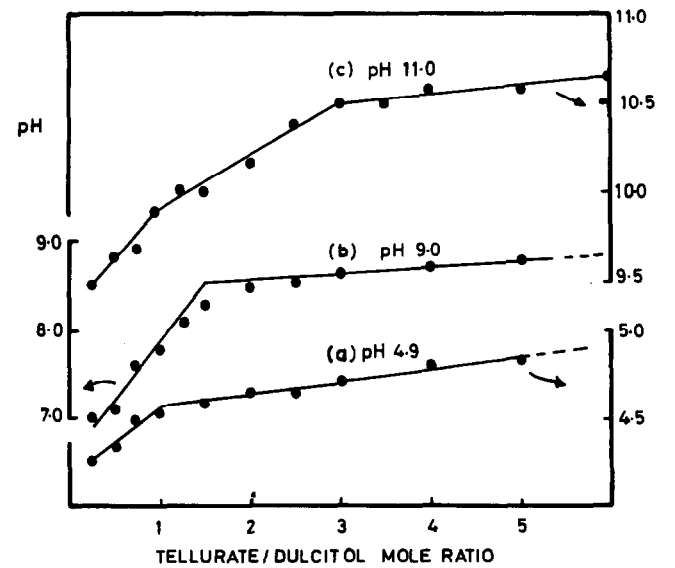

Fig. 2. Final pH values of telluric acid (0.010 M) at various *initial* pH, after addition of dulcitol, at 25°C.

consistent results at all other pH values, but indicated tellurate-polyol mole ratios between 1 and 2 in this pH range. The implication of these two seemingly different results was that a mixture of 1 : 1, 1 : 2 and 1 : 3 dulcitol-tellurate complexes were simultaneously present in the solutions. The absence of unambiguous discontinuities at the 2 : 1 tellurate-polyol mole ratio indicated that the 1 : 2 dulcitol-tellurate complex existed as a transient intermediate. The behaviour of other linear hexols was almost similar. With cyclohexols, only 1 : 1 complexes were indicated at all the pH values. Except for *scyllo*inositol for which there was hardly any pH change, corresponding pH measurements yielded consistent results.

The existence of 1 : 1 (at low pH) and 1 : 3 alditol-tellurates (at high pH) was further confirmed by Job's method of continuous variations[18] using conductance and pH measurements (Fig. 3). Regarding cyclohexol-tellurate systems, the changes in the conductance or pH of telluric acid caused by their presence were in most cases too small to give a conclusive Job's plot.

As a general rule, therefore, whereas cyclitols formed only 1 : 1 complexes, the linear hexols were able to complex, pH dependently, with up to three tellurates per molecule.

Sucrose[5] can similarly bind up to four tellurates per molecule.

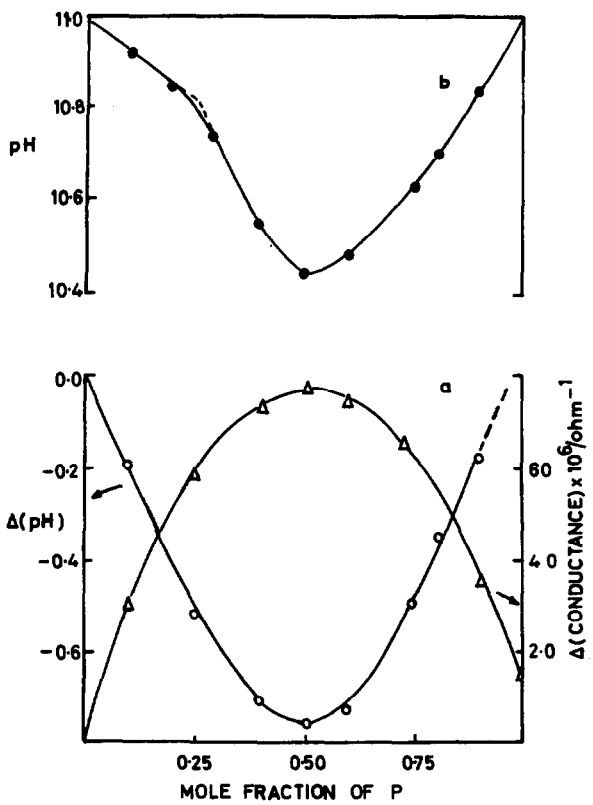

Fig. 3. Job's plot (change in conductance or pH at 25°C) for (a) dulcitol-telluric acid mixtures after 24 h or more, and (b) mannitol-telluric acid mixtures, each initially at pH 11, after 10 min or more. (P = polyol.).

(2) *Antimonate anions*

The conductance of potassium antimonate at its natural (7.45, 0.010 M) and higher pH was observed to be lowered by addition of increasing quantities of polyol. The Yoe–Jones[17] conductance plots showed evidence of only 1 : 1 complexes (Fig. 4). The presence of hexols in acidified potassium antimonate at pH 4.0 increased the conductance (Fig. 4) and lowered the pH (not shown) of the solution, with indication of only 1 : 1 polyol-antimonate complexes.

Corresponding pH measurements gave consistent results, although in the pH range 5–11 the readings did not show any significant deviation from the initial pH. A notable exception to this observation was the dulcitol-antimonate system, which showed definite and conclusive results throughout the entire pH range (4.0–12.0) investigated. The general trend at low and high pH was similar to that in Fig. 2.

Job's plots[18] (conductance and pH changes) at initial pH 4.0 showed maxima and minima, respectively, at polyol mole fraction 0.5 (see Fig. 3a), thus further confirming the existence only 1 : 1 complexes at low pH. At higher pH values, however, the changes in conductance or pH caused by the presence of these polyols were in most cases not large enough to give meaningful curves.

(3) *Stannate anions*

Solutions of sodium stannate at their natural pH (11.7, 0.010M) develop turbidity within 10–15 min, due to the formation of colloidal stannic acid;[19] however, *freshly* prepared solutions are usable. The stability of sodium stannate solutions is greatly increased by the presence of suitable polyols: equilibrated solutions containing sufficient amounts of various hexols hardly exhibit any turbidity.

Stannate-hexol systems closely resembled the antimonate analogues. When the conductance data at constant stannate concentrations was plotted against the stannate-polyol mole ratio,[17] the existence of only 1 : 1 complexes at pH 11.7–13.0 was evident (see Fig. 4d). With acyclic hexols, corresponding pH measurements gave consistent results. The pH of stannate solutions in the presence of cyclohexols did not vary significantly from the initial value. No confirmatory results were obtained using the method of continuous variations.[18]

Comparing the three aqueous polyol-oxyanion

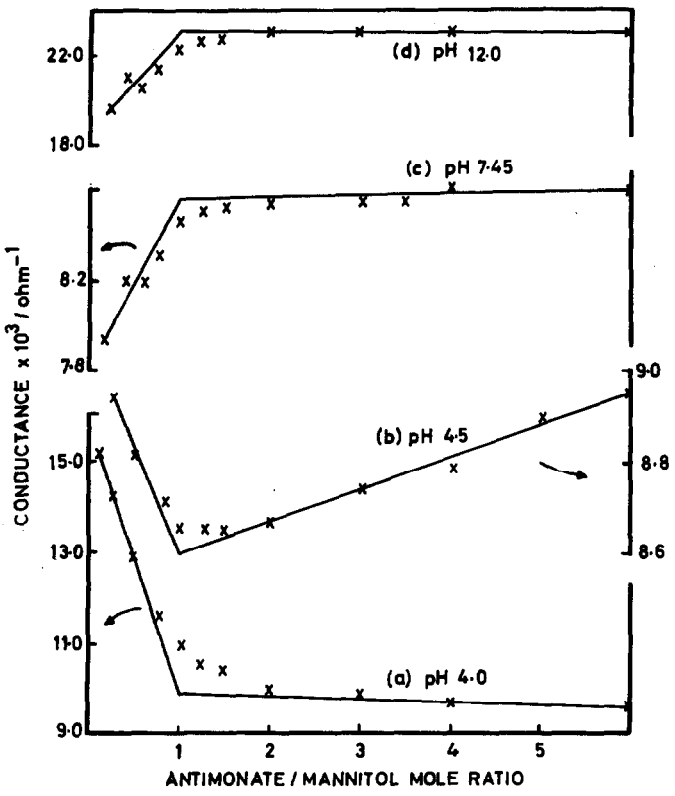

Fig. 4. Conductances of potassium antimonate (0.010 M) at various *initial* pH, after addition of mannitol, at 25°C.

systems, whereas equilibration times at 25°C progressively decreased from *ca.*24 hr for telluric acid at pH 4.8 to about 10 min at pH 11 for each polyol, with stannate- and antimonate-hexol solutions equilibration often took much longer, requiring up to 4 days with some cyclitols.

DISCUSSION

Tin, antimony and tellurium are three consecutive members of the same period along the Periodic Table. However, of the three isostructural and isoelectronic species $Sn(OH)_6^{2-}$, $Sb(OH)_6^-$ and $Te(OH)_6$, only telluric acid is able to form 1 : 3 polyol-oxyanion chelates with acyclic hexols. Calculations based on the Te–OH bond distances in $Te(OH)_6$ octahedra give an average value of 0.271 nm for the O–O distance in telluric acid in the solid state[8–11] and 0.274 nm in aqueous solution.[20] The corresponding distance in $Sb(OH)_6^-$ is quoted as 0.280 nm[21] in the solid state, and, like that in $Te(OH)_6$, is bound to be slightly longer in aqueous solution. It therefore still remains that in solution the O–O separation in the hexahydroxyantimonate anion is definitely larger than that in telluric acid. The O–O distance in $Sn(OH)_6^{2-}$ is, on the basis of periodicity, expected to be longer than that in $Sb(OH)_6^-$ by about 0.01 nm. In linear hexols, all the six carbon atoms may lie in the same plane. In this conformation, calculations (based on the mean bond lengths C–O = 0.143 nm and C–C = 0.154 nm, assuming tetrahedral angles at all the carbon atoms) show that the O–O distances in *gauche*- and *trans*-1,2-diol groups are 0.282 and 0.365 nm respectively, although in an eclipsed conformation the oxygens can approach each other to within 0.245 nm. Since complex-formation between polyols and oxyacids is thought to involve two hydroxyls from the oxyanion and two from the polyol[3], it is plausible that the $M(OH)_6$ (M = Sn, Sb, Te) species whose O–O distance is closest to that in a near-eclipsed 1,2-diol group would be able to form a relatively stable, near-planar five-membered ring without undue distortion of the two C–O bonds.

In this respect, $Te(OH)_6$ is apt to satisfy this requirement better than either $Sb(OH)_6^-$ or $Sn(OH)_6^{2-}$ ions. On the other hand, the O–O separation in *gauche*-1,2-diols is sufficiently close to that in antimonate and stannate anions for the formation of five-membered rings to be likely. Nevertheless the puckered nature of the rings so formed would render such complexes less stable than the tellurate analogues. Thus whereas the stability of the chelate formed by telluric acid with

a near-eclipsed 1,2-diol group is such that it allows the formation of three such rings on an acyclic hexol, antimonate and stannate complexes with *gauche*-1,2-diols are probably not stable enough as to allow more than one oxyanion to cling to one such molecule.

The relative (Fischer projection) configurations for five alditols studied are given in Fig. 5. Although internal rotation about the C–C bonds is possible, the configuration of each hexol is fixed by the OH groups being "locked" in position by intramolecular hydrogen bonding. It is therefore interesting to note that despite their differing configurations, acyclic hexols are each able to bind up to three tellurates per molecule. Due to the presumed stepwise nature of the complex-formation process,[6] it is reasonable to think that the initial complexation of a linear hexol with one tellurate ion reduces the H-bonding between the remaining four hydroxyls on the polyol. This effect is enhanced by the fact that intramolecular H–bonding decreases with pH. Thus at high pH the two effects permit the remaining two uncomplexed pairs of 1,2-diol groups on the alditol to rotate more freely about the C–C bonds, and consequently create a conformation that meets the specific structural features[3] required by two more tellurates. Consistent with this view is that the 1 : 3 hexol-tellurates are indeed observed only in strongly alkaline media.

Owing to the presence of six OH groups on the polyol, there are a number of ways in which hexahydroxyanions can combine with a linear hexol to form a 1 : 1 anionic complex. Nevertheless

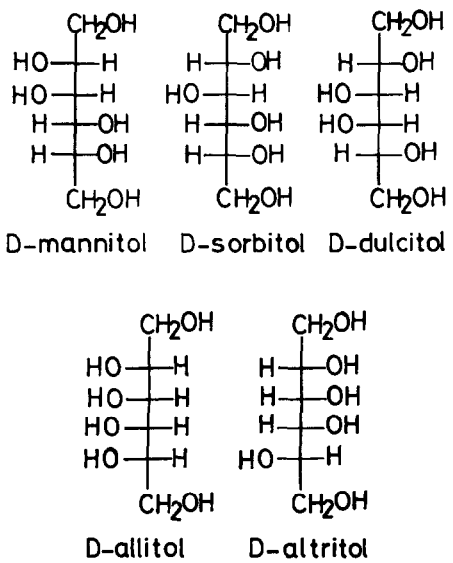

Fig. 5. Fischer projection configurations of some acyclic hexols studied.

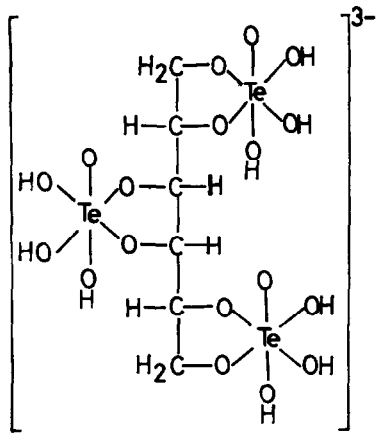

Fig. 6. Possible structure of a 1 : 3 acyclic hexol-tellurate complex.

molecular models show that formation of a 1 : 3 alditol-tellurate complex necessitates the adoption of only one possible structure (Fig. 6), that caters for minimum steric effects, ring size and stability. Any other structure may be discounted on the basis of the relatively poor complexing ability exhibited by 1,3-propanediol and its substituted derivatives, as compared to that with 1,2-propanediol or glycerol.[3] Inevitably, the hexol whose OH configuration in its normal state already meets such structural requisites should react fastest and (though not necessarily) form the most stable complexes. In conformity, it was observed that of the acyclic hexols investigated, dulcitol (Fig. 5, cf. Fig. 6) reacted fastest, and caused the largest deviations in the conductance and pH of each of the oxyacid anion solutions.

A common feature in cyclohexol-oxyanion systems encountered in this study was the exclusive formation of 1 : 1 complexes, even at high pH values. The O–O distance in the more stable chair form of *cis*- and *trans*-1,2-diol groups of cyclohexols are identical (0.282 nm). The O–O separation in $Sb(OH)_6^-$ ions in solution, as we have already seen, is very close to this value as compared to that in $Te(OH)_6$ or $Sn(OH)_6^{2-}$. Antimonate ions should therefore be able to form stronger 1 : 1 cyclitol complexes. Such complexation would to a large extent be expected to involve *cis*-1,2-diol groups, resulting in planar, or near-planar, five-membered rings. Consistent with this assertion is the observation that the cyclohexols possessing more *cis*-1,2-diol groups electrophoretically migrate faster in stannate solution.[16] The deviation of the O–O distances in $Sn(OH)_6^{2-}$ and $Te(OH)_6$ above and below that in 1,2-cyclohexol diol groups, respectively, is just about the same (~ 0.01 nm), and is certainly not so large as not to warrant

formation of fairly stable *cis*-stannate and tellurate cyclohexol complexes. Due to the presence of only one *cis*-1,2-diol group on *meso*inositol, it is not unexpected that 1 : 1 oxyanion chelates were exclusively formed with this compound. Complexation with *trans*-1,2-diol groups on the cyclohexol would result in severely puckered and correspondingly unstable chelates. For this reason, *scyllo*inositol, with all its three 1,2-diol groups *trans* to each other, is a poor complexing agent.

If this were all, a 1 : 2 polyol-oxyanion chelate would be afforded with *muco*inositol by complexation at each of the two *cis*-diol positions. Similar considerations would lead one to expect 1 : 2 cyclitol-oxyanion complexes from the *epi* and *neo*, and up to 1 : 3 such chelates with the *allo* and *cis* isomers. Molecular models, however, confirm that the exclusive formation of 1 : 1 complexes with each inositol throughout the entire pH range investigated arises from the presence of more than one hydroxyanion on a cyclohexol molecule being sterically unfavoured.

(*Received* 25 *July* 1983; *accepted* 2 *March* 1984)

Abstract—Sixteen complexes of general formula R_2SnL_2 and $R_2(L)SnOSn(L)R_2$ (where L = N-acetyl-L-leucine or N-acetyl-L-phenylalanine) R = CH_3, C_2H_5, n-C_4H_9, or n-C_8H_{17}) have been prepared by interaction between the ligand and R_2SnO in 2:1 or 1:1 molar ratio. The complexes were characterized by IR, ^1H NMR and ^{119}Sn Mössbauer spectroscopy. All the 2:1 complexes are assigned six-coordinate, distorted octahedral geometry with chelating carboxylate groups, while the 1:1 complexes have oxygen-bridged binuclear five-coordinate, trigonal-bipyramidal configurations. The amido –C=O and –NH groups are hydrogen bonded in the solid state.

Considerable interest has been shown in organotin(IV) derivatives of amino and N-acetylamino acids as possible biocides.[1,2] Much of this work has concerned triorganotin derivatives,[3–6] and relatively few diorganotin compounds of this type have been characterised.[7–12] We report here the synthesis and characterisation of a series of dialkyltin(IV) derivatives of N-acetyl-L-leucine (L_1) and N-acetyl-L-phenylalanine (L_2).

EXPERIMENTAL

Chemicals. N-acetyl-L-leucine, N-acetyl-L-phenylalanine and diethyltin(IV) oxide were prepared by the reported methods.[13,14] Dimethyl-, di-*n*-butyl-, and di-*n*-octyl-tin(IV) oxides were obtained from Alfa Products, U.S.A., and used as such.

Instruments. Melting points were determined in open capillaries, and are uncorrected. Elemental analyses were carried out by the Microanalytical Service, Calcutta University. Tin was estimated gravimetrically as SnO_2. Molecular weights were determined both by cryoscopy (in benzene or nitrobenzene) and by the Rast method (in molten camphor). IR spectra were recorded on Perkin Elmer 577 and Pye Unicam P321 instruments, in KBr or chloroform. ^1H NMR spectra were recorded on Tesla BS487 (80 MHz) and Varian Analytical (60 MHz) instruments, with TMS as internal standard. ^{119}Sn Mössbauer spectra were obtained with a Harwell 6000 Series spectrometer with samples cooled by liquid nitrogen (*ca.* 80 K) and source ($BaSnO_3$) at room temperature. Isomer shifts are relative to SnO_2 at room temperature.

Preparation of complexes. Complexes were prepared by refluxing the N-acetylamino acid and the dialkyltin(IV) oxide in 1:1 or 2:1 molar ratio in a benzene–ethanol mixture (3:1 v/v) with azeotropic removal of water. The mixture was filtered and the solvent removed. The 2:1 dimethyl- and diethyltin(IV) complexes were obtained as white solids, and were recrystallised from benzene. The dibutyl and dioctylderivatives were oils which solidified after 1–2 days in vacuum; they were then recrystallised from benzene. The 1:1 complexes were oils which solidified on trituration with petroleum ether (bp 60–80°C).

RESULTS AND DISCUSSION

Dialkyltin(IV) complexes of N-acetyl-L-leucine (L_1) and N-acetyl-L-phenylalanine (L_2) in 1:1 and 1:2 ratio have been prepared and characterised by analysis, molecular weight determination, IR,

*Author to whom correspondence should be addressed.

^{1}H NMR and ^{119}Sn Mössbauer spectroscopy. The complexes are all white solids, which are monomeric in solution (Table 1). The sharp melting points suggest that this structure is retained in the solid.

IR data

IR data for the amino acids and the complexes are given in Table 2. The free ligands show broad O–H absorption at 3000–2500 cm^{-1} which is absent in the spectra of the complexes, showing the deprotonation and coordination of the carboxylate groups. The values of $\Delta\nu$ [ν_{asy}(COO) – ν_{sym}(COO)] are all about 200 cm^{-1}, indicating that the carboxyl groups are chelated.[15]

The N–H stretching frequencies of the solid complexes are higher than those of the sodium salts, suggesting that the amido nitrogen is not coordinated, which would be consistent with its low basicity.[16] For some solid samples (Nos. 5, 9–11 and 15 of Table 2) and for chloroform solutions, the bands are sharp; those of the other solids are considerably broadened, indicating intermolecular hydrogen bonding, presumably to an amido carbonyl group of an adjacent molecule.[3,4,8]

The C=O stretching frequencies for the amido groups are slightly greater for the complexes than for the free ligands, the shift being greater for those which are not hydrogen bonded. For the remainder, the solution spectra show a further increase in

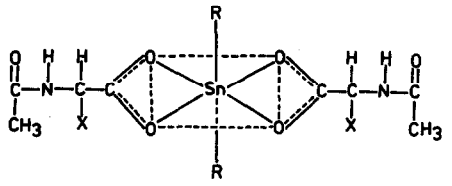
frequency, again consistent[4] with loss of hydrogen bonding on dissolution.



The presence of only one Sn–C band in the 590–610 cm^{-1} region indicates that the two alkyl groups are in *trans*-axial positions.[3,12,17] Bands assignable to the Sn–N stretching vibration are not observed in the spectra of the complexes, indicating that the ligand nitrogen atoms are not coordinated. For the 1:1 complexes (Nos. 13–20 of Table 2), a broad strong band at 640–610 cm^{-1} is assigned to an Sn–O–Sn stretching vibration.[18]

^{1}H NMR data

The ^{1}H NMR spectra of the ligands and the soluble complexes were recorded in DMSO, TFA and $CDCl_3$, and the data are given in Table 3. In

the spectra of the N-acetylamino acids themselves, the signal for the peptide group (CONH) proton is broad and appears at 7.93δ(L_1) and 7.67δ(L_2); it is shifted to higher field in the complexes (7.2–5.3δ), indicating non-coordination to tin and loss of hydrogen bonding.[4,19,20] The dimethyl- and diethyltin complexes show single resonances for the alkyl groups, indicating *trans* configurations.

^{119}*Sn Mössbauer data*

The 2:1 complexes have isomer shift (IS) values of *ca.* 1.35 mm s^{-1} and quadrupole splittings (QS) of *ca.* 3.45 mm s^{-1} (Table 4). These data cannot be directly interpreted in terms of the structure, since other diorganotin(IV) complexes with similar parameters have been assigned five-coordinate[10,21–23] or six-coordinate structures.[12,14,24,25] Indeed, when the other ligands have high electronegativity, the QS is governed mainly by the C–Sn–C bond angle;[26–28] the values observed here correspond to bond angles of 138–146°. However, in the light of the other data, the Mössbauer parameters are best interpreted in terms of distorted *trans* octahedral configurations.

The 1:1 complexes have lower QS values, corresponding to five-coordination. The calculated C–Sn–C bond angles are again 138–148°.

Structures

$R_2Sn(L)_2$ complexes (1:2). The Mössbauer, NMR and IR data suggest distorted *trans*-octahedral structures (Fig. 1) for all complexes in solution and for compounds 5, 9–11 (Table 2) in the solid state. For the other solid complexes, the IR data suggest dimeric, hydrogen-bonded structures (Fig. 2).

$R_2(L)SnOSn(L)R_2$ complexes (1:1). The 1:1 complexes are assigned five-coordinate trigonal-bipyramidal structures with Sn–O–Sn bridging and effectively linear C–Sn–C groups. In solution the complexes are monomeric (Fig. 3), as is the solid complex $[(L_1)Sn(C_2H_5)_2]_2O$. The remaining solid complexes appear from their IR spectra to have dimeric, hydrogen-bonded structures (Fig. 4).

STRUCTURAL STABILITY INDEX OF HETEROPOLY- AND ISOPOLY-ANIONS—II

KENJI NOMIYA and MAKOTO MIWA*
Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

(*Received* 14 *November* 1983, *accepted* 30 *March* 1984)

Abstract—The structural stability indexes of some previously unreported heteropoly- and isopoly-compounds are discussed. Compounds studied here are mono-substituted Keggin and Dawson heteropolyanions with the general formulas $[XZ(H_2O)M_{11}O_{39}]^{n-}$ and $[X_2Z(H_2O)M_{17}O_{61}]^{n-}$ (X is a heteroatom; Z is a substituted metal ion; M is Mo, or W), two Finke-type heteropolyanions with the formulas $[P_2W_{18}Z_4(H_2O)_2O_{68}]^{10-}$ and $[P_4W_{30}Z_4(H_2O)_2O_{112}]^{16-}$ (Z = Co(II), Cu(II), Zn(II)), heteropolyvanadates containing high valence heteroatoms $[XV_{13}O_{38}]^{7-}$ (X = Mn(IV), Ni(IV)), isopolyvanadate $[V_{10}O_{28}]^{6-}$, some heteropolyvanadates with capped-Keggin structures, and $[As_4W_{40}O_{140}]^{28-}$ as an inorganic cryptate. An additional rule concerning the conversion between the heteropoly- and isopoly-anions is proposed as the fourth rule. The actual stability of heteropolyanions with the small structural index is interpreted by the presence of a significant contribution from the heteroatom or other supporting metal ions.

Pope's proposal[1] concerning the heteropoly "blue" formation, i.e. only the heteropolyanions belonging to Type I (monooxo terminal groups) and the Type III (both monooxo and *cis*-dioxo terminal groups) can be converted to the reduced blue forms, has been disproved. For example, Yamase *et al.* have recently demonstrated the one-electron reduction of $[Mo_7O_{24}]^{6-}$ anion (Type II; *cis*-dioxo terminal groups) by an illumination ($\lambda > 300$ nm), analyzed the ESR spectrum of irradiated single-crystal and determined the crystal structure of the blue compound by the X-ray diffraction.[2–4] However, taking advantage of Pope's proposal we could introduce the structural stability on the basis of closed loop into the chemistry of heteropoly- and isopoly-compounds. In the previous paper,[5] using the interpenetrating loop $-O_c-M-O_b-M-O_c-$ formed by a junction of M ion and bridging oxygens (O_b, O_c) around the heteropolyanion cage, we defined the structural stability index (η) as the number of closed loops per MO_6 octahedron and discussed the relative stability of the polyanion skeletons, the degree of condensation and the interconversion within the same family of the heteropolyanion. These have been summarized in three rules; (1) the heteropolyanions with the larger structural stability index are more stable, (2) the heteropolyanions with an identical index within the same series can be interconverted or converted from one polyanion to another, and (3) the index reveals the degree of condensation. The index has been estimated according to $\eta = (\Sigma B \cdot C)/A$, where A is the number of MO_6 octahedra constituting the polyanion cage, B the number of MO_6 constituting the closed loop and C the number of closed loop. In this paper, we wish to report the structural stability indexes of the compounds, which have not been previously discussed, and to propose an additional rule about the conversion between the heteropoly- and isopoly-anions.

RESULTS AND DISCUSSION

In our view, the structural stabilities of heteropoly- and isopoly-compounds appear, to a first approximation, to be dominated by the number of closed loop, and the structural stability index appears to be representative of a topological index for such compounds. The problem is limited to only whether the closed loop exists or not in those compounds. For example, the difference between Mo and W in the $[XM_{12}O_{40}]^{n-}$ (M = Mo, W), although their actual stabilities

*Author to whom correspondence should be addressed.

are different, cannot be taken into account. This results in each of heteropolyanions $[XMo_{12-n}W_nO_{40}]^{m-}$ and $[XMo_{12-n}V_nO_{40}]^{m-}$ having the same index ($\eta = 2$) as the Keggin-type ion. Moreover, in the mono-substituted lacunary heteropolyanions $[XZ(H_2O)M_{11}O_{39}]^{n-}$ and $[X_2Z(H_2O)M_{17}O_{61}]^{n-}$ shown in Fig. 1 (X is a hetero-atom such as Si, P, As; Z is a substituted metal ion; M is Mo, W),[6,7] there exist the "homo"-closed loop such as $-O_b-M-O_c-M-O_b-$ and the "hetero"-closed loop such as $-O_b-M-O_c-Z-O_b-M-O_c-$, but since such loops are treated without distinction, their stability indexes become the same index ($\eta = 2$) as that of parent Keggin- and Dawson-type heteropolyanions. This is also the case for the di-substituted Keggin ions such as $[Ti_2PW_{10}O_{40}]^{7-}$ and $[\{C_pFe(CO)_2Sn\}_2W_{10}PO_{38}]^{5-}$, which have been recently isolated by Knoth *et al.*[8] From this standpoint, the structural stabilities of two Finke-type polyanions, $[P_2W_{18}Z_4(H_2O)_2O_{68}]^{10-}$ and $[P_4W_{30}Z_4(H_2O)_2O_{112}]^{16-}$ (Z = Co, Cu, Zn),[9,10] can be discussed (Fig. 2). Finke *et al.* have examined the reaction of a trivacant Keggin ion β-$[PW_9O_{34}]^{9-}$ ($\eta = 0.67$) with the inorganic Z(II) ions, with the goal of preparing $[PW_9(ZO)_3O_{34}]^{9-}$, which should contain a Z_3O_3 "mini surface" closely resembling a fragment of the "polar" $(000\bar{1})$ surface of ZO, and demonstrated that the di-substituted dimers $[PW_9Z_2(H_2O)O_{34}^{5-}]_2$ are unexpectedly formed, yet exclusively. In these polyanions, two $[PW_9O_{34}]^{9-}$ units are located above and below the three parts of four edge-sharing ZO_6 octahedra so that two tri-substituted Keggin ions may interpenetrate. The other Finke-type polyanion has been obtained by the reaction of trivacant Dawson ion α-$[P_2W_{15}O_{56}]^{12-}$ ($\eta = 0.8$), which was prepared by base degradation of α-$[P_2W_{18}O_{62}]^{6-}$, with the inorganic Z(II) ions. The structures have been determined by the ^{183}W-NMR and X-ray analyses.[9,10]

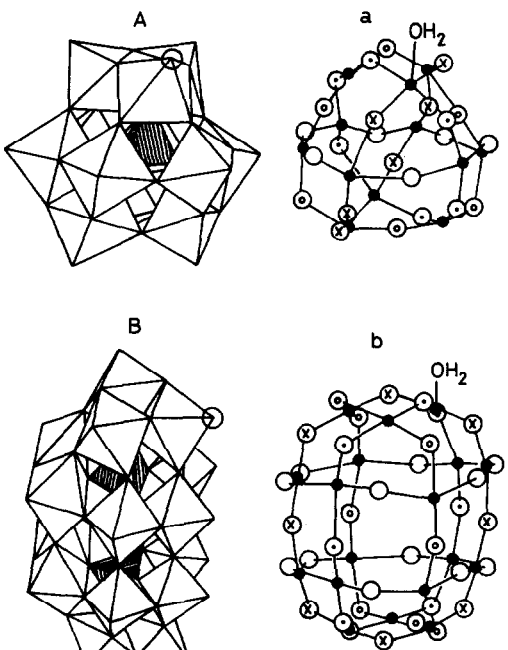

Fig. 1. Polyhedral models of the mono-substituted Keggin (*A*) and Dawson (*B*) heteropolyanions. The circles show the positions of water molecules. Framework bond models of (*A*) and (*B*) are shown in (a) and (b), respectively. Open circles are bridging oxygens and filled circles are molybdenum or tungsten atoms. Terminal oxygens and the internal heteroatoms are omitted. The uniformly marked oxygens identify one closed loop.

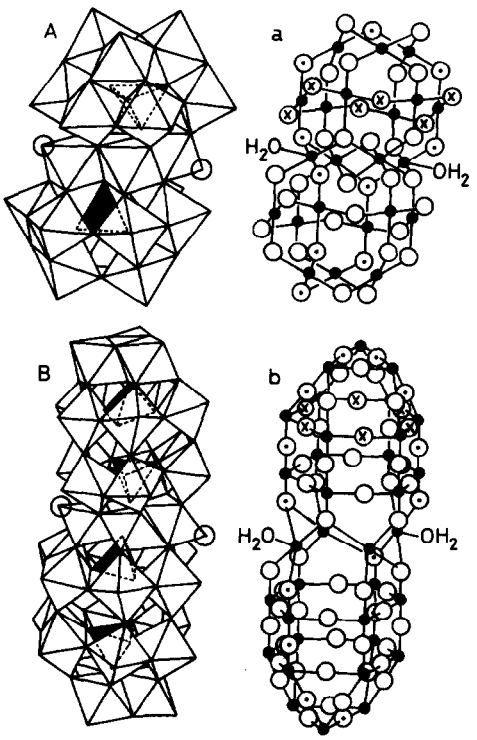

Fig. 2. Polyhedral models of Finke-type polyanions, $[P_2W_{18}Z_4(H_2O)_2O_{68}]^{10-}$ (*A*) and $[P_4W_{30}Z_4(H_2O)_2O_{112}]^{16-}$ (*B*).[9,10] The circles show the positions of water molecules. Framework bond models of (*A*) and (*B*) are shown in (a) and (b), respectively. Open circles are bridging oxygens, filled circles are tungsten atoms, and central four shaded circles are Z(Co, Cu, Zn). Terminal oxygens and the internal heteroatoms are omitted. The oxygens illustrated by cross within a circle represent one of local closed loops, and the oxygens by dot within a circle represent one of closed loops passing through two subunits.

In the first polyanion, we can find two local "homo"-closed loops and six "hetero"-closed loops, or $(B, C)_{homo} = (6, 2)$ and $(B, C)_{hetero} = [(6, 4) + (10, 2)]$, thus the stability index $\eta = (6 \times 2 + 6 \times 4 + 10 \times 2)/(18 + 4) = 2.55$ and in the second polyanion, we can find four "homo"- and six "hetero"-closed loops, or $(B, C)_{homo} =$

(6, 4) and $(B, C)_{hetero} = [(8, 4) + (14, 2)]$, thus the index $\eta = (6 \times 4 + 8 \times 4 + 14 \times 2)/(30 + 4) = 2.47$. It seems reasonable that these polyanions are obtained as main products, since the evaluated indexes are larger than those of initially desired tri-substituted Keggin- and Dawson-polyanions (both $\eta = 2$).

Some heteropolyvanadates with interesting structures have been known which have never been observed in the heteropolyanions of Mo and W. A heteropolyanion with the highest degree of condensation is the $[XV_{13}O_{38}]^{7-}$ (X = Mn(IV), Ni(IV)) compounds, which belong to Type **III** in the Pope's classification and their heteropoly "blue" compounds are also known (Fig. 3).[11] These polyanions consists of one XO_6 and 13-VO_6 octahedra always sharing edges and the structure is similar to that of $[W_{10}O_{32}]^{4-}$, but has a central heteroatom and three more VO_6 octahedra surrounding it, the crystallographic structure being shown in the reference.[12] Using a molecular model, we have estimated 4.92 as a stability index from $A = 13$ and $(B, C) = [6, 8) + (4, 4)]$. In view of the Mn(IV) and Ni(IV) octahedral complexes, these polyanions are known to be more stable than the Waugh-type ones $[XMo_9O_{32}]^{6-}$ ($\eta = 2$) both in the solid and in aqueous solution.[11] This fact is reasonable as expected from the large index viz. the first rule.

Recently Sasaki *et al.* have found that the 1 : 14 vanadophosphate polyanion exists as the only detectable heteropolyanion in a wide range of V : P ratios in the NaH_2PO_4–$NaVO_3$–H_2SO_4 aqueous system ($1/2 \leq V:P \leq 14$, $1 < pH < 6$) at room temperature using ^{31}P- and ^{51}V-NMR techniques.[13,14] In the polyanion twelve V atoms form the usual Keggin structure and the remaining two V atoms occupy the pits on the Keggin molecule, viz. "bicapped Keggin" structure is confirmed. The crystallographic structure of the stable *trans*-located bicapped Keggin ion has been shown in the reference.[14] One or more capped Keggin structures have never been observed in the heteropolyanion of Mo and W, because such species become positively charged.

Using molecular models, we counted the number of closed loops on a capped Keggin ion series of $[PV_{12+n}O_{40+n}]^{(15-3n)-}$ ($n = 1 - 4$) in Fig. 4. In the Keggin structure ion of $n = 0$, α-$[PV_{12}O_{40}]^{15-}$, there are six capping sites by trigonal bipyramidal VO_5 unit. However, since the total charges of the penta- and hexa-capped ions become zero and three positive, respectively, their structural parameters will be meaningless. In the monocapped Keggin ion of $n = 1$, there are the same number of closed loops as observed in the parent ion, because of no additional closed loop passing through the cap. Only a parameter A is varied from 12 to 13. The bicapped ion of $n = 2$ contains two types of isomer; one is the configuration that two caps are *trans*-located and the other that two caps are *cis*-located. In the "*trans*" isomer, there exists eight additional closed loops passing through six VO_6 octahedra and two *trans*-located VO_5 caps, besides the contribution

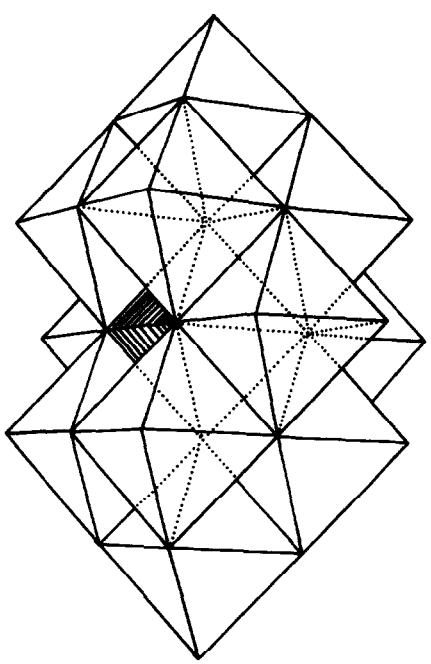

Fig. 3. Polyhedral model of the $[XV_{13}O_{38}]^{7-}$ (X = Mn(IV), Ni(IV)).[12] Shaded octahedron represents X.

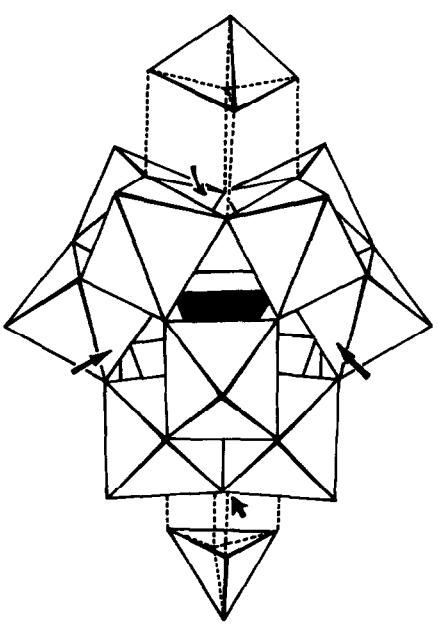

Fig. 4. Polyhedral model of the $[PV_{12+n}O_{40+n}]^{(15-3n)-}$ ($n = 1$–4).[13,14] Arrows show capping sites by trigonal bipyramidal VO_5 unit.

Table 1. Structural parameters of a capped Keggin heteropolyvanadate series $[PV_{12+n}O_{40+n}]^{(15-3n)-}$

	Formula	Structure and Configuration	A	(B, C)	η
n = 0	$PV_{12}O_{40}^{15-}$	Keggin structure	12	(6, 4)	2
n = 1	$PV_{13}O_{41}^{12-}$	monocapped Keggin structure	13	(6, 4)	1.85
n = 2	$PV_{14}O_{42}^{9-}$	bicapped Keggin structure			
		(1) "trans"-isomer	14	[(8, 8) + (6, 4)]	6.29
		(2) "cis"-isomer	14	(6, 4)	1.71
n = 3	$PV_{15}O_{43}^{6-}$	tricapped Keggin structure			
		(1) "cis-cis"-isomer	15	[(7, 3) + (6, 4)]	3
		(2) "trans-cis"-isomer	15	[(8, 8) + (6, 4)]	5.87
n = 4	$PV_{16}O_{44}^{3-}$	tetracapped Keggin structure			
		(1) "trans"-vacant isomer	16	[2(8, 8) + (8, 2) + (12, 2) + (6, 4)]	12
		(2) "cis"-vacant isomer	16	[2(7, 3) + (8, 8) + (6, 4)]	8.125

from the Keggin ion itself, or $(B, C) = (6, 4)$. On the other hand, in the "*cis*" isomer there is no additional loop passing through two *cis*-located VO_5 caps. Thus, only a parameter A is varied from 12 to 14 and the parameters (B, C) of the Keggin ion are not influenced by attaching two *cis*-caps. The tricapped Keggin ion of $n = 3$ contains also two types of isomer; one is the configuration that three caps are *cis*-located to each other, and the other that two of three caps are *trans*-located and the remaining cap is *cis*-located to them. In the former ("*cis–cis*") configuration, we can count three additional closed loops passing through four VO_6 octahedra and three VO_5 caps, besides the contribution from the Keggin ion itself. On the other hand, in the latter ("*trans-cis*") configuration, we can count eight closed loops passing through two *trans*-located caps and no closed loop through two *cis*-located caps as additional loops. The results are presented in Table 1. The structural stability indexes indicate that the capping markedly varies the structural stability of the parent Keggin ion, especially the monocapped ion and "*cis*" bicapped ion are less stabilized than the parent ion, whereas the "*trans*" bicapped ion is remarkably stabilized. The tetracapped polyanion of $n = 4$ has two types of isomer. They become substantially identical with the isomers of the bicapped ion, because the positioning way of two vacant sites in the six possible sites can be considered. As shown in Table 1, the stability indexes of them are much larger than that of "*trans*" bicapped ion. These are attributed to the presence of many closed loops passing through "*trans*"-located caps, "*cis-cis*"-located caps and four caps consisting of two sets of "*trans*"-caps, in addition to the closed loop of the parent Keggin ion. However, it has not been known whether the tetracapped polyanion is an existing material or not. When it is actually nonexistent, other factors should be taken into account for the interpretation such as the effects of the electric charge, the number and degeneracy of geometrical isomers in the polyanion, in addition to the structural stability index.

An isopolyanion with larger index than that observed in the isopolyanions of Mo and W such as $[Mo_6O_{19}]^{2-}$, $[W_6O_{19}]^{2-}$, $[W_{10}O_{32}]^{4-}$, metatungstate $[H_2W_{12}O_{40}]^{6-}$ $(\eta = 2)$ is found in the isopolyvanadate $[V_{10}O_{28}]^{6-}$. This isopolyanion contains two VO_6 octahedra with no oxo-type oxygens[15] which cannot be treated as "heteroatom" (Fig. 5). For the isopolyvanadate, we have estimated 2.8 as the stability index from $A = 10$ and $(B, C) = [(6, 2) + (4, 4)]$. This isopolyanion has been used as a starting material for the preparation of $[XV_{13}O_{38}]^{7-}$ compounds, but it has been also

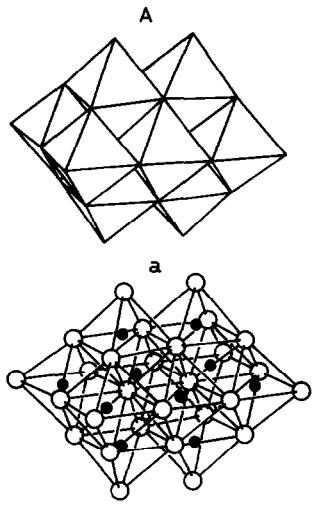

Fig. 5. Polyhedral model (A) of the $[V_{10}O_{28}]^{6-}$ and its framework bond model (a).[15] Open circles are oxygens and filled circles are vanadium atoms.

known to be recovered by a decomposition of the 1:13 heteropolyvanadate under an appropriate pH.[11] Noteworthily, it has been shown by ^{51}V-NMR that the aforementioned bicapped Keggin-ion readily decomposes to the isopolyvanadate by the raised pH of the aqueous solution.[14]

Here we wish to propose an additional rule; when a heteropolyanion decomposes, or degradates, into some isopolyanions under an appropriate condition, the isopolyanion possessing the

largest stability index is predominantly produced. This is the case not only for the heteropolyvanadate anions, but also for the Waugh-type $[XMo_9O_{32}]^{6-}$ and the Anderson-type $[XMo_6O_{24}H_6]^{3-}$ polyanions. The starting material in the preparations of the latter compounds is the $[Mo_7O_{24}]^{6-}$ ($\eta = 1$). When these heteropoly compounds are passed through a cation-exchange resin column and are converted to the soluble forms in non-aqueous solvents, the isopolyanion $[Mo_6O_{19}]^{2-}$ ($\eta = 2$) as a decomposed product or an impurity is predominantly produced.[16,17] The proposed rule predicts that a part or all of $[W_6O_{19}]^{2-}$, $[W_{10}O_{32}]^{4-}$ and $[H_2W_{12}O_{40}]^{6-}$ isopolytungstates will be possibly produced by degradation of some heteropolytungstates. In the preparation by the Brown–Mair method of various Keggin-type $[XW_{12}O_{40}]^{n-}$ polyanions,[18,19] the actual starting material is considered to be paratungstate $[H_2W_{12}O_{42}]^{10-}$ ($\eta = 0$) produced from an acidic aqueous solution of sodium tungstate. In this preparation, metatungstic acid is produced as by-product. Purification has been performed on the basis of the difference of thermal stabilities of the desired product and the metatungstic acid. In such a purification we have experienced that the metatungstic acid is also produced by thermal degradation of once formed dodecatungstometallic acid $H_n[XW_{12}O_{40}]$. This fact is also compatible with the rule.

In spite of $\eta = 0$, the Silverton-type polyanions $[XMo_{12}O_{42}]^{8-}$ (X = Ce(IV), Th(IV), U(IV)) are very stable and their counter cations can be exchanged without any decomposition of the skeleton.[20] This stability index is smaller than that ($\eta = 1$) of its starting material $[Mo_7O_{24}]^{6-}$. In this case, the high valence heteroatom of rare earth element should contribute significantly to the actual stability. In addition, it has been known that, in the preparation of the X = Co(III) compound in Anderson-type $[XMo_6O_{24}H_6]^{3-}$ ($\eta = 1$), the Evans–Showell-type heteropolyanion $[Co_2Mo_{10}O_{38}H_4]^{6-}$ ($\eta = 0$) is produced as major byproduct and the isolated X = Co(III) compound can be almost entirely converted to the latter compound in the presence of catalyst.[21] These facts are also attributed to the specific effect of the Co(III) ion as the heteroatom, because such phenomena have been known only in the case of X = Co(III) compound. Recently an interesting heteropolyanion $[As_4W_{40}O_{140}]^{28-}$, which shows a cryptate-like function, has been reported.[22,23] This compound consists of four $[AsW_9O_{33}]$ subunits and four WO_6 octahedra linking them, the former being considered as a half-Dawson-type polyanion (Fig. 6). This macrocyclic polyanion has four local closed loops belonging to the subunits and has no closed loop passing through inter-subunits. The stability index is estimated to be 0.6 from $A = 40$ and $(B, C) = (6, 4)$, indicating that this polyanion itself is metastable. Thus, the actual stability may possibly be due to the presence of other supporting elements and cations. This may lead to the apparent crown-ether or cryptate function.

The structural parameters of the compounds studied here are summarized in Table 2.

(*Received* 4 *October* 1983; *accepted after revision* 30 *March* 1984)

Abstract—New Schiff bases derived from 2-acetyl-1,8-dihydroxy-3,6-dimethylnaphthalene(H_2addn) and 1,2-propanediamine(pn), 2,3-butanediamine(pn) and 1,2-cyclohexyldiamine(chn) have been prepared and characterized as (H_4addn-diam). In this work is reported an improved experimental method which yields well characterized mononuclear species of H_4addn-en and H_4addn-pn with Cu(II), Ni(II) and Co(II). The Cu(II) complex has been studied by esr which unambigously shows a N_2O_2 coordination mode for the metal ion. Based on the spectral characteristics of these complexes we conclude that all metal atoms have the same coordination mode. Only one binulear complex, [$NiUO_2$(addn-en)] is reported in this work. All attempts to synthesize binuclear complexes with first transition series metal ions were unsuccessful.

Binucleating ligands and their mononuclear and binuclear metal complexes are of current interest and since the early 1970's the field has been extensively growing.[1–3] In order to synthesize and later compare this kind of metal complexes we selected as ligands Schiff bases derived from 2-acetyl-1,8-dihydroxy-3,6-dimethylnaphthalene(H_2addn) and 1,2-alkyldiamines, namely: ethylenediamine(en), 1,2-propanediamine(pn), 2,3-butanediamine(bn) and 1,2-cyclohexyldiamine(chn). Schiff bases derived from H_2addn with ethylenediamine, 1,3-propanediamine and diethylenetriamine and some mononuclear complexes of these ligands had already been reported;[2] however we observed that the chemical analyses of the complexes obtained with our ligands following the reported method were not in agreement with the expected stoichiometries. In fact, these solids were mixtures of the correct complexes and yellow impurities of unknown stoichiometries. We report on in this paper a modification of the reported method which yields uniquely the desired mononuclear complex together with a study of the complexes obtained.

Binuclear complexes. Cu/Cu, Ni/Ni, VO/VO, Ni/Cu with several Schiff bases have also been reported[2] however with the ligands employed in this communication all attempts we have made to get these using only VIIIb transition metals have been unsuccessful. In all cases we obtained not well characterized materials with slightly low metal contents. The only dinuclear complex obtained had to contain at least one cation with a strong affinity toward oxygen.

EXPERIMENTAL

Dehydroacetic acid was generously supplied by INDUKERN (Barcelona). 2-acetyl-1,8-dihidroxy-3,6-dimethylnaphthalene (H_2addn) was prepared from dehydroacetic acid by literature method.[4,5] Its purity was checked by elemental analysis, ^{1}H NMR, IR electronic and mass spectroscopy and compared to literature data.[2,4,5]

Preparation of the Schiff bases (H_4addn-diam; diam = en,, pn, bn, chn)

To a solution of H_2addn (1,2 g 0.0052 mol) in hot EtOH (80 cm^3), the corresponding diamine (0.0026 mol) dissolved in hot EtOH (10 cm^3) was added all at once. The mixture was refluxed for 2–3 hr. During this time a yellow (en, pn) or orange (chn, bn) solid was precipitated. While warm, the precipitate was filtered, washed with EtOH and dried at 70°C (Table 1). For chn, an additional

H_4addn-bn	orange	56.0 %	74.97	74.8	7.08	7.2	5.46	5.3

product was obtained after setting the filtered mother liquor at r.t. for few hours. The analyses were identical to these of the first precipitate, however the m.p. was very much different.

Preparation of mononouclear complexes M(H_2-addn-diam) (M = Cu, Ni, Co, diam = *ethylenediamine, 1,2-propanediamine*)

Copper(II) *or nickel*(II) *complexes.* A stirred suspension of H_4addn-diam (diam=en, pn) (0.001 mol) in hot MeOH (300 cm^3) was brought to reflux, and copper acetate monohydrate or nickel acetate (0.001 mol) dissolved in hot MeOH (50 cm^3) was added in small portions until the metal salt addition was finished (7–8 hr). The mixture was refluxed for an additional 2 hr period. During this time a coloured solid precipitated which was filtered, washed with MeOH and dried at 70 °C (Table 2).

Cobalt(II) *complexes.* The procedure was as before but all the operation was carried out under a nitrogen atmosphere and the solvents employed had been previously degassed (Table 2).

Preparation of UO_2Ni (addn-pn)

To a refluxing solution of Ni(H_2addn-pn) (0.001 mol; CH_2Cl_2, 70 cm^3) were consecutively and slowly added methanol (75 cm^3) and LiOH (0.002 mol; methanol, 25 cm^3). After keeping the solution at the boiling temperature for a $\frac{1}{2}$ hr, $UO_2(CH_3COO)_2$ (0.001 mol; methanol, 40 cm^3) was slowly added during 1 hr and the mixture was refluxed overnight. The solvent was slowly evaporated until the first precipitate appeared. After keeping the system at r.t. for a few hours the precipitate was filtered, washed with Et_2O and dried under vacuum (Table 2).

Physical measurements

Infrared spectra were obtained in the range 4000–250 cm^{-1} using a Beckman IR-20A spectrometer. Solid state spectra were recorded as KBr pellets. UV-visible near IR spectra were obtained with a Beckman Acta III and Beckman 2000 recording spectrometer, in EtOH or CH_2Cl_2 solutions. The ^{1}H NMR spectra were recorded at 80 MHz using a Brucker WP8054 spectrometer. The mass spectra of H_2addn was obtained using a Hewlet-Packard 2985 GC/MS system spectrometer. Electron spin resonance of the copper compounds were obtained at the X band (9.4093 GH_z) using a Varian spectrometer. Elemental Analysis were carried out with a Perkin–Elmer Elemental Analyzer 240B and the metal analysis using a EDTA method[6] after destroying the complexes with $HNO_3/HClO_4$ mixture acids.

RESULTS AND DISCUSSION

Ligands

All the diimines synthesized were very insoluble in almost all the common solvents and this fact seriously limited their study. The compound with ethylenediamine had been previously obtained by M. Vidali *et al.*[2] and our results were in accordance with them.

IR spectra show bands at 3400 cm^{-1} (ν(OH)), 1600 cm^{-1} (ν(CN)) and 1270–1280 cm^{-1} (ν(CO)) in agreement with the values reported in the literature.[4,7] Electronic spectra show bands at 22,500–23,000 cm^{-1} due to the azomethine group.[8]

Mononuclear complexes

By reaction of H_4addn-diam (diam=en, pn) with Cu(II), Ni(II) and Co(II) acetates six mononuclear complexes M(H_2addn-diam) were obtained. The Cu(II) and Ni(II) complexes with H_4addn-en were previously reported.[2] However we found that the metal contents of the complexes made following the reported method were low. Upon slow evaporation of a Cl_2CH_2 solution of "Cu (H_2addn-pn)" we observed that in fact these solids were composed of two materials, one amorphous and yellow and the other one crystalline and deep coloured. A pure crystalline solid was obtained by slow diffusion of ethyl acetate into a solution of "Cu(H_2addn-pn)" in pyridine. Analysis of this compound gave for the first time satisfactory elemental analysis for the stoichiometry proposed. In addition, we found that solids with satisfactory elemental analysis and good yields (Table 2) would be obtained directly from synthesis with a variation of the reported method that consists in a very slow addition of the metal acetate through a period of 7–8 hr as indicated in the experimental section.

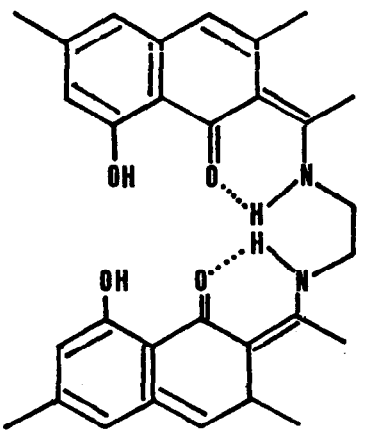

Fig. 1. H_4addn-diam.

All complexes synthesized decompose above 300°C and they are only soluble in very good solvating solvents (pyridine, dimethylsulfoxide, N,N-dimethylformamide, chloromethane...) the nickel(II) complexes are the least soluble of all of them.

IR spectra show bands at 3400 cm^{-1} ν(OH), 1630–1640 cm^{-1} (ν(CN)) and 1330–1345 cm^{-1} ($\nu(CO)$) compatible with a N_2O_2 coordination mode of the metal ion.[2,9]

The electronic spectra of the Cu(II) complexes (Table 3) show bands in the low energy region. The lowest energy bands at 14,815 cm^{-1} are assigned to a $^2E \rightarrow {}^2T_2$ d–d transition and they are in the range found for square planar N_2O_2 coordination mode as it is observed in the Cu(II) complexes derived from several salicylaldiimines[10–13] in which only the square planar N_2O_2 coordination mode can be found.

The electronic spectra of the Ni(II) complexes only show one band (at 17,544–17,241 cm^{-1}) which can be assigned to a d–d transition. Similar spectra are found in Ni(II) complexes with salicylaldiimines.[10,11] This band is assigned to the transition $^1A(F) \rightarrow {}^1B(G)$ for a d^8 ion in a C_{2v} local symmetry environment.

The electronic spectra of the Co(II) complexes (Table 3) is in general difficult to interpret due to spin-orbit and vibronic effects. Only a shoulder can be observed in the visible region for all of the complexes synthesized at 19231–18868 cm^{-1} which is assigned to d–d transitions. In the near infrared zone we found a weak band at 10,870 cm^{-1} for the complex with H_4addn-en. This spectra is compatible with a square planar N_2O_2 metal coordination mode as is observed in Co(II) complexes with salicylaldiimines.[10,14,15]

Although the spectral data strongly suggest the presence of the N_2O_2 isomer for all of the complexes synthesized, in our opinion these are not completely conclusive and, on the other hand, they do not give any information concerning purity with respect to the O_2O_2 isomers. Unfortunately no other proof has been given about it in this kind of complex, so we report on the esr spectra of the Cu(II) complexes which in our opinion, gives us definitive evidence for the N_2O_2 metal coordination mode.

EPR spectra for the Cu(II) complexes were recorded at room temperature in CH_3Cl solution. Figure 2 shows the typical first derivative of the spectra of the Cu(II) complexes.

The hyperfine structure of the spectra consists of four non symmetrical bands where the non symmetry is due to relaxation problems due to the

(a) This work.

coupling with the nuclear magnetic moment $I = 3/2$ of the ^{63}Cu atom, which is typical of almost all Cu(II) complexes. In the last two bands, at higher field, the superhyperfine structure is observable (five bands with relative intensities 1 : 2 : 3 : 2 : 1) due to the coupling with the two equivalents ^{14}N atoms ($I = 1$). The hyperfine and superhyperfine splitting constants a_1/g, a_2/g and g factor calculated from the spectra are shown in Table 7. The spectral characteristics of several Cu(II) complexes with Schiff bases[16] are also reported in Table 3. For all of them it has been established a square planar N_2O_2 metal coordination mode by X-ray diffraction studies. Due to the great similarity between them, we propose a similar structure for our two Cu(II) complexes.

Binuclear complexes Binuclear complexes with several Schiff bases, Cu/Cu, Ni/Ni, VO/VO, Ni/Cu are reported in the literature. However, we have not been successful in getting any homo- or hetero-dinuclear complexes using only VIIIb transition metals and the ligands reported in this communication.

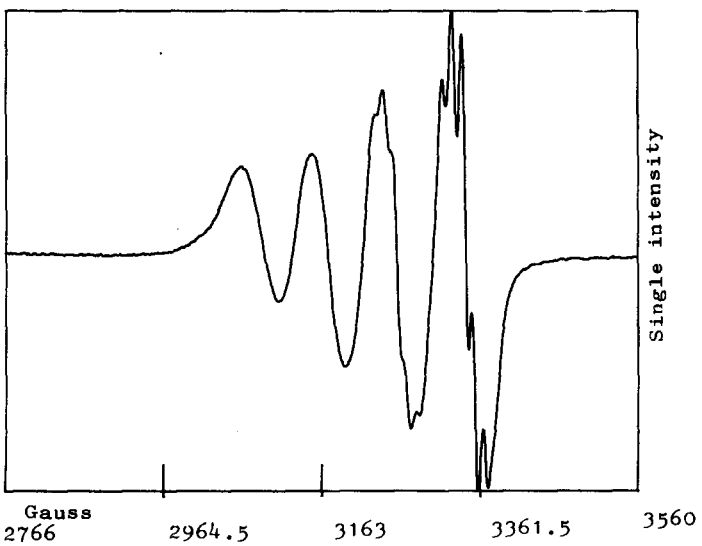

Fig. 2. First derivative esr spectra of Cu(H_2addn-en) at 298 K in CH_3Cl solution (frequency 9.4093 GH_z).

In addition to the reported method for Schiff base derivatives H_2addn we have tried many preparative routes for these homo- and heterobinuclear complexes with our ligands. In all cases, except one (UO_2Ni(addn-pn)) we have obtained black materials not well characterized with low metal contents. We think that it is due to the low reactivity of the phenolic moiety of the ligands, so only oxocations with strong oxygen affinity as UO_2^{2+} and perhaps VO^{2+} should give homo- or heteropolynuclear complexes with Schiff bases derived from 2-acetyl-1,8-dihydroxy-3,6-dimethylnaphthalene.

Acknowledgements—This work was supported in part by "Comisión Asesora de Investigatión Científica y Técnica". We are indebted to "Laboratoire de Chimie de Coordination of the CNRS" (Toulouse, France), specially Mr. A. Mari, for recording esr spectra.

(*Received* 21 *February* 1984; *accepted* 30 *March* 1984)

Abstract—Reaction of $UO_2(O_2CCH_3)_2$ with pentafluorobenzoic acid yields $UO_2(O_2CC_6F_5)_2$, which has been converted into the solvated complexes $UO_2(O_2CC_6F_5)_2L_2{\cdot}S$ [L_2 = 2,2′-bipyridyl (bpy), S = 0.33 (PhH) or 0.07 (*t*-BuOH); L = Ph_3PO, S = *t*-BuOH; L = Ph_3AsO, *S* = 0.40 (*t*-BuOH)] and the solvent free $UO_2(O_2CC_6F_5)_2L_2$ [L_2 = bpy; L = Ph_3PO]. The crystal structure of $UO_2(O_2CC_6F_5)_2$bpy (orthorhombic, space group $P2_12_12_1$; a = 18.45(2), b = 18.94(2), c = 7.069(8) Å, Z = 4] reveals distorted hexagonal bipyramidal stereochemistry with a *trans* UO_2 group, chelating pentafluorobenzoate ligands, and chelating 2,2′-bipyridyl, which is significantly displaced from the hexagonal plane. The structure of $UO_2(O_2CC_6F_5)_2(OPPh_3)_2{\cdot}t$-BuOH [rhombohedral, space group *R*3; a = 21.51(3) Å, α = 117.28(5)°, Z = 3] shows *trans* UO_2, pseudo *trans* Ph_3PO ligands, and one unidentate and one *disordered* chelating pentafluorobenzoate ligand, whilst *t*-BuOH could not be located because it is highly disordered. Relationships between $\nu(CO_2)$ frequencies and the carboxylate coordination are discussed, and $UO_2(O_2CC_6F_5)_2(OAsPh_3)_2{\cdot}0.40$ (*t*-BuOH) is considered to have stereochemistry similar to that of the phosphine oxide complex. The complexes undergo decarboxylation in dimethyl sulphoxide yielding pentafluorobenzene and carbonatodioxouranium(VI) species not $UO_2(C_6F_5)_2$ derivatives.

Although there has been some investigation of uranyl benzoates[1,2] and recent studies of uranyl *p*-aminosalicylates[3] and anthroates,[4,5] the chemistry of uranyl complexes with aromatic carboxylates has been neglected by comparison with the behaviour of uranyl alkanoates, aminopolycarboxylates, and pyridinecarboxylates.[6,7] In addition, little is known of complexes with fluorinated carboxylates. We now report a study of uranyl pentafluorobenzoate and its coordination derivatives with 2,2′-bipyridyl, triphenylphosphine oxide, and triphenylarsine oxide. Since the complexes are potential sources of uranyl pentafluorophenyl derivatives by decarboxylation reactions, a well established route to Main Group element fluorocarbon compounds[8,9] and of increasing value for transition metal analogues,[9–11] their thermal decomposition has also been studied.

RESULTS AND DISCUSSION

Preparations of dioxobis(pentafluorobenzoato)uranium(VI) derivatives

Uranyl pentafluorobenzoate was conveniently prepared by reaction of uranyl acetate with pentafluorobenzoic acid.

$$UO_2(O_2CCH_3)_2 + 2C_6F_5CO_2H \rightarrow UO_2(O_2CC_6F_5)_2 + 2CH_3CO_2H.$$

Some difficulty was experienced in obtaining the compound analytically pure, partly owing to solvent retention.

Reaction of uranyl pentafluorobenzoate with 2,2′-bipyridyl in ethyl acetate, in diethyl ether followed by crystallization from benzene, and in *t*-butanol yielded solvent-free $UO_2(O_2CC_6F_5)_2bpy$, $UO_2(O_2CC_6F_5)_2bpy.0.33(C_6H_6)$ and $UO_2(O_2CC_6F_5)_2bpy.0.07(t\text{-BuOH})$ respectively. In the last two cases, the solvent was retained on prolonged heating under vacuum. The compositions were established by ^1H NMR measurements and were consistent with analytical data. Reactions of uranyl pentafluorobenzoate with triphenylphosphine oxide and triphenylarsine oxide in *t*-butanol yielded $UO_2(O_2CC_6F_5)_2(OPPh_3)_2.t\text{-BuOH}$ and $UO_2(O_2CC_6F_5)_2(OAsPh_3)_2.0.40(t\text{-BuOH})$ respectively. The former complex was isolated solvent-free from a similar preparation in benzene containing a trace of ethanol.

Properties of dioxobis(pentafluorobenzoato)-uranium (VI) *compounds*

Vibrational assignments for structurally significant IR and, for representative compounds, Raman frequencies are given in Table 1. For $UO_2(O_2CC_6F_5)_2bpy$ and $UO_2(O_2CC_6F_5)_2(OPPh_3)_2$ there is little difference between the values for the solvent-free complexes and various solvates (Table 1), indicating that solvation does not cause significant structural modification. The separations between the $\nu(CO_2)$ frequencies for $UO_2(O_2CC_6F_5)_2$ and the bipyridyl complex are significantly less than that for sodium pentafluorobenzoate[12] (Table 1), indicative[13] of bidentate or bridging bidentate carboxylate coordination. (For $[(C_6F_5)_2Ph_3PO]TlO_2CC_6F_5]_2$, in which the $C_6F_5CO_2$ groups are both chelating and bridging,[14] the separation[15] is 161 cm^{-1}.) By contrast, the complexes $UO_2(O_2CC_6F_5)_2L_2$ ($L = Ph_3PO$ or Ph_3AsO) show two sets of $\nu(CO_2)$ frequencies (Table 1), one with a separation much larger than ionic, indicative[13] of unidentate carboxylate coordination, and one smaller than ionic, as expected for bidentate or bridging bidentate pentafluorobenzoate. Crystallography (next section) has confirmed the presence of both unidentate and chelating carboxylate ligands in $UO_2(O_2CC_6F_5)_2(OPPh_3)_2.t\text{-BuOH}$. This coordination arrangement differs from that proposed[16] for $UO_2(O_2CCH_3)_2(OPPh_3)_2$, viz. solely bidentate carboxylate groups. The $\nu(CO_2)$ frequencies for this complex (this work) show a very low separation compared with acetate ions[13] (Table 1) consistent with chelating acetate ligands.

[a] I.r. data. [b] Raman data. [c] E = P or As. [d] Not determined. [e] From ref.12. [f] From ref.13.

All uranyl pentafluorobenzoates show only one ν_{as}(OUO) frequency and, where Raman data were obtained, one ν_s(OUO) frequency (Table 1), and the IR and Raman values are not coincident. This is indicative of essentially linear OUO stereochemistry. Slight deviations ($<10°$) from linear OUO observed in the crystal structures of two of the complexes may not be meaningful (see below), and in any case such deviations may be too small to give two observable bands in both IR and Raman spectra. The ν(PO) and ν(AsO) frequencies (Table 1) of the $UO_2(O_2CC_6F_5)_2L_2$ (L = Ph_3PO or Ph_3AsO) complexes show the shifts from free ligand values[17,18] expected[19-22a] on coordination.

The molar conductances of the complexes in methanol are approximately half the values expected[23] for 1:1 electrolytes in this solvent, and indicate that substantial ionization occurs, e.g.

$$UO_2(O_2CC_6F_5)_2 \rightleftharpoons UO_2(O_2CC_6F_5)^+ + C_6F_5CO_2^-.$$

The ^{19}F NMR spectra in $(CD_3)_2SO$ (Experimental Section) show some broadening, which could be due to exchange phenomena associated with partial ionization. Better resolution is observed on heating and for $UO_2(O_2CC_6F_5)_2$ in ether, in which significant ionization is not expected. Only features indicative[24a] of uranium(VI) were observed in the visible spectra (Experimental Section), hence it is unlikely that broadening arises from paramagnetic species of lower oxidation state.

Crystal and molecular structures of $UO_2(O_2CC_6F_5)_2$bpy *and* $UO_2(O_2CC_6F_5)_2(OPPh_3)_2$·*t*-BuOH

The molecular structures of the complexes of uranyl pentafluorobenzoate with 2,2′-bipyridyl and triphenylphosphine oxide were determined by X-ray crystallography. The former is monomeric and has hexagonal bipyramidal stereochemistry around the uranium(VI) ion (Fig. 1). Oxygens O(3), O(4),O(5), O(6) from the two chelating pentafluorobenzoate ligands and the nitrogen atoms of bipyridyl, N(1) and N(2) occupy equatorial coordination sites. However, the bipyridyl ligand is twisted out of the plane described by O(3), O(4), O(5), O(6) and uranium, with N(1) and N(2) being symmetrically displaced from this plane by $-0.79(5)$ and 0.74(4) Å respectively (Table 2). The plane of the bipyridyl makes a dihedral angle of *ca.* 38° with the O(3), O(4), O(5), O(6) and uranium plane. Selected bond lengths and angles are given in Table 3.

The dioxouranium angle, O(1)–U–O(2), 172(2)°

[a]The planes are given by the equations (i) 0.341X - 0.573Y - 0.745Z - 0.572 = 0 for $UO_2(O_2CC_6F_5)_2$bpy and (ii) 0.255X + 0.815Y' - 0.597Z - 11.16 = 0 for $UO_2(O_2CC_6F_5)_2(OPPh_3)_2$.*t*-BuOH where X = *ax*, Y = *by*, Y' = *b*-($\frac{1}{2}$ + y) and Z = *cz*.

is seemingly distorted from the linear configuration usually found in molecular uranyl complexes.[25] Several other monomeric complexes have an apparently bent uranyl group, e.g. 176.6(6)° in $UO_2(trop)_2.EtOH$[26] (trop = tropolonate), 174.8° in $UO_2(ox)_2.(Hox)$[27] (Hox = quinolin-8-ol) and 174.2(6)° and 173.8(5)° respectively in the α and β forms of a uranyl Schiff base complex.[28] However, the difficulties associated with the accurate location of light atoms in the presence of very heavy ones in X-ray studies may serve to limit the accuracy of the determination of these angles. Nevertheless, the dioxouranium(VI) group may actually be distorted in capped polyhedra.[29]

Displacement of the 2,2′-bipyridyl ligand from the equatorial plane can be attributed to steric crowding of the uranium ion. The ionic radius of eight-coordinate uranium(VI) is only 0.86 Å.[30] Consequently, the angles O(1)–U–N(1) and O(2)–U–N(2) are both considerably contracted from the ideal value of 90° to 76(1)° and the intramolecular contracts O(1)...N(1), 2.66 Å and O(2)...N(2), 2.63 Å are somewhat shorter than the sum of the Van der Waal's radii of oxygen (1.40 Å) and nitrogen (1.50 Å).[31] This may also reflect the steric strain around uranium. The bites of the two pentafluorobenzoate ligands, 1.97 and 2.08 Å, are sufficiently small to allow hexagonal bipyramidal stereochemistry. However, the bite of the 2,2′-bipyridyl ligand is much larger, 2.62 Å, causing congestion around the uranium and consequently the twisting of this ligand from the plane. However, in view of the structure of $UO_2(O_2CC_6F_5)_2(OPPh_3)_2$.*t*-BuOH (below), it is surprising that steric strain is not relieved by adopting pentagonal bipyramidal stereochemistry with one unidentate pentafluorobenzoate.

The complex $UO_2(O_2CC_6F_5)_2(OPPh_3)_2$.*t*-BuOH is also monomeric (Fig. 2), but in this case, the stereochemistry is pentagonal bipyramidal with one unidentate and one chelating carboxylate. The pentafluorophenyl ring of the latter is disordered with occupancies of 64% in one position and 36% in the other, and the two rings are displaced up to

1 Å from each other. However, the unidentate carboxylate is not significantly disordered. The lattice solvent, *t*-BuOH, is also highly disordered and could not be satisfactorily located. Consequently, it was omitted from the analysis. Selected bond lengths and angles are given in Table 3.

The oxygens O(3), O(4) from the triphenylphosphine oxide molecules and O(5), O(6) and O(7) from the pentafluorobenzoate ligands occupy the equatorial positions in a *planar* arrangement (Table 2) unlike the structure of $UO_2(O_2CC_6F_5)_2bpy$. The triphenylphosphine oxide ligands are in a pseudo-*trans* configuration in keeping with their steric requirements, and are almost centrally disposed about the uranium ion which is almost on a pseudo-centre of symmetry. Consequently, the uranyl bonds, 1.63(3) and 1.87(4) Å, and angle, 171(2)°, are not considered to be significantly different from the usual values of *ca.* 1.70 Å each and 180° respectively. A similar effect occurs in the uranyl complex, $UO_2(hfa)_2NH_3$[32] (hfa = 1,1,1,5,5,5-hexafluoropentane-2,4-dionate), where the uranyl group is centric in a non-centric space group.

The five equatorial U–O distances range between 2.17(5) and 2.47(5) Å. The non-coordinated oxygen O(8) of the unidentate carboxylate is 3.93 Å from the uranium centre and hence is clearly non-bonding. In comparison with the 2,2′-bipyridyl complex in which there are short uranyl oxygen–nitrogen contacts, there are no uranyl oxygen-coordinated oxygen contacts less than twice the Van der Waal's radius of oxygen in the triphenylphosphine oxide complex.

The structures (Figs. 1 and 2) confirm conclusions as to the nature of the pentafluorobenzoate coordination derived from IR spectroscopy (above), and indicate that IR criteria developed for

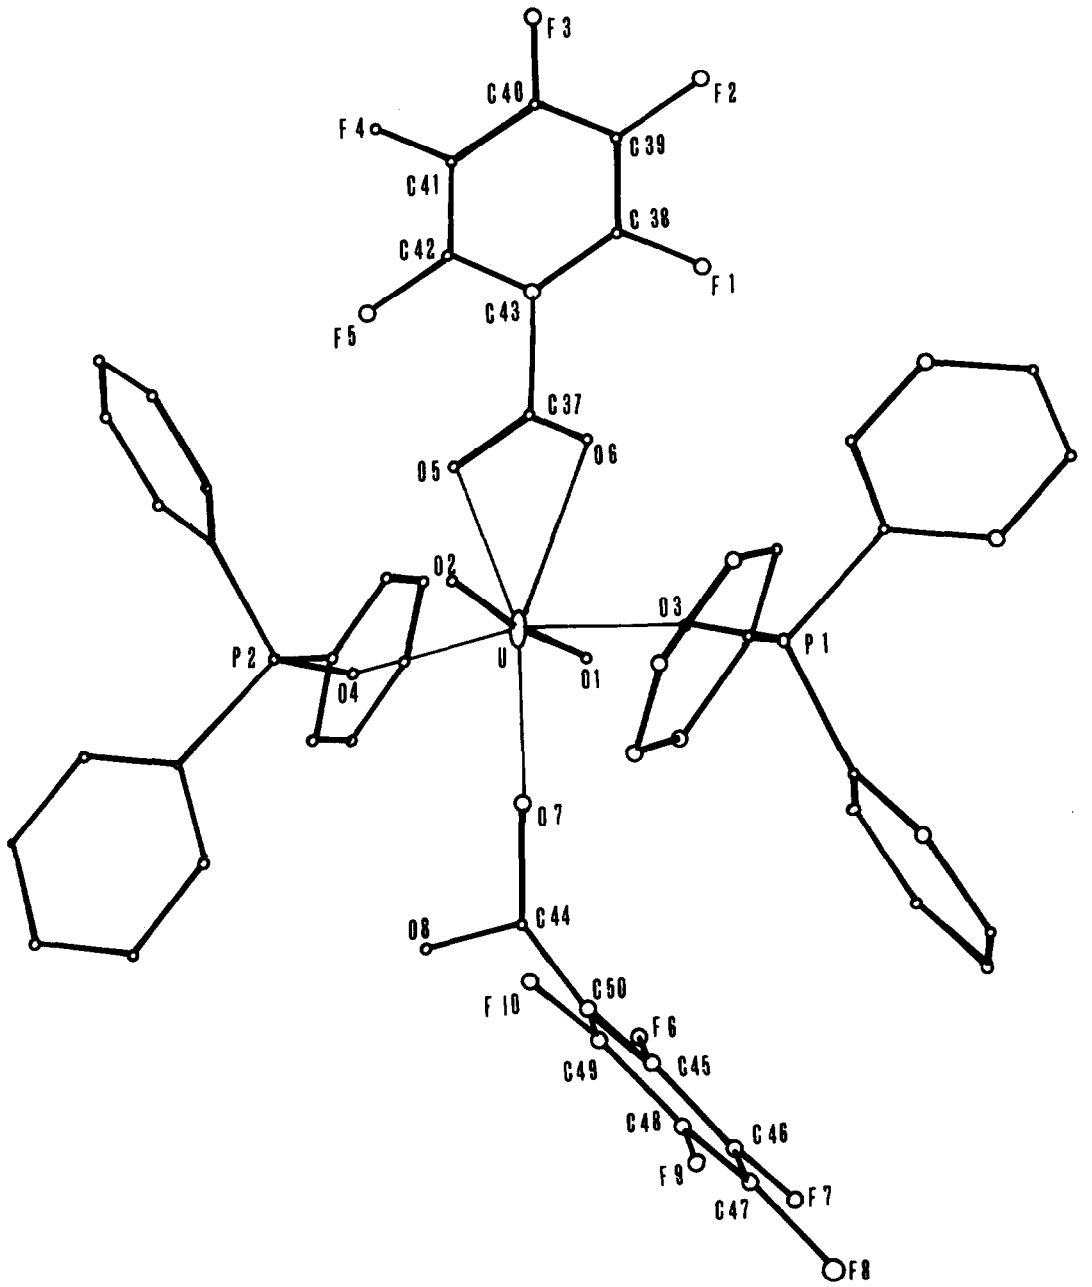

Fig. 2. Molecular structure of dioxobis(pentafluorobenzoato)-bis(triphenylphosphine oxide)uranium(VI).

acetate and trifluoroacetate coordination[13] are applicable to pentafluorobenzoate complexes. However, the inability of the IR method to distinguish chelating and bridging carboxylates is also readily apparent. For the chelating pentafluorobenzoates of the present complexes, the separations between the $\nu(CO_2)$ frequencies (*ca.* 160 cm^{-1}; Table 1) are comparable with that (161 cm^{-1})[15] for $[(C_6F_5)_2Ph_3POTlO_2CC_6F_5]_2$, in which the pentafluorobenzoate groups are both unsymmetrically bridging and chelating.[14]

The similarity between the $\nu(CO_2)$ frequencies of $UO_2(O_2CC_6F_5)_2(OPPh_3)_2.t$-BuOH and $UO_2(O_2CC_6F_5)_2(OAsPh_3)_2.0.40(t$-BuOH) makes it certain that the latter complex has pentagonal bipyramidal stereochemistry with one chelating and one unidentate carboxylate ligand. Further crystallographic study is needed to determine the structure of uranyl pentafluorobenzoate without added neutral ligands. In the light of the $\nu(CO_2)$ frequencies and a likely coordination number greater than six, the pentafluorobenzoate groups

are probably both bridging and chelating. To this stage it has not been possible to grow suitable single crystals.

Decomposition of dioxobis(pentafluorobenzoato)-uranium (VI) *complexes*

When solutions of $UO_2(O_2CC_6F_5)_2$ or $UO_2(O_2CC_6F_5)_2L_2$ (L_2 = bpy; L = Ph_3PO) in dimethyl sulphoxide [or $(CD_3)_2SO$] are allowed to stand at room temperature for an extended period or are heated, carbon dioxide is evolved and pentafluorobenzene formed. Spectroscopic data (Experimental Section) for the uranium containing products indicate the presence of uranyl groups, carbonate ligands,[22b] and O-bonded dimethyl sulphoxide[22c] [see, e.g. $UO_2F_2OS(CH_3)_2$[33]]. No bipyridyl was detected in the uranyl complex from decomposition of $UO_2(O_2CC_6F_5)_2$bpy. The products are probably dimethyl sulphoxide complexes of uranyl carbonate. Despite thorough drying of the solvent, traces of water may remain and provide the proton source for pentafluorobenzene formation,

$$\text{e.g.}\quad UO_2(O_2CC_6F_5)_2 + H_2O + n(CH_3)_2SO \rightarrow UO_2CO_3[(CH_3)_2SO]_n + CO_2 + 2C_6F_5H.$$

Since neither uranium(IV) species nor decafluorobiphenyl are formed, decarboxylation is not similar to the well-known reaction of carboxylic acids with uranyl ions.[24b] The likely path involves decarboxylation of a dissociated pentafluorobenzoate ion, protonation of the resulting carbanion giving pentafluorobenzene and base, which absorbs carbon dioxide to give carbonate.

Thermogravimetric analysis indicated that uranyl pentafluorobenzoate is stable to 250°, but decomposition of the bipyridyl and phosphine oxide complexes commences at lower temperatures. There is no evidence for formation of dioxo(pentafluorophenyl)uranium(VI) species, and the sole weight loss of particular interest is evolution of *t*-butanol from $UO_2(O_2CC_6F_5)_2$-$(Ph_3PO)_2$.*t*-BuOH prior to more extensive decomposition.

EXPERIMENTAL

(1) *General*

Microanalyses were by the Australian Microanalytical Service, Melbourne. Uranium was estimated gravimetrically as uranyl quinolin-8-olate,[34] after treatment of the compounds with dilute nitric acid. IR spectra (4000–650 or 400 cm^{-1}) were recorded as Nujol and hexachlorobutadiene mulls with Jasco IRA-1 or Perkin–Elmer 180 spectrophotometers. Identical spectra were obtained with AgCl or KBr plates, hence no carboxylate exchange reactions occur with the alkali halide plates. Bands of medium or greater intensity not listed in Table 1 are given below.† Raman spectra of crystalline solids in sealed capillary tubes were obtained on a Spex Ramalog 5 laser Raman spectrophotometer.† ^{19}F- and ^1H-NMR spectra were obtained with Bruker WH-90 or Perkin–Elmer R32 spectrometers. Proton chemical shifts are in ppm downfield from internal tetramethylsilane or sodium 3-trimethylsilypropanesulphonate and fluorine chemical shifts in ppm upfield from internal $CFCl_3$. The solvent was $(CD_3)_2SO$ or $(CD_3)_2SO/CDCl_3$. Integrations were satisfactory for the proposed compositions hence they are not listed. Conductances were measured at 20°C with a Wayne Kerr B221A bridge using a cell of standard design fitted with shiny Pt electrodes. Thermogravimetric analyses were carried out with a Mettler ME-21 microbalance with a Cahn temperature programmer. Visible and UV spectra (220–700 nm) were obtained with Pye-Unicam SP 800 or Varian Techtron 635 spectrophotometers.

(2) *Reagents and solvents*

Bis(acetato)dioxouranium(VI) dihydrate (Pronalys Grade) and 2,2′-bipyridyl were from May and Baker and pentafluorobenzoic acid was from Bristol Organics. Triphenylarsine oxide from the reported method[35] and triphenylphosphine oxide (Fluka) were recrystallized from benzene. Nitrogen was purified by BASF R3/11 oxygen removal catalyst and Union Carbide 13X molecular sieves. *t*-Butanol was degassed with purified nitrogen prior to use. Light petroleum (b.p. 40–60°) and ether were dried over sodium. Ethyl acetate was purified by the reported method.[36] Dimethyl sulphoxide was dried over potassium hydroxide and then was refluxed over and distilled from calcium hydride under nitrogen. Other solvents were not purified.

(3) *Pentafluorobenzoatouranium*(VI) *complexes*

Dioxobis(pentafluorobenzoato)uranium(VI). Pentafluorobenzoic acid (15.3 g), bis(acetato)dioxouranium(VI) dihydrate (15.4 g), and *t*-butanol (300 cm^3) were heated under reflux for 2.5 hr under nitrogen. The resulting solution was filtered through a Celite pad to remove unreacted bis(-acetato)dioxouranium(VI) and was partly evaporated under vacuum. Toluene (100 cm^3) was added.

†Full details of IR and Raman frequencies and mass spectra, which show only ligand-derived ions, are available from the Editor.

The *title compound* was isolated by evaporation to dryness under vacuum, was recrystallized three times from ethanol/toluene (1:50, v/v), and dried (60°, 10^{-3} mm, 10 hr), giving a yellow powder (43%), dec.temp., 250° (Found: C, 23.9; F, 27.1; U, 34.0%. $C_{14}F_{10}O_6U$ requires C, 24.3; F, 27.5; U, 34.4%). IR absorption (see also Table 1): 1553m, 1532s, 1483s, 1414m, 1120m, 1007m, 998s, 988m, 812m, 745m cm^{-1}. ^{19}F NMR spectrum: 141.8, br (at 60°, m, ^3J 20 Hz), F2, 6; 150.6, br (unresolved at 60°) F4; 162.2, m, F3, 5. T.G.A.: 0.01% weight loss at 25–250°. Visible spectrum (EtOH), $\lambda_{max}(\epsilon)$: 419 (27.7 mol^{-1} dm^3 cm^{-1}) nm. Mol. cond. (MeOH), 35.4 S cm^2 mol^{-1} (2.75×10^{-3} mol dm^{-3}).

2,2′-Bipyridyldioxobis(pentafluorobenzoato)uranium(VI). (i) 2,2′-bipyridyl (0.23 g) in ethyl acetate (3 cm^3) was added dropwise to a solution of dioxobis(pentafluorobenzoato)uranium(VI) (1.00 g) in boiling ethyl acetate (25 cm^3) giving a yellow precipitate of the *required compound*, which was washed with ethyl acetate and light petroleum (yield, 84%), m.p. 210–211° (dec.) (Found: C, 34.0; H, 1.1; F, 22.1%, $C_{24}H_8F_{10}N_2O_6U$ requires C, 34.0; H, 1.0; F, 22.4%). IR absorption: 1653m, 1525m, 1492s, 1432vs, 1171m, 1162m, 1005vs, 773vs cm^{-1}. ^{19}F NMR spectrum: 141.6, br (at 60°, m, ^3J 21 Hz), F2,6; 156.5, br (unresolved at 60°), F4; 162.2,m,F3,5. ^1H NMR spectrum: 7.39,m,H5,5′; 7.89,m,^3J(H4, H5), 5.9 Hz, ^3J(H4, H3), 7.9 Hz, H4,4′; 8.34, d, ^3J7.9 Hz, H3,3′; 8.63, dd, ^3J4.1 Hz, H6,6′. Visible spectrum (EtOH): $\lambda_{max}(\epsilon)$ 432 (43.5) nm. Mol. cond. (MeOH): 50.6 S cm^2 mol^{-1} (1.50×10^{-3} mol dm^{-3}). T.G.A., 47% weight loss from 221–286°.

(ii) A similar preparation in *t*-butanol gave a yellow precipitate, which was washed with light petrol and dried at 60° (10^{-3} mm, 10 hr). Further drying for longer periods and at 90° indicated constant retention of solvent (^1H NMR spectra) giving *2,2′-bipyridyldioxobis(pentafluorobenzoato)uranium(VI)-t-butanol* (14/1) (yield, 85%) m.p. 211–212°(dec.) (Found: C, 34.1; H, 1.2; F, 22.0. $C_{340}H_{122}F_{140}N_{28}O_{85}U_{14}$ requires C, 34.2; H, 1.0; F, 22.2%). IR absorption: as for the unsolvated species. ^1H NMR spectrum: as above (i), together with 1.11, s, CH_3.

(iii) A similar preparation in ether precipitated the impure title compound after several minutes (yield, 95%), dec. temp. 216–217° (Found: C, 32.9; H, 1.3%) (IR identification). Recrystallization from benzene and drying to constant composition (^1H NMR spectra) by heating under vacuum (60°/10^{-3} mm/3 hr) gave 2,2′-bipyridyldioxobis-(pentafluorobenzoato)-uranium(VI)-benzene (3/1) (Found: C, 35.8; H, 1.4; F, 23.2; N, 3.3. $C_{78}H_{30}F_{30}N_6O_{18}U_3$ requires C, 35.7; H, 1.2; F, 21.7; N, 3.2%). IR absorption: as for the unsolvated species plus 732m, 678w cm^{-1} due to benzene. ^1H NMR spectrum: 7.49, s, C_6H_6 in addition to features similar to those of the unsolvated complex.

Dioxobis(pentafluorobenzoato)bis(triphenylphosphine oxide)uranium(VI). (i) Triphenylphosphine oxide (0.81 g) in *t*-butanol (30 cm^3) was added dropwise to a solution of dioxobis(pentafluorobenzoato)uranium(VI) (1.00 g) in *t*-butanol (10 cm^3). Yellow crystals of *dioxobis(pentafluorobenzoato)bis(triphenylphosphine oxide)uranium-(VI)-t-butanol* (1/1) deposited on standing and were washed with petrol. Drying (60°, 10^{-3} mm, 4hr) did not change the composition (^1H NMR spectra) (yield, 58%), m.p. 104–110° (Found: C, 49.1; H, 3.0; F, 14.6%. $C_{54}H_{40}F_{10}O_9P_2U$ requires C, 49.0; H, 3.1; F, 14.4%). IR absorption: 1648m, 1500m, 1488m, 1438s, 1122s, 1079s, 1006m, 991s, 930m, 775m, 738m, 725vs, 693vs cm^{-1}. ^{19}F NMR spectrum: 141.6, br d, ^3J *ca.* 18 Hz, F2,6; 156.5, br, F4; 162.2, m, F3, 5. ^1H NMR spectrum: 1.14, s, CH_3; 4.20, s(br), OH; 7.54, m, aromatic. Mol. cond. (MeOH): 45.5 S cm^2 mol^{-1} (1.56×10^{-3} mol dm^{-3}). T.G.A., (under vacuum), 5.2% weight loss (28–105°) (Calc. for *t*-BuOH loss: 5.6%); 56.6% (28–420°).

(ii) Addition of petrol (b.p. 60–80°) to stoichiometric amounts of dioxobis(pentafluorobenzoato)uranium(VI) and triphenylphosphine oxide in benzene/ethanol (30:1, v/v) crystallized the unsolvated *title compound* (yield, 46%), m.p. 118–120° (Found: C, 48.6; H, 2.6; F, 15.2. $C_{50}H_{30}F_{10}O_8P_2U$ requires C, 48.1; H, 2.4; F, 15.2%). IR absorption: similar to that of the solvate, except that 1006m cm^{-1} was not observed. ^{19}F and ^1H NMR spectra: as for the solvate with omission of *t*-BuOH features. T.G.A., 55.6% weight loss (100–419°).

Dioxobis(pentafluorobenzoato)bis(triphenylarsine oxide)uranium-t-butanol (5/2). Triphenylarsine oxide (0.48 g) in *t*-butanol (3 cm^3) was added dropwise to a solution of $UO_2(O_2CC_6F_5)_2$ (0.50 g) in the same solvent (5 cm^3) at 80°. Yellow crystals of the *title compound* deposited on standing and had constant composition (^1H NMR) on drying at 60° (10^{-3} mm) (yield, 46%), m.p. 92–96° (Found: C, 45.4; H, 2.7; F, 14.0, $C_{252}H_{170}As_{10}F_{50}O_{42}U_5$ requires C, 45.4; H, 2.5; F, 13.9%). IR absorption: 1515m, 1438vs, 1275m, 1086m, 993s, 768s, 745s, 734s, 689s, cm^{-1}. ^{19}F NMR spectrum: 141.6, br, F2, 6; 155.0, br, F4; 162.2, br, F3, 5. ^1H NMR spectrum: 1.11, s, CH_3; 4.25, vbr, OH (intensity too low for integration); 7.73, m, aromatic.

Bis(acetato)dioxobis(triphenylphosphine oxide)uranium(VI). The complex was obtained by a

slight modification of the reported[16] method, m.p. 209–211°, lit.[16] m.p. 208–210°. IR absorption: 1486m, 1440vs, 1140m, 1120vs, 1090s, 1071m, 998m, 943m, 923s, 760s, 747s, 722vs, 698s, 687s, 672vs cm^{-1}.

(4) *Decomposition of dioxobis(pentafluorobenzoato)uranium(VI) complexes*

(i) Dioxobis(pentafluorobenzoato)uranium(VI) (0.92 g) was treated with dry dimethyl sulphoxide (10 ml) under purified nitrogen and the resulting solution was stirred at room temperature. A slow stream of nitrogen was passed over the reaction mixture and then through barium hydroxide solution. A slight precipitate of barium carbonate was obtained in 10 hr. On heating at 60–80° for 6 hr, precipitation of barium carbonate increased and an orange solid deposited from the dimethyl sulphoxide. The product was collected under nitrogen, washed with dry ether, dried (25°, 10^{-3} mm, 3 hr) and stored under nitrogen. IR absorption: 1460vs(br) [$\nu_{as}(CO_3)$], 1395s [$\nu_s(CO_3)$], 1018s(br) [CH_3rock], 985vs(br) [ν(SO)], 948vs [ν_{as}(OUO)], 930m, 918m, 880s cm^{-1}. Visible absorption (Nujol mull): 366, 418 nm. ^{1}H NMR spectrum (CF_3CO_2H): 3.17, s, CH_3. The product gave a positive qualitative test for carbonate and was hygroscopic.

(ii) A solution of 2,2′-bipyridyldioxobis(pentafluorobenzoato)-uranium(VI) in dry dimethyl sulphoxide was allowed to stand under nitrogen at room temperature until a precipitate formed. This was collected, washed with ether, and dried in the atmosphere. IR adsorption: 3400s(vbr) [ν(OH)], 1460vs(br) [$\nu_{as}(CO_3)$], 1410s [$\nu_s(CO_3)$], 990s [ν(SO) and CH_3 rock] cm^{-1}.

(iii) Decomposition in hexadeuterodimethyl sulphoxide. Samples of $UO_2(O_2CC_6F_5)_2$, $UO_2(O_2CC_6F_5)_2$bpy, and $UO_2(O_2CC_6F_5)_2(Ph_3PO)_2$ were dissolved in $(CD_3)_2SO$ under nitrogen and the ^{19}F NMR spectra were recorded at intervals. In all cases, only resonances attributable to the $C_6F_5CO_2$ group were observed initially, but on standing those due to pentafluorobenzene were also observed.

Extent of decomposition: $UO_2(O_2CC_6F_5)_2$: 5% and 30% C_6F_5H after 160 and 690 min. respectively at 25°; 7 and 30% C_6F_5H after 10 and 29 min at 60°. $UO_2(O_2CC_6F_5)_2$bpy: 4 and 26% C_6F_5H after 150 and 665 min at 25°; 12 and 54% C_6F_5H after 5 and 30 min at 60°. $UO_2(O_2CC_6F_5)_2(Ph_3PO)_2$: 5 and 20% C_6F_5H after 60 and 410 min at 26°. A solid isolated from the decomposition of the bipyridyl complex had IR absorption similar to that of the product from (ii) above.

(5) *Crystallography*†

Suitable crystals of $UO_2(O_2CC_6F_5)_2$bpy were obtained as yellow needles (unsolvated) upon mixing equimolar amounts of 2,2′-bipyridyl and $UO_2(O_2CC_6F_5)_2$ in acetone. Crystals of $UO_2(O_2CC_6F_5)_2(OPPh_3)_2.t$-BuOH were similarly obtained from *t*-butanol as pale yellow laths.

Crystal data. (i) $UO_2(O_2CC_6F_5)_2$bpy ≡ $C_{24}H_8F_{10}N_2O_6U$, M = 848.4, orthorhombic, space group $P2_12_12_1$; a = 18.45(2), b = 18.94(2), c = 7.069(8) Å, U = 2470 Å^3, Z = 4, D_c = 2.28 gcm^{-3}, F(000) = 1584, Mo–K_α radiation, λ = 0.7107 Å, μ_{Mo-K_α} = 65.0 cm^{-1}. (ii) $UO_2(O_2CC_6F_5)_2(OPPh_3)_2.t$-BuOH ≡ $C_{54}H_{40}F_{10}O_9P_2U$, M = 1323, rhombohedral, space group $R\bar{3}$; a = 21.51(3) Å, α = 117.28(5)°, U = 4189 Å^3, Z = 3, D_c = 1.57 g cm^{-3}, F(000) = 1782, Mo–K_α radiation, λ = 0.7107 Å, μ_{Mo-K} = 28.5 cm^{-1}.

Structure determination. (i) A single crystal of $UO_2(O_2CC_6F_5)_2$bpy was sealed in a thin walled capillary. Approximate cell dimensions and space group were determined from Weissenberg photographs. The crystal was mounted on an automatic four-circle diffractometer equipped with a Si(Li) detector and an energy discriminator. 3731 reflections were measured from $0 < 2\theta < 40°$ with a standard reflection monitored every 30 reflections. These data were corrected for absorption, Lorentz-polarization effects and averaged to give 1186 independent [F(*hkl*)] values.[37] The uranium atoms were located in a Patterson synthesis; all other atoms were located in successive difference Fourier syntheses. Hydrogen atoms were not included in the calculations. Structure factors were calculated using neutral scattering factor curves uncorrected for anomalous dispersion except for uranium.[38a,39] The structure was refined using the least-squares program LINUS[40] with unit weights and anisotropic thermal parameters for uranium and isotropic thermal parameters for all other atoms. The discrepancy indices were: $R = \Sigma(|F_o - F_c|)/\Sigma|F_o| = 0.053$ and $R' = \Sigma(|F_o|^2 - |F_c|^2)/\Sigma(|F_o|^2) = 0.104$. (ii) Similarly, a crystal of $UO_2(O_2CC_6F_5)_2(OPPh_3)_2.t$-BuOH was sealed in a capillary, 5350 *hkl* intensities were measured and indexed on a rhombohedral cell. Correction for absorption and averaging gave 1626 independent [F_o(*hkl*)] values.[37] A Patterson synthesis gave the

†Atomic coordinates, thermal parameters, and a complete set of bond lengths and angles have been deposited as Supplementary Data with the Editor, from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

uranium location as $(0, \frac{1}{2}, \frac{1}{2})$ suggesting position 3(e) of space group $R3$. Refinement in this space group located the triphenylphosphine oxide groups centred about the uranium but failed to locate the pentafluorobenzoate groups satisfactorily. Refinement in $R3$ showed that the uranium was slightly, but significantly, displaced from $(0, \frac{1}{2}, \frac{1}{2})$ and consequently was strongly pseudo-centric. Refinement was completed satisfactorily in R^3 by program SHELX[41] using 1303 reflections with $F_0 > \sigma(F_0)$ and unit weights. Rigid-group refinement was employed for the phenyl rings of the triphenylphosphine oxides and the pentafluorophenyl rings of the pentafluorobenzoate ligands. Carbon–carbon bond lengths were constrained to 1.38 Å and carbon-fluorine bond lengths to 1.35 Å. One pentafluorobenzoate ligand was disordered. Site occupancy factors for the disorder were refined but were constrained to sum to one. Several weak peaks in the final difference synthesis were attributed to the lattice solvent, *t*-butanol. Attempts to refine the molecule as a rigid tetrahedron led to unreasonably large temperature factors. The solvent was then omitted from the calculations. Uranium and phosphorus were refined anisotropically whereas all other atoms were given isotropic temperature factors. Hydrogen atoms were included in the refinement in calculated positions 0.95 Å from the atoms to which they are bound, with isotropic temperature factors. Neutral scattering factor curves corrected for anomalous dispersion were employed for all atoms.[38b] The discrepancy index was $R = 0.070$.

CONDUCTOMETRIC TITRATION STUDY OF THE REACTIONS OF SOME TRIALKYLPHOSPHINES WITH BROMINE, IODINE AND IODINE BROMIDE

GORDON S. HARRIS* and J. S. McKECHNIE
Chemistry Department, University of St. Andrews, St. Andrews, Fife, Scotland

(*Received* 19 *December* 1983; *accepted* 30 *March* 1984)

Abstract—The reactions of tributyl-, trioctyl-, and tricyclohexyl-phosphine with bromine, iodine and iodine bromide have been studied by conductometric titration in acetonitrile. In general, evidence was obtained for the formation, in solution, of highly conducting 0.5 : 1, 1 : 1, and 2 : 1 adducts. The 1 : 1 and 2 : 1 adducts (R_3PX_2 and R_3PX_4) were isolated and the electrolytic conductivity of their acetonitrile solutions measured. Values of molar conductivity are reported; these point to strong electrolyte behaviour, hence the 1 : 1 and 2 : 1 adducts must be formulated as the phosphonium salts, $R_3PX^+X^-$ and $R_3PX^+X_3^-$ respectively.

It is well known that organophosphines react readily with halogens to form 1 : 1 addition compounds (i.e. triorganophosphine dihalides, R_3PX_2) some of which are molecular (e.g. Me_3PF_2[1]) whilst others are ionic (e.g. $Ph_3PI_2 \equiv Ph_3PI^+I^{-2}$). We have previously shown that the molecular adducts may undergo partial ionisation when dissolved in solvents of high dielectric constant such as acetonitrile,[3] and that the ionic adducts behave as strong 1 : 1 electrolytes in this solvent.[4] Conductometric titration studies of various R_3P–X_2 systems in acetonitrile have shown that in addition to 1 : 1 adducts, numerous 2 : 1 adducts (i.e triorganophosphine tetrahalides, R_3PX_4) are readily formed, and that these too are strong 1 : 1 electrolytes.[4,5] Our conductance studies of compounds of these types have been, in the main, confined to halogen adducts of aromatic phosphines;[4,5] in this paper we report the results of a conductometric titration investigation of the reactions of some alkylphosphines (tri-*n*-butyl-, trioctyl-, and tricyclohexyl-phosphine) with iodine, bromine, and iodine bromide. Earlier workers have reported that these phosphines form 1 : 1 adducts with halogens[6–8] and that the iodine compounds give conducting solutions in nitrobenzene.[6]

RESULTS AND DISCUSSION

Conductometric titrations

These were carried out for the nine systems R_3P–X_2 (R = *n*-butyl, octyl, cyclohexyl†; $X_2 = Br_2$, I_2, IBr) in acetonitrile. Several types of behaviour were observed and graphs representative of these are shown in Figs. 1 and 2. The systems R_3P–Br_2 and R_3P–IBr gave conductometric titration graphs of similar type, exemplified by the graph of the Oc_3P–IBr system (A, Fig. 1). Breaks in the graph occur at the 0.5 : 1, 1 : 1 and 2 : 1 ratios corresponding to the formation, consecutively, of three adducts in solution, thus,

$$R_3P \xrightarrow{\frac{1}{2}X_2} \underset{[0.5:1\ \text{adduct}]}{R_3PX} \xrightarrow{\frac{1}{2}X_2} \underset{[1:1\ \text{adduct}]}{R_3PX_2} \xrightarrow{X_2} \underset{[2:1\ \text{adduct}]}{R_3PX_4}$$

The high values of conductivity at the breaks indicate that the adducts are ionic. The observed yellow colour and the UV spectra of the solutions at the 1 : 1 and 2 : 1 breaks confirm the presence of trihalide ion at these ratios, with the exception of the 1 : 1 ratio for the Bu_3P–Br_2 system. The reaction steps may thus be more fully represented as follows, with the modification, noted below, in the

*Author to whom correspondence should be addressed.

†Hereafter, the symbols Bu, Oc and Hex, respectively, are used for these organic groups.

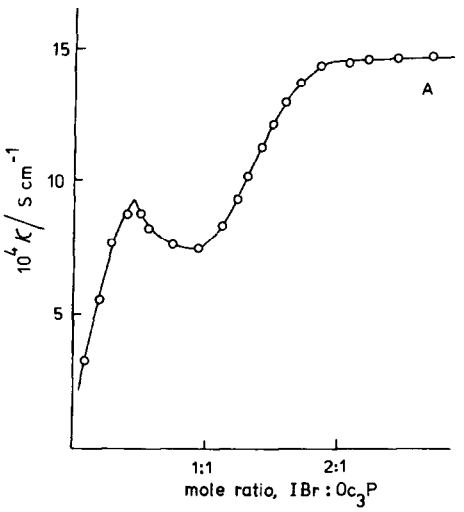

Fig. 1. Conductometric titration of trioctylphosphine with iodine bromide.

formulation of the 1 : 1 adduct in the Bu_3P–Br_2 system:

Step 1. $R_3P + \frac{1}{2}X_2 \longrightarrow \frac{1}{2}(R_3P)_2X^+X^-$ [0.5 : 1 adduct].

Step 2. $\frac{1}{2}(R_3P)_2X^+X^- + \frac{1}{2}X_2 \longrightarrow \frac{1}{2}(R_3P)_2X^+X_3^-$ [1 : 1 adduct].

Step 3. $\frac{1}{2}(R_3P)_2X^+X_3^- + X_2 \longrightarrow R_3PX^+X_3^-$ [2 : 1 adduct].

In the Bu_3P–Br_2 system the solution at the 1 : 1 mole ratio was colourless; tribromide ion was therefore not present and the 1 : 1 adduct must in this case be represented, $Bu_3PBr^+Br^-$. In the systems involving IBr, identification (by UV) of the trihalide anion as I_2Br^- confirmed that it is bromine that is bonded to phosphorus in the cation (e.g. $Oc_3PI_2Br_2 \equiv Oc_3PBr^+I_2Br^-$).

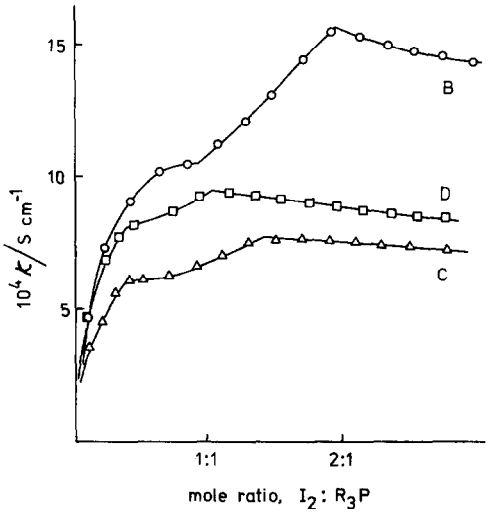

Fig. 2. Conductometric titration of R_3P with iodine. (B) Bu_3P–I_2. (C) Oc_3P–I_2. (D) Hex_3P–I_2.

The formation of a 0.5 : 1 adduct (R_3PX) in solution was of interest since an adduct of this stoicheiometry was not observed in a conductometric titration study of the systems Ph_3P–Br_2 and Ph_3P–IBr in acetonitrile;[4] however, in the systems Ph_3P–ICl in acetonitrile and Ph_3P–I_2 in nitrobenzene[10] there is evidence for the formation of highly conducting 0.5 : 1 adducts.

The three systems involving iodine gave conductometric titration graphs of shape different from the above systems, and from one another (B, C and D; Fig. 2). That of the Bu_3P–I_2 system (B, Fig. 2) had breaks at the 1 : 1 and 2 : 1 mole ratios and resembled closely the graph of the Ph_3P–I_2 system;[4] the reaction therefore occurs in two steps:

$$Bu_3P \xrightarrow{I_2} Bu_3PI_2 \xrightarrow{I_2} Bu_3PI_4.$$

Again, conductivity values at the breaks are high indicating that the adducts in solution are ionic—$Bu_3PI^+I^-$ and $Bu_3PI^+I_3^-$ respectively.

In the conductometric titration of trioctylphosphine with iodine, breaks in the graph occurred at the 0.5 : 1 and 1.5 : 1 ratios (C, Fig. 2). The first of these corresponds with the adduct Oc_3PI[$\equiv (Oc_3P)_2I^+I^-$]. The second break represents an adduct of formula Oc_3PI_3; this stoicheiometry is unexpected for a compound of phosphorus and we have not previously encountered it in any triorganylphosphine–halogen system. We propose, for this adduct, the dimeric formula $(Oc_3PI_3)_2$ which corresponds to $(Oc_3PI^+)_2I^-I_3^-$. The ionic structure accords with the high conductivity of the solution and the presence in the UV spectrum of absorption due to tri-iodide ion. Mixed-anion compounds of a similar kind are known e.g. $(Ph_3AsOH^+)_2Br^-Br_3^-$;[11,12] and, recently, we have isolated the phosphorus compound $(PhPBr_5)_2$, which also behaves as a mixed-anion compound, $(PhPBr_3^+)_2Br^-Br_3^-$.[13]

The graph of the Hex_3P–I_2 system (D, Fig. 2) had distinct breaks at the 0.5 : 1 and 1 : 1 mole ratios. Thus, conductometric titration gives evidence for Hex_3PI [$\equiv (Hex_3P)_2I^+I^-$] and Hex_3PI_2[$\equiv (Hex_3P)_2I^+I_3^-$] in acetonitrile solution, but this system and the previous one are unusual in that conductometric titration does not provide evidence for the presence of 2 : 1 adducts in solution.

Preparation of adducts

Attempts were made to prepare the adducts indicated by the conductometric titrations, from acetonitrile solutions of the components in the appropriate molar ratios. In no system however was a 0.5 : 1 adduct (R_3PX) isolated; all attempts to prepare compounds of this stoicheiometry yielded instead the 1 : 1 adduct (R_3PX_2). This suggests that the 0.5 : 1 adducts are probably not stable as solids and implies that there is some disproportionation of the 0.5 : 1 compounds in solution,

$$R_3PX \rightleftarrows \tfrac{1}{2}R_3PX_2 + \tfrac{1}{2}R_3P,$$

and presumably for solubility reasons it is the 1 : 1 adduct which crystallises from solution.

1 : 1 Adducts were readily obtained as crystalline solids from acetonitrile solutions of R_3P and halogen in the 1 : 1 molar ratio. The tri-*cyclo*hexylphosphine compounds crystallised as the monosolvates, $Hex_3PX_2 \cdot CH_3CN$.

2 : 1 Adducts were obtained for each system; those involving tri*cyclo*hexylphosphine were crystalline solids whilst those involving tributylphosphine and trioctylphosphine were oils and in one case a low melting solid. It is not unknown for phosphonium compounds to exist at room temperature as oils or semi-solids[14] and in the present case it is presumed that the long chain alkyl groups have an inhibitory effect on crystallisation of the ionic phosphonium trihalide structure.

The 1.5 : 1 adduct, Oc_3PI_3, indicated by the conductometric titration of the Oc_3P–I_2 system was obtained as a low melting solid. From the system Hex_3P–I_2, higher adducts (2 : 1, 3 : 1 and 4 : 1) were obtained as crystalline solids despite there being no conductometric titration evidence for their existence in acetonitrile solution. It must be assumed therefore that in acetonitrile at high mole ratios (greater than 1 : 1) further overlapping equilibria are involved

$$Hex_3PI_2 + I_2 \rightleftarrows Hex_3PI_4[\equiv Hex_3PI^+I_3^-]$$

$$Hex_3PI_4 + I_2 \rightleftarrows Hex_3PI_6[\equiv Hex_3PI^+I_5^-]$$

$$Hex_3PI_6 + I_2 \rightleftarrows Hex_3PI_8[\equiv Hex_3PI^+I_7^-].$$

The tendency for higher polyiodides to form in iodide-iodine systems is well known and, in particular, compounds containing the hepta- and ennea-iodide ions have been reported previously.[15]

Electrolytic conductance of the adducts

Electrolytic conductance measurements were made on acetonitrile solutions of the adducts in the concentration range 0.002–0.03 M. For each compound, points on the molar conductivity vs square root of molar concentration plot lay approximately on a straight line of negative slope. For the purpose of comparison, values of molar conductivity at concentration 0.01 M were taken from the graph and these are recorded in Table 1; the high values found indicate that all of the adducts behave as strong electrolytes in acetonitrile. Previous workers found that whereas trialkylphosphine diiodides gave strongly conducting solutions in nitrobenzene, the corresponding dibromides gave low values of conductivity suggesting non-electrolyte behaviour in this solvent.[6] Our results for acetonitrile solutions are consistent with all of these trialkylphosphine halogen adducts being formulated as ionic phosphonium halides and polyhalides as in the case of the corresponding halogen adducts with triphenylphosphine.[4,5]

EXPERIMENTAL

As most of the compounds involved in this work were extremely sensitive to moisture, all manipulations were carried out in a dry-box with a dry nitrogen atmosphere. A vacuum system was used in the purification and handling of volatile compounds. Apparatus and solvents were thoroughly dried before use.

Standard reagents and solvents were of the best grade available commercially and were purified by conventional methods. The alkyl phosphines used were purified thus: tri(*n*-butyl)phosphine—vacuum distillation; trioctylphosphine—fractional freezing; tricyclohexylphosphine—recrystallisation from acetone. Acetonitrile of a purity suitable for conductance measurements was obtained using the method described by Smith and Witten.[16] The halogen adducts of the alkyl phosphines were prepared in acetonitrile by admixture of the phosphine and halogen in the correct molar ratio; the mixture was kept overnight with shaking. Some adducts precipitated directly on mixing the components but more generally were obtained either by addition of diethyl ether to the acetonitrile solution or by freeze-drying of it. All of the adducts were extremely unstable hydrolytically and some were unstable thermally (halogen lost readily). Therefore analysis and other measurements were carried out soon after their preparation. Elemental analyses and properties of the adducts are given in the Table. Carbon, hydrogen and nitrogen were determined micro-analytically using a Perkin–Elmer model 240 Elemental Analyser; halogens were de-

[d]Oil at room temperature. [e]Bromine lost readily at room temperature. [f]The unsolvated forms have been reported (Ref. 7). [g]Although previously reported (Refs. 6, 7, 8), these compounds are included here to record their molar conductivity.

termined potentiometrically as silver halide after hydrolysis of the adduct.

Conductance measurements were made in a sealed cell of the dipping electrode type. The electrode supports were mounted on a ground glass cone which fitted a vessel containing the solution. The latter was prepared *in situ* in the dry-box. Conductance was measured by means of a Wayne–Kerr B641 Autobalance Bridge. The apparatus for conductometric titrations was of conventional type scaled down so that the entire titration could be carried out in the dry-box. UV spectra were recorded on a Unicam SP800 UV-visible recording spectrophotometer; the solutions were contained in stoppered cells. Trihalide ions have characteristic absorption in the UV which enables their identification.[17]

Abstract—Reaction of $[RhCl(PPh_3)_3]$ with [*o*-$MeC_6H_4CH_2MgBr$] affords high yields of the non-fluxional complex, $[Rh(CH_2C_6H_4Me)(PPh_3)_2]$ which has been shown crystallographically to contain a 1-3-η-benzyl group bound through the phenyl carbon atom that is not substituted with the methyl group. Crystals of this compound are triclinic, space group $P\bar{1}$, with $a = 10.561(6)$. $b = 17.705(3)$, $c = 10.934(4)$ Å, $\alpha = 80.69(3)$, $\beta = 116.86(4)$, $\gamma = 102.30(4)°$ and $Z = 2$. The structure was solved via the heavy-atom method and refined to $R = 0.032$ using 5379 diffractometer data with $I > 1.56(I)$. Attempts to prepare π-bonded xylylene complexes from this compound by reaction with base have been unsuccessful, but protonation followed by recrystallisation from acetone gives $[Rh\{(CH_3)_2CO\}_2(PPh_3)_2]BF_4$.

In a number of recent publications[1,2] we have detailed reactions of the *o*-methylbenzyl ligand with transition metal complexes and shown that its behaviour depends very much on the nature of the metal. Thus, with platinum(II), simple σ-bonded complexes are formed although these can undergo cyclisation to give xylylidene complexes on refluxing in xylene.[1] In contrast, simple σ-bonded complexes of ruthenium(II) have not been isolated, the cyclisation being so facile that even at −30°C the only isolable products contain a coordinated η^2:η^2-*o*-xylylene unit.[2]

We now report yet another mode of coordination for the *o*-methylbenzyl group, as a π-allyl (1-3-η-benzyl) ligand to rhodium.

RESULTS AND DISCUSSION

Reaction of $[RhCl(PPh_3)_3]$ with one mole equivalent of [*o*-$CH_3C_6H_4CH_2MgBr$] in diethyl ether results in a red compound analysing as $[Rh(CH_2C_6H_4CH_3)(PPh_3)_2]$. If this compound contained a simple σ-bonded alkyl group, as is the case for $[Pt(CH_2C_6H_4CH_3)_2L_2]$ (L = PEt_3 or PPh_3)[1] and $[Ni(CH_2C_6H_4CH_3)_2(PBu_3)_2]$[3], it would be a three coordinate 14e complex of rhodium(I). X-Ray crystallographic studies, however, show that the *o*-methylbenzyl ligand is bound as a 3e donor.

This allylic binding for benzyl ligands has now been reported for a number of different metals, the first such complex, $[Mo(C_5H_5)(CH_2C_6H_5)(CO)_2]$, having been isolated[4] in 1966. In rhodium chemistry, $[RhCl_2(CH_2Ph)PPh_3 \cdot PhCH_2Cl]$ prepared[5] from $[RhCl(PPh_3)_3]$ and $[PhCH_2Cl]$, [Rh(cod)(*o*-$RCHC_6H_4X$)] (cod = cyclo-octa-1,5-diene) arising[6] from reaction of styrene (R = Me, X = H), *o*-methylstyrene (R = Me, X = Me) or β-methylstyrene (R = Et, X = H) with $[RhCl(cod)]_2$ and [^{i}PrMgBr], $[Rh(CH_2C_6Me_5)\{P(O^iPr)_3\}_2]$ obtained[7] by deprotonation of $[Rh(C_6Me_6)\{P(O^iPr)_3\}_2]BF_4$ and $[Rh(C_5H_5)(PMe_3)(CH_3CHC_6H_5)]PF_6$ formed[8] on protonation of $[Rh(C_5H_5)(PMe_3)(C_2H_3C_6H_5)]$ are all believed to contain 1–3-η bound benzyl groups.

X-RAY STRUCTURE OF $[Rh(\alpha,1,2\text{-}\eta\text{-}6\text{-}CH_2C_6H_4CH_3)(PPh_3)_2]$

A diagram of the molecule appears in Fig. 1 and selected bond lengths and angles in Tables 1 and 2.

The complex exhibits distorted square planar geometry with the *o*-methylbenzyl group bound in an allylic fashion, via C(1), C(2) and C(3). There is no evidence to suggest that the alternative isomer (that in which C(7), the methyl substituted carbon atom of the phenyl ring is involved in bonding to the metal) is present in the solid state. As expected,[9] on account of the greater negative charge that resides on the α-carbon atom (C(1)) than on C(3), the rhodium atom is significantly closer to the exocyclic carbon atom (Rh–C(1) = 2.140 Å, Rh–C(3) = 2.286 Å). The difference (0.146 Å) is somewhat smaller than that observed in $[Co(CH_2C_6H_5)\{P(OMe)_3\}_3]$ (0.372 Å),[9] $[Mo(CH_2C_6H_4CH_3)(C_5H_5)(CO)_2]$ (0.21 Å)[10] and $[Rh(CH_2C_6Me_5)\{P(O^iPr)_3\}_2]$ (0.352 Å),[7] although similar to that found for [Rh(cod) (*o*-$CH_3CHC_6H_4CH_3$)] (0.153 Å).[6] Presumably the presence of a methyl group in the unbound *ortho* position causes a lengthening of the Rh–C(1) bond on account of steric interaction with the other ligands in the molecule.

As observed[7] for $[Rh(CH_2C_6Me_5)\{P(O^iPr)_3\}_2]$ the Rh–P bond *trans* to the methylene group is significantly longer than the other.

Table 1. Selected bond lengths (Å) for $[Rh(CH_2C_6H_5Me)(PPh_3)_2]$

Rh-P(1)	2.276(3)	C(3)-C(4)	1.407(7)
Rh-P(2)	2.223 (3)	C(4)-C(5)	1.408(8)
Rh-C(1)	2.140(8)	C(5)-C(6)	1.362(9)
Rh-C(2)	2.212(6)	C(6)-C(7)	1.309 (8)
Rh-C(3)	2.286(5)	C(7)-C(8)	1.517 (9)
C(1)-C(2)	1.406(6)	C(2)-C(7)	1.451 (7)
C(2)-C(3)	1.410(6)		

Although C(1), C(3), P(1), P(2), and Rh are all in the same plane the small bite size of the allyl group makes the C(1)–Rh–C(3) only 65.7°. This is compensated for by opening of all the other angles around rhodium, particularly P(1)–Rh–P(2) (101.6°) and C(3)–Rh–P(1) (98.1°). Furthermore, the effect of coordination of rhodium on the angles at C(2) is to decrease C(1)–C(2)–C(3) to 117.2°, a figure comparable with those found[11] in $[M(\alpha,1,2\text{-}CPh_3)(acac)]$, (M = Pd(116.1°) or Pt(114.6°), acac = 1,3-pentanedionate). The other external angle, C(1)-C(2)-C(7), opens slightly (122.4°).

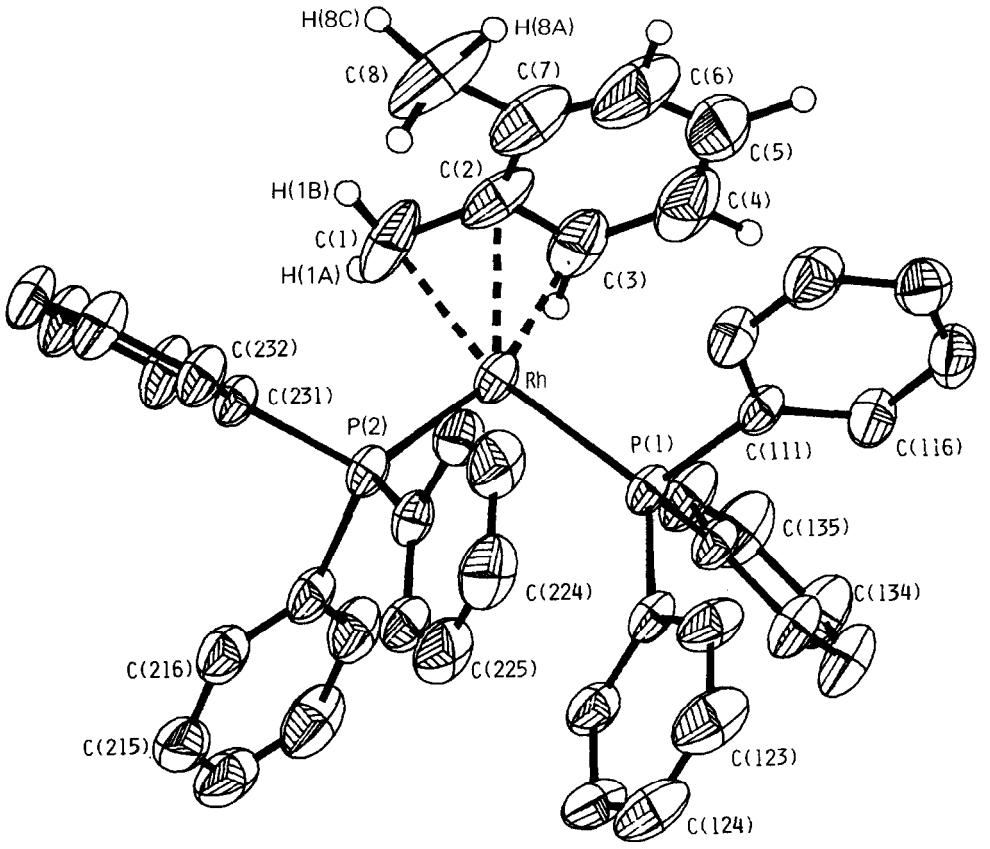

Fig. 1. Solid state structure and numbering scheme for $[Rh(CH_2C_6H_4Me)(PPh_3)_2]$.

Table 2. Selected bond angles (°) for $[Rh(CH_2C_6H_5Me)(PPh_3)_2]$

P(1)-Rh-P(2)	101.6(0)	C(3)-C(4)-C(5)	121.3(5)
P(1)-Rh-C(3)	96.1(2)	C(4)-C(5)-C(6)	116.8(5)
P(2)-Rh-C(1)	94.7(2)	C(5)-C(6)-C(7)	127.9(6)
C(1)-Rh-C(3)	65.7(3)	C(6)-C(7)-C(8)	126.2(5)
Rh-C(1)-C(2)	73.9(4)	C(2)-C(7)-C(6)	116.6(5)
Rh-C(3)-C(2)	68.9(3)	C(1)-C(2)-C(7)	122.4(4)
C(1)-C(2)-C(3)	117.2(4)	C(3)-C(2)-C(7)	119.7(5)
C(2)-C(3)-C(4)	118.1(5)	C(2)-C(7)-C(8)	117.0(5)

The co-ordination also affects the bonding of the hydrogen atoms to C(1) and C(3). Thus C(1) is significantly pyramidalised (Σ angles = 348°) with H(1A), particularly bent out of the main ligand plane (δ = 0.29 Å), whilst H(3), attached to C(3) is also displaced in a similar direction (δ = 0.18 Å).

In all 1-3-η-benzyl complexes that have previously been structurally characterised,[6,7,9-13] dimensions of the uncoordinated fragment of the phenyl ring resemble those of a *cis* 1–3-butadiene group. Uniquely, however, $[Rh(CH_2C_6H_4Me)(PPh_3)_2]$ displays apparent allylic character in the ring with the adjacent bond lengths, C(7)–C(6)(1.309 Å) and C(6)–C(5)(1.362 Å) being the shortest. This is somewhat surprising, particularly as the closely related [Rh(cod)(6,7-dimethylbenzyl)] exhibits[6] the more usual *cis*-1,3-butadiene type alternation of bond lengths.

SPECTROSCOPIC PROPERTIES

The ^{1}HYNMR spectrum of $[Rh(CH_2C_6H_4CH_3)(PPh_3)_2]$, apart from phenyl resonances, resembles that of $[Rh(cod)(o\text{-}CH_3CHC_6H_4CH_3)]$ showing a broad singlet at δ2.23 (CH_3) and multiplets at δ2.35*dd* (*syn* CH_2), 2.52*dt*(*anti*-CH_2), 5.5*bd* (C(3)*H*) and 6.6 m (C(4)*H* and C(6)*H*). The resonance from C(5)H is evidently obscured by the other phenyl resonances. Unlike the spectra of most 1-3-η-benzyl complexes, this spectrum is temperature invariant suggesting that a process such as that shown in Fig. 2 does not occur. This process, which is facile for symmetrically substituted benzyl groups does not occur in other *o*-methyl substituted 1-3-η-benzyl groups.[8] This is presumably because steric interactions of the methyl group with the rest of the molecule render form **II** a high energy species. The ^{31}PYNMR spectrum of $[Rh(CH_2C_6H_4Me)(PPh_3)_2]$ (see experimental) is temperature invariant and shows non-equivalent phosphorus atoms, suggesting that the solid state structure is preserved in solution.

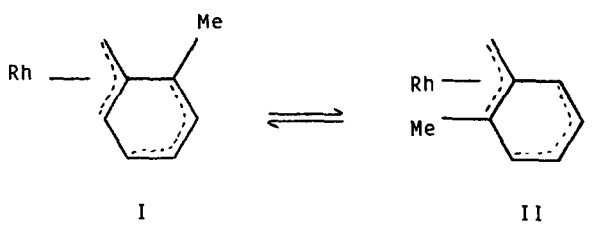

Fig. 2. Possible isomers for 1-3-η-*o*-methylbenzyl complexes.

REACTION CHEMISTRY

Protonation of $[Rh(CH_2C_6H_4Me)(PPh_3)_2]$ with fluoroboric acid leads to a red compound which gives $[Rh\{OC(CH_3)_2\}_2(PPh_3)_2][BF_4]$ on recrystallisation from acetone-diethylether, we presume that this reaction proceeds by protonation of the *o*-methylbenzyl ligand to give *o*-xylene although this has not been identified.

Attempts to prepare *o*-xylylene complexes by removal of a proton[14] have been unsuccessful. Although reactions occur, the products are too insoluble (reaction of [KOBu^t]) for characterisation.

EXPERIMENTAL

Microanalyses were by Elemental Microanalysis Ltd., and nuclear magnetic resonance spectra were recorded on Perkin–Elmer R12B (^{1}H) and Bruker WM250 (^{31}P) NMR spectrometers, the latter operating in the Fourier Transform mode with noise proton decoupling. All solvents were thoroughly dried by distillation from sodium diphenylketyl (tetrahydrofuran, diethylether, toluene and light petroleum (boiling range 40–60°C)) or calcium hydride (CH_2Cl_2) and degassed before use. All manipulations were carried out under dry oxygen free nitrogen using standard Schlenk line and catheter tubing techniques. Melting points were measured on an electrothermal melting point apparatus in sealed capillaries under nitrogen and are uncorrected.

$[RhCl(PPh_3)_3]$,[15] $[o\text{-}MeC_6H_4CH_2MgBr]$[2] were prepared by standard literature methods.

(1) *(α,1,2-η-6-methylbenzyl)bis(triphenylphosphine) rhodium*(I)

A suspension of $[RhCl(PPh_3)_3]$ (1.0 g) in diethylether (40 cm^3) was stirred with $[o\text{-}MeC_6H_4CH_2MgBr]$ (1.2 cm^3, 1.0M) for 16h. The orange solid remaining after filtration was extracted with toluene (10 cm^3) and the filtered toluene extract treated with petroleum (10 cm^3). The solution was filtered (several times) to remove precipitated $[MgCl_2]$, $[MgBr_2]$ and excess Grignard re-

agent. On cooling to −30°C, red crystals of the complex separated. These were collected and dried *in vacuo*. M.p. 162–165°C. Found: C, 72.23; H, 5.37; P, 7.91. Calc. C, 72.13; H, 5.33,; P 8.47%. NMR (C_6D_6)† δ 2.23s (CH_3); 2.35 *dd*, $J_{syn\text{-}anti\text{-}CH_2}$ = 5 Hz, J_{PH} = 10 Hz (*syn*-CH_2); 2.52*dt*, $J_{P(1)H}$ = $J_{P(2)H}$ = 5 Hz (*anti*-CH_2); 5.6 bd $J_{C(3)H-C(4)H}$ = 4Hz (C(3)*H*); 6.6 m (C(4)*H* and C(6)*H*). ^{13}C: δ19.61s (CH_3), δ42.85dd, J_{PC} = 10 Hz, J_{RhC} = 32 Hz (CH_2), 90.0d, J_{PC} = 14.6 Hz (C(3).). ^{31}P: δ39.85dd, J_{RhP} = 260 Hz, J_{PP} = 24 Hz; δ46.98dd, J_{Rh-P} = 342 Hz.

(2) *Bis(propan-2-one)bis(triphenylphosphine)rhodium(I) tetrafluoroborate*

The complex [$Rh(CH_2C_6H_4CH_3)(PPh_3)_2$] (0.5 g) was stirred with [HBF_4] (2 cm^3, 40%) in diethylether (40 cm^3) for 16 hr. The resulting red solid was collected by filtration and recrystallised from acetone-diethylether as brick-red crystals of the complex. Found: C, 61.14; H, 5.03; P, 8.20; Calc. C, 60.72; H, 5.06; P, 8.20%. NMR ($(CD_3)_2CO$)†, ^1H δ7.85*s* (CH_3). ^{31}P δ 50.55*d*, J_{RhP} = 202 Hz. IR max cm^{-1} 1656vs, 1664ssh (ν C = 0).

(3) *Reaction of* [$Rh(CH_2C_6H_4CH_3)(PPh_3)_2$] *with* [*KOBu^t*]

The complex [$Rh(CH_2C_6H_4CH_3)(PPh_3)_2$] (0.5 g) was stirred with [KOBu^t] in (0.2 g) in diethylether (40 cm^3) for 16 hr. The resulting orange-pink solid was insoluble in all common solvents and was not further characterised.

CRYSTALLOGRAPHIC STUDIES

Crystal data

$C_{44}H_{39}P_2Rh$, M = 731.9, triclinic, a = 10.561(6), b = 17.705(3), c = 10.934(4), Å, α = 80.69(3), β = 116.86(4), γ = 102.30(4)°, U = 1777.0 Å^3, space group $P\bar{1}$, Z = 2, D_c = 1.37 gm cm^{-3}, F(000) = 756, λ = 0.71069 Å, μ = (Mo-K_α) = 5.28 cm^{-1}.

DATA COLLECTIONS

Unit cell parameters were determined and intensity data collected at room temperature on an ENRAF–NONIUS CAD4 diffractometer using graphite-monochromated Mo-K_α radiation and an ω-2θ scan procedure.[16] 6231 data were measured of which 5382 were considered observed ($I \geq \sigma$ 1.56(I)). A semi-empirical absorption correction[17] using normalised and averaged ψ scan measurements from five reflections was applied to the data; the maximum and minimum transmission was 99.8 and 95.2% respectively.

STRUCTURE SOLUTION AND REFINEMENT

The structure was solved and developed by use of the heavy atom method. After isotropic refinement of all the non-hydrogen atoms, the DIFABS method of absorption correction[18] was further applied to the data. Refinement using anisotropic thermal parameters for all atoms revealed the location of all hydrogen atoms; however, bond length constraints were required for the refinement of the hydrogen atoms on the *o*-methylbenzyl ligand. In the final refinement, three strong low angle reflections were omitted and the blocked full-matrix least-squares was carried out with $\omega = 1/\sigma^2(F_0)^2 + 0.00015F_0^2$ weighting; the final R factors were:

$$R = \Sigma|\Delta F|/\Sigma|Fo| = 0.032 \text{ and}$$

$$R\omega = [\Sigma\omega\,|\,\Delta F\,|^2/\Sigma\omega\,|\,Fo\,|^2]^{1/2} = 0.033.$$

All computations were made using the SHELX–76[19] program on a Digital VAX–11/750 computer. Final atomic fractional coordinates, thermal parameters, complete lists of bond lengths and angles and structure-factor tables have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Acknowledgements—We thank the SERC for a fellowship (A.M.R.G.) a studentship (S.D.C.) and support in purchasing the diffractometer, VAX computer and the multi-nuclear NMR machine. We are also grateful to Johnson Matthey Ltd., for loans of rhodium trichloride.

(*Received* 20 *January* 1984; *accepted* 30 *March* 1984)

Abstract—Two compounds of the formulae $(dppeH_2)_3[MoCl_6]_2 \cdot 12H_2O$ **I** and $(dppeH_2)_3[Mo_2Cl_9]_2$ **II** are described. For compound **I**, which proved to be active in olefin epoxidation, the crystal structure was determined. The rose-pink crystals are triclinic, space group $P\bar{1}$ with $a = 13.715(9)$, $b_3 = 14.686(7)$, $c = 12.512(7)$ Å, $\alpha = 109.56(4)$, $\beta = 97{,}98(4)$ and $\gamma = 91.27(5)°$, $V = 2345$ Å, $D_m = 1.42$ and $D_c = 1.44\ gcm^{-3}$, $Z = 1$. Block-diagonal least squares refinement of the structure has led to a final value of the conventional R factor of 0.049 for the 3914 independent reflections with $I > 3\sigma(I)$. Bond distances are in the range: Mo–Cl 2.439(2)–2.469(2) Å, and P–C 1.771(9)–1.806(8) Å.

Investigations of the monomeric and dimeric molybdenum(III) complexes with chlorine of the formulae $MoCl_6^{3-}$ and $Mo_2Cl_9^{3-}$ are described in detail in the monograph of Stiefel[1] and particularly in the many papers of Wentworth[2] and Smith.[3] Recently a number of other papers dealing further with the above mentioned molybdenum(III) complexes have also been published.[4] Looking for new efficient catalysts for the epoxidation of olefins, two phosphonium salts of the following formulae: $(dppeH_2)_3[MoCl_6]_2 \cdot 12H_2O$ **I** and $(dppeH_2)_3[Mo_2Cl_9]_2$ **II** were obtained (where $dppeH_2^{2+} \equiv$ 1,2-ethanediylbis(diphenylphosphonium)–PH,P'H' cation).

EXPERIMENTAL

Preparation of the complexes

1. $(dppeH_2)_3[Mo_2Cl_9]_2$ **II.** The green Mo(III) acidic–water solution was prepared by reduction of ammonium paramolybdate with zinc amalgam in the presence of HCl.[5] The dppe solution in conc. HCl (0.022M) was added dropwise to the constantly stirred above Mo(III) solution until the precipitation was completed. The green colour changed to pinkish–red. Then, the pink precipitate was separated, washed with conc. HCl and then dry methanol, and finally dried under vacuum. Found: C, 42.1; H, 3.6; Cl, 28.4; Mo, 17.0. Calc for $C_{39}H_{39}Cl_9Mo_2P_3$: C, 42.1; H, 3.2; Cl 28.7; Mo, 17.3%.

2. $(dppeH_2)_3[MoCl_6]_2 \cdot 12H_2O$ **I.** To the red solution from 1, an additional 40 cm^3 of the dppe solution in conc. HCl were added, and then the whole mixture was saturated with argon and left in the cold under argon for several days. The pinkish–rose crystal which appeared were washed with dry methanol and finally dried. Found C, 46.8; H, 4.8; Cl, 21.3; Mo, 9.7. Calc for $C_{39}H_{51}Cl_6MoO_6P_3$: C, 46.0, H, 4.7; Cl, 20.7; Mo, 9.4%.

$(dppeH_2)_3[MoCl_6]_2 \cdot 12H_2O$ *for the X-ray diffraction*

The $Cs_3Mo_2Cl_9$[3a] was dissolved in 12N HCl solution of dppe (0.025 M) and heated to 70°C until a saturated solution was obtained. This solution was filtered and saturated with gaseous HCl for 1 hr and finally left for 3 days without any

contact with air. The above procedure resulted in the deposition of pinkish–rose crystals.

The electronic spectra of the compounds were recorded in MgO and KBr with the Beckmann 5420 type Spectrophotometer. The IR spectra in KBr and Nujol were measured with the Perkin–Elmer 180 type spectrophotometer.

The crystal structure of **I** was determined by X-ray analysis. Direct methods with MULTAN programs were used to locate the Mo, Cl and P atoms, while difference-Fourier syntheses yielded the C and O atoms. The C and P bonded hydrogen atoms were placed in geometrically calculated positions at a distance 1.0 Å for C–H and 1.4 Å for P–H.[6a] Refinement gave R = 0.049 and $R_w = 0.059$.† A difference synthesis computed towards the end of the refinement process was featureless and water hydrogen atoms were not localized. All calculations were performed with the Syntex XTL/XTLE programs.[18] Table 1 summarizes principal interatomic distances and angles. Figures 1 and 2 show the crystal structure of $[HP(C_6H_5)_2(CH_2)_2(C_6H_5)_2PH]_3[MoCl_6]_2 \cdot 12H_2O$.

†Atomic co-ordinates, thermal parameters and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS

The particular form of the Mo(III) complexes with chlorine in aqueous HCl solutions depends strongly on both the concentration of the acid and of molybdenum.[3a] In the highly acidic solutions containing small amounts of molybdenum(III), $MoCl_6^{3-}$ predominates. With the increasing concentration of molybdenum, the monomeric anion turns partly into $Mo_2Cl_9^{3-}$. In other words, at high concentrations of both, the equilibrium can be written formally as:

$$Mo_2Cl_9^{3-} + 3Cl^- \rightleftharpoons 2MoCl_6^{3-}.$$

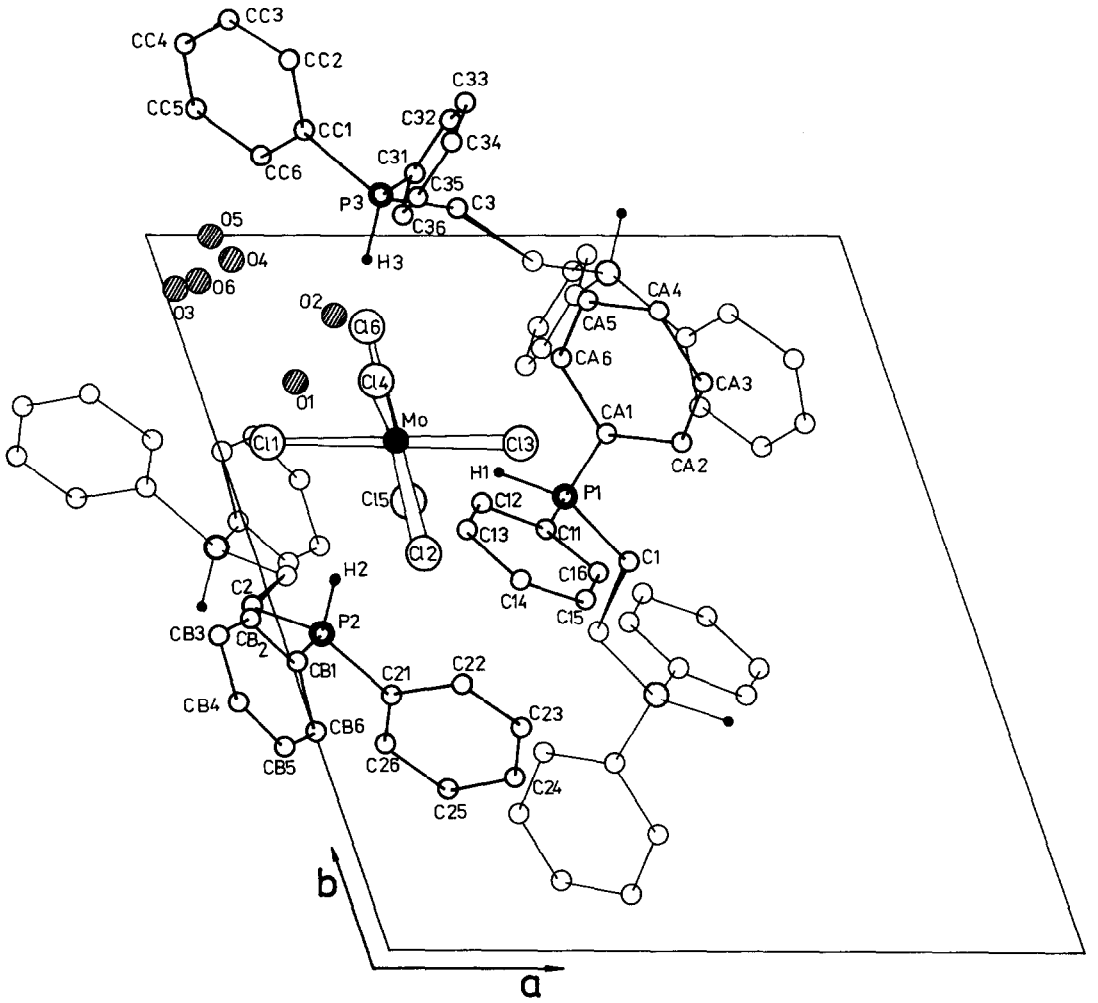

Fig. 1. The crystal structure viewed down *c* showing atom numbering.

Due to the reaction of the dppe solution in HCl with Mo(III) dissolved in the HCl–H_2O system, the pink amorphous deposit of $(dppeH_2)_3[Mo_2Cl_9]_2$ was formed. On the other hand, the monomeric complex did not precipitate from this solution. The $(dppeH_2)_3[MoCl_6]_2 \cdot 12H_2O$ crystals resulting from the red solution left after separation of the compound **II**, was additionally saturated with dry HCl. This effect is most probably due to the low concentration of the $MoCl_6^{3-}$ anion which does not suffice for the precipitation of the monomer. The dppe in the HCl solution is also insufficient for the precipitation of the monomeric phosphonium compound from the dilute K_3MoCl_6 solution in 12N HCl.

One should pay attention to the fact that the freshly precipitated $(dppeH_2)_3[Mo_2Cl_9]_2$ dissolves partially in concentrated HCl due to monomerisation of **II** according to the previously quoted equilibrium equation (which contributes to some loss of $(dppeH_2)_3[Mo_2Cl_9]_2$ in the course of the synthesis).

The precipitated **I** and **II** do not dissolve any more neither in HCl, nor in the majority of other solvents. They are relatively stable under air but under influence of humidity, they oxidize slowly towards some unidentified products.

The IR spectra of **I** and **II** are almost identical. They both lack the $\nu Mo = O$ vibration band at *ca.* 950 cm^{-1}.[7] Nevertheless, the absorption bands at 330, 285, 280 and 268 cm^{-1} for **I**, and at 290 and 226 cm^{-1} for **II** correspond with different vibrational modes of Mo–Cl and Mo–Cl–Mo. The exact interpretation and differentiation of those modes in respect to the monomeric and dimeric compounds is not quite clear in the literature. The 305 and 280 cm^{-1} bands are attributed by some authors[8] to the vibrations of the Mo–Cl–Mo bridges, while others[4a,9] ascribed them to the terminal Mo–Cl vibrations. The "ragged" band at *ca.* 900 cm^{-1} and another one at 2400 cm^{-1} are affected by the phosphonium fragment of the $dppeH_2^{2+}$ cation as has been proved for dppe · 2HCl.[10] In the free phosphine those two bands do not appear. The 2400 cm^{-1} band is

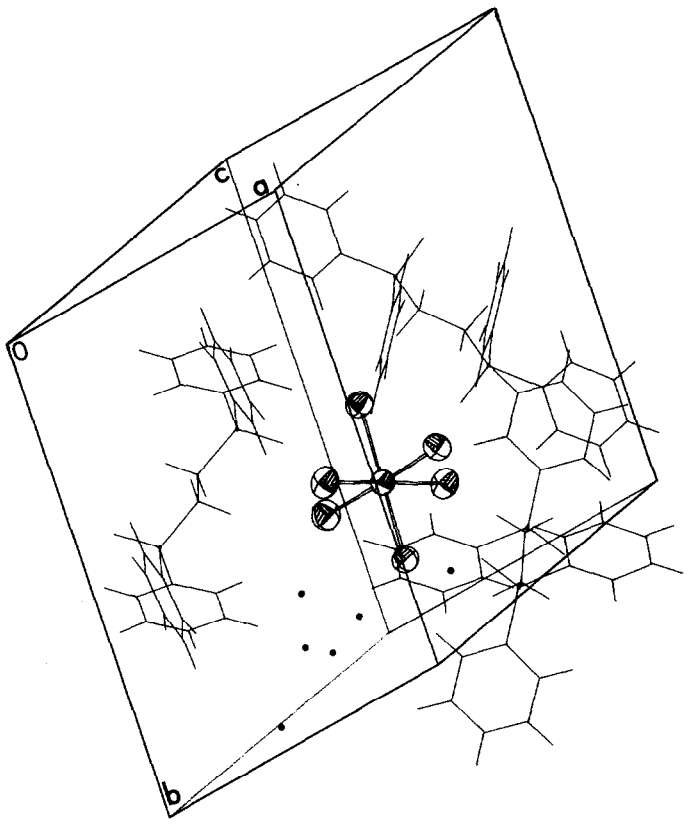

Fig. 2. The packing of the crystal.

caused by νP–H vibrations.[11] The band at 3500 cm^{-1} in the IR spectrum of $(dppeH_2)_3[MoCl_6]_2 \cdot 12H_2O$ gives evidence of the presence of water which was also confirmed by X-ray analysis. This water contributes most probably to the low stability of the respective crystals which gradually turn into the amorphous pink powder. The vacuum drying of crystals results in the total "liberation" of water. This is the reason why there is a poorer (although still satisfactory) agreement between the results of elementary analysis and the calculated composition of the monomeric compound than in the case of the dimeric one. Due to the extremely low solubility of **I** and **II**, their electronic spectra could be recorded only in the solid state. Those spectra resemble, both in respect of the band positions and shape, the reflexion spectra of K_3MoCl_6, $Cs_3Mo_2Cl_9$ and a whole series of the similar compounds.[3c] The observed electronic transitions for $(dppeH_2)_3[MoCl_6]_2 \cdot 12H_2O$ are typical of the numerous Mo–d^3 compounds and they can be described as similar to these, characterising the rigorously regular octahedron.[12] The electronic transitions in $(dppeH_2)_3[Mo_3Cl_9]_2$ (Table 2) should be discussed in the light of the recent results of Trogler[4c] who attributed the three d–d bands (ν_1, ν_2, ν_3) to $e' \rightarrow e'(^1E)$, $a_1' \rightarrow e'(^1E)$ and $a_1' \rightarrow a_2''$ transitions (D_{3h}).

The $MoCl_6^{3-}$ ion has (taking into account the measurement error) the structure of a regular octahedron similar to that found in K_3MoCl_6.[13] The average Mo–Cl bond length is equal to 2.45(1) Å. In the crystals of **I** there are three crystallographically independent $\{HP(C_6H_5)_2$

Table 2. Visible absorption spectra λ_{max} cm^{-1} of compounds **I** and **II**

Compounds	ν_4	ν_3	ν_2	ν_1
I	23 810	ca. 19 000	14 925	
II	23 530	19 230	15 150	13 160

$(CH_2)_2(C_6H_5)_2PH\}^{2+}$ cations with their own symmetry centres. The $P–C_{bridge}$ and $P–C_{Ph}$ average bond lengths are equal to 1.795(9) and 1.784(9) Å, respectively, and are slightly smaller than the corresponding bond lengths of 1.838(8) and 1.815(8) Å, respectively, in a dppe coordinated to a metal ion[14] (C_{bridge} = methylene carbon atom, C_{Ph} = phenyl carbon atom). There are also differences in the $C_{Ph1}–P–C_{bridge}$, $C_{Ph_2}–P–C_{bridge}$ and $C_{Ph1}–P–C_{Ph2}$ bond angles which in the phosphonium ion equal 109.7(5)°, 109.5(5)° and 113.2(5)°, respectively, while in the coordinated phosphine, the angles of $C_{Ph}–P–C_{bridge}$ and $C_{Ph}–P–C_{Ph}$ are 104.4° and 104.6°, respectively.

Although the data for the phosphonium cation of R_3PH^+ type are not available to us, in general, the P–C bond lengths in phosphonium groups are shorter by about 0.02–0.04 Å than those in phosphines free or coordinated to a metal ion.[15] Consequently, the P–C bond becomes shorter and C–P–C angle increases because of stronger repulsions between the carbon atoms.[16]

From the examined compounds there is only $(dppeH_2)_3[MoCl_6]_2 \cdot 12H_2O$, which proves to be an active catalyst in the process of olefin epoxidation, while both substances are inactive in the decomposition reactions of the organic hydroperoxides.[17]

(*Received* 7 *February* 1984; *accepted* 30 *March* 1984)

Abstract—1-hydroxyethylidene-1,1-bisphosphonic acid (HEDP) is a phosphonate chelate with several diagnostic and therapeutic applications. Previous studies have indicated that calcium complex aggregation occurs in the basic range of pH; results from this study indicate that complex aggregation occurs throughout the physiological range of pH as well. Calcium complex formation data were used for PQ analyses and plots of the derivative of Z with respect to total diphosphonate at constant free calcium ion concentration were shown to provide valuable information with regard to model selection. A link-addition stepwise complex formation model was shown to be most appropriate; a robust feature of all aggregate formation models examined is a strong pH dependence of polynuclear complex formation in the pH range 5.5–7.0.

Much of the currently available literature on the formation of polynuclear complexes is attributable to, or derived from, work done in European laboratories in the 1940s, 50s and 60s. L. G. Sillén was directly or indirectly responsible for most of that work and has published extensively on analytical and graphical techniques for identifying such solution systems (e.g. Refs. 1–4). When computers became available in the late 1950s and 60s for routine data analysis, Sillén was among the first to develop expertise in computer modeling of complex solution equilibria using non-linear least squares techniques.[5–7] As the number of parameters in a system becomes larger statistical measures such as error square sums and correlations, and formation curve data, become less sensitive to differences between models. With current levels of computing power and the refinement of simulation techniques and computer graphics it is now recognized that visual comparisons are equally as important as statistical measures in determining the suitability of a particular model for a complex solution system.[8,9]

Aqueous solutions of calcium and 1-hydroxyethylidene - 1, 1 - bisphosphonic acid (HEDP) provide an example of a system in which individual species, hence a particular model, are difficult to identify.[10–14] Several conjectures have been made regarding solution composition and stability constants involved in this system, the most recent studies involving macromolecular techniques and sophisticated non-linear least squares approaches which indicate that polynuclear aggregation is likely to occur. Analysis of pH titration data is entirely inadequate in this situation and formation curve data by itself may not be sufficient to allow discrimination of various types of stepwise polynuclear complex formation. This work involves a computer graphics based simulation technique which allows a sensitive visual comparison of formation data derived from various polynuclear complex formation models and experimental data; it is based on a derivation by Sillén describing average numbers of ligand molecules and central atoms per complex.

EXPERIMENTAL

All solutions were prepared using reagent grade deionized water produced by a four cartridge Millipore water purification unit, and having typical measured resistance of 18 MΩ and organic impurities on the order of ppb. Calcium standard solutions were 0.100 M Radiometer standards, stored in plastic containers enclosed in evacuated metal cans. Ionic strength in all experiments was maintained at 0.10 M with Baker reagent grade tetramethylammonium chloride (TMACl), and base titrations were done with tetram-

*Author to whom correspondence should be addressed.

ethylammonium hydroxide (TMAOH), supplied as Eastman 10% aqueous reagent grade.

HEDP used in all experiments was supplied as a disodium salt by Proctor and Gamble. The salt was converted to the pure acid form by passing through a Dowex cation exchanger prepared by eluting with 1 M HCl followed by pure water until pH reached approx. 5. The HEDP solutions were then standardized by titrating with TMAOH. Yield from the cation exchange column was found to be 97%, and solutions were checked for metal complex impurities by UV-visible spectroscopy.

Precautions were taken throughout the preparation of solutions and the execution of experiments to exclude atmospheric CO_2 by bubbling with pre-purified N_2 gas which had been passed through a series of gas washing bottles containing concentrated NaOH and pure deionized water. This provided N_2 gas free of any trace of CO_2 and saturated with water vapor. The gas was then directed to a 9 l. Pyrex storage container with an Ascarite vent, to recently prepared solutions, or to the reaction vessel. Bubbling with the water saturated gas avoided any loss of volume from the reaction vessel and proved effective in maintaining CO_2-free solutions. CO_2 is eliminated from pure water by bubbling for approx. 30 mins.

All experiments were done in a water-jacketed 250 cm^3 beaker, closed at the top and with inlet ports for a mechanical stirrer, Radiometer calcium and reference electrodes, a Radiometer combined pH electrode, a line supplying CO_2-free nitrogen gas, and titrant delivery tips for either or both of $CaCl_2$ and TMAOH. Calcium electrode performance was rapid and reproducible for all but the very lowest of free calcium ion concentrations; a slight hysteresis effect was noted in electrode response when titrating a solution of constant calcium ion concentration with a base followed by an acid. In order to avoid any inconsistancy due to this effect, standards and samples were titrated in exactly the same manner with the initial approach to the desired pH from the same direction, etc. Standard curves were obtained before and after each run by titrating a 0.100 M solution of TMACl with 0.100 M $CaCl_2$ calcium standard. Standard curves were generally within 1–2 tenths of a millivolt down to the μM level and were averaged by the computer program which processed the raw data. Radiometer equipment was used for all experiments, including two PHM-84 research meters, two ABU12 autoburets, a TTT80 titrator, and strip chart recorder.

RESULTS

Preprocessed but unsmoothed data from pH titration experiments done at 1 : 1 and 2 : 1 ratios of total calcium to total diphosphonate are shown in Figs. 1 and 2, respectively. Careful examination of these plots of unsmoothed data reveals a slight kink in each of the titration curves near the beginning of the plateau region just after the second equivalence point. This characteristic of the curves represents the onset of significant amounts of polynuclear complex formation, as discussed later. At the lowest levels of total calcium and total HEDP, where little complexation of any kind is occurring, the third equivalence point begins to

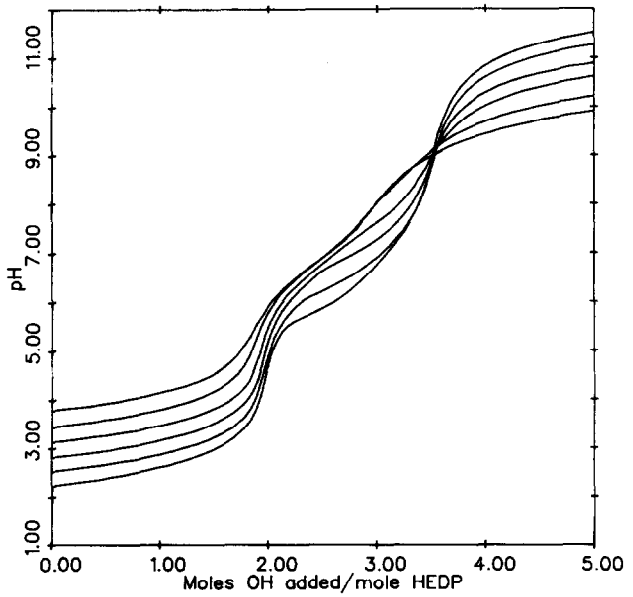

Fig. 1. Experimental pH titration data at 1 : 1 ratios of total calcium to total HEDP. Total diphosphonate concentrations are 0.100, 0.220, 0.480, 1.100 and 2.300 mM.

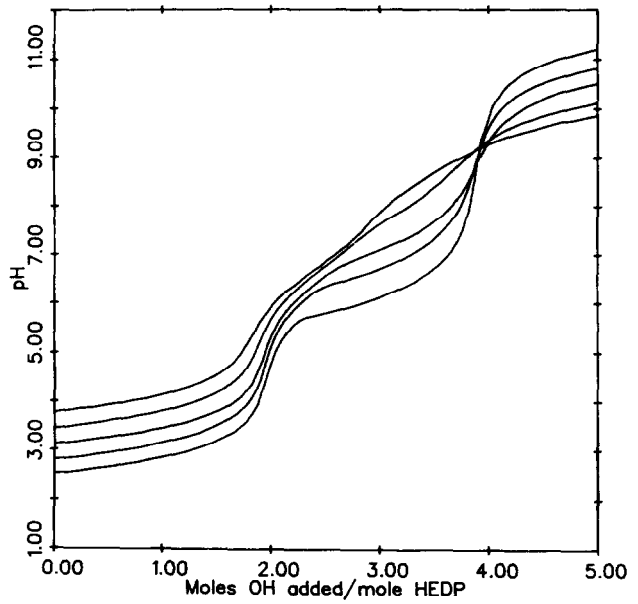

Fig. 2. Experimental pH titration data at 2 : 1 ratios of total calcium to total HEDP. Concentrations of total diphosphonate are 0.100, 0.220, 0.480, 1.100 and 2.300 mM.

appear. In comparing Figs. 1 and 2 it is noted that titration curves for 2 : 1 ratios of CATOT to DPTOT are shifted downward considerably in the neutral range of pH relative to 1 : 1 titrations, representing a higher degree of complexation.

Calcium ion titrations done at constant pH 8.0 are plotted as formation number ((CATOT–Ca^{2+})/DPTOT) vs free calcium ion concentration in Fig. 3. Formation number in these experiments is noted to be a function of total diphosphonate as well as calcium ion concentration, indicating the presence of polynuclear species.[15] In modeling to be discussed later, only data from approximately the lower two-thirds of these formation curves were used since it has been previously shown that solutions with a Ca/DP ratio greater than 2 : 1 eventually precipitate.[16] Data with ratios less than 2 : 1 are used in parameter fitting since the solution reactions may safely be assumed to be at a stable equilibrium.

MODELING OF TITRATION DATA

Some previous workers[12,14] had not considered the formation of polynuclear complexes in modeling the Ca-HEDP system; others had formulated a polynuclear model[11,13,16] involving specific large

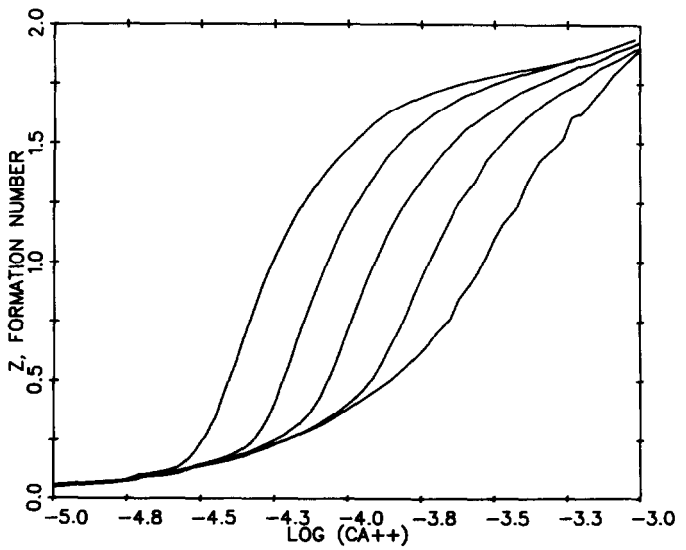

Fig. 3. Experimental calcium complex formation curves at a constant pH 8.0. Total diphosphonate concentrations are 0.100, 0.219, 0.478, 1.030 and 2.300 mM.

aggregate species which fit the data well but required an unnecessarily large number of physical parameters and seemed to lack specific evidence for the species chosen. The approach taken here is to develop a simpler model (i.e. fewest parameters) which is consistent with formation curve data that implies the existence of stepwise polynuclear species. Sillén described three such models of stepwise polynuclear complex formation where the overall complex formation constant varies as a function of aggregate size.[2] In these "core-links" models only two additional parameters are necessary to describe the formation of a whole series of polynuclear aggregates. Instead of specifying the largest complex in the model this formulation is represented by an infinite series and the experimental data determine the importance of the larger aggregates, as well as allowing one to calculate the concentration distribution of the aggregates, average species size, etc. Although the particular models Sillén had applied to other systems do not adequately describe the HEDP equilibria, another type of stepwise polynuclear model has been derived which goes a long way toward the stated objective of having the fewest number of parameters while doing a better job of fitting experimental data over a broad range of conditions.

The application of a stepwise complex formation model to these data has been justified by *PQ* analysis, a model-independent approach to determining the average numbers of metal ions and ligand molecules per aggregate over the range of the formation data.[4] The expressions used to determine $\bar{P}$ and $\bar{Q}$ from the Ca–HEDP formation data are:

$$\bar{P} = \frac{Z}{R - \alpha_0} = \text{average Ca per complex} \quad (1)$$

$$\bar{Q} = \frac{1 - \alpha_0}{R - \alpha_0} = \text{average DP per complex} \quad (2)$$

where

$$R = \text{const} - \int \left(\frac{\partial Z}{\partial \log \text{DPTOT}}\right)_{Ca^{2+}} d(\log \text{Ca}) \quad (3)$$

$$\log \alpha_0 = \text{const} + R - \int Z_{\text{DPTOT}}\, d(\log \text{Ca}) \quad (4)$$

$$Z = \frac{\text{CATOT} - [Ca^{2+}]}{\text{DPTOT}}. \quad (5)$$

At the lowest levels of free calcium ion concentration complex formation is negligible ($Z \approx 0$), free diphosphonate is approximately equal to DPTOT and thus the constants above are equal to 1.0 and -1.0, respectively. Plots of $\bar{P}$ vs $\bar{Q}$ show whether certain complexes are preferred (clustering of points) or whether stepwise complexation is occurring (a straight line with a slope equal to the combining ratio).

To evaluate R in eqn (3), 25 least squares splines were computed for values of Z vs log(DPTOT) at 25 levels of constant free calcium ion concentration. Derivatives of these splines were calculated at each value of log [DPTOT] for each of the values of log $[Ca^{2+}]$, another spline was computed for the derivatives vs log $[Ca^{2+}]$ and these curves at constant DPTOT were integrated starting at $Z \approx 0$. This provided values of R at 25 levels of free calcium ion concentration for each of the formation curves. Formation curves were then integrated from the region of negligible complex formation up to the 25 successive levels of log $[Ca^{2+}]$ and the fraction of uncomplexed diphosphonate, α_0, was calculated from the values of R and the formation curve integral at each free calcium ion level. These values were used in turn to calculate $\bar{P}$ and $\bar{Q}$ and plots of P vs Q demonstrated a uniform and linear relationship, supporting the occurrence of stepwise polynuclear complex formation. Furthermore, as discussed in the results section to follow, an intermediate calculation in this *PQ* analysis, namely the determination of $[\partial Z/\partial(\log \text{DPTOT})]_{Ca^{2+}}$ vs log $[Ca^{2+}]$, proved to be extremely useful in discriminating between various stepwise models.

Model calculations of formation curves or pH titration curves were done by finding the roots of the non-linear equations describing the mass balances of calcium ion, protons and diphosphonate.[17] The mass balances included the simpler species as listed in Table 1, as well as stepwise species described below, and a root-finding technique described by Powell[18] was used to solve the system.

Stepwise aggregate species were included in the mass balance expressions in the following manner. For simplification in the following discussion $A = \text{CaDP}$, $B = \text{Ca}_2\text{DP}$; total calcium in the polynuclear species then equals ATOT plus 2*BTOT while total diphosphonate equals ATOT + BTOT. The three Sillen stepwise formation models each involve two constants: k_0, a constant affecting horizontal displacement of the formation curves, and k, which affects separation. The overall formation constant for a particular stepwise aggregate, k_n, is a function of k and k_0. The difference in the three Sillen models has to do with the way k_n varies with respect to aggregate size, for example:

$$k_n = k_0 k^n,$$

Table 1. Parameters used in or estimated from model 7

or

$$k_n = k_0 n k^n,$$

or

$$k_n = k_0 k^n / n.$$

For the relation $k_n = k_0 k^n$ (model 1), the equilibrium expressions for the series of aggregate species are:

$$A + B \leftrightarrow AB \qquad AB = k_1[A][B] = k_0 k[A][B]$$

$$A + 2B \leftrightarrow AB_2 \qquad AB_2 = k_2[A][B]^2 = k_0 k^2[A][B]^2$$

$$A + 3B \leftrightarrow AB_3 \qquad AB_3 = k_3[A][B]^3 = k_0 k^3[A][B]^3$$

$$A + nB \leftrightarrow AB_n \qquad AB_n = k_n[A][B]^n = k_0 k^n[A][B]^n.$$

The total quantity of A (i.e. CaDP) in the series of aggregates is calculated from:

$$\text{ATOT} = A + AB + AB_2 + AB_3 + \ldots + AB_\infty.$$

Substituting in the previous relations and expressing as a summation:

$$\text{ATOT} = [A] + k_0[A] \sum_{n=1}^{\infty} (k[B])^n.$$

This geometric series can be shown to converge for $|k[B]| < 1.0$ and has the closed form expression

$$\text{ATOT} = [A] + \frac{k_0 k[A][B]}{1 - k[B]}.$$

The series describing BTOT involves the square of the geometric series and can be reduced to the closed form expression

$$\text{BTOT} = [B] + \frac{k_0 k[A][B]}{(1 - k[B])^2}.$$

Likewise, similar closed form expressions can be derived for the other two Sillen overall stepwise formation models. These expressions, as well as three other models employing k_n as an overall formation constant, are presented as models 1–6 in Table 2.

Additionally, models 1–3 in Table 2 were implemented assuming that the formation constants, k_n, represented not overall formation constants, but rather equilibrium constants for addition of a subsequent link (Ca_2DP) to the aggregate. In model 7, for example, where $k_n = k_0 k^n$, the algebra is the following:

$$A + B \leftrightarrow AB \qquad AB = k_0 k[A][B]$$

$$AB + B \leftrightarrow AB_2 \qquad AB_2 = k_0^2 k^3[A][B]^2$$

$$AB_2 + B \leftrightarrow AB_3 \qquad AB_3 = k_0^3 k^6[A][B]^3$$

$$AB_3 + B \leftrightarrow AB_4 \qquad AB_4 = k_0^4 k^{10}[A][B]^4$$

$$AB_{n-1} + B \leftrightarrow AB_n \qquad AB_n = k_0^n k^{n(n+1)/2}[A][B]^n$$

then

$$\text{ATOT} = [A] + [A] \sum_{n=1}^{\infty} (k^{n(n+1)/2} k_0^n [B]^n).$$

This expression is not reducible to a closed from but does converge provided that $|k| < 1.0$. The series must be evaluated term by term with an appropriate criterion for termination. Similar expressions may be derived for models 7–9 in Table 2.

RESULTS

The various stepwise formation models presented in Table 2 were evaluated initially by running a simulation graphics program[8] at a Tektronix graphics terminal, and manually altering the formation constants. The set of five formation curves, along with the experimental data, would be

Table 2. Summary of core-link models

Model	k_n	ATOT	BTOT
1	k_0k^n	$A + \frac{k_0kAB}{1-kB}$	$B + \frac{k_0kAB}{(1-kB)^2}$
2	k_0nk^n	$A + \frac{k_0kAB}{(1-kB)^2}$	$B + \frac{k_0kAB(1+kB)}{(1-kB)^3}$
3	k_0k^n/n	$A-k_0A\cdot\ln(1-kB)$	$B + \frac{k_0kAB}{1-kB}$

5	k_0-nk	$A + (\frac{AB}{1-B})(k_0 \frac{K}{1-B})$	$B + (\frac{AB}{(1-B)^2})(k_0 - \frac{k(1+B)}{1-B})$
6	$k_0(1-k^n)$	$A + k_0AB(\frac{1}{1-B} - \frac{k}{1-kB})$	$B + k_0AB(\frac{1}{(1-B)^2} - \frac{k}{(1-kB)^2})$
7	k_0k^n	$A + A\sum_{n=1}^{\infty}(k \frac{n(n-1)}{2} k_0^nB^n)$	$B + A\sum_{n=1}^{\infty}(nk \frac{n(n+1)}{2} k_0^nB^n)$
8	k_0nk^n	$A + A\sum_{n=1}^{\infty}(n!k \frac{n(n+1)}{2} k_0^nB^n)$	$B + A\sum_{n=1}^{\infty}(nn!k \frac{n(n+1)}{2} k_0^nB^n)$
9	k_0k^n/n	$A + A\sum_{n=1}^{\infty}(\frac{k \frac{n(n+1)}{2} k_0^nB^n}{n!})$	$B + A\sum_{n=1}^{\infty}(\frac{nk \frac{n(n+1)}{2} k_0^nB^n}{n!})$

notes: k_n for models 1-6 represent overall formation constants; k_n for models 7-9 represent link-addition constants.

displayed immediately after entering trial values for constants, allowing determination of good initial estimates prior to least squares minimization. Little or no difference was observed in models 1–3 except in regard to magnitude of the constants required; shapes and separations of the curves in the best cases were virtually identical and it was not possible in any case to produce a crossover point, i.e. that point on the formation curves where Z is independent of total diphosphonate, greater than $Z = 1.5$. This value for the crossover point may be explained in the following way: best observed values of k were in the range 0.01–0.2 and $[Ca_2DP] \approx 0.1$ mM, yielding a product $kB \approx 10^{-5}$. If it is assumed that nearly all DP is present as either stepwise cores (CaDP) or links (Ca_2DP) at the crossover point then, for model 1:

$$Z = \frac{\text{complexed Ca}}{\text{total HEDP}} = \frac{\text{ATOT} + 2^*\text{BTOT}}{\text{ATOT} + \text{BTOT}}$$

where

$$\text{ATOT} = \text{total CaDP} = A + \frac{k_0kAB}{1-kB}$$

$$\text{BTOT} = \text{total } Ca_2DP = B + \frac{k_0kAB}{(1-kB)^2}.$$

Since $kB << 1.0$,

$$\text{ATOT} = A + k_0kAB, \quad \text{BTOT} = B + k_0kAB$$

and if most of the CaDP and Ca_2DP is incorporated in polynuclear aggregates at the higher formation numbers then $k_0kAB \gg A,B$ and ATOT $\approx$ BTOT. Therefore, $Z = 3^*\text{ATOT}/2^*\text{ATOT} = 1.5$. The situation is similar for all of models 1–6, implying that models which employ k_n as an overall formation constant are inappropriate.

Strong evidence for the interpretation of the

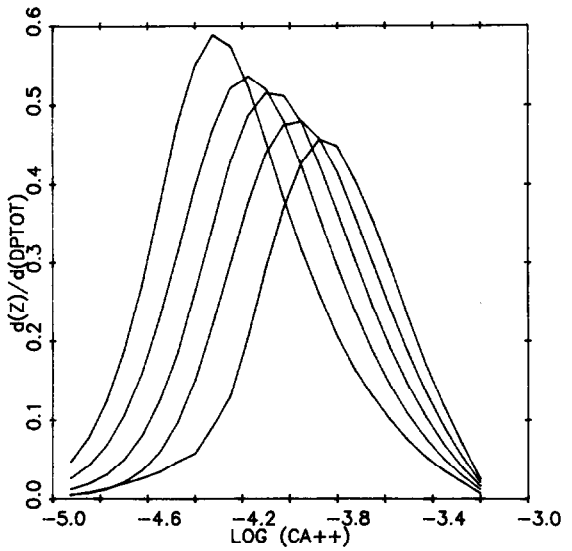

Fig. 4. Intermediate output from *PQ* analysis. Partial derivatives of Z with respect to DPTOT at constant $[Ca^{2+}]$ for model 1 simulated at pH 8.0.

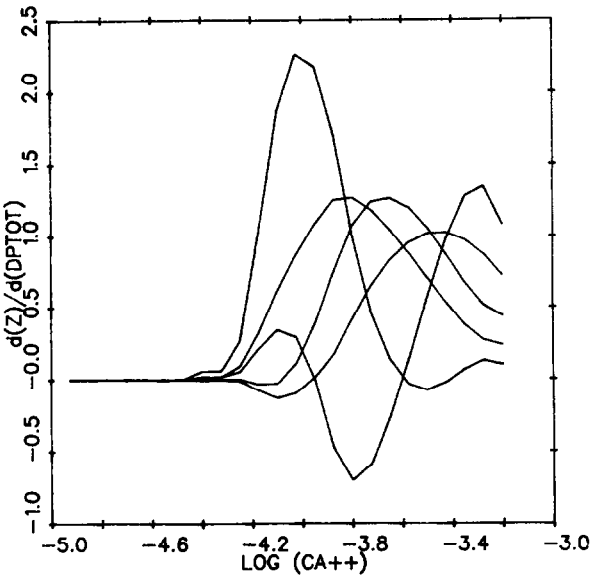

Fig. 6. Intermediate output from *PQ* analysis. Partial derivatives of Z with respect to DPTOT at constant $[Ca^{2+}]$ for Grabenstetter model simulated data at pH 8.0.

stepwise k_n as link-addition association constants is presented by plots of intermediate results in the *PQ* analysis. Several formation curve data sets were generated from the various stepwise models, incorporating about the same amount of random error as was observed in the actual experimental data. These data sets were then processed by a program designed to do a *PQ* analysis, i.e. a strictly model independent determination of average numbers of calcium ions and diphosphonate molecules per complex. When the intermediate results of this calculation were plotted it was noticed that there were striking differences between the various data sets, differences much greater than might be noticed among the original formation curves from which they were produced. The plots of $[\partial Z/\partial(\log \mathrm{DPTOT})]_{Ca^{2+}}$ vs $\log Ca^{2+}$ are shown in Figs. 4–7. These derivative plots are a sort of qualitative fingerprint for the various types of polynuclear complex formation, showing dramatic differences in form compared to the subtle

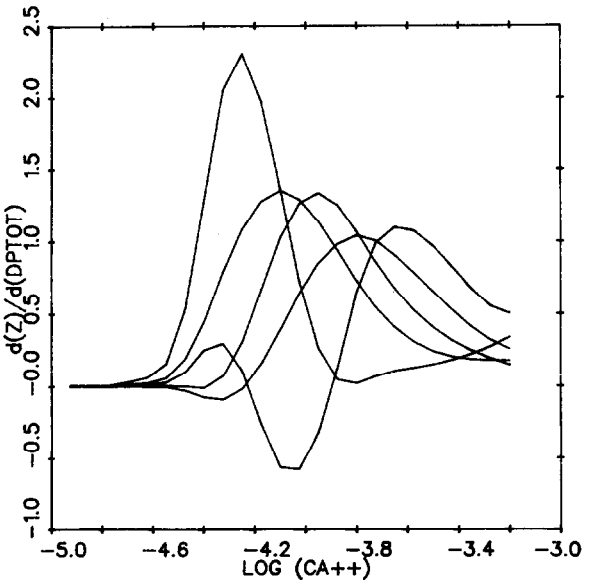

Fig. 5. Intermediate output from *PQ* analysis. Partial derivatives of Z with respect to DPTOT at constant $[Ca^{2+}]$ for model 7 simulated data at pH 8.0.

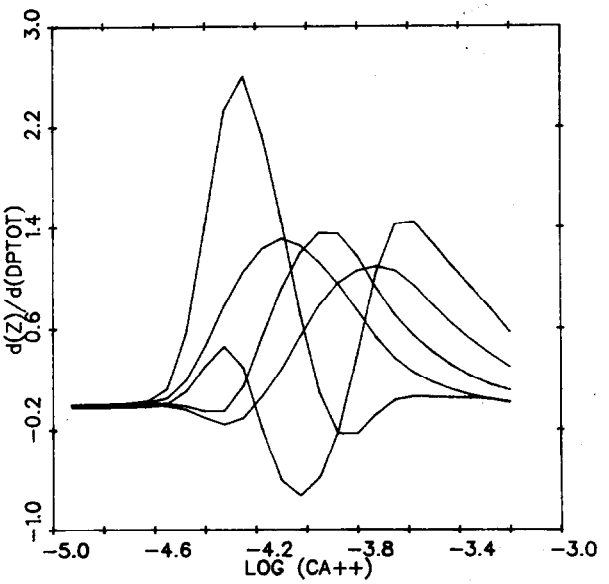

Fig. 7. Intermediate output from *PQ* analysis. Partial derivatives of Z with respect to DPTOT at constant $[Ca^{2+}]$ for actual experimental data at pH 8.0.

differences in spacing of curves in the original plots of formation number vs free calcium ion. It is evident in Figs. 4–7 that model 1 data produces entirely different derivative curves than either model 7 or the actual experimental data. Another model suggested by Grabenstetter,[11] which is not a stepwise model but does include C3D2 and C7D4 complexes, produces derivative curves which are similar to curves produced by the experimental data but no so close a match as with derivative curves produced from model 7 data. The similarity of the Grabenstetter model with model 7 is due to the correspondence and importance of two aggregates common to both models, C3D2 and C7D4. Based on these observations it was decided to do final parameter estimation using stepwise complex formation model 7, the link addition model corresponding to Sillén model 1.

Final parameter estimates are shown in Table 1 for model 7; experimental data and model generated curves using these constants are shown in Fig. 8. It was noted that best fits were obtained when species having 10–15 or more Ca_2DP links were present in small but significant concentrations. These aggregates have a marked pH dependence in the region pH 5–7, increasing in concentration by several orders of magnitude for a relatively small change in pH. In the basic range of pH the concentration of aggregate species is relatively constant.

DISCUSSION

The use of interactive graphics for visual observation of changes in formation curves and plots of the derivative of Z with respect to DPTOT is a powerful technique for discriminating between various complex formation models and for establishing good initial estimates for least squares minimization. Derivative curves decisively ruled out the interpretation of k_n as an overall stepwise formation constant, as opposed to constants for addition of subsequent links to an aggregate.

Formation curve data is considerably more sensitive to changes in solution conditions than pH titration data, and is thus more useful in determining metal complex formation constants. pH titration data exhibits relatively small changes, even in simple mono-nuclear systems, for given changes in conditions. Formation curves on the other hand may shift back and forth as a function of pH, up and down as a function of metal ion concentration and in polynuclear systems may also be a function of ligand concentration. Therefore in this type of complex forming solution system much more useful information is gained by titrating with the metal ion at constant pH than by titrating with a base at constant MTOT.

With regard to this particular system it is concluded that aggregate species of calcium and HEDP are important in the physiological range of pH and exhibit dramatic pH dependence in the range 5–7. The CaHDP complex has a well-determined constant and is important in the neutral region. Previously reported values of K_{Ca_2DP} in the range of 10^{10}–10^{12} are grossly high and probably represent an apparent formation constant for aggregate species.

(*Received* 18 *November* 1983; *accepted* 16 *April* 1984)

Abstract—The reaction between CdI_2 and benzenecarbothioamide (BCTA) in ethanol produces crystalline $[Cd(BCTA)_2I_2]$ but in 1,2-dichloroethane it yields $[Cd(BCTA)I_2]$ in powder form. $[Cd(BCTA)_2I_2]$ has been characterized by X-ray crystallography, and both complexes have also been identified by infrared spectra in the solid phase, ^1H NMR, and electrical conductivity studies in solution. The crystals of $[Cd(BCTA)_2I_2]$ are monoclinic, space group $P2_1/c$, with $a = 747.6(1)$ pm, $b = 1958.7(13)$ pm, $c = 1363.6(6)$ pm, $\beta = 110.307(3)°$ and $Z = 4$. Least-squares refinement of the structure based on 4260 observations led to final discrepancy indices of $R = 0.043$ and $R_w = 0.054$. The geometry around the cadmium atom is slightly distorted from the tetrahedral. The BCTA is coordinated through the sulphur atom: Cd–I(1) = 277.2(1) pm, Cd–I(2) = 272.6(1) pm, Cd–S(1) = 256.7(3) pm, Cd–S(2) = 257.5(2) pm. The electrical conductivity studies and NMR and IR spectra are consistent with the structure found for $[Cd(BCTA)_2I_2]$ and suggest a dimeric *trans* symmetric tetrahedral structure with halogen bridging (C_{2h}) for $[Cd(BCTA)I_2]$.

Although usually lacking structural X-ray diffraction data, there have been numerous studies published concerning complexes of the halides of group IIB metals with a variety of thioamide compounds.[1,2] In the particular case of complexes of benzenecarbothioamide, however, little work has been done.[3,4] It is known that, with some exceptions,[5] benzenecarbothioamides have a strong tendency to coordinate with metals via the sulphur atom of the thioarbonyl group,[6,7] thus behaving as weak bases according to Pearson's HSAB theory.[8] Since the halides of group IIB metals are soft Lewis acids,[9] stable complexes may be expected to be formed between these two groups of compounds. Although the halides of group IIB metals generally form tetrahedral monomeric complexes, tetrahedrally coordinated dimer monoadducts with halogen bridging and both tetrahedral and octahedral polymers are also common.[10,11]

Part of a comprehensive investigation into the compounds formed by the halides of group IIB metals interacting with a variety of benzenecarbothioamides, the present article reports a structural study of the compounds resulting from the reaction between cadmium(II) iodide and benzenecarbothioamide (BCTA).

RESULTS AND DISCUSSION

Neither adduct is sensitive to moisture. They are both soluble in methanol, ethanol, DMSO and acetonitrile, and insoluble in chloroform and carbon tetrachloride. The milimolar conductivities in acetonitrile of $Cd(BCTA)_2I_2$ ($17\,\Omega^{-1}cm^2mol^{-1}$) and of $Cd(BCTA)I_2$ ($26\,\Omega^{-1}cm^2mol^{-1}$) are lower than the values reported for 1:1 electrolytes.[12]

The structure of $Cd(BCTA)_2I_2$. In the $Cd(BCTA)_2I_2$ molecule (Fig. 1), the cadmium atom is surrounded by two atoms of iodine and two sulphur atoms belonging to the two molecules of BCTA.† On the basis of the bond angles measured at the central atom (Table 1) the complex may be described as having distorted tetrahedral coordination. The Cd–I distances are in the range previously reported for Cd–I bonds.[13] The Cd–S distances lie between the 245 pm found in dichlorobisthioureacadmium(II),[14] in which there is also distorted tetrahedral geometry about the metal atom, and the 260 pm of bisethylenethioureacadmium(II) thiocyanate.[15]

The two molecules of BCTA coordinated to the cadmium atom are crystallographically independent and differ somewhat one from another. Table 2 lists a number of significant data which we interpret as follows. Molecule I seems to be bent between the phenyl ring and the thioamide group with a torsion angle (ϕ) of 5.5°. In molecule II, on the contrary, this torsion angle is 34°. A similar situation has been found in $Cu(BCTA)_3Cl$, in which one of the ligand molecules has a small torsion angle (16.8°) compared with the other two (30.9° and 39.5°).[7] In $Hg(BCTA)I_2$, which is a dimer, the ligand molecule has a torsion angle of 25.3°.[16]

The lengths of the C–S and C–N bonds in the two ligand molecules are within the expected range of values for molecules with a thioamide group.[17]

†Atomic positional and thermal parameters, complete tables of bond distances and bond angles, planes, torsion angles, interatomic contacts greater than 3.0 and less than 3.5 Å and a list of F_0/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

		C(15)-C(16)-C(17)	119.4(8)	C(25)-C(26)-C(27)	119.3(9)
		C(12)-C(17)-C(16)	121.4(8)	C(22)-C(27)-C(26)	120.7(9)

In both ligand molecules the length of the C–C bond joining the phenyl ring and the thioamide group is rather greater than the 146.6 pm normal in $C(sp^2)$—$C(sp^2)$ bonds.[18] This implies less conjugation than normal.

The bond lengths and bond angles in the phenyl rings of the two ligand molecules are as expected for an aromatic ring and agree well with those found for N,N-dimethylbenzenecarbothioamide[19] and in the copper and mercury complex referred to above.[7,16]

IR spectra. The most significant bands of the IR spectra of BCTA[5] and the two adducts are shown in Table 3. In both adducts the NH_2 vibrations in the plane with the exception of $\rho(NH_2)$, are considerably stronger due to a conjugation effect resulting from the mesomeric delocalization mentioned above. $\rho(NH_2)$ may contain a signifiant contribution from ν(CS), which would explain its appearing in the adducts at lower frequencies than in the free ligand. The out-of-plane NH_2 deformation vibrations are weak, and they seem not to have undergone any significant modifications.

The ν(CN) mode of the BCTA–NCS group at 1400 cm^{-1} appears at higher frequencies in the adducts, whereas the ν(CS) vibration at 880 cm^{-1} in the free ligand shifts lower in both complexes and is split in $Cd(BCTA)_2I_2$. Both these shifts are to be expected when there is coordination with the metal via the sulphur atom, for the CN bond is thereby strengthened, and the CS bond weakened, by the mesomeric effect mentioned above. The presence of two different conformations of BCTA may explain the splitting of the ν(CS) peak and of

other unassigned peaks observed in $Cd(BCTA)_2I_2$ but not in the monoadduct. The flattening of the ν(CC) mode in the complexes may be due to coupling with ν(CS), which is common in thioamides.

Table 3 also includes the far-infrared band observed in the spectra of the solid adducts, together with the proposed assignments. Two bands at 334 and 320 cm^{-1} in $Cd(BCTA)_2I_2$ and a band at 342 cm^{-1} in $Cd(BCTA)I_2$ may be attributed to ν(CdS).[2,20] Cd–I vibrations often lie below 200 cm^{-1},[21] and in the spectrum of $Cd(BCTA)_2I_2$ two moderate-to-strong bands at 164 and 138 cm^{-1} may be assigned to the symmetric and antisymmetric Cd–I modes. The existence of these two bands, together with the two assigned to ν(CdS), is a strong indication of C_{2v} symmetry in the adduct,[22] with tetrahedral geometry about the metal atom. The spectrum of $Cd(BCTA)I_2$ is rather different in this region, one of the bands lying at much lower frequency than in $Cd(BCTA)_2I_2$. This behaviour can only be explained on the assumption that the monoadduct has a dimer structure with iodine bridging between the cadmium atoms. If so, the strong band at the higher frequency must correspond to the terminal Cd–I stretching mode (ν_t) and the 108 cm^{-1} band to Cd–I bridge stretching (ν_b).[13,23] This assignment implies a ν_t/ν_b ratio of 0.81, which falls within the range 0.63–0.85 for binuclear complexes.[24] The presence of a single ν(CdS) band, one terminal Cd–I stretching mode and another bridging mode, all of them IR-active, therefore suggests that the monoadduct $Cd(BCTA)I_2$ has a *trans* symmetric tetrahedral dimer structure (C_{2h}).[25]

NMR spectra. The ^1H NMR spectrum of free BCTA shows two separate broad singlets at 9.75 and 9.40 ppm which are due to two different kinds of proton (*cis* and *trans* to the thiocarbonyl sulphur) and reflect the restricted rotation about the carbon–nitrogen bond, which has partial double bond character.

In $Cd(BCTA)_2I_2$ the NMR spectrum shows a single peak for each amide proton which has been shifted to low field (9.80 and 9.48 ppm). The retention of the separate signals for the amide protons, together with the shift to low fields, is interpreted as showing the preservation of the

partial double-bond character of the carbon–nitrogen bond and indicates coordination through the sulphur atom of the ligands.[26]

The NMR spectrum of $Cd(BCTA)I_2$ shows two broad singlets at 9.68 and 9.35 ppm which are due to the amide protons. The presence of the two amide proton signals also supports coordination through the sulphur atom in the monoadduct. The fact that, unlike the case of $Cd(BCTA)_2I_2$, the two signals observed in the NMR spectrum lie at higher field than in free BCTA does not rule out coordination via the sulphur atom, since this behaviour has also been observed in other cadmium monoadducts.[27]

EXPERIMENTAL

Preparation of $Cd(BCTA)_2I_2$. CdI_2 (4 mmol) was dissolved in dry cold ethanol and added to a solution of 8 mmol of BCTA in the same solvent. The resulting mixture was stirred for 24 hr, and after addition of carbon tetrachloride and prolonged cooling, bright yellow crystals formed which were separated by decanting off excess solvent, washed with carbon tetrachloride and dried *in vacuo*. (R = 97%), m.p. 132°C. Found: Cd, 17.03; C, 26.11; H, 2.18; N, 4.37. Calc. for $C_{14}CdH_{14}I_2N_2S_2$: Cd, 17.55; C, 26.25; H, 2.20; N, 4.37%.

Preparation of $Cd(BCTA)I_2$. A solution of BCTA in dry 1,2-dichloroethane was gradually stirred into a suspension of 4 mmol of CdI_2 in the same solvent. The resulting suspension was stirred for 24 hr and the supernatant filtered off. The white solid remaining was washed with carbon tetrachloride and dried *in vacuo*. ($R = 93\%$), m.p. 155°C. Found: Cd, 22.90; C, 15.87; H, 1.31; N, 2.69. Calc. for $C_7CdH_7I_2NS$: Cd, 22.23, C, 16.70; H, 1.40; N, 2.78%.

Analytical methods. After digestion with HNO_3/H_2O_2 and adjustment to pH 6 with hexamethylenetetramine, the cadmium was titrated with standard EDTA solution and xylenol orange.[28] C, H and N were analyzed in a Perkin–Elmer 240 microanalyzer.

Other determinations. The IR spectra were recorded using a Perkin–Elmer 180 spectrophotometer with a far-IR accessory. The samples were run as KBr discs and as Nujol and Fluorolube mulls between CsI pellets in the 4000–250 cm^{-1} region and also as Nujol mulls between polyethylene windows in the 400–50 cm^{-1} region. The conductivity measurements were carried out with a WTW LF-3 type conductivity bridge and LT A type electrode using 10^{-3} M solutions in acetonitrile. ^1H NMR spectra were obtained in DMSO solvent with tetramethylsilane as the internal standard using a Hitachi–Perkin–Elmer R 24-A apparatus.

Structure analysis. A crystal of $Co(BCTA)_2I_2$ of $0.3 \times 0.3 \times 0.2$ mm was selected to collect intensities on a Phillips PW 1100 four-circle automatic diffractometer at room temperature using graphite-monochromated MoK_α radiation ($\lambda = 0.71070$ Å) and employing ω-2θ scan technique. 5434 independent reflections were collected and of these 4260 for which $I > 2\sigma(I)$ were used in the structure determination and refinement. Lp corrections were applied to the data as were empirical absorption corrections.

The structure was solved and developed by the heavy-atom method. The hydrogen atom positions on the benzenecarbothioamide ligand were calculated geometrically and included with fixed isotropic thermal parameters set equal to those of the atoms to which they are bonded. Full-matrix least-squares refinement with anisotropic temperature factors for the remaining atoms converged at $R = 0.043$ and $R_w = 0.054$. The weighting scheme used in the last cycle was $w = k/\sigma^2$, $\sigma = A + BF_0$[29] where A and B are 4.0875, −0.6059 ($0.3 < F_0 < 3.2$); 2.6376, 0.0101 ($3.2 < F_0 < 7.2$); 4.0000, −0.1390 ($7.2 < F_0 < 20.0$); 1.4679, 0.0000 ($20.0 < F_0 < 50.6$); −0.6209, 0.0373 ($50.6 < F_0 < 410.7$) and $k = 0.4954$. The scattering factors were taken from International Tables.[30] Final difference Fourier maps showed no distinguishing features. All refinements were done with the X-ray System.[31]

Crystal Data. $C_{14}H_{14}CdI_2N_2S_2$, M = 640.61, monoclinic, space group $P2_1/c$ (C_{2h}^5 No. 14), $a = 7.476(1)$, $b = 19.587(13)$, $c = 13.633(6)$ Å, $\beta = 110.307(3)°$, $V = 1872$ Å^3, $Z = 4$, $D_c = 2.272$ g cm^{-3}, $F(000) = 1192$, $\mu = 46.35$ cm^{-1}.

(*Received* 6 *December* 1983; *accepted after revision* 16 *April* 1984)

Abstract—Electronic absorption and magnetic circular dichroism (MCD) spectra in UV-vis region of Waugh-structure $[XMo_9O_{32}]^{6-}$ (X = Ni(IV), Mn(IV)) ion in aqueous solution and solid IR spectra have been measured. The Ni(IV) ion in the polyanion has a low-spin d^6 electronic configuration and the Mn(IV) ion has a d^3 configuration. Visible absorption spectrum of the nickelate(IV) polyanion is interpreted to be mainly governed by charge-transfer transitions of the "ligand", Mo_9O_{32}, to Ni(IV) ion, rather than d–d transitions, while visible absorption of the manganate(IV) polyanion is governed, to a great extent, by d–d transitions. It is indicated by the MCD spectrum that the splitting of the first d–d absorption in the manganate(IV) polyanion is due to a contribution of the spin-forbiden transition, rather than from a trigonal splitting of the spin-allowed transition. Absorption and MCD spectra in UV region are due to charge-transfer transition within a common "ligand", which are less influenced by the kind of heteroatom, Ni(IV) or Mn(IV). The MCD pattern by the intra-ligand charge-transfer is especially characteristic of the Waugh-structure polyanions.

INTRODUCTION

Enneamolybdo polyanions with the formula $[XMo_9O_{32}]^{6-}$, the so-called Waugh-type heteropolyanion, have been known for only two cases, viz. in which a heteroatom is such as Mn(IV) and Ni(IV) of unusually high oxidation states. The polyanion is constituted of the "ligand", Mo_9O_{32}, formed by edge-sharing condensation of nine octahedral oxomolybdates and the heteroatom located in an octahedron of bridged oxygens. Two compounds have been prepared first by Hall.[1] Crystal and molecular structures of $[MnMo_9O_{32}]^{6-}$ ion are established; the MnO_6 octahedron has D_3 symmetry.[2,3] Visible absorption spectrum has been assigned on the basis of d^3 ion.[4,5] Hyperfine structure of its single-crystal ESR spectrum has been well-analyzed.[6,7] Recently, the chirality of one of the enantiomers was demonstrated by observing a Pfeiffer effect.[8] The $[NiMo_9O_{32}]^{6-}$ anion, an isomorph of the manganate(IV) polyanion, is diamagnetic and the central Ni(IV) ion is a low-spin d^6 ion.[9] Absorption spectrum of the nickelate(IV) polyanion has been measured by several workers, but discussion is lacking.[4,10,11]

In this paper, absorption and magnetic circular dichroism (MCD) spectra in the UV-vis region of two polyanions in aqueous solution and solid IR spectra are presented. Visible absorption of the nickelate(IV) polyanion is interpreted to be mainly governed by charge-transfer transition of the "ligand" to Ni(IV) ion, rather than by d–d transitions, while that of the manganate(IV) polyanion is governed by d–d transitions to a great extent. Absorption and MCD spectra in the UV region are due to an intra-ligand charge-transfer, which is less influenced by the kind of heteroatom. The MCD pattern is especially characteristic of the Waugh-structure of polyanions and it may be usable as a tool for structural classification of other polyanions.

EXPERIMENTAL

Electronic absorption spectra were measured by a Hitachi 340–spectrophotometer with an attached computer-key board. The intensity is ex-

*Author to whom correspondence should be addressed.

pressed in terms of the molar absorptivity ϵ which has the units of $mol^{-1}dm^3cm^{-1}$. MCD spectra were recorded by a JASCO J-40AS spectropolarimeter mounted with 10.0 kG electromagnet. The MCD intensity is expressed in terms of $\Delta\epsilon = \epsilon_l - \epsilon_r$, which has the units of $mol^{-1}dm^3m^{-1}G^{-1}$. IR spectra were recorded with a JASCO IR-G spectrophotometer. Measurements were made at room temperature.

The enneamolybdo-manganate(IV) and -nickelate(IV) compounds were prepared by the method of Baker and Weakley.[4] The orange–red (Mn) and red–black (Ni) crystals were recrystallized three times from hot water at pH 3–4. These compounds were soluble only in water. Found: H, 2.11; N, 5.05. Calc. for $(NH_4)_6[MnMo_9O_{32}]\cdot 6H_2O$: H, 2.20; N, 5.10%. Found: H, 2.05; N, 4.90. Calc. for $(NH_4)_6[NiMo_9O_{32}]\cdot 6H_2O$: H, 2.20; N, 5.09%. Green–blue hexamolybdocobaltate(III) compound, one of the Anderson-structure heteropolyanions, was prepared according to the Hall's method,[1] in order to compare with a spectrum of the enneamolybdonickelate(IV) polyanion. Found: H, 2.23; N, 3.35. Calc. for $(NH_4)_3[CoMo_6O_{24}H_6]\cdot 7H_2O$: H, 2.68; N, 3.49%.

RESULTS AND DISCUSSION

Visible absorption and MCD spectra. The spectra of $[NiMo_9O_{32}]^{6-}$ ion, measured in aqueous solution, are shown in Fig. 1. There are three precedents for electronic absorption of this anion, but an assignment of bands and an origin of transitions have not been discussed.[4,10,11] The absorption spectrum shows two broad bands at 17.7×10^3 cm^{-1} (ϵ 762) and 25–27 $\times 10^3$ cm^{-1} (ϵ 2300–2600) and the MCD spectrum shows apparent A-term shapes near the absorption positions. The Ni(IV) ion in the polyanion has a low-spin d^6 electronic configuration, but the spectral features are remarkably different from those of usual d^6 Co(III) complexes such as $[Co(en)_3]^{3+}$ and $[Co(NH_3)_6]^{3+}$ ions.[12] As an appropriate reference to an octahedral d^6 ion under similar oxomolybdate environments, the absorption and MCD spectra of $[Co^{III}Mo_6O_{24}H_6]^{3-}$ ion were also measured in aqueous solution (Fig. 2). This anion has the so-called Anderson structure; the Co(III) as a heteroatom is located in an octahedral cavity of a crown of six MoO_6 octahedra formed by edge-sharing and the "ligand" Mo_6O_{24} is protonated. Two absorption bands at 16.56×10^3 cm^{-1} (ϵ 18.0) and 24.21×10^3 cm^{-1} (ϵ 18.0) are due to the first and the second spin-allowed d–d transitions of a low-spin d^6 ion, respectively, and both MCD bands at 16.39×10^3 cm^{-1} ($\Delta\epsilon = -1.74 \times 10^{-3}$) and 23.26×10^3 cm^{-1} ($\Delta\epsilon = -1.89 \times 10^{-3}$) are observed as B-term shape. These spectra are a typical feature of many low-spin Co(III) complexes. The $|\Delta\epsilon_{max}|/\epsilon_{max}$ values for the two transitions are both 1×10^{-4}.

The $[NiMo_9O_{32}]^{6-}$ ion is isomorphous with $[MnMo_9O_{32}]^{6-}$, the site symmetry of a MnO_6 octahedron being confirmed as D_3.[2] The symmetry of a NiO_6 octahedron is probably lower than that of CoO_6 moiety in the hexamolybdopolyanion (D_{3d}).[13,14] This may lead to, more or less, the increasing absorbances of the nickelate(IV) poly-

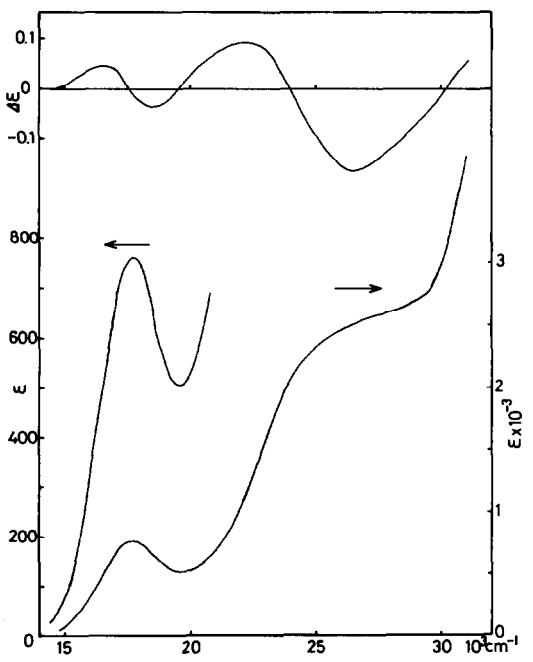

Fig. 1. Electronic absorption and MCD spectra in vis region of $(NH_4)_6[NiMo_9O_{32}]\cdot 6H_2O$ in aqueous solution.

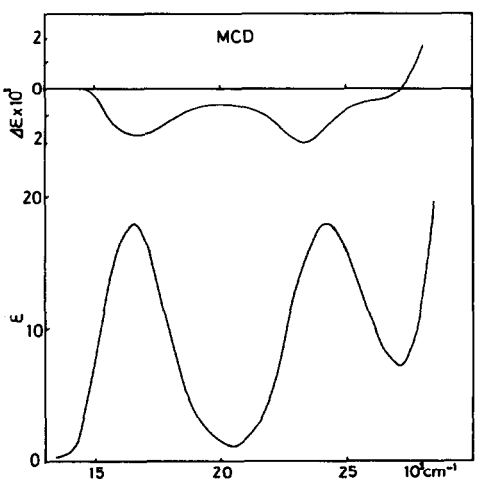

Fig. 2. Electronic absorption and MCD spectra in vis region of $(NH_4)_3[CoMo_6O_{24}H_6]\cdot 7H_2O$ in aqueous solution.

anion. Nevertheless, the $|\Delta\epsilon_{max}|/\epsilon_{max}$ values for observed A-term shapes have the values with the same order ($\sim 10^{-4}$) as those of the Co(III) hexamolybdopolyanion. This is caused by the fact that the MCD intensity also increases correspondingly with the increased absorption. Moreover, the MCD band observed in the first *d–d* transition band region of many low-spin Co(III) complexes is generally B-term with a negative sign, in which the A-term is swamped, although an A-term shape in the second *d–d* band region is sometimes observed in the Co(III) oxalato complexes.[15] Thus, it is conclusively suggested that the intense absorption and the observed A-term shape MCD of the nickelate(IV) are governed by some transitions other than *d–d* transitions.

In the nickelate(IV), in order to stabilize the unusual oxidation state of central Ni(IV) ion with the "ligand", the strong interaction between Ni(IV) ion and the ligand should be taken into account. Thus, the charge-transfer transitions of the Mo_9O_{32} to Ni(IV) may be plausibly assigned to the observed bands. This type of transition (ligand to heteroatom) has been observed in other polyanions; at 27×10^3 cm^{-1} ($\epsilon \sim 1000$) in $[Co^{III}{}_2Mo_{10}O_{38}H_4]^{6-}$ anion[16] and at 25×10^3 cm^{-1} (ϵ 1180) in $[Co^{III}W_{12}O_{40}]^{5-}$ anion,[17] in which those MCD appear as B-term shapes with positive sign. For octahedral Ni(IV) complexes with N-coordinating ligand, it has been well-established that two intense absorption bands in the visible region can be assigned as ligand-to-metal charge-transfer transitions.[18,19]

The lower frequency absorption band in the visible region implies, to a small extent, the *d–d* transition character. The higher frequency absorption band may be superimposed by the tail of the intra-ligand charge-transfer, which is observed in the UV region.

The spectral form of the $[MnMo_9O_{32}]^{6-}$ ion in aqueous solution has been known to depend markedly on the pH.[4] The absorption and MCD spectra of the polyanion, measured in the aqueous solution of pH 4.3, are shown in Fig. 3. The Mn(IV) ion is isoelectronic with Cr(III) ion of d^3. The spin-forbidden transitions ($^2E, {}^2T_{1g} \leftarrow {}^4A_{2g}$) at 14.4×10^3 cm^{-1} (ϵ 3) and near 15×10^3 cm^{-1}, and the first spin-allowed transition ($^4T_{2g} \leftarrow {}^4A_{2g}$) near 20×10^3 cm^{-1} are seen. Schatz *et al.* have suggested that the MCD can greatly aid in the detection of assignment of spin-forbidden Cr(III) transition.[12] This is also the case for the spin-forbidden transitions of the manganate(IV) polyanion. In fact, the MCD in the region of ca 15×10^3 cm^{-1} is relatively large in comparison with the intensity of absorption, i.e.

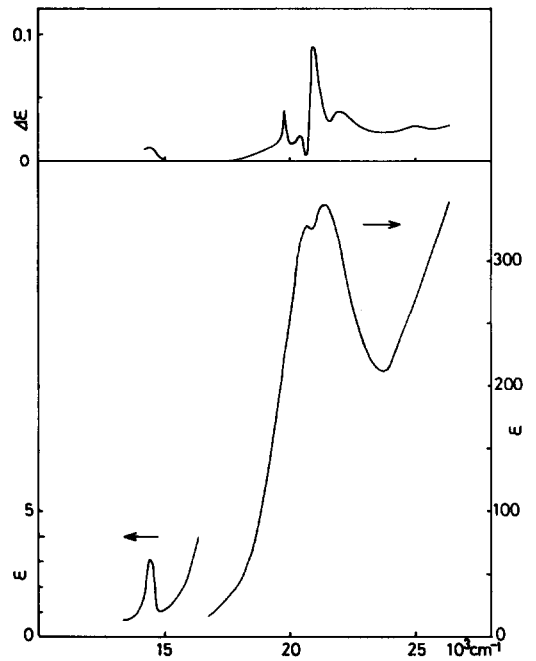

Fig. 3. Electronic absorption and MCD spectra in vis region of $(NH_4)_6[MnMo_9O_{32}] \cdot 6H_2O$ in aqueous solution.

$|\Delta\epsilon_{max}|/\epsilon_{max} = 4 \times 10^{-3}$. The absorbance of the first spin-allowed transition is more intense than those of common Cr(III) complexes,[12] and therefore possibly contain, to some extent, the charge-transfer transition of the ligand to Mn(IV) ion. The second spin-allowed transition ($^4T_{1g}(F) \leftarrow {}^4A_{2g}$) near 25×10^3 cm^{-1} is masked by the steeply-increasing absorbance in the UV region. However, this band is explicitly shown by a small and broad band with positive sign in the MCD spectrum.

A splitting of the first transition (20.7×10^3 and 21.4×10^3 cm^{-1}, ϵ 329 and 346, respectively) has been due to a trigonal distortion of the MnO_6 octahedron, that is, due to a splitting of $^4T_{2g}$ term in D_3 symmetry.[4,5] However, another possibility can be also considered. For example, Pope *et al.* have suggested that one of the components of the split band may be due the superposition of a spin-forbidden band ($^2T_{2g}$) on the main absorption.[20] Two possible assignments are distinguishable by the MCD spectrum. In the trigonal complexes such as $[Cr(ox)_3]^{3-}$ and $[Cr(en)_3]^{3+}$, an apparent A-term shape of MCD in the first transition region has been usually observed. It has been attributed to a superposition of B-terms of opposite sign, belonging to $^4E_a \leftarrow {}^4A_2$ and $^4A_1 \leftarrow {}^4A_2$.[12] However, in this manganate(IV) polyanion, the MCD in the first transition region shows many components with positive sign. Furthermore, a sharp and unique MCD band is observed at 19.8×10^3 cm^{-1}, which may be due to the spin-forbidden transition ($^2T_{2g} \leftarrow {}^4A_{2g}$).

Such a transition in the first *d–d* transition region has been also suggested by Jørgensen.[21] These suggest that the observed splitting arises from a contribution of the $^2T_{2g}$ state, rather than from a trigonal splitting of the $^4T_{2g}$ state.

UV absorption and MCD spectra. The UV absorption and MCD spectra of two polyanions are shown in Fig. 4. Absorptions at 41.7×10^3 cm^{-1} (ϵ 44500) in the nickelate(IV) and at $41.7 \times 10^3\,cm^{-1}$ (ϵ 45700) in the manganate(IV), are due to the charge-transfer within the common ligand. These bands are more shifted to high frequency region in comparison with those of Co(III) hexamolybdopolyanion ($31–32.5 \times 10^3$ cm^{-1} shoulder) and of Keggin structure polyanions (X = P, 32.6×10^3 cm^{-1}, ϵ 23900; X = Si, 33.3×10^3 cm^{-1}, ϵ 21000; for the tetrabutylammonium salts in acetonitrile).

The MCD of the intra-ligand charge-transfer is less influenced by the heteroatom. It should be noted that the MCD spectral pattern is characteristic of the Waugh-structure of polyanions and can be distinguished from those of other types of polyanions such as Keggin- and Anderson-types. The MCD in the UV region of Anderson-structure Co(III) polyanion is shown in Fig. 5 and those of Keggin-structure dodecatungsto- and dodecamolybdo-polyanions have been previously reported.[22] In the chemistry of polyanions, the MCD of intra-ligand charge-transfer may be usable as a powerful tool for structural classification.

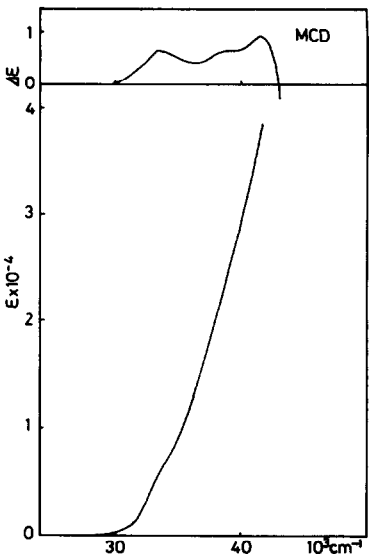

Fig. 5. Electronic absorption and MCD spectra in UV region of $(NH_4)_3[CoMo_6O_{24}H_6] \cdot 7H_2O$ in aqueous solution.

IR spectra. The IR spectra of two enneamolybdopolyanions, measured in KBr disk, are shown in Fig. 6. They are very similar to each other. Characteristic bands of the Waugh-structure unit are presented in the range of 1000–400 cm^{-1}. The spectrum consists of two prominent groups of bands; one at higher frequency region (930–830 cm^{-1}) and the other at lower one (720–490 cm^{-1}). Detailed analysis of vibration of these ions has not been performed yet.

Each MoO_6 octahedron in the Mo_9O_{32} unit has two terminal oxygens in the *cis* position and four edge-sharing oxygens, two oxygens of the latter

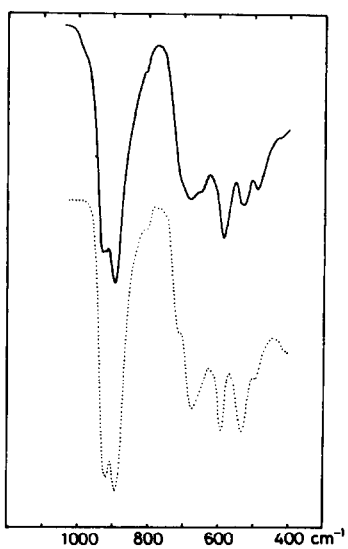

Fig. 6. IR spectra measured in KBr disk of $(NH_4)_6[XMo_9O_{32}] \cdot 6H_2O$; X = Mn (—) and Ni (· · · ·).

being coordinated to the heteroatom. Generally, the Mo-terminal oxygen bond has a double-bond character and its force constant is larger than those of the Mo-bridged oxygen bonds.[23] Moreover, it has been known that the stretchings between Mo atom and terminal oxygen atoms appear at the highest frequency region among all the vibrations of the intra-MoO_6 and the inter-MoO_6.[24] If this is the case, the band group of 930–830 cm^{-1} may be tentatively assigned as Mo-terminal oxygen stretchings.

METAL COMPLEXES OF SOME ASYMMETRIC DIAMINODIAMIDE LIGANDS—III[1,2]

RATES OF CONVERSION FROM OCTAHEDRAL TO SQUARE PLANAR COMPLEXES OF Ni(II)

MARIEL M. MUIR,* JOSE A. DIAZ,[3] LOURDES M. TORRES, and PORFIRIO NAZARIO
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

(*Received* 17 *January* 1984; *accepted* 16 *April* 1984)

Abstract—Dissociation of the two amide protons from complexes of asymmetric diaminodiamides with Ni(II) in aqueous solution occurs under moderately basic conditions. The loss of the protons is accompanied by a conversion of the complex from octahedral to square planar. The rates of conversion for complexes NiL^{2+} were measured spectrophotometrically and were found to depend linearly on $[OH^-]$. The diaminodiamide ligands used were S, R, S- and S, S, S-N, N′-dialanylpropylenediamine (DAPN), S, S-N, N′-dialanylethylenediamine (DAEN), R-N, N′-diglycylpropylenediamine (DGPN), and N, N′-diglycylethylenediamine (DGEN). The rates varied in the order SS-DAEN > DGEN > SRS-DAPN > R-DGPN ≈ SSS-DAPN.

The dissociation of amide protons at acidic or neutral pH in metal complexes of peptides or other amides is well known.[2,4–13] The previous paper in this series[1] reported the equilibria in aqueous solution between Ni(II) and a series of asymmetric diaminodiamides of general formula H_2N–C*HR–CO–NH–C*HR′–CH_2–NH–CO–C*HR–NH_2. The ligands used were: *S*, *R*, *S*- and *S*, *S*, *S*-*N*, *N*′-dialanylpropylenediamine (DAPN, R = R′ = CH_3), *S*, *S*-dialanylethylenediamine (DAEN), R = CH_3, R′ = H), *R*-N, N′-diglycylpropylenediamine (DGPN, R = H, R′ = CH_3), and N, N′-diglycylethylenediamine (DGEN, R = R′ = H). The absolute configuration at each asymmetric carbon is indicated by *S* or *R*. DAPN has three asymmetric carbon atoms, each marked in the general formula. In DAEN only the outer two and in DGPN the centre one of the marked carbon atoms are asymmetric. The N, N′ indicates bonding of the two alanyl or glycyl groups to different nitrogen atoms of the central diamine moiety.) The equilibrium constants were determined for the formation of the octahedral complexes NiL^{2+} and NiL_2^{2+} and for deprotonation and conversion to the square planar $NiH_{-2}L$.[1,13]

$$Ni^{2+} + L \overset{K_1}{\rightleftharpoons} NiL^{2+} \quad (1)$$

$$NiL^{2+} + L \overset{K_2}{\rightleftharpoons} NiL_2^{2+} \quad (2)$$

$$NiL^{2+} \overset{K_{1AB}}{\rightleftharpoons} NiH_{-2}L + 2H^+. \quad (3)$$

The values of the equilibrium constants showed a significant degree of stereoselectivity for these complexes, especially for the processes corresponding to K_2 and K_{1AB}.[1] This was attributed to steric effects, which seemed greatest for K_{1AB}, the constant for the amide deprotonation and octahedral – square planar conversion. To further analyze these steric effects and to try to determine the probable structure for the octahedral complex NiL^{2+}, it was of interest to study the rates of the conversion for the same series of ligands used for the equilibrium studies.[1] The rates for the system DGEN – Ni(II) have been reported.[14] The conversion was slow and dependent on the pH.

RESULTS AND DISCUSSION

The kinetic studies were carried out at constant pH values greater than 8.5 in order to force the reactions to completion. First, the aquonickel(II) complex and the ligand hydrochloride were mixed

*Author to whom correspondence should be addressed.

and the protons on the ligand partly neutralized. Upon adjustment of the pH to a basic value, the formation of the octahedral complex NiL^{2+} was assumed to be very fast compared to the subsequent conversion to the square planar complex. This was consistent with observations of the short time required by the system to reach equilibrium at lower pH values, where the predominant species formed is NiL^{2+}. In general, the rates of formation of octahedral Ni(II) complexes are very fast compared to the slow rates observed in this work.[15]

The reactions were followed at several pH values above 8.5. Linear first-order plots of log $(A - A_\infty)$ as a function of the time were obtained over several half-lives, which also suggests that the above assumption is valid. The value of k_{obs} was a linear function of $[OH^-]$, which is similar to the result reported[14] for the DGEN system. In that study it was suggested that the removal of the first peptide hydrogen is the rate-determining step and that the second peptide hydrogen was released more rapidly.

The intermediate species $NiH_{-1}L^+$ could not be detected in solution and the equilibrium studies[1] confirm that no appreciable concentration of $NiH_{-1}L^+$ builds up during the reaction. Thus, the reaction sequence can be written as:

$$Ni^{2+}(aq) + L \xrightarrow{\text{fast}} NiL^{2+} \quad (4)$$

$$NiL^{2+} + OH^- \xrightarrow{k_2} NiH_{-1}L^+ + H_2O \quad (5)$$

$$NiH_{-1}L^+ + OH^- \xrightarrow{\text{fast}} NiH_{-2}L + H_2O \quad (6)$$

and the rate expression as:

$$\frac{d[NiH_{-2}L]}{dt} = -\frac{d[NiL^{2+}]}{dt} = k_{obs}[NiL^{2+}] = k_2[NiL^{2+}][OH^-] \quad (7)$$

Some average values for k_{obs} are listed in Table 1 and the values of k_2 in Table 2. All rate constants were calculated by a linear least squares routine and the standard deviations reported are the standard deviations in the slopes of the lines. The intercepts of the plots of k_{obs} as a function of $[OH^-]$ were all zero within experimental error, so no hydroxide-free term is included in the rate expression. Data for several runs obtained with a pH-stat are included in Table 1. These agreed well with the data obtained spectrophotometrically using buffers for pH control.

The relative rates are in the order:

SS-DAEN > DGEN > SRS-DAPN > R-DGPN ≈ SSS-DAPN.

For the DGEN system, when the ligand to metal ratio exceeded 1:1, a second term in the rate law was observed and interpreted as due to reaction of the bis complex, NiL_2^{2+}.[14] This could not be observed for the systems with SS-DAEN, SRS-DAPN, or SSS-DAPN, which is consistent with

the lower stability observed for the NiL_2^{2+} complex for those ligands compared to DGEN.[1]

The observed order of reactivity permits an assignment of the probable structure for the octahedral complex NiL^{2+}, which was not possible with only the equilibrium data.[1] Two possible structures have been suggested[14] for the 1:1 octahedral complex, as shown in structures **I** and **II**. The structure

I

II

assignment depends on the choice of the rate-determining step. There are two possibilities for this. One is that the rearrangement of the monoprotonated intermediate to the square planar form is the slow step. This is not consistent, however, with similar conversions for the Ni(II): trien system,[16] which are very fast, nor with the slow rate of formation of $CuH_{-2}L$ for these ligands.[17,18] The more likely possibility, which fits well with the data from this work, is that the slow step is not the conversion of the octahedral to the square planar form but rather the change from carbonyl to amido nitrogen coordination when the proton from the amide bond is lost.

For the terdentate structure **II**, the monoprotonated intermediate from the octahedral complex in the SRS–DAPN:Ni(II) system can have all methyls nearly equatorial, but for the SSS–DAPN:Ni(II) at least one axial methyl group is obtained. Then if deprotonation and change of coordination from oxygen to nitrogen (effectively a substitution reaction) is the slow step, the SSS–DAPN complex would react more slowly than the SRS–DAPN complex, as observed. However, if rearrangement of the octahedral to the square planar form were the rate-determining step, then the rate for the SSS–DAPN complex should be faster, not slower, than the rate for the SRS-complex. Thus, the most reasonable assumption about the mechanism is consistent with the relative rates if the octahedral complex has the terdentate structure **II**. All the ligands in this study had the same skeletal structure, so no variation in ring sizes was observed. Such a variation might be helpful in confirming this assignment.

EXPERIMENTAL SECTION

Materials

The syntheses and characterization of the ligands have been reported,[19] as have the methods[2] for standardization of aqueous solutions of the ligand dihydrochloride salts and of $NiCl_2$.

Analytical grade boric acid and sodium borate decahydrate were used without further purification. Morpholine was distilled with a long fractionating column. Morpholinium chloride was prepared by two methods.

(a) To 43.5 cm^3 of morpholine in a 200 cm^3 round bottom flask in an ice bath was slowly added with stirring 42 cm^3 of 12 M HCl. The mixture was allowed to stand several days in the refrigerator. The product precipitated as long needles.

(b) Dry HCl gas was bubbled through freshly distilled morpholine. A bulky precipitate formed. This was dissolved in a minimal volume of boiling isopropyl alcohol to which a few drops of water were added. On cooling, the product precipitated as long needles. After a second recrystallization, the product was filtered under N_2, washed with diethyl ether, and dried in a vacuum desiccator over P_2O_5.

Trimethylamine hydrochloride was recrystallized by dissolving in boiling ethanol, cooling, adding ether, and cooling in the refrigerator overnight. The precipitate was filtered, washed with ether and dried in a vacuum desiccator over P_2O_5 for several days.

Buffer solutions

Three different types of buffers were used: morpholine–morpholinium chloride, borate–boric acid, and trimethylamine. A typical preparation for each type is given below.

Borate—boric acid buffer. In a 250 cm^3 volumetric flask were placed 0.309 g (0.00500 mol) of boric acid, 4.10 g (0.0489 mol) of sodium borate, and 16.5 g KCl. Water was added to the mark. The final pH was 8.88.

Morpholine—morpholinium chloride buffer. Morpholine (2.17 g, 0.00249 mol) was mixed with 0.59 g (0.00469 mol) of morpholinium chloride and 18.2 g of KCl in a 50 cm^3 volumetric flask. Water was added to the mark. The final pH was 9.05.

Trimethylamine buffer. Trimethylammonium chloride (2.285 g, 0.0239 mol) was partly neutralized by adding 0.1 g (0.0025 mol) of NaOH. To this were added 2.372 g KCl and the volume adjusted to 50 × cm^3 with water. The pH was 9.25.

Kinetic studies

A stock solution of complex was prepared by adding 3.00 cm^3 of an approx. 0.02 M aqueous solution of the ligand dihydrochloride $[H_2L]Cl_2$ to 3.00 cm^3 of 0.0195 M $NiCl_2$ solution, 0.1 M in KCl. The ionic strength of the ligand solution was adjusted with KCl so that the final ionic strength of the reaction mixture of buffer and complex would be 1.0 M. Standard NaOH was added to give a ratio a of base to ligand of nearly 2. The solution was kept in a constant temperature bath at 25.0°C.

A buffer solution (2.70 cm^3) was placed in a quartz 1.00 cm spectrophotometer cell. This was placed in the thermostatted cell compartment of a Hitachi-Perkin Elmer 139 spectrophotometer. The wavelength of the spectrophotometer was set to 415 nm, which is the wavelength of maximum absorbance for the planar complex, the final product, and the spectrophotometer was adjusted for 100% T with buffer solution in the reference cell. When both solutions had reached thermal equilibrium, 0.30 cm^3 of the stock solution of complex was injected with a syringe into the buffer solution in the sample cell. The absorbance was recorded as a function of time until no further change in absorbance could be observed. The pH of the reaction mixture was measured. The change in pH from the initial value for the buffer solution was not more than 0.03 pH units.

(*Received* 4 *October* 1983, *accepted* 16 *April* 1984)

Abstract—The investigation of the inhibitory activity on the Ca,Mg-dependent ATP-ase substrate of some Cu(II) and Ni(II) complexes with polyamines and imidazole derivatives is reported. These results show that the Cu(II) complexes have high inhibitorial effect with the exception of the following very stable compounds: square planar $[Cu(N\text{-}PropIm)_2(NCS)_2]$, distorted octahedral $[Cu(bipy)_2(NCS)_2]$ and five coordinate $[Cu(Me_6tren)(NCS)]$ (SCN). The Ni(II) derivatives present a medium inhibitorial activity except to the stable tetrahedral $[Ni(N\text{-}PropIm)_2(NCS)_2]$, hexacoordinate [Ni(dpt)(tn)(NCS)] (SCN) and fivecoordinate $[Ni(dpt)(tn)]Br_2$ and $[Ni(Me_6tren)(NCS)]$ (SCN). An explanation of these conclusions is reported.

The adenosine triphosphatase (ATP-ase) is an enzyme very significant for the organism. This enzyme is, membrane bonded with outer cell position a convenient model to study different types of complexes, since chloride and other anion concentrations in the intercellular medium are high enough to exclude the hydrolysis of the complexes. The ATPase is extracted from rabbit muscles.[1]

In particular Ca, Mg-dependent ATP-ase has been selected to investigate the factors influencing the biological activity of the coordination compounds, the donor capability and the different hindrance of the coordinated ligand (polyamines and imidazole derivatives) and the structure of the complexes.

Copper (II) and Ni(II) complexes give the possibility of studying the above stereochemical factor.

The inhibitorial effect of the Cu(II) and Ni(II) compounds with polyamines and imidazole derivatives on the Ca, Mg-dependent ATP-ase mash has now been studied to verify the above cited chemical behaviour.

EXPERIMENTAL

All the investigated complexes were prepared and characterized according to the previous papers.[2–8]

*Author to whom correspondence should be addressed.

The extraction method of the sarcoplasmatic reticulum (SR) containing ATP-ase is obtained by the skeletal muscles of a particular type of rabbits selected as a certain line. The inhibitorial activity of the ligands and the complexes with aqueous solution ATP-ase is determinated by the amperometric titration.[9] All the ligands have no inhibitorial activity.

RESULTS AND DISCUSSION

Copper (II) complexes. The thiocyanate compounds $[Cu(den)(NCS)_2]$ and $[Cu(dpt)(NCS)_2]$, $[Cu(Me_6tren)(NCS)](SCN)$, $[Cu(en)_2(SCN)_2]$, $[Cu(bipy)_2(NCS)_2]$, $[Cu(N\text{-}PropIm)_4]Cl_2$, $[Cu(N\text{-}PropIm)_2Cl_2]$, $[Cu(N\text{-}PropIm)_4]Br_2$, $[Cu(N\text{-}PropIm)_2Br_2]$ and $[Cu(N\text{-}PropIm)_2(NCS)_2]$ (where den = diethylentriamine, dpt = 3, 3′-diaminodipropylamine, Me_6tren = tris(2-dimethylaminoethyl)amine, en = ethylenediamine, bipy = α, α'-bipyridine and N-PropIm = N-propylimidazole) have been previously prepared.[2-7] They are generally characterized by magnetic moments, infrared spectra, electronic spectroscopy in solid and in the solution state and molar conductivity values. The polyamine ligands bind through all the nitrogen atoms of the amino groups. The N-PropIm behaves as an monodentate N-bonded ligand. From these experimental data we were able to find the stereochemistry in the solid state of these compounds which are: square pyramidal, trigonal bipyramidal, tetragonally distorted hexacoordinate and tetrahedral.

In Table 1 are reported the complexes, their inhibitorial activity with respect to Ca, Mg-dependent ATP-ase mash and the stereochemistry of the solid compounds.

The stereochemistry of these solid complexes is preserved also in methanol or in aqueous solution as confirmed by the same shape of the reflectance and the absorption spectra and by the conductivity values with the exception of the $[Cu(den)(NCS)_2]$ and $[Cu(dpt)(NCS)_2]$ derivatives. The last complexes, distorted square pyramidal in the solid state, in solution lose one of the two thiocyanate groups in the coordination sphere changing their structure in square planar species.[2]

The high inhibitorial effect of the $[Cu(den)(NCS)_2]$ and $[Cu(dpt)(NCS)_2]$ on the enzyme, 72 and 77% respectively, is due to the introduction in the Cu(II) coordination sphere of two $-S^-$ anions in the apical positions so that the stereochemistry is modified to tetragonally distorted hexacoordinate.

The $[Cu(Me_6tren)(NCS)]$ SCN and $[Cu(bipy)_2(NCS)_2]$, trigonal bipyramidal and tetragonally distorted octahedral respectively in the solid state have low inhibitorial effect, 25–26%, because these structures are particularly stable in solution: this fact is due to a partial substitution of the $-S^-$ anions of the ferment without modification of the stereochemistry.

In the $[Cu(en)_2(SCN)_2]$, tetragonally distorted hexacoordinate, the inhibitorial activity is 83% because the two slightly bonded thiocyanate groups are easily substituted by the donor atoms of the enzyme. In this case the stereochemistry is preserved also in ATP-ase mash.

The inhibitorial effect between 75 and 95% of the complexes $[M(L)_2X_2]$ and $[M(L)_4]X_2$, where L = N-PropIm, X = Cl, Br, tetrahedral in the solid state, can be so explained. The $[Cu(L)_2X_2]$ derivatives replace the halides in the coordination sphere with thiol groups and the structure is rearranged in solution to tetragonally distorted octahedral with other two $-S^-$ anions that are bonded in the apical positions of the complexes. The $[Cu(L)_4X_2]$ compounds are rearranged in ATPase mash and bind two thiol groups in axial positions instead of the halides that before were out of the inner sphere. The stereochemistry, in both case, is modified to tetragonally distorted octahedral. Only in the $[Cu(N\text{-}PropIm)_2(NCS)_2]$, *trans*-square planar in solid state, have we observed that the inhibitorial activity drops to 0%, probably because of the high stability of this compound.

Nickel(II) complexes. We have now extended this study to the Ni(II) complexes $[Ni(dpt)(tn)]Br_2$, $[Ni(dpt)(tn)(NCS)]$ (SCN), $[Ni(Me_6tren)(NCS)]$ (SCN), $[Ni(trien)(en)]Cl_2$, $[Ni(tn)_3](ClO_4)_2$, $[Ni(NEtIm)_6]Cl_2$, $[Ni(N\text{-}PropIm)_6]Cl_2$ and $[Ni(N\text{-}PropIm)_2(NCS)_2]$ (where dpt = 3, 3′-diaminodipropylamine, tn = 1, 3-diaminopropane, Me_6tren = tris(2-dimethylaminoethyl)amine, trien = triethylenetetramine, N-EtIm = N-ethylimidazole and N-PropIm = N-propylimidazole).[6-8]

These derivatives have been previously prepared and characterized by magnetic moments, infrared spectra, electronic spectroscopy in solid and in solution state and molar conductivity values. The polyamine ligands bind through all the nitrogen atoms of the amino groups; the N-EtIm and N-PropIm behave as monodentate N-bonded.

In the Table are reported the complexes, their inhibitorial activity in the ATP-ase mash and their solid stereochemistry.

The structure of these solid complexes is preserved both in methanol and in ATP-ase aqueous solution as confirmed by the same shape of the electronic and absorption spectra and by the conductivity data.

In the solid hexacoordinate $[Ni(dpt)(tn)(NCS)]$ (SCN) the inhibitorial effect is 15% because the

Table 1. Inhibitory activity of the Cu(II) and the Ni(II) complexes

Complex	Inhibitory activity %(±2) $c = 10^{-4}$M	Stereochemistry in the solid state
$[Cu(den)(NCS)_2]$	72	distorted square pyramidal
$[Cu(dpt)(NCS)_2]$	77	distorted square pyramidal
$[Cu(Me_6tren)(NCS)](SCN)$	25	trigonal bipyramidal
$[Cu(en)_2(SCN)_2]$	83	tetragonal distorted octahedral
$[Cu(bipy)_2(SCN)_2]$	26	tetragonal distorted octahedral
$[Cu(N\text{-}PropIm)_4]Cl_2$	75	tetrahedral
$[Cu(N\text{-}PropIm)_2Cl_2]$	87	distorted tetrahedral
$[Cu(N\text{-}PropIm)_4]Br_2$	83	tetrahedral
$[Cu(N\text{-}PropIm)_2Br_2]$	95	distorted tetrahedral
$[Cu(N\text{-}PropIm)_2(NCS)_2]$	0	trans square planar
$[Ni(dpt)(tn)(NCS)](SCN)$	15	distorted octahedral
$[Ni(dpt)(tn)]Br_2$	0	square pyramidal
$[Ni(N\text{-}PropIm)_2(NCS)_2]$	0	distorted tetrahedral
$[Ni(N\text{-}PropIm)_6]Cl_2$	29	octahedral
$[Ni(N\text{-}EtIm)_6]Cl_2$	43	octahedral
$[Ni(trien)(en)]Cl_2$	51	octahedral
$[Ni(tn)_3](ClO_4)_2$	25	octahedral
$[Ni(Me_6tren)(NCS)](SCN)$	25	trigonal bipyramidal

NCS group, weaker than a nitrogen atom of the polyamine, is partially displaced by the $-S^-$ anion of the enzyme.

The [Ni(dpt)(tn)] Br_2, square pyramidal in solid state, has no inhibitorial effect: this fact is due to the bonds being very strong and shorter than those of the preceding hexacoordinate derivative and so it is difficult to substitute the positions of the chelating polyamines with thiol groups of the enzyme.

For the solid octahedral complexes $[Ni(L)_6]$ Cl_2, where L = N-PropIm and N-EtIm, the inhibitorial activity is 29% and 43% respectively because the N-PropIm is more basic than the N-EtIm and N-PropIm can be more difficultly substituted by the $-S^-$ anions of the ATP-ase.

The increase of the inhibitorial effect of these complexes with respect to the nickel polyamine derivatives is due to a lower coordinating strength of the alkyl-imidazole in comparison with the chelating ligands.

In the solid octahedral [Ni(trien)(en)] Cl_2 the high value of 51% is due to the easy substitution on the inner sphere by thiol groups of the enzyme with respect to the pentacoordinate [Ni(dpt)(tn)] Br_2.

The solid octahedral $[Ni(tn)_3]$ $(ClO_4)_2$ has an inhibitorial effect of 25% in ATP-ase mash, a value higher than that of [Ni(dpt)(tn)(NCS)] (SCN) because the $-S^-$ anions of the enzyme can be easily substituted in the perchlorate derivative: the chelate effect of the dpt is stronger than the tn ligand.

The [Ni(Me_6tren)(NCS)] (SCN) presents a value of 25% as the [Cu(Me_6tren)(NCS)] (SCN) because in these very stable trigonal bipyramidal deriva-

tives only a partial substitution of the coordinated thiocyanate occurs with the thiol group of the ATP-ase.

Finally in the tetrahedral $[Ni(N\text{-}PropIm)_2(NCS)_2]$ the inhibitorial activity is 0%, as the analogous square planar Cu(II) derivative, because of the high strength of the bonds in these complexes.

It is important to note that in all the Ni(II) derivatives the stereochemistry did not change from the solid state to the ATP-ase mash.

CONCLUSIONS

As far as the inhibitory mechanism the interaction of the complexes in aqueous solution ATP-ase occurs with the sulphur anion(s) of the thiolate groups of the enzyme.

In the $M(L)_nX_2$ (where M = Pd(II), Pt(II), L = isoxazole, benzoxazole and imidazole derivatives; $n = 2$–4; X = Cl, Br, I)[10] and $Pd(ox)(L)_n$ (where ox = oxalate; L = precedent heterocyclic ligands; n = 1,2)[11] the replacement of the $-S^-$ anions of the ATP-ase produces square planar species without modification of the solid stereochemistry.

In the Cu(II) complexes the stereochemistry is generally modified from the solid state to the ATP-ase mash because the $-S^-$ anions replace the counteranions and/or another possible coordination site, while in the nickel derivatives the solid structure is preserved also in the solution ferment.

We can conclude that the inhibitorial activity depends for the Cu(II) and Ni(II) complexes very strongly on the stereochemical factor resulting from the type and the steric hindrance of the coordinate ligands.

STEREOCHEMICAL VERSATILITY OF Cu(II): Cu(II) COMPLEXES OF BENZYL METHYL KETONE SEMICARBAZONE

ANIL JAGGI, SULEKH CHANDRA and K. K. SHARMA*
Department of Chemistry, Zakir Husain College, Ajmeri Gate, Delhi 110006, India

(*Received* 4 *January* 1984; *accepted* 16 *April* 1984)

Abstract—Copper(II) complexes of the general composition Cu(ligand)$_2$X$_2$ (where X = Cl, Br, NO_3, ClO_4 and $\frac{1}{2}SO_4$) and Cu(ligand)$(CH_3COO)_2$ have been synthesised with benzymethylketonesemicarbazone. All the complexes prepared have been characterised by elemental analysis, magnetic moment, conductance, IR, electronic and electron spin resonance spectral studies. The complexes Cu(ligand)$_2$X$_2$ (X = Cl, Br, NO_3) and Cu(ligand)$(CH_3COO)_2$ may have tetragonal symmetry while the Cu(ligand)$_2$X$_2$ (ClO_4 and $\frac{1}{2}SO_4$) may be five-coordinate trigonal bipyramidal in structure.

Cambell *et al.*[1,2] have reported the electronic spectra and the esr spectra of Cu(II) complexes of the type Cu(ligand)$_2$X$_2$ where X = Cl, Br and the ligands are the semicarbazones of cyclopentanone methylisopropylketone and diacetylketone. Their results show that the stereochemistry of these complexes changes from six-coordinate tetragonal to five coordinate trigonal bipyramidal, as the alkyl group on the ketone becomes bulky. In the present studies we report the synthesis and stereochemistry of Cu(II) complexes of benzylmethyl ketonesemicarbazone. Our results show that the stereochemistry of these complexes also depends on the coordinated anions, i.e. with chloride, bromide, nitrate and acetate, the complexes have six-coordinate tetragonal geometry but perchlorate and sulphate impart pentacoordinate geometry.

EXPERIMENTAL

(a) *Preparation of semicarbazone*

The semicarbazone of the ketone was prepared as described in the literature.[2,3]

(b) *Preparation of complexes*

The complexes were prepared by mixing the hot aqueous solution of the hydrated Cu(II) salts and the benzylmethyl ketonesemicarbazone in the molar ratio 1:2. On cooling the solution a crystalline complex precipitated out in each case. In all the cases good analytical results were obtained for CuL_2X_2 (X = Cl, Br, NO_3, ClO_4 and $\frac{1}{2}SO_4$) and $CuL(CH_3COO)_2$ see Table 1. The chloro, bromo and nitrate complexes are soluble in water, ethanol and methanol, while the acetate, sulphate and perchlorate complexes are poorly soluble in water as well as common organic solvents.

Physical measurements

The magnetic susceptibilities were measured (at 298 K) on a Gouy balance, using Hg[Co(CNS)$_4$] as the calibrating agent. Infrared spectra of the complexes were recorded on Perkin–Elmer 621 automatic recording spectrophotometer, the KBr medium. Electronic spectra of the complexes were recorded on DMR-21 automatic recording spectrophotometer in Nujol mull. The esr spectra of the polycrystalline samples of the complexes were recorded on a Varian E4–ESR spectrometer operating at ~9.4 GHz and 100 KHz with field modulation and phase-sensitive detection.

Carbon and hydrogen analyses were performed in the microanalytical laboratory. The nitrogen contents of the complexes were determined using Kjeldahl's method. The copper in the complexes was estimated gravimetrically by precipitation as CuCNS.

RESULTS AND DISCUSSION

The composition of the complexes are given in Table 1. With the exception of Cu(ligand)-$(CH_3COO)_2$ all the other complexes have the gen-

*Author to whom correspondence should be addressed.

eral composition $Cu(ligand)_2X_2$ where X = Cl, Br, NO_3, ClO_4 and $\frac{1}{2}SO_4$. Similarly all the complexes exhibit normal magnetic moments corresponding to one unpaired electron (1.88–2.0 BM) the only exception being $Cu(ligand)(CH_3COO)_2$ which shows a subnormal magnetic moment (1.54 BM). The low solubility value and low magnetic moment of $Cu(ligand)(CH_3COO)_2$ indicate a polymeric structure for the complex.

The infrared bands for the ligand and complexes and their possible assignments are presented in Table 2. The IR spectrum of the ligand exhibits characteristic bands for νC–H, νN–H, νC=O and δNH and νC=N. A broad band at 3580 cm^{-1} in the ligand may be assigned to non-bonded νN–H and a series of bands in the range 3000–3400 cm^{-1} may be assigned to bonded νN–H and νC–H modes. A band at 1740 cm^{-1} is characteristic of carbonyl group absorption whereas the bands at 1580 and 1470 cm^{-1} are assignable to νC=N and amide I coupled with each other. A strong band at 1430 cm^{-1} is mainly due to (νC–N + δNH) and is known as amide II band due to secondary amine. Fraser and Price[6] suggested that this may be due to out-of-phase combination of O–C–N and N–H vibrational modes. However, the corresponding in-phase mode primarily due to C–N stretching is the strong band at 1295 cm^{-1} and is so called amide III which in fact is a combination of (νC–N + δNH_2). Thus in the region ranging from 1150–100 cm^{-1}, there are three bands at 1130 and 1000 cm^{-1} assignable to δNH_2. A strong band at 920 cm^{-1} is due to δ(O=C–N) and a group of bands at 775 and 690 cm^{-1} are assigned to π(O=C–N_2) as suggested by Campbell *et al.*[7] The spectra of the complexes reported here contain most of these bands and also the band corresponding to the anions. The characteristic band in the ligand, at 1740 cm^{-1} due to νC=O group is shifted towards lower frequency by ~ 40 cm^{-1}. The amide II band which appears at 1430 cm^{-1} in the ligand, is also shifted towards lower frequency in the complexes. These observations suggest a possibility of coordination through C=O oxygen. A strong band at 1580 cm^{-1} in the ligand apparently has a large contribution from νC=N. Further a coordination[8] through O increases the double bond character of the CN bond. It has been observed that this band is shifted towards higher frequency side in the complexes. On the basis of above observations we propose that the ligand behaves as bidentate coordinated through oxygen of the carbonyl group and nitrogen of the hydrazinic residue.

$Cu(ligand)_2X_2$ (X = Cl, Br, NO_3)

The $Cu(ligand)_2X_2$ (X = Cl, Br, NO_3) complexes may be considered to have a tetragonal structure, with planar arrangement of the ligand molecule around the Cu(II), and the anions occupying the axial position.

w = weak, s = strong, m = medium; * L = Benzylmethylketonesemicarbazone

complexes have either D_{4h} or C_{4v} symmetry, and the E_g and T_{2g} levels of the ^2D free-ion term will split into B_{1g}, A_{1g} and B_{2g}, E_g levels respectively. Thus three spin allowed transitions are expected in the visible and near-IR region, but only a few complexes are known, in which such bands are resolved either by Gaussian analysis or single crystal polarization studies.[9] These bands have been assigned due to the $^2B_{1g} \rightarrow {}^2A_{1g}$ $(d_{x^2-y^2} \rightarrow d_{z^2})$, $^2B_{1g} \rightarrow {}^2B_{2g}$ $(d_{x^2-y^2} \rightarrow d_{xy})$ and $^2B_{1g} \rightarrow {}^2E_g$ $(d_{x^2-y^2} \rightarrow d_{xz}, d_{yz})$ transitions in order of increasing energy. The energy level sequence will depend on the amount of tetragonal distortion due to the ligand field and the Jahn–Teller effect.[10] The electronic spectra of the complexes reported here show only a broad absorption ranging 13,800–14,800 cm^{-1} and a well defined shoulder at 16,300–16,600 cm^{-1} (Table 3). This may be assigned to the $^2B_{1g} \rightarrow {}^2A_{1g}$ and $^2B_{1g} \rightarrow {}^2B_{2g}$ is usually not observed as a separate band in tetragonal field.[11] The splitting of the ^2E_g state is a measure of the in-plane and the axial field. Since the in-plane field is approximately constant in the present complexes, the change of the position of the bands would be mainly due to the axial field. In the complexes reported here the $^2B_{1g} \rightarrow {}^2A_{1g}$ transition is shifted to higher energy, the order being Cl < Br < NO_3.

All the complexes show isotropic esr spectra characteristic of tetragonal Cu(II) complexes. g_0-values are given in Table 4. The anisotropic g-values have been calculated using the following expressions,[13-15]

$$g_{\parallel} = 2 - \frac{8\lambda}{\Delta E_2}, \quad \text{and} \quad g_{\perp} = 2 - \frac{2\lambda}{\Delta E_3}$$

where

$$\lambda = 823\ cm^{-1} \quad \text{and} \quad \Delta E_2 = {}^2B_{1g} \rightarrow {}^2B_{2g},$$

and

$\Delta E_3 = {}^2B_{1g} \rightarrow {}^2E_g$ excitation energies respectively.

The stronger interaction along the z axis is to be accompanied by an increase in the value of $g_{\parallel}$. The stronger axial bonding however, leads to an increase in the length of bond in the xy plane, which results in a decrease of both in-plane covalency and the energy of $d_{x^2-y^2} \rightarrow d_{xy}$ transition.[16] Both these factors tend to increase the value of $g_{\parallel}$. The $g_{\parallel}$-values for the complexes studied follow the order, $Cu(ligand)_2(NO_3)_2 > Cu(ligand)_2Cl_2 > Cu(ligand)_2Br_2$. This appears to be the order of the

strength of metal–anion interactions for nitrate, chloride and bromide. Our results are in agreement with the respective position of the anions as given in the spectrochemical series.[11]

In axial symmetry the g-values are related by the expression,[10] $G = (g_\parallel - 2)/(g_\perp - 2)$, which measures the exchange interaction between copper centres in the polycrystalline solid. According to Hathaway,[17–20] if the value of G is greater than four, the exchange interaction is negligible, whereas when the value of G is less than four, a considerable exchange interaction is indicated in the solid complex. The calculated G values are given in Table 4. The G values in these complexes are greater than four suggesting that there are no interactions between the copper centres in solid. The following structure may be suggested for the complexes.

Fig. 1.

Cu(ligand) $(CH_3COO)_2$

As discussed earlier this complex is insoluble in water as well as in common organic solvents and shows a subnormal magnetic moment (1.54 BM). These observations suggest a polymeric structure for this complex. The $\nu_a(COO^-)$ and $\nu_s(COO^-)$ of acetate ion[16] are observed at 1560 and 1416 cm^{-1} respectively. The separation between the two ν(C–O) is much larger in unidentate complexes than in the free ion.[16] In the case of bidentate complexes, the separation between the two frequencies is smaller than in the free ion values and in the bridging complex. In this complex, the $\nu_a(COO^-)$ and $\nu_s(COO^-)$ are obtained at 1555 and 1420 cm^{-1}, respectively.

The electronic spectrum of this complex see Table 2, exhibits bands corresponding to the tetragonal geometry. The esr spectrum of this complex is much different than for the chloro bromo an nitrate complexes. $g_\parallel$ and $g\perp$ values for the complex are much greater than for the chloro, bromo and nitrate complexes. This difference may be attributed to the polymeric nature of the complex. g-values of the same order have already been reported for dimeric Cu(II) acetate.[20b] The G value has been found in the complex to be less than four (1.797) which suggests exchange interaction between the copper centres in the solid state.

Cu(ligand)$_2$$(ClO_4)_2$ and Cu(ligand)$_2$$(SO_4)$

The infrared spectra of these complexes exhibit bands corresponding to the unidentate behaviour of the perchlorate and sulphate group[21] and a five-coordinated structure can be suggested for these complexes. There are two basic configurations[22] that can be adopted—trigonal bipyramidal (TBP) and square pyramidal (SP). In practice, there appears to be very little difference in energy,[23] between the two configurations.

The two configurations SP and TBP are characterized by the ground state $d_{x^2-y^2}$ and d_z^2 respectively.[24,25] The esr spectra of Cu(II) complexes provide a very good basis for distinguishing between these two ground states. For systems with $g_3 > g_2 > g_1$ the ratio[26] of $(g_2 - g_1)/(g_3 - g_2)$ (hereafter called parameter R) is a very useful parameter for this purpose. If the ground state is predominantly d_z^2 the value of R is greater than one. On the other hand for the ground state predominantly $d_{x^2-y^2}$ the value of R is less than one. The complexes under study show the value of R is greater than one (Table 4) indicating d_z^2 as the ground state. Thus these complexes may be five-coordinate trigonal bipyramidal.

The electronic spectra of these complexes exhibit a single absorption band at 12,000 cm^{-1} (see Table 3) which may be assigned to $^2A_1 \rightarrow {}^2E''$ transition. These are similar to earlier reported trigonal bipyramidal Cu(II) complexes.[4]

(*Received* 5 *September* 1983; *accepted after revision* 16 *April* 1984)

Abstract—Distorted tetrahedral symmetry of cobalt in cinchoninium tetrachlorocobaltate(II) ($C_{19}H_{24}ON_2[CoCl_4].2H_2O$) has been postulated on the basis of reflectance spectra, magnetic moment measurements and ESR spectra. The covalent character of the metal–ligand bonds was inferred from the reflectance spectra. The presence of magnetic dipolar interactions was inferred from the ESR spectra.

The cinchonine dihydrochloride ($C_{19}H_{22}ON_2.2HCl$) forms crystalline compounds with tetrachloro-complexes of Co(II), Cu(II), Zn(II), Cd(II) and Hg(II) of the general formula: $C_{19}H_{24}ON_2[MCl_4].2H_2O$ (where M—metal ion).[1] The IR spectra have shown the existence of interactions between the central ion and the two atoms of cinchonine molecule: oxygen atom in the hydroxyl group at the carbon atom joining the quinoline ring to quinuclidine one and nitrogen atom in the quinuclidine group.[1]

The crystallographic investigations pointed out that the complexes of Co(II), Zn(II), Cd(II) and Hg(II) are isomorphous.[2] The crystal structure of the complex of cadmium was solved by Oleksyn *et al.*[3] According to these authors the orthorhombic unit cell contains tetrachlorocadmate anion, cinchoninium cation and two water molecules. The authors observed some deviations from the ideal tetrahedral coordination at the central atom connected with the fact that two of the four chloride ions are involved in hydrogen bonds.

The aim of the present work was to obtain more precise information concerning distortion of the coordination tetrahedron and the type of interactions between ligands and central ion. From isomorphous series of the complexes the cinchoninium tetrachlorocobaltate(II) was chosen as an object of magnetic and optical investigations.

*Author to whom correspondence should be addressed.

EXPERIMENTAL

The polycrystalline cinchoninium tetrachlorocobaltate(II) was prepared as described in Ref. 1. The Co(II)-complex diluted with isostructural Zn-complex was obtained by evaporation of the water solution of both complexes mixed in the appropriate ratio.

Reflectance spectra were recorded with a Beckman DK 2A spectrophotometer in the range of 200–2500 nm with $BaSO_4$ as a standard. Magnetic susceptibility measurements were performed in the temperature range 4–350 K using a Faraday balance. ESR spectra were recorded at 4 K and at 77 K using an ESR spectrometer (constructed at the Technical University, Wrocław, Poland) operating in X-band with modulation frequency 100 kHz.

RESULTS AND DISCUSSION

In the reflectance spectrum of the cinchoninium tetrachlorocobaltate(II) the bands appear at 5410 cm^{-1} (ν_2) and at 15015 cm^{-1} (ν_3) (taken at the centre of the bands) (Fig. 1)—assigned to the transitions: $^4A_2 \rightarrow {}^4T_1(F)$ and $^4A_2 \rightarrow {}^4T_1(P)$, respectively—which indicates the tetrahedral coordination of Co(II).[4] The values of crystal field parameter $\Delta_{tetra} = \nu_1[^4A_2 \rightarrow {}^4T_2(F)]$ and Racah parameter B′ were estimated using the relations derived by Cotton and Goodgame.[5] The value of crystal field splitting Δ_{tetra} is equal to 3090 cm^{-1}. The Racah parameter B′ has a value of about

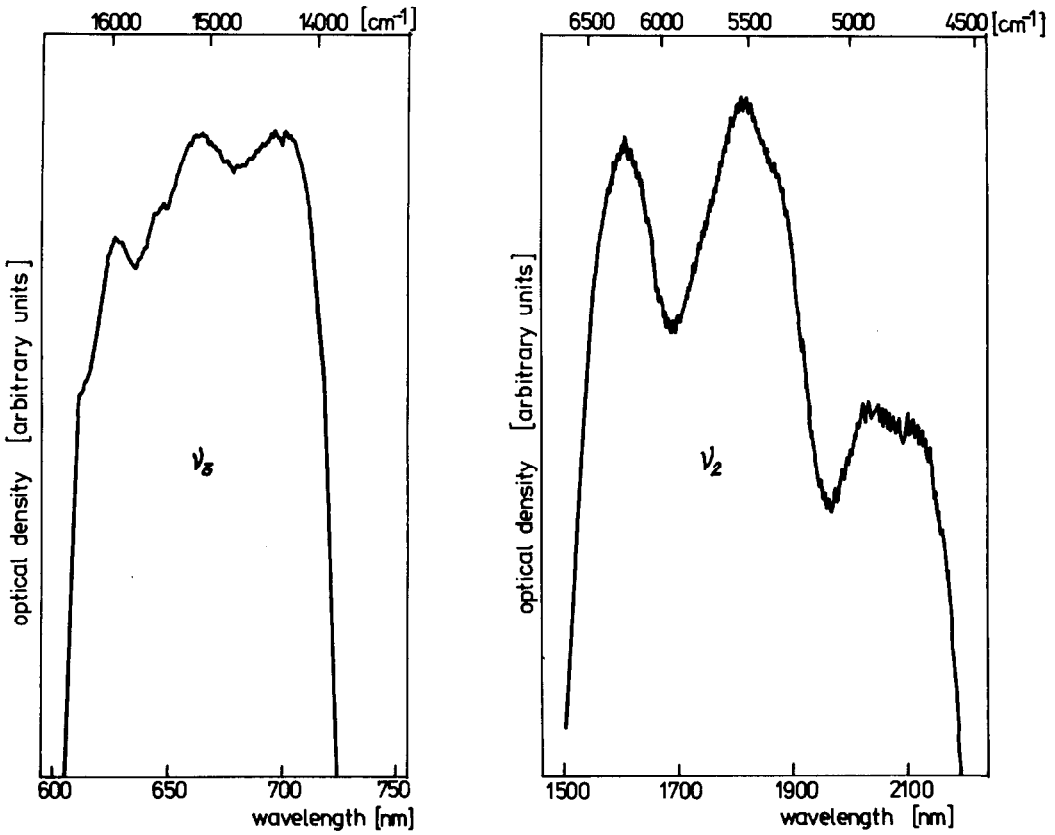

Fig. 1. Reflectance spectrum of cinchoninium tetrachlorocobaltate(II) in the range of transitions: $\nu_2[^4A_2 \rightarrow {}^4T_1(F)]$ and ν_3 $[^4A_2 \rightarrow {}^4T_1(P)]$.

745 cm^{-1} which represents an appreciable reduction from the free-ion value[6] B = 980 cm^{-1} and indicates significant covalent character of the metal-ligand bonds. This conclusion corroborates the suggestion of Oleksyn *et al.*[4] concerning formation of hydrogen bonds between chloride ions present in the first coordination sphere of Co^{2+} and protons from cinchoninium cation and water molecules. Indeed, the bonding of protons to chloride ions results in lowering of their electronegativity and in consequence changes the character of metal–ligand bonds into more covalent.

The absorption band ν_2 reveals a structure which may be due to the spin-orbit coupling and/or to the lowering of the site symmery of Co^{2+} ion. As shown by Ferguson[7] two limiting cases may be considered: 1st, the spin-orbit splitting is dominating over the splitting by the low symmetry crystal field; 2nd, the low symmetry crystal field splitting is large as compared with the spin-orbit splitting. In the first case the combined effect of the tetrahedral crystal field and the spin-orbit coupling results in splitting of the $^4T_1(F)$ term into four states. In the second case three components are obtained from the $^4T_1(F)$ term due to the strong interaction with low symmetry crystal field. Each of these components is then split into two levels by the spin-orbit coupling.

The absorption band ν_2 is split into three components and corresponds to the case for which low symmetry crystal field splitting is greater than spin-orbit splitting. The low energy component of the ν_2 band reveals an additional splitting, most probably related to the spin-orbit coupling. The absorption band ν_3 is more complicated, due to the contribution of the transitions between quartet ground state and the levels originating from the doublet terms of higher energy.

Further information concerning symmetry of the environment of the central Co(II) ion can be obtained from measurements of magnetic susceptibility. The plot of reciprocals of magnetic susceptibility corrected for diamagnetism ($\chi_{dia} = -335 \times 10^{-6}$ c.g.s.u.)[8] and for temperature independent paramagnetism ($\chi_{t.i.p.} = 8N\mu_\beta^2/\Delta_{tetra} = 675 \times 10^{-6}$ c.g.s.u.,[9] where N = Avogadro's number, μ_β = Bohr magneton, $\Delta_{tetra} = 3090$ cm^{-1}—crystal field splitting calculated from reflectance spectra) vs absolute temperature is a straight line with θ value close to zero. The μ_{eff} value, equal to 4.59 μ_β, confirms tetrahedral coordination of Co^{2+}.[10]

In the ESR spectrum of the Co(II)-complex taken at 4 K an asymmetric signal appears with g-factors: 5.610 ± 0.005 and 2.138 ± 0.005 for the low field and high field component, respectively (Fig. 2, solid line). At 77 K the signal is strongly broadened. Narrowing of the signal and good resolution of its components may be achieved by dilution of the cinchoninium tetrachlorocobaltate(II) with an isostructural Zn-complex. The dashed line in Fig. 2 represents the signal of such complex (Co:Zn ratio 1:2) recorded at 4 K. All three features of the highly aniso-

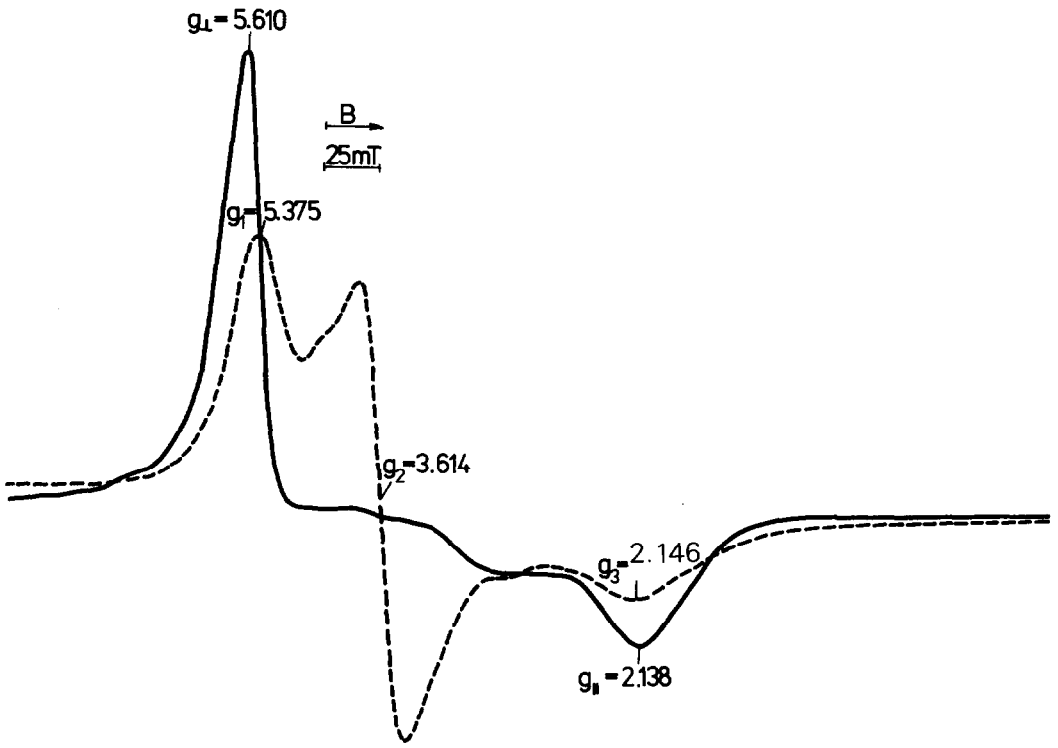

Fig. 2. ESR spectra of cinchoninium tetrachlorocobaltate(II) pure (—) and diluted with isostructural Zn(II) complex (----) in the molar ratio 1:2. Spectra taken at 4 K.

tropic ESR signal are well resolved with $g_1 = 5.375 \pm 0.005$, $g_2 = 3.614 \pm 0.005$, $g_3 = 2.146 \pm 0.005$, whereas in the pure Co(II)-complex the g_2 component is only slightly marked. Such changes in the shape and width of the ESR signal occurring upon dilution with the diamagnetic Zn-complex may be caused by weakening of the dipolar interactions between Co^{2+} ions.

The g-tensor values and the relaxation characteristics of the ESR signal of cinchoninium tetrachlorocobaltate(II) are very similar to those reported by Bencini *et al.*[11] for pseudotetrahedral high-spin complexes of Co(II) containing halides and phenylphosphine oxide or quinoline as ligands. The interpretation of single crystal data performed by these authors, based on the angular overlap model, allows us to assign the ESR spectra of Co(II)-complex to a $M_S = -1/2 \rightarrow +1/2$ transition of Co^{2+} in pseudotetrahedral environment, assuming nonparallel g- and D-tensors and large absolute value of the zero-field splitting.

The distortion of the $CoCl_4^{2-}$ tetrahedron, indicated by anisotropy of the ESR signal as well as by splitting of the ν_2 band in reflectance spectra may be related to the presence of cinchonine in the outer sphere of the complex. The interaction of cinchonine with Co^{2+} ion was shown by one of us previously[1] on the basis of IR spectra. This conclusion is in agreement with the model proposed by Oleksyn *et al.*[3]

Acknowledgements—The authors are greatly indebted to Professor M. Che, University Paris VI, France, for allowing measurements of reflectance spectra and to Mrs M. Chatry for taking the spectra. We wish to thank Professor P. Hagenmuller and Professor M. Pouchard, University of Bordeaux I, France, for allowing measurements of magnetic susceptibility and Dr. J-C. Grenier for the help in performing the measurements. We thank also Dr. H. Drulis, Institute for Low Temperature and Structure Research, Wrocław, Poland, for taking the ESR spectra at liquid helium temperature.

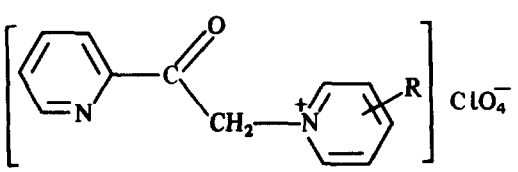
(*Received* 3 *January* 1984; *accepted* 16 *April* 1984)

Abstract—The title pyridinium salts and pyridinium ylide-platinum(II) complexes have been reduced through a one-electron process at more positive potentials by 0.3 ~ 0.6 V than the corresponding ylides. Both the reduced pyridinium salts and Pt(II)-ylide complexes reacted with dioxygen, followed by elimination of the *N*-methylene and ylide protons to form pyridinium ylides and Pt(II)-pyridinium ylide complexes containing the three-coordinate ylide carbon atom, respectively.



Reduction of pyridinium salts is of chemical as well as biological interest in relation to the behaviour of co-enzymes, NAD^+ and $NADP^+$. Although reductions of *N*-alkyl pyridinium salts have been widely investigated,[1] no attention has been paid to reductive behaviours of pyridinium compounds having an *N*-ylide bond and of related compounds. In the course of studies of pyridinium ylide-metal complexes[2–4] we have investigated the electrochemical reductions of substituted pyridinium 2-pyridylcarbonylmethylides (**I**), their dichloroplatinum(II) complexes (**II**), and substituted *N*-(2-pyridylcarbonyl)methylpyridinium perchlorates (**III**), together with substituted *N*-benzylpyridinium perchlorates (**IV**).

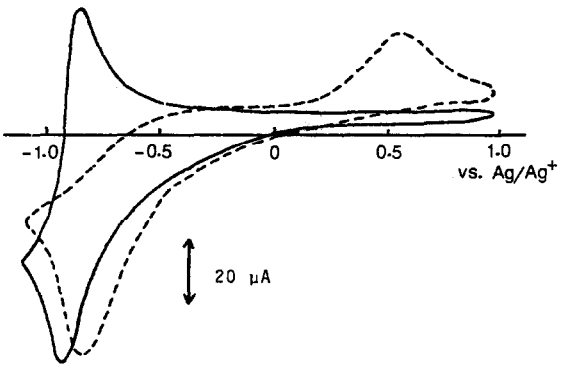

Fig. 1. Cyclic voltammetric scans of $Y_{CN}H$ under the nitrogen atmosphere (———) (a) and in the presence of dioxygen (------) (b) in acetonitrile (0.1 M[NBu^n_4]ClO_4); scan rate 0.5 V s^{-1}.

R	I	II	III	IV
4–CN	Y_{CN}	$Y_{CN}Pt$	$Y_{CN}H$	B_{CN}
4–C(O)Me	Y_{CM}	$Y_{CM}Pt$	$Y_{CM}H$	B_{CM}
4–C(O)OMe	Y_{AC}	$Y_{AC}Pt$	$Y_{AC}H$	B_{AC}
4–Me	Y_{ME}	$Y_{ME}Pt$	$Y_{ME}H$	B_{ME}
3,5–Me_2	Y_{LU}	$Y_{LU}Pt$	$Y_{LU}H$	

Figure 1(a) shows a cyclic voltammetric scan of $Y_{CN}H$ in acetonitrile under the nitrogen atmosphere. A reversible cathodic peak appears at −0.94 V vs Ag/Ag^+. The coulometry at this potential indicated that the wave corresponds to a one-electron reduction process. A cyclic voltammetric scan of B_{CN} also exhibited a reversible one-electron reduction wave at nearly the same potential (see Table 1). Thus, the reduction seems to be active in the pyridinium rings. Although $Y_{CM}H$ and $Y_{AC}H$ as well as B_{CM} and B_{AC} also gave essentially reversible redox waves, $Y_{ME}H$, $Y_{LU}H$, and B_{ME} exhibited irreversible reduction waves. On the other hand, all the ylides exhibited irreversible reduction peaks at more negative potentials because of electron-rich carbanion groups bound with the pyridinium nitrogen atom.

In the presence of dioxygen (O_2) the cyclic voltammetry of $Y_{CN}H$ gave an irreversible reduction peak at −0.85 V and the appearance on the return sweep of an anodic peak at +0.58 V (Fig. 1b). This anodic peak potential was identical with the peak potential for an oxidation of Y_{CN}. Moreover, the electronic absorption spectrum measured under the controlled potential electrolysis at −0.95 V for $Y_{CN}H$ displayed a new band at 494 nm whose intensity increased with performing the electrolysis. This band is identical with that of Y_{CN}. The reduced pyridinium salt is reasonably considered to react with O_2 immediately to form O_2^- and the pyridinium salt, as was seen in reactions of N,N' - dimethyl - 4,4' - bipyridinium radical with O_2.[5] Thus, the basic O^{2-} may eliminate the N-methylene proton of $Y_{CN}H$ to yield Y_{CN} (Scheme).

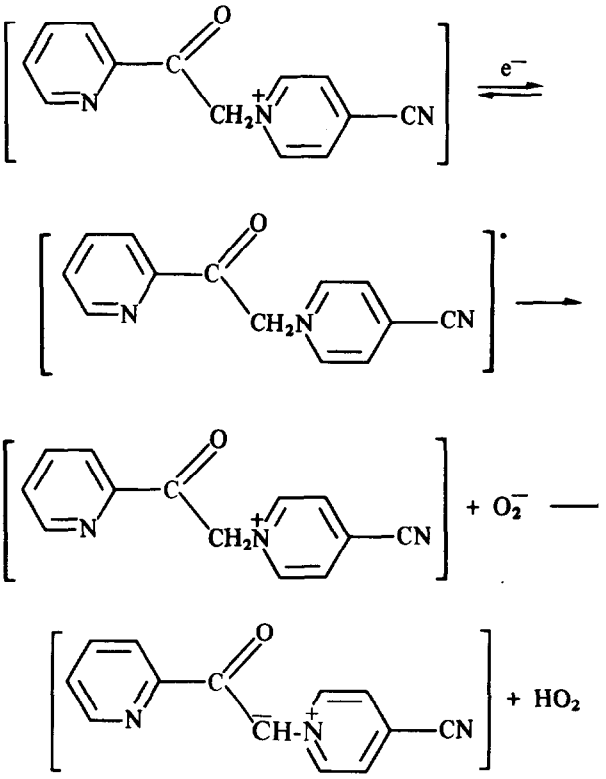

Table 1. Cathodic peak potentials of cyclic voltammetry[a] and peak separations in parentheses[b]

R	CN	CM	AC	ME	LU
Y_R	-1.50(-)	-1.44(-)	-1.61(-)	-2.02(-)

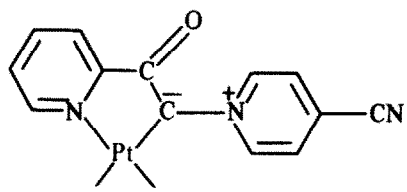
Y_RH	-0.94(60)	-1.00(110)	-1.07(70)	-1.60(-)	-1.70(-)
B_R	-0.93(60)	-1.00(60)	-1.06(60)	-1.70(-)	



a) V vs. Ag/Ag^+ in acetonitrile. b) mV and (-) indicates irreversible reduction waves.

Table 2. IR carbonyl stretching frequencies of substituted pyridinium 2-pyridylcarbonyl-methylides and related compounds in Nujol mulls (cm^{-1})

R	CN	CM	AC	ME	LU
Y_R	1531	1510	1500	1529	1530
Y_RPt	1685	1695	1690	1694	1696
Y_RH	1705	1705	1715	1701	1721

An acetonitrile solution of $Y_{LU}H$ giving an irreversible cathodic peak at -1.70 V was electrolyzed at -1.30 V in the presence of O_2 to exhibit an absorption band at 450 nm ascribable to Y_{LU}. This finding suggests that O_2^- eliminates the N-methylene proton of $Y_{LU}H$ to yield Y_{LU}, since O_2 is reduced to O_2^- at -1.30 V in acetonitrile.[6] Moreover, an acetonitrile solution containing both $Y_{LU}H$ and B_{CN} was electrolyzed at the controlled reduction potential B_{CN} (-1.00 v) in the presence of O_2 to given the absorption band due to Y_{LU}, which also indicates the same proton-elimination by O_2^- formed by the reaction of the reduced B_{CN} with O_2.

The Pt(II)-ylide complexes (II) showed the IR ν(C=O) bands at $160 \sim 190\ cm^{-1}$ higher frequencies than the free ylides, indicating the ylide carbon-to-platinum bonding of II (Table 2).[2,3] The electronic configuration of the ylide carbon atom in Y_RPt seems to be close to that in the corresponding Y_RH, since the latter compounds are regarded as ones where the ylide carbon atom of a corresponding ylide is linked with proton instead of the metal ion. In fact, cyclic voltammograms of Y_RPt under nitrogen atmosphere exhibited quite a similar reduction behaviour to that of Y_RH. However, cathodic peak potentials of Y_RPt (R = CN, CM, and AC) are somewhat more negative than those of the corresponding Y_RH. This seems to be due to weaker electron-withdrawing effect of the Pt(II) ion than proton, which is noticed also in lower ν(C=O) frequencies of Y_RPt than those of Y_RH (Table 2). Although a cyclic voltammogram of $Y_{CN}Pt$ in acetonitrile showed a cathodic peak at -1.14 V owing to the reversible one-electron reduction, in the presence of O_2 the reversible reduction wave was changed to an irreversible one, followed by the occurrence of an anodic peak at -0.26 V. The visible absorption spectrum observed for $Y_{CN}Pt$ under the controlled potential electrolysis at -1.14 V showed a new band at 669 nm. This finding resembles that observed for the electrically reduced $Y_{CN}H$. Assuming that the one-electron reduced $Y_{CN}Pt$ complex also is oxidized by O_2 and that the ylide proton is eliminated by O_2^-, the band at 669 nm may be ascribed to the new Pt(II)-ylide complex (V) having the three-coordinate ylide carbon. The ylide proton of $Y_{CN}Pt$

V

can be expected to be eliminated by bases. In fact, we have confirmed that addition of an excess of triethylamine or ethylenediamine to Y_{CN} in acetonitrile showed an absorption band at the same wavelength as the above-mentioned electrolysis of the complex in the presence of O_2. Moreover, the three-coordinate (sp^2) geometry of the ylide carbon ligating platinum has been confirmed by the X-ray analysis of $[(C_5H_4NC(O)CNC_5H_3Me_2\text{-}3,5)(NH_2CH_2CH_2NH_2)Pt(II)]^+ClO_4^- \cdot 2H_2O$ which was prepared by the reaction of $Y_{LU}Pt$ with ethylenediamine.[7] This complex showed an absorption band at 572 nm in acetonitrile which was the same as the band maximum observed under the controlled potential electrolysis of $Y_{LU}Pt$ at -1.70 V in acetonitrile in the presence of O_2.

EXPERIMENTAL

Materials

Substituted pyridinium 2-pyridylcarbonylmethylides (I) were prepared according to the literature methods.[3] Substituted N-(2-pyridylcarbonyl)methylpyridinium perchlorates (III) were prepared by reactions of 2-(bromoacetyl)pyridinium bromide[9] with corresponding substituted pyridines in benzene, followed by exchange of the bromide ion with the perchlorate ion and recrystallized from water. Substituted N-benzylpyridinium perchlorates (IV) were prepared by reactions of benzylbromide with substituted pyridines in benzene, followed by the procedures described for compounds (III).

Preparation of dichloro(substituted pyridinium 2-pyridylcarbonylmethylide)Pt(II) (II)

A dichloromethane (30 cm^3) solution of dichlorobis(dimethylsulphide)Pt(II)[10] (0.18 g, 50 mmol) was added dropwise to Y_{CN} (0.11 g, 50 mmol) in the same solvent (30 cm^3) and the solution was stirred for 2 hr. A yellow precipitate of $Y_{CN}Pt$ was collected by filtration, washed with dichloromethane, and dried *in vacuo* (0.19 g, 74% yield); m.p. 273°C (dec.). Found: C, 31.37; H, 1.70; N, 8.47%. Calc. for $C_{13}H_9N_3OCl_2Pt$: C, 31.88; H, 1.85; N, 8.58%. The salts, $Y_{AC}Pt$ and $Y_{CM}Pt$, were also prepared in the same way. $Y_{AC}Pt$, m.p. 266°C (dec.). Found: C, 32.54; H, 2.52; N, 5.52%. Calc. for $C_{14}H_{12}N_2O_2Cl_2Pt$: C, 33.18; H, 2.39; N, 5.53%. $Y_{CM}Pt$, m.p. 229°C (dec.). Found: C, 31.34; H, 2.18; N, 5.09%. Calc. for $C_{14}H_{12}N_2O_3Cl_2Pt$: C, 32.17; H, 2.31; N, 5.36%.

$Y_{ME}Pt$ and $Y_{LU}Pt$ were prepared according to the literature.[3]

Physical measurements

Cyclic voltammetric scans were performed using a Nikkokeisoku NPS-2 potentiosweeper, a Hokuto-denko HA-104 potentiostat, and a Riken-denshi F-3DP *xy* recorder. A Beckman-type platinum working electrode was used. An acetonitrile solution of 0.01 M $AgNO_3$ equipped with a Ag wire was the reference electrode and a platinum plate (2 × 2 cm^2) was the counter electrode. All cycles were recorded on 1×10^{-3} M compounds in acetonitrile solutions containing 0.1 or 0.05 M $[NBu^n_4][ClO_4]$ as a supporting electrolyte. Electronic and IR absorption spectra were recorded on Union-giken 401 and Hitachi 215 spectrophotometers, respectively.

VI. CONCLUDING REMARKS. 200

I. INTRODUCTION

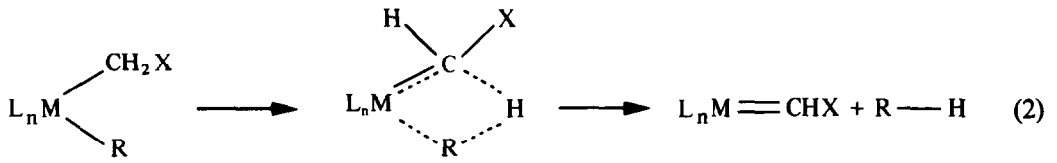
The search for mild, homogeneous ways of activating hydrocarbon CH bonds is one of the most challenging and intellectually stimulating problems facing organo-transition metal chemists today. Many reactions in which simple CH bonds are activated by interaction with soluble transition metal complexes have been reported in the last 20 years.[1–3] Some systems have been developed that can carry out the relatively mild functionalization (metallation) of even the most difficult hydrocarbon CH bond, i.e. that found in methane. However, most successes have been with the intermolecular activation of aromatic CH bonds and the intramolecular activation of a range of CH bond types in coordinated ligands.[4–6] These latter reactions, initially termed ortho-metallations but now generally referred to as cyclometallations, have allowed a great deal of controlled mechanistic studies to be carried out giving insight into how transition metals can activate such normally inert groups.

A mechanistic similarity exists for nearly all of the early systems that were developed.[1-6] In the case of cyclometallation reactions an oxidative–addition pathway involves the CH bond being added to the metal center to generate a hydride and chelated alkyl (aryl) function. In the case of metal centers such as Rh(I), Ir(I) and Pt(II) the addition occurs to a d^8 metal center to give a d^6, oxidized configuration which is then either stable or else undergoes reductive loss of the hydride with a leaving group. In other systems either reductive loss of ligands or a dissociation step (either thermally or photochemically induced) precedes the oxidative addition of the CH bond. The most extensively studied species capable of intermolecularly activating CH bonds in simple hydrocarbons are the transition metal polyhydrides and the Pt(II)/acid systems. In the platinum systems developed by a number of workers, activation of aromatic, benzylic and even aliphatic CH bonds takes place in complex, acidic mixtures as detected by catalyzed H/D exchange reactions.[7-9] The activation step involves oxidative-addition to a Pt(II) center; Pt metal and Pt(IV) salts being inactive under the reaction conditions. The polyhydride complexes, typified by Cp_2MH_3(M=Nb, Ta), involve initial reductive elimination of H_2 to generate the unsaturated, active species.[10] Compounds of this type can cause extensive H/D exchange in aromatic rings. Special mention must be made of some recently developed systems. Tungstenocene, generated either photochemically or thermally, has been shown to be active towards both aliphatic and aromatic CH bonds,[11] while the unsaturated iridium cyclopentadienyl intermediates developed by Bergman[12] and Graham[13] are very good at oxidatively adding hydrocarbons. The coupling of iridium complexes with readily hydrogenated olefins has allowed Crabtree to be able to mildly dehydrogenate saturated alkanes.[14] Again in these cases the act of CH bond activation involves an oxidative-addition pathway.

It must be pointed out that although the cyclometallation reaction is believed to proceed by an oxidative-addition pathway for Pt(II), the extensive and well studied cyclopalladation reaction almost certainly is electrophilic in nature.[15] Similarly the large number of oxidations and coupling reactions of aromatic compounds catalyzed by Pd^{2+} occurs via a predominantly electrophilic mechanism.[16]

Over the past 5 years a body of literature has developed in which a new type of hydrocarbon activation can be observed. Typically this involves early *d*-block, lanthanide or actinide elements in their highest formed oxidation states. For *d*-block elements the d^0-metal configuration precludes the oxidative-addition pathway characteristic of the vast majority of CH bond activations, either by the systems mentioned or by metal surfaces. Very recent and exciting work by Watson and Marks has shown that such systems are capable of activating even methane itself. Hence, it appears that a new and potentially very important type of hydrocarbon activation is emerging. This paper reviews the present literature on this subject, dealing both with the intramolecular metallation of ligands as well as the activation of "free" hydrocarbons themselves.

II. CH BOND ACTIVATION IN ALKYL GROUPS



1. *α-Hydride abstraction*[17]

It might at first sight appear strange to find this important reaction included in a review of CH bond activation. However, from the purist's point of view it involves a cyclometallation reaction at a d^0-metal center to generate a two membered ring! The reaction has a number of characteistics found in more distal CH bond activations, except that the new metal–carbon bond that is formed is a π-bond. The classical (if one can consider a reaction only nine years old as classical) example of α-hydride abstraction is the initial reaction discovered by Schrock (1).[18]

$$Cl_2Ta(CH_2CMe_3)_3 + 2LiCH_2CMe_3 \rightarrow Ta(=CHCMe_3)(CH_2CMe_3)_3 + 2LiCl + Me_4C \qquad (1)$$

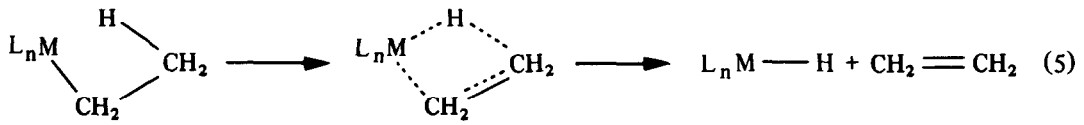
During the course of the reaction the α-CH bond is activated by the Ta(V) center and the hydrogen atom is lost from the complex with a leaving group, either Cl or R, to generate the alkylidene function. If one counts the alkylidene ligand as CR_2^{2-} then the tantalum maintains its highest oxidation state. It is not the purpose of this paper to review the extensive literature on α-hydride abstraction processes, a number of excellent reviews by Schrock being already available.[17] However, it is important to mention that theoretical studies by Hoffman *et al.*[19] have indicated that the course of the reaction proceeds through a concerted pathway in which the α-hydrogen is transferred to the leaving group with no net change in metal oxidation state throughout the course of the reaction.

A four-center transition state can be postulated in which metal–carbon and carbon–hydrogen bonds are being both broken and formed (2).

(2)

This proposed pathway is of direct relevance to the mechanisms of both more distal and intermolecular CH bond activations.

Recently a number of photochemically induced α-hydride abstractions on d^0-metal centers have been reported, e.g. (3),[20] (4)[21]



$$(OAr')_2Ta(CH_3)_3 \rightarrow (OAr')_2Ta(=CH_2)(CH_3) + CH_4 \quad (3)$$
$$(OAr' = 2,6\text{-di-}tert\text{-butylphenoxide})$$

$$(Bu^tN)_2Re(CH_2SiMe_3)_3 \rightarrow (Bu^tN)_2Re(=CHSiMe_3)(CH_2SiMe_3) + Me_4Si. \quad (4)$$

It is yet to be determined whether the thermal and photochemical activation of α-CH bonds are mechanistically related.

2. *β-Hydrogen abstraction and benzyne formation*

The abstraction of β-hydrogens from metal alkyl groups is a common decomposition pathway and can readily occur at d^0-metal centers.[22] However, the formation of an intermediate hydrido-olefin (which may or may not dissociate the olefin) must be considered a special case of CH bond activation as the alkyl group itself is acting as a unique type of leaving group (5).

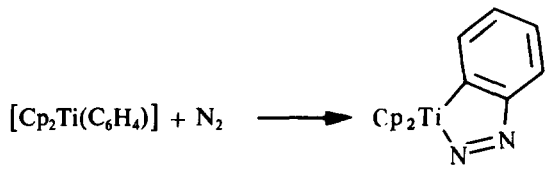
(5)

Again a four-center transition state is the expected pathway for the reaction.

In contrast to this behavior the activation of β-(ortho) CH bonds of aryl groups has characteristics similar to more distal CH bond activations. Here the hydrogen does not remain on the metal but is lost with a suitable leaving group. A number of important examples of this reaction are known (6),[23] (7),[24] (8).[25]

$$Cp^*TaMe_3Ph \longrightarrow Cp^*Ta(C_6H_4)Me_2 + MeH$$

(6)



In the case of the tantalum complex the resulting benzyne (*o*-phenylene) group is sufficiently stable to be structurally characterized. The structural data is supportive of the idea that the ligand is best considered as $C_6H_4^{2-}$, i.e. the metal maintains a d^0-configuration.[23]

Two other examples involve the thermal generation of intermediate benzyne complexes from the bis-phenyl compounds $Cp_2M(C_6H_5)_2$ (M=Ti, Zr)(7) and $Cp^*_2U(C_6H_5)_2$ (8)

$$Cp_2Zr(C_6H_5)_2 \rightarrow [Cp_2Zr(C_6H_4)] + C_6H_6 \quad (7)$$

$$Cp^*_2U(C_6H_5)_2 \rightarrow [Cp^*_2U(C_6H_4)] + C_6H_6 \quad (8)$$

In both these cases the benzyne complex is too reactive to isolate, even reacting in the case of M=Ti with dinitrogen (9).[26]

(9)

The overall sequence of events can hence be considered the activation of the *ortho*-CH bonds and their eventual functionalization.

3. *γ-Hydrogen abstraction*

Unlike α- and β-hydrogen abstraction, the activation of γ-CH bonds in alkyl groups is generally recognized as being an example of *distal*-CH bond activation. The rationale for this thinking is that the metal is having minimal influence through the carbon chain on the CH bond being activated. Unfortunately, the effect that metal substituents have on γ-CH bonds, for instance, in neopentyl (CH_2CMe_3) or trimethylsilyl (CH_2SiMe_3) groups is not known. It is hence not possible to say whether metals such as Ta(V), Th(IV) or Pt(II) are electronically activating (or deactivating) these CH bonds. Metallation of these types of ligands at the γ-position has been observed both at dinuclear centers[27] and also in mononuclear complexes.[28] For the case of cyclometallation at Pt(II) (10) Whitsides *et al.* have carried out a thorough kinetic and mechanistic study.[29]

$$cis\text{-}Pt(PR_3)_2(CH_2CMe_3)_2 \rightarrow \overline{Pt(CH_2CMe_2CH_2)}(PR_3)_2 + CMe_4. \quad (10)$$

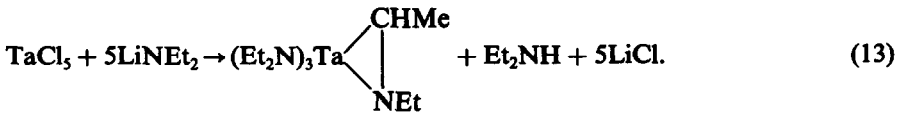
Only one example of the cyclometallation of these groups at d^0-metal centers has been reported. The complexes $C\overset{*}{p}_2ThR_2$(R=CH_2SiMe_3, CH_2CMe_3) undergo the smooth loss of one equivalent of Me_4X(X=C or Si) to generate a four-membered metallocycle (11.)[30]

$$C\overset{*}{p}_2Th(CH_2XMe_3)_2 \rightarrow C\overset{*}{p}_2\overline{Th(CH_2XMe_2CH_2)} + XMe_4 \quad (11)$$

In the case of X = Si the product was characterized by X-ray diffraction techniques. Kinetic data for the reactions showed they are unimolecular, and labelling studies showed that the γ-CH bonds are activated directly.[30]

4. *Activation of other* CH *bonds in alkyl groups*

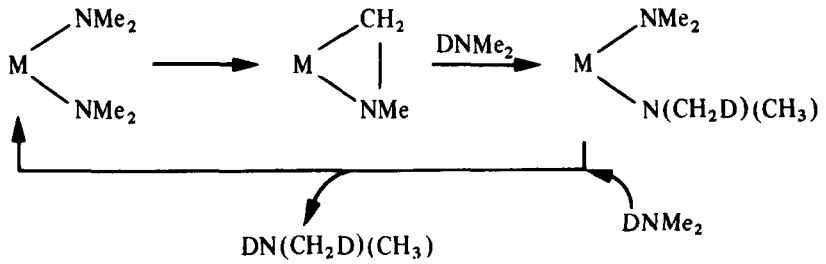
The γ-CH bond represents the most distal part of alkyl ligands that have been activated intramolecularly. This is not surprising due to the tight restrictions that are placed on the structure of the ligand by the presence of other more facile reactions such as α- and β-hydrogen abstraction. There are numerous reactions reported in which the sp^2CH bonds of Cp co-ligands are activated to cleavage.[31] Use of the $C\overset{*}{p}(C_5Me_5)$ ligand normally reduces this type of reaction. However, in the case of the thermolysis of $C\overset{*}{p}_2TiMe_2$ Bercaw has shown that the product is obtained via initial α-hydrogen abstraction to generate a methylidene function which then activates and adds a CH bond of one of the $C\overset{*}{p}$-methyl groups.[32] Labelling studies clearly show that the generated methane does not contain hydrogen atoms from the $C\overset{*}{p}$-methyl groups (12).



$$(C_5Me_5)_2Ti(CD_3)_2 \rightarrow [(C_5Me_5)_2Ti(=CD_2)] + CD_4 \rightarrow (C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)Ti\text{–}CD_2H \quad (12)$$

III. CYCLOMETALLATION OF HETERO-ATOM DONOR LIGANDS

1. *Activation of β-CH bonds in amido ligands*



The dialkylamido ligand is an important group in early transition metal chemsitry. Its use as an ancillary ligand has made significant contributions to the isolation of metal complexes with low coordination numbers and complexes containing metal–metal bonds.[33,34] Unlike the extensive cyclometallation chemistry associated with amine complexes of the Gp VIII metals,[4-6] analogous reactions with early transition metals are less extensive. One of the first reactions reported in which

the β-CH bonds of dialkylamido groups is cleaved at a d^0-metal center involved in the treatment of $TaCl_5$ with $LiNEt_2$ (13).[35]

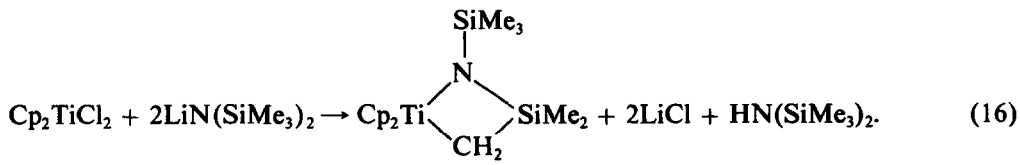
$$TaCl_5 + 5LiNEt_2 \rightarrow (Et_2N)_3Ta(CHMe)(NEt) + Et_2NH + 5LiCl. \quad (13)$$

Due to the large steric pressure around the metal atom, generation of amine occurs with metallation of the β-CH bond. More recent work by Nugent *et al.* has demonstrated that this type of reaction is in fact common for a number of d^0-metal dimethylamido complexes.[36] However, the generation of the iminomethyl group had to be inferred from its reactions. Hence, he has shown that $(CH_3)_2ND$ in the presence of $M(NMe_2)_x$ (M=Zr, x = 4; Nb, Ta, x = 5 and W, x = 6) undergoes catalytic scrambling of deuterium into the methyl groups This result can be explained if one proposes a reversible metallation of the dimethylamido group along with facile exchange of dimethylamine with coordinated dimethylamido groups (14).

$$M(NMe_2)_2 \rightarrow M(CH_2)(NMe) \xrightarrow{DNMe_2} M(NMe_2)(N(CH_2D)(CH_3)) \quad (14)$$

$$M(NMe_2)(N(CH_2D)(CH_3)) \rightarrow M(NMe_2)_2 + DN(CH_2D)(CH_3)$$

Furthermore, it was demonstrated that once formed the azametallocyclo-propane underwent facile insertion of olefins, allowing aminomethylation of olefins to be catalyzed by complexes of this type (15).



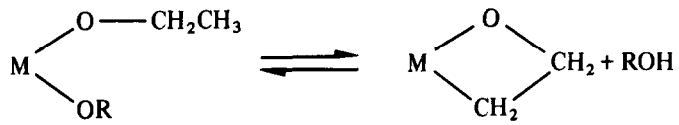
$$Me_2NH + CH_2{=}CHC_3H_7 \rightarrow MeNHCH_2C(Me)HC_3H_7. \quad (15)$$

Addition of $LiNMe_2$ to the complex $C\overset{*}{p}TaMe_3Cl$ initially generates the substitution product $C\overset{*}{p}Ta(NMe_2)Me_3$.[36b] However, at ambient temperatures this decomposes by loss of methane to generate the cyclometallated, imine complex (15a). A kinetic study showed a first order dependence with a kinetic isotope effect (k_H/k_D) of 9.7 at 34°C.[36b] when using $N(CD_3)_2$.

$$C\overset{*}{p}_2Ta(NMe_2)Me_3 \rightarrow C\overset{*}{p}Ta(NMeCH_2)Me_2 + MeH. \quad (15a)$$

2. γ-CH *bond activation in dialkylamido and alkoxide ligands*

The sterically very demanding ligand bis-(trimethylsilyl)amide, $N(SiMe_3)_2$, has received considerable attention due to its ability to impose low coordination numbers on a variety of transition metals.[33] It was demonstrated as early as 1974 by Bradley *et al.* that it was possible to activate the γ-CH bonds in this ligand leading to a cyclometallated product containing a four-membered ring (16). In this case the four-membered ring contains four different elements.[36c]



$$Cp_2TiCl_2 + 2LiN(SiMe_3)_2 \rightarrow Cp_2Ti(N(SiMe_3))(SiMe_2)(CH_2) + 2LiCl + HN(SiMe_3)_2. \quad (16)$$

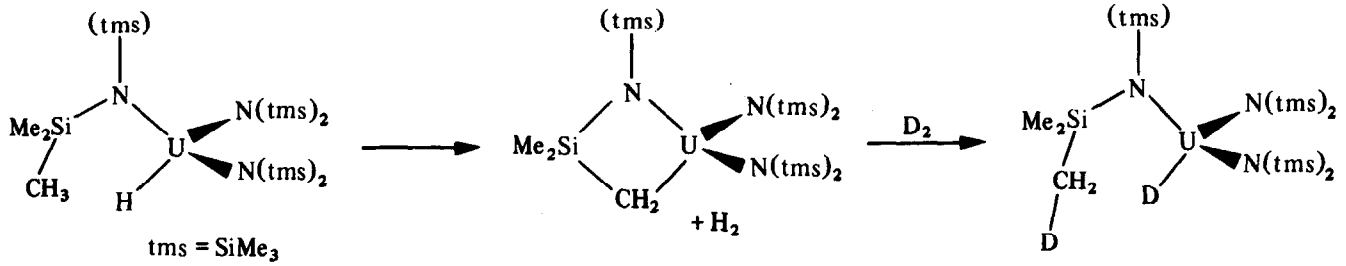
Later work by Andersen has shown that both Zr(IV) and the actinide metal centers Th(IV) and U(IV) can similarly activate and metallate this bond. A reinvestigation of reaction (16) by this group has shown that the cyclometallation step probably occurs from a monosubstituted product $Cp_2TiCl[N(SiMe_3)_2]$ by loss of HCl.[36d] The zirconium analogue was prepared by addition of

$LiN(SiMe_3)_2$ to $Cp_2Zr(H)Cl$ to give the metallacycle directly. Presumably the leaving group in this case is the hydride ligand.[36d] In the case of the actinide systems,[37] it was shown possible to catalytically deuterate the $SiMe_3$ groups using D_2 (Scheme I). The catalytic cycle makes use of a hydride ligand as a leaving group for the metallation reaction coupled with the reverse hydrogenolysis of the metal–carbon bond so formed (Scheme I).

Thermal elimination of alkane from the complexes $R_2M(N(SiMe_3)_2]_2$ was shown to proceed with the loss of two hydrogens from the γ-carbon,[38] leading to a bridging alkylidene as shown (Scheme II). Presumably initial γ-CH bond activation is followed by α-hydride abstraction from the generated metallacycle. When equimolar mixtures of $Me_2Zr[N(SiMe_3)_2]_2$ and $Et_2Hf[N(SiMe_3)_2]_2$ were mixed and thermolyzed, a 1 : 2 : 1 mixture of dinuclear complexes containing Zr_2, ZrHf and Hf_2, respectively, was isolated.[39] Due to the dimeric nature of these products, confirmed by X-ray crystallography,[38] whether one or both of the hydrogen abstraction steps occurs intermolecularly is uncertain. On treatment with dmpe, the dimers both cleave and undergo a rearrangement to bis-cyclometallated complexes (Scheme II).[39] During the course of this reaction, the initially unmetallated amide ligand has transferred a γ-hydrogen to the initially bridging alkylidene group. The fact that the analogous titanium complex does not undergo the same thermal reactions is good support for the idea that the reaction does not involve a radical pathway (*vide infra*).

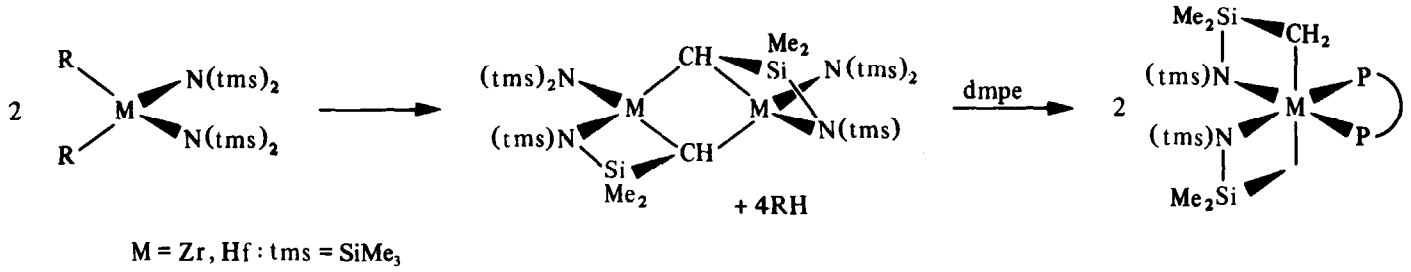
Early transition metal ethoxides have been shown to be active catalysts for H/D exchange in CH_3CH_2OD.[36] Deuterium is incorporated exclusively into the methyl group. The reversible formation of a four membered metallocycle was proposed (17), with a reverse alcoholysis of the metal–carbon bond formed. An intriguing observation was that multiple exchange occurred,[36] implying that α-hydride abstraction from the metallocycle was somehow taking place.

(17)



3. *Distal* CH *bond activation in aryloxide ligands*

The ligand 2,6-di-*tert*-butylphenoxide (OAr′) has been shown to undergo cyclometallation at a number of early transition metal centers. In the case of tantalum, introduction of the ligand onto the metal by way of its lithium salt yields the tri-chloro compound shown by X-ray diffraction to be mononuclear.[40] Treatment of this compound with methyl lithium gives the expected substitution product $Ta(OAr')_2Me_3$ (Fig. 1) (18).[41]



$$TaCl_5 \xrightarrow{2LiOAr'} Ta(OAr')_2Cl_3 \xrightarrow{3LiMe} Ta(OAr')_2Me_3. \qquad (18)$$

On thermolysis this complex undergoes the smooth loss of first one and then a second equivalent of methane to generate the mono-cyclometallated and bis-cyclometallated compounds (Scheme III).[42] The cyclometallation involves the activation and cleavage of an α-CH bond to generate a six-membered metallocycle. Labelling studies using $Ta(OAr')_2(CD_3)_3$ show that the methane comes from direct loss of the leaving group with the activated hydrogen, giving CD_3H.[43] Kinetic data show that both steps of the reaction are unimolecular.[44] In contrast to these thermal reactions, the photolysis of the tri-methyl complex leads to the rapid and efficient formation of a methylidene complex with loss of one equivalent of methane (3). At 25°C over a period of a few hours this complex "isomerizes" to the mono-cyclometallated species.[20] This step is intriguing as it demonstrates that alkylidene groups, apart from their known importance in olefin metathesis[45] and implied involvement in olefin polymerization,[46] can be active functional groups for aliphatic CH bond activation. The CH bond is "added" to the tantalum–carbon double bond, and in some respects represents the reverse of an α-hydride abstraction.[17] Labelling studies clearly differentiate the thermal and photochemical routes to the mono-metallated complex (Scheme IV).

Addition of $LiCH_2SiMe_3$ to $Ta(OAr')_2Cl_3$ leads directly to an alkylidene complex (Fig. 2).[41,43] On thermolysis this complex again undergoes cyclometallation of the aryloxide groups, although in this case no intermediate mono-metallated complex could be isolated.[43] Hence, three possible pathways for the reaction exist (Scheme V). However, irrespective of which pathway is operative one of the steps must again involve addition of the aliphatic CH bond to an alkylidene group.

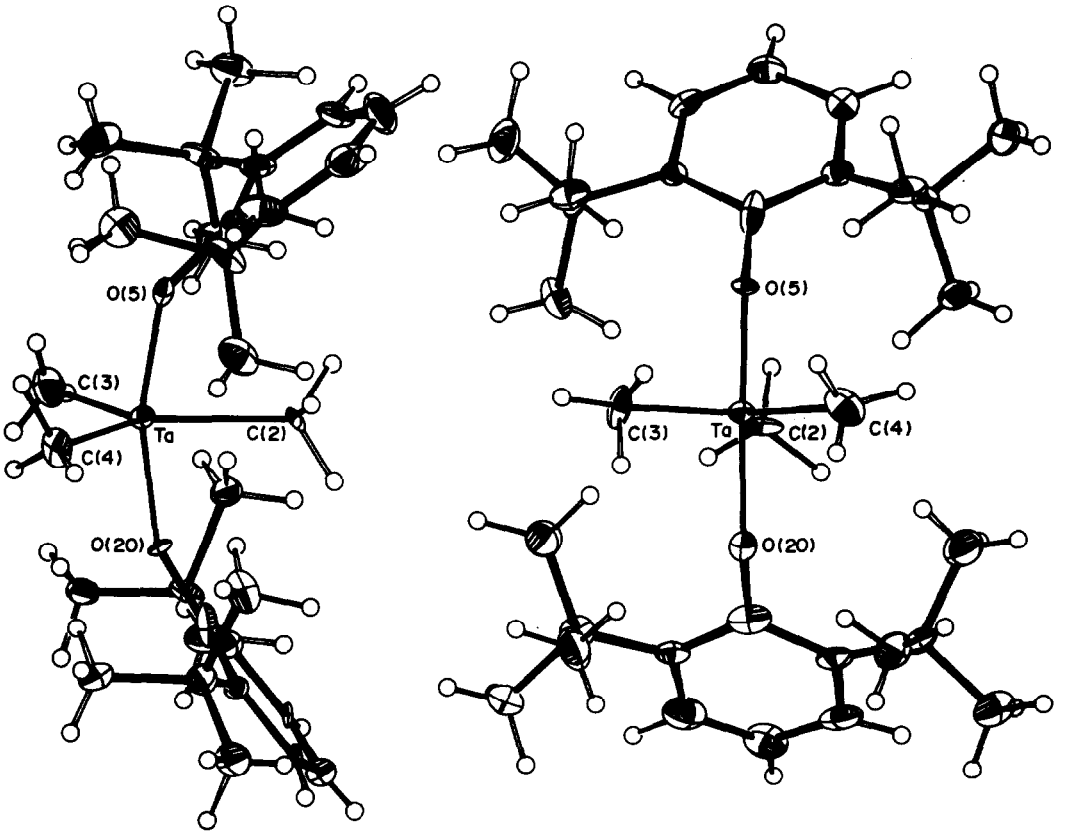
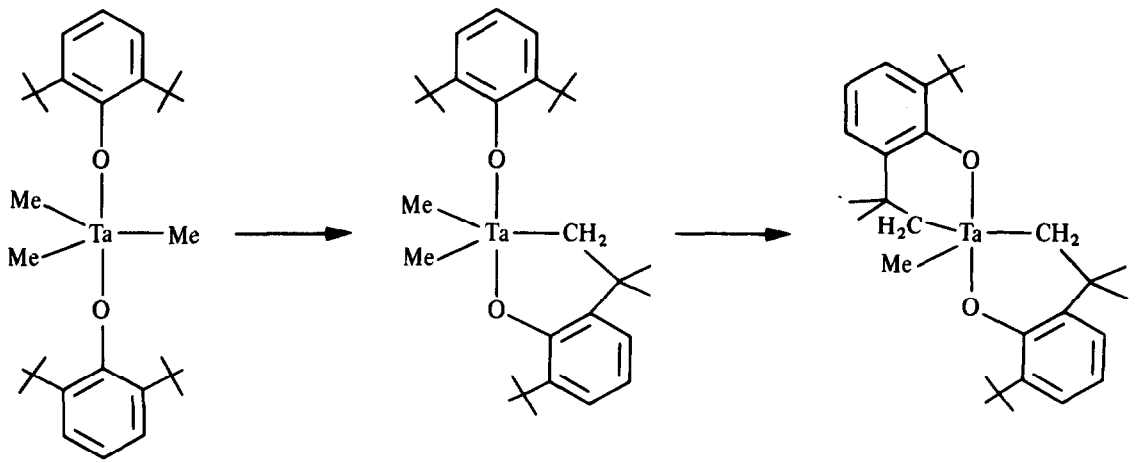
Scheme II. Thermal metallation behavior of the complexes $R_2M[N(SiMe_3)_2]_2$ (M = Zr, Hf) (from Refs. 38 and 39).





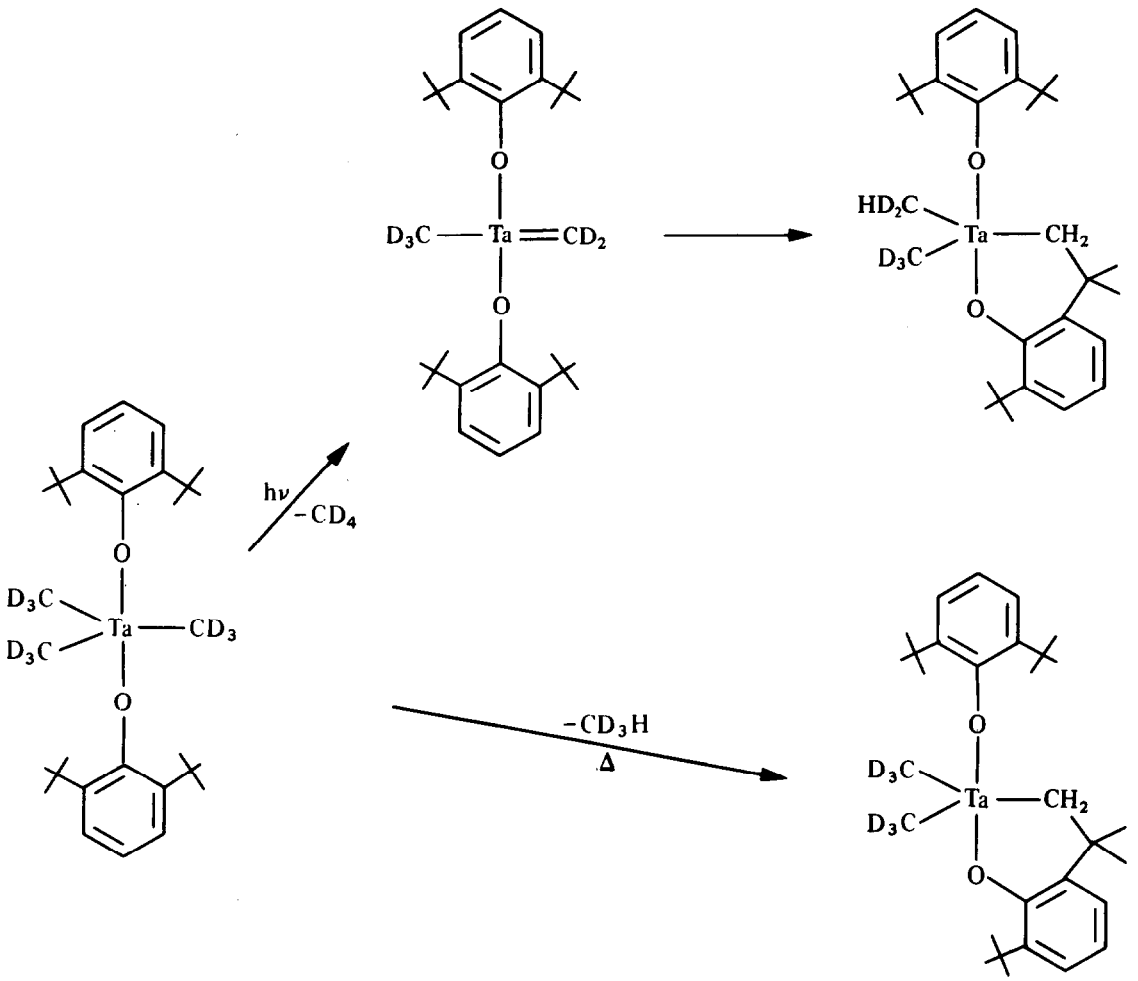


Fig. 1. Two ORTEP views of the molecule $Ta(OAr')_2Me_3$ showing the distorted tbp geometry and relatively close approach of ϵ-CH bonds. Some pertinent bond distances (Å) and angles (°) are: Ta–O = 1.94(av), Ta–C(3) = 2.136(10), Ta–C(4) = 2.138(10), Ta–C(2) = 2.248(10), O–Ta–O = 164.1(2), C(3)–Ta–C(4) = 104.7(4).

The treatment of $Ta(OAr')_2Cl_3$ with phenyl-lithium leads directly to a mono-metallated complex which has been structurally characterized (Fig. 3).[43] Presumably this facile metallation occurs from a tri-phenyl complex, although it is possible that loss of HCl or benzene occurs from an intermediate compound $Ta(OAr')_2(Ph)_2Cl$. On thermolysis the mono-metallated compound undergoes loss of one equivalent of benzene and formation of a bis-metallated species. The structure of this complex can be readily deduced from its ^1H NMR spectrum (Fig. 4).[47]

Scheme III. Thermal activation of the ϵ-CH bonds in $Ta(OAr')_2Me_3$, OAr' = 2,6-di-*tert*-butylphenoxide (from Ref. 42).

Scheme IV. Comparison of the thermal and photochemical reactivity of $Ta(OAr')_2Me_3$, OAr' = 2,6-di-*tert*-butylphenoxide (from Ref. 20).

If *o*-tolyllithium is used in the reaction then the initial product is $Ta(OCH_2)(OAr')(o\text{-tol})_2$ (OCH_2 = cyclometallated OAr'). However, on thermolysis the bis-metallated product contains a mixture of *meta*- and *para*-tolyl groups, the aryl ligand having undergone isomerization.[47] The obvious explanation for this result is the intermediacy of a benzyne complex which rapidly undergoes insertion of the aliphatic CH bond. This idea breaks down when one realizes that it is impossible for an *o*-tolyl group to isomerize to a *p*-tolyl through only one intermediate, it needs two benzyne complexes to be formed successively. Furthermore, the aryl group was shown to undergo isomerization in the bis-cyclometallated product itself, a 50/50 mixture of *p*- and *m*-tolyl groups being given irrespective of the isomer initially used.[47] These results can be explained if the bis-cyclometallated complex is in equilibrium with a mono-metallated benzyne complex at high temperature (Scheme VI). Use of LiC_6D_5 conclusively shows that the benzyne complex is only formed once bis-metallation has taken place. At high temperatures the deuterium label is scrambled statistically over all aliphatic and Ta–Ph positions as a result of the equilibrium in Scheme VI.[47] Although attainable only at high temperature, the equilibrium demonstrates in the ring closure that activation of aliphatic CH bonds is possible by insertion into one of the metal–carbon bonds of a benzyne (*o*-phenylene) ligand.

Thermolysis of the complexes $M(OAr')_2(CH_2Ph)_2$(M=Ti, Zr) (Fig. 5) leads to the loss of one equivalent of toluene and formation of a mononuclear, monometallated compound (Scheme VII).[48] This behavior contrasts with the case of the γ-CH activation of the $N(SiMe_3)_2$ ligands which led to dinuclear complexes with loss of two equivalents of alkane (Scheme II). If the tetraalkyl $M(CH_2SiMe_3)_4$(M = Ti, Zr) is heated with excess Ar'OH, the mono-metallated, bis-aryloxide

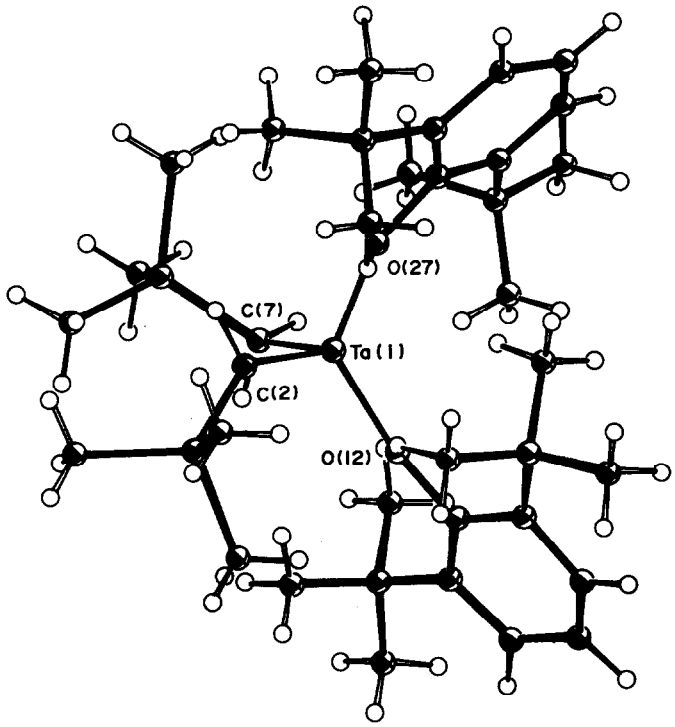

Fig. 2. An ORTEP view of $Ta(OAr')_2(=CHSiMe_3)(CH_2SiMe_3)$ showing the pseudo-tetrahedral environment and almost linear Ta–O–C angles. Some pertinent bond distances (Å) and angles (°): Ta–O = 1.86(av), Ta–C(2) = 1.888(29), Ta–C(7) = 2.165(24), Ta–O–C = 170(av).

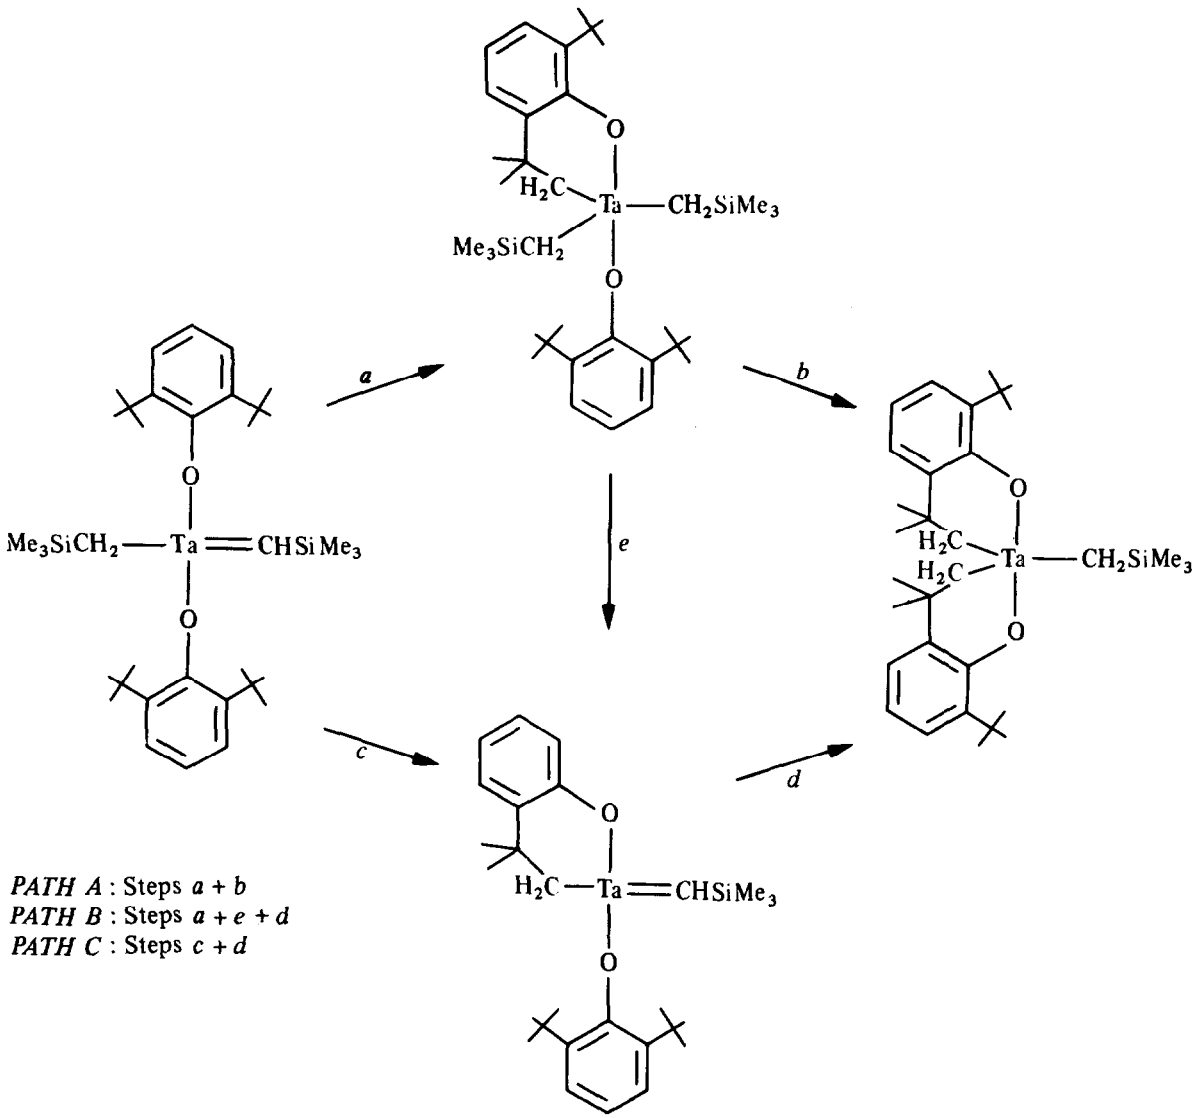
complex $\overline{M(O–CH_2)}(OAr')_2$ is generated (Scheme VII). The stage at which alkane loss and cyclometallation occurs is unknown. However, the fact that the previous complex reacts with Ar'OH to give an identical product indicates the intermediacy of $M(OAr')_2(CH_2SiMe_3)_2$.[48] If only two equivalents of HOAr' is heated with $Ti(CH_2SiMe_3)_4$ a complex mixture is given. From this mixture a series of complexes $\overline{Ti(O–CH_2)}(OAr')(CH_2SiMe_3)(L)$ (L = neutral donor ligand) can be precipitated by addition of excess L in hexane. For L = pyridine an X-ray diffraction study clearly shows the presence of the cyclometallated chelate (Fig. 6). Although the complex $\overline{Zr(O–CH_2)}(OAr')_2$ reacts with HCl to give the mono-halide $Zr(OAr')_3Cl$ all attempts to reverse this reaction, (19), i.e. cyclometallation with loss of HCl, have failed.



$$\overline{Zr(OC_6H_3Bu^tCMe_2CH_2)}(OAr')_2 + HCl \rightarrow Zr(OAr')_3Cl. \quad (19)$$

IV. MECHANISTIC ASPECTS OF INTRAMOLECULAR CH BOND ACTIVATION AT d^0-METAL CENTERS

The elucidation of the mechanism of these cyclometallations is essential to our understanding of the intermolecular activation of hydrocarbons by similar metal centers. Two pathways are generally considered, one being a homolytic initiation involving free radicals while the other contains a multicenter transition state. It is difficult to see how a radical pathway could be extrapolated to intermolecular activations with ease, however, the multicenter pathway can be generalized for both inter- and intra-molecular activations. Although it is now generally accepted that the activation occurs via a four-center transition state it is important to review the data which argues against the homolytic pathway.

1. *Homolytic pathway*

This mechanism probably gains consideration due to the fact that the majority of cyclometallation reactions at these d^0-metal centers involve alkyl leaving groups. The facile (sometimes explosive) thermal decomposition of a large number of early transition metal per-alkyl

Scheme V. Possible pathways for the observed thermal reactivity of $Ta(OAr')_2(=CHSiMe_3)(CH_2SiMe_3)$, OAr' = 2,6-di-*tert*-butylphenoxide (from Ref. 43).

complexes is thought in part to be due to initial homolysis of the metal alkyl bond leading to a radical chain process.[49,50] Hence the impression that metal–alkyl bonds are thermally unstable on these metals. Strong support from a mixture of general chemical considerations and labelling studies is available to show that radicals are not generated during the above cyclometallations.

For example, the thermolysis of $Ta(OAr')_2(CH_3)_3$ in C_6D_6 or $C_6D_5CD_3$ does not result in the formation of any CH_3D, only CH_4 being generated (Scheme IV).[43] Similarly homolytic bond scission during the γ-CH bond activation of $Cp^*_2Th(CH_2SiMe_3)_2$ is ruled out by the observations that no deuterium incorporation into the Me_4Si group occurs when the reaction is carried out in cyclohexane-d_{12}.[30] Strong support against homolytic initiation is also obtained by studying the thermal stability of electronically identical complexes, only some of which do undergo cyclometallation. Hence, although the complexes $R_2M[N(SiMe_3)_2]_2$(M=Zr, Hf) readily lose alkane at 160°C *in vacuo* to form the dimeric, γ-metallated complex (Scheme II),[38] the titanium analogue is thermally stable at 190°C for extended periods.[38] The lack of metallation in this complex will be discussed later. However, the important point is that the metal–carbon bond in these systems does not undergo homolysis under conditions where cyclometallation does not occur. In fact it is generally accepted that the Ti–R bond is significantly weaker than the alkyl bond to its 2nd and

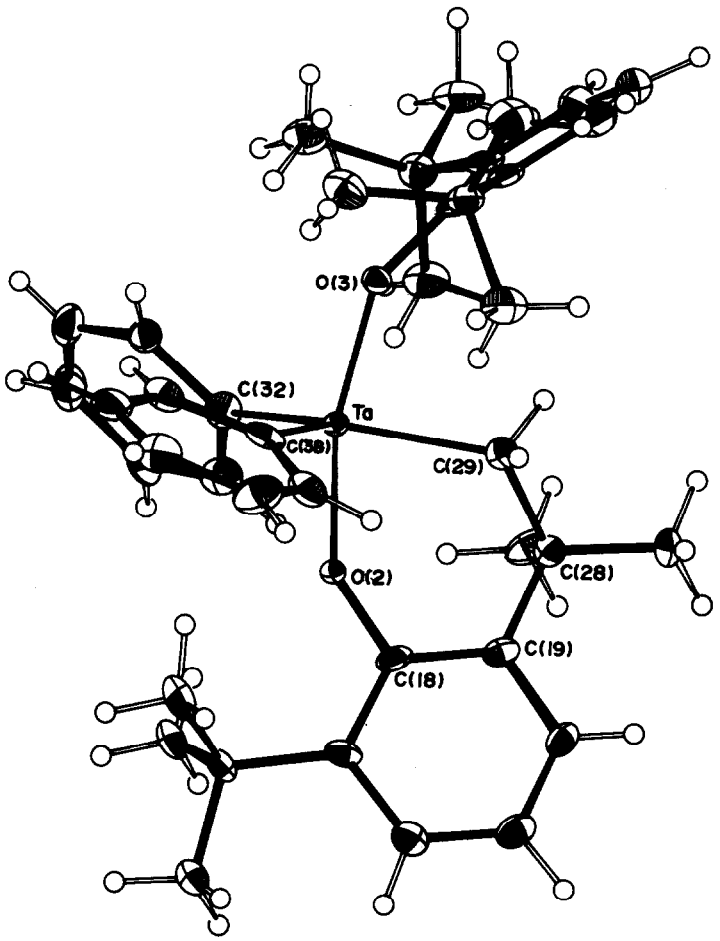


Fig. 3. An ORTEP view of the monocyclometallated complex $\overline{Ta(OC_6H_3Bu^tCMe_2CH_2)}(OAr')(Ph)_2$ emphasizing the six-membered chelate ring generated on metallation of the OAr' ligand.

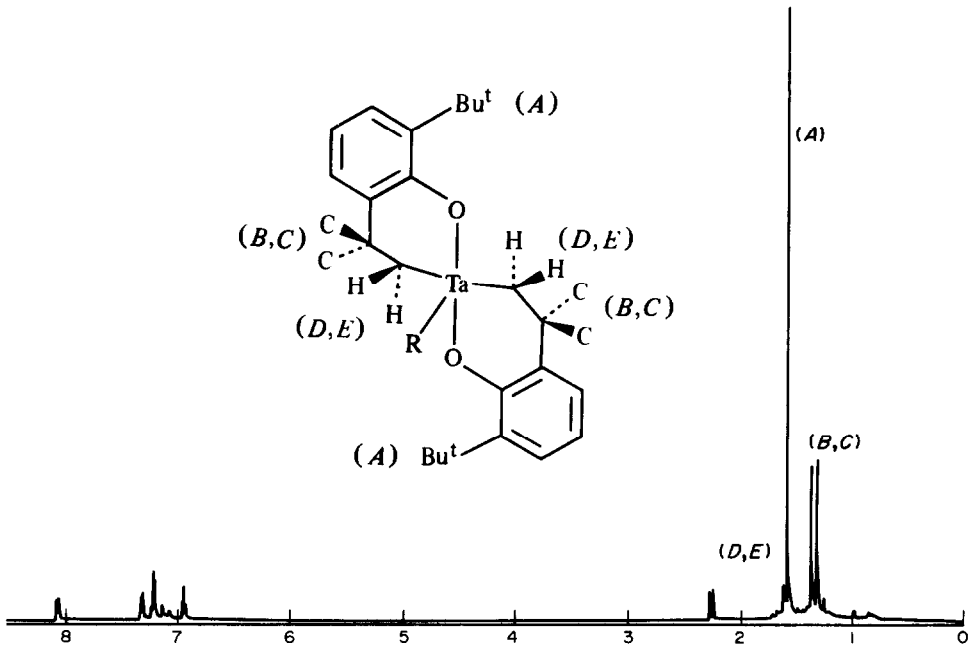

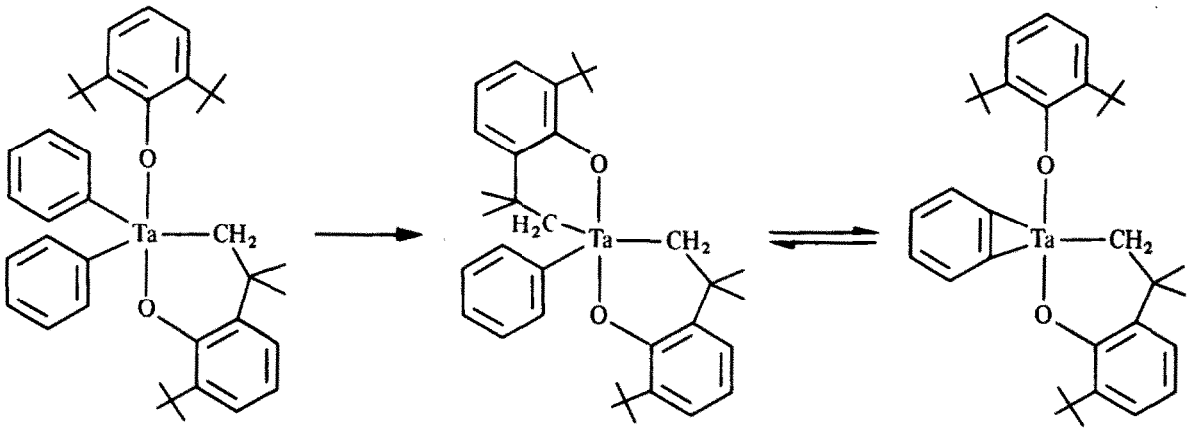

Fig. 4. Expected structure and the ^1H NMR spectrum of the bis-cyclometallated complex $\overline{Ta(OC_6H_3Bu^tCMe_2CH_2)_2}(Ph)$. Due to the molecular symmetry the metallated methylene protons appear as AB patterns while the CMe_2CH_2 methyl groups in the chelate ring are non-equivalent.

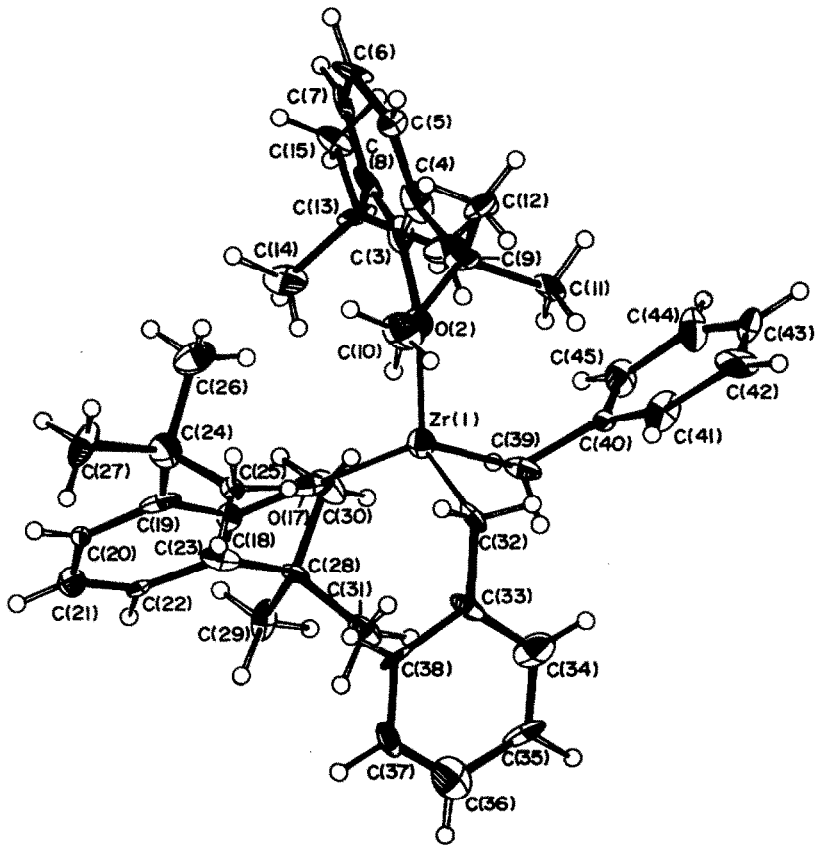
Scheme VI. The thermal reactivity of the complex $Ta(OC_6H_3Bu^tCMe_2CH_2)(OAr')(Ph)_2$ showing high temperature equilibrium with a benzyne (*o*-phenylene) complex (from Ref. 47).

3rd row congeners.[51] Again although the complex $Ta(OAr')_2(CH_3)_3$ undergoes thermal metallation, the complexes $Ta(OAr^*)_2Me_3$(OAr^* = 2,6-di-isopropylphenoxide; 2,6-dimethylphenoxide) are thermally stable for large periods of time, no CH_3D being given in deuterated solvents.[52] Hence the Ta–CH_3 bond in a mononuclear TaO_2C_3 environment is not inherently unstable and is only lost when groups that can be cyclometallated are present.

2. *Multicenter pathway*

It is now generally accepted that both α- and β-hydrogen abstraction in metal alkyl complexes occurs via a four-center transition state. This type of pathway for more distal CH bond activations



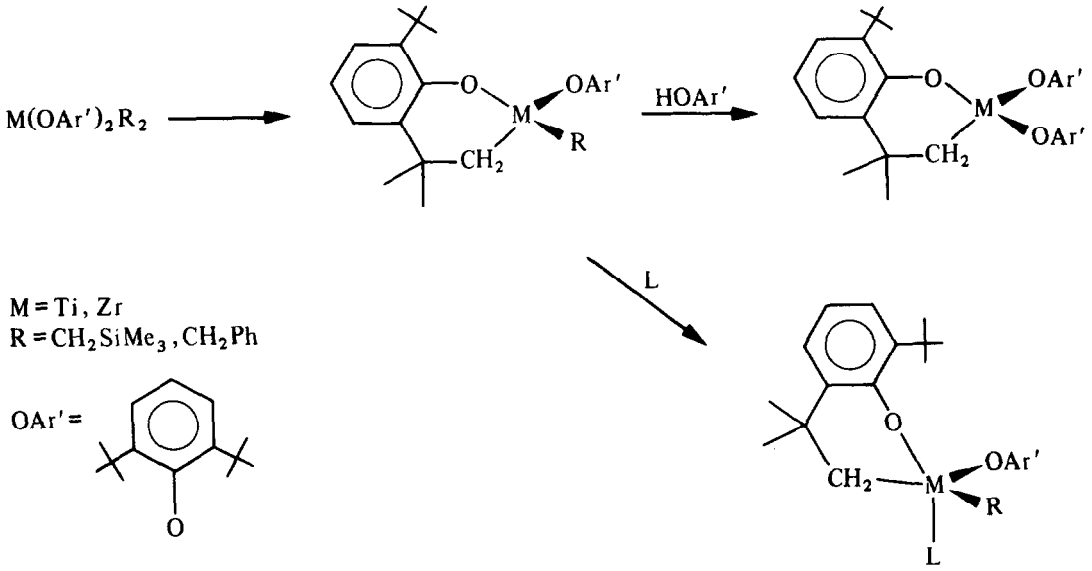


Fig. 5. An ORTEP view of the molecule $Zr(OAr')_2(CH_2Ph)_2$. Some pertinent bond distances (Å) and angles (°) are: Zr–O = 1.93(av), Zr–C = 2.25(av), Zr–O–C = 172(av).

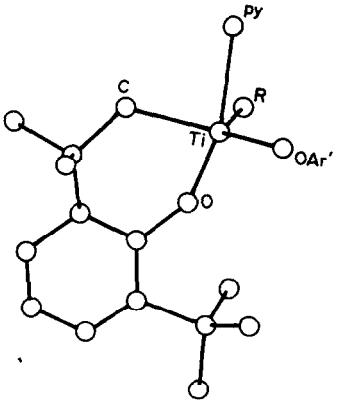
Scheme VII. Reactivity of the complexes $R_2M(OAr')_2$(M = Ti, Zr; R = CH_2Ph, CH_2SiMe_3; OAr' = 2,6-di-*tert*-butylphenoxide).

at d^0-metal configurations is not preferred just by default, evidence being against the homolytic path. On the contrary, there is now kinetic data and other evidence in direct support of this pathway.

Marks *et al.* have reported a kinetic study of the γ-CH bond activation during the thermolysis of complexes $C\overset{*}{p}_2Th(CH_2XMe_3)_2$(X = C, Si) (Reaction 11).[30] Quantitatively monitoring the reaction by ^1H NMR showed first-order kinetics, the neopentyl group ring closing faster than the silicon analogue. Activation parameters are collected in Table 1. Similar measurements by our group at Purdue on the cylometallation of 2,6-di-*tert*-butylphenoxide have been carried out on reactions at Ta, Ti and Zr metal centers (Table 1).[42,52] On tantalum we have compared the kinetics of the first and second ring closure reactions (Scheme III). A series of kinetic runs on the two complexes $M(OAr')_2(CH_2Ph)_2$ have also been made (Scheme VII). An example of a first-order plot for the titanium complex and also a plot of ln (k/T) vs $T^{-1}(K^{-1})$ are given in Figs. 7 and 8. Activation parameters using either Arrhenius or Activated Complex Theory are collected in Table 1.

One characteristic of all four reactions is the presence of a negative value for the entropy of activation. In the case of the four-coordinate complexes this value is both large and negative. These entropy changes suggest the presence of a highly ordered transition state and can be compared with the large, positive values found for the cyclometallation of neopentyl groups on Pt(II).[29] Here,



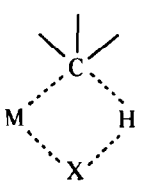


Fig. 6. A representation of the geometry found in the solid state for the complex $Ti(OC_6H_3Bu^tCMe_2CH_2)(OAr')(CH_2SiMe_3)(py)$ showing only the chelate ring and donor atoms of the other ligands. Some pertinent bond distances (Å) are: Ti–O (chelate) = 1.810(4), Ti–OAr' = 1.850(4), Ti–C (chelate) = 2.095(6), Ti–CH_2SiMe_3 = 2.131(6), Ti–N(py) = 2.293(5).

Whitesides has interpreted the data as indicative of a rate-determining reductive elimination of alkane from the Pt(IV) hydridoalkyl formed by oxidative-addition of the γ-CH bond.[29] These entropy changes (Table 1) are hence further evidence against a dissociative or homolytic pathway, the transition state clearly could not represent a process *decreasing* the coordination environment of the metal. A multicenter pathway is hence implicated. In the example shown (20)

(20)

the four-center transition state involves four-electrons, two each from the CH bond to be broken and the M–X bond of the leaving group. Evidence that the CH bond is being broken in the transition state comes from the observation of large kinetic isotope effects, e.g. a k_H/k_D of 9.7 for reaction 15a. Consideration of this type of transition state allows one to make certain assumptions concerning the nature of complexes that will undergo such cyclometallations.

(i) *Ligand geometry*. Clearly this mechanistic pathway requires the CH bond that is to be activated to come into close proximity of the metal and the eventual leaving group. This requires not only the correct geometry for the ligand, but also in order to force the CH bond onto the metal one requires steric bulk. This necessity for steric bulk in the metal coordination sphere can be seen by considering the distal cyclometallation reactions outlined above. The recognition that steric pressure is essential for mild cyclometallation was recognized early by Cope *et al.* and later successfully exploited by Shaw and others in order to design, with some rationality, ligands that would more readily cyclometallate.[54]

The rationale for this steric dependence has been argued to be entropic. As early as 1915 it was recognized that ring closure reactions for organic molecules were enhanced by the presence of substituents on the carbon skeleton.[55] This phenomenon is referred to as the "gem-dimethyl" or "Thorpe–Ingold" effect.[55,56] In the case of cyclometallation reactions it can be argued that the attainment of the highly restrictive transition state in which the ligand geometry is effectively "trapped" represents a severe loss of entropy over the ground state in which the ligand is free to move. Restricting the movement of the ligand in the ground state by introducing considerable bulk both on the ligand and in the coordination sphere will hence reduce this entropic loss. The faster rate of cyclometallation of the complex $Ti(OAr')_2(CH_2Ph)_2$ over its zirconium analogue can be seen from Table 1 to be entropic in nature. This can be rationalized if one considers the coordination sphere about each metal. Although the four ligands are identical, Ti–X bonds are consistently

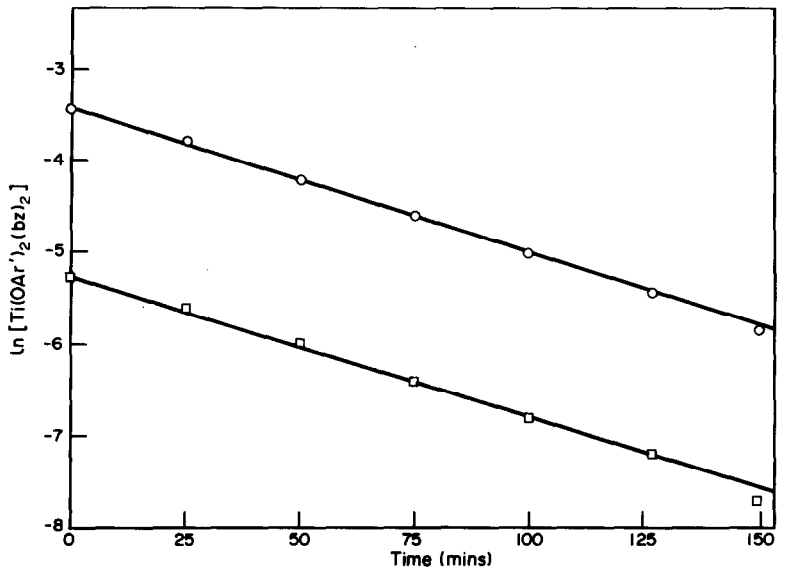

Fig. 7. First-order plot for the disappearance of $Ti(OAr')_2(CH_2Ph)_2$ at 95°C to generate the mono-cyclometallated complex (Scheme VII). Initial concentrations are 0.032M(2) and 0.005(1).

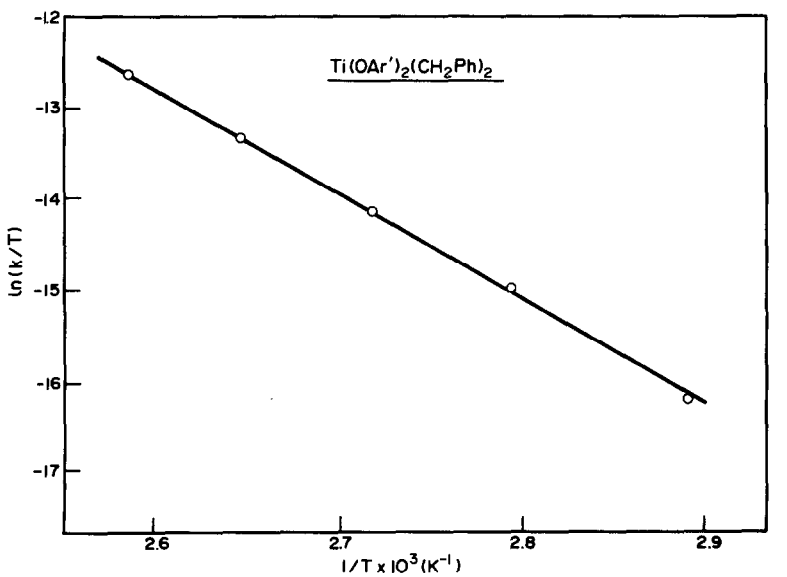
0.1–0.2A shorter than Zr–X bonds. Hence, the coordination sphere is contracted in the titanium complex. This will have the effect of not only "pulling in" the CH bond to be metallated, but also making ring closure easier.

However, the presence of too much bulk in the coordination sphere, or bulk of the wrong type, can be a hindrance and not a help in some situations. In the complexes $R_2M[N(SiMe_3)_2]_2$ (M=Ti, Zr, Hf) only the 2nd and 3rd row elements undergo thermal metallation.[38] It can be argued that the more compact coordination sphere of the titanium complex "cuts off" the γ-CH bond from the metal, not allowing it access to the metal center for activation. The possibility that these reactions may occur inter-molecularly due to the dimeric nature of the products is an uncertainty in considering the mechanism.

(ii) *Leaving group.* If one carries out a rough thermodynamic assessment of the transition state one can see that one is forming a new M–C bond along with an H–X bond. This is occurring at



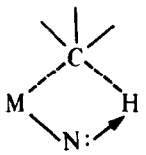


Fig. 8. Plot of $ln\ (k/T)$ vs $T^{-1}(K^{-1})$ for the cyclometallation of OAr' in $Ti(OAr')_2(CH_2Ph)_2$ (see Table 1).

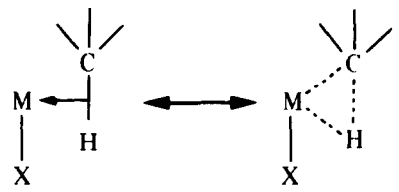
the expense of the C–H and M–X bonds. If one considers alkyl leaving groups, i.e. X=R, then the equation appears pretty well balanced. From the data in Table 1, it can be seen for the complexes $M(OAr')_2(CH_2Ph)_2$(M=Ti, Zr) that there is little enthalpic difference to the reaction, despite the fact that Zr–CH_2Ph bonds are known to be at least 10 kcal mol^{-1} stronger than the Ti–CH_2Ph bond.[51] This is entirely consistent with the four-center transition state, as one is both making and breaking M–C bonds. Hence, as for a given alkyl the bond strengths run approximately parallel down a triad, it is not surprising to find little difference in $\Delta H\ddagger$ for these two reactions.

This thermodynamic consideration may also explain why, unlike GpVIII cyclometallation reactions, halide ligands do not appear to be good leaving groups for this type of reaction. Even accounting for back reactions between the cyclometallated product and the generated HX(X=Cl, Br), early transition metal halides do not readily undergo cyclometallation reactions. For example, thermolysis of the compounds $Ta(OAr')_2Cl_3$, $Ti(OAr')_2Cl_2$ and $M(OAr')_3Cl$ (M=Ti, Zr, Hf) under vacuum at temperatures of 170–200°C causes no reaction except sublimation.[52] One explanation is that the halide group is sterically very small. However, the complexes $M(OAr')_3Cl$ are extremely crowded and for M=Ti, Zr the metallated complexes $M(O\text{-}CH_2)(OAr')_2$ can be independently synthesized (19). This lack of metallations involving halide groups can be explained by the high strength of the M–Cl bond for early transition metals. This bond has a dissociation energy of 100–120 kcal mol^{-1} compared to 45–60 kcal mol^{-1} for alkyl groups bound to the same metal. The reaction appears, therefore, to be enthalpically inhibited.

A similar rationale can be applied to the use of alkoxide or dialkylamide leaving groups, but a complexity is present for these hetero-atom donor leaving groups. The four center transition state indicated (20) does not have any net charge. However, the charge distribution *within* the trapezoid is not indicated. Clearly this will depend on the electronegativity of the elements involved. For X=C one imagines a rather uniform distribution of charge. In the case of OR and NR_2 leaving groups, the availability of lone-pairs on the donor atom is an added complexity. This is illustrated (21).



(21)

In effect the pathway, although still multicenter, is now appearing to be highly electrophilic in character in which the metal activated CH bond is protonating the lone pair of the leaving group (base). One is then left with a coordinated alcohol or amine after the ring closure is complete. This pathway is the reverse of the alcoholysis or aminolysis of metal–carbon bonds.[57] Enthalpically the situation is now difficult to assess, because the bond to the leaving group has not been completely broken. However, structural data clearly show that on d^0-metal centers bond lengths to coordinated alcohols and amines are much longer than to alkoxides and amides[58] so that the bond has been considerably weakened by its protonation.

Analysis of the postulated transition state also helps understand the high activity of alkylidene groups for intramolecular CH bond activation (Scheme IV). Although entropic factors will be similar, the new metal–carbon bond will be formed only at the expense of the π-component of the M=C bond. Hence enthalpically the situation appears more favourable than simple alkane for alkyl exchange.

(iii) *The metal.* Clearly the metal center must have available to it empty orbitals of the correct symmetry with which to interact with the CH bond in the transition state. This is not a problem with most early transition metal d^0-compounds. There is a large body of evidence, both structural and spectroscopic, that it is possible for CH bonds to act as two-electron donating groups to electron deficient metal centers.[59,60] This typically is found where the metal would be two electrons short of attaining a stable, 18-electron count. More recently work by Green has shown that such interactions are possible in the ground state to d^0-metal centers such as Ti(IV).[61,62] In particular, strong interaction to the α- and β-CH bonds was structurally characterized. It is hence reasonable to assume that this may be the initial type of interaction between the electron deficient metal and the CH bond to be activated (22).

(22)

This three-center, two-electron bond then weakens the CH bond and leads into the four-center transition state in which the hydrogen atom is transferred to the leaving group.

The solid state structure of the complex $Yb[N(SiMe_3)_2]_2$ (dmpe) has been found to contain an interaction between one of the methyl groups and the metal in the ground state.[63] The hydrogen atoms on this group were refined and shown to be pointing *away from* the metal center in contrast to situations with *d*-block metals where M . . . HC type interactions are prevalent. The structure was interpreted in terms of the CH_3 group bridging between the Yb metal atom and Si atom, there being considerable lengthening of the Si–CH_3 bond (Fig. 9). The implications of this observed ground state structure on the known γ-CH bond activation in this ligand is that one would expect the Yb–CH_3 interactions to increase the acidity of the γ-hydrogens. This would allow the reaction to proceed in a transfer of the acidic hydrogen to the leaving group. All evidence so far available does not point to a process in which the leaving hydrogen is lost *exo* to the complex, i.e. to an external base similar to an S_E2 process.

In the solid state structure of complexes containing the 2,6-di-*tert*-butylphenoxide (OAr′) ligand, it is typically found that one of the CH bonds of the *tert*-butyl groups is pointing almost directly at the metal center. In the case of the complex $Ta(OAr')_2Me_3$ distances range from 2.8 to 3.0A while in the chloride $Ta(OAr')_2Cl_3$ (Fig. 10) one of the CH bonds seems to "occupy" the position *trans* to the axial chloride in a square based pyramidal structure. The Ta–H distance was refined to 2.67A. Although it is very doubtful that any significant ground state interaction is taking place in these complexes, the attainment of a multicenter transition state between the metal and these CH bonds is clearly very feasible.

Another factor to consider is the influence that the ancillary ligands have on both the energy and availability of metal orbitals with which the CH bond can interact. This is a difficult effect to evaluate even qualitatively. However, one would predict that ligands that reduce the electron deficiency of the metal center, e.g. strong π-donor ligands such as NR_2, will tend to inhibit interactions to CH bonds.

IV. INTERMOLECULAR CH BOND ACTIVATION

1. *Mechanistic considerations*

Unlike in the previous sections where mechanism was considered last, it is useful to reverse the situation for intermolecular hydrocarbon activation just so that one can see what one is up

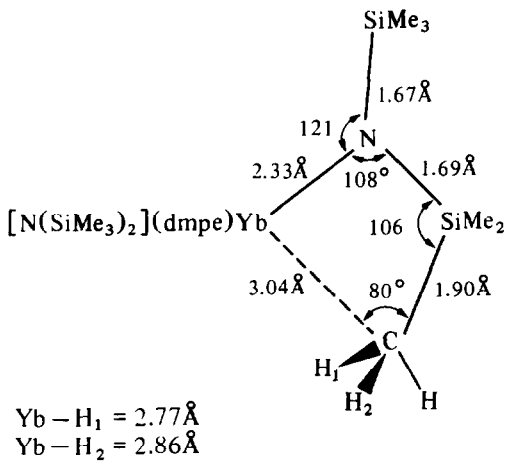


Fig. 9. Representation of the Yb–CH_3 ground state interaction found in the solid state structure $Yb[N(SiMe_3)_2]_2$ (dmpe) (dmpe = $Me_2PCH_2CH_2PMe_2$) (from Ref. 63).

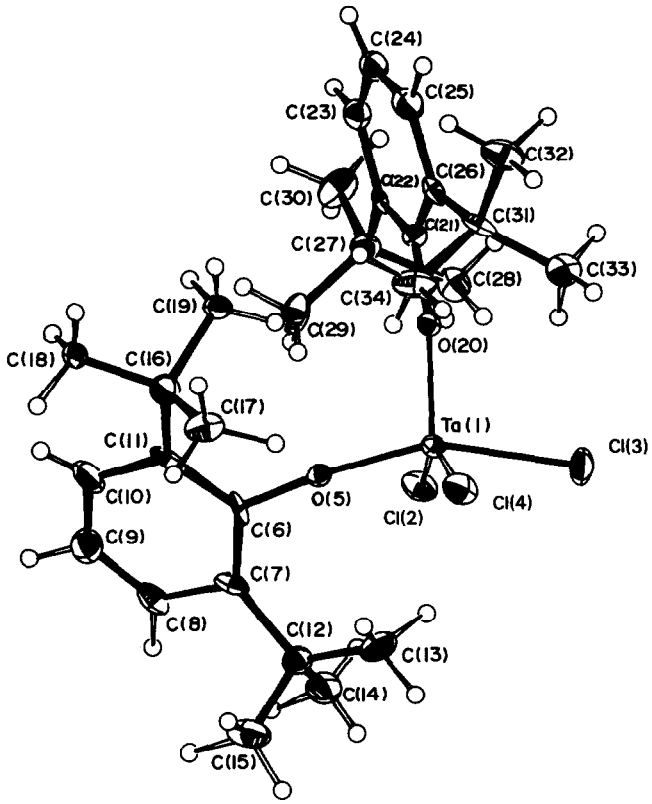

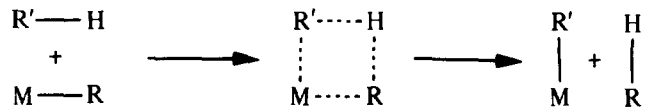

Fig. 10. An ORTEP view of the molecule $Ta(OAr')_2Cl_3$ showing the close approach of an ϵ-CH bond to the axial position of a square-pyramidal geometry.

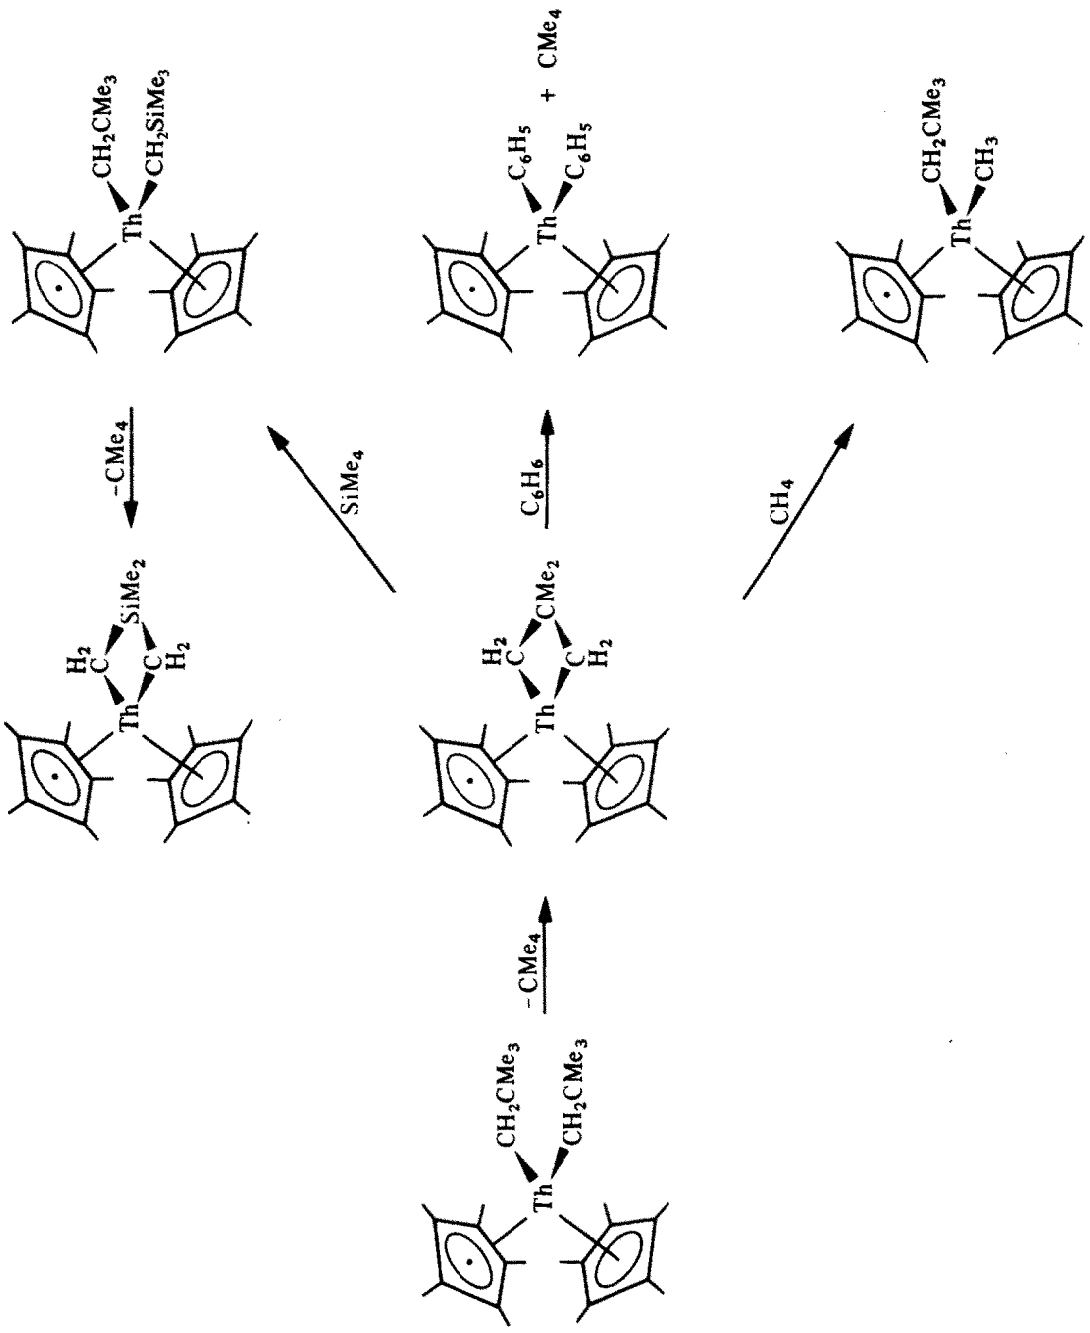
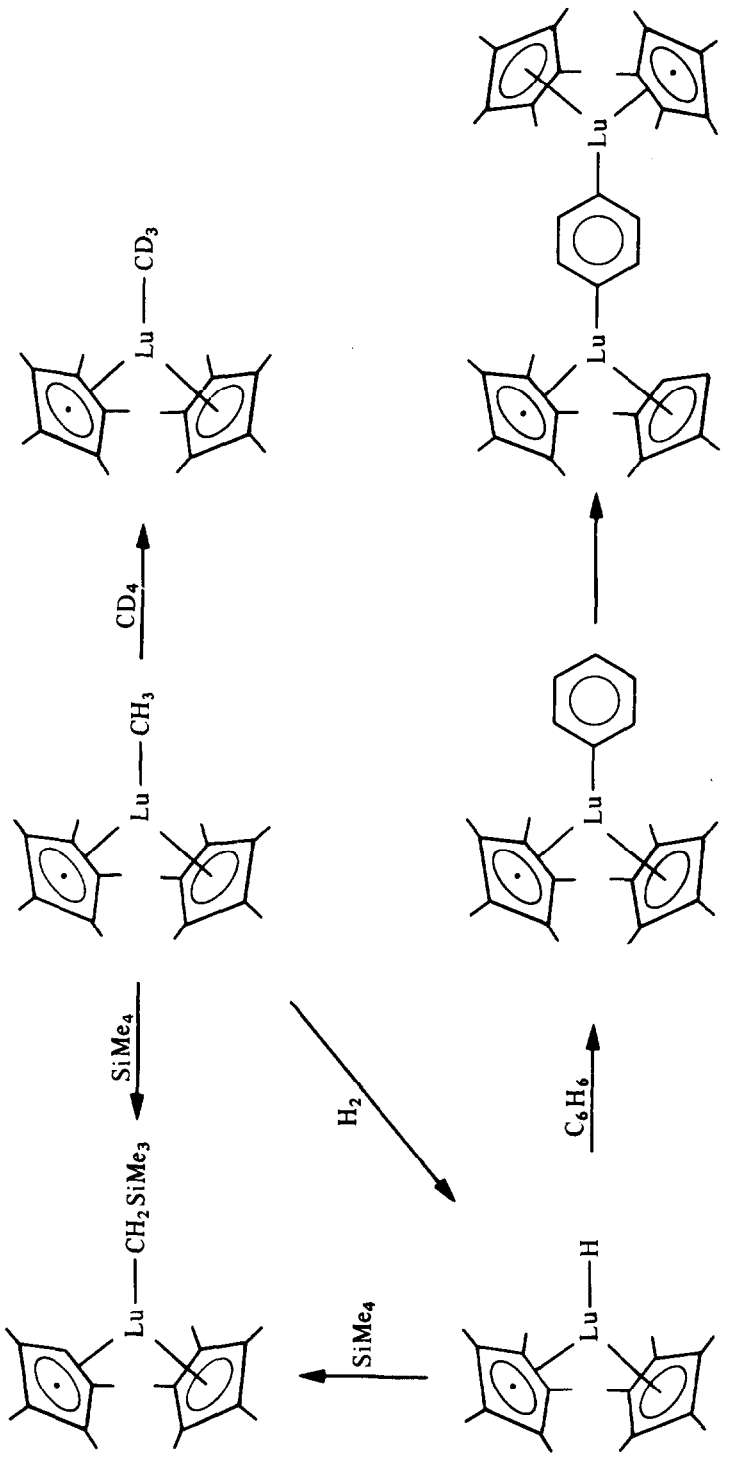
against. Extrapolating from the results for cyclometallation reactions it is possible to envisage how a d°-metal center might activate a CH bond in a normally inert hydrocarbon. Initially, the CH bond must enter the coordination sphere of the metal, interact with one of the metal orbitals and then progress through a transition state in which the new metal–carbon bond is formed and the hydrogen atom is lost with the leaving group (23).

(23)



From the previous discussions one would clearly choose an alkyl leaving group on enthalpic grounds, and the overall reaction would hence represent an alkyl exchange. Clearly what is against the intermolecular reaction is its bi-molecular nature and the strongly negative values of $\Delta S\ddagger$ one might expect in order to achieve the transition state.

An intermolecular reaction which is of direct relevance to this problem is the hydrogenolysis of d°-metal alkyl complexes.[64] This is now a common reaction and one of excellent synthetic utility.[65,66] The mechanism of this reaction has been discussed and proposed to be via a four-center transition state.[67,68] The more extensively documented reactivity of H_2 with d°-metal alkyls over alkyl exchange reactions may be a reflection of the steric differences between H_2 and alkane CH bonds. In terms of electron donating ability one predicts that CH bonds would be superior to H_2 due to the latter's higher ionization potential.[69]



The systems that successfully activate hydrocarbons are small and can be discussed individually.

2. *Activation of aromatic* CH *bonds by benzyne intermediates*

Any reaction in which aromatic CH bonds are activated represents a somewhat special case due to the presence of the aromatic π-bonds with which the molecule can initially bond to the d°-metal allowing the CH bonds to come into close proximity with the metal for activation.

Scheme VIII. Activation of sp^2- and sp^3-CH bonds by Cp^*_2Th derivatives (from Refs. 30 and 72).

Scheme IX. Activation of hydrocarbons by derivatives of Cp^*_2Lu (from Refs. 73–75).

Erker has demonstrated that the thermal formation of benzyne groups from the complexes Cp_2MAr_2 (Reaction 7) (M=Ti, Zr) is reversible. Hence the thermolysis of bis-tolyl derivatives in benzene results in the formation of mixed phenyl, tolyl derivatives. Direct exchange of aromatics can be ruled out. The final products were analyzed by photolysis and characterization of the generated biphenyl molecules.[70]

Marks has demonstrated similar reactivity for the uranium complex $C\overset{*}{p}_2U(C_6H_5)_2$. Thermolysis in C_6D_6 generates the complex $C\overset{*}{p}_2U(C_6H_4D)(C_6D_5)$, the deuterium being incorporated into the ortho-position. Under identical conditions the uranium complex undergoes benzene exchange approximately 10^2 times faster than $Cp_2Zr(C_6H_5)_2$.[71] In both of these reactions the CH bond is inserting into the highly strained metal–carbon bond of a metallocyclopropane ring.

Although a benzyne complex has been shown to be able to reversibly activate aliphatic CH bonds intramolecularly (Scheme VI),[47] the intermolecular generation of an alkyl, aryl complex by reaction of a benzyne complex with an alkane has yet to be documented.

3. *Hydrocarbon activation by* $C\overset{*}{p}_2\overline{Th(CH_2CMe_2CH_2)}$

As mentioned previously, Marks *et al.* have demonstrated that complexes containing thoracyclobutane rings can be prepared by thermolysis of the complexes $C\overset{*}{p}_2Th(CH_2XMe_3)_2$ (X=C, Si) (Reaction 11).[30] The neopentyl derivative $C\overset{*}{p}_2\overline{Th(CH_2CMe_2CH_2)}$ undergoes a number of intermolecular reactions with hydrocarbons (Scheme VIII).[72] Benzene reacts to yield the di-phenyl compound with overall loss of neopentane. The first step of the reaction represents a ring opening reaction, in which the aromatic CH bond is activated. The second step may involve direct aryl for alkyl exchange, or else proceed via a benzyne intermediate. The use of toluene yields a 75/25 mixture of aromatic and benzylic products.[30]

The thoracyclobutane ring can also activate Me_4Si and even methane itself.[72] The products are initially the mixed alkyl, neopentyl derivatives but in the case of Me_4Si a further ring closure occurs to generate the metallo-silacyclobutane ring (Scheme VIII). This silicon analogue does not undergo any of these ring opening reactions. The rationale for this is the decrease in ring strain due to the longer C–Si bonds. Accurate thermochemical measurements[72] indicate a difference in ring strain of 10 kcal mol^{-1} for these metallocycles giving much more driving force for the hydrocarbon activation by $C\overset{*}{p}_2\overline{Th(CH_2CMe_2CH_2)}$.

4. *Hydrocarbon activation by* $C\overset{*}{p}_2LuR$(R=H, Me)

In a series of papers[73–75] Watson has reported the remarkable organometallic chemistry of complexes containing the $C\overset{*}{p}_2Lu$ unit. Both inter- and intra-molecular activation of sp^2 and sp^3 CH bonds can take place (Scheme IX).[74] Perhaps the most remarkable reactivity involves the observation of methane exchange on the complex $C\overset{*}{p}_2LuMe$.[75] This reaction occurs readily at 70°C in cyclohexane-d_{12} and can be followed by ^1H and ^{13}C NMR using labelled methane ($^{13}CH_3$). A similar reactivity was noted for the yttrium analogue. Kinetic studies showed the reaction to be first-order in methane and a four-center transition state was proposed.

Both the complexes $C\overset{*}{p}_2M(CH_3)$(M=Lu, Y) exist as assymetric dimers in the solid state containing one bridging methyl group. The Lu–Me–Lu angle was determined to be almost linear by X-ray diffraction and can be pictured as an Lu–CH_3 group acting as a two electron donor to the other metal through one of the CH bonds. One can imagine this interaction to be a model of the initial methane–Lu interaction that eventually leads to alkane exchange.

VI. CONCLUDING REMARKS

The ability of d^0-metal centers to activate, cleave and in some cases functionalize normally inert CH bonds has clearly been demonstrated. All present mechanistic data can be accommodated into a multicenter transition state in which the new metal carbon bond is formed at the direct expense of a metal–ligand (leaving group) bond. The future for hydrocarbon activation at d^0-metal centers appears bright, especially in view of the recently demonstrated mild activation of even methane itself.

POLAROGRAPHIC STUDY OF Eu(III)-SUCCINATE-ETHYLENEDIAMINE AND Eu(III)-MALONATE-ETHYLENEDIAMINE MIXED SYSTEMS

MADHU SHIVHARE and MUKHTAR SINGH*
Chemistry Department, Agra College, Agra 282002, India

(*Received* 1 *November* 1983, *accepted after revision* 16 *April* 1984)

Abstract—The mixed complexes of Eu(III) with succinate ($succ^{2-}$) and malonate (mal^{2-}) and ethylenediamine (en) have been studied polarographically at 25°C and at constant ionic strength, μ = 0.1 ($NaNO_3$) and pH 6. The reduction of the complexes in each case is quasi-reversible and diffusion-controlled. In each system three mixed complexes are formed, viz. $[Eu(succ)(en)]^+$, $[Eu(succ)(en)_2]^+$ and $[Eu(succ)_2(en)]^-$ with stability constants $\log \beta_{11}$ = 9.2, $\log \beta_{12}$ = 17.5 and $\log \beta_{21}$ = 11.7; and $[Eu(mal)(en)]^+$, $[Eu(mal)_2(en)_2]^-$ and $[Eu(mal)_3(en)]^{3-}$ with stability constants $\log \beta_{11}$ = 11.4, $\log \beta_{22}$ = 19.08 and $\log \beta_{31}$ = 13.5 respectively.

Macero *et al.*[1,2] studied polarographically the formate and acetate complexes of Eu(III). Zutshi[3] reported results on Eu(III)-benzoate and salicylate complexes in formamide water mixtures. Holleck[4] reported complexation of Eu(III) with citrate, tartrate, salicylate and lactate ions. Onstott[5] studied the polarographic behaviour of Eu(III) in the presence of ethylenediamine tetraacetic acid (EDTA) and concluded that the formation of different complex species is pH dependent. Tananaeva and Kostromina[6] also studied polarographically the complexing of Eu(III) with EDTA at different pH values. Lal[7–9] has studied polarographically the complexation of Eu(III) with some amino acids viz. L-proline, DL-tryptophan and L-histidine. In all these systems the reduction of Eu(III) is quasi-reversible and diffusion-controlled. Eu(III) forms two successive complexes with L-proline, while a single complex is formed each with DL-tryptophan and L-histidine. A critical examination of the work of Lal, however, shows that while computing the values of stability constants the total (analytical) concentration has been considered instead of the free ligand concentration which ought to have been calculated from the pH of the solution and pK_a of each amino acid. Very recently, Rao and Singh[10] have reported that for the system Eu(III)-crotonic/acrylic acid while the reduction of Eu(III) is quasi-reversible in 1.0 M $NaClO_4$, the Eu(III) complexes with these acids are reduced reversibly at d.m.e. Bhansali and Nemade[11] have reported a polarographic study of Eu(III)-hydroxamic acid complexes. In both hydroxamic acids—phenyl acetohydroxamic acid (PAHA) and acetohydroxamic acid (AHA)—the polarographic reduction of Eu(III) has been found to be quasi-reversible and diffusion-controlled.

From the foregoing survey of the literature it is evident that the mixed complexes of Eu(III) with carboxylate ions and ethylenediamine have not been studied polarographically so far. The present paper therefore reports our results of polarographic study on Eu(III)-succinate-ethylenediamine and Eu(III)-malonate-ethylenediamine mixed systems.

EXPERIMENTAL

All the chemicals used were of A.R. grade. Ethylenediamine was A.R., BDH product and its stock solution was prepared in doubly distilled water. Stock solution (0.025 M) of Eu_2O_3 (Sigma, U.S.A.) was prepared by dissolving the oxide in the minimum amount of perchloric acid and diluting it with doubly distilled water. The concentration of Eu_2O_3 was kept constant at 0.5×10^{-3} M in each case. Potassium salts of succinic and malonic acids were used as the source of $succ^{2-}$ and mal^{2-} ions. The ionic strength was maintained constant at $\mu = 0.10$ ($NaNO_3$). Polarograms were obtained by means of a manual polarograph (Toshniwal CL 02) in conjunction with Toshniwal polyflex galvanometer (PL 50). Throughout the measurements

*Author to whom correspondence should be addressed.

the current at the end of the drop (i.e. the maximum current) was recorded. Purified nitrogen was used for removing the dissolved oxygen. All the measurements were made at 25 ± 0.1°C. Saturated calomel electrode (S.C.E.) was used as reference electrode. The d.m.e. had the following characteristics (0.1 M $NaNO_3$, open circuit): m = 3.98 mg/sec, t = 2.2 sec, $m^{2/3}\ t^{1/6}$ = 2.90 $mg^{2/3}\ sec^{-1/2}$, h_{corr} = 55 cms.

RESULTS AND DISCUSSION

The reduction of Eu(III) in succinate, malonate and ethylenediamine media separately, was found to be quasi-reversible and diffusion-controlled. The same was true in the case of the mixed systems. The wave heights are diffusion-controlled as the plots of i_d vs $h_{corr}^{1/2}$ are linear and pass through the origin. The stability constants of simple complexes of Eu(III) with succinate, malonate and ethylenediamine were determined separately prior to the study of the mixed ligand systems. Identical conditions were maintained in both the simple and mixed systems. Millicoulometric[12] studies indicate that one electron is involved in the reduction process in each case.

NATURE OF THE REDUCTION

The slopes of linear plots of $\log i/i_d - i$ vs $E_{d.e.}$ are of the order of 90 mV. The value is appreciably greater than the theoretical value of 59 mV expected for a one-electron reversible reduction process. The fact that α is greater than 0.5 at different concentrations of the ligands shows that reduction of Eu(III) is not totally[13] irreversible. The standard rate constant ($k_{s,h}$) of the electrode reaction of Eu(III) in the presence of increasing concentrations of the ligands is of the order of 1×10^{-3} cm/sec. This clearly[14] shows that the reduction of Eu(III) is quasi-reversible in the presence of increasing concentrations of the ligands. The reversible half-wave potential ($E'_{1/2}$) was determined by Gellings method.[15]

The pK_1 and pK_2 values of ethylenediamine at 25 ± 0.1°C and at $\mu = 0.1$ ($NaNO_3$) were determined by the titration method[16] using a glass electrode. These worked out to be: $pK_1 = 7.18$ and $pK_2 = 9.96$. The free ligand concentration, [en], was calculated from the pH value of the solution and pK values of the ligand.

(i) E(III)-*succinate and* Eu(III)-*malonate system*

Plots of $E'_{1/2}$ vs log [$succ^{2-}$], and vs log [mal^{2-}] are smooth curves thereby showing the formation of successive complexes. DeFord and Hume's[17] method has been applied to determine the stability constants of successive complexes. The polarographic characteristics and F_j [X] functions of Eu(III)-succinate and Eu(III)-malonate systems, respectively, are listed in Tables 1 and 2. With $succ^{2-}$, Eu(III) forms three successive complexes, viz $[Eu(succ)]^+$, $[Eu(succ)_2]^-$ and $[Eu(succ)_3]^{3-}$ with stability constants, log $\beta_1 = 2.9$, log $\beta_2 = 4.5$ and log $\beta_3 = 5.9$ respectively. With mal^{2-} Eu(III) forms four successive complexes, viz., $[Eu(mal)]^+$, $[Eu(mal)_2]^-$, $[Eu(mal)_3]^{3-}$ and $[Eu(mal)_4]^{5-}$ with stability constants log $\beta_1 = 4.1$, log $\beta_2 = 5.6$, log $\beta_3 = 6.6$ and log $\beta_4 = 8.5$ respectively.

(ii) Eu(III)-*ethylenediamine system*

Plot of $E'_{1/2}$ vs log [en] is a straight line thereby showing the formation of single complex species. The composition and stability constant of this species have been determined by Lingane's[18] method. The composition of the complex works

Table 1. Eu(III)-succinate system. $[Eu^{3+}] = 0.5 \times 10^{-3}$ M; $\mu = 0.1$ ($NaNO_3$); pH 6; temp. = 25 ± 0.1°C

out to be $[Eu(en)_2]^{3+}$ with stability constant log $\beta_2 = 14.4$.

(iii) Eu(III)-*succinate-ethylenediamine mixed system*

The concentration of succinate was varied from 0 to 0.1 M keeping [en] constant at 0.72×10^{-7} M. The $E_{1/2}$ values were more negative than those obtained in the absence of en (Table 4) thereby showing the formation of mixed complexes. The system was repeated at another concentration of en (1.47×10^{-7} M). The method of Schaap and McMasters[19] was used to determine the composition and stability constants of the mixed complexes. The polarographic characteristics and F_{ij} [X, Y] functions (X = $succ^{2-}$, Y = en) of this system have been presented in Table 5. From the plots of F_{ij} [X, Y] data vs [$succ^{2-}$] the following intercept values for constants A, B, C and D are obtained.

For series 1: log A = 0.30, log B = 3.20, log C = 4.84 and log D = 6.11.

For series 2: log A = 0.90, log B = 3.57, log C = 5.0 and log D = 6.21.

The stability constants have been calculated from these constants. Three mixed complexes, as noted below are formed:

$[Eu(succ)(en)]^+$; $\log \beta_{11} = 9.2$
$[Eu(succ)(en)_2]^+$; $\log \beta_{12} = 17.5$
$[Eu(succ)_2(en)]^-$; $\log \beta_{21} = 11.7$.

The results of the present study are summarised in the following diagram where the numerical values shown are the equilibrium constants for the reactions indicated:

The mixing constant (K_m) for the reaction

$$1/2[Eu(succ)_2]^- + 1/2[Eu(en)_2]^{3+} \rightleftharpoons [Eu(succ)(en)]^+$$

is given by the relation

$$\log K_m = \log \beta_{11} - 1/2(\log \beta_{20} + \log \beta_{02}).$$

This works out to be +0.5. The positive value of log K_m indicates that the mixed complex $[Eu(succ)(en)]^+$ is more stable than the parent binary complexes, $[Eu(succ)_2]^-$ and $[Eu(en)_2]^{3+}$.

The equilibrium constants for the following disproportionation reactions

$$2[Eu(succ)(en)]^+ \rightleftharpoons [Eu(succ)_2]^- + [Eu(en)_2]^{3+} \quad (1)$$

$$2[Eu(succ)_2(en)]^- \rightleftharpoons [Eu(succ)_3]^{3-} + [Eu(en)_2]^{3+} + succ^{2-} \quad (2)$$

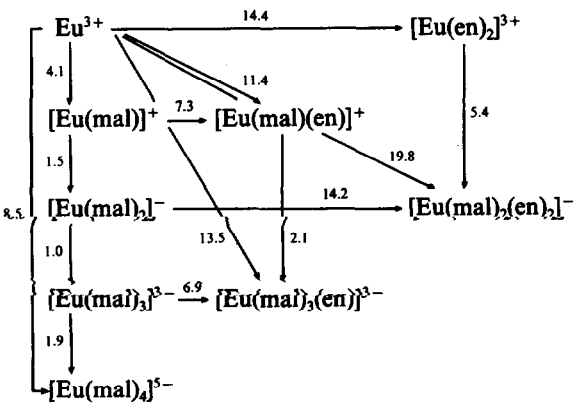
work out to be −0.5 and 3.1 respectively. The negative log value of equilibrium constant for the reaction (1) shows that the formation of mixed species, $[Eu(succ)(en)]^+$ is favoured over the binary complexes. This is in agreement with the conclusion arrived at on the basis of log K_m value. The positive log value for the reaction (2), however, shows that the mixed complex $[Eu(succ)_2(en)]^-$ is not favoured over the binary complexes.

The stability of the three mixed complexes follows the order:

$$[Eu(succ)(en)_2]^+ > [Eu(succ)_2(en)]^- > [Eu(succ)(en)]^+.$$

(iv) Eu(III)-*malonate-ethylenediamine system*

The concentration of malonate, was varied from 0 to 0.1 M keeping [en] (the free ligand concentration) constant at 0.72×10^{-7} M. The $E_{1/2}$ values were more negative than those obtained in the absence of en (Tables 2 and 5) thereby showing the formation of mixed complexes. The system was repeated at another concentration of en (1.47×10^{-7} M). The method of Schaap and McMasters was used to determine the composition and stability constants of the mixed complexes. The polarographic characteristics and F_{ij} [X, Y] functions [X = mal^{2-}, Y = en) of this system have been presented in Table 5. From the plots of F_{ij} [X, Y] data vs $[mal^{2-}]$ the following intercept values for constants A, B, C, D and E are obtained.



For series 1: log A = 0.30, log B = 4.44, log C = 5.77, log D = 6.77 and log E = 8.60.

For series 2: log A = 0.90, log B = 4.60, log C = 6.14, log D = 7.0 and log E = 8.90.

The stability constants have been calculated from these constants. Three mixed complexes, as noted below, are formed:

$[Eu(mal)(en)]^+$; $\log \beta_{11} = 11.4$
$[Eu(mal)_2(en)_2]^-$; $\log \beta_{22} = 19.8$
$[Eu(mal)_3(en)]^{3-}$; $\log \beta_{31} = 13.5$.

The results of the present study are summarised in the following diagram where the numerical values shown are the logarithms of the equilibrium constants for the reactions indicated:

The mixing constant (K_m) for the reaction

$$1/2[Eu(mal)_2]^- + 1/2[eu(en)_2]^{3+} \rightleftharpoons [Eu(mal)(en)]^+$$

is given by the relation

$$\log K_m = \log \beta_{11} - 1/2(\log \beta_{20} + \log \beta_{02}).$$

This works out to be −1.4. A negative value of log K_m indicates that the mixed complex, [Eu-

$(mal)(en)]^+$ is less stable than the parent binary complexes, $[Eu(mal)_2]^-$ and $[Eu(en)_2]^{3+}$.

The equilibrium constants for the following disproportionation reactions

$$2[Eu(mal)(en)]^+ \rightleftharpoons [Eu(mal)_2]^- + [Eu(en)_2]^{3+} \quad (1)$$

$$2[Eu(mal)_2(en)]^{3-} \rightleftharpoons [Eu(mal)_4]^{5-} + [Eu(en)_2]^{3+} + 2mal^{2-} \quad (2)$$

work out to be +2.8 and +6.0 respectively. The large positive values of equilibrium constant for the reactions (1) and (2) show that the formation of the mixed species $[Eu(mal)(en)]^+$ and $[Eu(mal)_3(en)]^{3-}$ is not favoured over the binary complexes.

The stability of the mixed complexes follows the order:

$$[Eu(mal)_2(en)_2]^- > [Eu(mal)_3(en)]^{3-} > [Eu(mal)(en)]^+.$$

POLAROGRAPHIC STUDY OF MIXED LIGAND COMPLEXES OF Pb(II) WITH CARBOXYLATE IONS AND IMIDAZOLE

MADHU SHIVHARE and MUKHTAR SINGH*
Chemistry Department, Agra College, Agra 282002, India

(*Received* 21 *November* 1983; *accepted* 16 *April* 1984)

Abstract—Mixed complexes of Pb(II) with some carboxylate ions, viz. tartrate ($tart^{2-}$), malonate (mal^{2-}) and citrate ($citr^{3-}$); and imidazole (im) have been studied polarographically at 25°C and at constant ionic strength μ = 2.0 ($NaNO_3$) and at pH 6. The polarographic reduction of the complexes in each case is reversible and diffusion-controlled. Pb(II) forms a single mixed complex with tartrate and imidazole, viz [Pb(tart)(im)] with stability constant $\log \beta_{11} = 4.19$; with mal^{2-} and im, three mixed complexes, [Pb(mal)(im)], [Pb(mal)$(im)_2$] and [$Pb(mal)_2(im)]^{2-}$ with stability constants $\log \beta_{11} = 4.3$, $\log \beta_{12} = 7.3$ and $\log \beta_{21} = 5.5$ respectively are formed. With $citr^{3-}$ and im a single mixed species, $[Pb(citr)(im)]^-$ with stability constant $\log \beta_{11} = 8.0$ is formed. Various equilibria involved in the mixed systems have been discussed.

Although the polarographic method has been widely used in single[1] ligand systems, no general discussion of the application of the method to the study of mixed-ligand complexes was published until 1961 when Schaap and McMasters[2] extended DeFord and Hume's[3] polarographic method for studying single ligand complexes. This extension of the polarographic method of DeFord and Hume by Schaap and McMasters to the study of mixed ligand complexes has opened new vistas in the field of coordination chemistry. Since then many mixed-ligand systems[4] have been studied polarographically. A survey of the literature reveals that single ligand complexes of Pb(II) with various carboxylate ions have been studied polarographically by several workers.[5–12] These carboxylate ions include acetate, formate, oxalate, tartrate, citrate, malonate, succinate, glutamate, adipate and phthalate. With most of the carboxylate ions Pb(II) forms successive complexes. The composition and stability constants of these complexes have been determined by DeFord and Hume's method. However, simple complexes of Pb(II) with imidazole have not been studied polarographically so far. Li *et al.*[13] and Tanford and Wagner[14] have studied the complexes of Cd(II) with imidazole and it has been stressed that imidazole acts as a monodentate ligand. Kim *et al.*[15] have studied the mixed complexes of Pb(II) with histidine and hydroxide ion in the pH range 9–13 and determined the composition of the complexes by applying Schaap and McMasters method. Gaur and Bahgel[16] have reported that Pb(II) forms only one mixed complex with formate and maleate ions.

In earlier publications[17–19] we have reported polarographic studies on the composition and stability constants of mixed ligand complexes of Cd(II) with imidazole and various carboxylate ions. However no polarographic studies on the mixed complexes of Pb(II) with imidazole and carboxylate ions have been attempted so far. The present paper reports the results of a polarographic study on the composition and stability constants of mixed complexes of Pb(II) with imidazole and some carboxylate ions, i.e. tartrate, citrate and malonate.

EXPERIMENTAL

All the chemicals used were of analytical reagent grade and their solutions were prepared in double-distilled water. The ionic strength was maintained constant at $\mu = 2.0$ ($NaNO_3$). Imidazole and potassium salts of tartaric, malonic and citric acids were used as ligands. The concentration of Pb(II) was kept at 1×10^{-3} M. Polarograms were obtained by means of a manual polarograph (Toshniwal CL 02) in conjunction with Toshniwal polyflex galvanometer (PL 50). Throughout the measurements the current at the end of the drop (i.e. the max-

*Author to whom correspondence should be addressed.

imum current) was recorded. Purified nitrogen was used for removing the dissolved oxygen. All the measurements were made at 25 ± 0.1°C. Saturated calomel electrode (S.C.E.) was used as a reference electrode. The d.m.e. had the following characteristics (2.0 M $NaNO_3$, open circuit): m = 1.52 mg/sec; t = 3.04 sec; $m^{2/3}t^{1/6}$ = 1.59 $mg^{2/3}$ $sec^{-1/2}$, h_{corr} = 51 cm.

RESULTS AND DISCUSSION

The polarographic reduction of Pb(II) in the presence of $tart^{2-}$, mal^{2-}, $citr^{3-}$ and im separately, was found to be reversible and diffusion-controlled. The same was true in the case of the mixed systems as the slopes of $E_{d.e.}$ vs log $i/i_d - i$ plots were of the order of 31 ± mV and the plots of i_d vs $h_{corr}^{1/2}$ were linear and passed through the origin.

The pK_a value of im at 25 ± 0.1°C and at $\mu = 2.0$ ($NaNO_3$) has been determined by titration method[20] using a glass electrode. This worked out to be 7.09. The free ligand concentration, [im], was calculated from the pH value of the solution and pK_a value of the ligand.

(i) Pb(II)-$tart^{2-}$, Pb(II)-mal^{2-} *and* Pb(II)-$citr^{3-}$ *systems*

The stability constants of simple complexes of Pb(II) with carboxylate ions and imidazole were determined separately prior to the study of mixed ligand systems. Identical conditions were maintained in both the simple and mixed systems.

Plots of $E_{1/2}$ vs log[$tart^{2-}$] and log[mal^{2-}] are smooth curves thereby indicating the formation of successive complexes. DeFord and Hume's method has been applied to determine the stability constants of successive complexes. The polarographic characteristics and $F_j[X]$ functions of Pb(II)-$tart^{2-}$ and Pb(II)-mal^{2-} systems, respectively, are listed in Tables 1 and 2. With $tart^{2-}$, two successive complexes, viz., [Pb(tart)] and $[Pb(tart)_2]^{2-}$ with stability constants $\log \beta_1 = 1.30$ and $\log \beta_2 = 2.90$ respectively are formed. With mal^{2-} three successive complexes, viz. [Pb(mal)], $[Pb(mal)_2]^{2-}$ and $[Pb(mal)_3]^{4-}$ with stability constants $\log \beta_1 = 2.6$, $\log \beta_2 = 3.3$ and $\log \beta_3 = 4.5$ are formed respectively. The values of $\log \beta_1$, $\log \beta_2$ and $\log \beta_3$ for Pb(II)-mal^{2-} system obtained by Gaur and Palrecha[12] at $\mu = 2.0$ and 30°C are respectively 2.6, 3.6 and 4.3. A comparison of these values with those obtained in the present study shows that there is a difference of ±0.3 and ±0.2 log unit in the values of $\log \beta_2$ and $\log \beta_3$ respectively. This may be attributed partly to a difference in the temperature in the two cases and partly to the experimental error involved in the reproducibility of $E_{1/2}$ values. The plot of $E_{1/2}$ vs log[$citr^{3-}$] is a straight line which shows the formation of a single complex. The composition and stability constant are determined by Lingane's[1] method. The composition of the complex works out to be $[Pb(citr)]^-$ with stability constant $\log \beta_1 = 3.4$.

(ii) Pb(II)-im *system*

Plot of $E_{1/2}$ vs log[im] is a smooth curve thereby showing the formation of successive complexes. The composition and stability constants of the

complexes have been determined by DeFord and Hume's method. An analysis of $F_j[X]$ functions (Table 4) reveals the formation of three successive complexes, viz $[Pb(im)]^{2+}$, $[Pb(im)_2]^{2+}$ and $[Pb(im)_3]^{2+}$ with stability constants, $\log \beta_1 = 2.9$, $\log \beta_2 = 4.3$ and $\log \beta_3 = 6.3$.

(iii) Pb(II)-$tart^{2-}$-im *system*

[$tart^{2-}$] was varied from 0 to 0.6 M keeping [im] constant at 0.0064 M. The $E_{1/2}$ values were more negative than those obtained in the absence of im (Tables 1 and 5) thereby showing the formation of mixed complexes. The composition and stability constants of the mixed complexes have been determined by Schaap and McMasters method.[2] The polarographic characteristics and $F_{ij}[X, Y]$ functions [X = $tart^{2-}$, Y = im) of this system at fixed concentration (free) of im (0.0064 M) are presented in Table 5. From the plots of $F_{ij}[X, Y]$ data vs [$tart^{2-}$] the following intercept values for constants A, B and C are obtained.

$\log A = 1.30$, $\log B = 2.07$ and $\log C = 3.17$. An

analysis of these constants shows the formation of only one mixed complex, [Pb(tart)(im)] with stability constant $\log \beta_{11} = 4.19$.

The results of the present study are summarised in the following diagram where the numerical values shown are the logarithms of the equilibrium constants for the reactions indicated:

The mixing constant (K_m) for the reaction

$$\tfrac{1}{2}[Pb(tart)_2]^{2-} + \tfrac{1}{2}[Pb(im)_2]^{2+} \rightleftharpoons [Pb(tart)(im)]$$

is given by the relation

$$\log K_m = \log \beta_{11} - \tfrac{1}{2}(\log \beta_{20} + \log \beta_{02}).$$

This works out to be +0.59. The positive value of log K_m indicates that the mixed complex [Pb(tart)(im)] is more stable than the parent binary complexes, $[Pb(tart)_2]^{2-}$ and $[Pb(im)_2]^{2+}$.

The equilibrium constant (log value) for the following disproportionation reaction

$$2[Pb(tart)(im)] \rightleftharpoons [Pb(tart)_2]^{2-} + [Pb(im)_2]^{2+}$$

works out to be −1.8. The negative log value shows that the formation of mixed species [Pb(tart)(im)] is favoured over the simple binary complexes. This is in agreement with the conclusion arrived at on the basis of log K_m value.

(iv) Pb(II)-*malonate-imidazole system*:

$[mal^{2-}]$ was varied from 0 to 0.6 M keeping [im] constant at 0.0032 M. The composition and stability constants were determined by Schaap and McMasters method. The system was repeated at another concentration (free) of im (0.0064 M). The polarographic characteristics and $F_{ij}[X, Y]$ functions ($X = mal^{2-}$, $Y = im$) of this system at fixed [im] are presented in Table 6. From the plots of $F_{ij}[X, Y]$ data vs. $[mal^{2-}]$; the following intercept values for the constants A, B, C and D are obtained.

For series 1: log A = 0.69, log B = 3.14, log C = 3.47 and log D = 4.64.
For series 2: log A = 1.30, log B = 3.47, log C = 3.60 and log D = 4.77.

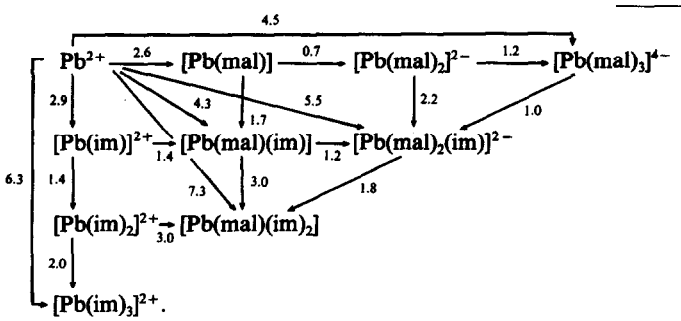
0.20	6.07	0.475	33	412.99	19.84	79.20	22.60
0.25	5.94	0.481	33	674.45	26.33	89.32	22.12
0.30	5.94	0.487	33	1076.58	35.21	104.00	23.33



The stability constants of the mixed complexes have been calculated from the values of these constants. Three mixed complexes as noted below are formed:

$$[Pb(mal)(im)]; \quad \log \beta_{11} = 4.3$$

$$[Pb(mal)(im)_2]; \quad \log \beta_{12} = 7.3$$

$$[Pb(mal)_2(im)]^{2-}; \quad \log \beta_{21} = 5.5.$$

The results of the present study are summarised in the following diagram where the numerical values shown are the logarithms of the equilibrium constants for the reactions indicated:

The mixing constant (K_m) for the reaction

$$\tfrac{1}{2}[Pb(mal)_2]^{2-} + \tfrac{1}{2}[Pb(im)_2]^{2+} \rightleftharpoons [Pb(mal)(im)]$$

is given by the relation

$$\log K_m = \log \beta_{11} - \tfrac{1}{2}(\log \beta_{20} + \log \beta_{02}).$$

This works out to be + 0.5. The positive log value shows that the mixed complex, [Pb(mal)(im)] is more stable than the parent binary complexes, $[Pb(mal)_2]^{2-}$ and $[Pb(im)]^{2+}$.

The equilibrium constants for the following disproportionation reactions

$$2[Pb(mal)(im)_2] \rightleftharpoons [Pb(mal)_2]^{2-} + [Pb(im)_2]^{2+} \quad (1)$$

$$2[Pb(mal)(im)_2] \rightleftharpoons [Pb(mal)_2]^{2-} + [Pb(im)_3]^{2+} + im \quad (2)$$

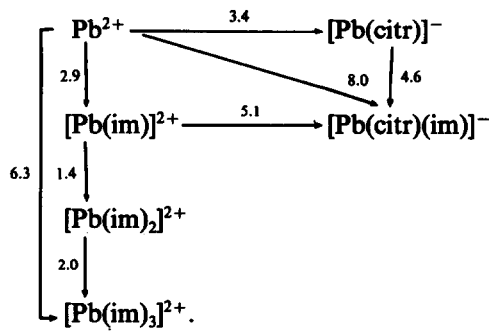
$$2[Pb(mal)_2(im)]^{2-} \rightleftharpoons [Pb(mal)_3]^{4-} + [Pb(im)_2]^{2+} + mal^{2-} \quad (3)$$

work out to be -2.0, -5.0 and -2.20 respectively. The large negative log values show that the formation of mixed complexes, $[Pb(mal)(im)]$, $[Pb(mal)(im)_2]$ and $[Pb(mal)_2(im)]^{2-}$ is favoured over the simple ones.

The stability of these mixed complexes follows the order:

$$[Pb(mal)(im)_2] > [Pb(mal)_2(im)]^{2-} > [Pb(mal)(im)].$$

(v) Pb(II)-*citrate-imidazole system*:



$[citr^{3-}]$ was varied from 0 to 0.3 M keeping [im] constant at 0.0032 M. The system was repeated at another concentration (free) of im(0.0064 M). The composition and stability constants were determined by Schaap and McMasters method. The polarographic characteristics and $F_{ij}[X, Y]$ functions ($X = citr^{3-}$, $Y = im$) are presented in Table 7. From the plots of $F_{ij}[X, Y]$ data vs. $[citr^{3-}]$, the following intercept values for constants A, B, C and D are obtained.

For series 1: log A = 0.60, log B = 2.38, log C = 3.64 and log D = 3.97.

For series 2: log A = 1.20, log B = 2.60, log C = 3.66 and log D = 4.20.

An analysis of these constants shows the formation of only one mixed species, $[Pb(citr)(im)]^-$ with $\log \beta_{11} = 8.0$. A negative value of $\log \beta_{12}$ precludes the formation of the species, $[Pb(citr)(im)_2]^-$.

The results of the present study are summarised in the following diagram where the numerical values shown are the logarithms of the equilibrium constants for the reactions indicated:

TRANSITION METAL COMPLEXES WITH 1,3-BIS-(2-HYDROXYPHENYL)-1,3-PROPANEDIONE—I

MONONUCLEAR COMPLEXES

F. TEIXIDOR, A. LLOBET, L. ESCRICHE and J. CASABÓ*
Departament de Química Inorgànica, Universitat Autònoma de Barcelona, (Bellaterra), Barcelona, Spain

(*Received* 17 *November* 1983; *accepted* 16 *April* 1984)

Abstract—Reaction of 1,3-(2-hydroxyphenyl)-1,3-propanedione ($BhPPH_3$), a ligand with three possible sites of coordination acting as a chelating agent, with metal acetates results in the formation of mononuclear species $M(BhPPH_2)_2S,S'$ (M=Mn, Fe, Co, Ni, Zn; S,S'=CH_3OH, C_2H_5OH or H_2O); $M'(BhPPH_2)_2$ (M'=Cu, Pd), and $M''(BhPPH_2)_3S,S'$ (M''=Fe, Al). The complexes have been studied by ^{1}H-NMR when possible, and IR spectra. The position of the methine proton (=CH−) at 6.88 ppm in $Zn(BhPPH_2)_2S,S'$ indicates that $BhPPH_3$ behaves in mononuclear complexes as a common β-diketone. Most of the complexes lose S,S' molecules on heating but a crystal structure of $Zn(BhPPH_2)_2 \cdot 2C_2H_5OH$ indicates that the C_2H_5OH molecules are oxygen bonded to the metal centre.

The chemistry of β-diketones has received considerable interest through the years.[1–3] They appear to have been investigated with virtually every metal and metalloid[4] in the periodic table, mainly due to the interest in the structure and reactivity of these compounds.[5] On the other hand, in the last decade a growing interest in physico-chemical studies, homogeneous catalysts and the design of compounds with unusual properties[6] has stimulated the development of discrete di- and tri-nuclear complexes. Ligands such as β-triketones and the analogous β-ketophenols,[6,7] diamine Schiff base derivatives of 1,3,5-triketones, keto-acids and ketophenols[8] have been shown to form homo- and heterodi-nuclear complexes. To our knowledge a very limited literature about tri-nucleating ligands exists.[9,10] It has been proven that the heterodinuclear complexes may be obtained more easily when the ligand contain two sites with different ligand field strengths, e.g. O_2O_2 and N_2O_2. However, concern is increasing to obtain stable mononuclear complexes of these polychelating ligands since they, may be transformed by heating into homodinuclear complexes,[6] e.g. the mononuclear Cu(II) chelate of 2-acetoacetylphenol which is obtained at 15°C. rearranges to the binuclear chelate on heating.[11] With the aim of obtaining a ligand that (a) has three possible compartments, with one of these compartments more reactive and clearly different from the other two, and (b) the synthesis of homotri-, and heterotrinuclear complexes, we have tested for the first time as a complexing agent the compound 1,3-bis-(2-hydroxyphenyl)-1,3-propanedione. ($BhPPH_3$)

As may be seen in Fig. 1 there are three possible sites of coordination, two of them equivalent (ketophenol) and the β-diketone. In this paper we have reacted $BhPPH_3$ with stoichiometric amounts of metal salts and have obtained pure mononuclear complexes with the metal chelated, in all cases, by the β-diketone group. An overnight refluxing of some of these complexes yielded again the starting mononuclear material. Forthcoming papers will deal with the synthesis and physical properties of di and trinuclear complexes.

EXPERIMENTAL

General

IR spectra were obtained on a Beckman IR-20A as KBr pellets. The ^{1}H NMR and ^{13}C-NMR were recorded on a Bruker WP8OSY. The mass spectrum was recorded in a HP5985 GC/MS system. The TLC were done using DC-Alufolien Kieselgel

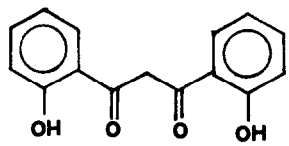

Fig. 1.

60 F_{254}(Merck). All reagents were analytical grade and were used as received. The complexes were analysed in our laboratories as follows: The transition metal ions by titration with EDTA and C,H on a Perkin–Elmer 240B. All yields are quoted relative to $BhPPH_3$.

Synthesis of 1,3-*bis*-(2-*hydroxyphenyl*)-1,3-*propanedione* ($BhPPH_3$)

The synthesis was performed as previously reported[12] however it afforded much better yield when dilute hydrochloric acid ($\simeq 5\%$) was used instead of acetic acid.[13]

Synthesis of complexes of general formula $M(BhPPH_2)_2 \cdot S,S'$

In Table 1 the meaning of M,S and S', the colour, the yields and the observed and calculated analyses for the different complexes are indicated.

Synthesis of $Zn(BhPPH_2)_2 \cdot CH_3OH \cdot H_2O$

This preparation describes a typical procedure. Subsequent descriptions include only the essential differences. To 25 cm^3 of warm methanol in a 100 cm^3 beaker was added 512 mg (2 mmol) of $BhPPH_3$. After complete dissolution hydrated zinc acetate 220 mg (1 mmol) in 15 cm^3 of warm methanol was added. Almost instantly, a pale yellow crystalline solid begins to separate. The contents of the beaker was stirred and kept warm for an additional five minute period. After cooling the mixture to 25°C the solid was separated by filtration and washed with methanol and ether. The pale yellow solid was dried under vacuum.

Crystals suitable for an X-ray analysis were obtained in the following way. The crude compound was dissolved in the minimum amount of tetrahydrofuran (THF) and ethanol was added (approximately four times the volume of THF). Upon the slow evaporation of the mixture large pale yellow crystals with general formula $Zn(BhPPH_2)_2 \cdot 2EtOH$ were obtained.

The syntheses concerning Mn, Co, Ni, Cu and Fe have been done in a similar way. However, the $Fe(BhPPH_2)_2 \cdot CH_3OH \cdot H_2O$ complex was obtained using Mohr's salt in water solution.

Synthesis of $Pd(BhPPH_2)_2$

Under N_2, to 25 cm^3 of warm methanol in a 100 cm^3 three necked flask were added 512 mg (2 mmol) of $BhPPH_3$. After this dissolved, lithium methanolate (2 mmol)[14] and $PdCl_4Na_2$ (1 mmol) were subsequently added in this order. On cooling the resulting reddish solution a dark yellow solid separated which was filtrated and washed with

water, methanol and ether. The solid was dried under vacuum.

Synthesis of $Al(BhPPH_2)_3$.

To 50 cm^3 of warm absolute ethanol in a 100 cm^3 beaker was added 512 mg of $BhPPH_3$. After complete dissolution, 250 mg (0.67 mmols) of $Al(NO_3)_3 \cdot 9H_2O$ in 20 cm^3 of warm absolute ethanol was added. After a few minutes a yellowish solid separated which was filtered and washed with ethanol. Yield 250 mg, 49% (Analyses as indicated in Table 1). The pH of the resulting mother liquor was acidic and upon a very slow addition of concentrated aqueous NH_3 till pH 5[15] more solid was collected. Yield 150 mg, 28%. However, the analysis of this second fraction was not completely satisfactory. A TLC of this last solid in a mixture of chloroform–methylene chloride (1/2, v/v) displayed three spots with Rf = 0.045; 0.22 and 0.34; the color intensity of the latter corresponding to pure $Al(BhPPH_2)_3$ being much stronger than the other two.

Synthesis of $Fe(BhPPH_2)_3$

The synthesis was run as for $Al(BhPPH_2)_3$. Yield, 40%. No attempt was made to get a better yield by increasing the pH of the solution.

Solvent or water molecules elimination

In all cases, except for $Fe(BhPPH_2)_2 \cdot CH_3OH \cdot H_2O$, the S,S′ molecules have been eliminated by heating the crude solid in an oven at 110–120°C for 5–10 hr. Analyses of the resulting solids have been performed indicating the stoichiometries $M(BhPPH_2)_2$.

RESULTS

Synthetic studies

The complexes $M(BhPPH_2)_2S,S'$ (M=Mn, Fe, Co, Ni, Zn; S,S′ = CH_3OH or H_2O) (see Table 1) and $M'(BhPPH_2)_2$ (M′ = Cu, Pd) were prepared by treating the corresponding hydrated metal acetate with $BhPPH_3$ in methanol.

$$M(CH_3COO)_2 \cdot xH_2O + 2BhPPH_3 \xrightarrow{MeOH} M(BhPPH_2)_2 \cdot yMeOH \cdot zH_2O + 2CH_3COOH + (x-z)H_2O \quad (y,z = 0 \text{ or } 1)$$

In a similar way, the aluminium and Fe(III) complexes were prepared from the metal nitrates and $BhPPH_3$ in methanol. In these cases the yields found were low because of the increasing acidity of the medium.

$$M(NO_3)_3 \cdot xH_2O + 3BhPPH_3 \xrightarrow{MeOH} M(BhPPH_2)_3 + 3NO_3^- + 3H^+.$$

A better yield was obtained by addition of aqueous NH_3, but, care must be taken not to exceed pH = 5.[15] Even at this pH two additional products, not yet identified and in low yield have been found in addition to $Al(BhPPH_2)_3$.

The S,S′ molecules were easily removed on heating at 110–120°C for a few hours yielding complexes of stoichiometry $M(BhPPH_2)_2$. The only case where those molecules have not been removed at these temperatures is the $Fe(BhPPH_2)_2 \cdot CH_3OH \cdot H_2O$ complex. In addition, these S,S′ molecules are easily replaceable, e.g. the dissolving of $Zn(BhPPH_2)_2 \cdot CH_3OH \cdot H_2O$ in a mixture containing tetrahydrofuran:ethanol (1/4, v/v) afforded the complex $Zn(BhPPH_2)_2 \cdot C_2H_5OH$. Efforts are now underway to correlate this exchange with the geometry and bulkiness of the alcohol.

Spectral studies

The IR spectra of the M(II) complexes exhibit very characteristic absorptions at 1620(s), 1590(s), 1520(vs), 1480(m) cm^{-1}, common in all of them Figure 2 shows the 1700–1400 cm^{-1} range for $Cu(BhPPH_2)_2$. Based on the work of Pinchas and coworkers[16] the absorptions at 1590 and 1520 cm^{-1} are tentatively assigned to C⁻⁻O and C⁻⁻C stretching modes, respectively. Absorptions at ≃3440 cm^{-1} in the complexes with solvent molecules are indicative, and consistent with the analytical data for OH groups in the molecule. The IR spectra of the non-solvated complexes display an almost identical pattern in the 1700–1400 cm^{-1} area, however in certain compounds a few differ-

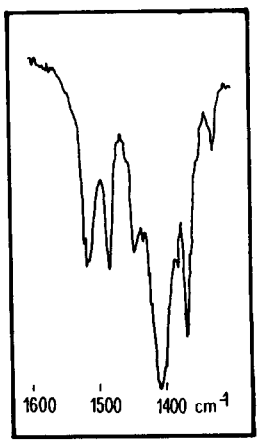

Fig. 2. IR spectrum of the complexes with general formula $M(BhPPH_2)_2 \cdot S,S'$ in the 1700–1400 cm^{-1} spectral range.

ences are observed in the 1250–1400 cm^{-1} region of the spectrum, basically two bands at 1350 and 1330 cm^{-1} in the solvated complex coalesce into one at 1330 cm^{-1}. The absence of the band at ≃3400 cm^{-1} is, however, the best indication for a non-solvated complex. In general, the IR spectra of the M(III) complexes do not differ qualitatively from those of the M(II) complexes.

The ^{1}H NMR spectra of $Zn(BhPPH_2)_2S,S'$ and $Al(BhPPH_2)_3$ are almost identical in the aromatic region. (See Fig. 3). Mainly, three groups of signals may be considered in this region (6.5–.8.5 ppm) at ≃8, 7.3 and 6.9 ppm with integrations 2:2:5, respectively. The feature of intensity 5, which is in fact a group of three signals is assigned to two protons of each benzene group of the $BhPPH_2$ moiety and to the methine (=CH–) proton. On comparison with the ^{1}H-NMR of non-coordinated $BhPPH_3$ the methine signal has been tentatively assigned at 6.85 ppm on the $Zn(BhPPH_2)_2 \cdot CH_3OH \cdot H_2O$ complex. No assignment of this (=CH–) proton signal in the $Al(BhPPH_2)_3$ complex has been made because of additional splitting of the group at 6.9 ppm. The phenolic proton resonance is observed at 10.8 ppm in $Al(BhPPH_2)_3(d\text{-}HCCl_3)$ and 11.1 ppm in $Zn(BhPPH_2)_2 \cdot CH_3OH \cdot H_2O$ (d_6-DMSO). The S,S' (methanol, ethanol, water) ^{1}H-NMR resonances occur in the region 1–5 ppm depending on the alcohol. Two groups of signals at 4.1 ppm (triplet) and 3.2 ppm (doublet) (relative intensities 1:3) are observed in $Zn(BhPPH_2)_2 \cdot CH_3OH \cdot H_2O$. In $Zn(BhPPH_2)_2 \cdot C_2H_5OH$ (See Fig. 3) three groups of signals at 4.4 ppm (triplet), 3.6 ppm (quadruplet of doublets) and 2.1 ppm (triplet) with relative intensities of 1:2:3 are observed. No significant differences were observed in the ^{1}H-NMR spectrum of $Zn(BhPPH_2)_2$, except for the absence of the S,S' signals, with respect to the solvated $Zn(BhPPH_2)_2$: S,S' complexes.

DISCUSSION

The ligand $BhPPH_3$ ≡ 1,3-bis-(2-hydroxyphenyl)-1,3-propanedione presents (Fig. 1) three possible sites of coordination acting as a chelating agent; two of them equivalent, and one, the β-diketone moiety, different and the most reactive. As a consequence it was expected that molenuclear complexes similar to these obtained with common β-diketones would be obtained. The shift of the enolic proton from 4.8 ppm in free $BhPPH_3$ to ≃7 ppm (methine protons) in complexed $BhPPH_2$ supports this expectation. The existence of S,S' molecules with –OH groups suggested to us that the Zn atom is in an octahedral arrangement of oxygens, four from the β-diketone moiety and two from the solvent or water molecules. (see Fig. 4). This geometry was further corroborated by an X-ray diffraction study[17] of $Zn(BhPPH_2)_2 \cdot 2EtOH$, the observed Zn–O distances being 2.02 Å for the equatorial Zn–O bonds and 2.17 Å (ethanol) for the axial bonds. These values compare well with others reported in the literature, e.g. in Zinc bis (benzoylacetonate)-monoethanolate, $Zn(bzac)_2 \cdot EtOH$[18] having a pseudo-square pyramidal geometry the Zn–O bond distances to the benzoylacetonate groups are approximately 1.99 Å and that to the ethanol molecule is 2.06 Å. The slightly longer distances observed in $Zn(BhPPH_2) \cdot 2EtOH$ may be due to the higher coordination of the Zn atom in this complex.

The similárity of all the IR spectra for the M(II) complexes is a good indication for a structure common in all of them and resembling that of the $Zn(BhPPH_2)_2 \cdot 2EtOH$ complex.

Few differences are believed to happen in the coordination of the central metal by the $BhPPH_3$ ligand in the non solvated complexes. The 1700–1400 cm^{-1} IR region of these complexes indicates they are oxygen-bonded β-diketonato complexes as are the solvated complexes. However, there is not enough data, at the present moment,

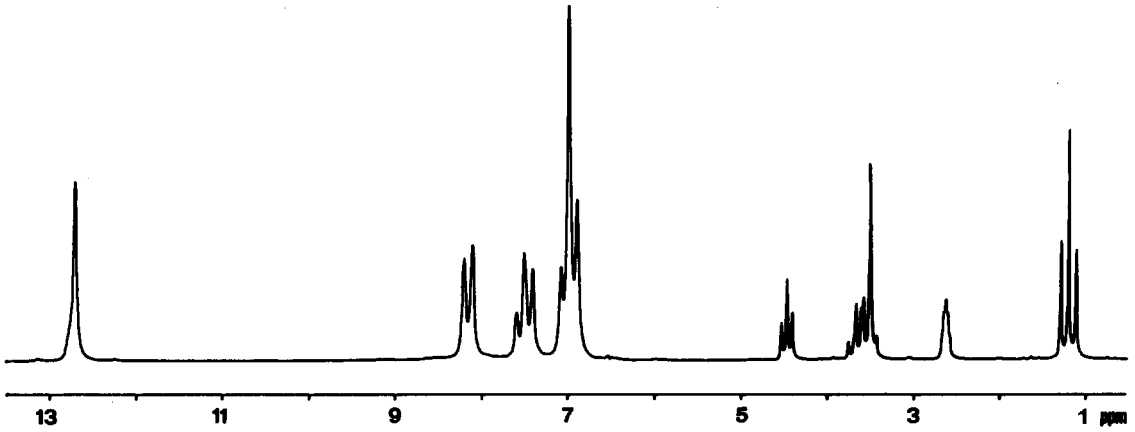

Fig. 3. ^{1}H-NMR spectrum of the complex $Zn(BhPPH_2)_2 \cdot 2CH_3CH_2OH$ in d_6-dmso.

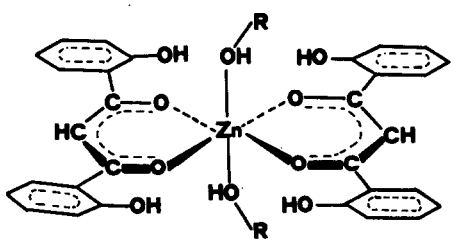

Fig. 4. Proposed structure for the complexes $Zn(BhPPH_2)_2 \cdot 2ROH$. Phenylic protons have been omitted for clarity.

to speculate on the total coordination about the central metal. Even though the solvating molecules are removed, a hexacoordination with all oxygens is possible via the phenolic oxygens.

A POLAROGRAPHIC STUDY OF THE MIXED COMPLEXES OF Pb(II) WITH OXALATE AND MALONATE IONS

G. RUIZ-CABRERA, J. C. RODRÍGUEZ-PLACERES, F. RAMOS-STEFFENS and A. ARÉVALO*
Department of Physical Chemistry, University of La Laguna, Teneriffe, Canary Islands, Spain

(*Received* 17 *January* 1984; *accepted* 16 *April* 1984)

Abstract—The coordinated mixed Pb(II)-oxalate–malonate system has been polarographically studied in aqueous medium. The ionic strength has been maintained constant at $\mu = 1.0$ by using $NaClO_4$. Application of the Schaap and McMasters method detected only the existence of the $[Pb–ox–mal]^{2-}$ complex, the overall stability constant of which was $\beta_{11} = 4.1 \times 10^5$.

The various coordination equilibria are discussed on the basis of statistical aspects.

Systematic studies have been carried out in this Department for several years on mixed coordination equilibria in aqueous and aqueous-organic media.[1–6] Analysis of mixed coordinated systems by using bidentate ligands has proved useful in establishing structural aspects[5] and particular characteristics of metal ion coordination chemistry.[4] In this paper we report the analysis of the Pb(II)–oxalate–malonate coordinated system in aqueous medium.

EXPERIMENTAL

Each of the $i - E$ curves was plotted with a Metrohm E506 polarograph with an E505 polarographic stand. Two Ag/AgCl/NaCl sat. Metrohm EA427 electrodes were used as counter and reference electrodes and the working electrode was of mercury drops. The temperature in the cell was 25 ± 0.05°C and the Pb(II) concentration was 0.099 mM. Ionic strength was adjusted in all cases to $\mu = 1.0$ M with $NaClO_4$. Measurements of pH were carried out with a pHM84 digital potentiometer with a GK 2401C Radiometer combined electrode. With the exception of the soln. of Pb(II) in the absence of ligand, which was polarographed at pH 5, all the rest were polarographed at a pH of 7.5 in order to ensure that the concentration of both the oxalate and malonate ions was not below 99% of the total concentrations of their respective salts.[7,8] The concentration of metal ion was constant at 0.099 mM in all recordings. Drop-time was controlled at 3.0 s.

The sodium perchlorate and sodium oxalate were Merck products of p.a. quality, the malonic acid from Carlo Erba R.P.E. and the sodium hydroxide used in the preparation of the sodium malonate and for adjusting the pH was also of p.a. quality from May and Baker.

RESULTS AND DISCUSSION

The plots of $\log[(\bar{i}_d - \bar{i})/\bar{i}]$ vs E show that the discharges occurred by a reversible bielectronic process. The values for the reversible half-wave potentials were directly obtained from these plots. The application of the Schaap and McMasters method[9] to determine mixed complexes requires prior knowledge of the constants of simple complexes, so we have previously studied the simple Pb(II)–oxalate and Pb(II)–malonate systems at a constant ionic strength $\mu = 1.0$ adjusted with $NaClO_4$,[10] using the De Ford and Hume method[11] to demonstrate stabilization of the complexes with 1 and 2 oxalate ligands and with 1, 2 and 3 malonate ligands, respectively. The corresponding formation constants are shown in Table 1.

It seems logical from the above to accept that the F_{00} function of Schaap and McMasters presents at the most the following expression:

$$F_{00} = \{1 + \beta_{01}[mal] + \beta_{02}[mal]^2 + \beta_{03}[mal]^3\} + \{\beta_{10} + \beta_{11}[mal] + \beta_{12}[mal]^2\}[ox] + \{\beta_{20} + \beta_{21}[mal]\}[ox]^2. \quad (1)$$

(*): interpolated value

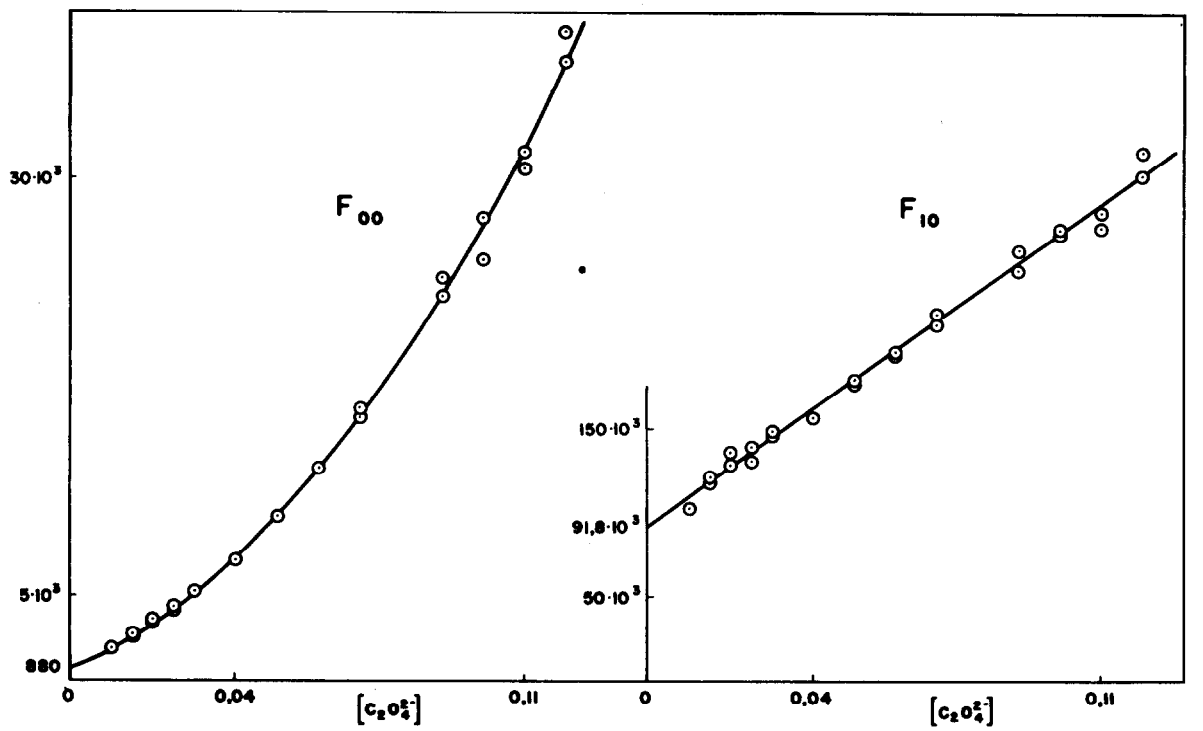

Fig. 1. Plot of the functions F_{00} and F_{10} vs $[ox^{2-}]$. Study with $[mal^{2-}] = 0.2$ M.

If the concentration of malonate is maintained constant while that of oxalate is varied, the F_{00} function becomes:

$$F_{00} = A + B[ox] + C[ox]^2 \qquad (2)$$

where A, B and C represent the arrangements expressed in (1). These coefficients may be calculated by a Leden-type treatment.

Six experimental studies were carried out in all. Table 2 gives the reversible half-wave potentials together with the limiting diffusion currents and the values of the F_{00} and F_{10} functions for the study carried out at a constant concentration of malonate of 0.2 M. The plot of the successive F_{i0} functions, Fig. 1, confirms the expected linear dependence of the F_{10} function vs [ox].

In every case it was observed that the value of A calculated from expression (1) agreed satisfactorily with that determined experimentally. The values of A, B and C obtained from the six studies carried out are given in Table 3.

The data of B, notably greater than $\beta_{10} = 10^{4}$,[10] reveal the presence of mixed complexes with an oxalate ion.

Figure 2 shows a good linear dependence of the

Table 3. Pb(II)–Na_2ox–Na_2mal–$NaClO_4$ system $\mu = 1.0$

$[mal^{2-}]$/M	A	B.10^{-3}	C.10^{-6}
0,02	20	17,7	1,5
0,05	70	32	1,6
0,08	150	45,8	1,5
0,10	220	48,8	2
0,12	310	58,9	1,8
0,20	880	91,8	1,8

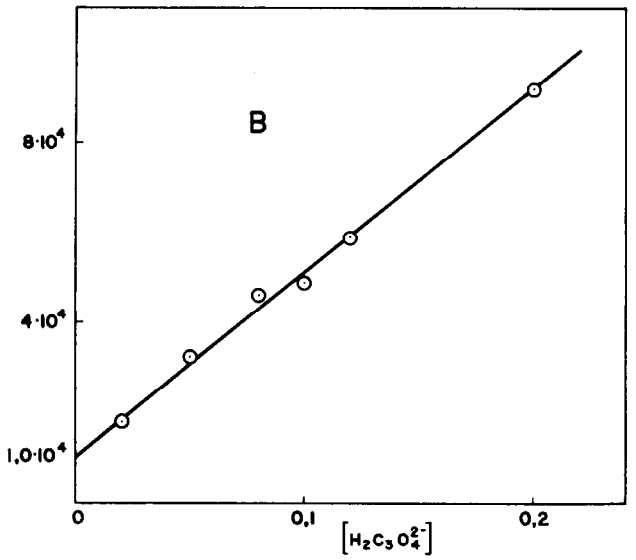

Fig. 2. Plot of coefficient B vs [mal^{2-}].

values of B vs [malonate] allowing β_{10} to be obtained from the intercept at [malonate] = 0 and β_{11} from the slope. Adjusting by square minima method gives $\beta_{10} = 1.1 \times 10^4$ and $\beta_{11} = 4.0 \times 10^5$. The value of β_{10}, in good agreement with that obtained from the study of the simple Pb(II)–malonate system: $\beta_{10} = 1.0 \times 10^4$,[10] provides further evidence for the validity of the results.

The values of C: (a) are relatively close to the stability constant of the complex

$$[Pb(C_2O_4)_2]^{2-}: \beta_{20} = 1.9 \times 10^6$$

and (b) do not show any regularity which would allow us to assume the stabilisation of the complex

$$[Pb(C_2O_4)_2(H_2C_3O_4)]^{4-}.$$

This result is similar to that observed in the study of the Cu(II)–oxalate–malonate system[5] and it suggests the impossibility of the malonate ligand to be coordinated to Pb^{2+} by the extreme positions of the probable octahedral structure of this ion.

Watters' formulae

The constant obtained from the mixed complex can be compared with that statistically predictable which was evaluated according to the formulae proposed by Watters[12]:

$$\beta_{11} = 2\beta_{20}^{1/2}\beta_{02}^{1/2} = 2,8.10^5$$

it is in good agreement with the value obtained experimentally:

$$\beta_{11} = 4,0.10^5.$$

ANALYSIS OF THE COORDINATION EQUILIBRIA

All the results corresponding to the coordination equilibria of the Pb(II) ion with oxalate and malonate ligands are shown in the scheme in Fig. 3. The stepwise constants are logarithmically expressed.

Let us first consider the equilibria of the Pb(II) with only one ligand. Table 4 gives the values of K_i/K_{i+1} for the Pb(II)–malonate system, and they are compared with those obtained for the oxalate and succinate[13] and those expected, taking into account only statistical factors and octahedral coordination.[14]

The formation of the 1:1 complex is greatly favoured by entropic factors while, due to steric effects, the formation of complexes with a greater number of ligands will be progressively hindered, particularly as the length of the chain is increased.

These predictions agree qualitatively with the tendency observed in Table 4 for K_1/K_2, although it is impossible to evaluate their influence quantitatively in order to compare if the one consideration alone interprets the results obtained. The relative proximity between the values calculated for K_1/K_2 in both cases, and the fact that it diminishes with the ion size increase would be justified by the similar influence of the entropic effects and the greater steric hindrance as the length of the chain is increased.

The high values of K_1/K_2 and the relatively low values of K_2/K_3 seem to point to the low relative stability of the complexes with two malonate and/or succinate ligands.

The tendency of the complexes $Pb(H_2C_3O_4)$ and PbC_2O_4 to take a malonate ion as second ligand is

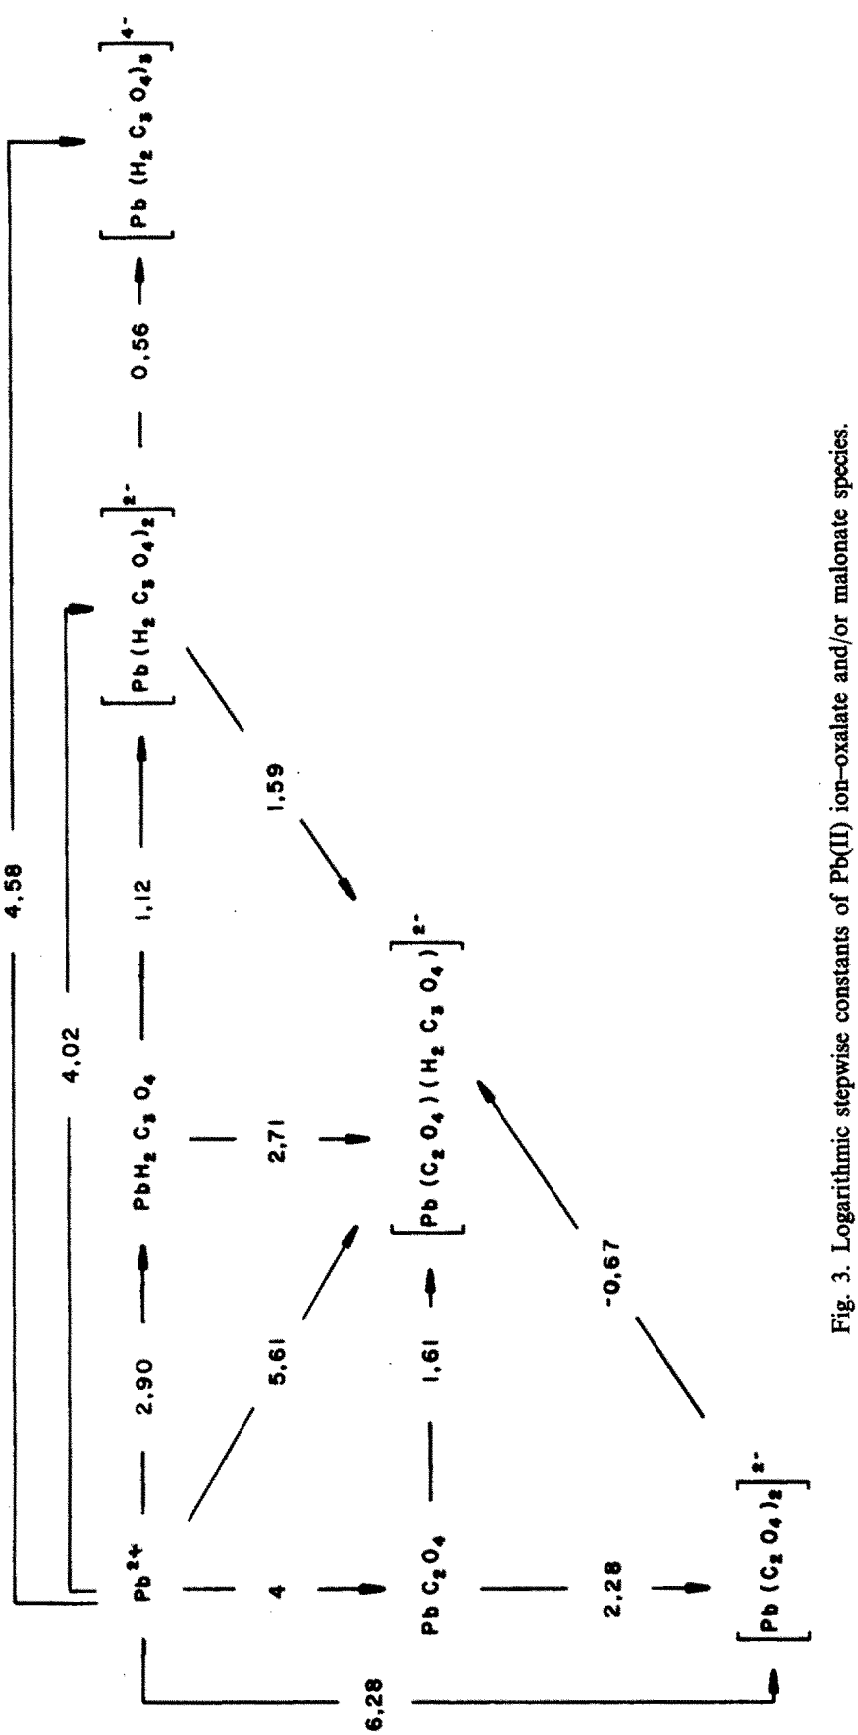

Fig. 3. Logarithmic stepwise constants of Pb(II) ion–oxalate and/or malonate species.

K_2/K_3	9,75	-	3,56	1,24

seen as follows:

$$PbH_2C_3O_4 + H_2C_3O_4^{2-} \rightleftharpoons [Pb(H_2C_3O_4)_2]^{2-}$$
$$\log K_{(1)} = 1.12 \quad (1)$$

$$PbC_2O_4 + H_2C_3O_4^{2-} \rightleftharpoons [Pb(C_2O_4)(H_2C_3O_4)]^{2-}$$
$$\log K_{(2)} = 1.61. \quad (2)$$

Theoretically, taking into account statistical factors alone, it would be expected that the equilibrium (2) were the more stable, its constant being greater than that of (1) by the statistical factor of 2, ($\log K = 0.301$). The difference found, $\log K = 0.49$, is slightly greater than that expected.

The tendency of the same complexes to coordinate an oxalate ion as second ligand should also be observed:

$$PbH_2C_3O_4 + C_2O_4^{2-} \rightleftharpoons [Pb(C_2O_4)(H_2C_3O_4)]^{2-}$$
$$\log K_{(3)} = 2.71$$

$$PbC_2O_4 + C_2O_4^{2-} \rightleftharpoons [Pb(C_2O_4)_2]^{2-}$$
$$\log K_{(4)} = 2.28.$$

Considerations analogous to those above are valid in this case in which the difference found, $\log K = 0.43$, is also slightly greater than expected.

Both results indicate a greater relative stability of the mixed complex than could be expected on the basis of the constants of the simple complexes $[Pb(H_2C_3O_4)_2]^{2-}$ and $[Pb(C_2O_4)_2]^{2-}$.

This greater stability is also reflected in the value calculated by means of the equation proposed by Watters: $(\beta_{11})_w = 2.8 \times 10^5$, lower by 30% than that obtained experimentally, which is a shift similar to that found in the analysis of the equilibria discussed earlier in this work.

(*Received* 20 *February* 1984; *accepted* 16 *April* 1984)

Abstract—A new cyano-bridged binuclear complex of Fe(II) can be prepared by mixing pentacyano(ammine)ferrate(II) with 4-cyanopyridine at a mole ratio 2:1. IR and UV-VIS spectra, together with kinetic data on ligand substitution, point to the following structure: $(NC)_5Fe–NC–Fe(CN)_4(N⬡–CN)^{6-}$, both in solid state and in aqueous solution, thus demonstrating that cyanide forms a bridge between two iron atoms which is much more stable than that formed by 4-cyanopyridine.

The interest in ligand-bridged complexes stems from their importance as intermediates in electron- or energy-transfer reactions.[1,2] Binuclear complexes are also important for structural, redox and substitution studies of bidentate ligands.[3] On the other hand, cyanoferrate complexes may be used as simple models for biological systems such as cytochromes or haemoglobin.[4]

In this work, we report the preparation and spectral and kinetic properties of the new binuclear iron complex obtained from $[Fe(CN)_5(NH_3)]^{3-}$ and N⬡–CN (4-cypy) mixed at a mole ratio 2:1. Both cyanide and 4-cypy are ambidentate ligands, so that two different bridged complexes may be synthesized. In a recent paper,[5] we attributed the visible spectra of a stoichiometric mixture in aqueous solution of $[Fe(CN)_5(NH_3)]^{3-}$ and $[Fe(CN)_5(4\text{-cypy})]^{3-}$ to a binuclear complex bridged by 4-cypy. This conclusion must now be corrected in view of the present investigation. Information about the degree of metal–metal interaction in the new species will also be disclosed.

EXPERIMENTAL

Sodium pentacyano(ammine)ferrate(II) trihydrate was obtained following Kenney *et al.*[6] 4-cypy was of analytical reagent grade. Deionized water was used throughout.

In order to verify the formation of a binuclear complex when $[Fe(CN)_5(NH_3)]^{3-}$ and 4-cypy were mixed in aqueous solution at a mole ratio 2:1 we resorted to the well-known continuous variations and mole ratio methods.[7] In the first case, 9 aqueous solutions of $[Fe(CN)_5(NH_3)]^{3-}$ and 4-cypy were mixed in variable proportions (0.1–0.9), the total concentration being constant and equal to 8×10^{-4} M. After 4 hr, the absorbance (A) of the solutions was measured at $\lambda = 400$ nm and at room temperature. In the second case, A was measured in similar conditions, but now maintaining [4-cypy] $= 2 \times 10^{-4}$ M and varying the metal concentration from 0 to 4.5×10^{-4} M. In both cases, duplicate runs were made using a Metrolab RC 325 spectrophotometer.

The preparation of the solid binuclear complex was carried out by reacting 0.8 mmol of 4-cypy and 1.6 mmol of $[Fe(CN)_5(NH_3)]^{3-}$ in 10 cm^3 of water. After 1 hr in the dark at room temperature, the mixture was cooled at 0 °C for 30 min. The precipitate obtained was filtered at 0 °C and kept in a desiccator over P_4O_{10}.

Iron and sodium analyses were made by atomic absorption spectroscopy. A Varian Techtron AA5 spectrometer was used for this purpose, and $Na_2[Fe(CN)_5NO].2H_2O$ was the chosen standard.

UV-VIS spectra of the sample were made in aqueous solution (immediately after dissolution) at a $C = 2.4 \times 10^{-4}$ M in the range 200–600 nm on a Perkin–Elmer Coleman 124 spectrophotometer.

IR spectra were obtained as KBr pellets, using a Perkin–Elmer 580B spectrophotometer.

Ligand substitution kinetic experiments were accomplished at pseudo-first-order conditions: [complex] = 8×10^{-5} M; [py] = 0.1 M. The absorbance changes corresponding to the reaction:

$$Fe_2(CN)_{10}(4\text{-cypy})^{6-} + 2\,py \rightarrow 2\,Fe(CN)_5(py)^{3-} + 4\text{-cypy} \quad (1)$$

were measured on a Metrolab RC 325 visible spectrophotometer at $\lambda = 365\,nm$ (maximum of the final product) and $T = (25.0 \pm 0.2)$ °C.

RESULTS

Figure 1 shows the results obtained by applying the method of continuous variations. Y is defined as the difference between A of the mixture and A of the initial complex, $[Fe(CN)_5(NH_3)]^{3-}$. x is the

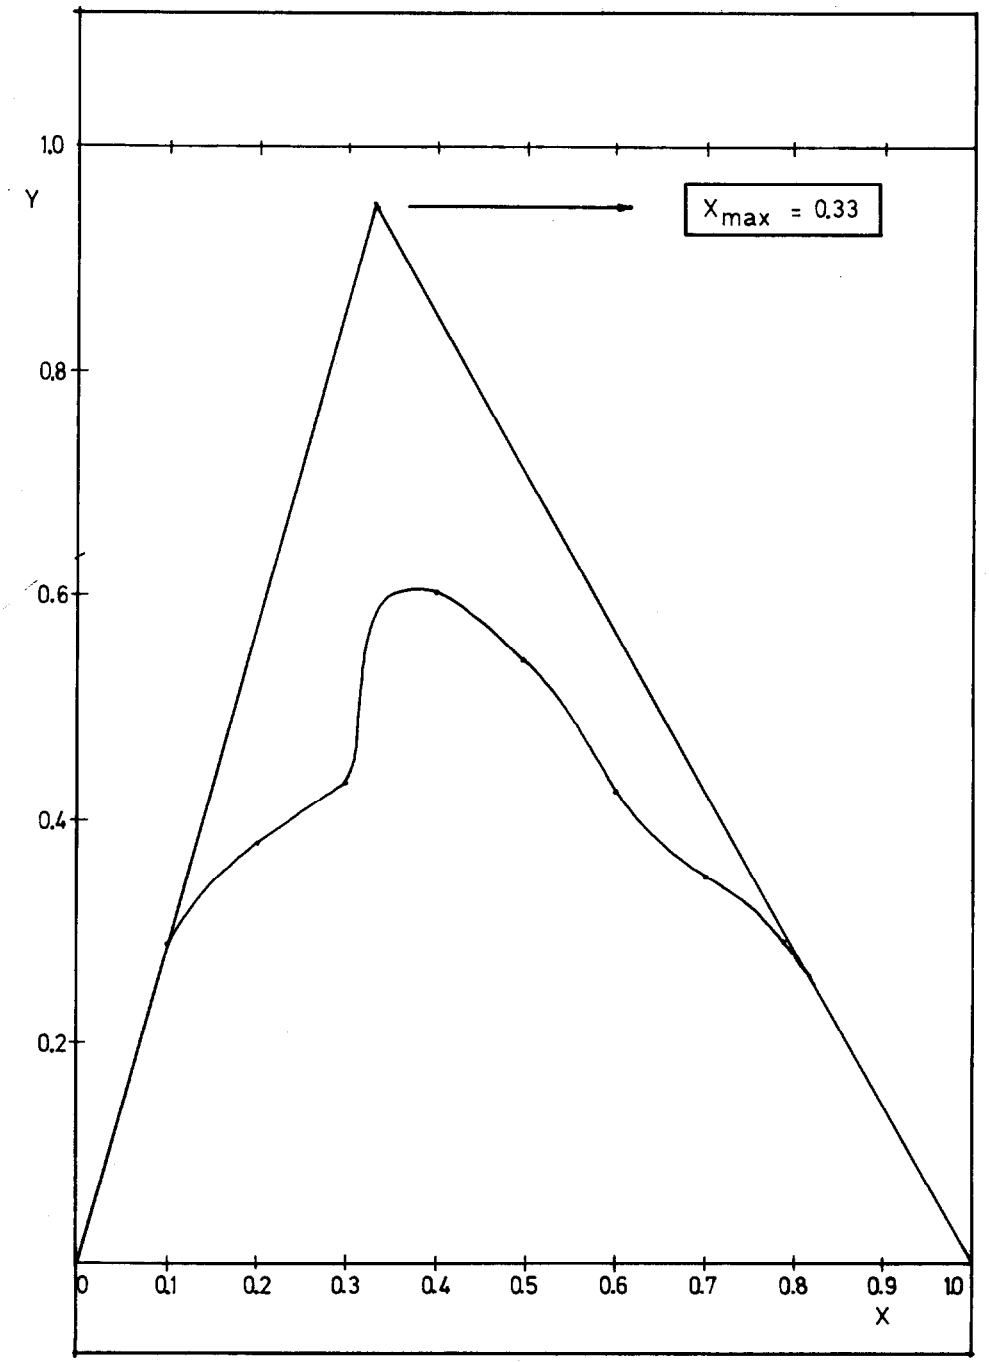

Fig. 1. Job's analysis at 400 nm for the reaction between $[Fe(CN)_5(NH_3)]^{3-}$ and 4-cypy in aqueous solution. Total concentration – 8×10^{-4} M.

proportion of 4-cypy to $[Fe(CN)_5(NH_3)]^{3-}$ ($x < 1$). From the intersection of the tangents to the curve at $x = 0$ and at $x = 1$, a value of $x_{max} = 0.33$ results, and from the equation:

$$m/n = (1 - x_{max})/x_{max} \quad (2)$$

where m/n is the stoichiometric ratio iron:4-cypy,[7] m/n equals 2. The different curvatures for $x \rightarrow 0$ and for $x \rightarrow 1$ indicates formation of more than one complex between $[(Fe(CN)_5(NH_3)]^{3-}$ and 4-cypy.[8,9]

The mole ratio method gives the results shown in Fig. 2. Y is defined as above, while $[Me]/[L] = [Fe(CN)_5(NH_3)^{3-}]/[4\text{-cypy}]$. Two sharp discontinuities at $[Me]/[L] = 1$ and 2 indicate formation of a monomeric complex[9] and a binuclear one, respectively.

Experimental iron and sodium contents of the

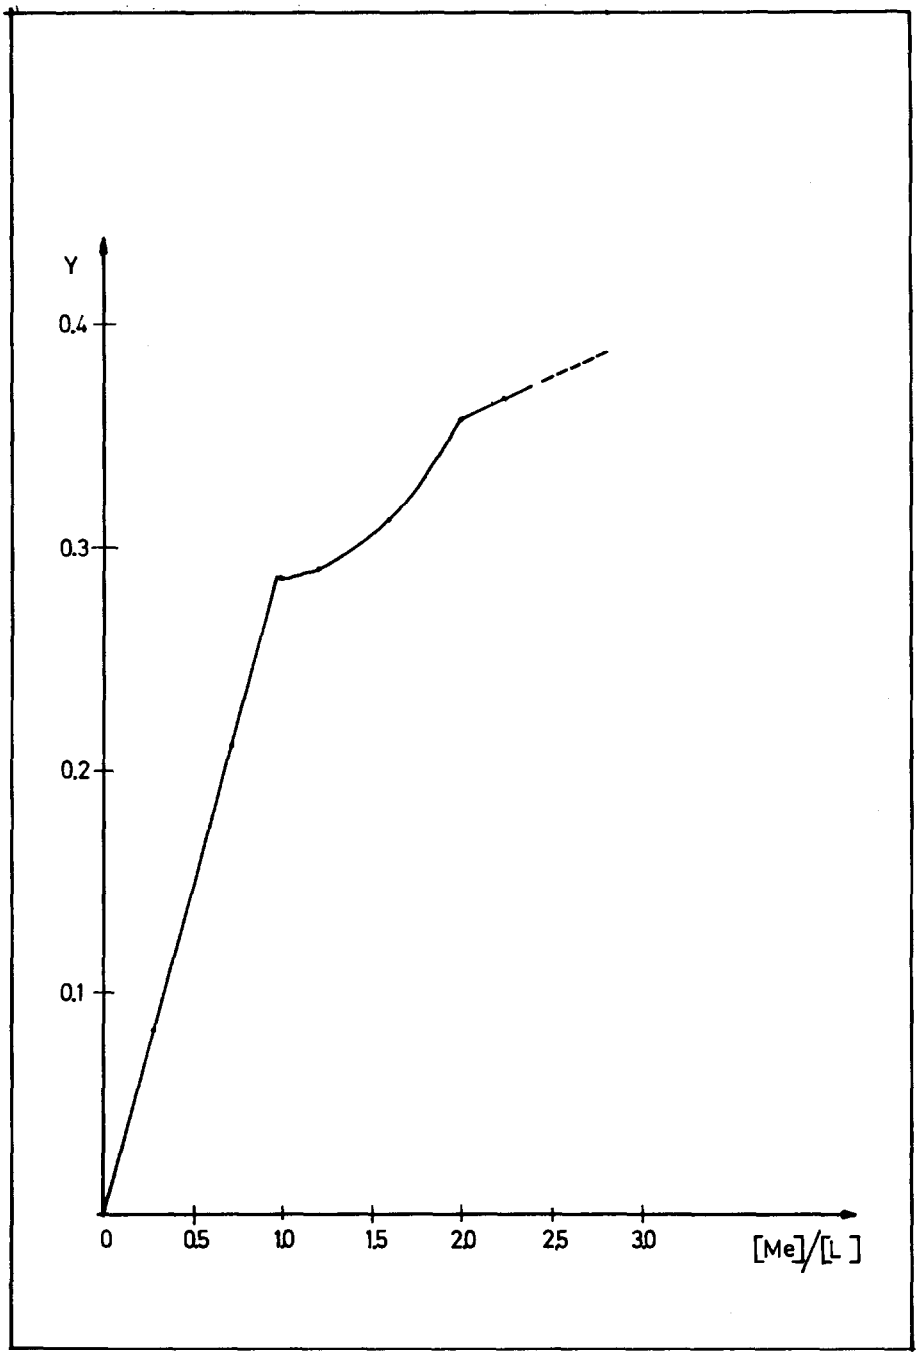

Fig. 2. Mole ratio analysis at 400 nm for the reaction between $[Fe(CN)_5(NH_3)]^{3-}$ and 4-cypy in aqueous solution. [L] = [4-cypy] = 2×10^{-4} M.

solid sample were 16.7 and 21.3% respectively, while corresponding theoretical values (calculated for $Na_6[Fe_2(CN)_{10}(4\text{-cypy})].3H_2O$) were 16.8 and 20.7%.

The UV-VIS spectrum showed bands at λ = 470, 400 and 268 nm (error = $\pm$2 nm), with ϵ = 3.7, 2.0 and 3.8 $\times$ 10^3 M^{-1} cm^{-1} (error $\simeq$ $\pm$5%) respectively.

IR bands appeared at 3470, 2245, 2115, 2055, 1655, 1620, 1488, 1412, 1215, 1018, 835, 825, 570, 560, 535, 495 and 415 cm^{-1} (error $\cong$ 0.5%).

In order to obtain the pseudo-first-order rate constant k_{-1} for process (1), values of ln $(A_\infty - A_t)$ were represented vs time t. Plots were linear up to three half-lives and from their slopes, a value of $k_{-1} = (1.3 \pm 0.1) \times 10^{-3}\, s^{-1}$ was determined.

DISCUSSION

When $[Fe(CN)_5(NH_3)]^{3-}$ is dissolved in water, the ion $[Fe(CN)_5(H_2O)]^{3-}$ is rapidly generated.[10] With ligand L in excess, monomeric species of the type $[Fe(II)(CN)_5L]^{n-}$ can be obtained in good yields. However, if the ratio $[Fe(CN)_5(H_2O)^{3-}]$/[L] is 2:1, dimeric complexes can be synthesized.[11] In this work, when L = 4-cypy, a new ion of formula $[Fe_2(CN)_{10}$ (4-cypy)$]^{6-}$ appeared in aqueous solution, as verified from the continuous variations and the mole ratio methods. Figures 1 and 2 show, in effect, complex formation at the stoichiometric ratio iron:4-cypy = 2:1. Moreover, the solid sodium salt prepared at 0°C has the formula $Na_6[Fe_2(CN)_{10}(4\text{-cypy})].3H_2O$, as deduced from iron and sodium analyses.

With the empirical formula of the new species known, we proceed to investigate its structure. The visible band at 470 nm (ϵ = 3.7 $\times$ 10^3 M^{-1} cm^{-1}) can be assigned to a charge transition $d_\pi(Fe) \rightarrow \pi^*$ (4-cypy), by comparison with data for the monomeric complex $[Fe(CN)_5(4\text{-cypy})]^{3-}$ (λ_{max} = 476 nm, ϵ_{max} = 5.5 $\times$ 10^3 M^{-1} cm^{-1}).[9] If we consider the structure Fe(II)–NC–⟨⬡⟩N–Fe(II), this band must be shifted to higher λ values (with an increase in ϵ) when compared to the mononuclear compound. This occurs in the case of binuclear Fe(II) complexes bridged by aromatic heterocyclic ligands,[11] as shown in Table 1. In the present complex, the observed shift is opposite (i.e. to lower λ and ϵ values) and similar to that produced when a coordinated cyanide is protonated at low values of pH.[9,10] On the other hand, the band at 400 nm corresponds to analogous bands belonging to cyanide-bridged complexes (see Table 1). Although the charge transfer $d_\pi(Fe) \rightarrow \pi^*$ (nitrile end of 4-cypy) is expected to fall at a similar value of λ (405 nm), the experimental value of ϵ (2.0 $\times$ 10^3 M^{-1} cm^{-1}) is much lower than the expected one (7.4 $\times$ 10^3 M^{-1} cm^{-1}). Therefore, from UV-VIS studies, the formation of an Fe(II)–NC–Fe(II) bridge is deduced, and the previous assignment[5] must be corrected.

IR data confirm the above conclusion, Indeed, when a nitrile group is bonded to strong π donors such as $[Ru(NH_3)_5]^{2+}$ or $[Fe(CN)_5]^{3-}$, $\nu_{CN(nitrile)}$ must be shifted *ca.* 60 cm^{-1} below the value for the free ligand (2242 cm^{-1}).[16] The observed value for the complex studied here (2245 cm^{-1}) is clear evidence that 4-cypy is not coordinated through the

nitrile group to a $[Fe(CN)_5]^{3-}$ moiety. Moreover, in the cyanide stretching region, two bands are observed at 2115 and 2055 cm^{-1} (with an approximate intensity ratio of 1;9) which must be due to bridging and terminal cyanides respectively; it is well accepted that bridge formation causes a positive shift in $\nu_{CN(cyanide)}$.[15,17,18] A small blue shift of the 4-cypy characteristic frequencies (when compared to the $[Fe(CN)_5(4\text{-cypy})]^{3-}$ complex[9]) and new bands at 835 and 535 cm^{-1} can also be attributed to the $[(NC)_5Fe\text{–}NC\text{–}Fe(CN)_4(4\text{-cypy})]^{6-}$ structure.

The value obtained for k_{-1} ($1.3 \times 10^{-3}\ s^{-1}$) is slightly higher than that corresponding to 4-cypy dissociation from its monomeric complex with $Fe(CN)_5^{3-}$ ($1.02 \times 10^{-3}\ s^{-1}$).[12] This fact agrees with the shift to lower values of λ_{max} and both phenomena may be accounted for by the decrease of π backbonding Fe→4-cypy caused by the inductive effect of a second $[Fe(CN)_5]^{3-}$ group coordinated *trans*- to 4-cypy. The rate constant for bridge rupture is nearly 10 times more rapid than that of 4-cypy dissociation;[13] the observed rate constant thus corresponds to the latter process.

In conclusion, the new complex must be formulated as sodium tetracyano (4-cyanopyridine)ferrate(II)-μ-cyano-pentacyanoferrate(II) trihydrate: $Na_6[(NC)_5Fe\text{–}NC\text{–}Fe(CN)_4(N\text{⬡}\text{–}CN)].3H_2O$. Its spectral and kinetic properties are not very different from those of the monomeric complex $[(NC)_5Fe\text{–}N\text{⬡}\text{–}CN]^{3-}$, pointing to a small interaction between the metallic centres. The mixed-valence complex (II–III) must present an electron delocalization of *ca.* 1%.[11] The greater stability of an Fe(II)-NC-Fe(II) bridge compared to that of an Fe(II)–NC-⬡N–Fe(II) bridge may be explained by considering that while the formation rate constants must be of the same order of magnitude,[10] the dissociation rate is nearly 5 times greater for the Fe(II)–NC-⬡N bond[12] than for the Fe(II)–NC bond.[13]

Acknowledgements—We thank CONICET, SUBCYT and UNT for financial support, Dr. G. Bossi for AA measurements, Lic. M. E. García Posse for running IR spectra and Dra. D. A. de Iglesias for permission given to use the UV-vis spectrophotometer.

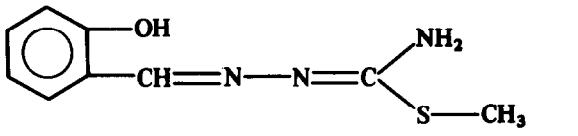
SYNTHESIS, PHYSICOCHEMICAL PROPERTIES AND VOLTAMMETRIC CHARACTERIZATION OF SOME NEW Fe(III) COMPLEXES WITH SEMICARBAZONE-BASED LIGANDS

VUKADIN M. LEOVAC,* LUKA BJELICA and LJILJANA JOVANOVIĆ
Institute of Chemistry, Faculty of Sciences, V. Vlahovića 2, 21000 Novi Sad, Yugoslavia



(*Received* 10 *February* 1984; *accepted* 16 *April* 1984)

Abstract—Several bis(ligand) octahedral complexes of iron(III) with salicylaldehyde semi-, thiosemi-, and S-methylthiosemi- carbazones have been synthesized and characterized by elemental analysis, conductivity and magnetic measurements, electronic and IR spectra, as well as by linear sweep and cyclic voltammetry. General procedures for the syntheses of all types of complexes have been established, giving better defined reaction conditions. Physicochemical properties of the novel complexes have been related to those of the already known compounds of the same type.

It has been established[1–4] that salicylaldehyde semicarbazone (H_2L^1), thiosemicarbazone (H_2L^2), and S-methylthiosemicarbazone (H_2L^3):

($X{=}O \sim H_2L^1$; $X{=}S \sim H_2L^2$)

(H_2L^3)

use in coordination with Fe(III) the following sets of donor atoms: ONO, ONS and ONN, respectively. Depending on pH of the reacting medium, these ligands can take part in coordination either as mono- (HL^-) or di-anion (L^{2-}). The syntheses of the following types of octahedral bis(ligand) chelate complexes of Fe(III): $[Fe(HL)_2]X$ (X = Cl, etc., HL = HL^1, HL^3)[1,4]; Fe(HL)L (HL = HL^3, L = L^3)[4]; and $M[FeL_2]$ (M = Li, NH_4, etc. L = L^1, L^2)[1,3] have been reported in addition to the mono(ligand) complexes $Fe(HL)Cl_2$ (HL = HL^1, HL^2, HL^3).[1,2,4]

Not all types of Fe(III) bis(ligand) complexes have been prepared with each of the above ligands so, we have investigated the preparation of the missing complexes (i.e. $Fe(HL^1)L^1$, $Li[FeL_2^1]$, $[Fe(HL^2)_2]Cl$, $Fe(HL^2)L^2$, and $Li[FeL_2^3]$). The novel complexes have been characterized both crystalline and in solution, and their physicochemical properties have been related to those of the already known compounds.

EXPERIMENTAL

Chemicals and methods

The ligands employed in syntheses were prepared according to procedures described earlier.[5,6] For all syntheses only the Merck $FeCl_3{\cdot}6H_2O$ reagent grade was used. Other chemicals for syntheses were also of p.a. quality of different make.

The voltammetric, conductometric and spectrophotometric measurements were carried out in spectroscopic and freshly distilled p.a. solvents, respectively. The salts serving as supporting electrolytes (tetrabutylammonium perchlorate, TBAP, lithium perchlorate and lithium chloride) were used after recrystallization.

The C,H,N analysis procedure and magnetic susceptibility measurements have been described earlier.[7]

Chlorine was determined by combustion after Schöniger followed by titration with silver nitrate.

For all measurements the air-dry complexes were used except for voltammetric investigations, where drying at 110°C was applied.

Conductivity measurements were carried out using a conductivity meter Radiometer CDM3.

*Author to whom correspondence should be addressed.

IR spectra were recorded in KBr, employing a Perkin–Elmer 457 instrument.

Electronic spectra within the range of 37,000–12,500 cm^{-1} were recorded for the solutions of complexes in N,N-dimethylformamide (DMF) on a Cary 219 spectrophotometer.

Voltammetric experiments were carried out in the thoroughly deaerated (with purged nitrogen) 1 mM solutions of complexes in DMF, containing 0.1 M supporting electrolyte. An AMEL three-electrode set-up was used together with a Hewlett Packard 7044A x–y recorder, or a Hewlett Packard 1741A storage oscilloscope for recording the voltammograms. As the working electrode a glassy carbon disc (geometric surface area: 7 mm^2) was used with a Pt ring counter electrode. An aqueous saturated calomel electrode (Ingold) served as reference and all potentials are reported with respect to this electrode. The experiments were carried out at room temperature, and IR drop corrections were made, when necessary.

Preparation of complexes

For a comparative study of the novel and the already synthesized complexes we prepared all of them according to our own procedures. Since some significant alterations were made in the already known procedures, we have included them here, along with the original ones.

$[Fe(HL^1)_2]Cl{\cdot}H_2O$. The mixture of 1.0 g of $FeCl_3{\cdot}6H_2O$ and 1.2 g of H_2L^1 was dissolved by heating in 15 cm^3 of EtOH (pH 0.4). By adding aqueous ammonia the pH was adjusted to 1.0. This was accompanied by a change of colour of the solution from yellow–brown to deep-purple. The solution was left at room temperature for 24 hr. The black crystals obtained were filtered off and washed with EtOH and Et_2O. Yield: 0.8 g.

$[Fe(HL^2)_2]Cl$. 0.6 g of $FeCl_3{\cdot}6H_2O$ was dissolved by heating in 15 cm^3 of EtOH and mixed with 0.5 g of $NaOAc{\cdot}3H_2O$. After addition of the acetate pH changed from the initial 1.5 to 2.0. The precipitated NaCl was, after solution cooling to room temperature, filtered off and 0.95 g of H_2L^2 was added to the solution. The mixture was heated gently for 5 min with constant stirring. The ligand dissolution was accompanied by precipitation of black crystals, which, after keeping the reacting mixture at room temperature for 1 hr, were filtered off and washed with EtOH and Et_2O. Yield: 0.9 g.

$Fe(HL^1)L^1{\cdot}H_2O$. 0.50 g of $[Fe(HL^1)_2]Cl{\cdot}H_2O$ was dissolved by heating in 30 cm^3 of MeOH. The warm mixture was filtered, then 0.1 g of $LiOAc{\cdot}2H_2O$ added to the solution and the reacting mixture heated for about 10 min. A colour change from deep-purple to brown was noticeable. The reacting mixture was left at room temperature for 5 hr. The black crystals were washed with MeOH and Et_2O. Yield: 0.35 g.

$Fe(HL^2)L^2$ was prepared in a way analogous to the preceeding one. In contrast to the former one, this complex was also obtained by a direct synthesis, as follows:

The mixture of 0.6 g of $FeCl_3{\cdot}6H_2O$ and 1.0 g of $NaOAc{\cdot}3H_2O$ was dissolved by heating in 15 cm^3 of EtOH. The NaCl was filtered off, and to the solution (pH 6) a portion of 0.8 g of H_2L^2 was added. The mixture was heated gently to the complete ligand dissolution (about 10 min). The obtained microcrystalline black precipitate was filtered off and washed with EtOH and Et_2O. Yield: 0.70 g.

$Li[FeL_2^1]{\cdot}3H_2O$. The mixture containing 0.70 g of $[Fe(HL^1)_2]Cl{\cdot}H_2O$ and 0.080 g of $LiOH{\cdot}H_2O$ in 10 cm^3 of EtOH was heated gently† for 5 min and the solution after filtration left at room temperature for 24 hr. The microcrystalline black crystals were washed with the EtOH–Et_2O (1:1) mixture, and finally with Et_2O. Yield: 0.35 g.

$Li[FeL_2^2]{\cdot}H_2O$. The mixture of 0.45 g of $Fe(HL^2)L^2$ and 0.080 g of $LiOH{\cdot}H_2O$ in 7 cm^3 of MeOH was heated for 5 min. Dissolution of the starting complex was accompanied by formation of the needle-like black–green crystals, which, after solution cooling to room temperature, were filtered off and washed with MeOH and Et_2O. Yield: 0.35 g.

$Li[FeL_2^3]{\cdot}H_2O$. 0.94 g of $Fe(HL^3)L^3$ was added into 20 cm^3 of MeOH and all heated gently. Afterwards, to it was added 0.125 g of $LiOH{\cdot}H_2O$ dissolved in 5 cm^3 of MeOH, and the reacting mixture heated gently to complete dissolution of the complex. After warm filtration, 10 cm^3 of Et_2O were added and the solution left in a closed vessel at room temperature for 15 hr. The black cubic crystals obtained (which if powdered are of dark-green colour) were filtered off and washed with MeOH and Et_2O. Yield: 0.60 g.

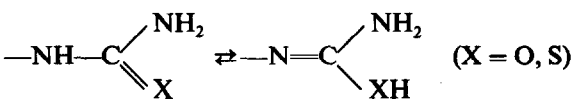
If the solution after filtration was transferred to an evaporating dish and left to concentrate at room temperature to one third of the starting volume, greenish flaky crystals were formed. The crystals were washed with 10 cm^3 of MeOH–Et_2O (1:1) mixture, and finally with Et_2O. Yield: 0.60 g. (This, easier soluble, modification was chemically identical to the former one.)

†Overheating of the mixture resulted in complex degradation and precipitation of the ligand.

$Fe(HL^1)Cl_2 \cdot 2H_2O$. The mixture of 0.45 g of H_2L^1 and 1.5 g of $FeCl_3 \cdot 6H_2O$ was dissolved by heating in 5 cm^3 of acetone. The green solution after filtration was left in an open Erlenmeyer flask for about 3 days. The black crystals were filtered off and washed with EtOH and Et_2O. Yield: 0.20 g.

$Fe(HL^2)Cl_2 \cdot H_2O$. 0.80 g of $FeCl_3 \cdot 6H_2O$ and 0.50 g of H_2L^2 were dissolved by heating in 7 cm^3 of EtOH and left at room temperature for 24 h. The black crystals were filtered off and washed with EtOH, then with 20 cm^3 of the EtOH–Et_2O (1:1) mixture and finally wiht Et_2O. Yield: 0.35 g.

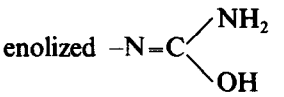
Complexes $[Fe(HL^3)_2]Cl$, $Fe(HL^3)L^3$ and $Fe(HL^3)Cl_2$ were prepared following strictly the procedures described earlier.[4]



RESULTS AND DISCUSSION

Syntheses and general characteristics of complexes

The results of elemental analysis of the complexes obtained by the above procedures have been presented in Table 1.



Formation of different types of complexes is made possible by coordination of the ligand either as a mono- or di-anion. The mono-anion, HL^-, results from deprotonation of the phenolic OH group, leading to formation of the cationic complex, $[Fe(HL)_2]^+$†. For an efficient crystallization of this complex, the ethanolic solution of the Fe(III) salt ought to have pH 1–2. This can be adjusted by adding the necessary amount of either aqueous ammonia, or ethanolic solution of $NaOAc \cdot 3H_2O$.

Complexes of the non-electrolyte type, Fe(HL)L, to which in a DMF solution (as it will be discussed later on) corresponds, most probably, a dimeric formula $[Fe(HL)_2][FeL_2]$, are formed as the result of a further deprotonation of the ligand, leading to its di-anionic form, L^{2-}. This deprotonation is made possible in the case of semi- and thiosemi- carbazones by a tautomeric equilibrium:

taking place at the chalcogen atom. In contrast to this, the di-anion form in the case of S-methylthiosemicarbazone is formed by deprotonation (apart from phenolic group) of the coordinated NH_2 group.[4]

Syntheses of the crystalline complexes of the non-electrolyte type with all three ligands were accomplished in two different ways, i.e. by direct and indirect synthesis. The first method involved reacting the ethanolic solution of Fe(III) hydroxo-acetate (obtained in the reaction of $FeCl_3 \cdot 6H_2O$ and $NaOAc \cdot 3H_2O$, after removal of NaCl) and a stoichiometric amount of the ligand. The indirect synthesis can be realized either by reacting the methanolic solution of the cationic complex and an excess of $LiOAc \cdot 2H_2O$, or, by mixing the methanolic solutions of the corresponding cationic and anionic complex in a stoichiometric ratio. In all three cases the complexes of a satisfactory purity are formed. This holds for H_2L^2 and H_2L^3 complexes, while the direct synthesis in the case of H_2L^1 resulted in $[Fe(HL^1)_2]OAc \cdot H_2O$. This indicates a hindered deprotonation of the OH group from the

The anionic type of complexes, i.e. the corresponding lithium salts, $Li[FeL_2] \cdot xH_2O$, were obtained in the reaction of alcoholic solutions of either cationic, or, non-electrolyte complexes and a smaller excess of $LiOH \cdot H_2O$.

In contrast to the above group, the mono-(ligand) complexes can be obtained from concentrated solutions of $FeCl_3 \cdot 6H_2O$ and the corresponding ligand in EtOH and Me_2CO, respectively, in the presence of an excess of the Fe(III) salt.

All described complexes are black crystals, while in powdered state they are brown. The exception is $Li[FeL_2^3] \cdot H_2O$ which is green. The complexes are mostly soluble in MeOH, EtOH and DMF; the solubility of the anionic and mono(ligand) complexes being generally the highest and that of the non-electrolyte type the lowest. The former two types of complexes are moderately soluble in water, the others being practically insoluble. Dissolution in water is often accompanied by the complex decomposition. All the complexes are insoluble in Et_2O.

On the basis of the data presented in Table 2, it can be concluded that mono(ligand) and cationic complexes are thermally less stable than other types of complexes. The common characteristic of the non-electrolyte complexes is that they are susceptible to certain changes at higher temperatures, which are not easily observable due to

†Isolation of the crystalline $[Fe(HL^1)_2]Cl.H_2O$, described earlier,[1] was not possible with the $FeCl_3.6H_2O$ at our disposal without a pH adjustment; the later fact was not mentioned in the original work.

their dark colour. After these changes, on elevation of temperature, the substance decomposes with evolution of gaseous products. Thus, no melting occurs. Some other complexes behave similarly.

Molar conductivity

The results of molar conductivity measurements have been presented in Table 2. Although the selected solvents, MeOH and DMF, are not the best for conductivity measurements, due to their possible interactions with the dissolved complexes,[8] they were chosen to support the suggested formulae, for the reason of a relatively good solubility of the studied complexes. In general, the conductivities of all types of complexes are lower in DMF than usually expected for 1:1 electrolytes (65–90) while the values measured in MeOH fall mostly within the range for 1:1 electrolytes (80–115).[8]

The lower conductivity of cationic complexes in DMF can be explained by possible interaction of the complexed Fe(III) species with almost unsolvated Cl^- (the donor/acceptor properties of

DMF and Cl^- are about the same),[9] resulting thus in the ion-pair formation. The same holds for anionic complexes where Li^+ solvation by DMF must be taken into account. In addition, although it is not obvious from the first sight, the non-electrolyte complexes in DMF may be still present in the dimeric form, i.e. $[Fe(HL)_2][FeL_2]$, as it was confirmed by voltammetric study (see later). The extremely low conductivity of these complexes (with the exception of the thiosemicarbazone one) can be explained also by interactions of the weakly solvated constituent cation and anion. In contrast to this, the suggested dimeric structure for non-electrolyte complexes could not be confirmed in MeOH, because of low solubility of the two complexes and the inconvenience of MeOH as solvent in voltammetric measurements. Finally, the supposed dimeric formula of the mono(ligand) complexes in DMF, i.e. $[Fe(HL)_2][FeCl_4]$, is suggested (apart from the voltammetric experiments) by the data characteristic for 1:1 electrolytes.

Magnetic susceptibilities

As can be seen from Table 2, all of the complexes, with the exception of $Li[FeL_2^2]\cdot H_2O$, have at room temperature the values for effective magnetic moments characteristic for the high-spin octahedral Fe(III) complexes (term $^6A_1$). This means that neither a change in charge of the complex/ligand, nor even a change of the set of coordinated atoms from N_2O_4 (in H_2L^1) via $N_2O_2S_2$ (in H_2L^2) to N_4O_2 (in H_2L^3), have enough influence on the strength of the ligand field sufficient to change the spin state of the central Fe(III) ion. The only exception is, as stated above, $Li[FeL_2^2]\cdot H_2O$, which as well as the earlier described di-hydrate $Li[FeL_2^2]\cdot 2H_2O$ (μ_{eff} (300) = 2.19 B.M.),[3] has the effective magnetic moment characteristic for a low-spin Fe(III) state (term $^2T_2$).

Such low μ_{eff} values for the obtained complex, as well as for the already reported di-hydrate, is not, undoubtedly, a consequence of the change of charge on the ligand, but is due to the strong polarizing effect of the Li^+ ion.[3]

IR spectra

As has been already mentioned,[1-3] each of the ligands under consideration use three donor atoms† in coordination. Two donor atoms are common for all three ligands, namely: oxygen from the phenolic hydroxyl and nitrogen from the azomethine group. The third donor atom in H_2L^1 is oxygen of the C=O group,[1] the sulphur of the analogous C=S group[2] in H_2L^2 and the nitrogen from the NH_2 group[3] in H_2L^3.

The IR spectra of the ligands and complexes described here, indicate that the above donor atoms are engaged in coordination. The strong band appearing at 1270 cm^{-1} in the IR spectra of all three ligands, assigned to valence vibration of the phenolic C–O group,[12] is shifted in the complexes toward higher energies ($1290 \pm 10\ cm^{-1}$), indicating that the oxygen takes part in coordination.

The very strong and sharp band for the azomethine group, ν(C=N), which in the spectra for free ligands H_2L^2 and H_2L^3 is at $1600 \pm 10\ cm^{-1}$, is shifted for complexes by about $10\ cm^{-1}$ to lower energies,[13,14] while in the case of H_2L^1 complexes it is shifted by the same amount in the opposite direction.[10]

The very strong band ν(C=O)(H_2L^1), appearing at $1690\ cm^{-1}$ in the ligand spectrum is also shifted due to coordination towards lower frequencies ($\Delta\nu = 45\ cm^{-1}$).

An indication that the sulphur atom in H_2L^2 (as the third donor atom) is coordinated, is the absence of the bands at 1070 and 1370 cm^{-1}, corresponding to ν_s and ν_{as}(C=S) in the free ligand spectrum.[15]

Coordination of nitrogen from the NH_2 group of H_2L^3 can be substantiated by its deprotonation leading to a di-anionic form of the ligand, and by a shift of the strong and sharp $\delta(NH_2)$ band from 1635 to $1600\ cm^{-1}$. It should be mentioned that this band in the spectra for other two ligands is not well separated from the main ν(C=N) band. Therefore, it appears as a shoulder at $1615\ cm^{-1}$, remaining in complexes, practically, at the same position.

Electronic spectra

The corresponding electronic spectral data for all types of complexes in DMF are given in Table 3. It is common for all complexes that only a few well developed absorption maxima ($\epsilon < 7{,}000$) are formed in the visible region, the other appearing as broad absorption bands or shoulders. Thus, the main spectral characteristics of a particular type of complexes arise in UV region, where they are influenced by the structure of the ligand involved in coordination. Generally, the UV spectra of cationic and mono(ligand) species resemble the

†In Refs. 10 and 11 the examples have been reported for a bidentate coordination of salicylaldehyde semicarbazone.

spectra of ligand alone, with usually two well separated absorption bands. For thiosemi- and S-methylthiosemi- carbazone complexes the main absorption occurs at $\sim 30{,}000\ cm^{-1}$ ($\epsilon > 30{,}000$) and in the range of 32,000–34,000 cm^{-1} (ϵ30,000–40,000) where two insufficiently separated absorption maxima are observed. The exceptions are the semicarbazone complexes of the same type, where one of two main peaks appearing in the spectrum of the ligand alone at 31,000 cm^{-1} in the complexes disappears. The other significant maximum in these spectra at $\sim 36{,}000\ cm^{-1}$ ($\epsilon > 30{,}000$) is also present in the spectrum of the ligand itself.

The spectra for all three anionic complexes differ from each other and from those for corresponding ligands. The common characteristic of $Li[FeL^2_2]$ and $Li[FeL^3_2]$ is the appearance of a band at $\sim 36{,}000\ cm^{-1}$ ($\epsilon > 20{,}000$) which does not exist in the corresponding ligand spectrum. This reflects the structural/electronic differences of the ligand in H_2L and L^{2-} form.

Electronic spectra of non-electrolyte type of complexes resemble the superimposed spectra of the corresponding cationic and anionic species. It also may be a confirmation of the supposed dimeric structure of the non-electrolyte complexes in DMF solutions.

Finally, it is well known that the electronic spectra of iron(III) complexes contain only exceptionally *d–d* transitions; the bands being sometimes overlapped by the strong charge transfer absorptions.[16] Hence, it might be expected that all absorptions in the studied complexes occuring below $29{,}000\ cm^{-1}$ belong to $d - \pi^*$ interactions. The absorptions at >29,000 cm^{-1}, since they are in

some way present in the ligand spectrum, may be attributed to the ligand π–π^* transitions.

Voltammetric studies

It has been found that shapes of cyclic voltammograms for some complexes are greatly affected by the nature of the supporting electrolyte present in the solution. In the presence of an "inert" electrolyte, such as TBAP, the voltammetric curves, with exception of those for the anionic complexes, are ill-defined and difficult to interpret. The addition of LiCl to the solutions of H_2L^2 and H_2L^3 complexes resulted in much better defined voltammograms. This favourable effect can be ascribed both to the ability of Fe(III) to form relatively stable complexes with chloride, and to the ion-pairing effect of the lithium ion. Hence, all the voltammograms presented were recorded for the complex solutions containing 0.1 M lithium chloride. On the other hand, it appeared that the electrode reactions in the presence of this electrolyte are coupled to a number of chemical reactions†.

We have presented here the voltammetric characteristics for the novel complexes in comparison to those of the already known compounds. To facilitate discussion, all the reduction-oxidation peaks have been identified and denoted by capital letters.

Cyclic voltammogram for the newly synthesized cationic complex $[Fe(HL^2)_2]Cl$ (Fig. 1) is quite similar to that (shown in the inset) for the analogous compound in the H_2L^3 series.[18] Thus, similarity of the cyclic voltammograms is another confirmation of the supposed complex type. From the difference between the first and the second scan it can be concluded that only the main reduction

†A detailed electrochemical study of the full range of Fe(III) complexes with all three ligands, including the possible reaction schemes, will be described elsewhere.[17]

peak (denoted as C) and its oxidation counterpart (F) are directly related to the species present in the bulk; the other peaks being the consequences of coupled chemical reactions. The detailed studies showed that the species corresponding to peak C is not a bis(ligand) complex cation $[Fe(HL^2)_2]^+$, but a mono(ligand) one, $[Fe(HL^2)Cl_x]^{2-x}$, where x is most likely equal to 3. The C–F separation is, within the range of scan rates employed, characteristic for an apparent quasi-reversible one-electron process, involving chemical complications. The reduction peak D (oxidation counterpart: E), which in this case is much less separated from peak C if compared to the picture shown in the inset, obtained at the same sweep rate, can be assigned to the reduction of the anionic species $[FeL_2^2]^-$, formed by a chemical reaction following the electronation at C. After an oxidation at potential E, this species undergoes a further oxidation at peak H (reduction counterpart: A), after which follows another chemical reaction. Peak G (counterpart: B) represents the oxidation of $FeCl_2$, resulting from another chemical reaction i.e. the ligand releasing process occuring after the reduction at peak C.

The cyclic voltammograms presented for $Li[FeL_2^3]$ (Fig. 2) were recorded within two complementary potential amplitudes. The reason was the inability of the voltammetric equipment employed to complete a full cycle when an asymmetric potential signal was applied. It is evident that voltammetric behaviour of complexes of this type is much simpler than of the former ones. The

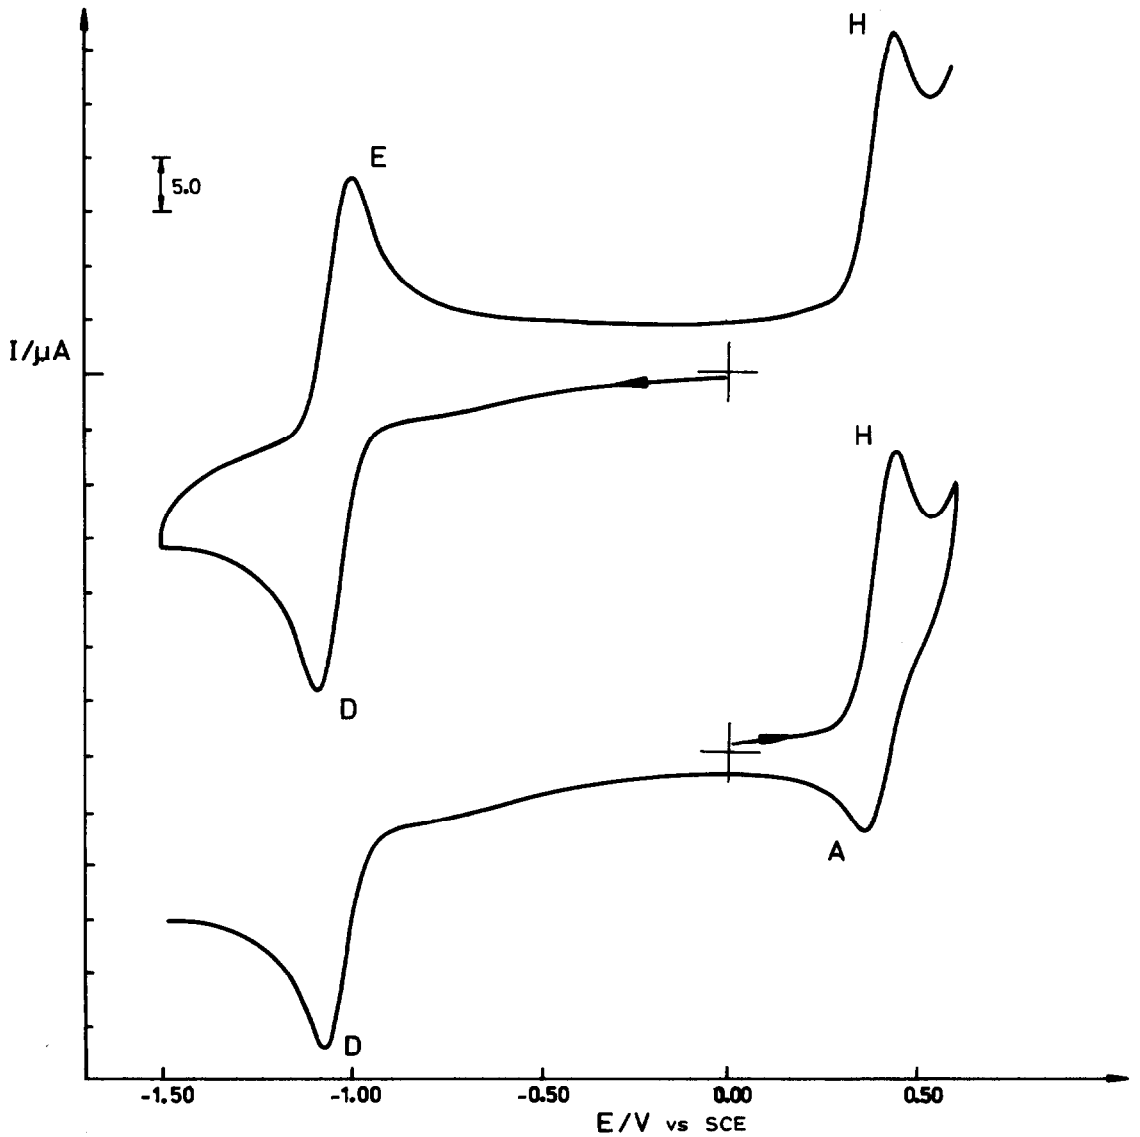

Fig. 2. Cyclic voltammograms for $Li[FeL_2^3]$; 1 mM DMF solution, 0.1 M LiCl. Sweep rate: 0.200 V s^{-1}.

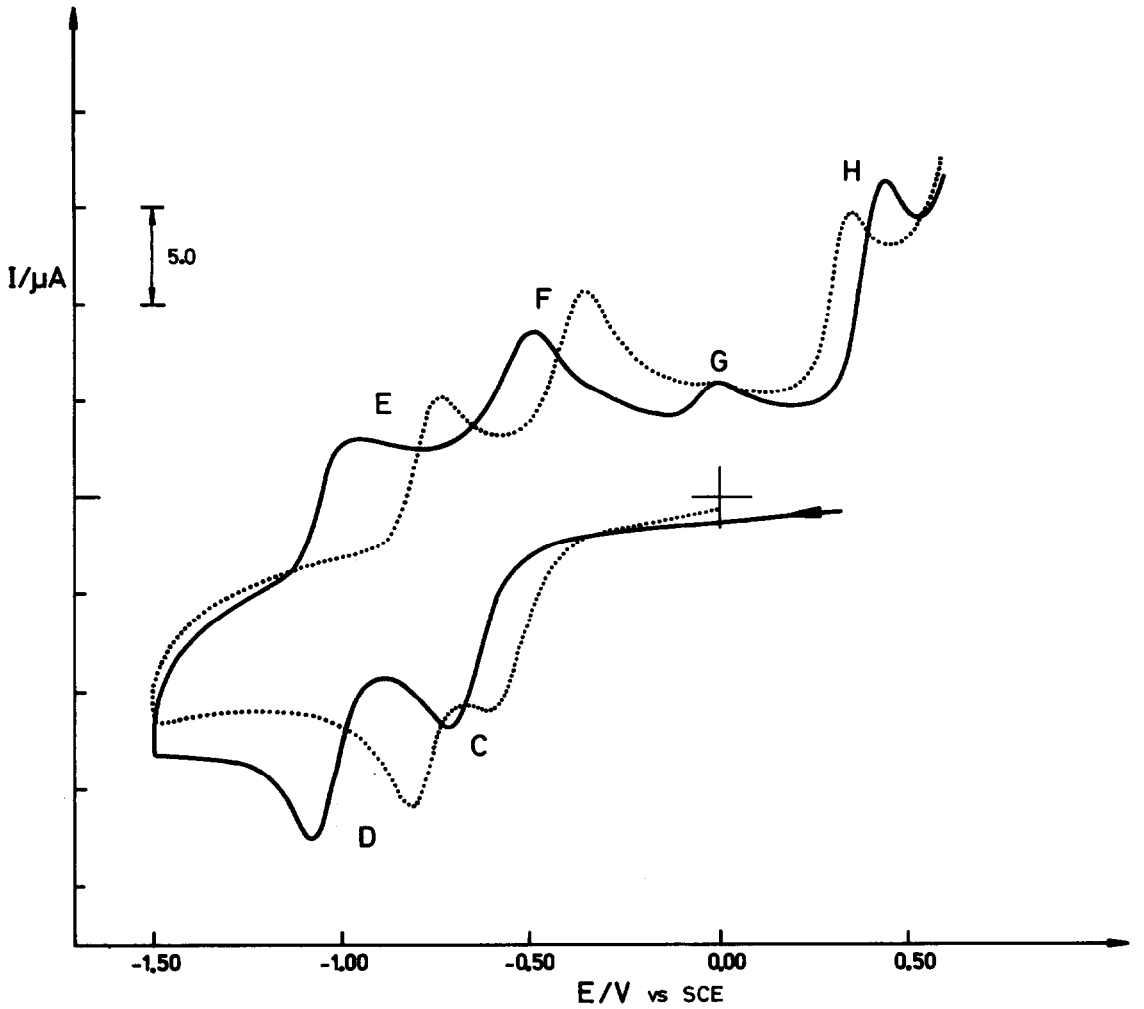

Fig. 3. Cyclic voltammograms for 0.5 mM DMF solutions of non-electrolyte complexes, 0.1 M LiCl. ....., $Fe(HL^2)L^2$; ———,$Fe(HL^3)L^3$. Sweep rate: 0.200 V s^{-1}.

complex is reduced in a one-electron quasi-reversible process (peak D; counterpart: E) and oxidized in a similar process (peak H; counterpart: A). The peak assignation was accomplished on the basis of the voltammograms for $[Fe(HL^3)_2]Cl$ and $Fe(HL^3)L^3$, as well as for $Li[FeL_2^2]$.[19]

Since for the anionic complex solutions containing TBAP or $LiClO_4$ the cyclic voltammograms obtained were generally of the same shape as the above ones, it can be concluded that Cl^- ion has no effect on the primary reactants, nor on the electrode reaction products. The difference in D/E peak potentials for the voltammograms recorded in the presence of TBAP and Li salts, respectively, consists in their anodic shifting with increasing Li^+ concentration, due to the ion-pair formation of Li^+ with both the reduced dianionic $[FeL_2]^{2-}$ and (to some extent) the original $[FeL_2]^-$ species.

Cyclic voltammograms for the non-electrolyte type of complexes, $Fe(HL^2)L^2$ and $Fe(HL^3)L^3$ (Fig. 3) do not reflect properties of the one unique species, but, as it can be concluded from the voltammograms shown in Figs. 1 and 2, they are composed of the parts characteristic for the corresponding cationic and anionic complex. This gives strong support to the idea that a more appropriate coordination formula for these complexes in DMF solutions should be $[Fe(HL)_2][FeL_2]$‡. As it has been already mentioned, this was also confirmed in the complex synthesis by mixing solutions of the corresponding constituent complexes. It should be mentioned that a similar conclusion on a dimeric nature is also valid for $Fe(HL)Cl_2$ complexes, whose more correct coordination formula, as stated above, should be $[Fe(HL)_2][FeCl_4]$.

Some cyclic voltammetry data on the non-electrolyte complexes obtained at glassy carbon

‡Another piece of evidence suggesting the same could be gained from the rotating disc experiments, resulting in two well defined waves, characteristic for pure cationic and anionic complexes, respectively.

[a]In DMF solution, complex 0.5 mM(taken as dimer), 0.1 M LiCl supporting electrolyte. [b]Sweep rate, in V s^{-1}. [c]Electrode potentials in V vs. SCE. Letters in parentheses denote the corresponding peak. [d]In μA mM^{-1} $V^{-1/2}$ $s^{1/2}$. [e]Ill-defined peak. [f]Irreversible oxidation at H, no reduction peak A at the subsequent scan. [g]Due to the coupled chemical reaction, no peak A appear at this sweep rate.

electrode have been given in Table 4. Comparing the peak potentials for C/F, D/E and A/H couples for these complexes, it can be concluded that the thiosemicarbazone complexes are more easily reduced/oxidized than those of the other two classes of complexes. The effect is most pronounced in the case of D/E couple corresponding to bis(ligand) anionic species, where two sulphur atoms involved in coordination can facilitate stabilization of the product formed by the electron transfer.

The $\Delta E_p/\Delta \log v$ analysis gave a slope of about 60 mV per tenfold increase in sweep rate for peaks C/F, but less than 30 mV for all other peak couples. This indicates the possible kinetic complications, described above.

The voltammograms for the H_2L^1 complexes were not well defined (especially at higher sweep rates) in all supporting electrolytes used. Hence, they were less suitable for analysis. The exception was the anionic complex which behaves similarly to the analogous compounds described above.

Abstract—Unsubstituted (**1**) and 3,7,10-trimethyl substituted (**2**) 1-(4′-tolyl)-silatranes were synthesized. ^{1}H, ^{13}C, ^{15}N and ^{29}Si NMR spectra were recorded and assigned. The conformation of the **2** stereoisomers in solution were characterized by the NMR spectra. **1** is monoclinic, $P2_1/c$, with $a = 13.454(2)$, $b = 13.888(2)$, $c = 14.345(2)$ Å, $\beta = 99.10(2)°$. The major stereoisomer fraction of **2** is orthorhombic, *Pbca*, with $a = 12.168(2)$, $b = 13.754(4)$, $c = 20.260(3)$ Å. The structures were solved by direct methods and were refined by least squares to R values of 0.039 and 0.066 for 3523 and 2158 reflexions. The N→Si distances are **1**: 2.169(2) (mean) and **2**: 2.236(3) Å. The solid state conformation of the **2** major stereoisomer fraction is different from that in solution and this is the first example of a silatrane crystal structure where the silatrane moiety lacks C_3 symmetry.

The crystal structures of 1-hydrogen-3,7,10-trimethylsilatrane[1] and 1-chloromethyl-3,7-dimethylsilatrane[2] of the C-methyl substituted silatrane series have been determined and the X-ray structure determination of 1-chloromethyl-3,7,10-trimethylsilatrane is also referenced in the literature[3] though no atomic coordinates or molecular geometry have yet been published.

To elucidate the effect of the C-methyl substitution on the molecular geometry (particularly on the length of the N→Si approach) we synthesized 1-(4′-tolyl)-silatrane (**1**) [1-(4′-tolyl)-2,8,9-trioxa-5-aza-silatricyclo[3.3.3.$0^{1,5}$]-undecane] and 1-(4′-tolyl)-3,7,10-trimethylsilatrane (**2**) [1-(4′-tolyl)-2,8,9-trioxa-3,7,10-trimethyl-5-aza-silatricyclo[3.3.3.$0^{1,5}$]-undecane) and their conformation was studied by NMR and X-ray crystal structure analysis.

EXPERIMENTAL

(1) *Synthesis*

1-(4′-tolyl)-silatrane (**1**) was prepared according to Frye *et al.*[4] The crude product was recrystallized from petroleum ether. M.p. 196–198°C (Lit.: 195–195.5°C[5]). 1-p-tolyl-3,7,10-trimethylsilatrane (**2**): p-$CH_3C_6H_4Si(OCH_3)_3$ (17.0 g, 80 mmol) and $N[CH_2CH(OH)CH_3]_3$ (15.3 g, 80 mmol) was reacted in 50 cm^3 xylene at 110–112°C for 2 hr in the presence of KOH catalyst (0.2 g). The methanol by-product (7.5 cm^3) was distilled from the system. The crude product was precipitated by adding 20 cm^3 petroleum ether to the solution. The compound was recrystallized from benzene. Yield: 19.3 g (78%), m.p.: 147–148°C. [Found: C, 61.1 (62.5); H, 8.03 (8.20); N, 4.17 (4.55); Si, 9.23 (9.13)%]. IR (cm^{-1}): 263m, 330s, 431m, 514s, 546s, 626vs, 667w, 703w, 770vs, 810m, 885s, 975vs, 982vs, 1060s, 1070s, 1092m, 1105vs, 1150vs, 1180m, 1268w, 1330w, 1375m, 1460w, 1500w, 1596w, 2890m, 2975s, 3070w.
MS (*m/e*): 307(16%) (M^+), 216 (100%)($M-R^+$).

(2) *The separation of the stereoisomers of 2*

The synthesis of **2** leads to a mixture of diastereomers. The theoretical isomer ratio is 1 : 3. Their separation was performed by HPLC using a HPLC-DUPONT 830 chromatograph, normal phase Chromsil column, dichloromethane : hexane = 1 : 4 eluent, UV detector (254 nm). The minor stereoisomer had shorter retention time. Crystals for single crystal X-ray analysis were prepared from the fraction of the major stereoisomer.

(3) *NMR studies*

The ^{15}N and ^{29}Si-NMR spectra were recorded at 2.35T on a JEOL FX-100 spectrometer. ^{13}C and ^1H-NMR spectra were recorded at 4.7 and 7.0T on Bruker spectrometers WP200 SY and WH300, respectively. Samples were taken in $CDCl_3$ solutions and TMS was used as internal reference standard for the ^1H, ^{13}C and ^{29}Si spectra. The ^{15}N-NMR chemical shifts were determined relative to external aqueous $K^{15}NO_3$ then were converted to external nitromethane ($\delta_{CH_3NO_2} = 0.0$ ppm). Shifts upfield from the reference have negative values.

(4) *Crystallographic studies*

Unit cell determinations and intensity data collections were performed on an Enraf–Nonius CAD4 diffractometer. Unit cell parameters were obtained by least squares refinement of the setting angles of 25 carefully centered high-angle reflexions.

Crystal data. Compound **1**: $C_{13}H_{19}NO_3Si$, F.wt. = 265.4 a.m.u., monoclinic, a = 13.454(2), b = 13.888(2), c = 14.345(2)Å, β = 99.10(2)°, V = 2646.6(1.9) Å^3, space group $P2_1/c$, Z = 8, D_c = 1.332 gcm^{-3}, $F(000)$ = 1136, $\mu(Mo\text{–}K_\alpha$–, λ = 0.7107 Å) = 1.7 cm^{-1}. Compound **2**: $C_{16}H_{25}NO_3Si$, F.wt. = 307.5 a.m.u., orthorhombic, a = 12.168(2), b = 13.754(4), c = 20.260(3) Å, V = 3390.7 (2.0) Å^3, space group *Pbca*, D_c = 1.205 gcm^{-3}, μ ($Mo\text{–}K_\alpha$–) = 1.4 cm^{-1}.

Data collection

CAD4 diffractometer, graphite monochromated $Mo\text{–}K_\alpha$ radiation, 2θ–ω scan.

Compound **1**: $1.5 \leq \theta \leq 25°$, 4134 non-zero unique intensities collected, 3523 observed [$F^2 \geq 2\sigma(F^2)$].

Compound **2**: $1.5 \leqq \theta \leqq 30°$, 3282 non-zero unique intensities, 2158 observed [$F^2 \geqq 2\sigma(F^2)$].

The solution and refinement of the structures

Both structures were solved by direct methods and subsequent Fourier syntheses. Hydrogen atomic positions were generated from assumed geometries. No absorption correction was applied.

Compound **1**: Difference maps clearly showed partial disorder in molecule B of the asymmetric unit. Multiplicities of disordered atoms were refined in isotropic least squares and were kept fixed during full-matrix anisotropic refinement. No hydrogen atomic parameters were refined. The final R-values were: $R = \Sigma|\Delta F|/\Sigma|F_0| = 0.039$, $R_w = [\Sigma|w\Delta F^2|/\Sigma wF_0^2]^{1/2} = 0.054$ with $w = [\sigma^2(F) + 0.25(pF_0)^2]^{-1}$, $p = 0.01$.

Compound **2**: The structure was refined by full-matrix anisotropic least-squares. Hydrogen atomic coordinates with isotropic temperature factors were also refined in two final cycles. $R = 0.066$, $R_w = 0.067$, w as in compound **1**.

Final atomic coordinates, thermal parameters and lists of F_0/F_c values have been deposited with the Editor as supplementary data.† Programs, computer and sources of scattering factors are given in Ref. 6.

DISCUSSION

NMR results

Due to the incomplete chromatographic separation of the **2** diastereomers the NMR spectra of the pure minor stereoisomer could only be recorded. The fraction of the major component always contained some of the minor stereoisomer as was observed in the spectra.

The chemical shifts (ppm) of **1** and **2** are listed

†Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre for inclusion in their Data Base. Copies are also available, on request, from the Editor at Queen Mary College.

in Table 1. The silatrane skeleton consists of three fused five-membered rings (Si–O–C–C–N). ^{1}H-NMR data indicate a homogeneous conformational state of the rings in the minor component of **2** with quasi-equatorial methyl groups in the dominant conformation as shown by the ^{3}J coupling constants. One of the methyl groups adopts a quasi-axial position, however, in the major stereoisomer component (^{3}J = 6.0 and 6.6 Hz). This result is further supported by the ^{13}C-NMR spectrum since the chemical shift increase caused by an axial methyl group in β position is smaller than that induced by an equatorial one,[7] facilitating also the assignment of the NCH_2 signals. The change in J_{gem} accounts for small deformations in the ring bearing the axial methyl group. This arrangement enhances the conformational stability of the silatrane moiety as was shown by temperature-dependent NMR measurements.[8]

The crystal structures

The two molecules of the asymmetric unit of **1** are depicted in Fig. 1 and the molecules of **2** in Fig. 2. Bond distances and angles observed in the silatrane moieties are given in Tables 2 and 3.

The single crystal of **2** subjected to X-ray struc-

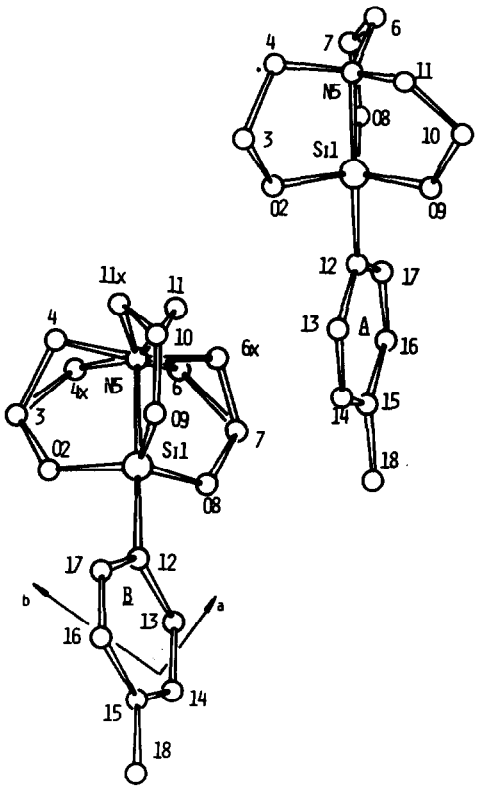

Fig. 1. The two molecules of the asymmetric unit of compound **1**. Numbers are for carbon atoms unless indicated otherwise. Hydrogen atoms are omitted for clarity. Site occupancy factors of the disordered carbon atoms in molecule B are 0.85 (C(6), C(4), C(11)) and 0.15 (C(4)x, C(6)x, C(11)x).

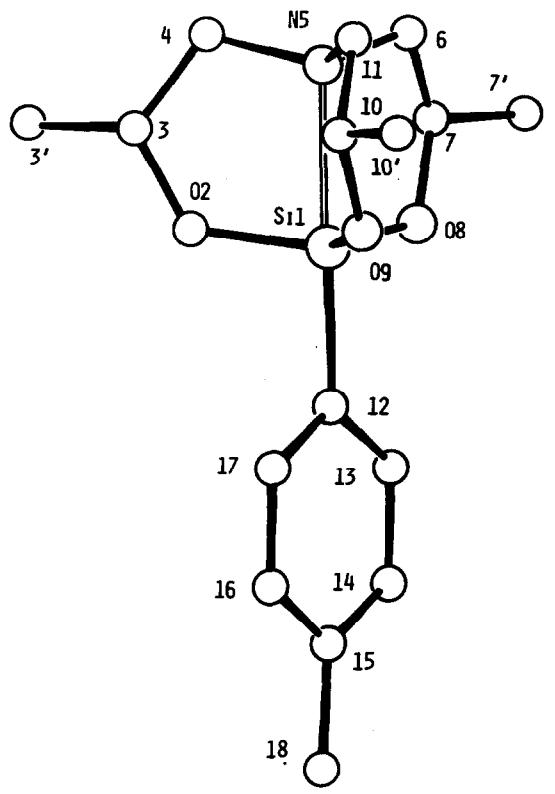

Fig. 2. The molecular diagram of compound **2**.

ture analysis contains molecules of the major stereoisomer component (see Fig. 3).

The length of the N→Si dative bond (*d*) is longer by 0.067 Å in **2** than in **1**. This result is contradictory to the findings of Demidov *et al.*[3,9] who reported the same *d* distances (2.12 Å) for the unsubstituted, 3,7-dimethyl- and 3,7,10-trimethyl-substituted chloromethyl derivatives, stating that the N→Si interaction is unaffected by methyl substitution in the silatrane skeleton.

The most important factor in the formation of the peculiar N→Si interaction is the electron withdrawing property of the apical substituent on silicon. The correlation utilizing the inductive Taft constant[10] of the *p*-tolyl group results in a calculated *d*-value of 2.172 Å, while the correlation of the group electronegativity with *d*[11] predicts a 2.163 Å long dative bond. The two methods give rather good approximations of the bond length observed in **1** and the significant deviation in **2** may be attributable to the methyl substitution.

The methyl substituents may have electronic effects besides causing conformational changes in the silatrane skeleton. As electron-releasing groups they may reduce the electron-withdrawing effect of the oxygen atoms attached to silicon. The less-positive silicon atom forms a weaker interaction with the lone pair from nitrogen.

Considerable changes also take place in the silatrane moiety on methyl substitution. The silatrane skeleton is formed by three five-membered rings of envelope-like conformation. In derivatives, unsubstituted in the silatrane skeleton, carbon atoms in α-position to nitrogen sit on the flaps of the envelopes. The remaining atoms [Si, O, C(β), N] form a quasi-planar moiety. The mean deviation of these atoms from their weighted least squares planes in **1** (averaged over the six rings in the asymmetric unit omitting disordered carbon atoms with the lower site-occupancy) is 0.035 Å and the normal distance of the flap carbon atoms from this plane is 0.455 Å.

Contrary to **1**, the methyl substituted carbon atoms (in β-position to nitrogen) in **2** are out of the quasi-planar moiety formed by the Si, O, C(α), N atoms (Fig. 3). The mean distance of the plane-forming atoms from their weighted least squares planes is 0.014 Å, while the average distance of the C(β) atoms from this plane is 0.325 Å. All methyl substituents are in quasi-equatorial position (the mean deviation of the methyl carbon atoms from the plane is 0.117Å). The average O–C–C–N

torsion angle is less by 10° in **2** [29(1)°] than in **1** [39(2)°]. Thus the solid state conformation of the **2** major stereoisomer fraction is different from that in solution as indicated by the NMR data. Axial methyl groups present in solution may result from ring inversion.

Though collective conformational transitions are assumed for the silatrane moiety with the retention of the C_3 symmetry,[8,9] the crystal structure of **2** is the first example of a silatrane skeleton without C_3 symmetry (Fig. 3). While C(3) and C(7) atoms lie on the same side of the least squares

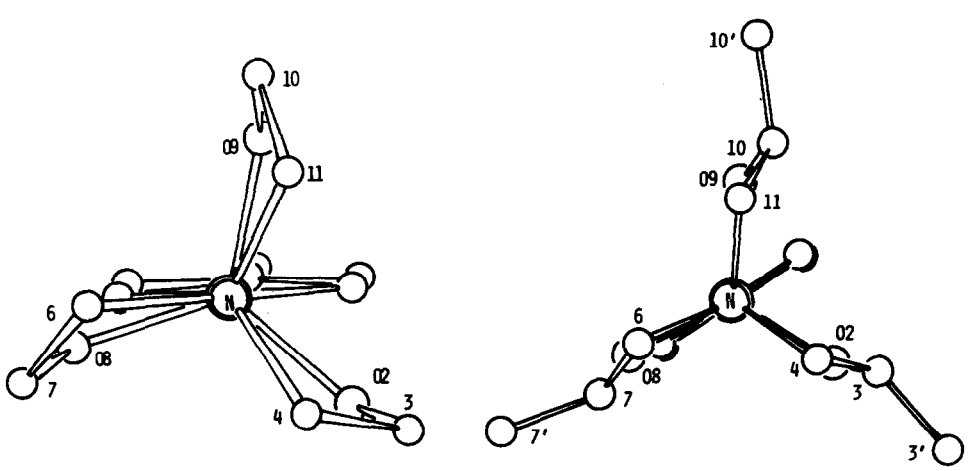

Fig. 3. Compounds **1** (molecule A) and **2** as viewed down the N→Si bond axis.

planes defined by the other four atoms of their five-membered rings, C(10) is on the opposite side. Thus "flap-atoms" C(3) and C(10) face each-other and the C(3′) and C(10′) methyl groups point to opposite directions.

The configurations around the silicon and nitrogen atoms are in good correlation with d in both compounds. The distance of silicon from the plane formed by the equatorial oxygen atoms (ΔSi) and the distance of nitrogen from the plane of its substituent carbon atoms (ΔN) were shown to be in linear correlation with d.[11] Strong N→Si interaction leads to the formation of a more regular trigonal bipyramid around silicon which lies closer to the equatorial plane. The flattened tetrahedron around the nitrogen atom changes inversely with d: a weaker interaction (longer d) results in a more flattened tetrahedron. The observed and calculated ($\Delta\text{Si} = 0.488d - 0.863$; $\Delta\text{N} = -0.391d + 1.214$ Å) values are as follows: Compound **1** observed [calculated]: ΔSi = 0.204(2) [0.195], ΔN = 0.3663(2) [0.3659], compound **2**: ΔSi = 0.2360(9) [0.2282], ΔN = 0.357(3) [0.340] Å.

Acknowledgement—We thank Prof. G. Fritz (Karlsruhe, F. R. G.), Drs L. Szilágyi (Debrecen, Hungary) and E. Kocsi (Budapest, Hungary) for their valuable contribution in the NMR measurements and the chromatographic work.

SYNTHESIS AND SOME REACTIONS OF TRIS (PENTAFLUOROPHENYL) ANTIMONY COMPOUNDS

PREM RAJ*, A. K. SAXENA, KIRAN SINGHAL and ASHOK RANJAN
Department of Chemistry, Lucknow University, Lucknow 226 007, India

(*Received* 1 *March* 1984; *accepted* 16 *April* 1984)

Abstract—$(C_6F_5)_3Sb$ has been found to react with interhalogens and halo-pseudohalogens, IX(X = Cl, Br, N_3 and NCO), pseudohalogen $(SCN)_2$ and elemental sulphur to give oxidative addition products (**I–VI**). $(C_6F_5)_3SbS$(**VI**) may also be prepared by the reaction of $(C_6F_5)_3SbCl_2$ with H_2S. Metathetical reactions of $(C_6F_5)_3SbCl_2$ with appropriate metallic salts yield covalent pentacoordinate disubstituted products (**V, VII–XII**) of the general formula, $(C_6F_5)_3SbY_2$ (Y = NCS, NCO, –ONCMe$_2$, –ONCMePh –$\overline{NCO(CH_2)_2CO}$ and *p*–$NO_2C_6H_4OCO$). Treatment of $(C_6F_5)_3SbCl_2$ with aqueous NaN_3 gives the binuclear oxo-bridge compound, $[(C_6F_5)_3Sb—O—Sb(C_6F_5)_3](N_3)_2$ · (**III**) and (**IV**) are also accessible by displacement reaction of (**I**) or (**II**) with the corresponding metallic salt. Molecular weight, conductance measurements, and IR spectra on the new organoantimony(V) derivatives have been obtained.

Reductive cleavage reactions of $(C_6F_5)_3SbS$ with hexaaryldileads, Ar_6Pb_2(Ar = Phenyl, *p*-tolyl) produce $(C_6F_5)_3Sb$ and the corresponding bis(triaryllead) sulphide but treatment of $(C_6F_5)_3SbX_2$(X = NCO, Cl) with Ar_6Pb_2 gave Ar_4Pb and Ar_2PbX_2 together with $(C_6F_5)_3Sb$.

$(C_6F_5)_3SbCl_2$ and bis(triorganotin)sulphides undergo exchange of anionic groups.

Despite a considerable interest in the chemistry of hydrocarbon derivatives of antimony(III) and antimony(V), very few studies have been devoted to the corresponding fluorocarbon analogues.[1–3] Although the synthesis of tris(pentafluorophenyl) antimony[4] was reported as early as 1964, studies on vibrational spectra together with the preparation of dihalides, $(C_6F_5)_3SbX_2$ were only made after a decade.[5] Since then a single reference[6] describing the chemical behaviour of $(C_6F_5)_3Sb$ and the isolation of a few tris(pentafluorophenyl) antimony oxy has appeared.

As a part of our research programme on organoantimony(V) compounds[7] coupled with the limited published data on such compounds further investigation on pentafluorophenyl antimony(III) and antimony(V) has been undertaken.

It may be noted that organometallic compounds based on fluorocarbons have been reported not only to possess interesting properties but also provide instructive comparison with compounds based on hydrocarbon ligands.[8] In the present communication we wish to report: (i) oxidative addition reactions of $(C_6F_5)_3Sb$ with interhalogens, halo-pseudohalogens, pseudohalogen and elemental sulphur; (ii) metathetical reactions of $(C_6F_5)_3SbCl_2$ and $(C_6F_5)_3SbIX$(X = Cl, Br) with metallic salts to give disubstituted pseudohalide, oximate, amide and carboxylate and halo-pseudohalo derivatives, respectively; (iii) reductive cleavage of $(C_6F_5)_3SbS$ and $(C_6F_5)_3SbX_2$(X = NCO, Cl) with hexaaryldilead compounds, and (iv) action of $(C_6F_5)_3SbCl_2$ on bis(triorganotin) sulphides.

EXPERIMENTAL

Tris(pentafluorophenyl)antimony[4] was prepared from pentafluorophenyl magnesium bromide, C_6F_5Br(Imperial Smelting Company, Bristol) and antimony trichloride(Fluka) and was converted to the corresponding dichloride in the reported manner.[5] Hexaaryldileads[9] and bis(triorganotin) sulphides[10] were synthesised by the reported methods.

Iodine monochloride (Fluka) was distilled before use. Iodine monobromide was prepared and purified by the published method.[11]

Fresh iodine isocyanate[12], iodine-azide[13] and thiocyanogen[9] in approximately known concentrations were generated in an appropriate solvent

by standard methods. Freshly prepared metallic salts except NaN_3, were dried *in vacuo* before use.

All solvents were purified and dried by standard procedures and reactions were carried out under anhydrous conditions.

IR spectra were recorded in the range 4000–200 cm^{-1} by using KBr/CsI pellets on a Perkin–Elmer 577 spectro-photometer. The molar conductance of 10^{-3} M solutions was determined at 25°C with a Phillips Conductivity assembly PR–9500. Molecular weight was determined cryoscopically in benzene using a Beckmann thermometer of accuracy of ±0.01°C.

Typical experimental details of the reactions are described below. Relevant IR assignments, analytical data and molar conductance values are listed in Tables 1–2.

Oxidative addition reactions

Reaction of $(C_6F_5)_3Sb$ *with* ICl *and* IBr, **(I, II)**. A solution of iodine monochloride (0.325 g · 2 mmol) in acetonitrile (40 cm^3) was added dropwise to a stirred solution of tris(pentafluorophenyl)antimony (1.246 · 2 mmol) in the same solvent (50 cm^3) at −5°C during 1 hr. The reactants were allowed to attain room temperature and stirred further for 30 min to ensure complete reaction. Concentration of the solution followed by the addition of petroleum–ether (bp. 60–80°C) afforded off white crystalline solid, tris(pentafluorophenyl) antimony (V) chloride iodide, m.p. 165–66°C.

Similarly, 1:1 molar reaction of tris(pentafluorophenyl) antimony (1.246 g, 2 mmol) and iodine monobromide (0.414 g, 2 mmol) yielded tris(pentafluorophenyl) antimony(V) bromide iodide, m.p. 126°C.

Reaction of $(C_6F_5)_3Sb$ *with* IN_3 *and* INCO, **(III, IV)**. A freshly generated solution of iodine azide (0.338 g, 2 mmol) in acetonitrile (50 cm^3) at −10°C was added to a precooled (−10°C) vigorously stirred solution of tris(pentafluorophenyl) antimony (1.246 g, 2 mmol) in the same solvent (50 cm^3) during 15 min under nitrogen atmosphere. The reactants were stirred for 1 hr at initial temperature and then allowed to come at room temperature. The solution was evaporated under reduced pressure and cooled overnight, after adding petroleum–ether (bp. 40–60°C) (10 cm^3). A pale yellow crystalline solid thus obtained was characterised as tris(pentafluorophenyl)antimony azide iodide **(III)**, m.p. 260°C.

$(C_6F_5)_3SbINCO$ **(IV)** was obtained as a white crystalline solid by the method described above by

employing an equimolar ratio of the corresponding reactants, m.p. 82°C.

Reaction of $(C_6F_5)_3Sb$ *with* $(SCN)_2$, **(V)**. A freshly prepared solution of thiocyanogen (0.25 g, 2 mmol) in CCl_4(30 cm^3) was added to a stirred tris(pentafluorophenyl) antimony (1.246 g, 2 mmol) solution in CCl_4(50 cm^3) at −5°C during 15 min. The reaction mixture was subsequently stirred for 1 hr and warmed to room temperature. The removal of the volatiles under reduced pressure afforded a pale yellow solid. After recrystallisation from ethanol it was characterised as tris(pentafluorophenyl)antimony diisothiocyanate **(V)**, m.p. 205°C (d).

Reaction of $(C_6F_5)_3Sb$ *with sulphur*, **(VI)**. A solution of tris(pentafluorophenyl)antimony (1.246 g, 2 mmol) in acetonitrile (50 cm^3) was refluxed with elemental sulphur (0.064 g, 2 mmol) for 1 hr under nitrogen atmosphere. The solution was concentrated and cooled overnight to afford off-white crystalline solid. It was characterised as tris(pentafluorophenyl)antimonysulphide **(VI)**, m.p. 122°C.

The same product **(VI)** was obtained when the reaction was repeated in benzene as solvent.

(ii) *Metathetical reactions*

Reaction of $(C_6F_5)_3SbCl_2$ *with* AgSCN *and* KNCO, (V and **VIII**). Tris(pentafluorophenyl)antimony dichloride (1.3888 g, 2 mmol), and silver thiocyanate (0.464 g, 4 mmol) were stirred together in benzene (100 cm^3) at room temperature for 3 hr and then refluxed for 1 hr to ensure completion of the reaction. Silver chloride was filtered off and concentration of the solution under reduced pressure followed by the addition of petroleum–ether (bp. 40–60°C) yielded off-white crystalline tris(pentafluorophenyl) antimony diisothiocyanate (V), m.p. 205°C.

Similarly, 1 : 2 molar reaction of tris(pentafluorophenyl)antimony(V) dichloride (1.388 g, 2 mmol) and potassium cyanate (0.324 g, 4 mmol) was found to give tris(pentafluorophenyl)antimony(V) diisocyanate, m.p. 250°C (d).

Reaction of $(C_6F_5)_3SbCl_2$ *with* NaN_3, **(VII)**. An aqueous solution of sodium azide (0.264 g, 4 mmol) was added to an ethereal solution of tris(pentafluorophenyl)antimony dichloride (1.388g, 2 mmol) and the mixture was stirred for 3 hr at room temperature. The ether layer was separated and dried over sodium sulphate. It was then evaporated and cooled to yield off-white crystalline solid which was characterised as oxybis(tris(pentafluorophenyl)antimony)diazide **(VII)**, m.p. 280°C.

Reaction of $(C_6F_5)_3SbICl$ *with* KNCO, **(IV)**. A suspension of potassium cyanate (1 g, 1.24 mmol) in acetonitrile was added to a solution of tris(pentafluorophenyl)antimony chloride iodide (0.785 g, 1 mmol) in the same solvent (60 cm^3) and refluxed for 3–4 hr. The mixture was then filtered

to remove potassium chloride and unreacted potassium cyanate. The filtrate was concentrated under vacuum to afford white solid, which was recrystallised from petroleum–ether (bp. 40–60°C) and characterised as tris(pentafluorophenyl)antimony(V) iodide isocyanate, m.p. 82°C.

The similar procedure as described above was adopted to obtain tris(pentafluorophenyl)antimony(V) iodide azide from tris(pentafluorophenyl)antimony chloride iodide (0.785 g, 1 mmol) and sodium azide (0.08 g, 1.23 mmol). Compounds **(III)** and **(IV)** may also be prepared by the reaction of tris(pentafluorophenyl)antimony bromide iodide with the corresponding metallic salt.

Preparation of tris(pentafluorophenyl)antimony disubstituted amide, -oximate and carboxylate derivatives **(IX, X–XII).** In a typical experiment tris(pentafluorophenyl)antimony dichloride (0.694 g, 1 mmol) and sodium succinimide (0.238 g, 2 mmol) in benzene (60 cm^3) was stirred at room temperature for 3 hr. Sodium chloride was filtered off and the filtrate was concentrated under vacuum followed by the addition of *n*-hexane (10 cm^3) and on scratching yielded a white solid. It was recrystallised from petroleum–ether (bp. 40–60°C) and characterised as tris(pentafluorophenyl)antimony disuccinimide **(IX)** m.p. 245°C.

Compounds **(X)–(XII)** were synthesised from tris(pentafluorophenyl)antimony dichloride and the corresponding sodium salt of oxime or carboxylate in 1 : 2 molar ratio, respectively under conditions similar to those described for the disuccinimide.

(iii) *Reductive cleavage reactions*

Reaction of $(C_6F_5)_3SbS$ *with* Ar_6Pb_2(1 : 1). To an acetonitrile solution (50 cm^3) of tris(pentafluorophenyl)antimony sulphide (0.652 g, 1 mmol) hexaphenyldilead (0.876 g, 1 mmol) in the same solvent (30 cm^3) was added and stirred for 3 hr at room temperature. The solution was concentrated and petroleum–ether (bp. 60–80°C) was added to precipitate a white crystalline solid characterised as bis(triphenyllead) sulphide, m.p. 140–141°C (lit,[14] m.p. 139–143°C). After filtering the precipitate, the filtrate was concentrated and cooled to yield off-white crystals of tris(pentafluorophenyl)antimony m.p. 74°C (lit.,[4] m.p. 74°C).

Similarly, reaction of tris(pentafluorophenyl) antimony sulphide with hexa-*p*-tolyl dilead produced bis(tri-*p*-tolyllead) sulphide m.p. 143–144°C (lit.,[14] m.p. 144°C) and tris(pentafluorophenyl)-antimony, m.p. 74°C (lit.,[4] m.p. 74°C).

Reaction of $(C_6F_5)_3Sb(NCO)_2$ *with* Ph_6Pb_2 (1 : 1). To a refluxing solution of hexaphenyl dilead (0.876 g; 1 mmol in chloroform (50 cm^3) was added dropwise a chloroform solution of tris(pentafluorophenyl)antimony diisocyanate (0.707 g, 1 mmol). The reactants were refluxed for 5 hr and then cooled at ice temperature. The solid thus separated was filtered off and identified as diphenyllead diisocyanate m.p. 230–235°C (d). (Found: C, 38.98; H, 2.29; N, 6.29; Calc. for $C_{14}H_{10}N_2O_2Pb$; C, 39.17; H, 2.348; N, 6.52; IR ν_{asy}(NCO2180 cm^{-1}). The filtrate was concentrated to dryness under vacuum and then treated with *n*-hexane/benzene mixture (1 : 1, 10 cm^3) to afford insoluble tetraphenyl lead, m.p. 227–238°C (lit.,[11] m.p. 228°C). The filtrate on concentration and cooling gave tris(pentafluorophenyl)antimony, m.p. 74°C (lit.,[4] m.p. 74°C).

Similarly, reaction of tris(pentafluorophenyl)-antimony dichloride (0.694 g, 1 mmol) and hexaphenyl dilead (0.876 g, 1 mmol) afforded diphenyllead dichloride m.p. 285°C (lit.,[11] m.p. 284–286°C), tetraphenyllead m.p. 226–227°C (lit.,[11] m.p. 228°C) and tris(pentafluorophenyl)antimony, m.p. 73°C (lit.[4] m.p. 74°C).

(iv) *Action of* $(C_6F_5)_3SbCl_2$ *on bis(triorganotin)-sulphides*

Reaction of $(C_6F_5)_3SbCl_2$ *with* $(Bu_3Sn)_2S$. To a well stirred ice cold solution of tris(pentafluorophenyl)antimony dichloride (0.614 g, 1 mmol) in chloroform (50 cm^3) bis(tributyltin)sulphide (0.616 g; 1 mmol) in the same solvent (40 cm^3) was added drop-wise during half an hour. The reactants were further stirred for 3 hr and simultaneously allowed to attain room temperature. The solution was concentrated to dryness and the residue was dissolved in hot petroleum-ether (bp 60–80°C). The solution was cooled and filtered, the solid was identified as tris(pentafluorophenyl)antimony sulphide m.p. 122°C. The filtrate was concentrated at reduced pressure to yield tributyltin chloride, characterised as tributyltin fluoride m.p. 242°C (lit.,[11] m.p. 244°C).

Under similar conditions tris(pentafluorophenyl)antimony dichloride (0.694 g; 1 mmol) afforded tris(pentafluorophenyl)antimony sulphide m.p. 122°C and triphenyltin chloride m.p. 105°C, (lit.,[11] m.p. 105–107°C).

RESULTS AND DISCUSSION

(i) *Oxidative addition reactions*

Freshly generated solutions of thiocyanogen $(SCN)_2$ and iodine-azide and -isocyanate in acetonitrile were found to react separately with tris(pentafluorophenyl)antimony at − 10°C to give high yields of respective oxidative addition product in which antimony is in the pentavalent state.

Reaction with $(SCN)_2$ was performed in the dark to retard its polymerization.

$$(C_6F_5)_3Sb + (SCN)_2 \rightarrow (C_6F_5)_3Sb(NCS)_2 \quad (1)$$

$$(C_6F_5)_3Sb + IX \rightarrow (C_6F_5)_3SbIX \quad (2)$$

$$(X = N_3, NCO).$$

Whereas reactions of $(SCN)_2$ have earlier been demonstrated to cleave metal–carbon bonds (M = Sn, Pb)[9] those of IN_3 and INCO are being reported for the first time with an organometallic compound. However, reactions involving regio and stereospecific additions of IN_3 and INCO to olefins and other systems in synthetic organic chemistry are well known.[12,13]

Parallel reactions of interhalogens, viz. ICl and IBr with $(C_6F_5)_3Sb$ under identical conditions as described above were found to produce mixed halo derivatives (**I & II** Table 1).

$$(C_6F_5)_3Sb + IX \rightarrow (C_6F_5)_3SbIX, \quad (3)$$

$$X = Cl, Br.$$

It may be added that ICl, IBr and $(SCN)_2$ behave as electrophilic reagents towards symmetrical tetraorganometallic derivatives of group IVB(M = Ge, Sn, Pb)[9,11] and cleave the metal-carbon bond(s) to different extents depending upon the relative strength of electrophile used. However, no traces of any pentafluorophenyl-thiocyanate or -halide or of corresponding bis(pentafluorophenyl) derivative, $(C_6F_5)_3SbX$(X = NCS, N_3, NCO, Cl, Br), the products normally expected from the possibility of metal-carbon bond cleavage were observed in the above described reactions.

Elemental sulphur was also found to add oxidatively to $(C_6F_5)_3Sb$ in refluxing benzene or acetone solution in a dry nitrogen atmosphere to give tris(pentafluorophenyl)antimony sulphide (**VI**). Similar observations have been made for triarylantimony (III) compounds.[1]

$$(C_6F_5)_3Sb + S \rightarrow (C_6F_5)_3SbS \quad (4)$$

$(C_6F_5)_3SbS$ can also be obtained by passing H_2S gas in alcoholic–ammonia solution of $(C_6F_5)_3SbCl_2$. The molecular weight of sulphide derivative determined cryoscopically in benzene indicates that it exists as a monomer. It may be mentioned that tris(perfluoroalkyl)antimony has been reported not to react with sulphur.[15]

(ii) *Metathetical reactions*

$(C_6F_5)_3SbCl_2$ is an important source for obtaining various disubstituted tris(pentafluorophenyl)-antimony(V) derivatives (**V, VIII–XII**, Table 1). Thus the treatment with the corresponding sodium or silver salts in benzene under mild conditions leads to the replacement of both the chloride atoms. The metallic chlorides separate immediately in each case after mixing the reactants.

$$(C_6F_5)_3SbCl_2 + 2MY \rightarrow (C_6F_5)_3SbY_2 + 2MCl \quad (5)$$

M = Ag; Y = NCO, NCS

M = Na; Y = $ONCMe_2$; ONCMePh, $\overline{NCO(CH_2)_2CO}$, and $OOCC_6H_4NO_2 - p$.

In sharp contrast, $(C_6F_5)_3AsCl_2$ has been reported to give monosubstituted products.[16] This difference in behaviour can be attributed to the greater tendency of antimony to expand its coordination sphere, and to the lower element–chlorine bond energy.

Formation of oxo-bridge compound (**VII**). Reaction of aqueous NaN_3 with $(C_6F_5)_3SbCl_2$ in ether solution, however, yielded binuclear oxo-bridge compound (**VIII**, Table 1) instead of $(C_6F_5)_3Sb(N_3)_2$.

$$(C_6F_5)_3SbCl_2 + 2NaN_3 \rightarrow [(C_6F_5)_3Sb{-}O{-}Sb(C_6F_5)_3](N_3)_2 + 2NaCl. \quad (6)$$

Formation of such a binuclear derivative is not surprising since Goel *et al.* have reported that $R_3Sb(N_3)_2$(R = Me, Ph) could only be prepared and isolated in the presence of hydrazoic acid in benzene. One of the most usually employed methods for the preparation of organometallic azides involving a water/ether system as described above resulted in the formation of oxo-bridge compound $[R_3Sb{-}O{-}SbR_3](N_3)_2$.[17]

Selective replacement reactions. Equimolar reactions involving mixed halogen compounds $(C_6F_5)_3SbIX$(X = Cl, Br) and metallic salts in benzene produced mixed iodo-pseudohalo derivatives, through selective replacement of chloride or bromide group by a pseudohalo group. The iodide invariably remains bonded to the antimony irrespective of the nature of the metallic salt used.

$$(C_6F_5)_3SbICl + NaN_3 \rightarrow (C_6F_5)_3SbI(N_3) + NaCl \quad (7)$$

$$(C_6F_5)_3SbIBr + MNCO \rightarrow (C_6F_5)_3SbI(NCO) + MBr \quad (8)$$

$$(M = K, Ag).$$

This behaviour of tris(pentafluorophenyl)antimony mixed halides is somewhat different from those observed for similar reactions of mixed halides of diaryl-lead(IV) and -tin(IV), where both the different halo groups are replaced by the anionic groups.[18,19] It may be added that in case of group IVB metals identically placed iodide is more readily replaced by silver salts and the chloride and bromide are replaced by the anions attached to the alkali metals.[10] Selective replacement of halo groups (Cl, Br) have earlier been reported in case of mixed tetrahalocyclopentane tellurates(IV).[20]

The products (**III** and **IV** obtained through exclusive replacement of halo group are similar to those obtained by the oxidative addition method (eqn 2) mentioned above and had similar m.p. and superimposable IR spectra.

(III) *Reductive cleavage reactions*

(a) *Reaction of* $(C_6F_5)_3SbX_2$(X = NCO, Cl) *with* Ar_6Pb_2. Exploratory work reveals that higher valent metallic halides, viz. Cu(II), Hg(II) and Fe(III) cleave the Pb–Pb bond in hexaorganodilead compounds while themselves getting reduced to the lower oxidation state.[21,22] It was therefore, considered worthwhile to study the reactions of tris(pentafluorophenyl)antimony dichloride and diisocyanate against Pb–Pb bond. The former are readily reduced to $(C_6F_5)_3Sb$ in the sense of equation shown below

$$Ar_6Pb_2 + (C_6F_5)_3SbX_2 \rightarrow Ar_4Pb + Ar_2PbX_2 + (C_6F_5)_3Sb \quad (9)$$

Ar = Phenyl, *p*-tolyl

X = Cl, NCO.

The reaction appears to involve the cleavage of Pb–Pb bond and Pb–C bond in hexaaryldilead yielding stable Ar_4Pb and unstable Ar_2 Pb (eqn 10) which further reduces the perfluorophenyl antimony(V) to perfluorophenyl antimony(III) (eqn 11).

$$Ar_3Pb—PbAr_3 \rightleftharpoons Ar_4Pb + Ar_2Pb \quad (10)$$

$$Ar_2Pb + X_2Sn(C_6F_5)_3 \rightarrow (C_6F_5)_3Sb + Ar_2PbX_2 \quad (11)$$

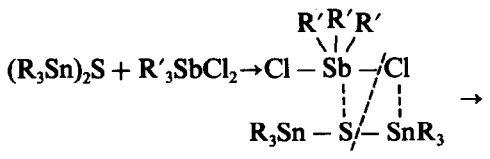
(b) *Reaction of* $(C_6F_5)_3SbS$ with Ar_6Pb_2. It has been reported by Okawara *et al.* that the Sb–S bond in triorganoantimony sulphides is semipolar in nature, which facilitates the resonance hybrid of sulphides in the ground state due to which triorganoantimony(V) sulphides are more reactive.[23,24]

$$R_3Sb^+–S^- \rightleftharpoons R_3Sb = S.$$

It is therefore not surprising that on reaction of $(C_6F_5)_3SbS$ with hexaaryldileads insertion of sulphur into Pb–Pb bond takes place.

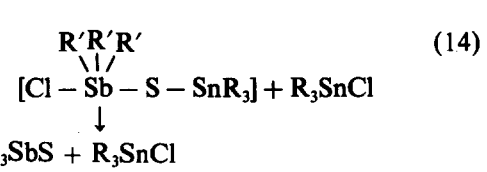
$$(C_6F_5)_3SbS + Ar_3Pb—PbAr_3 \rightarrow Ar_3Pb–S–PbAr_3 + (C_6F_5)_3Sb \quad (12)$$

The reaction seems to proceed through initial rupture of Pb–Pb bond followed by the insertion of sulphur which may be attributed to the enhanced semipolar nature of Sb–S bond in tris(pentafluorophenyl)antimony sulphides, which facilitates the homolytic fission of Pb–Pb bond coupled with the remarkable reactivity of Pb–Pb bond.[25] In the process tris(pentafluorophenyl)antimony(V) is reduced to tris(pentafluorophenyl)antimony (III). Similar results have been observed for the reactions of triorganoantimony sulphides with hexaarylditins.



It can be thus concluded that the reactions of hexaaryldileads with tris(pentafluorophenyl)antimony(V) derivatives proceed via two different pathways depending upon the nature of the anion attached to antimony atom. In the case of sulphide derivative (eqn 12) cleavage of the Pb–Pb bond is favoured while in the other cases (X = NCO, Cl dissociation of hexaaryldileads to Ar_4Pb and Ar_2Pb occurred (eqn 9). Both these reactions thus lend support to an earlier held view that the reactions of hexaorganodileads with different reagents differed mechanistically.[25]

(iv) *Action of* $(C_6F_5)_3SbCl_2$ *on bis(triorganotin)-sulphide*



Bis(triorganotin)sulphides were found to react with tris(pentafluorophenyl)antimony dichloride in 1 : 1 molar ratio resulting in the complete exchange of anionic groups.

$$(R_3Sn)_2S + (C_6F_5)_3SbCl_2 \rightarrow 2R_3SnCl + (C_6F_5)_3SbS. \quad (13)$$

The separation of the products does not pose much difficulty due to the difference of the solubilities in organic solvents. The reaction seems to proceed via a four- centred cyclic transition state involving sulhpur atom as represented below

$$(R_3Sn)_2S + R'_3SbCl_2 \rightarrow Cl-Sb(R'R'R')-Cl \rightarrow R_3Sn-S-SnR_3$$

$$[Cl-Sb(R'R'R')-S-SnR_3] + R_3SnCl \rightarrow R'_3SbS + R_3SnCl \quad (14)$$

(where R′ = C_6F_5; R = C_4H_9, C_6H_5).

An analogous mechanism has been proposed for the reaction of $[Ph_3Sn]_2O$ and $HgCl_2$.[26]

The molar conductance values of 10^{-3} M solution in acetonitrile of the newly synthesised tris(pentafluorophenyl)antimony(V) compounds range between 13–35 mol^{-1} cm^2, which indicate their non-conducting nature.[27] The values for compounds (I–IV) containing a halide atom are almost of the same order and higher than the rest of the compounds but do not suggest conducting behaviour.

The observed molecular weight data of the compounds in freezing benzene were found comparable with those of theoretical values which suggests that these compounds exist as monomers.

The newly isolated compounds are stable at room temperature and soluble in organic solvents, viz. chloroform, acetonitrile, benzene etc. Compounds (II), (IV) and (VIII), however decompose on storage. Isocyanate derivatives were also found to be moisture sensitive.

IR SPECTROSCOPY

All the isolated compounds (I–XII; Table 1) exhibit IR absorptions characteristic of C_6F_5 group and are in conformity with those reported earlier for tris(pentafluorophenyl)antimony and its dihalides.[5,28] The IR frequencies due to fundamental modes of vibrations of the anionic groups are listed in Table 2.

Absorptions associated with the various modes of vibrations of the pseudohalide groups have been identified and indicate the nature of bonding to the antimony atom. The chalcogenate group, NCX(X = S or O) gives rise to three fundamental modes of vibrations due to the $\nu(C\equiv N)$, $\nu(C-X)$ and $\delta(NCX)$. The observed frequencies for these modes of vibrations are listed in Table 2, and are fully consistent with a N-bonded NCX group, in consonance with the usual iso-structure of the hydrocarbon counter parts of the antimony(V).[29] The vibrations associated with the N_3 stretchings and bending modes (**III** and **VII**, Table 2) suggest the presence of a covalently bonded linear N = N = N group. The asymmetric N = N = N stretching is fairly shifted to higher frequency as compared to $Ph_3Sb(N_3)_2$[17,28] or $Ph_3SnI(N_3)$[30] but other modes of vibrations are not significantly changed. Compound (**VII**), however, exhibits an additional strong band at 705 cm^{-1}, which can be safely assigned to the ν(Sb–O–Sb)[29,6] vibration, indicating the formation of an oxo-bridge binuclear derivative.

Tris(pentafluorophenyl)antimony disuccinimide (**IX**) displays a strong band at 1700 cm^{-1} assignable to "ester-like" CO group. The symmetric stretching mode appears at 1235 cm^{-1}. Pattern and position of the bands are comparable with those of reported triarylantimony diamides.[7]

The separation (375 cm^{-1}) between the asymmetric and symmetric (O = C = O) stretching frequencies for tris(pentafluorophenyl)antimony di(*p*-nitrobenzoate), which occur at 1685 cm^{-1} and 1310 cm^{-1}, respectively, in the solid state suggest the presence of a monodentate "ester-like" carboxylate group with a penta-coordinate structure about the antimony atom. In chloroform solution the 1685 cm^{-1} band is shifted to 1682 cm^{-1} but the symmetric (O – C–O) stretching frequency remains unchanged and thus carboxylate group retains its unidentate character in solution as well.[29,31] The non-conducting and monomeric nature and the absence of carboxylate ion in the IR spectra further rules out the possibility of an ionic structure.

The IR spectra of O-tris(pentafluorophenyl)antimony dioximates (**XI** and **XII**) do not exhibit any band in the region 3000–3380 cm^{-1}, assignable to the intramolecularly hydrogen bonded OH in free oximes.[32] The C = N vibrations *ca.* 1630 ± 5 cm^{-1} appear as medium bands and are lowered by *ca.* 40 cm^{-1} as compared to the free oximes (~ 1668 cm^{-1}). The lowering of the νC = N vibration may be attributed to the stabilization of the C = N bond by resonance with the non-bonding electron pair on oxygen atom of the amino group. However, this type of lowering may also be related to the mass effect as has been observed earlier, in case of group IVB elements.[33]

The appearance of a medium band in the region 915–925 cm^{-1} can be attributed to a N–O stretching vibration[34] while the Sb–O stretching is tentatively assigned at 480 ± 5 cm^{-1} on the basis of reported Sb–O frequencies in the corresponding organoantimony oxinate derivatives.[35]

A noticeable feature of the IR spectra of all the isolated disubstituted compounds is the absence of the ν_{sym} (Sb–C) absorption corresponding to the *t*-mode which should be located in the region 250–300 cm^{-1} as reported by earlier workers.[5,6]

Thus on the basis of IR evidences coupled with their monomeric and non-conducting nature and in accordance with the structures of other organoantimony(V) compounds,[6,7,17,29] the newly synthesised disubstituted derivatives (except for (VII)) can reasonably be assigned a trigonal bipyramidal structure with the anionic groups at the axial positions and C_6F_5 groups occupying the equatorial positions. A trigonal bipyramidal structure containing an oxygen bridge (Sb–O–Sb) can be proposed for compound (VII).

Acknowledgement—The authors are thankful to the Head of the Chemistry Department, Lucknow University for providing the necessary Laboratory Facilities, the Director RSIC, Lucknow for obtaining IR spectra and Council of Scientific and Industrial Research, New Delhi for financial assistance (KS & AR).

PROTONATION EQUILIBRIA AND COMPLEX FORMATION ABILITY OF 2-AMINO-3-AMINOMETHYL-4,6-DISUBSTITUTED PYRIDINES

Z. CIMERMAN and Z. ŠTEFANAC*
Laboratory of Analytical Chemistry, Faculty of Science, University of Zagreb, Strossmayerov trg 14, 41000 Zagreb, Yugoslavia

(*Received* 18 *January* 1984; *accepted* 16 *April* 1984)

Abstract—The protonation equilibria of 2-amino-3-aminomethyl-4,6-disubstituted pyridines were studied by potentiometric titrations and by UV and ^{13}C NMR spectrometry. Protonation constants $\log K_1$ and $\log K_2$ potentiometrically determined for 4-methoxymethyl-6-methyl (8.959 and 5.778), 6-methoxymethyl-4-methyl (8.964 and 5.407), and 4,6-dimethyl derivative (9.141 and 6.604), were compared with the values obtained by the spectrometric methods. Complex formation of these compounds with Cu(II), Ni(II), Zn(II) and Co(II) was investigated in solution whereby the outstanding effect of the pH value was established and the presence of the species with 1 : 1 and 2 : 1 ligand to metal ratios confirmed. Stability constants obtained by potentiometric titrations show a decrease of the complex stability in the order Cu > Ni > Zn with respective $\log \beta_1$ values of 5.85, 3.56 and 2.93. Series of complexes isolated in the crude state were characterized by elemental analyses and spectrometric data, the latter serving also as the basis for making an attempt at the discernment of the coordination mode and sites.

Manifold approaches pursued in the studies of aminopyridines comprise also the correlations of structure and ionization.[1] The complex formation ability of a number of these heteroaromatic ligands presents another interesting topic.[2–7] In both cases additional substituents have been shown to play a decisive role depending on the species and position of substituents. Therefore with available newly synthesised 2-amino-3-aminomethylpyridines bearing two more substituents we performed concurrently the determination of protonation constants and the investigation of complexation ability. The series comprised 4-methoxymethyl-6-methyl (ligand **I**), 6-methoxymethyl-4-methyl (ligand **II**) and 4,6-dimethyl (ligand **III**) derivative.

The behaviour of the complexes formed with transition metals in solution and the characteristics of isolated crude species are discussed.

EXPERIMENTAL

Apparatus

The IR spectra were recorded in KBr or CsBr pellets with Perkin–Elmer spectrophotometers Models 457 and 580B. The mass spectra were taken on a Varian MAT CH7 or a CEC 21-110C instrument. Electronic absorption spectra were obtained using a Perkin–Elmer spectrophotometer Model 200. ^{13}C NMR spectra were recorded on a Jeol JNM–FX–100FT spectrometer in D_2O with tetramethylammonium chloride as internal standard at room temperature.

The pH was measured at (25.0 ± 0.2)°C with a Radiometer PHM-64 pH/mV meter providing a reading accuracy to within ± 0.002 pH units. Radiometer glass electrode G202 B and saturated calomel electrode K-401 were used. Before each measurement the assembly was standardized with two buffer solutions: 0.05 mol dm^{-3} potassium hydrogenphthalate ($pH_{25°C}$ = 4.008) and 0.01 mol dm^{-3} sodium tetraborate ($pH_{25°C}$ = 9.180).

Materials

Deuterium oxide, 99.5 atom. % D and dideutero-sulphuric acid, 99.5 atom. % D, 96–98% in D_2O were purchased from E. Merck, Darmstadt. Sodium deuteroxide was prepared by dissolving sodium in D_2O. Tetramethylammonium chloride, for synthesis, E. Merck, Darmstadt was recrystallized from the ethanol/petroleum ether system. All other chemicals and solvents were of analytical purity grade, Kemika, Zagreb. The quartz doubly distilled water was used throughout.

Procedures

Preparation of ligands. 2-amino-3-aminomethyl-4-methoxymethyl-6-methylpyridine (ligand **I**), 2-amino-3-aminomethyl-6-methoxymethyl-4-methylpyridine (ligand **II**) and 2-amino-3-aminomethyl-4,6-dimethylpyridine (ligand **III**) were obtained as dihydrochlorides by courtesy of Dr. D. Korunčev, Pliva, Pharmaceutical and Chemical Works, Zagreb. Free amines were prepared and purified to analytical grade according to the procedure described in Ref. 8. The pure products were checked by elemental analyses, IR and ^{1}H NMR spectrometric data.

Preparation of metal complexes. For all complexes 0.1 mol dm^{-3} solutions of ligands and metal salts were used. The complexes Cu(ligand **I**)$_2$ $SO_4 \cdot 2H_2O$ and Cu(ligand **III**)$_2SO_4 \cdot 2H_2O$ crystallized after mixing a methanolic solution of the corresponding ligand with an aqueous solution of cupric sulphate in the 3:1 molar proportion.

Zn(ligand **I**)$_2SO_4$ precipitated readily from a methanolic solution containing zinc sulphate and a threefold excess of ligand **I**.

Cu(ligand **I**)$SO_4 \cdot 3H_2O$ was prepared by mixing equimolar amounts of ligand **I** and cupric sulphate dissolved in minimum quantities of methanol and water, respectively. The complex crystallized from this solution after it had been evaporated to half of the volume and kept at 0°C for several days.

Cu(ligand **I**)$_2(ClO_4)_2$ crystallized by the addition of a saturated aqueous solution of sodium perchlorate to the aqueous solution containing ligand **I** and cupric sulphate in the 3:1 molar proportion.

Zn(ligand **I**) $[B(C_6H_5)_4]_2$ and Ni(ligand **I**)$_2$ $[B(C_6H_5)_4]_2$ precipitated from an aqueous solution containing equimolar amounts of metal(II) salt and ligand **I** in the presence of sodium tetraphenylborate.

Characterization of isolated complexes

Cu(ligand **I**)$_2SO_4 \cdot 2H_2O$, $C_{18}H_{34}N_6O_8SCu$, violet crystals, m.p. 197°C (decomp.). Found (calc.): C 39.58 (38.74); H 6.46 (6.14); N 15.07 (15.06); S 5.37 (5.74); Cu 11.16 (11.38)%.

IR spectrum, $\tilde{\nu}$ cm^{-1} rel. intensity: 3420 b, 3250 b, 3120 b, 2930 m, 1640 sh, 1620 s, 1592 m, 1570 sh, 1470 m, 1450 m, 1395 m, 1325 w, 1190 m, 1170–1070 vs, vb, 975 m, 865 vw, 800 w, 690 w, 613 s, 550 w, 420 vw.

Cu(ligand **III**)$_2SO_4 \cdot 2H_2O$, $C_{16}H_{30}N_6O_6SCu$, violet crystals, m.p. 215°C (decomp.). Found (calc.): C 38.87 (38.58); H 6.02 (6.07); N 17.01 (16.87); Cu 12.76 (12.26)%.

IR spectrum, $\tilde{\nu}$ cm^{-1} intensity: 3420 b, 3260 b, 3140 b, 2960 w, 2920 w, 1640 s, 1620 s, 1595 s, 1570 sh, 1505 m, 1475 m, 1450 m, 1390 m, 1330 w, 1215 w, 1010–1170 vs,vb, 975 m, 855 vw, 800 m, 700 vw, 612 s, 550 vw, 535 w, 410 w.

Zn(ligand **I**)$_2SO_4$, $C_{18}H_{30}N_6O_6SZn$, white powder, m.p. 257 °C (decomp.). Found (calc.): C 41.09 (41.27); H 5.96 (5.77); N 16.28 (16.04)%.

IR spectrum, $\tilde{\nu}$ cm^{-1} rel. intensity: 3420 b, 3320 s, 3240 sh, 3190 s, 2930 m, 1650 s, 1600 s, 1595 sh, 1575 s, 1470 m, 1450 s, 1420 m, 1400 m, 1330 w, 1200 s, 1165 sh, 1145 sh, 1110 vs, 1070 s, 1055 s, 975 s, 825 m, 810 m, 675 m, 650 s, 613 s, 590 m, 550 vw, 490 vw, 290 vw.

Cu(ligand **I**)$SO_4 \cdot 3H_2O$, $C_9H_{21}N_3O_8SCu$, green crystals. Found (calc.): C 27.43 (27.37); H 5.91 (5.36); Cu 16.28 (16.09)%.

Determination of the protonation constants of ligand I by ^{13}C nuclear magnetic resonance. Samples were obtained in the following way: a 0.447 mol dm^{-3} solution of ligand I was prepared by dissolving a weighed amount of compound in D_2O and dividing it into a series of aliquots. The pD of each aliquot was adjusted with a concentrated solution of NaOD or D_2SO_4 in D_2O, and the ionic strength of 2.0 (NaCl) was maintained. From the measured pH the pD of the samples was calculated from: pD = pH + 0.4.[9] The values for ^{13}C chemical shifts δ(ppm) obtained with tetramethylammonium chloride as internal standard were converted to the TMS scale by adding 56.5 ppm to each value.

Determination of stability and protonation constants by potentiometric titrations. A vessel with a capacity of 50 cm^3, thermostatted at (25.0 ± 0.2)°C was used for the potentiometric titrations. The vessel's cap was equipped with inlets for the two electrodes, the burette and the nitrogen flow. Titrant (0.2 mol dm^{-3} NaOH) was added from a 2.5 cm^3 automatic burette with an accuracy of volume addition of ± 0.003 cm^3. The solution was stirred during the titration with a magnetic stirrer in addition to being blown through by the nitrogen stream.

The ligands, converted into the protonated form by adding a standard HNO_3 solution in excess, were titrated in the absence (protonation constants) and in the presence (stability constants) of metals. The concentrations of metals in titration samples varied (ligand to metal ratios were 1:2, 1:4, 1:6, 1:8, 1:10 and 1:20). A constant ionic strength of 0.35 (KNO_3) was maintained during the measurements.

The measured pH values were converted into the hydrogen ion concentrations according to Irving *et al.*[10]

The protonation and stability concentration constants were calculated on a Univac 1110 computer at the Zagreb University Computing Centre using the Miniquad programme.[11]

UV/VIS spectrophotometric measurements. The UV spectra of aqueous ligand solutions were taken at various pH values. Bathochromic shifts were observed with decreasing pH of the solutions (Fig. 3). The UV/VIS spectra of ligands and complexes taken in the methanolic medium are summarized in Table 1.

The modified continuous variation method of Job[12] and the molar ratio method of Yoe and Jones,[13] were both pursued throughout in determining the ligand to metal ratio.

The apparent stability constants were calculated from the data obtained by the continuous variation method using the programme of Likussar[14] and the PDP-8/E (058/10-Syst.) DEC computer.

RESULTS AND DISCUSSION

Protonation equilibria of ligands

Three well separated inflections in potentiometric titration curves of ligands **I**, **II** and **III** (Fig. 1) prove that all ligands have three protonation steps. However, it was possible to calculate with sufficient precision only the first two

protonation constants (Table 2). The values of the third constant were too low to achieve the reliability range with the concentrations (5 × 10^{-3} mol dm^{-3} solutions) applied. According to the literature data for amino- and aminomethyl-pyridines[1] the first constant was tentatively assigned to the protonation of the 3-aminomethyl group and the second constant to the protonation of the ring nitrogen. As experimental evidence for presumed protonation equilibria of ligands, the protonation constants of particular functional groups of ligand **I** were determined by ^{13}C nuclear magnetic resonance spectrometry.

Assignment of aliphatic carbon atoms and the C-5 aromatic carbon atom was performed on the basis of the one-bond carbon-proton couplings observed in the undecoupled spectra. The remaining four aromatic carbon atoms were preliminarily assigned using the literature data for chemical shifts of structurally resembling monosubstituted pyridines.[15–17] A significant effect of substituents in positions 3, 4 and 6 of the pyridine ring was not expected, since in all cases aliphatic groups are bound straight to the ring. Carbon-proton couplings through two and/or three bonds to 5-H as well as to protons of aliphatic groups confirmed the assignment of aromatic carbon atoms. The chemical shifts, splitting patterns, coupling constants and assignment of the ^{13}C NMR resonances of ligand **I** at pD 11.5 are summarized in Table 3.

The pD dependence of the chemical shifts is shown in Fig. 2. A decrease in pD from 11 to 8 is accompanied by upfield shifts of C-3 and 3-CH_2 resonances, indicating protonation of the 3-aminomethyl group.[18] As the pD decreases further, the resonance pattern of all ring carbon atoms significantly changes. Signs and $\Delta\delta$ amounts roughly correspond to those noted for the protonation of the pyridine, except in the case of C-5 where a small upfield shift is observed.[19] The differences in the range $1 < \Delta\delta < 5$ ppm can be explained if the number, the nature and arrangement of substituents are considered. Thus, changes in the spectra of ligand I in the pD range from 8 to 4 can be reasonably ascribed to the protonation of the ring nitrogen. Further decreasing of pD down to 0.1 changes insignificantly the ^{13}C NMR spectra. It is obvious that extremely acidic conditions are necessary for the protonation of the 2-amino group of ligand **I**. This is in accordance with very weak basicity of the amino group observed for 2- and 4-monoaminopyridines, as well as with the resonance equilibria presumed by Albert for monocations.[1] Charge delocalization over both nitrogens, in the manner of an amidinium cation, effectively prevents addition of the second proton.

Logarithmic values of protonation constants K_1 and K_2 determined graphically from the plot δ vs pD are 6.3 and 9.4, respectively.

Table 2. Protonation constants of the ligands determined by potentiometric titration in aqueous solution at (25.0 ± 0.2)°C, I = 0.35 (KNO_3)

Ligand	log K_1 ± S.D.	log K_2 ± S.D.	log β_2 ± S.D.
I	8.959±0.002	5.778±0.004	14.737±0.003
II	8.964±0.002	5.407±0.004	14.371±0.003
III	9.141±0.001	6.604±0.002	15.745±0.002

Table 3. Chemical shifts, splitting patterns and coupling constants in the ^{13}C NMR spectrum of ligand I by pD 11.5

Chemical shifts, δ_{TMS} (ppm)	Splitting pattern (coupling constant J, Hz)			Assignment
23.66	quartet (127.0)	doublet (~2)		6-CH_3
37.00	triplet (136.7)			3-CH_2
59.13	quartet (142.8)	triplet (~4)		4-CH_3
72.28	triplet (144.0)	quartet (~5)	doublet (~5)	4-CH_2
115.56	doublet (163.6)	quartet (~4)	triplet (~4)	C-5
117.66		triplet (~5)	doublet (~5)	triplet (~5) C-3
147.73		triplet (~4)	triplet (~4)	C-4
156.40		quartet (~6)	doublet (~2)	C-6
157.91		triplet (~4)		C-2

The digital resolution of 1.2 Hz makes unobtainable distinct multiplets in cases of small coupling constants.

The potentiometrically determined values for the protonation constants of ligand I (Table 2) differ from the values obtained by ^{13}C NMR by 0.5 logarithmic units in the case of K_1 and by 0.4 logarithmic units in the case of K_2. These deviations may be expected, since the potentiometric titrations were done in H_2O, and the NMR measurements in D_2O.[9] Additional reasons for the disagreement of the corresponding results are different ionic strength, concentrations and temperatures of solutions measured by both methods. As the thermodynamic corrections were not accomplished it has to be called to mind that the potentiometric concentration constants are compared with spectrometric mixed constants.

The correlation of protonation constants of ligands I, II and II (Table 2) shows differences in basicity between the ligands, being more explicit in the case of the second constant related to the protonation of the heterocyclic nitrogen. The basicity of ligands decreases in the order ligand III > ligand I > ligand II.

The influence of the 4- and 6-substituted groups on the basicity of the ring nitrogen is also evidenced from the UV spectra. Decreasing pH in the range of the protonation of the ring nitrogen causes bathochromic shifts of the lower energy transition maxima by all ligands according to the behaviour of 2-aminopyridines.[20] The plot of λ_{max} vs pH (Fig. 3) shows the same sequence of the ligands' basicity decrease as the potentiometrically determined constants.

The log K_1 values obtained are merely comparable with the one cited for the primary amino group of 3-aminomethylpyridine as pK_a 8.04 being very likely only an approximate value.[1] The explanation for the differences of log K_1 within the series of ligands I, II and III has to be ascribed to the nature and arrangement of additional substituents on the pyridine ring. Their base-strengthening or base-

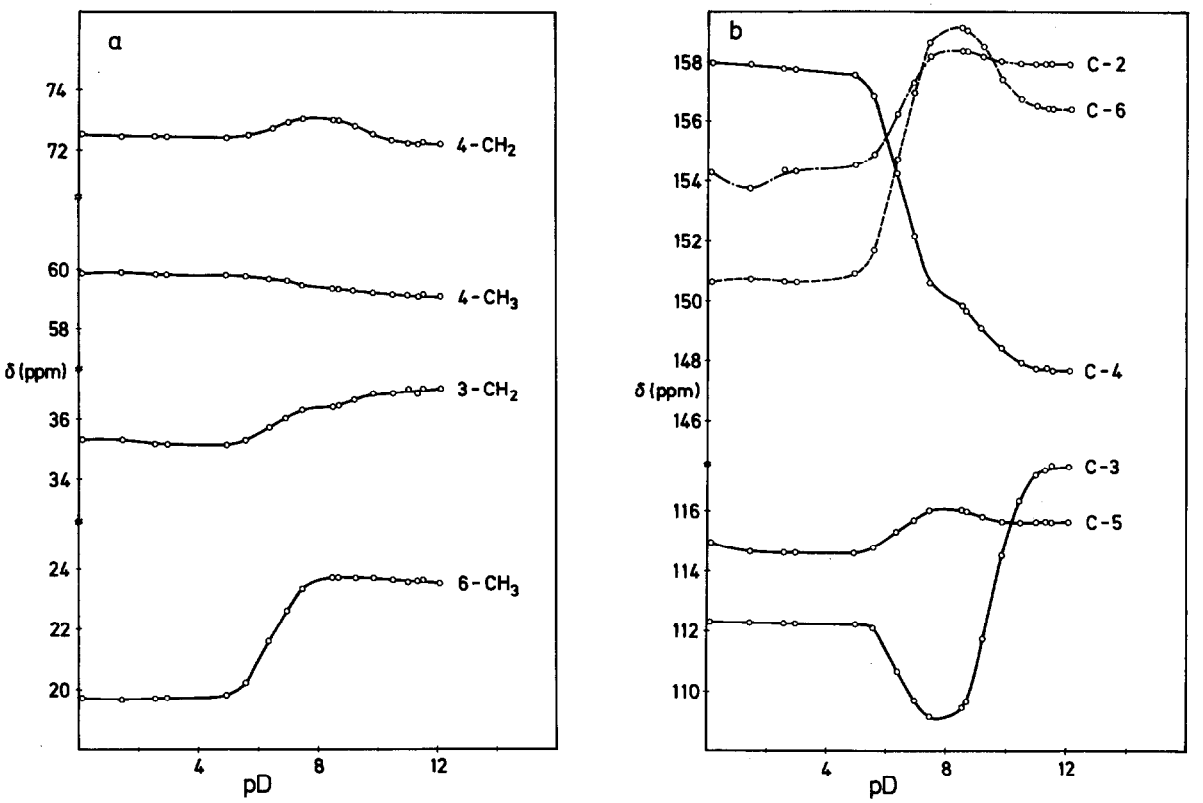

Fig. 2. pD dependence of the ^{13}C chemical shifts of ligand I: (a) resonances of aliphatic carbon atoms; (b) resonances of aromatic carbon atoms.

weakening effects are more evidently reflected by the differences in $\log K_2$ values related to the proton uptake by pyridine nitrogen. The specification of the net result and the symbol of the mesomeric and inductive effects of the methyl, aminomethyl and methoxymethyl substituents with regard to their positions as well as a potentially evoked steric hindrance of the latter in the 6-position is inaccessible. Therefore the $\log K_2$ values of the studied ligands cannot be meaningfully correlated either with one another or with the data from the literature for the pyridine bearing the very same remaining two substituents, i.e. amino and methyl group.

Complexes with Cu(II), Ni(II), Zn(II) *and* Co(II)

In solution complexes of ligands **I**, **II** and **III** with Cu(II), Ni(II) and Zn(II) are formed immediately. The formation of complexes with Co(II) is very slow at room temperature. The complex formation is affected by the pH of the solution (Fig. 4). A significant increase of ligands' complexation ability is observed by increasing pH in the range $5 < pH < 7$ with optimal conditions for complex formation about $pH \geq 8$. The conditions mentioned before are valid for aqueous and methanolic media.

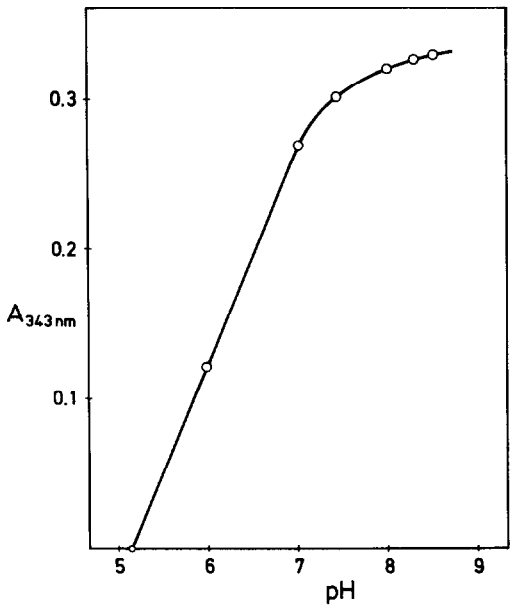

Fig. 4. Effect of pH on complex formation of ligand I with Cu(II). [Cu(II)] = 4×10^{-4} mol dm^{-3}; [ligand I] = 1.2×10^{-3} mol dm^{-3}.

In distinction from 2-picolylamine which forms 1:1, 2:1 and 3:1 complexes[2,3,6] with ligands **I**, **II** and **III** only the presence of 1:1 and 2:1 species was evidenced in solution. The ligands bearing the methyl (**I** and **III**) or methoxymethyl group (**II**) in the 6-position conform in this respect understandably to 6-methyl-2-picolylamine which forms unstable strongly dissociated 3:1 complexes.[4] The spectrophotometrically determined ligand to metal ratio of the species formed in the methanolic solution is 2:1 for the complexes of Zn(II), Ni(II) and Co(II) (Table 4). In the case of the complex of ligand **I** with Zn(II) simultaneous presence of the 1:1 species is observed. The equilibrium of 1:1 and 2:1 species is most probably the reason for high relative errors obtained for apparent stability constants of Cu(II) complexes.

Judging from apparent constants determined by UV spectrophotometry (Table 4), the stability of 2:1 complexes decreases in the order Co > Ni > Zn.

Potentiometric stability constants (Table 5) for all studied complexes could not be determined because of a very low formation rate of Co(II) complexes. In some systems precipitation took place during titration. Since the data could only be taken before the start of precipitation, the number of data was sometimes insufficient to attain good precision [in the case of ligand **I** and Zn(II)]. Table 5 illustrates that the stability of the complexes decreases following the sequence Cu > Ni > Zn. It is the usual stability sequence proposed for the complexes of transition metals.[21] The inversion of this stability sequence observed by comparing apparent constants for Co(II) and Ni(II) complexes (Co > Ni) is characteristic of the complexes of pyridines, having substituents in α-position to the heterocyclic nitrogen.[22]

Considering the ligands, the complex stability decreases in the order ligand **III** > ligand **I** ≥ ligand **II**. This order indicates a low influence of ligands' total basic strength on the complex stability more effected by the steric hindrance of the bulky methoxymethyl group positioned in the neighbourhood of the coordination sites.

Preparation of the crude complexes was not always successful, although the conditions were

Table 4. Ligand to metal ratios and apparent stability constants determined by UV spectrophotometry in methanolic solutions

Complex	λ_{max} (nm)	[Ligand]+[Me(II)] (mol dm^{-3})	[Ligand]/[Me(II)]	log K'	Rel. error (%)

* The limited number of obtainable experimental data due to precipitation in the system worsened the precision.

carefully checked. Due to easy decomposition of most often very unstable complexes recrystallization had to be avoided and it was not always possible to obtain pure compounds.

Characterization of the prepared complexes by elemental analyses indicated 2:1 and 1:1 ligand to metal ratios, corresponding to the results of the measurements in solution. The results of elemental analyses were confirmed to a certain extent by fast atom bombardment mass spectrometry (FAB) with glycerol used as dispersant.[23] In the mass spectra obtained for positive ions, the characteristic distribution of ^{63}Cu and ^{65}Cu isotopes with the relative abundances of 100 and 44.7% respectively served well to distinguish not only the molecular ions but also a number of copper containing fragment ions. The molecular formulae corresponding to the 2:1 ligand to metal ratio were found for copper complexes of ligands I and III with sulphate anion as well as of ligand I with perchlorate anion.

The established partial fragmentation pathways were based in addition to the expected isotope peaks pattern also on the presence of several metastables denoted with asterisks in the schemes given above. The mass spectra of nickel and zinc complexes taken under analogous conditions were not amenable to a detailed interpretation.

The attempt to elucidate the coordination mode in complexes of the 2:1 ligand to metal ratio is based merely on the IR spectra taken in the 200–4000 cm^{-1} region.

For interpretative comparison the well documented data on the corresponding complexes of 2-aminomethylpyridine[6] and 6-methyl-2-aminomethylpyridine[5] have been taken. These compounds behave as bidentate ligands even in the case of the 6-methyl derivative with evidenced influence of a remarkable steric interference. The sterically hindered 2-aminopyridine was also shown to appear as bidentate in nickel complexes containing two molecules of the ligand.[7]

Presuming that because of the steric arrangement the studied ligands behave as bidentate too, alternative sets of two coordination sites have to be considered: nitrogen atoms of the 2-amino and 3-aminomethyl groups as well as those belonging to the pyridine ring and the 2-amino group.

More exaggerated changes in the regions of 3000–3500 and 1600–1700 cm^{-1} of the IR spectra of the amino group bearing ligands are caused by association than by coordination. Therefore lower N–H stretching accompanied by higher in-plane

bending frequencies than expected for free groups, observed consistently for all investigated complexes has only a limited reliability as an evidence for coordination of nitrogen atoms of both amino groups. On the basis of changes in the 800–200 cm^{-1} region a far more reliable conclusion could be arrived at supposing that carefully checked assignments of the characteristic bands are submitted. From the isotopic labelling it was possible only to assign by deuteration the band of ligand **I** at 650 cm^{-1} (N,N-d_2 at 450 cm^{-1}) as belonging to 3-aminomethyl group out-of-plane bending vibration. In Cu(II) and Zn(II) complexes this band of a characteristic broadened shape is shifted to 690 and 675 cm^{-1}, respectively. In the nickel complex the region is overlapped with one of strong tetraphenylborate absorption bands which are the only bands to be found below 800 cm^{-1} in this spectrum. The band at 520 cm^{-1} in the spectrum of ligand **I**, (505 cm^{-1} of ligand **III**) ascribed to CCN skeletal bending vibrations is, as presumed, shifted to 550 cm^{-1} in copper and zinc complexes.

The remaining bands characteristic of the ligand are too vague even for hypothetical consideration. Thus the bands at 610 and 420 cm^{-1} in the case of ligand **I** or at 610 and 410 cm^{-1} for ligand **III** assigned to pyridine in-plane and out-of-plane ring deformation are not well defined in the spectra of complexes. Namely, the first band is hidden by absorption of sulphate or perchlorate while the second one appears simply as a weak, broadened deviation of the spectrum curve. It ought to be mentioned however, that no shifts of these bands to higher frequencies have been observed either.

As the assignments of bands characteristic of metal–ligand bonds are lacking, the proposal for nitrogen atoms of both amino groups to act as coordination sites appears artificial indeed. But further investigations indispensable as the complement of the insufficient evidence are not feasible with regard to the means at disposal.

The absorption bands concerned show the well-known characteristic differences noted for coordinated as compared to free anions.

A very wide band with broad maxima at 1145, 1115 and 1090 cm^{-1} dominates in the spectrum of Cu(ligand **I**)$_2$$(ClO_4)_2$ complex. The emphasized intensity and manifold splitting even if the absorption of the ligands' ether groups is considered could be interpreted by means of coordinated perchlorate.[24] However, the absence of the band at 930 cm^{-1} as well as the fact that a single sharp band is present at 628 cm^{-1} unambiguously point at the free anion,[25] and therefore a four-coordination of copper in the [Cu(ligand **I**)$_2$]$(ClO_4)_2$ complex species.

The absorption corresponding to the C–O–C asymmetric stretching of ligands **I** and **III** is overlaid by a very strong and very broad band at 1170–1070 cm^{-1} in the spectra of Cu(ligand **I**)$_2$ and Cu(ligand **III**)$_2$ complexes with sulphate. The accompaniment by a strong sharp band at 613 cm^{-1} complements the pattern characteristic of the free sulphate. Considering as more plausible the analogy rather with potentially π-bonding than with σ-bonding ligands, e.g. 1,3-propylenediamine, the four-coordination of copper has been assumed.[26]

Therefore the corresponding complexes have been formulated as dihydrates [Cu(ligand **I**)$_2$-$SO_4 \cdot 2H_2O$ and [Cu(ligand **III**)$_2$]$SO_4 \cdot 2H_2O$. Shoulders at 1165 and 1145 cm^{-1} on the very strong, broad absorption band centered at 1110 cm^{-1} in part appertaining to the ligands' ether groups as well as the bands of 1070 and 1055 cm^{-1} joined to the fact that the band at 613 cm^{-1} is accompanied by an additional one at 650 cm^{-1} have been taken as evidence for the sulphato complex [Zn(ligand **I**)$_2$$SO_4$].

The positions of bands characteristic of tetraphenylborate in the spectrum of the nickel complex although corresponding to those of the free anion have not been taken as a proof. The presumption of the species [Ni(ligand **I**)$_2$][$(BPh_4)_2$] is based on the light pink colouration congruent with yellow complexes of the four-coordinated nickel with diamines[27] and substituted pyridines.[24,28] The congruence is extended further to the complexes of the higher coordinated nickel present in solution only. Thus the dissolving of the crude pink complex afforded a light blue acetone and a greenish blue methyl isobutylketone solution. Besides, a solution identical with the latter has been obtained by extraction of a mixture set up for the preparation of the nickel complex with perchlorate as anion. The greenish blue colouration of the extract changed to pink after three days.

In addition, the feature of absorption bands due to NH stretching and in-plane bending vibrations of both amino groups resembles the 3100–3500 and 1600–1650 cm^{-1} regions of the complex Cu(ligand **I**)$_2$$(ClO_4)_2$ with presumably four-coordination of the metal.

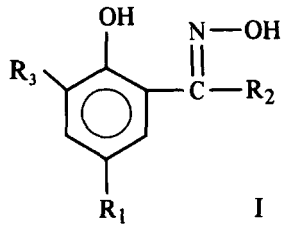
THE HYDROPHILIC LIPOPHILIC BALANCE OF HYDROXYOXIMES AND THE MECHANISM OF COPPER EXTRACTION



J. SZYMANOWSKI
Politechnika Poznanska, Pl.Sklodowskiej-Curie 2, Poznan, Poland

(*Received* 3 *January* 1984; *accepted* 16 *April* 1984)

Abstract—The polarity of some model hydroxyoximes is discussed and their *HLB* coefficients are estimated. It is shown that the rate of copper extraction by the hydroxyoximes can be related to the oxime hydrophilic lipophilic balance. The extraction mechanism is discussed for hydroxyoximes exhibiting different hydrophobicity. It is shown that the contribution of the volume reaction is less than 10% and higher than 90% for oximes which contain not less than 11 and not more than 3 carbon atoms in the alkyls, respectively.

In recent years the mechanism of copper extraction by hydroxyoxime extractants has been the subject of many investigations and discussions. Taking into account the low solubility of the hydroxyoximes in the aqueous phase and their tendency to be adsorbed at the interface of organic hydrophobic diluent–water systems, it was elucidated that the reaction between copper and the commercial hydroxyoxime extractants proceeds in the interphase. Appropriate extraction data supporting this mechanism have been described in several independent papers.[1–7]

The oxime molecule may be adsorbed at the interface due to the presence of the polar phenolic and oximino groups and appropriate long alkyl, preferably located at position 5 directly opposite to the phenolic group.

I

The penetration range of the oxime molecules into the aqueous phase depends upon the length of the alkyl groups and must increase as the molecular mass of the oxime decreases, i.e. as the length of the alkyl radicals decreases. The oxime molecule then becomes more hydrophilic, i.e. less hydrophobic, and the solubility of the oxime in the aqueous phase is increased. Thus, as the length of the alkyl radicals decreases the reaction mechanism may change, and depending upon the oxime hydrophobicity the reaction may proceed either at the interface, in the bulk of the aqueous phase or simultaneously in both.[8–12]

In surfactant chemistry surface active agents are characterized by the hydrophilic lipophilic balance, abbreviated as *HLB*.[13–14] This parameter determines the hydrophilicity of surfactants and is directly connected to the surfactant properties and adsorption abilities at the interface. However, surfactant properties are also influenced by other parameters and therefore the relations between surfactant properties and their *HLB* values are usually different although analogous for different homologous series.[15,16] Therefore the discussion in this work will be limited only to oximes of formula I, where R_1 and R_2 represent alkyls and R_3 represents hydrogen. The relationship between *HLB* and the mechanism of copper extraction will be discussed. We have recently given a short description of the *HLB* system.[11]

EXPERIMENTAL

Extraction data was determined for some pure hydroxyoximes of formula I, where R_1 represents a longer alkyl (C_1–C_{12}) and R_2 represents a shorter alkyl (C_1–C_3). The results published by Preston and Luklinska[17] were also considered. The experimental conditions were as follows: rising drop method, $T = 30°C$, 0.02 M oxime in toluene, 0.02 M $Cu(ClO_4)_2$ in $HClO_4$ solution at pH 0.9.

HLB^G coefficients were determined according to the relation:

$$HLB^G = 20\,\frac{M_H^{eff}}{M} \qquad (1)$$

where M_H^{eff} is the effective molecular mass of the hydrophilic groups in the oxime molecules, M is the molecular mass of the hydroxyoxime and HLB^D coefficients were calculated using increment numbers as determined by Davies[18], using the following relationship:

$$HLB^D = 7 + \Sigma\Delta HLB_i^D \qquad (2)$$

where ΔHLB_i^D are the increment numbers determined by Davies.

The effective molecular mass of the phenolic group was assumed to be 17 and the effective molecular mass of the oximino group was calculated from polarity data determined for model hydroxyoximes by means of gas chromatography, according to the method previously used for non-ionic surfactants.[19-24] The increment number for the oximino group was also determined from our gas chromatographic data. The influence of the chromatographic parameters and of the oxime structure upon different polarity parameters will be discussed separately.[24]

RESULTS

The hydrophilic lipophilic balance of hydroxyoximes

The influence of the percentage by weight of phenolic and oximino groups upon the polarity index of hydroxyoximes (PI), where: PI = 100 log $(C - 4.7) + 60$, and the carbon number C corresponds to the location of the methanol peak on the hydrocarbon scale, is shown in Fig. 1. The experimental points are fairly linear and the influence of the hydrophilic groups upon the oxime polarity may be qualitatively estimated from the gradients. They characterize the increase of the polarity index per 1% wt content of the hydrophilic groups and show the much higher influence of the phenolic group in comparison to the oximino group. The slopes equal 13.16 and 6.76 for the phenolic and oximino groups, respectively. Thus, under our experimental conditions the phenolic group shows a polarity twice that of the oximino group. The effective molecular mass of the oximino group is thus: $M_{NOH}^{eff} = M_{OH}\ 6.76/13.16 = 8.7$, and the group number is then: $\Delta HLB_{NOH}^D = \Delta HLB_{OH}^D\ 6.76/13.16 = 1.0$.

The relation between HLB coefficients on the Griffin and Davies scales estimated for hydroxyoximes of formula I, where the sum of carbon atoms in R_1 and R_2 can be varied from 1 to 15, is shown in Fig. 2. The non-linearity arises because the HLB^G coefficient is proportional to the percentage by weight of the hydrophilic groups, while the HLB^D coefficient is an additive function of the hydroxyoxime structure. Both functions are monotonous, and HLB^G and HLB^D decrease as the length of the alkyl groups increases. For the hydroxyoximes considered HLB^G and HLB^D are related to the number of carbon atoms in both

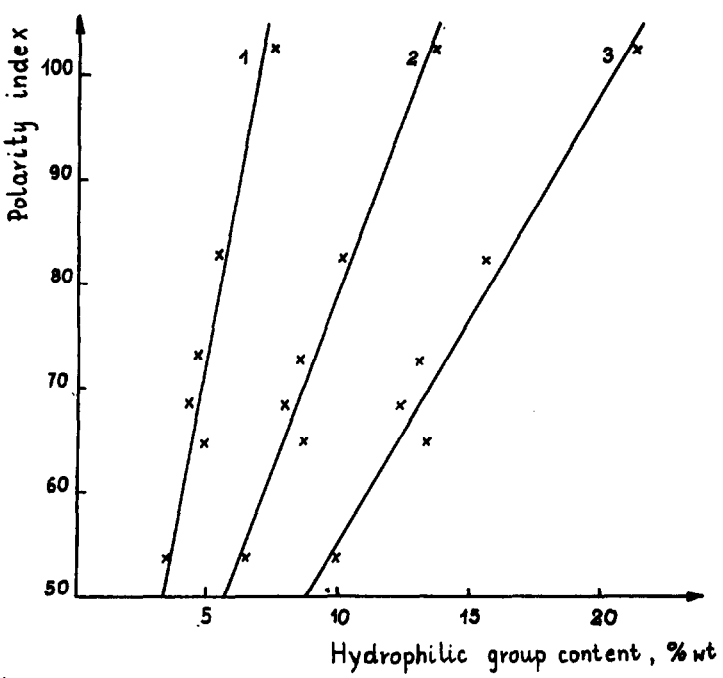


Fig. 1. The influence of the content of hydrophilic groups in hydroxyoximes upon the polarity index (1—OH, 2—NOH, 3—OH + NOH).

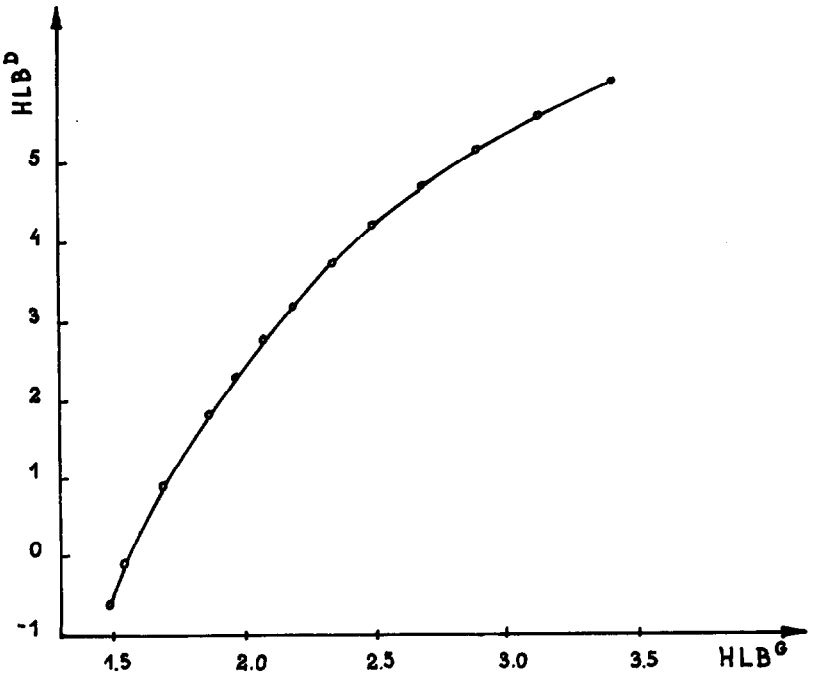

Fig. 2. The relation between HLB coefficients of hydroxyoximes.

alkyls according to the following relations:

$$HLB^G = \frac{514}{137 + 14n} \quad (3)$$

$$HLB^D = 9.9 - 0.475(7 + n) \quad (4)$$

where n denotes the sum of the carbon atoms in both the alkyls. Thus, the relation between the considered *HLB* coefficients is as follows:

$$HLB^G = \frac{514}{331 - 29.5HLB^D} \quad (5)$$

For the hydroxyoximes considered HLB^G values vary in the range 1.5–3.5, and the HLB^D values vary from -1 to 6. These low *HLB* values are in agreement with the very low solubility of the hydroxyoximes in aqueous solutions. The hydroxyoximes polarity can be compared, for example to the polarity of adducts of ethylene oxide and commercial nonylphenol, containing from 0 to 1 oxyethylene units in the molecule, i.e. to mixtures of nonylphenol and 2-hydroxyethyl-nonylphenyl ether obtained when the mole ratio of the ethylene oxide to nonylphenol does not exceed 1.

Hydrophilic lipophilic balance and the regions of copper extraction by the hydroxyoximes

Such high hydrophobicity of hydroxyoximes supports the interfacial mechanism for the oxime reaction with copper. The largest part of the hydroxyoxime molecule should be within the organic region of the interphase as the weakly hydrophilic groups cannot penetrate deeply into the aqueous phase. However, due to the very low hydrophilicity of hydroxyoximes having a large alkyl group, the decrease in the length of the hydrocarbon chain causes a sharp increase in the polarity, although the hydrophobic part of the molecule always dominates the hydrophilic groups. However, the oxime molecule may penetrate more deeply into the aqueous layer in the direct neighbourhood of the interface, and eventually a change in the extraction mechanism occurs. In the homogeneous phase the reaction proceeds more quickly than in a heterogeneous system with a small interfacial area.[25] The relations between the logarithm of the relative extraction rates and the estimated values of the *HLB* coefficients are shown in Figs. 3 and 4. Due to the non-linear relation between the HLB^G and HLB^D coefficients relations which were different but similarly shaped were obtained. In the region of low *HLB* values (below $HLB^G = 2.2$ and $HLB^D = 3$) the extraction rate depends strongly upon the oxime structure, e.g. a long alkyl group in position 3 sharply decreases the extraction rate, whilst a long alkyl in position 5 when R_2 is short increases the extraction rate (points on Figs. 3 and 4 at $HLB^G = 2$ and $HLB^D = 2.3$). The influence of oxime structure upon extraction rate is observed in the region where extraction proceeds at the interface, or the interfacial reaction definitely dominates the vol-

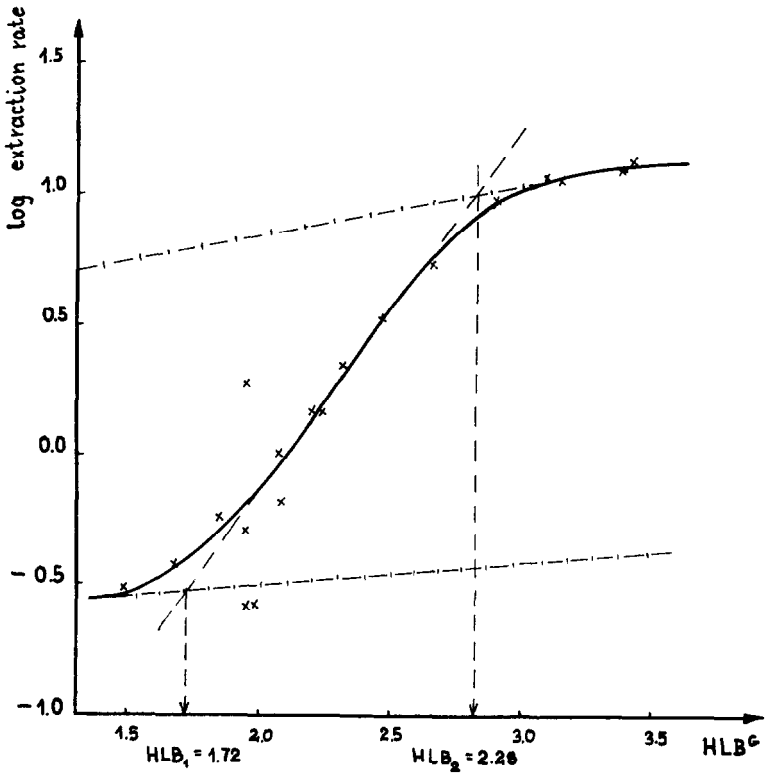

Fig. 3. The influence of the hydrophilic lipophilic balance upon copper extraction by hydroxyoximes.

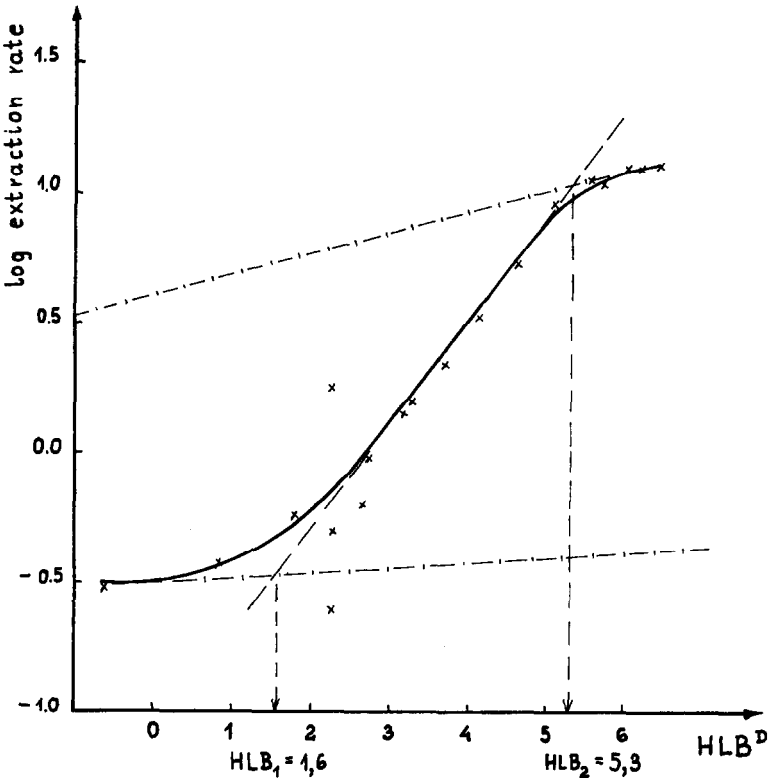

Fig. 4. The influence of the hydrophilic lipophilic balance upon copper extraction by hydroxyoximes.

ume reaction in the aqueous phase. In surfactant chemistry it is well known that adsorption properties of surface active agents depend upon the structure of the hydrophobic part of the molecule and therefore in the region of low *HLB* values the discussion should be limited to the homologous series of hydroxyoximes where the length of the R_2 group is fixed but the length of the R_1 group may differ. The structure of the R_1 group should be similar in all the compounds investigated; a straight chain R_1 group is preferred.

From the data presented in Figs. 3 and 4 the regions of bulk reaction, interfacial reaction and of the mixed mechanism were obtained when appropriate asymptotes to the curves were drawn and the points of intersection determined. The obtained values of critical *HLB* coefficients and equivalent numbers of carbon atoms in both alkyls are given in Table 1. Reasonable agreement was observed between the critical numbers of carbon atoms calculated from HLB^G and HLB^D coefficients.

The results obtained show that under our experimental conditions the extraction of copper by hydroxyoximes proceeds at the interface or in the bulk of the aqueous phase when the number of carbon atoms in both alkyls is not less than 11 or not greater than 3, respectively. For oximes having a total of from 3 to 11 carbon atoms in both alkyls the extraction occurs at the interface as well as in the bulk of the aqueous phase.

The critical length of the alkyl groups can change slightly depending upon the experimental conditions and upon the method used for the extraction rate determination. This is due to different hydrodynamic conditions and different physico chemical parameters describing the extraction system; in particular the influence of the diluent type should be quite substantial.

Mechanism of copper extraction

For hydroxyoximes of formula **I**, where the number of carbon atoms in both alkyls is not greater than 3 the reaction with copper proceeds in the homogeneous aqueous phase. When diffusion does not influence the process, the reaction can be described according to Pratt and Tiley[25] by the following steps:

$$Cu^{2+} + RH = CuR^+ + H^+ \quad (6)$$

$$CuR^+ + RH = CuR_2 + H^+ \quad (7)$$

$$\overline{CuR_2} = CuR_2 \quad (8)$$

where the bar determines the organic phase.

The slowest step is the formation of the intermediate 1 : 1 complex, and if only the forward reaction is considered the following kinetic equation is obtained:

$$v = k[RH][Cu^{2+}]. \quad (9)$$

When kinetic studies are carried out at relatively low oxime concentrations (below 0.1 M)[7,17,26] then the concentration of oxime in the aqueous phase is proportional to that in the organic phase. At concentrations higher than 0.1 M the concentration of oxime in the aqueous phase is approximately constant and does not depend upon concentration of oxime in the organic phase. In the case discussed here, because of the low oxime concentration and the use of toluene as a diluent, oxime association in the organic phase can be neglected.[4,17,27,28] Thus,

$$v = k'[\overline{RH}][Cu^{2+}]. \quad (10)$$

However, when kinetic experiments are carried out at higher oxime concentrations (above 0.1 M or above 0.01 M when an aliphatic hydrocarbon is used as the diluent) oxime association should be considered.[4,6,27–29]

For hydroxyoximes having a total of not less than 11 carbon atoms in both alkyl groups the reaction proceeds in the interphase. Thus, the generally accepted mechanism[1,30] with some modifications[4,7] can be considered:

$$Cu^{2+}_{int} + RH_{ad} = CuR^+_{int} + H^+_{int} \quad (11)$$

$$CuR^+_{int} + RH_{int} = CuR_{2int} + H^+_{int} \quad (12)$$

$$\overline{CuR_2} = CuR_{2\,int} \quad (13)$$

Table 1. Critical HLB values and equivalent length of the alkyl groups

Critical parameter	HLB^G	n^G	HLB^D	n^D
HLB_1	1.72	11.6	1.6	10.5
HLB_2	2.82	3.2	5.3	2.6

where the subscripts "ad" and "int" denote molecules adsorbed at the interface and present in the interfacial layers, respectively (Fig. 5). The formation of the complex 2 : 1 is the slowest step.

However, in this case further data and explanation is needed to support this mechanism. The surface activity of hydroxyoximes and their adsorption at the interface of an organic-aqueous surface is apparent[31–34] and the assumption that the adsorbed molecule of the oxime reacts with copper in the first step (reaction 11) is justifiable. However, the resulting charged complex, probably hydrated, must show a higher hydrophilicity than the oxime molecule and therefore it will penetrate more deeply into the aqueous layers in the neighbourhood of the interface. Thus, it is very improbable that such a strongly orientated complex will react with a second adsorbed oxime molecule. It is more probable that it will react with an oxime molecule in the interfacial aqueous layer or after its very slow reorientation with an oxime molecule in the interfacial organic layer. It seems that the reorientation of the oxime molecules can proceed more easily and more quickly than the reorientation of the charged hydrated complex. If the formation of complex 2 : 1 is the slowest step, then the intermediate complex 1 : 1 has to accumulate in the interphase and must exist in rather high concentrations. Its existence within the interphase is more probable.[35] Thus, blocking of the interface by the copper complex is possible. This may result in the formation of an interfacial film.[2,36,37]

If we assume reaction (12) is the slowest step and consider only forward reaction then the following relationship is obtained:

$$v = \frac{k[Cu^{2+}_{int}][RH_{ad}][RH_{int}]}{[H^{+}_{int}]}. \qquad (14)$$

Under perfect hydrodynamic conditions:

$$[Cu^{2+}_{int}] = [Cu^{2+}] \quad \text{and} \quad [H^{+}_{int}] = [H^{+}] \qquad (15)$$

and depending upon the location of the oxime molecule taking part in the slowest step:

$$[RH_{int}] = [RH] \quad \text{or} \quad [RH_{int}] = [\overline{RH}]. \qquad (16)$$

When the concentration of oxime in the organic phase is sufficiently low, as was described previously, then the concentration of oxime in the aqueous phase becomes proportional to that in the organic phase and oxime association in the organic phase can be neglected. Thus, in both cases considered

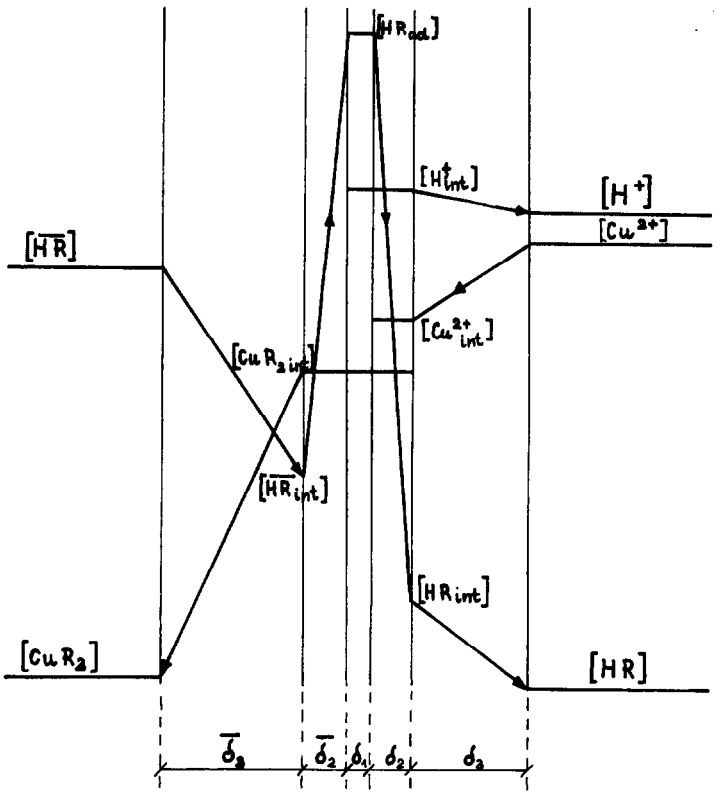

Fig. 5. Reagent concentrations in the interfacial region (δ_1—adsorption layer, $\delta_2\delta_2^1$—interfacial layers, δ_3, δ_3^1—diffusion layers).

similar expression for the extraction rate is obtained:

$$v = \frac{k[Cu^{2+}][\overline{RH}][RH_{ad}]}{[H^+]}. \quad (17)$$

The concentration of adsorbed oxime molecules is equivalent to the surface excess. A general relationship between the surface excess and the bulk oxime concentration is given by:

$$\Gamma = a[\overline{RH}]^b \quad (18)$$

where a and b are empirical coefficients.

For very low oxime concentrations it may be assumed that $b = 1$. Thus, $[RH_{ad}] = a[\overline{RH}]$ and the relationship described by Freiser[38,39] is obtained:

$$v = \frac{k[Cu^{2+}][\overline{RH}]^2}{[H^+]}. \quad (19)$$

For concentrations of oxime greater than 10^{-3} M in an aliphatic diluent or greater than 4×10^{-2} M in toluene the coefficient b can be assumed to be 0.[4,26] Thus,

$$v = \frac{k[Cu^{2+}][\overline{RH}]}{[H^+]}. \quad (20)$$

A similar kinetic equation has been reported previously.[7,30,40] However, in most cases the experimentally determined reaction order towards oxime varied between the border values 2 and 1, and sometimes even became zero.[2,4,5,17,37] This is due to diffusion processes which occur under experimental conditions[41] and sometimes also to incorrectly selected oxime concentration at which the above simplifications do not apply.

It is also improbable that under experimental conditions in which a large interface is formed an equilibrium concentration of adsorbed molecules is obtained.[2,31,42] Probably, the concentration of oxime at the interface is lower than that predicted by the interfacial tension isotherm, and moreover, it can change during the experiment. In considering this problem it is necessary to obtain data by means of real dynamic methods, e.g. the method of oscillating jets or drops.

For oximes containing a total of from 3 to 11 carbon atoms in the alkyl groups both the bulk and interfacial reactions must be considered. Thus, the reaction rate is equal to:

$$v = v_v + v_s = k_v[Cu^{2+}][\overline{RH}] + \frac{k_s[Cu^{2+}][\overline{RH}]^n}{[H^+]} \quad (21)$$

where v_v, v_s are the extraction rates for volume and interfacial processes, respectively, k_v, k_s are the specific rates constants for volume and interfacial processes, respectively n is the empirical coefficient characteristic of the experimental conditions being used.

The kinetic parameters required to solve eqn (22) cannot be obtained from our data. However, we can estimate the contribution of the volume reaction to the overall extraction rate for oximes having different numbers of carbon atoms in the alkyl groups. The contribution (β) of the volume reaction to the measured reaction rate (v) can be expressed by the following equation:

$$v = v_v\beta + v_s(1 - \beta). \quad (22)$$

Thus,

$$\beta = \frac{v - v_s}{v_v - v_s} \cdot 100\%. \quad (23)$$

The estimated values are presented in Fig. 6. The lower limit of the shaded area was calculated by assuming that the rates of the interfacial and volume reactions are constant and independent of the length of the alkyl groups. The upper limit was calculated by considering linearly extrapolated values of the interfacial and volume reaction rates.

The results obtained show that for oximes having a total of not less than 11 carbon atoms in the alkyl groups the contribution of the volume reaction is less than 10%, while for oximes having a total of not more than 3 carbon atoms the contribution is above 90%. A contribution of 50% is obtained for oximes containing 6–7 carbon atoms in the alkyl groups.

Some predictions can also be made for the commercial hydroxyoximes having a branched nonyl group (P 50, SME 529 and Lix 65N). The extra aromatic ring in Lix 65N is equivalent only to a little more than 3 carbon atoms in the aliphatic chain. In surfactant chemistry such an assumption is usually made when the polarity, the hydrophilic lipophilic balance and/or critical micelle concentrations are discussed. Thus, the minimum contribution of the volume reaction can be estimated as follows: P 50—about 20%, SME 529—about 15% and Lix 65N—about 15%. However, these contributions can be sharply increased when the commercial extractants are contaminated with oximes of lower molecular mass obtained as by-products in the acylation of nonylphenol with benzoyl chloride, benzotrichloride or acetyl anhydrate in the presence of aluminum chloride, i.e. during the manufacture of SME 529 and Lix 65N.

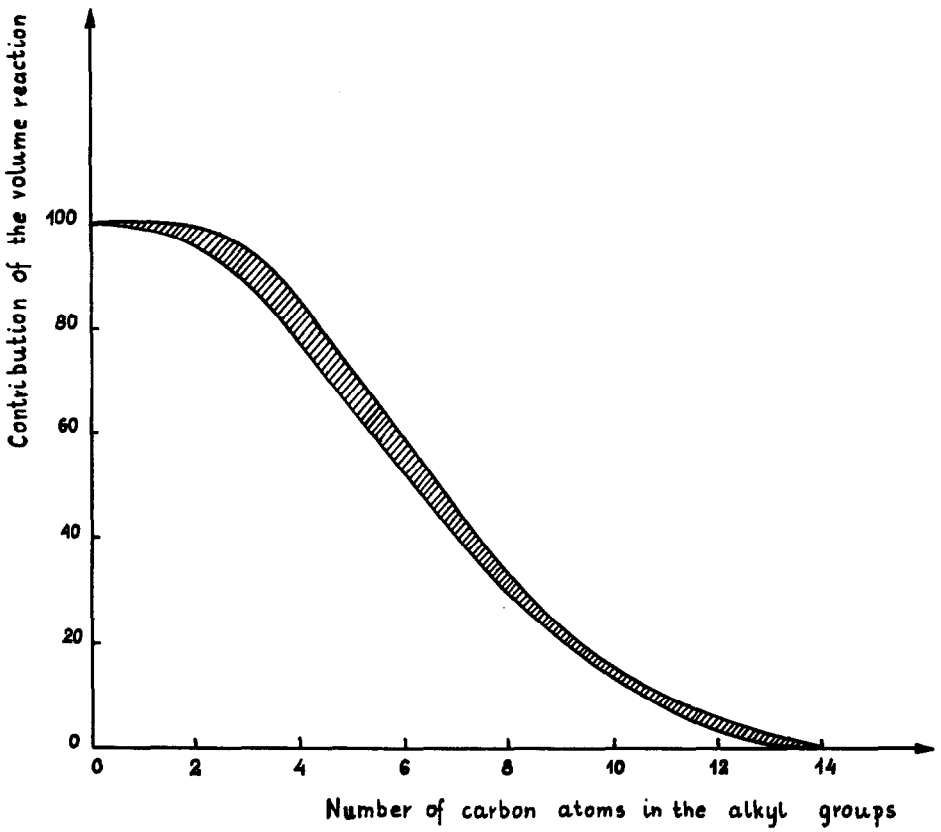

Fig. 6. The influence of the number of carbon atoms in the alkyl groups upon the contribution of the volume reaction.

Comments upon the mechanism of copper extraction by commercial extractants

Most of the authors who have investigated the kinetics of copper extraction used commercial reagents, either directly or after some kind of purification. We believe that such a kinetic and interfacial data can be misinterpreted, and that commercial extractants, even after "purification", are not the most suitable reagents for mechanistic studies. The following points should be stressed here.

1. Commercial nonylphenol is formed from an identified propylene trimer which is a mixture of several components, not only the isomers of nonene. We have observed about 30 components in a commercial nonylphenol; the main component comprising only about 25%.

2. Commercial nonylphenol contains only about 90% 4-alkylphenol. It also contains about 10% 2-alkylphenol and less than 2% alkylphenyl ether. Small amounts of other impurities can be also present. The presence of these by-products and derivatives formed during the oxime manufacture has not been discussed in the literature. The removal of the above by-products either from raw nonylphenol or from the extractant manufacturing process is very difficult.

3. It is probable that commercial reagents also contain small amounts of ketones or aldehydes which did not react completely in the oximation step.

4. Lesser or greater amounts of the dealkylated oximes are present in commercial extractants. They influence the extraction mechanism and enhance the contribution of the volume reaction. Thus, parallel complexation of copper by alkylated and dealkylated oximes should be considered. Additional equilibria should be also discussed:

$$R'_2Cu = R'R''Cu = R''_2Cu \qquad (24)$$

where R'H and R''H denote alkylated and dealkyalted oximes, respectively.

5. Taking into account oxime isomerisation the use of P 50 or SME 529 rather than Lix 65N should be preferred. In most of the published papers the structure of the separated E-Lix 65N isomer was not proved, and the given statements can not be accepted in the meaning of the organic chemistry.

6. As complete analysis of commercial extractants is not possible the impurity content can not be determined and the quality of the separated fraction can not be proved. Moreover, the separation of pure oximes having the high purity necessary for kinetic and mechanistic studies is very difficult.

7. When the raw material or the separated fractions are stored it is possible that some components may precipitate and the isomerisation of oximes may occur.

8. Those reagents are rendered unsuitable for kinetic, mechanistic or interfacial studies, especially when an interfacial mechanism is been deduced.

CONCLUSIONS

The rate of copper extraction by hydroxyoximes can be related to the oxime hydrophilic lipophilic balance.

Depending upon the oxime hydrophilicity either the interfacial reaction, the volume reaction or both of these must be considered.

The contribution of the volume reaction is less than 10% and higher than 90% for oximes which contain a total of not less than 11 and not more than 3 carbon atoms in the alkyl groups, respectively.

The minimum contribution of the volume reaction for commercial extractants can be estimated as follows: Lix 65N—5%, SME 529—15% and P 50—20%.

Commercial oxime extractants are not the most suitable reagents for the kinetic and mechanistic studies of copper extraction as their use can cause misleading results.

COMPARATIVE STUDY OF HYDROXO-FLUORO AND HYDROXO-SULPHIDO MIXED LIGAND COMPLEXES OF ALUMINIUM(III) AND GALLIUM(III)

IMRE TÓTH*, LÁSZLÓ ZÉKÁNY and ERNŐ BRÜCHER
Department of Inorganic and Analytical Chemistry, Lajos Kossuth University, H-4010 Debrecen, Hungary

(*Received* 26 *October* 1983; *accepted after revision* 16 *April* 1984)

Abstract—The mixed ligand complex formation had been studied in the aluminate–fluoride, gallate–fluoride, aluminate–sulphide and gallate–sulphide systems by spectrophotometric as well as potentiometric methods using glass and sulphide selective electrodes. The formation of the species $Al(OH)_3F^-$ and $Ga(OH)_2S^-$ has been demonstrated and the equilibrium constants have been determined. Similar interaction could not be detected in the aluminate–sulphide and gallate–fluoride systems.

The differences in behaviour of the metal ions to the characteristically hard fluoride and soft sulphide ligands can be interpreted in that the Ga^{3+} ion may form complexes with charged soft ligands too, its behaviour then differing from that of the typically hard Al^{3+} ion.

The development in the semiconductor industry has led to a considerable increase in the demand for high-purity gallium and its compounds.[1] Virtually the only raw material source for gallium production is the aluminate liquor in the Bayer alumina production cycle; the essence of the various procedures is always the selective separation of gallium from a large excess of aluminium. Liquid-liquid extraction methods of separation are currently finding increasing application.[2] Accordingly, there may well be practical importance to a study of the differences in coordination chemical properties of aluminium(III) and gallium(III), which are well known to behave very similarly.

The stability constants of the Al^{3+}-fluoro complexes are higher than those of the corresponding Ga^{3+} complexes; in aqueous solution the species AlF_6^{3-} has been identified, whereas the coordination of more than three F^- ions to Ga^{3+} in solution has not been described.[3]

Data on the hydroxo complexes are much more contradictory; their study, particularly at moderate pH values, is greatly hampered by the formation of very complex polynuclear species.[4] This is probably the reason why the stability data on the hydroxo-fluoro mixed ligand complexes are unknown, even though the reaction between $Al(OH)_3$ and F^- is a familiar one in classical analysis, and the reaction between aluminate and F^- ions is utilized for quantitative analytical purposes.[5]

It is also well known that the addition of $(NH_4)_2S$ to a solution of Al^{3+} ions results in the precipitation of $Al(OH)_3$ and the behaviour of Ga^{3+} is similar. However, in the presence of Zn(II), Pb(II) or As(III) gallium(III) mixed-sulphides can be precipitated and the various ZnS minerals always contain traces of gallium too, in the absence of aluminium. In the study of the Ga^{3+}–OH^-–S^{2-}–Zn^{2+} system the formation of species $Ga(OH)_2S^-$ has been assumed but the stability constant was not determined.[6]

The presence of polynuclear hydroxo complexes need not be considered at pH > 10, where the metal ions are present only as $M(OH)_4^-$ (M = Al or Ga)[4], and our investigations were therefore carried out in this pH range.

EXPERIMENTAL

Chemicals and analytical methods

Gallium nitrate and aluminium nitrate stock solutions were prepared by dissolving 5N gallium (Timföldgyár és Aluminiumkohó, Ajka) and aluminium (p.a., Reanal) in nitric acid. The concen-

*Author to whom correspondence should be addressed.

trations of the metal ions in the solutions were determined complexometrically.

The KOH solution used for the pH-potentiometric titrations was stored in an argon atmosphere. Its concentration was measured pH-potentiometrically with potassium hydrogen phthalate (Merck).

The Na_2S stock solution was prepared by dissolution of $Na_2S \cdot 9H_2O$ (p.a., Merck) in boiled-out bidistilled water; it was stored in an argon atmosphere. Its concentration was determined by oxidation with KIO_3 in basic medium to sulphate,[7] or in acidic medium to sulphur,[8] with back-titration of the excess KIO_3. The agreement of the results of the determinations within 1% showed that all of the sulphur in the Na_2S solution was in the oxidation state -2.

The aluminate and gallate solutions were obtained from the $M(NO_3)_3$ solutions by the addition of excess KOH solution to yield $K[M(OH)_4]$ solutions. The passage of CO_2 led to the separation of precipitates of $M(OH)_3$, which can be centrifuged. The precipitates were redissolved to remove nitrate, and again precipitated with CO_2. The metal contents of the resulting $K[M(OH)_4]$ solutions were determined complexometrically.

The NaF solution was prepared from NaF (p.a., Reanal) by direct weighting.

Procedures

Spectrophotometric measurements were made at 25 ± 0.2°C with a Beckmann Acta M IV instrument.

Potentiometric experiments were performed at 25 ± 0.2°C and constant ionic strength: 0.5 mol dm^{-3} KNO_3. OP-208 and OP-208/1 Radelkis pH-meters, a Radiometer GK2401B combined electrode, a Radelkis OP-S 07110 sulphide-selective electrode, and an OP 8202 Ag/AgCl reference electrode incorporated with a ceramic-filter KNO_3 salt bridge were used. The pH-meter was calibrated with freshly-prepared saturated $Ca(OH)_2$ solution (Reanal, pH = 12.454) and 0.01 mol dm^{-3} $Na_2B_4O_7 \cdot 10H_2O$ (Reanal, pH = 9.18). The stoichiometric equilibrium constants were calculated from the measured pH values with the method of Irving *et al.*[9] In 0.5 mol dm^{-3} KNO_3 solution the stoichiometric ionic product of water was determined to be $pK_w = 13.83 \pm 0.01$.

During titrations, the absence of CO_2 and O_2 was ensured by passage over the solutions of argon freed from oxygen with alkaline pyrogallol solution. A magnetic stirrer was used for mixing.

Sulphide ion concentration was determined via calibration curves. At 25°C and constant ionic strength the electrode potential (E) is as follows:[10]

$$E = \text{const.} - 0.0296 \log [S^{2-}]. \quad (1)$$

The constants describing the protonation equilibria of the S^{2-} ion are $K_1^H = [HS^-]/[S^{2-}][H^+]$ and $K_2^H = [H_2S]/[HS^-][H^+]$; these can be used to express the S^{2-} ion concentration:

$$[S^{2-}] = \frac{T_S}{1 + K_1^H[H^+] + K_1^H K_2^H [H^+]^2} \quad (2)$$

where $T_S = [S^{2-}] + [HS^-] + [H_2S]$. Since log $K_2^H = 7.0$ and log $K^H = 13.9$[11], if pH > 9.0 we have $K_1^H K_2^H [H^+]^2 \ll K_1^H [H^+]$ and $K_1^H [H^+] \gg 1$, so that eqns (1) and (2) give

$$E = \text{const.} - 0.0296 \log \frac{T_S}{K_1^H [H^+]}. \quad (3)$$

In analytical chemistry the pH-dependence of the electrode potential as in eqn (3) is generally taken into account with the use of buffers; this is usually not possible in coordination chemical equilibrium investigations. The pH-dependence can be taken into account through the simultaneous measurement of the H^+ ion concentration, but even then the S^{2-} ion concentration can be calculated only if K_1^H is known[11]; this can cause problems, because of the uncertainty in the protonation constant.

If the values of K_1^H and K_2^H are considered, it holds in the interval $9 < pH < 11.5$ that $T_S = [HS^-]$, and thus eqn (3) can be written as

$$E = \text{const.}' - 0.0296(pH - p[HS^-]). \quad (4)$$

Calibration curves plotted on the basis of eqn (4) are to be seen in Fig. 3. The very good linearity demonstrates the applicability of the method. For calibration plots recorded at five different times the slope is almost the theoretical one: -28.81 ± 0.05; the intercept too is very reproducible, with a mean value of -502.5 ± 0.3 mV. The concentration range is $pT_S = 2$–4.5, with pH = 9.0–11.5.

RESULTS AND DISCUSSION

(a) *Aluminate–fluoride and gallate–fluoride systems*

The interactions between aluminate or gallate and fluoride ions were studied pH-potentiometrically at constant total metal ion concentration (0.01 moldm^{-3}) and at variable total fluoride ion concentration. The results are presented in Fig. 1.

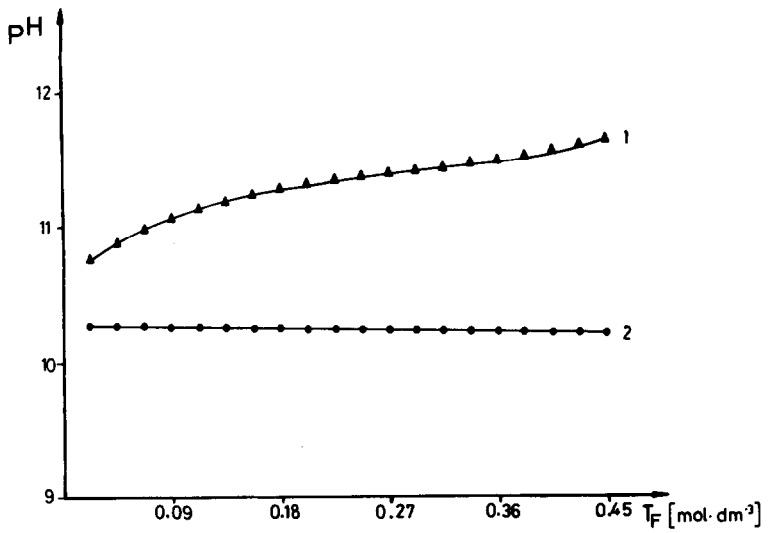

Fig. 1. Variation of pH as a function of the total fluoride concentration in the aluminate–fluoride and gallate–fluoride systems. $T_M = 0.01$ mol dm^{-3}; $C_{KNO_3} = 0.5 - T_F$ mol dm^{-3}. Al^{3+}(1), Ga^{3+}(2).

It may be seen from Fig. 1 that the addition of F^- leads to a pH increase in the aluminate solution, whereas the pH in the gallate solution is unchanged. The pH change in the aluminate–fluoride system was interpreted by the assumption of the following simple equilibrium:

$$Al(OH)_4^- + F^- \rightleftharpoons Al(OH)_3F^- + OH^- \quad (5)$$

$$K_m = \frac{[Al(OH)_3F^-][OH^-]}{[Al(OH)_4^-][F^-]}. \quad (6)$$

The equilibrium constant K_m can be calculated for each experimental point via the following equations: $T_{Al} = [Al(OH)_4^-] + [Al(OH)_3F^-]$; $T_F = F^- + [Al(OH)_3F^-]$ and $T_{OH^-} = [OH^-]_{T_F=0} + [Al(OH)_3F^-]$.

In the concentration interval $T_F = 0-0.36$ mol dm^{-3}, log $K_m = -2.20 \pm 0.13$. The constants calculated at higher T_F values exhibited a slight shift; this indicates that, although the average ligand number at the highest T_F value too is only $\bar{n} = 0.55$, a small degree of formation of the species $Al(OH)_2F_2^-$ may be assumed. In connection with the parent fluoro complexes, it is known that the difference between the stepwise stability constants is only -1.1 log unit;[13] on this basis it may be assumed that the difference between the stepwise constants is likewise not large when the mixed ligand complexes are formed. However, the equilibrium constant describing formation of the complex $Al(OH)_2F_2^-$ cannot be determined under the concentration conditions we employed.

The data in Fig. 1 indicate that Ga^{3+} does not form a mixed ligand complex under these conditions. This is probably the consequence of the relatively stronger Ga–OH bonds which result in the higher stability of the complex $Ga(OH)_4^-$.

Under conditions similar to those above, we were unable to detect the formation of mixed hydroxo–halo complexes in the gallate–chloride, gallate–bromide and gallate–iodide systems either.

(b) *Aluminate–sulphide and gallate–sulphide systems*

The interaction between the gallate and sulphide ions was studied via the HS^- absorption band with maximum at 230 nm.[11] The spectra of solutions with a constant total sulphide concentration and various concentrations of $K[Ga(OH_4)]$, but free from foreign ions, were compared with the spectra of solutions of identical composition, but not containing sulphide. The resulting spectra may be seen in Fig. 2(a). Before the spectra in Fig. 2(b) were recorded, the increase in the pH of the solutions, due to the base excess in the gallate solution, was compensated by the addition of perchloric acid.

The changes visible in Figs. 2(a) and (b) point to the interaction of the gallate and sulphide ions, the extent of which increases as the gallate concentration rises, while it decreases with increase of the OH^- ion concentration. Similar studies were made on the aluminate–sulphide system, but a change indicative of an interaction was not observed.

In the potentiometric investigations, gallate and aluminate solutions with concentrations of 1.0×10^{-3}, 3×10^{-3}, 5×10^{-3} and 1.0×10^{-2} mol dm^{-3} were titrated with 5.0×10^{-2} mol dm^{-3} Na_2S solution, with simultaneous measurement of the pH and the potential of the sulphide-selective electrode. Fig. 3 depicts the experimental results, together

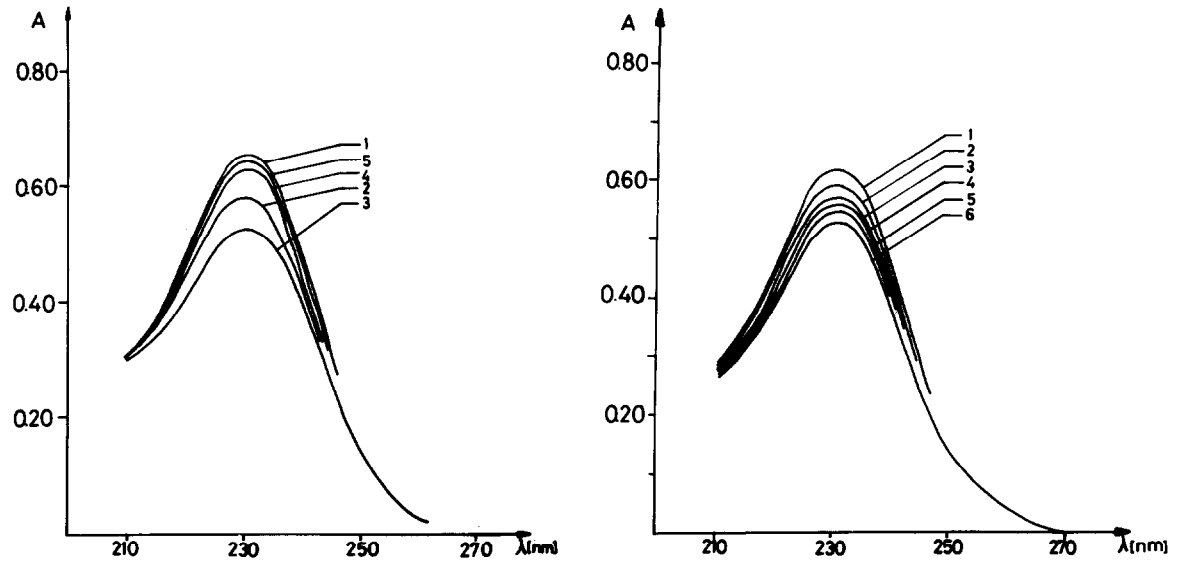

Fig. 2. Spectra of sulphide solutions at various total gallium concentrations. d = 10 mm; $T_S = 8.4 \times 10^{-5}$ mol dm^{-3}; (a) T_{Ga}(mol dm^{-3}) and pH: 0 and 11.0 (1), 1.0×10^{-4} and 10.8 (2), 1.0×10^{-3} and 11.2 (3), 3.0×10^{-3} and 11.8 (4), 7.0×10^{-3} and 12.8 (5). (b) pH = 10.1; T_{Ga}(mol dm^{-3}): 0.0 (1), 1.0×10^{-4} (2), 1.0×10^{-3} (3), 5×10^{-3} (4), 7.0×10^{-3} (5), 1.0×10^{-2} (6).

with the calibration plot recorded in the absence of the metal ions.

The findings of an interaction between gallate and sulphide ions (Fig. 2), and of a lower sulphide ion concentration in the presence of gallate ion (Fig. 3), may be interpreted by assumption of the following equilibrium:

$$Ga(OH)_4^- + HS^- \rightleftharpoons Ga(OH)_2S^- + OH^- + H_2O \quad (7)$$

$$K'_m = \frac{[Ga(OH)_2S^-][OH^-]}{[Ga(OH)_4^-][HS^-]}. \quad (8)$$

Of the equilibrium concentrations necessary for calculation of K'_m, $[OH^-]$ and $[HS^-]$ are direct experimental data, while $[Ga(OH)_2S^-]$ and $[Ga(OH)_4^-]$ can be calculated via the following material balances: $T_S = [HS^-] + [Ga(OH)_2S^-]$ and $T_{Ga} = [Ga(OH)_4^-] + [Ga(OH)_2S^-]$.

The value of the equilibrium constant calculated for the experimental points is log $K'_m = -1.72 \pm 0.08$. The mixed ligand complex $Ga(OH)_2S^-$ predominates at pH values around 9 but its concentration decreases with increasing pH and at pH > 12 is negligible.

Naturally, the equilibrium in eqn (7) cannot be

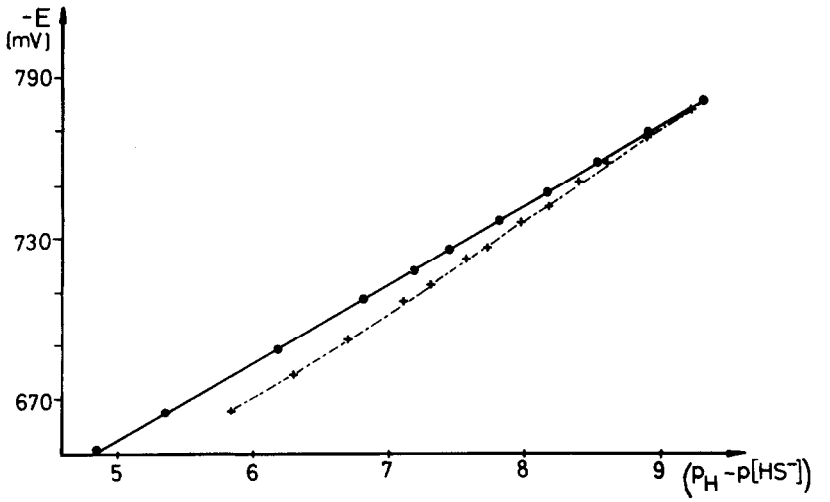

Fig. 3. Variation of the potential of the sulphide-selective electrode as a function of (pH − p[HS$^-$]): T_{Ga} = 5.0×10^{-3} mol dm^{-3}, I = 0.5 mol dm^{-3} KNO_3 (—×—); I = 0.5 mol dm^{-3} KNO_3 (-●-).

differentiated with a potentiometric method from an equilibrium in which an HS^- ligand replaces an OH^- ion and a species $Ga(OH)_3SH^-$ is formed. The numerical value of $K''_m = [Ga(OH)_3SH^-][OH^-]/[Ga(OH)_4^-][HS^-]$ is the same as that of the constant in eqn (8). Although a number of examples are known where HS^- behaves as a ligand[13,14] the simultaneous coordination of OH^- and HS^+ ions has been assumed only in the formation of Zn(OH)(SH), and even here merely as a possible alternative to the species $ZnS \cdot H_2O$.[15]

In aqueous solution, Al^{3+} and Ga^{3+} are generally considered to behave very similarly. Nevertheless, aluminate and gallate ions display opposite behaviour with fluoride and sulphide ligands. Although it is true that the interactions between aluminate and fluoride, and between gallate and sulphide, are not very strong, and can be observed only at a comparatively low OH^- ion excess, these findings do suggest a definite difference in the complex-forming tendencies of the Al^{3+} and Ga^{3+} ions.

The sulphide ion is a soft ligand, though because of its high basicity it also forms very stable, poorly soluble compounds with several not typically soft metal ions.[16]

Since the Al^{3+} ion forms stronger electrostatic bonds than the Ga^{3+} ion, the fact that there is no interaction between Al^{3+} and S^{2-}, whereas there is such an interaction between Ga^{3+} and S^{2-}, can only be explained by the participation of the Ga^{3+} 3*d* electrons in the bonding formed. The charge density of those of the Ga^{3+} d^{10} electrons with the appropriate direction may be shifted slightly towards the empty *d* orbitals of the sulphide ion; accordingly, besides the electrostatic interaction, a weak covalent bond may also develop. The formation of such a weak $d\pi$–$d\pi$ bond is given as the explanation of the stability of the complexes of In^{3+} (which has similar properties to those of Ga^{3+}) with various substituted carboxylic acids.[17] A metal→ligand electron shift is similarly assumed from an IR and ^{1}H-NMR spectroscopic study of complexes of Ga^{3+} and In^{3+} with various ligands containing the mercapto group.[18] It has been concluded from thermodynamic data that Ga^{3+} does not behave as typically hard in the formation of the Ga(III)-azide complexes; a part is also played in this by the properties of the ligand.[19] Thus, in agreement with these literature data,[17–19] our experimental results show that the Ga^{3+} ion may also form complexes with charged soft ligands; its behaviour then differs from that of the typically hard Al^{3+} ion, and to a certain extent is reminiscent of that of the similarly d^{10} Zn^{2+} ion.

(*Received* 7 *March* 1984; *accepted* 17 *April* 1984)

Abstract—Reaction of phenylimido tungsten tetrachloride with MeOH and *t*-butylamine gave the dimeric complexes $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$ and $[W(NPh)(\mu\text{-}OMe)(OMe)_2Cl]_2$. With ethanol $[W(NPh)(\mu\text{-}OEt)(OEt)_2Cl]_2$ was formed whereas *iso*propyl and *neo*pentyl alcohols gave the monomeric complexes $[W(NPh)(OR)_4(NH_2CMe_3)]$ (R = $CHMe_2$, CH_2CMe_3); *t*-butanol gave $[W(NPh)(OCMe_3)_3Cl(NH_2CMe_3)]$ which could not be converted to $[W(NPh)(OCMe_3)_4]$. Further reaction of $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$ with $o\text{-}HOC_6H_4CH = NC_6H_3Me_2$(salim-H) gave the salicylaldimine complex $[W(NPh)(OMe)_3(salim)]$. The products were characterised by analytical data, IR, ^1H NMR, ^{13}C NMR and mass spectroscopy. The crystal and molecular structures of the title complexes have been determined from single crystal X-ray diffractometer data. Crystals of $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$ are triclinic with $a = 8.473(7)$, $b = 10.776(5)$, $c = 7.683(3)$ Å, $\alpha = 102.26(3)$, $\beta = 102.68(4)$, $\gamma = 71.13(6)°$, space group $P\bar{1}$ Crystals of $[W(NPh)(OCMe_3)_3Cl(NH_2CMe_3)]$ are monoclinic with $a = 9.341(2)$, $b = 29.608(7)$, $c = 10.257(2)$ Å, $\beta = 106.28(2)°$, space group, $P2_1/c$. Both structures were solved by Patterson and Fourier methods and refined to $R = 0.075$ for the 1022 observed data of $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$ and to $R = 0.074$. For the 2033 observed data of $[W(NPh)(OCMe_3)_3Cl(NH_2CMe_3)]$. The former molecule is shown to be a dimer, the two halves of the molecule being related by a centre of symmetry. Both W atoms adopt a distorted octahedral coordination geometry and they are linked by two methoxy bridges. *Trans* to one of the bridging donors is the phenyl imido group with a W–N bond length of 1.61(4) Å; the remaining coordination sites are filled with methoxy groups. The structure of $W(NPh)(OCMe_3)_3Cl(NH_2CMe_3)$ is monomeric with the phenylimido group *trans* to the NH_2CMe_3 ligand in a distorted octahedral coordination geometry. Remaining sites are filled with the chloride and 3 $OCMe_3$ ligands. The W–N (imido) bond length is 1.71(2) Å, whilst W–N(amine) is 2.40(2) Å

Although many examples of early transition metal alkoxides are known, a few complexes only have been prepared which additionally contain the multiply-bonded organo-imido function, W=NR.[1] Those reported to date include the silyloxy complexes $(Me_3SiO)_3V(NSiMe_3)$,[2] $(Me_3SiO)_3V(N\text{-}t\text{-}Bu)$ and $(Me_3SiO)_2M(N\text{-}t\text{-}Bu)_2$(M = Cr, Mo)[3] prepared from the metal oxychloride and HMDS or *t*-BuNHSiMe$_3$, the tungsten complexes $WO(NR)(OEt)_2$[4] and $(t\text{-}BuO)_2W(N\text{-}t\text{-}Bu)_2$[5] which result from alcohol exchange of halide or amido ligands of complexes already containing the imido moiety, and the rhenium complexes $(Me_3SiO)Re(N\text{-}t\text{-}Bu)_3$ and $Re_3(N\text{-}t\text{-}Bu)_4O_4(OSiMe_3)_3$.[6] We report here the synthesis and characterisation of organo-imido alkoxides of tungsten(VI) which are readily prepared from a variety of alcohols under mild conditions. preliminary account of this work has already appeared.[7]

RESULTS AND DISCUSSION

Preparation of complexes. In benzene solution phenylimido tungsten tetrachloride reacts with four equivalents of MeOH in the presence of excess ammonia to give, on recrystallisation, yellow, air and moisture sensitive crystals of $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$ (**1**) Triethylamine may also be used as base but the best yields and cleanest product were obtained by addition of 5 equivalents of *t*-butylamine to $[W(NPh)Cl_4]_n$ in petroleum ether, followed by 4 equivalents of MeOH. Addition of the MeOH/*t*-butylamine mixture to $[W(NPh)Cl_4)]_n$ resulted in several petroleum ether soluble products of which the major component was (**1**) but considerable insoluble material also formed. Extraction of this residue with toluene and cooling the solution yielded a crystalline product analysing as $[W(NPh)(OMe)_3Cl]_n$ (**3**) where it is proposed n = 2. Methylimido tungsten tetrachloride reacted with $MeOH/Me_3CNH_2$ to give $[W(NMe)(\mu\text{-}OMe)(OMe)_3]_2$ (**2**) in approximately 50% yield but the petroleum ether insoluble material did not yield a single crystalline product on extraction with toluene.

The X-ray crystal structure analysis of (**1**) shows the molecule to be a dimer with the two halves centrosymmetrically related. Each tungsten adopts a distorted octahedral coordination geometry with oxygen donors of 2 methoxy groups forming bridges between them. The phenylimido group is *trans* to one of these bridges. A view of the molecule is shown in Fig. 1. Bond distance and angle data are given in Tables 1 and 2.

The phenylimido group is essentially linear with a W–N̂–C(1) angle of 174(2)°. The short W–N bond distance of 1.61(4)° indicates considerable multiple bond character for this bond and the value is in accord with that predicted (1.71 Å) by Nugent and Haymore for a W–N triple bond.[1] It also lies within the range of values found (1.61–1.77 Å) in other tungsten imido complexes.[8,9] A slight *trans* lengthening of the W–O(1′) bond (2.16 Å) is noted resulting in an asymmetric bridging arrangement. The three terminal methoxy ligands approach more closely to the tungsten atom than do their bridging counterparts with observed W–O distances of 1.92(3), 1.92(2) and 1.89(3) Å. These bond lengths are comparable with those observed in other alkoxide complexes.[10] The slightly longer distances of 2.05(2) and 2.16(2) Å for W–O(1) and W-O(1′) respectively are also in accord with those found in comparable bridging alkoxy groups.

The octahedral coordination geometry is distorted away from an ideal arrangement with the atoms O(1), O(2), O(3), and O(4) being displaced away from the imido nitrogen towards the *trans* donor (the average angle subtended by N and each of the above four O donors at W is 99°). Such a distortion has been observed in other complexes involving the phenylimido and related, nitrido, ligands where a relatively short M–N distance is found.[11]

Reaction of EtOH with phenylimido tungsten tetrachloride gave a toluene soluble product analysing as $W(NPh)(OEt)_3Cl$ (**4**) for which pre-

liminary X-ray crystallographic results show a bridging ethoxide. *iso* Propyl and *neo*pentyl alcohols reacted to give yellow crystalline complexes $[W(NPh)(OR)_4(NH_2CMe_3)]$ [R = $CHMe_2$ (**5**), R = CH_2CMe_3 (**6**)] with little apparent formation of petroleum ether insoluble material. Replacement of Me_3CNH_2 by PMe_3 occurred for (**5**) but the product $[W(NPh)(OCHMe_2)_4(PMe_3)]$ (**9**) could only be obtained as an oil and was characterised by IR and proton NMR spectroscopy.

t-Butanol reacted with $W(NPh)Cl_4$ and *t*-butylamine to give the complex $W(NPh)(OCMe_3)_3Cl(NH_2CMe_3)$ (**7**), this being the only product even with excess alcohol and extended reaction periods. This complex failed to give clean reaction products on further reaction with $LiOCMe_3$ or *t*-butanol in the presence of ammonia gas. However, reaction of phenylimido tungsten tetrachloride with four equivalents of $LiOCMe_3$ in diethyl ether gave $W(NPh)(OCMe_3)_4$ which was recently reported by Schrock.[12] Phenylimido tungsten tetrachloride when reacted with *t*-butanol/NH_3 failed to give a characterisable product.

The X-ray crystal structure analysis of (**7**) shows this molecule to be monomeric with the expected distorted octahedral coordination geometry. There are no unusual intermolecular contacts. Bond length and angle data are listed in Tables 3 and 4. Figure 2 gives a view of the molecule and shows the phenylimido and amino ligands occupying *trans* coordination sites. The geometry of the former group conforms to the expected as outlined for (**1**) with an approximately linear bridging mode (W–N(1)–C(1) 171(1)°) and a short W–N(1) bond distance of 1.71(2) Å indicating essentially triple bond character. The increase in the average N(1)–W-donor angle to 98.2° is also expected and has been commented on previously for (**1**). The *trans* influence of the phenylimido group is apparent from the long W–N(3) bond distance of 2.40(2) Å, a value which is longer than in comparable complexes.[13] It reflects the purely σ-nature of the W–N (amino) bond. The two *trans* tertiary butoxide groups have W–O distances {W–O(2) 1.86(1) and W–O(4) 1.91(2) Å} which are indistinguishable from one another and from their *cis* counterpart [W–O(5) 1.85(1)]. The three are consistent with a measure of π-donation from the oxygen donors. The W–Cl bond distance of 2.500(4) is long and has a value lying at the upper limit of the range for this ligand.[14]

Results of preliminary work show that $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$ (**1**) is a convenient starting material for the synthesis of other W(VI) imido complexes. Thus reaction with *o*-$HOC_6H_4CH{=}NC_6H_3Me_2$ (salim-H) gave the salicylaldiminato complex $[W(NPh)(OMe)_3(salim)]$ for which we propose structure (**8**) based on the preference, determined crystallographically in (**1**)

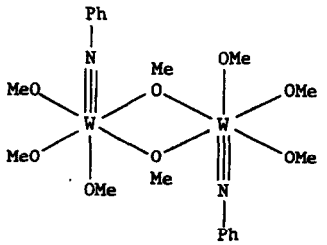
and (7), for the neutral ligand to coordinate *trans* to the imido function.



IR spectra. Characteristic ν(C–O) and ν(M–O) IR absorptions are shown in Table 5. Bridging and terminal modes were assigned for (4) by comparison with the complexes $[M(OEt)_5]_2$ (M = Nb, Ta[15]) but as the other proposed dimers do not react with bridge splitting ligands L(L = Py, PPh_3, PMe_3, etc.) the specific absorptions attributable to bridging alkoxide cannot be ascertained by comparison with a monomeric species. However, the complexes are most likely alkoxy bridged as in (1), with ν(M–Cl) falling in the vicinity of 320 cm^{-1}. In addition to absorptions found for *iso* propoxides, the spectrum of complex (5) contains a strong doublet at 1365 and 1350 cm^{-1} characteristic of *gem*-dimethyl groups.[16] The *neo*-pentoxy complex (6) shows only two ν(C–O) absorptions at similar frequency to the free ligand. In the ν(M–O) region of the *t*-butoxy complex (7), containing mutually *trans* alkoxides and a *trans* chloro alkoxide, three strong absorptions occurred.

We have been unable to assign ν(WN) for the complexes since the 1100–1300 cm^{-1} metal imido region contains several ligand vibrations. In the case of the dimers (1)–(4), this region is free of absorptions. However we note a strong band near 1380 cm^{-1} in the phenyl imido complexes, which shifts to 1310 cm^{-1} in the methylimido complex (2), and which, although outside the recognised range,[1] may represent this vibration.

NMR spectra. Well-resolved singlets at δ 4.34 and 4.59 ppm (1 : 3 ratio) were observed for bridging and terminal methoxy groups in the hydrogen-1 NMR spectrum of complex (1) indicating little intermolecular exchange at 32 °C. Another isomer (bridging and terminal methoxide singlets at 4.42 and 4.63 ppm respectively,—ratio 1 : 3) was found consistently at 20% of the total after repeated recrystallisations of samples obtained from NH_3, Et_3N or Me_3CNH_2 base reactions. At lower temperatures, peak broadening obscured the minor component resonances so that dynamic processes could not be studied. However since the X-ray cyrstallographic structure of (1) showed bridging methoxide *trans* to the phenylimido moiety, structures (1a) and (1b) are not preferred and a species of higher association may be present.

(1a)

(1b)

Several methoxide resonances were observed for the proposed dimer $[W(NPh)(OMe)_3Cl]_2$ but precipitation occurred before frozen-out spectra could be obtained at lower temperatures. Similarly, a complex set of quartets arose for the methylene quartet of the ethoxy group in $[W(NPh)(OEt)_3Cl]_2$ with little apparent freezing out at low temperatures before solubility problems were encountered.

For the *iso*propoxy complex (5), the CH septet appeared at δ 4.98 ppm, occurring 0.4 and 0.6 ppm downfield from the α-CH proton resonances of the terminal methoxy and *neo*pentoxy groups respectively in (1) and (6). Although not structurally characterised in these complexes we believe the *t*-butylamine nitrogen to lie *trans* to the phenylimido group, as found for the *t*-butoxy complex (7). Molecular models indicate less steric crowding for four equatorial *iso*propoxides in which the α-CH protons are directed above the plane, orientated so that they would experience anisotropy effects associated with the W≡NPh function. While it is apparent that the influence should reduce on increasing the C–O–W bond angle, the CH septet does not shift when the bulky Me_3CNH_2 ligand is replaced by PMe_3. Protons attached to the α-carbon of the *neo*pentoxy ligands are directed away from the influence of anisotropy which is reflected in the higher field shift. The lone doublet observed for the methyl groups of (5) and the methylene singlet of (6) suggest lack of the asymmetry, in accord with the structures proposed.

In the aromatic region, the *ortho* protons appear to be influenced by anisotropy effects generated at the imido linkage, as well as by alkoxide proximity. The aromatic protons in (1) compose a roughly symmetrical sextet, the lower field triplet comprising of 2 protons. For *iso*propoxy complex (5) the *ortho* protons shift further downfield while the *neo*pentoxy complex(6) produces a two proton lower-field triplet and a one proton triplet at higher field. Although the aromatic region shows apparent deceptive simplicity it is interesting to note that with small cross-ring couplings, the latter triplet approximates to the A part of an AB_2 system.

Methoxide resonances in a ratio of 2 : 1 observed

[a]Calculated figures are given in parentheses. [b]Data for $CDCl_3$ solutions. [c]Assignment given in parentheses, s=singlet, d=doublet, m=multiplet, t=triplet, sep=septet, b=broad. [d]Structures proposed as alkoxy bridged dimers. [e]Characterised by X-ray crystallography. [f]183-W sidebands at 4.80 and 4.92 ppm. [g]J = 6 Hz. [h]*b* = bridging alkoxide, *t* = terminal alkoxide. [i]Resonance overlap.

for salicylaldiminato complex (**8**) are tentatively ascribed to two mutually *trans* methoxides and methoxide *trans* to the phenoxy ligand respectively. The upfield shift of 0.72 ppm for the methine proton compared with the free ligand confirmed coordination of the salim.

Carbon-13 spectra of the complexes (Table 6) show deshielding of the alkoxy α-carbon on coordination and little change for the remainder. The methoxy dimer (**1**) exhibits three α-carbon resonances in approximate ratio of 1 : 2 : 1 of which the lower field resonance is tentatively assigned to bridging methoxide and the remaining 2 : 1 resonances to *trans* terminal and *trans* bridging methoxide respectively. Both the *iso*propoxy and *neo*pentoxy complexes show only one α-carbon resonance being consistent with the four meridional alkoxides proposed. The *t*-butoxy complex (**7**) exhibits two α-carbons in an approximate 2 : 1 ratio, the former assigned to two mutually *trans*-*t*-butoxides and the latter to *t*-butoxide *trans* to chloride.

Strong deshielding of the *ipso* aromatic carbons occurs in the complexes similar to nitro benzene[17] where electron withdrawal from the ring is found. Table 7 shows increased *ipso*-carbon deshielding with increase in + I effect of the alkoxy *R* group but steric effects may also be involved. However C-*para* shows increasing shielding with increasing *R* group + I effect, where steric considerations are not important. The inconsistent *t*-butoxy complex probably involves deshielding contributions from chlorine which are manifest in the complex [W(NPh)Cl_4(NCEt)]. Bond order and excitation energy would vary little in the PhNW system of complexes (**5**), (**6**) and (**7**), correlation of electron density with chemical shift may be apparent, making C-*para* sensitive to electron donation from the alkoxy ligands. If oxygen and imido nitrogen share tungsten π-orbitals of similar energy a mechanism for this essentially *cis* effect would exist.

Mass spectra. Parent molecular ions were not observed for any of the complexes and only for the larger alkoxides were low abundant species (0.1–0.5%) observed with the correct isotope pattern. For [W(NPh)$(OCHMe_2)_4(NH_2CMe_3)$] (**5**) the species $W(NPh)(OCHMe_2)_n^+$ were observed for $n = 1$, 3 and 4 but not for $n = 2$. Data for lower mass components showed that considerable synthetic chemistry had occurred in the mass spectrometer with the low abundant molecular ions $WO(OCHMe_2)_n^+$ ($n = 3$, 2), $W(NPh)O(H)_2^+$, $W(NPh)OH^+$, $W(NPh)O^+$ and even $CpWH_2^+$. The *neo*pentoxy complex (**6**) exhibited W(NPh)$(OCH_2CMe_3)_3(OCCMe)^+$ as the only imido species present but mass data for $WO(OCH_2CMe_3)_4^+$ and other species related to this by methyl group loss were identified. Isotope patterns consistent with fragment $W(OCH_2CMe_3)_3(OCH_2CMe_2)^+$, $W(OCH_2CMe_3)_3(OCH_2CMe_2CH_2)^+$ and $W(OCH_2CMe_3)_3(OCHCMe_2)^+$ were also observed.

Several fragments were observed for W(NPh)$(OCMe_3)_3Cl(NH_2CMe_3)$ (**7**) but the profusion of peaks at lower mass number did not allow a reliable determination of metastable peaks. The mass spectrum showed the most abundant species were derived from the loss of $OCMe_3$ groups with the fragments $W(NPh)(OCMe_3)_nCl^+$ ($n = 3$, 2, 1), $W(NPh)(OCMe_3)_n^+$ ($n = 3$, 2) and similar species $W(OCMe_3)_nCl^+$ ($n = 3$, 2), resulting from loss of the imido function.

EXPERIMENTAL

$WOCl_4$ was prepared by reaction of WO_3 with thionyl chloride;[18] $[PhNWCl_4]_n$ by reaction of $WOCl_4$ with phenylisocyanate.[19] Trimethylphosphine was prepared by a literature method.[20] Alcohols were distilled from the magnesium alkoxide under nitrogen prior to use and *neo*pentyl alcohol was used as supplied. *t*-Butylamine was distilled from calcium hydride and stored in a Schlenk flask under N_2. Petroleum ether and toluene were distilled from sodium wire under N_2. All manipulations were carried out under streams of nitrogen using normal air-sensitive techniques. IR spectra were recorded on a Perkin–Elmer 597 spectrometer, ^1H NMR on a Varian T60 Model spectrometer and ^{13}C NMR spectra on a Jeol FX60 spectrometer. Mass spectra were obtained on an AEI MS 902 instrument at Queen Mary College, with direct insertion using probe temperatures ranging from 50–65° at 70 eK and accelerating voltages of 4, 6 or 8 kV. Data were based on ^{182}W and ^{35}Cl. Analytical data were obtained by Professor A.D. Campbell and associates, University of Otago, New Zealand. Melting points were determined in sealed tubes under nitrogen on an electrothermal melting point apparatus and are uncorrected.

Di-μ-methoxyhexakismethoxybis(phenylimido) ditungsten(VI) (**1**). *t*-Butylamine (2.53 cm^3, 24 mmol) was added to a well stirred suspension of finely ground phenylimido tungsten tetrachloride (2.0 g, 4.8 mmol) in petroleum ether (150 cm^3). Methanol (1.0 cm^3, 25 mmol) in petroleum ether (50 cm^3) was immediately added and the mixture stirred for 6 hours. The yellow solution was filtered, the precipitate washed with petroleum ether (50 cm^3) and the combined filtrates reduced to *ca.* 30 cm^3 *in vacuo*. On cooling in dry ice–acetone the complex separated as yellow microcrystals which were filtered off and washed with cold (*ca.* −40 °C)

[a]Benzene 128.5 ppm, relative to TMS. Positive values indicate deshielding, negative values indicate shielding.

[b]Values taken from ref.8. [c]Values taken from ref. 17. *para*-Carbon assigned from relative peak height, *ortho*- and *meta*-carbons tentative assignment.

petroleum ether (20 cm^3). Reduction in volume of the mother liquors and cooling to −78 °C gave a further crop of crystalline material. Yield: 1.2 g (63%).

IR (Nujol) bands at 1578 w (aromatic C=C), 1380s, 1170m, 1152m, 1100s, 1060s and 1010 (ν(C–O)), 868s, 860s and 790 (monosubstituted benzene), 570w, 525s (ν(M–O) terminal), 502s (ν(M–O) bridge), 390w, 328w, 289w cm^{-1}.

Dichloro-di-μ-methoxytetramethoxybis(phenylimido)ditungsten(VI) (**3**). Methanol (0.47 cm^3, 11.5 mmol) and *t*-butylamine (1.52 cm^3, 14.4 mmol) in petroleum ether (50 cm^3) were added to phenylimido tungsten tetrachloride (1.2 g, 2.9 mmol) suspended in petroleum ether (80 cm^3) and the mixture stirred for 6 hours and filtered. The residue was extracted with toluene (2 × 50 cm^3), the solution filtered and the combined extracts reduced in volume to *ca.* 15 cm^3. On standing at −20 °C the solution deposited the complex as a microcrystalline solid. Yield: 0.58 g (51%), similar IR spectrum to (**1**).

Dichloro-di-μ-ethoxytetraethoxybis(phenylimido)ditungsten(VI) (**4**). Ethanol (0.67 cm^3, 11.5 mmol) and *t*-butylamine (1.1 cm^3, 14.7 mmol) in petroleum ether (50 cm^3) were added to phenylimido tungsten tetrachloride (1.2 g, 2.9 mmol) suspended in petroleum ether (60 cm^3) and the mixture stirred for 4 hr. The solvent was filtered off and discarded. The yellow residue was extracted with warm toluene (2 × 30 cm^3) and the combined extracts filtered. Reduction of the volume to *ca.* 10 cm^3 and standing the solution at −20 °C gave the complex as yellow crystals. Yield: 0.82 g (64%).

IR (Nujol) bands at 1580w (C=C, aromatic), 1430s, 1355s, 1272m and 1090s (ν(C–O) terminal), 1030s (ν(C–O) bridge), 920s (ν(C–O) terminal), 882s (ν(C–O) bridge), 805w, 760s and 688s (monosubstituted benzene), 640s, 600m, 555s, 528s, (ν(W–O) terminal), 480s, (ν(W–O) bridge), 382m, 326m, 320m, 284m cm^{-1} (ν(W–Cl) terminal).

*t-Butylaminotetra*isopropoxy*(phenylimido)tungsten*(VI) (**5**). *t*-Butylamine (1.26 cm^3, 12 mmol) was added to phenylimido tungsten tetrachloride (1.0 g, 2.4 mmol) suspended in petroleum ether (100 cm^3). *iso*Propanol (0.75 cm^3, 9.9 mmol) in petroleum ether (50 cm^3) was added immediately and the mixture stirred for 6 hr. The yellow solution was filtered and the solvent volume reduced to *ca.* 5 cm^3 whereupon the complex precipitated as yellow crystals. Cooling the solution to −76 °C gave further crystalline material which was filtered, washed with cold petroleum ether (10 cm^3 at *ca.* −76 °C) and dried *in vacuo*. Yield: 1.0 g (71%).

IR (Nujol) bands at 1600m and 1580s (NH), 1480s, 1355s, 1320s, 1272s, 1215m, 1160s and 1105s, (ν(C–O) terminal), 1025m, 1005m, 974s, (ν(C–O) terminal), 922m, 910m, 840s, 785m, 758s and 688s (mono substituted benzene), 580s (ν(W–O) terminal), 535s, 450s, 420m, 320m, 290m cm^{-1}. *m/e* 509.1 $[W(NPh)(OCHMe_2)_4^+]$, 450.2 $[W(NPh)(OCHMe_2)_3^+]$, 375.0 $[WO(OCHMe_2)_3^+]$, 332.8 $[W(NPh)(OCHMe_2)^+]$, 291 $[W(NPh)(O)H_2]$, 290 [W(NPh)(O)H], 289.8 [W(NPh)(O)], 248.9 $[WCpH_2]$.

*t-Butylaminotetra*neopentoxy*(phenylimido)tungsten*(VI) (**6**). *neo*Pentanol (1.0 g, 11.5 mmol), phenylimido tungsten tetrachloride (1.2 g, 2.9 mmol) and *t*-butylamine were reacted together and the product isolated as for complex (**5**). Yield: 1.25 g (63%).

IR (Nujol) bands at 1600m (NH), 1470s, 1358s, 1272m, 1288m, 1258m, 1056s and 1018s (ν(C–O) terminal), 933m, 840m, 785m, 755m, and 682 (mono substituted benzene), 645s (ν(W–O)), 450m, 400w, 342w cm^{-1}. *m/e* 588.9 $[W(NPh)(OCH_2CMe_3)_3(OC_2{=}CMe)^+]$, 528.6 $W[OCH_2CMe_3)_3(OCH_2CMe_2CH_2)^+]$, 515.5 $[W(OCH_2CMe_3)_3(OCH_2CMe_2)^+]$, 514.6 $[W(OCH_2CMe_3)_3(OCHCMe_2)^+]$.

tris(t-butoxy)t-butylaminochloro(phenylimido)tungsten(VI). (**7**). *t*-Butanol (1.45 cm^3, 15.5 mmol) in petroleum ether (30 cm^3) was added to phenylimido tungsten tetrachloride (1.3 g, 31.0 mmol) in petroleum ether (60 cm^3) containing *t*-butylamine (1.64 cm^3 15.5 mmol) as for (**5**). After stirring for 4 hr the solution was filtered, the solvent removed, and the residue held *in vacuo* to remove excess *t*-butanol. The remaining solid was dissolved in petroleum ether (30 cm^3), the solution concentrated to *ca.* 10 cm^3 and left to stand at −20°C giving the complex as large yellow crystals. Yield: 1.32 g (70%).

IR (Nujol) bands at 1600w (C=C, aromatic), 1580, 1564w (NH), 1480s, 1358s, 1260w, 1225m, 1164s, 1130w, 1120w, 1024m, 955s, (ν(C–O) terminal), 780s, 758s and 590m (mono substituted benzene), 575m, 550m and 538m (ν(W–O)), 464m, 380w, 370w, 350w, 280w $(\nu(W\text{–}Cl)^{cm^{-1}}$.

Tetra-t-butoxy(phenylimido)tungsten(VI). The complex was prepared by adding $LiOCMe_3$ (1 g, 12 mmol) in diethyl ether (20 cm^3) to $[W(NPh)Cl_4]_n$ (1.3 g, 3 mmol) dissolved in diethyl ether (30 cm^3) and stirring the solution for 12 hr. After filtering, the solvent was removed and the residue recrystallised from petroleum ether. The properties of the complex were recently described.[12]

Tetrachloro(methylimido)tungsten(VI). Tungsten oxytetrachloride (5.5 g, 16.1 mmol) and methylisocyanate (0.95 cm^3, 16.1 mmol) were refluxed in benzene (75 cm^3) for 12 hr. The solution was

filtered while hot and the volume reduced to *ca.* 30 cm^3 whereupon orange crystals of the product were deposited. Yield: 2.3 g (40%). Reduction of the solvent volume gave further product which was contaminated with $WOCl_4$. (Found: C, 3.9; H, 1.0; N, 3.6. CH_3Cl_4NW requires C, 3.4; H, 0.9; N, 3.9%.) The complex (0.1 g) was dissolved in propionitrile and the solvent removed to give a yellow solid soluble in chloroform. ^1H NMR $\delta(CDCl_3)$ 2.44 (t, 3H, Me), 2.65 (q, 3H, CH_2), 6.83 (s, 3H, NMe), ^{183}W sidebands at 6.74 and 6.92 ppm.

Di-μ-methoxyhexakismethoxybis(methylimido) ditungsten(VI) (**2**). Methanol (4.1 cm^3, 10.2 mmol) in petroleum ether (50 cm^3) was reacted with a mixture of methylimido tungsten tetrachloride (0.9 g, 2.56 mmol) and *t*-butylamine (1.34 cm^3, 12.7 mmol) as for the preparation of $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$ (**1**). The resulting colourless solution was filtered and the solvent removed to give a white solid shown to be the pure complex by ^1H NMR. Yield: 0.48 g (57%). Recrystallisation from petroleum ether/CCl_4 (1 : 1) gave the complex as large colourless prisms.

IR (Nujol) bands at 1458s, 1304s, 1280m, 1158s, 1100s and 1070s and 1020s (ν(C–O)), 800m, 720w, 575s, 510s (ν(W–O)), 420m, 330m, 295m cm^{-1}.

N(Phenyl-3,4-dimethyl)salicyldiminato(phenylimido)trismethoxytungsten(VI) (**8**). To a solution of di-μ-methoxyhexakismethoxybis(phenylimido)-ditungsten(VI) (1.2 g, 3.0 mmol) in benzene 30 cm^3) was added N(phenyl-3,4-dimethyl)-salicylaldimine (0.68 g, 3.0 mmole) in benzene (20 cm^3) and the solution stirred for 3 hr. The solvent was removed *in vacuo* and the resulting oil washed with petroleum ether (50 cm^3) followed by diethyl ether (2 × 50 cm^3 portions) to give the complex as a yellow solid. Yield: 1.77 g (99%).

IR (Nujol) band at 1595s, 1536m, 1455s, 1358m, 1332m, 1300s, 1192m, 1143s, and 1050s (ν(C–O) terminal), 990w, 948w, 918w, 885w, 840m, 760s, 750s, 685m, 668m, 560s and 530s and 500s (ν(W–O)), 420w, 400m, 318m, 280w cm^{-1}.

Tetra-iso-*propoxy(phenylimido)trimethylphosphinetungsten*(VI) (**9**). Trimethylphosphine (0.15 cm^3, 1.36 mmol) was added to *t*-butylamino-tetra-*iso*-propoxyphenylimidotungsten(VI) (**5**) (0.5 g, 0.85 mmol) dissolved in petroleum ether (30 cm^3) and the mixture stirred for 3 hr. The solution was filtered and the solvent removed to give a yellow-brown gum which failed to solidify on standing or by attempted crystallisation from petroleum ether or CCl_4. Yield: 0.5 g (100%).

IR (Nujol) bands at 1600m (C=C, aromatic), 1580m (PMe_3), 1480s, 1360s, 1320s, 1275s, 1215m, 1160s, and 1120s (ν(C–O) terminal), 1064m, 1022m, 970s,b (PMe_3 and (C–O) terminal), 900m, 840s, 790s, 760s and 590s (monosubstituted benzene), 600s (ν(W–O)), 525m, 450m, 423m, 380w, 300w cm^{-1}. ^1H NMR $\delta(CDCl_3)$ 1.2 (*d*(J = 6 Hz), 24H, Me), 1.24 (*d*(J = 3 Hz), 9H, PMe_3), 4.87 (septet 4H, methylenes), 6.84 (m, 5H, aromatic Hs).

X-ray data collection and structure solution Crystals of both $[W(NPh)(\mu\text{-}OMe)(OMe_3)]_2$ and $W(NPh)(OCMe_3)_3Cl(NH_2CMe_3)$ were sealed under nitrogen in capillaries and mounted on an Enraf–Nonius CAD4 diffractometer. For each crystal cell constants were determined from a least-squares refinement of the setting angles of 23 reflections.

Crystal data for $[W(NPh)(\mu\text{-}OMe)(OMe)_3]_2$: $C_{20}H_{34}N_2O_8W_2$, M = 399.1 triclinic, space group $P\bar{1}$, $a = 8.473(7)$ $b = 10.776(5)$, $c = 7.683(3)$ Å, $\alpha = 102.26(3)$, $\beta = 102.68(4)$, $\gamma = 71.13(6)°$, $U = 640(1)$ Å^3, $z = 1$, d(calc.) = 2.071 g cm^{-3}, $\mu(MoK_\alpha)$ = 86.4 cm^{-1}. A total of 1752 independent data was collected ($\theta_{max} = 21°$) with MoK_α radiation using the $\omega/2\theta$ scan mode.

A variable ω scan width of $(0.9 + 0.347 \tan\theta)°$ was calculated for each reflection as well as a variable horizontal aperture width of $(1.9 + 1.2 \tan\theta)$ mm. A maximum scan time of 80 sec was set for each reflection where $\theta < 17°$ but this was raised to 90 sec for reflections with $\theta > 17°$ but $< 21°$. A marked drop in intensity of the 3 standards monitored was noted during data collection (final intensities had fallen to 80% of their starting values) and the data were scaled to take account of this (even during the crystal alignment process the peaks were broad and some showed signs of splitting). An empirical absorption correction[21] was applied with maximum and minimum transmission factors of 0.999 and 0.439 respectively being determined. The structure was solved by Patterson and Fourier methods and refined by a full-matrix least squares method. The final cycle converged to an R of 0.075 for the 84 variables and 1022 data for which $F^2 > 3\sigma(F^2)$. In the refinement the atoms of the phenyl ring were treated as a rigid group (C–C, 1.395; C–H, 1.08 Å). Anisotropic thermal motion was assumed for the W, N and O atoms; for all other atoms isotropic thermal motion was assumed. The atomic scattering factors were taken from the tabulations of Cromer and Waber,[22] anomalous dispersion corrections were by Cromer.[23] The function minimized during refinement was $\Sigma w(|F_o| - |F_c|)^2$; unit weights were used.

Crystal data for $W(NPh)(OCMe_3)_3Cl(NH_2CMe_3)$: $C_{22}H_{52}N_2O_4W_1Cl_1$, M = 628.0, monoclinic, space group $P2_1/c$, $a = 9.341(2)$, $b = 29.608(7)$, $c = 10.257(2)$ Å, $\beta = 106.28(2)$, $U = 2723(2)$ Å^3, $z = 4$, d(calc.) = 1.532 g cm^{-3}, μ =

($Cu\text{-}K_\alpha$) = 91.7 cm^{-1}. A total of 3145 independent data was collected (θ_{max} = 58°) with CuK_α radiation using the $\omega/2\theta$ scan mode. A variable ω scan width of (0.8 + 0.142 tanθ) was calculated for each reflection as well as a variable horizontal aperture width of (2.0 + 1.1 tanθ) mm. A maximum scan time of 99 sec was set for each reflection where $\theta < 30°$ but this was raised to 120 sec for the remainder of the data. A significant drop in intensity of the 3 standards monitored (final intensities fell to ~90% of their starting values) and the data were scaled to take account of this. An empirical absorption correction was applied[21] with maximum and minimum transmission factors of 0.999 and 0.527 respectively. The structure was solved by Patterson and electron density methods and the final least squares cycle converged to values of R and R_w of 0.074 and 0.077 respectively for the 290 variables and 2023 data for which $F^2 > 3\sigma(F^2)$. For this compound, only the W and Cl atoms were refined anisotropically. The atomic scattering factors were taken from the tabulations of Cromer and Waber,[22] anomalous dispersion corrections were by Cromer.[23] In the refinement, the atoms of the phenyl ring were treated as a rigid group (C–C, 1.395; C–H, 1.08 Å). The function minimised was $\Sigma w(|F_o| - |F_c|)^2$; a weight of $1.066/(\sigma^2(F) + 0.008269F^2)$ was calculated for each reflection. The nitrogen atom of the Me_3CNH_2 group was identified on the basis of its different geometry in comparison with the oxygen atoms of the three $OCMe_3$ groups. Hydrogen sites, however, could not be unequivocally assigned to peaks on a final difference map. Initially no distinction was made between N and O atoms and the values of the thermal parameters determined were in support of the assignment made. The positions of the methyl hydrogen atoms were idealized at a C–H distance of 1.08 Å. Final atomic coordinates with isotropic thermal parameters for both compounds tables of anisotropic thermal parameters, tables of calculated hydrogen sites and lists of $F_o|F_c$ have been deposited with the Editor as supplementary material.†

Acknowldegements—We thank S.E.R.C. for initial support for this research (A. J. N. and D. C. B.).

†Atomic co-ordinates for these structures have also been deposited with the Cambridge Crystallographic Data Centre for inclusion in their Data Base. Copies are also available on request from the Editor at Queen Mary College.

MIXED LIGAND Cu(II) AMINO ACID COMPLEXES CONTAINING 2,2′-BIPYRIDYL. CYCLIC VOLTAMMETRIC STUDIES OF THE REDUCTION IN AQUEOUS MEDIA

GEORGE THOMAS and P. S. ZACHARIAS*
School of Chemistry, University of Hyderabad, Hyderabad 500134, India

(*Received* 8 *February* 1984; *accepted* 17 *April* 1984)

Abstract—The reduction of the title ternary complexes was studied by cyclic voltammetry in aqueous media. Reversible one-electron reduction was involved generating an intermediate Cu(I) species which subsequently dissociated to Cu^0 at the mercury electrode. The intermediate ternary Cu(I) amino acid complexes were found to be less unstable than the corresponding Cu(I) binary complexes. The pH-dependence of these ternary complexes was also studied.

Ternary complexes of Cu(II) containing a bidentate aromatic nitrogen base such as 2,2′-bipyridyl (BPY) and a bidentate oxygen donor ligand, have been shown to possess unusual stabilization.[1] When the bidentate oxygen donor ligand is replaced by a ligand such as glycine containing O and N donor atoms, the stability of the resultant ternary complexes is reduced but it is still higher than that for CuN_4 chromophore.[2] Ternary complexes containing an amino acid as a second ligand are of considerable significance as they are potential models for enzyme-metal ion-substrate complexes and have close similarity to biologically important Cu(II) mixed amino acid complexes, containing L-histidine and L-threonine.[3] Ternary complexes of the type Cu(BPY)(AA), where AA is the amino acid, are studied extensively by different workers.[4] But its redox behaviour has not yet been studied in detail except for a brief polarographic study of its reduction.[5] This report deals with the result of an extensive study of the reduction of Cu(II)(BPY)(AA)† complexes using cyclic voltammetry.

EXPERIMENTAL

The complexes discussed here, were prepared using a reported method[5] and purified by using prep. tlc on silica gel with *n*-butanol–water–methanol (20 + 40 + 40) solvent system. Cyclic voltammograms were recorded using a PAR model 370 electrochemistry system which includes the 174A polarographic analyzer, 175 universal programmer, RE 0074 X–Y recorder, and a 377 A cell system. The electrochemical measurements were done using hanging mercury drop electrode (HMDE), a platinum-wire auxiliary electrode, and a saturated calomel electrode (SCE).

RESULTS AND DISCUSSION

Cyclic voltammograms (CV) were recorded from aqueous solutions of the samples at mercury electrode in the range +0.1 to −0.6 V vs SCE. Cyclic voltammetric behaviour of the Cu(II) complexes are similar and a representative voltammogram is shown in Fig. 1(a). The relevant CV data for all complexes are given in Table 1. Each complex displays one reduction peak C at ~ -0.23 V and on reverse scan an anodic peak D appears at ~ -0.15 V. At slow scan rates ($\nu < 0.01\ Vs^{-1}$) an additional anodic peak B appears at $\sim +0.02$ V and in such cases, a new cathodic peak A, at ~ -0.03 V appears from second and subsequent scans. This behaviour is shown in Fig. 1(b), and is very similar to that of binary Cu(II) complexes of amino acids.[6] In these binary complexes peaks C and D are established as due to a one-electron redox process of the $Cu(II)(AA)_2$ complex. In an analogous manner

†AA = Gly, Ala, Ile, Val and Ser

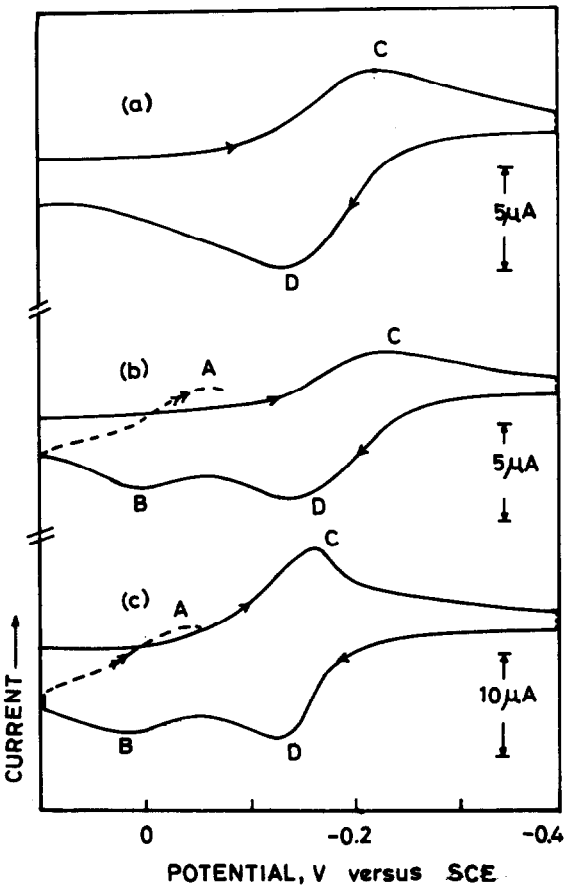

Fig. 1. Cyclic voltammograms recorded at HMDE, at 25°C. (a) Cu(BPY)(Ala) at 20 mV/s; (b) Cu(BPY)(Ala) at 10 mV/s; (c) $Cu(BPY)_2$ at 20 mV/s.

peak C of the ternary bipyridyl complexes results from a one-electron reduction and peak D from the re-oxidation of the reduced species. This can be represented by eqn (1).

$$Cu(II)(BPY)(AA) \overset{1e}{\rightleftharpoons} [Cu(I)(BPY)(AA)]. \quad (1)$$

The electrogenerated Cu(I) amino acid complexes are unstable in aqueous media and can dissociate or disproportionate to give Cu(O) at the electrode.[6-8] The peaks B and A at slow scan rates result from the redox process represented in eqn (2).

$$Cu^0(Hg) \overset{2e}{\rightleftharpoons} Cu^{2+}(aq). \quad (2)$$

In Cu(II)(BPY)(AA) complexes, peaks B and A develop only at slow scan rates ($\sim 0.01\ Vs^{-1}$), whereas in binary Cu(II) amino acid complexes these peaks are observable even at scan rates as high as $0.1\ Vs^{-1}$. This suggests that the intermediate Cu(I)(BPY)(AA) has a longer life-time than the corresponding Cu(I) binary amino acid complexes.

The binary Cu(II) bipyridyl complex, $Cu(BPY)_2$ gives a CV profile similar to that of binary Cu(II) amino acid complexes,[6] $Cu(AA)_2$, and is shown in Fig. 1(c). It also displays peaks corresponding to the C–D and A–B couples. From a comparison of this behaviour with that of binary Cu(II) amino acid and dipeptide[8] complexes, the peaks C and D are attributed to a one-electron redox process similar to that in eqn (1) and the peaks A and B to the process similar to that in eqn (2). This CV profile (appearance of peaks A and B at normal scan rates) indicates that the $Cu(I)(BPY)_2$ intermediate has a shorter life-time than that of Cu(I)(BPY)(AA) complexes mentioned earlier. The ternary bipyridyl Cu(II) complexes, Cu(II)(BPY)(L), where L has both O and N donor atoms (CuN_3O chromophore) is known to be more stable than the binary bipyridyl [$Cu(II)(BPY)_2$] complexes.[1,2] The observed stability of the intermediate Cu(I) species [Cu(I)(BPY)(AA)] over the Cu(I) bipyridyl species [Cu(I)(BPY)] can also be of similar origin.

Table 1. Cyclic voltammetric data on the reduction of Cu(II)(BPY)(AA) complexes[a]

Complex	E_p,C	E_p,D	ΔE_p,C-D	$E^{o'}$,C-D
(1) Cu(BPY)(Gly)	-0.220	-0.145	0.075	-0.183
(2) Cu(BPY)(Ala)	-0.215	-0.135	0.080	-0.175
(3) Cu(BPY)(Ile)	-0.240	-0.150	0.090	-0.195
(4) Cu(BPY)(Val)	-0.255	-0.160	0.095	-0.208
(5) Cu(BPY)(Ser)	-0.225	-0.135	0.090	-0.180

[a]All results were obtained in aqueous solution (0.6–0.8 mol dm^{-3}) of the complexes at pH about 7.5. Scan rate: $0.02\ Vs^{-1}$. Potentials are expressed in volts verses SCE.

Protonation. It is known that the structure of Cu(II) amino acid complexes is dependent on the pH conditions and the metal-to-ligand ratio. Hence the pH-dependence of the CV pattern of these ternary complexes were studied in the acid-pH range (the pH was decreased gradually by the stepwise addition of $HClO_4$). All ternary complexes show a similar behaviour on protonation. As the pH decreases the peaks C and D decrease in height and finally disappear. At the same time a new set of cathodic (C′) and anodic peaks (D′) appear at ~ -0.11 and ~ -0.05 V respectively and finally at low pH values (~ 3.2) they become the only set of peaks (Fig. 2). This new pair of peaks corresponds to a one-electron reversible redox process ($\Delta E_p \simeq 60$ mV; $i_pa/i_pc \simeq 1$). The decrease in height and the final disappearance of peaks C and D are due to the continuous depletion of the starting complex, Cu(BPY)(AA) due to protonation.

In the case of the protonation of binary[6] $[Cu(AA)_2]$ and ternary[7] [Cu(II)(A)(B)] Cu(II) amino acid complexes they completely dissociate to free Cu(II) ions at pH about 3.2. This was demonstrated by the appearance of the characteristic redox peaks of free Cu(II) ions (shown in Fig. 2 for comparison). But, for the bipyridyl ternary systems the peaks C′ and D′ do not correspond to free Cu(II) ions. The binary Cu(II) bipyridyl complex, $Cu(II)(BPY)_2$, also show a behaviour similar to that of ternary Cu(II)(BPY)(AA) complexes on protonation (Fig. 2). These observations show that the end product of the protonation of the ternary [Cu(II)(BPY)(AA)] and binary $[Cu(II)(BPY)_2]$ bipyridyl Cu(II) complexes is the same. The monobipyridyl Cu(II) complex,[4] $Cu(BPY)(H_2O)_2$, which is stable even at very low pH values can be a definite possibility as the end product of the protonation of the above complexes.

(*Received* 29 *November* 1983; *accepted* 17 *April* 1984)

Abstract—Solutions of $Fe_2(NO)_4I_2$ in DMF exhibit EPR spectra characteristic of $[Fe(NO)_2]^+$ at concentrations of 2×10^{-4} mol dm^{-3}, and of an equilibrium mixture of $[Fe(NO)_2]^+$, $Fe(NO)_2I$, and $[Fe(NO)_2I_2]^-$ at higher concentrations: in THF solutions only $Fe(NO)_2I$ is observed, regardless of concentration. Addition of excess halide ions X^- (X=Cl, Br, I) to the DMF solution yields $[Fe(NO)_2X_2]^-$, but addition of excess I^- or Br^- to the THF solution yields $[Fe(NO)_2I_2]^-$ or $Fe_2(NO)_4Br_2$ respectively. In mixed THF/Et_3N solutions, mixtures of $[Fe(NO)_2]^+$, $Fe(NO)_2I$, and $[Fe(NO)_2I_2]^-$ are again formed, and subsequent addition of a thiol RSH causes formation of $[Fe(NO)_2(SR)_2]^-$, a precursor of $Fe_2(NO)_4(SR)_2$. A scheme is suggested to describe the steps in the preparatively useful conversion of $Fe_2(NO)_4I_2$ into $Fe_2(NO)_4(SR)_2$.

The μ_2-diiodo complex $Fe_2(NO)_4I_2$ reacts[1] with thiols in the presence of a base, in THF solution, to yield the Roussin esters $Fe_2(NO)_4(SR)_2$, in a preparatively useful procedure (eqn 1),

$$Fe_2(NO)_4I_2 + 2RSH + 2B \xrightarrow{THF} Fe_2(NO)_4I_2 + 2BH^+I^-. \quad (1)$$

It has been reported[2] that according to conductance measurements in dilute solutions (5×10^{-5} to 10^{-3} mol dm^{-3}) of $Fe_2(NO)_4I_2$ in DMF, complete dissociation occurs (eqn 2),

$$Fe_2(NO)_4I_2 \rightarrow 2[Fe(NO)_2]^+ + 2I^-. \quad (2)$$

It was suggested from Λ_i values, that the $Fe(NO)_2^+$ ion is essentially unsolvated in DMF. We have observed[3] in DMF solution the formation of mononuclear iron species such as $[Fe(NO)_2(SR)_2]^-$ $Fe(NO)_2(SR)(DMF)$ and $[Fe(NO)_2(DMF)_2]^+$, characterized by EPR spectroscopy, and we report here the results of an EPR study of the dissociation of $Fe_2(NO)_4I_2$ and of its reactions with halide ions and with thiols.

Because the conversion of $Fe_2(NO)_4I_2$ to $Fe_2(NO)_4(SR)_2$ is, for experimental convenience, carried out in THF, while the conductance measurements were performed[2] in DMF solutions, we have studied the EPR spectra of $Fe_2(NO)_4I_2$ in both these solvents.

RESULTS AND DISCUSSION

A dilute solution of $Fe_2(NO)_4I_2$ in DMF (2×10^{-4} mol dm^{-3}) shows a five-line EPR spectrum assignable to $Fe(^{14}NO)_2^+$ (see Table 1). No coupling assignable either to ^{127}I or to the hydrogens of coordinated solvent molecules was observed. This observation is consistent both with the complete ionisation of $Fe_2(NO)_4I_2$, according to eqn (1), as found[2] by conductance at this concentration, and also with the unsolvated nature of the cation, deduced[2] from the application, to the molar conductivities of the ions, of Walden's rule in the form $\Lambda_i \times r_i$ = constant for a medium of fixed viscosity. The failure to observe hyperfine coupling other than to ^{14}N in this cation is surprising since reaction of $Fe_2(NO)_4(SMe)_2$ with DMF yields[3] the complexes $[Fe(NO)_2(SMe)(DMF)]$ and $[Fe(NO)_2(DMF)_2]^+$, in both of which coupling to the unique hydrogen of coordinated DMF is clearly resolved. The question of the solvation of $[Fe(NO)_2]^+$ and of the other mononuclear iron complexes described in this work, is perhaps best left open.

More concentrated solutions in the same solvent (10^{-1} mol dm^{-3}) exhibit more complex spectra com-

†X = $^{35,37}Cl(I = 3/2)$; $^{79,81}Br(I = 3/2)$; $^{127}I(I = 5/2)$: hyperfine couplings due to individual isotopes of chlorine or bromine were not resolved.
‡Not resolved.
§Data in H_2O from Ref. 4.

prising, in addition to the five line spectrum of $[Fe(NO)_2]^+$, a six-line spectrum assignable to $Fe(NO)_2I$ and an eleven-line spectrum assignable to $[Fe(NO)_2I_2]^-$. The assignments follow straightforwardly from the multiplicites ($I(^{127}I) = 5/2$) and from the previous observation[4,5] of these and similar species in aqueous or ethanolic solutions, where they were generated by the action of NO gas on mixtures of Fe(II) and halide ions: in addition, the ion $Fe(NO)_2I_2^-$ has been isolated[6] in analytically pure form as its $(Ph_3P)_2N^+$ salt. The large line-widths of $Fe(NO)_2I$ and $Fe(NO)_2I_2^-$ in DMF solution prevented resolution of the coupling to ^{14}N. This was, in general, not resolved[4,5] in either aqueous or ethanolic solutions.

These observations are consistent with the occurrence of the following independent equilibria (eqn 3), characterised by the equilibrium constants K_1 – K_3:

$$2[Fe(NO)_2]^+ + 2I^- \overset{K_1}{\rightleftharpoons} 2Fe(NO)_2I \overset{K_2}{\rightleftharpoons} Fe_2(NO)_4I_2 \overset{K_3}{\rightleftharpoons} [Fe(NO)_2]^+ + [Fe(NO)_2I_2]^- \quad (3)$$

Measurements of the absolute concentrations of the paramagnetic ions by EPR spectroscopy yielded values for these constants at 240 K, in DMF:

$\log_{10}K_1$, 2.58 ± 0.09; $\log_{10}K_2$, 2.71 ± 0.36; $\log_{10}K_3$, − 2.78 ± 0.57.

For the dependent equilibria (eqns 4–6),

$$Fe(NO)_2^+ + 2I^- \overset{K_4}{\rightleftharpoons} [Fe(NO)_2I_2]^- \quad (4)$$

$$Fe_2(NO)_4I_2 \overset{K_5}{\rightleftharpoons} 2[Fe(NO)_2]^+ + 2I^- \quad (5)$$

$$2Fe(NO)_2I \overset{K_6}{\rightleftharpoons} [Fe(NO)_2]^+ + [Fe(NO)_2I_2]^- \quad (6)$$

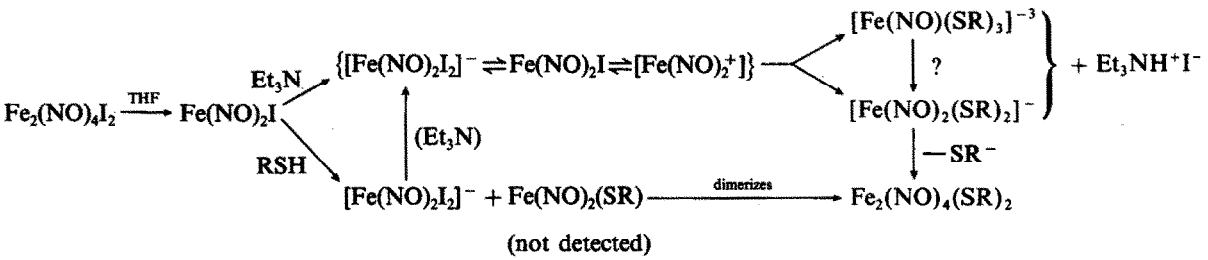
the values (240 K) are: $\log_{10}K_4$, 5.10 ± 0.38; $\log_{10}K_5$, − 7.88 ± 0.30; $\log_{10}K_6$, − 0.07 ± 0.22; where $K_4 = K_1^2K_2K_3$, $K_5 = (K_1^2K_2)^{-1}$, and $K_6 = K_2K_3$.

The precision of the values is necessarily low, as not all the independent species are observable by EPR spectroscopy. The concentration of I^- was determined from the charge balance, after measurement of the concentrations of $[Fe(NO)_2]^+$ and $[Fe(NO)_2I_2]^-$: the concentration of undissociated $Fe_2(NO)_4I_2$ was determined from the mass balance after measurement of the concentration of all the mono-iron complexes, and deduction of the I^- concentration.

Addition of excess of potassium iodide to a DMF solution of $Fe_2(NO)_4I_2$ (10^{-2} mol dm^{-3}) gave, as expected, $[Fe(NO)_2I_2]^-$ as the sole paramagnetic species detected. Similarly, addition of excess of KBr or KCl to such a solution yielded $[Fe(NO)_2Br_2]^-$ and $[Fe(NO)_2Cl_2]^-$ respectively. The only other paramagnetic species detected was $Fe(NO)_2Br$: $Fe(NO)_2Cl$ was not observed under these conditions. The chloro- and bromo-complexes were identified by comparison of their EPR spectra with those recorded[4,5] earlier in ethanol/water mixtures. Their ready formation is further evidence of the lability of halide ions in these species, (see eqn 3). In $Fe(NO)_2Br$ alone we were able to resolve the ^{14}N hyperfine coupling (see Table 1).

In contrast to the behaviour of $Fe_2(NO)_4I_2$ in DMF, solutions in THF over a similar range of concentration (10^{-1}–10^{-4} mol dm^{-3}) showed only a single paramagnetic species, $Fe(NO)_2I$. Neither $[Fe(NO)_2]^+$ nor $[Fe(NO)_2I_2]^-$ was detected at any concentration, while no paramagnetic species at all were detected in chloroform solution. Upon addition of an excess of iodide ions to the THF solutions, the spectrum of $Fe(NO)_2I$ was replaced by that of $[Fe(NO)_2I_2]^-$ but upon addition of an excess of bromide ions, the EPR spectrum disappeared. We conclude that, in THF, halide exchange to yield $Fe(NO)_2Br$ is followed by complete dimerisation to yield the diamagnetic $Fe_2(NO)_4Br_2$. In support of this interpretation, it was found that a solution of preformed $Fe_2(NO)_4Br_2$ in THF gave no detectable EPR spectrum.

The position of the equilibrium (eqn 7)



$$Fe_2(NO)_4X_2 \rightleftharpoons 2Fe(NO)_2X \qquad (7)$$

depends upon both the solvent, and the nature of X. That it lies further to the right, in any given solvent, when X = I than when X = Br or SR is consistent with the magnitude of the Fe–Fe interaction in these species. In $Fe_2(NO)_4I_2$, the Fe–Fe distance is[7] 3.05 Å, while in $Fe_2(NO)_4(SEt)_2$ it is[8] only 2.72 Å. The bond angles in the Fe_2X_2 rings in these two compounds are virtually identical, and using these angles, and a reasonable estimate, 2.38 Å, of the Fe–Br bridging distance, an estimate of *ca.* 2.8 Å is obtained for the Fe–Fe distance in $Fe_2(NO)_4Br_2$. The diamagnetism of these systems suggests that the Fe–Fe interaction is bonding, and hence it is deduced that this interaction contributes least to the stability of the dimer when X = I and most when X = SR.

Although only $Fe(NO)_2I$ was formed in solutions of $Fe_2(NO)_4I_2$ in THF, addition of triethylamine to such a solution yielded a mixture of $[Fe(NO)_2]^+$ $Fe(NO)_2I$, and $[Fe(NO)_2I_2]^-$: using pure triethylamine as the solvent, the only paramagnetic species detected was the solvo-cation $[Fe(NO)_2(NEt_3)_2]^+$, in which hyperfine coupling to the ^{14}N of two coordinated solvent molecules was detected, with $A(^{14}NEt_3)$ of 4.8 G.

Upon addition of a thiol (chosen throughout as *i*-PrSH, for convenience in spectral assignment, since this thiol has only a single α-hydrogen) to a solution of $Fe_2(NO)_4I_2$ in THF/Et_3N, the spectrum characteristic of $[Fe(NO)_2]^+$, $Fe(NO)_2I$, and $[Fe(NO)_2I_2]^-$ was replaced by a spectrum characteristic of two paramagnetic species (**1**) [$g = 2.029$; $A(2^{14}N) = 2.6$G; $A(2^1H) = 1.3$G] and (**2**) [$g = 2.040$; $A(1^{14}N) = 13.5$G]. Species (**1**) was readily identified[3] as the anion $[Fe(NO)_2(SPr^i)_2]^-$, and we have shown previously[3] that anions of the general type $[Fe(NO)_2(SR)_2]^-$ can readily lose RS^- to yield $Fe_2(NO)_4(SR)_2$. The identification of species (**2**) poses more of a problem: it is a mono-nitrosyl species, but no coupling to hydrogen is resolvable. Another mono-nitrosyl species having a similar large A value is formed from $Fe_4S_4(NO)_4$ and SH^-, but this latter, upon oxidation by air is replaced by a species having $A(^{14}N)$ of 5.0 G, typical of $[Fe(NO)(SR)_3]^-$ species.[9] Hence we tentatively identify the 13 G species as a reduced anion $[Fe(NO)(SR)_3]^{-x}$ ($x > 1$): if $[Fe(NO)(SR)_3]^{-x}$ is formed from $Fe_2(NO)_4I_2$ or any of its dissociation products by substitution, without change of the formal oxidation state of the iron, then $x = 3$. The fate of this 13 G species has not been established, but conversion of similar mono-nitrosyl iron complexes to di-nitrosyl species under mild conditions is well established. For example, reaction of either $Fe(NO)(S_2CNMe_2)_2$ or $Fe_4S_4(NO)_4$ with MeS^- yields[9] $[Fe(NO)_2(SMe)_2]^-$; reduction of $Fe_4S_4(NO)_4$ yields[10] $[Fe_4S_3(NO)_7]^-$; while $[Fe(CO)_3NO]^-$ yields $[Fe(NO)_2X_2]^-$ (X = Cl, Br, I) with haloalkanes,[6] and $[Fe(NO)_2(SR)_2]^-$ with alkanethiols.[9] Hence it is possible that the 13 G mono-nitrosyl species could be converted firstly to a di-nitrosyl, and thence to $Fe_2(NO)_4(SR)_2$.

When the thiol was added to the THF solution of $Fe_2(NO)_4I_2$ prior to the addition of any Et_3N, the resulting EPR spectrum was quite different from that obtained in the presence of the amine. Upon addition of the thiol, the spectrum of $Fe(NO)_2I$ was replaced by that of $[Fe(NO)_2I_2]^-$, but no other paramagnetic species were detected. We interpret this as arising from displacement of iodide by SR to yield $Fe(NO)_2SR$ which immediately dimerises to yield the isolable product $Fe_2(NO)_4(SR)_2$; the displaced iodide ion then coordinates to a further $Fe(NO)_2I$ to yield

Scheme 1. Steps in the conversion of $Fe_2(NO)_4I_2$ to $Fe_2(NO)_4(SR)_2$.

$[Fe(NO)_2I_2]^-$, (eqns 8–10):

$$Fe(NO)_2I + RSH \rightarrow Fe(NO)_2SR + H^+ + I^- \quad (8)$$

$$2Fe(NO)_2SR \rightarrow Fe_2(NO)_4(SR)_2 \quad (9)$$

$$Fe(NO)_2I + I^- \rightarrow [Fe(NO)_2I_2]^-. \quad (10)$$

In contrast to the ready dissociation of $Fe_2(NO)_4I_2$, the esters $Fe_2(NO)_4(SR)_2$ undergo very little dissociation, even in highly polar solvents, as discussed above. In support of eqns (8) and (9), it was found that reaction of $Fe_2(NO)_4I_2$ with a 100-fold excess of *i*-PrSH in THF, even in the absence of any amine, leads to formation of $Fe_2(NO)_4(S\text{-}i\text{-}Pr)_2$ in 93% isolated yield.

We can accordingly suggest the sequence of reactions involved in the conversion of $Fe_2(NO)_4I_2$ to $Fe_2(NO)_4(SR)_2$ in THF solutions (see Scheme 1): with the exception of $Fe(NO)_2SR$ all the paramagnetic species in this Scheme have been detected by EPR spectroscopy. Triethylammonium iodide is insoluble in THF, and it is the precipitation of this salt from the solution which drives the equilibria towards the formation of $Fe_2(NO)_4(SR)_2$ in preparatively useful yields when stoichiometric quantities of $Fe_2(NO)_4I_2$ and RSH are employed.

The sequence of reactions leading from $Fe_2(NO)_4I_2$ to $Fe_2(NO)_4(SR)_2$ is at last partially reversible, in DMF. Addition of excess potassium iodide to a DMF solution of $Fe_2(NO)_4(SMe)_2$ gave $[Fe(NO)_2I_2]^-$ as the sole paramagnetic species detectable: likewise, addition of potassium bromide gave $[Fe(NO)_2Br_2]^-$. However, no paramagnetic halogeno complexes were observed upon addition of either KF or KCl to $Fe_2(NO)_4(SMe)_2$: the observed EPR spectrum in each case indicated a mixture of $Fe(NO)_2(SMe)(DMF)$ and $[Fe(NO)_2(DMF)_2]^+$.

EXPERIMENTAL

Literature methods[11–13] were used for the preparation of $Fe_2(NO)_4Br_2$, $Fe_2(NO)_4I_2$ and $Fe_2(NO)_4(SR)_2$. Solutions for EPR examinations were prepared using dry, redistilled solvents, deoxygenated with a stirring nitrogen stream: all manipulations of solutions were made under dry nitrogen.

EPR spectra were measured in 1 mm quartz capillaries using a Bruker ER 200D Spectrometer. Di-*t*-butyl nitroxide was used as the standard in the measurement of line positions; diphenyl picryl hydrazyl was used as the standard in the measurement of intensities.

SYNTHESIS AND CHARACTERISATION OF PENTACOORDINATED RUTHENIUM(II) HYDRAZONE DERIVATIVES†

S. A. PARDHY, K. JOSEPH, SARADA GOPINATHAN and C. GOPINATHAN*

Inorganic Chemistry Division, National Chemical Laboratory, Poona 411 008, India

(*Received* 11 *November* 1983; *accepted after revision* 17 *April* 1984)

Abstract—Several new pentacoordinated ruthenium(II) compounds, $Ru(PPh_3)_2L$, of Schiff bases LH_2 are reported. The Schiff bases used have been derived from isonicotinoyl hydrazone and β-diketones or salicylaldehyde, or azines and mixed azines obtained from salicylaldehyde, benzoylacetone or 2-hydroxyacetophenone. These new compounds are highly coloured crystalline solids, stable and monomeric in toluene. They readily absorb carbon monoxide gas to give a carbonyl derivative of the type $Ru(PPh_3)_2CO(L)$ in quantitative yields.

Wilkinson *et al.*[1] reported the preparation and characterisation of several ruthenium(II) bis-triphenylphosphine-Schiff base complexes having an octahedral geometry. The Schiff bases used for this study were derived from aliphatic diamines and β-diketones or aromatic aldehydes. A *trans* structure for the phosphine groups was ascertained for all these complexes.

Little is mentioned in the literature about pentacoordinated ruthenium(II) phosphine complexes of tridentate hydrazones and azines. Dibasic tridentate chelating ligands are reported to form unstable ruthenium(II) complexes probably because of the formation of coordinately unsaturated ruthenium.[1] It is probable that stable complexes of pentacoordinated ruthenium(II) may be formed from hydrazones and azines. Several hydrazones of isonicotinoyl hydrazide (a) and azines (b) of salicylaldehyde

(a)

$R = H, CH_3, CF_3$
$R' = C_4H_3SCOCH_2, CH_3COCH_2$
$C_6H_5COCH_2, C_6H_4OH$

(b)

$R,R' = H$ or CH_3

and hydroxyacetophenone, listed below, have been used for our study:

1. Acetylacetone-isonicotinoyl hydrazone [acac-inh]H_2.[2,3]
2. Trifluoroacetylacetone-isonicotinoyl hydrazone [tfacac-inh]H_2.[2]
3. Thenoylacetone-isonicotinoyl hydrazone [ta-inh]H_2.[2]
4. Trifluorothenoylacetone-isonicotinoyl hydrazone [tfta-inh]H_2.[2]
5. Benzoylacetone-isonicotinoyl hydrazone [ba-inh]H_2.[2]
6. Salicylaldehyde-isonicotinoyl hydrazone [sa-inh]H_2.[4]
7. Salicylaldehyde azine [sa-a]H_2.[5]
8. Salicylaldehyde-benzoylacetone azine [saba-a]H_2.[6]
9. 2-Hydroxyacetophenone azine [ha-a]H_2.[7]
10. Salicylaldehyde-2-hydroxyacetophenone azine [Saha-a]H_2.[6]

EXPERIMENTAL

Reactions were carried out under dry, oxygen-free nitrogen using dry, degassed solvents. Acetylacetone-isonicotinoyl hydrazone was prepared as reported earlier.[3]

Salicylaldehyde-2-hydroxyacetophenone azine [saha-a]H_2. This was obtained from 2-hydroxyacetophenone hydrazone (1.50 g; 0.01 mol) and salicylaldehyde (1.22 g; 0.01 mmol) by refluxing them (2 hr) in methanol (30 cm^3). The crystals obtained on cooling the contents were recrystallised from benzene. M.p. 163°. Found: C, 70.72; H, 5.47;

Calc. for $C_{15}H_{14}O_2N_2$: C, 70.86; H, 5.51%. Mol.wt by mass spectrum, 254.

Ru(PPh$_3$)$_2$(acac-inh). The disodio derivative of the ligand [acac-inh]H_2 was prepared from oil-free sodium hydride (0.057 g; 20% excess of 0.002 mol), ligand (0.219 g; 0.001 mol) and ether (30 cm^3). The dry sodio derivative was suspended in benzene (30 cm^3) and $Ru(PPh_3)_3Cl_2$ (0.96 g; 0.01 mol) was added to it and the mixture refluxed overnight. The contents were then centrifuged to remove the precipitated sodium chloride. The benzene extract was concentrated to get brown crystals of the product. Yield 0.5 g (60%).

Ru(PPh$_3$)$_2$(saha-a). This compound was obtained from the reaction between the disodio derivative of the ligand [saha-a]H_2 (prepared from 0.057 g of sodium hydride and 0.304 g of the ligand) and $Ru(PPh_3)_3Cl_2$ (0.96 g; 0.001 mol) similar to the previous preparation. The dark coloured crystals weighed 0.57 g (65%).

Ru(PPh$_3$)$_2$(CO)(saha-a). $Ru(PPh_3)_2$(saha-a) (0.10 g) was dissolved in benzene (10 cm^3), warmed upto boiling and pure carbon monoxide bubbled through it for 30 min. The solution was evaporated *in vacuo* and washed with hexane to get a yellow solid. The yield was quantitative. Found: C, 68.63; H, 4.54; P, 6.34. Calc. for $Ru(P_2C_{36}H_{30})(CO)(C_{15}H_{12}O_2N_2)$: C, 68.95; H, 4.64; P, 6.85%.

Other ligands and ruthenium compounds were prepared similarly (Table 1).

RESULTS AND DISCUSSION

Isonicotinoyl hydrazone derivatives of β-diketones or salicylaldehyde reacted with $Ru(PPh_3)_3Cl_2$ in the presence of sodium hydride to give chlorine-free pentacoordinated ruthenium(II) complexes. Salicylaldehyde azine, 2-hydroxyacetophenone azine and the other two mixed azines also gave similar products. These compounds were found to be monomeric in toluene (vapour pressure osmometry). Unlike the light coloured hexacoordinated ruthenium(II) complexes, these new products were highly coloured crystalline compounds (Table 1).

Infrared spectra (ν in cm^{-1}) of isonicotinoyl hydrazone derivatives show ν N–H ~ 3200 cm^{-1} and characteristic amide I band ν C=O ~ 1665 cm^{-1}.[3] Complete absence of these bands in all the ruthenium(II) compounds suggests the loss of N–H proton through enolisation of carbonyl group during the complex formation. The high frequency shift of enolic/phenolic νC–O is consistent with oxygen coordination to ruthenium. The νN–N[8] occurring in the ligands in the range of 1010–1030 cm^{-1} undergoes a slight positive shift in their complexes indicating the coordination of one of the azomethine nitrogens to ruthenium. Further, the deformation mode of the pyridine ring of the free hydrazone at about 620 cm^{-1} shows no shift in the complexes indicating the non-coordination of the ring nitrogen.

Similarly azine derivatives also have given chlorine-free ruthenium(II) complexes. The tridentate nature of the azine ligand is confirmed from the splitting of νC=N [1600, 1590 cm^{-1}] and νN–N (940, 910 cm^{-1}].[9] Similar features are observed by us in the tin(IV) and titanium(IV) complexes of these ligands.[5,10]

^{31}P NMR spectra of azine complexes have been obtained using 85% phosphoric acid as external standard. The proton decoupled spectra of the complexes furnish only a singlet in the region

+29 ppm (positive value, lower field relative to phosphoric acid). Octahedral ruthenium(II) complexes with *trans* phosphine groups also have given a singlet for ^{31}P NMR spectra. Hence these azine compounds can presumably possess a trigonal bipyramidal geometry around ruthenium having *trans* phosphorus atoms as shown below:

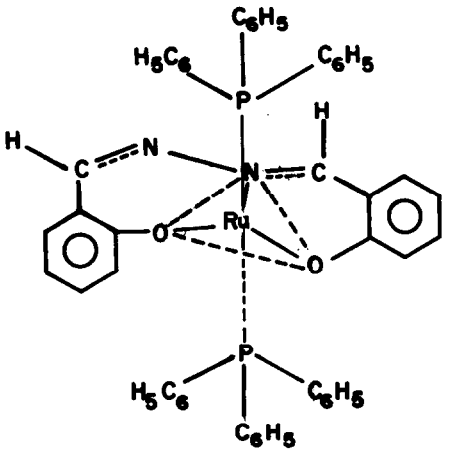

Fig. 1.

In benzene these ruthenium complexes reacted with carbon monoxide under refluxing conditions (30 min) giving $Ru(PPh_3)_2(CO)L$ in quantitative yields. The appearance of a single $\nu C{\equiv}O \sim 1940\ cm^{-1}$ confirms the formation of mono-carbonyl complexes. The pale yellow colour of the carbonyl complexes indicates them to be coordinately saturated species probably having octahedral geometry.

The electronic spectra of the ligands and their ruthenium compounds were obtained in chloroform solutions in the concentration range of 10^{-3}–10^{-5} molar at ambient temperature. The spectra of the ligands have shown absorption bands in the region ~260–280 nm which can be considered to be a $\pi \rightarrow \pi^*$ benzenoid band. The most intense band in the long wave length region ~330–360 nm for azines and thenoyl isonicotinoyl hydrazone might be considered to be caused by the lengthening of the π system due to the interaction of aromatic ring. The complexes derived from isonicotinoyl hydrazone exhibit an intense additional band ~440 nm (Table 2). Relatively higher intensities ($\epsilon = 10{,}000$) suggest that most probably

these are ligand-to-metal charge-transfer transitions. A hypsochromic shift for the long wave length band of azine is observed in the spectra of azine derivatives of ruthenium. This may probably be due to the formation of two dissimilar rings when the metal complex is formed thereby distorting the planarity of the azine ligand.

All these azine and hydrazone derivatives have retained the absorption characteristics of $Ru(PPh_3)_3Cl_2$. We could not confidently assign the *d–d* transition bands in these complexes as the spectra did not give distinct absorption bands in the visible range 450–700 nm within the solution concentrations used by us.

CALCULATION OF THE ^{13}C MAGNETIC SHIELDING IN CYCLOPENTADIENYL COMPLEXES BY ELIMINATING EFFECTS DUE TO CHARGE

NATALIYA A. OGORODNIKOVA* and DMITRII N. KRAVTSOV
A. N. Nesmeyanov Institute of Organo-Element Compounds, Academy of Sciences, Vavilov Street 28, Moscow, U.S.S.R.

(*Received* 2 *February* 1984; *accepted* 17 *April* 1984)

Abstract—A method for estimating the contributions of different factors to the ^{13}C NMR chemical shifts of a ligand has been proposed which is based on elimination of the charge effect and a determination of the combined effect of the remaining factors (the coordination effect). This enabled the authors to establish a relationship between the ^{13}C NMR data and the chemical properties of cyclopentadienyl metal compounds.

As regards the ^{13}C NMR spectroscopy of organometallic compounds of transition metals, no general satisfactory theoretical or empirical relationships to estimate the contributions of different factors to chemical shifts have yet been established.[1-3]

An attempt has been made[4] to estimate the net charges in the cyclopentadienyl rings of nonparamagnetic pentahapto-cyclopentadienyl complexes with transition or non-transition metals on the basis of the ^{19}F NMR data for their *p*-fluorophenyl derivatives according to Taft's approach.

The aim of this work was to estimate the combined effect of the factors arising from coordination, on the ^{13}C chemical shifts of the cyclopentadienyl ligand by using the proportionality factor for ^{13}C NMR chemical shifts 128.5 ppm per unit of charge[5] and the data on electron density in cyclopentadienyl ring for a number of complexes.[4]

RESULTS AND DISCUSSION

Our approach will be illustrated by the example of ferrocene. The net charge f in the cyclopentadienyl ring of the ferrocene molecule is 0.26 e (Table 1), the net charge decrease on each carbon atom with respect to the cyclopentadienyl anion is (1.0–0.26): 5 = 0.15 e (Table 2, Column 2), which must result in some de-shielding of carbon atoms by 0.15 × 128.5 = 19.3 ppm (Column 3) as compared with the cyclopentadienyl anion (δ 102.8 ppm, two first lines of Table 2). Then the chemical shift of the carbon atoms of a planar cyclopentadienyl ring having the same charge as it has in ferrocene $\delta\ Cp^{-0.26}$, must be 102.8 + 19.3 = 122.1 ppm (Column 4). In reality it is 67.9 ppm in ferrocene (Column 5). Hence the combined effect of factors not involving the charge is 67.9 − 122.1 = − 54.2 ppm (Column 6). These values are graphically represented in Fig. 1.

Table 2 (Column 6) lists the calculated coordination effect (this will be our short notation for the combined effect of factors not involving the charge and arising from coordination, on chemical shifts of the ring carbon nuclei) for all the investigated cyclopentadienyl compounds of transition and non-transition metals. The resulting picture is much clearer than that which can be derived directly from the ^{13}C chemical shifts.

Indeed, the change of shielding of the carbon atoms of a cyclopentadienyl ligand produced by coordination with metal may be both larger and smaller than it is in the cyclopentadienyl anion (Fig. 2). The information that can be derived from chemical shifts is not characteristic of the metal nature, since the shielding of carbon atoms of the cyclopentadienyl ring for non-transition metal compounds lies within the range of shielding of transition metal compounds (Fig. 2).

At the same time, the coordination effect in all the investigated cyclopentadienyl compounds of both transition and non-transition metals is a shielding one, being markedly higher for transition than for non-transition metals. The coordination effect (Table 3) is at a maximum in iron-subgroup metallocenes, nearly the same in cyclopentadienyl-

manganese- and -rheniumtricarbonyl, still rather high in diene complexes of rhodium, much smaller in Pd, Cu and Mo compounds, and quite small in Tl and alkali metal compounds. It can easily be seen that this series correlates fairly well with the metal-ring bond strength.

It is most convenient to illustrate this relationship on the example of the preparation of some cyclopentadienyl metal compounds from others. Indeed, the reaction of cyclopentadienyl compounds of non-transition metals Li, Na, K, Tl with halogenides, carbonyl, nitrosyl, phosphine halogenides and other complex halogenides of metals is the most general method for preparing mono-, bis-, and poly-cyclopentadienyl metal compounds. Reactions of copper cyclopentadienyltriethylphosphine or palladium allylcyclopentadienyl (representatives of the group of transition metal complexes where the coordination effect is relatively small) with iron chloride yield ferrocene.[17,18]

These are followed by compounds with a much stronger metal-ring bond. In most reactions of (diene)cyclopentadienyl complexes of rhodium the Rh–Cp fragment remains unaffected. Then, cyclopentadienylmanganese- and -rheniumtricarbonyl are very stable, and ferrocene, ruthenocene, and osmocene are extremely stable compounds.

We will now give a more detailed characterisation of these groups of compounds.

In cyclopentadienyl compounds of alkali metals the position of the ^{13}C chemical shift is practically independent of the nature either of metal or solvent and is about the same as the ^{13}C chemical shift for the "free" cyclopentadienyl anion (Table 4). The obvious reason is that the de-shielding effect of charge decrease in the cyclopentadienyl rings in alkali metal compounds is not high with respect to the cyclopentadienyl anion (Table 2, Column 3) and is normally offset by the combined shielding effect of other factors (Column 6). When, under the influence of solvent, the metal atom moves farther away from the cyclopentadienyl ring, the shielding effect of coordination decreases, but the negative charge in the ring, and therefore the shielding effect

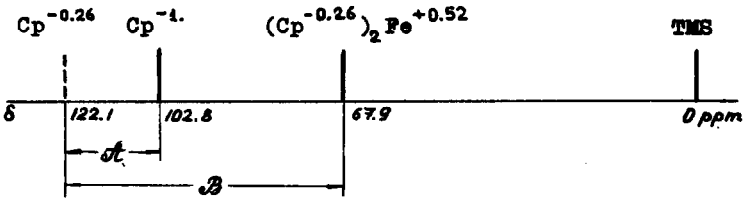

Table 2. The change in shielding of ^{13}C nuclei of the cyclopentadienyl ligand upon coordination with metal

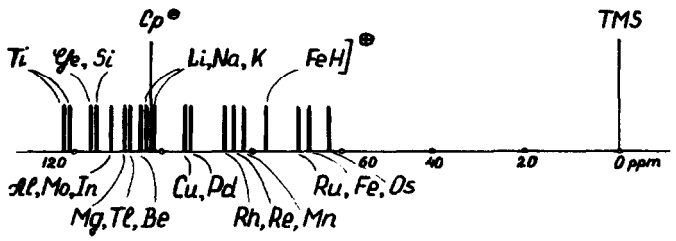
of the charge, increases and the two effects compensate each other. For this reason, the ^{13}C NMR data for cyclopentadienyl compounds of alkali metals are insufficient for deciding in what particular form the corresponding compound is present in solution. The degree to which the state of cyclopentadienyl ring approaches that of anion may be determined from the ^7Li NMR shifts of cyclopentadienyl lithium in different solvents,[7] the ^{19}F NMR shifts of *p*-fluorophenylcyclopentadienyl compounds of alkali metals[6] (Table 4), as well as from the spin–spin coupling constants $^1J(^{13}C, ^1H)$ of cyclopentadienyl compounds of alkali metals[5,9] (Table 4).



Cyclopentadienylthallium merits special attention. As regards the polarity of the metal-ring bond this complex is not different from the copper derivative (Table 1), but the coordination effect with thallium is not high and, according to this characteristic, it falls into the category of non-

transition metals (Table 3) which is quite consistent with its actual chemical properties.

The next group includes compounds of palladium, copper and molybdenum, the metals of Groups VIII, I and VI of the Periodic Table, respectively. $PdCp(C_3H_5)$, $CuCp(PEt_2Ph)$ and $MoCp_2(NO)I$ are compounds of quite different types. Their respective electron densities in the cyclopentadienyl ring are also different (Table 1). However their coordination effects are close (Table 3) and they exhibit similar chemical behaviour, namely the tendency for the σ, π-rearrangement of the cyclopentadienyl group.

The hypothesis that the lability of the π-cyclopentadienyl group in allylcyclopentadienylpalladium is due to its possible rearrangement into that of σ-bonded type during the reaction was first advanced by Nesmeyanov and Rubezhov as early as in 1964[18] and was later used by Werner[21] to explain the reactions between allylcyclopentadienyl compounds of palladium and a number of Lewis bases. In 1980 he published a paper in which the σ, π-rearrangement of the cyclopentadienyl group in allylcyclopentadienyl compounds of palladium was demonstrated experimentally.[22] If the tert-butyl group is in position 2 of the allyl ligand, then, on addition of a phosphine molecule, the π-cyclopentadienyl group is transformed into that of the σ-bonded type. If it is the methyl group which is located in position 2 of the allyl ligand, the complex resulting from reaction with phosphine exists in solution as a mixture of two isomers, π-cyclopentadienyl-σ-allyl and π-allyl-σ-cyclopentadienyl, in comparable concentrations. The σ, π-rearrangement of the cyclopentadienyl group in allylcyclopentadienylpalladium is initiated by introduction of additional phosphine ligand.

It has been supposed that the oxidative addition of monohapto-cyclopentadienyl compound of copper at the carbon–halogen bond may be the first

step of reactions between pentahapto-cyclopentadienylphosphine complexes of copper and different organic halides.[23] Actually, the proton spectrum of cyclopentadienyltriethylphosphinecopper in liquid sulphur dioxide at $-70°C$ contains three lines with area ratio 2 : 2 : 1. Such a spectrum indicates that the solution contains the σ-cyclopentadienyl compound.[24] The SO_2 molecule, being a Lewis base, may play the same role in the solution of copper compound as the phosphine molecule in allylcyclopentadienylpalladium, provoking the σ, π-rearrangement of the cyclopentadienyl group.

In reactions of the copper and palladium compounds in question the σ, π-rearrangement may be promoted by the approaching reactant molecules as well.

The σ, π-rearrangement of the cyclopentadienyl ligand may be assumed to occur as well in bis-(cyclopentadienyl)nitrosyl complexes of molybdenum $MoCp_2(NO)X$ where X is a one-electron ligand.

X-ray examination of these complexes has shown that their two cyclopentadienyl rings are structurally identical but exhibit asymmetric bonding to the metal atom with two relatively short, one intermediate, and two long Mo–C bond dis-

tances.[25,26] These complexes may be considered as twenty-electron ones. Several ideas have been advanced to obviate this quite unusual situation and to explain the equivalence of the protons and carbon atoms of the rings in the NMR spectra of these complexes at normal temperature.

King proposed that they contain one trihapto- and one pentahapto-cyclopentadienyl rings, with the trihapto-ring rapidly rotating about the metal-ring axis and fast exchange taking place between the rings.[27] Cotton considered the equivalent rings as donors of four electrons[28] and believed that such a peculiar type of the ring-metal bonding was merely a transient situation in the rapid exchange of the pentahapto- and monohapto-cyclopentadienyl rings.[29] According to McCleverty, the apparent equivalence of the cyclopentadienyl groups could arise via electronic interchange of the two rings through η^5-, η^4-, η^3-, η^2- and η^1-bonding modes. Consequently, the compounds must react in solution in a way typical of species containing M–C σ bonds.[30] In fact, he showed that reactions between bis(cyclopentadienyl)nitrosyliodide of molybdenum and different acids such as HI, RCO_2H, or $RCOCH_2OCR$ involved cleavage of cyclopentadiene and formation of the corresponding iodide, carboxylate, or β-diketonate.[31] Furthermore, reactions with dienophiles yielded Diels–Adler adducts.[32]

From the above data one may draw the conclusion that the complexes characterized by an intermediate coordination effect show a tendency for σ, π-rearrangement of the cyclopentadienyl ligands. Complexes having a high effect of coordination with the metal do not show such a tendency.

Hence, the proposed method of estimation of the contributions of different factors to the ^{13}C NMR chemical shifts of the ligand consisting in elimination of the effect of charge and determination of the combined effect of the remaining factors (the coordination effect) permits us to establish the relationship between the ^{13}C NMR data and the chemical properties of cyclopentadienyl compounds of a large variety of metals.

KINETICS OF THE REACTION OF DI-μ-ACETATODI-μ-OXALATODIAQUODIRUTHENIUM(II,III) ANION WITH N-(2-HYDROXYETHYL)-ETHYLENEDIAMINE-TRIACETATOAQUOTITANIUM(III)

YOICHI SASAKI,† MARIA A. EVERHART and JOSEPH E. EARLEY*
Department of Chemistry, Georgetown University, Washington, D.C. 20057 U.S.A.

(*Received* 13 *March* 1984; *accepted* 14 *April* 1984)

Abstract—Reduction of $[Ru_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2]^-$ by N-(2-hydroxyethyl)–ethylenediaminetriacetatoaquotitanium(III) [Ti(HEDTA)] involves several distinct stages. The first stage has a half-time of less than 1 ms, and is interpreted as a substitution reaction leading to a multinuclear intermediate. The second stage has a second-order rate constant of $5 \times 10^3\ M^{-1}s^{-1}$ [25°C, $\mu = 0.1$ m ($LiCF_3SO_3$)]. The rate-limiting process for the second stage is electron transfer within the assembled multinuclear complex. Subsequent slower stages correspond to breakup of the multinuclear Ru(II)$_2$–Ti(IV) complex formed by electron transfer. The overall rate of reduction of this oxidant by Ti(HEDTA) is less than the corresponding rate for the reaction in which Ti^{3+} acts as reductant, mainly because the stability of the binuclear complex is reduced by the presence of the aminoacid ligand. The data are consistent with the conclusion that the ligand increases the rate of intramolecular ET, probably by reducing geometric change associated with oxidation of Ti(III) to Ti(IV).

In previous papers,[1] we have shown that electron-transfer (hereafter, ET) reactions having Ru(III) complexes as oxidants and Ti(III) species as reductants involve a variety of mechanisms. In the absence of suitable bridging groups, outer-sphere ET occurs if an electron-delocalizing ligand is present on either redox partner. If a ligand that has an open coordination-position and also a pi-electron system that facilitates overlap between electron–donor and electron–acceptor orbitals, is present on the oxidant, then an inner-sphere mechanism prevails. In most cases of this type, formation of a multinuclear complex determines the overall redox rate, since the rate of intramolecular ET is faster than the substitution reaction. However, there is evidence for rate-limiting ET if 3-formylpentane-2,4-dione is the bridging ligand. Carboxylate ligands are efficient bridges, and generally give rise to substitution-limited reactions. However, when $Ru_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2^-$ is the oxidant, ET from Ti^{3+} (through the remote carboxyl group of a μ-oxalato ligand bridging two ruthenium atoms) is slower than the corresponding reaction of monomeric carboxylato-Ru(III) oxidants.

Aminoacid ligands on one of the redox partners can alter the kinetics of oxidation-reduction reactions in at least two ways. On the one hand, differences in substitution-rate[2] can cause differences in rates of formation (or decomposition) of the multinuclear intermediates of inner-sphere reactions; on the other hand, variation of ligands in the first coordination-spheres of oxidant and reductant metal-ions can give rise to substantial differences in the free energy change for intramolecular ET step. Such differences can alter the rate of intramolecular ET within a bridged complex.[3] This latter effect is parallel to the influence of free-energy changes on the rates of ET in the encounter-complexes of reactions involving outer-sphere mechanisms. We now report the effect of an aminoacid ligand on the rate of a Ru (III)–Ti(III) reaction that, in the absence of the ligand, is rate-limited by ET through the bridging ligand.

EXPERIMENTAL

Bis μ-oxalato-μ-diacetatodiaquodiruthenium (II,III) anion

$Ru_2(CH_3COO)_4Cl$ (0.2 g) was added to a solution made by dissolving 0.15 g of oxalic acid in 200 cm^3 of water. The solution was allowed to stand at room temperature until no further change in absorption spectrum occurred (4 *d*). The dark product passed directly through Sephadex G–10 and Dowex 50 columns (though the starting complex was retained) but was retained on Sephadex G–15. The product moved as a single band when eluted from Sephadex G–15 with acidified 0.2% LiCl. Solutions for kinetic runs were prepared by dilution of chromatographic-column effluents, without intermediate preparation of solid. The spectrum of the solutions was reproducible and was the same whether Sephadex or Dowex 50 was used to remove unreacted $Ru_2(CH_3COO)_4Cl$. The peak at 475 nm which is characteristic of $Ru_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2^-$ was both sharper and up to 50% more intense in these solutions than in solutions of the same ruthenium concentration prepared from the solid identified as $[HRu_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2 \cdot 2H_2O]$.[2d]

N-(2-hydroxyethyl)-ethylenediaminetriacetatoaquotitanium(III) (hereafter designated as Ti (HEDTA)) was prepared by reacting Ti^{3+} with a $HEDTA^-$ solution that had a concentration that was 30–50% larger than neccessary for stoichiometric formation of the Ti(HEDTA) complex. Procedures and reagents used for kinetic studies were generally as previously described.[1] A microcomputer-linked Durrum stopped-flow spectrophotometer was used. About 1000 points were taken during each kinetic run.

When Ti(HEDTA) was added to solutions containing $[Ru_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2]^-$, absorbance between 375 and 550 nm decreased by 25% during the time of mixing (1 ms). This was followed by a biphasic absorbance increase, which preceeded slower absorbance-decrease. Absorbance decrease in this case was sufficiently slow as to be neglected for the purpose of fitting the biphasic increase, and was not studied further. In the case of the reaction of the same oxidant with Ti^{3+}, initial absorbance-decrease was not observed, absorbance–increase was monophasic, and the eventual absorbance–decrease was faster than when Ti(HEDTA) was reductant. In the case of the reaction of the same oxidant with Ti^{3+}, spectrophotometric titration showed that one mole of $[Ru_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2]^-$ was consumed for each mole of Ti(III) added.

Kinetic data for the absorbance–increase observed when Ti(HEDTA) was reductant were fitted in terms of a double exponential, yielding two rate constants. The rate constant for the faster change (which accounted for 80% of the absorbance–increase) was designated k_f, that for the slower change was designated k_s. A linear-least-squares program was used to estimate a trial value of k_s from kinetic data taken near the absorbance maximum. Using this value, a second linear-least-squares treatment was applied to data taken during the main absorbance increase to estimate a trial value for k_f. Alternatively, the limiting absorbance-value corresponding to the faster relaxation was estimated and used in the linear-least-squares treatment of the initial data. All the data was then displayed on a CRT and compared with simulation, using the parameters derived by the double-least-squares program. Parameters were adjusted, taking account of instrumental factors, until the simulation agreed with the data within experimental scatter. Reproducibility of k_f was ± 10%.

As before,[2d] kinetic data for Ti^{3+}-reductions were fitted to a double exponential, yielding a rate constant, k_f, corresponding to the absorbance–increase and another, k_s, corresponding to the eventual absorbance–decrease. Kinetic data for both reductions are given in Table 1.

In the case of the Ti(HEDTA) reaction, the value of k_f is linearly dependent on reductant concentration, with a second-order rate constant $k_{2f} = 5 \pm 10^3\ M^{-1}s^{-1}$, but is nearly independent of ionic strength and acidity. The slower reaction measured by k_s and the ultimate absorbance–decrease were not systematically investigated. Results obtained in the case of the reduction of the oxidant by Ti^{3+} are qualitatively similar to those observed earlier,[1d] again showing less than first-order dependence on [Ti(III)] and evidence of approach to a high-[Ti(III)]-low-acid limiting rate. The data listed in Table 1 are consistent with a high-[Ti(III)]-low-acid limiting rate constant of about $10^2\ sec^{-1}$.

DISCUSSION

As in the case of previous Ru(III)–Ti(III) reactions we have studied, the main chemical change in the process of current interest is oxidation of Ti(III)–Ti(IV), with concomitant reduction of Ru(III)–Ru(II). Rates of outersphere Ru(III)–Ti(III) reactions depend on the thermodynamic driving-force in a straightforward way. The rate of the absorbance increase that we observe is more than an order of magnitude faster than the outer-sphere ET rate that is predicted on the basis of the

redox potentials of the two couples involved.[1] We conclude that the reaction of present interest proceeds by means of a mechanism that is faster than outer-sphere ET, namely inner-sphere ET involving a multinuclear intermediate.

Ti(HEDTA) reduces $Ru(NH_3)_5NCS^{2+}$ with a (substitution-limited) second-order rate constant of $3 \times 10^4\ M^{-1}s^{-1}$, which value is higher than the corresponding value for the reaction involving Ti^{3+} and the same oxidant. This indicates that the ligand increases the lability of the water molecule coordinated to Ti(III). Rates of substitution-limited redox reactions of Ti^{3+} depend on the charge type of the redox partners. On the basis of this information, one would expect that the rate of formation of the multinuclear intermediate in reaction of $[Ru_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2]^-$ with Ti(HEDTA) would be greater than $5 \times 10^5\ M^{-1}s^{-1}$. The initial rapid (1 ms) bleaching that we observe can be taken to correspond to formation of an intermediate in which Ti(III) is joined to the diruthenium moiety by an oxalato ligand. In the case of the corresponding reduction involving the Ti(III) aquoion, the intermediate has a formation constant of 300/M: the stability of the intermediate in the reaction of present interest should be somewhat less. On this basis, the absorbance–increase measured by k_f would be due to ET within that intermediate. If the formation of the intermediate is a rapid prior equilibrium, and the formation constant for that intermediate is not large, one would expect that

$$k_f = k_{ET}K[\text{Ti(HEDTA)}]$$

The rate constant k_f, for reaction of $[Ru_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2]^-$ with Ti(HEDTA), is linearly dependent on reductant concentration yielding a second order rate constant (k_{2f}) of $5 \times 10^3\ M^{-1}s^{-1}$. Variation in ionic strength, or in acidity, has little effect on this rate constant. Since Ti(HEDTA) is uncharged, the effect of ionic strength on K should be small. Since the formation of Ti(HEDTA) is complete, no serious acid-dependence of the prior equilibrium is expected. In order to obtain k_{ET} for the Ti(HEDTA) reaction from k_f, an estimate of K is needed. On the basis of comparable reactions, a value of $10\ M^{-1}$ seems reasonable, as an upper limit. Thus the lower limit for k_{ET} is $5 \times 10^2\ s^{-1}$.

The second-order kinetics observed in the reaction of $[Ru_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2]^-$ with Ti(HEDTA) contrasts sharply with previously reported kinetics for reaction of Ti^{3+} with the same oxidant. Our present data on this reaction confirm the prior report that, at high $[Ti^{3+}]$ and low $[H^+]$ a limiting rate is reached. Although the qualitative features of the earlier work have been reproduced, the limiting rate now reported has a somewhat higher value than that reported earlier. This divergence may mainly reflect an ionic strength influence on the formation constant of the multinuclear complex, and/or on the intramolecular redistribution of charge, however the possibility that the divergence arises in the preparation of the oxidant solutions has not been ruled out. (Precipitation may cause rearrangement of $[Ru_2(CH_3COO)_2(C_2O_4)_2(H_2O)_2]^-$.)

The presence of the aminoacid ligand causes a gross change in kinetic behavior. Difference in extinction coefficients brings into prominence the initial intermediate-formation reaction which is not directly (or at least not easily) observable in the absence of the ligand. The presence of the aminoacid changes the formation constant of the intermediate. In the case of Ti^{3+}, the intermediate has a stability constant of $2 \times 10^2\ M^{-1}$. The more negative charge of the complex reductant would be expected to give rise to a less-stable intermediate, and this in turn accounts for the difference in dependence of rate on [Ti(III)] that is observed.

In the presence of the aminoacid ligand there in no acidic proton on the reductant. Base catalysis that is a general feature of Ti(III) redox reactions is not present in this case. Even without formation of a conjugate base, the rate of intramolecular ET seems faster (by about two orders of magnitude) when the ligand is present than when it is absent. Presence of HEDTA would be expected to reduce geometric differences between Ti(III) and Ti(IV) that retard oxidation of Ti(III)–Ti(IV), and hence to increase the rate of the ET reaction. The effectiveness of proton dissociation in fostering intramolecular ET is presumably connected with reducing the same barrier. The presence of the ligand decreases stability of the intermediate and hence reduces overall redox rate.

Acknowledgement—A travel grant from the Yoshida Foundation to Y.S. is gratefully acknowledged. $LiCF_3SO_3$ and CF_3SO_3H solution were kindly supplied by Dr. Patrizia Barone.

THE REACTION OF PENTABORANE(9) WITH SODIUM CYANIDE AND SODIUM CYANOTRIHYDROBORATE

J. G. TAYLOR and M. G. H. WALLBRIDGE*
Department of Chemistry, University of Warwick Coventry CV4 7AL, England

(*Received* 9 *April* 1984; *accepted* 14 *April* 1984)

Abstract—The reaction of pentaborane(9) with NaCN occurs in a 1:1 molar ratio at temperatures between −30° and +10°C to yield the complex $Na[B_5H_9CN]$, which can be isolated in the form of a dioxanate. When excess pentaborane(9) is used the reaction is relatively clean and yields predominantly the $[B_9H_{14}]^-$ ion. With $NaBH_3CN$ no intermediates of the type $Na[B_5H_9CN]$ are detected, and the major product is the $[B_9H_{14}]^-$ ion, but no hydrogen is evolved in the reaction. Structures for the intermediate anions are suggested. No monocarbon carbaboranes were detected in any of the reactions.

The boron hydrides are usually described as being electron deficient, and not unexpectedly therefore they react with a range of nucleophiles. Interactions with the cyanide ion in particular are varied and lead to bridging,[1] cleavage,[1] and adduct[2] type products, depending on the borane used, as shown in eqns (1)–(3).

$$B_2H_6 + CN^- \rightarrow [H_3BCNBH_3]^- \quad (1)$$

$$B_4H_{10} + 2CN^- \rightarrow [BH_3CN]^- + [B_3H_7CN]^- \quad (2)$$

$$B_{10}H_{14} + 2CN^- \rightarrow [B_{10}H_{13}CN]^{2-} + HCN \quad (3)$$

The adduct type reaction, (3), was of interest to us since the $[B_{10}H_{13}CN]^{2-}$ anion can be protonated to give $B_{10}H_{12}CNH_3$, which is a useful precursor to CB_{10} and CB_9 carbaborane frameworks, where the carbon atom has become incorporated into a cage system.[3] We were encouraged to investigate the reaction with pentaborane(9), B_5H_9, (**1**), for two reasons. Firstly, a preliminary investigation had reported the formation of a simple 1:1 salt, $Na[B_5H_9CN]$, but the product had not been further characterised.[1] Secondly, we had shown in related studies that (**1**), on reaction with the hydride ion as a nucleophile, underwent a rearrangement reaction with the evolution of hydrogen to yield the $B_9H_{14}^-$ ion.[4]

Here we describe the results of investigations of the action of both NaCN and $NaBH_3CN$ on (**1**), at low and ambient temperatures.

EXPERIMENTAL

The reactions were performed using standard vacuum line techniques. In order to facilitate the recording of the ^{11}B NMR spectra, the 100 cm³ round-bottomed reaction flask was fitted with a side-arm incorporating a 5 mm diameter NMR tube that could be flame-sealed. The ^{11}B NMR spectra were recorded at a frequency of 128.4 MHz on a Bruker WH400 spectrometer. No deuterated lock solvents were used, and peaks in the spectra were externally referenced to BF_3.etherate (0 ppm). The IR spectra were recorded on a Perkin–Elmer 580 spectrometer by means of KBr disks. Carbon and hydrogen analyses were performed by Elemental Micro-Analysis Ltd., Devon. Reagent grade pentaborane(9), sodium cyanide, sodium cyanotrihydroborate, 1, 2-dimethoxyethane and 1, 4-dioxan were used, the solvents being dried over lithium aluminum hydride prior to vacuum-line transfer.

Reaction of pentaborane(9) *with* NaCN *and* $NaBH_3CN$

Dry finely ground sodium cyanide (0.31 g, 6.3 mmol) and degassed 1, 2-dimethoxyethane (10 cm³) were placed in a 100 cm³ round-bottomed flask fitted with a side-arm which contained a small sintered disc, and a sealed-on 5 mm NMR tube

*Author to whom correspondence should be addressed.

which had a constriction where it could be sealed-off. Pentaborane(9) (0.40 g, 6.3 mmol) was then condensed into the flask under vacuum at − 196°C. In the low-temperature experiments the reaction temperature was allowed to rise slowly over 30 min, and was then maintained at −25°C by means of a slush-bath (CCl_4) for 2 hr. The temperature was then allowed to rise to +10°C over 4 hr. The reaction mixture was stirred magnetically at the different temperatures, and the sodium cyanide dissolved slowly over the 6 hr period affording a colourless solution. Checks made at various times confirmed that no hydrogen was evolved during the reaction. An aliquot of the clear solution was filtered into the NMR tube through a small sintered glass disc, and the tube was then sealed-off and stored at −196°C. The remaining solution was evaporated to give a clear oil which turned pale-yellow after 3–4 hr at room temperature. Addition of dry 1, 4-dioxan (20 cm^3) to the original cold reaction mixture followed by removal of the solvent under vacuum yielded a slightly oily white solid. Washing with aliquots (10 cm^3) of 1, 4-dioxan followed by pumping yielded a dry white solid (1.50 g). Found: C, 34.9; H, 7.76, B, 21.6. Calc. for $NaB_5H_9CN.1.5C_4H_8O_2$: C, 34.4; H, 8.61, B, 22.1%. The IR spectrum of the solid showed bands at 2500(s), 2460(s) and 2380(s) cm^{-1} from ν(B–H), and 2250(s), 2210(sh) and 2200(sh) cm^{-1} from ν(C–N), where s = strong and sh = shoulder.

The reactions of (**1**) with both NaCN and $Na[BH_3CN]$ at room temperature were performed in a similar manner, except that the mixture was allowed to warm to room temperature immediately after the transfer of (**1**). The reactions appeared to be complete after 3–4 hr as judged by the disappearance of (**1**) from the ^{11}B NMR spectra, and the dissolution of the sodium cyanide.

RESULTS AND DISCUSSION

Sodium cyanide and (**1**) react in dimethoxyethane in a 1:1 molar ratio over the temperature range −30° to +10°C. The reaction is slow in that the solid cyanide dissolves over about 6 hr, but the initial reaction products definitely arise from a 1:1 molar reaction, since when excess cyanide is used only 1 mole dissolves per mole of

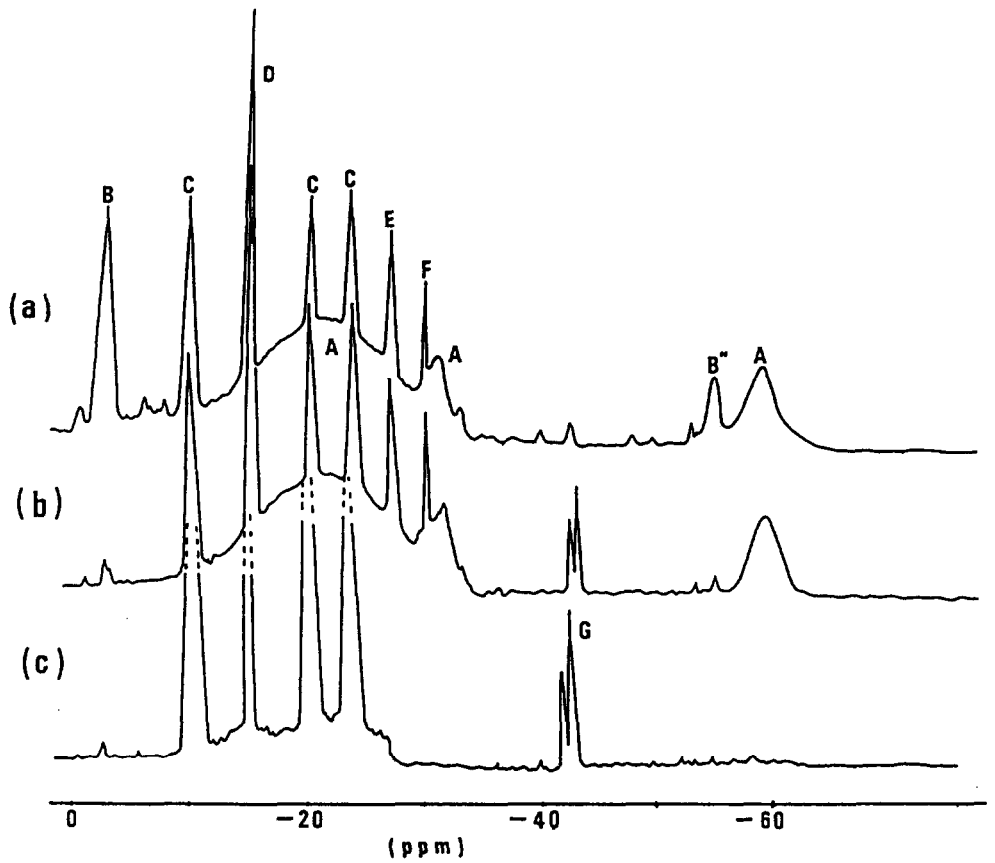

Fig. 1. (a) $^{11}B\{^1H\}$ NMR spectrum at +10°C of B_5H_9/NaCN (1:1 molar ratio) in 1, 2-dimethoxyethane. (b) A similar mixture allowed to react at +25°C. (c) A mixture of B_5H_9/NaCN (2:1 molar ratio) allowed to react at +25°C.

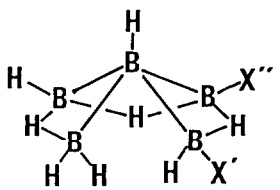
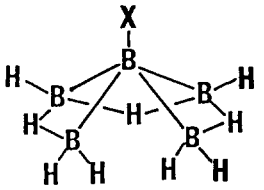
(1). However, in contrast the 1 : 1 molar mixture will react further with an exess of (1) as described below. A notable feature is that only minute traces of hydrogen were detected over the course of the reaction. This is in contrast to the reaction involving the hydride ion where, in addition to the 1 mole of hydrogen expected, further hydrogen is evolved as the reaction proceeds.[4]



The reaction may be followed conveniently by changes in the $^{11}B\{^1H\}$ NMR spectrum recorded at 10°C. A typical spectrum, as shown in Fig. 1(a), is obtained from a reaction mixture (1:1 molar ratio) which had been allowed to warm from −30° to +10°C over 6 hr, when all the solid sodium cyanide had dissolved. The major part of the reaction products (for a mass balance of the different products see details of the 1:1 molar reaction run at room temperature given below) consists of three very broad resonances (labelled A in Fig. 1a) with relative intensities of 3:1:1.

The peaks narrow slightly on cooling to −60°C, but do not show any ^{11}B–^1H coupling at either temperature. The broadness of the peaks, and the lack of any ^{11}B–^1H coupling, is reminiscent of the spectra of other substituted pentaborane compounds including the unsymmetrical adducts $B_5H_9.2L$ (L = NMe_3 or PMe_3).[4-6] These resonances would appear therefore to be best assigned to an open-cage species, *arachno*-$[B_5H_9CN]^-$, (2), in which the cyanide group is attached to the B(2) or B(3) positions. Such a species is iso-electronic and -structural with *arachno*-B_5H_{11}. The resonance of intensity 3 then arises from the three unsubstituted basal boron atoms, which are either equivalent due to a fluxional process, or not resolved within the very broad peak. The high-field resonance is assigned to the apical boron atom B(1), and the remaining resonance to the B–CN group.

peratures. The low-field resonance, B (intensity 4), exhibits a ^{11}B–^1H coupling of 94 Hz which is intermediate between the values normally associated with B–H (terminal) (*ca.* 140 Hz) and B–H (bridging) (*ca.* 40 Hz).[7] However, the high-field signal, B′, (intensity 1) does not show any ^{11}B–^1H coupling, and presumably arises from a B–CN group. It would appear therefore as though the initial attack of the cyanide ion occurs at the apical boron atom, yielding an ion as in (2), or possibly occupies a bridging position between the apical site and one of the basal atoms causing asymmetry in the field around the apical boron, and a broadening of the resonance. Although nucleophilic substitution in (1) is usually found to occur at the basal borons, it is known that such substitution can also occur at the apical position as in $B_5H_9 \cdot 2L$ [L = PMe_3,[8] $Ph_2P(CH_2)PPh_2$[5]]. Also since the room temperature product appears to be basal substituted, it is relevant that a rapid isomerisation process is known to occur in alkyl- and halopentaboranes, when the group is transferred at ambient temperatures or above from the apical to basal positions.[6]



Species C (Fig. 1a) arises from the *arachno*-$[B_9H_{14}]^-$ ion, as shown by a comparison of ^{11}B NMR chemical shifts and coupling constants,[9] and becomes a major product if the reaction is run at room temperature as outlined below. The species D and E were not unambiguously identified, but it is likely that D is an end product of B–H condensation reactions [i.e. $(B_nH_n)^{2-}$], in view of the presence of $[B_9H_{14}]^-$, and small amounts of the $[B_3H_8]^-$ ion (F) also observed. The chemical shift and ^{11}B–^1H coupling constant of D do in fact compare well with those of the $[B_{12}H_{12}]^{2-}$ ion.[10]

A solid product can be isolated from the reaction mixture by the addition of 1, 4-dioxan. After washing and pumping dry the IR spectrum shows evidence for the existence of B–H (*ca.* 2500 cm^{-1}), C ≡ N (*ca.* 2200 cm^{-1}) and co-ordinated dioxan. The solvated species appears to have a composition best represented by $Na[B_5H_9CN] \cdot 1.5C_4H_8O_2$.

(1)

(X'=CN, X''=H; X'=H, X''=CN)

(2)

(X = CN)

The two resonances B, B′ in Fig. 1(a) arise from a reactive low-temperature intermediate, since they disappear at the same rate over a few hours when the NMR sample is warmed to room temperature, and do not appear at all in reaction mixtures which have been held throughout at ambient tem-

When the reaction (1:1 molar ratio) was carried out at 25°C over 4 hr, the ^{11}B NMR spectrum of the clear solution (Fig. 1b) was similar to that discussed above, but no signals due to the species B were observed. The overall mass balance (based on the ratios of integrated intensities in the ^{11}B NMR spectrum) for the different products was approximately $[B_5H_9CN]^-$ (55%), $[B_9H_{14}]^-$ (20%), species D, $[B_{12}H_{12}]^{2-}$? (20%), and $[B_3H_8]^-$ (5%). The other unknown minor species E in the low-temperature spectrum also disappears on warming, but does so at a different rate to B, and we assume therefore that these two species are not related.

Significant changes did occur in the final spectrum when 2 moles of (**1**) was allowed to react with 1 mole of cyanide at 25°C for 4 hr. In this case no resonances due to either species A or B were observed, and the spectrum contained essentially only resonances arising from the $[B_9H_{14}]^-$ ion, (Fig. 1c) species D again presumably $[B_{12}H_{12}]^{2-}$, and also $[BH_3CN]^-$, (G), which was only formed in any significant quantity when excess of (**1**) was present. The relative proportions of these three products from the integrated ratios were 80, 10 and 5% respectively, with other minor resonances making up the remaining 5% of the products. The reactions involving an excess of (**1**) were always the cleanest, giving the minimum number of products, and again a noteworthy feature of the reaction is the absence of any hydrogen being evolved over the 4 hr reaction time.

Only a few reactions between (**1**) and $Na[BH_3CN]$ were investigated. The 1:1 molar reaction carried out at room temperature showed no broad signals (A or B) assigned to $[B_5H_9CN]^-$ as above. Instead the major products were again the $[B_9H_{14}]^-$ anion, and the species, $[B_{12}H_{12}]^{2-}$?, together with smaller quantities of F, $[B_3H_8]^-$ and traces of unreacted $[BH_3CN]^-$, and $[BH_3CNBH_3]^-$.

All of the reactions described were carried out many times with very little variation in the results. Possibly the most interesting point is the fate of the cyanide ion, in that the only obvious product which incorporates it is the $[B_5H_9CN]^-$ ion, but in many of the reactions it would appear to act as an intermediate in the conversion of (**1**) to higher borane anions. We have not detected any incorporation of the cyanide ion into the borane fragment, to form a monocarbon carbaborane as found with $B_{10}H_{14}$; instead it acts as a simple substituent as in the $[B_5H_9CN]^-$ ion. We have not detected any HCN in the reactions, and in view of these results it is tempting to speculate that the conversion of (**1**) to higher anions may be generally catalysed by anions, and of the three investigated in any detail (H^-, BH_4^- and CN^-) it is not surprising that hydrogen evolution occurs with the hydridic ions. We are currently investigating further whether other non-hydridic anions are also capable of achieving similar transformations.

Acknowledgement—We thank Dr. R. E. Williams for a gift of pentaborane(9), and the S.E.R.C. for support of this work.

DICARBOXYLATE RHODIUM COMPLEXES WITH DIOLEFINS AND CARBON MONOXIDE

L. A. ORO,* M. T. PINILLOS and M. P. JARAUTA
Departamento de Química Inorgánica, Universidad de Zaragoza, Zaragoza, Spain

(*Received* 2 *March* 1984; *accepted* 14 *April* 1984)

Abstract—Dinuclear rhodium complexes of the type $[Rh_2(C_2O_4)(diolefin)_2]$ (diolefin = 1,5-cyclooctadiene,2,5-norbornadiene and tetrafluorobenzobarrelene) with bridging oxalate ligands have been obtained by reaction of [Rh(acac)(diolefin)] with oxalic acid (2 : 1 mol ratio). The use of a 1 : 1 molar ratio affords $[Rh(HC_2O_4)(COD)]$, that reacts with [Ir(acac)(COD)] yielding the heterodinuclear [(COD)Rh(C_2O_4)Ir(COD)] complex. Treatment of $[Rh_2(C_2O_4)(diolefin)_2]$ complexes with phenanthroline type ligands leads to ionic complexes of formula [Rh(diolefin)(phen)][Rh(C_2O_4)(diolefin)]. Bubbling of carbon monoxide through solutions of the diolefin complexes leads to the formation of carbonylrhodium species of formula $[Rh_2(C_2O_4)(CO)_2L_2]$ (L = CO, PPh_3, *t*-BuNC) or $[Rh(CO)_2(phen)]$ – $[Rh(C_2O_4)(CO)_2]$. Other related malonate complexes are also described.

A number of organorhodium(I) compounds containing bidentate oxygen anions have been reported.[1] In particular the β-diketonate anions form a variety of complexes which have six-membered rings. Concerning rhodium(I) complexes which have five-membered rings, some tropolonate derivatives have been recently reported.[2] We describe in this paper some organorhodium complexes with the oxalate group. This dicarboxylate anion forms well-defined complexes which have five-membered rings, and it is able to function as a bidentate ligand to two metals simultaneously. In contrast, monocarboxylate anions in rhodium(I) chemistry are usually bound in a symmetrical *syn–syn* bridging.[3]

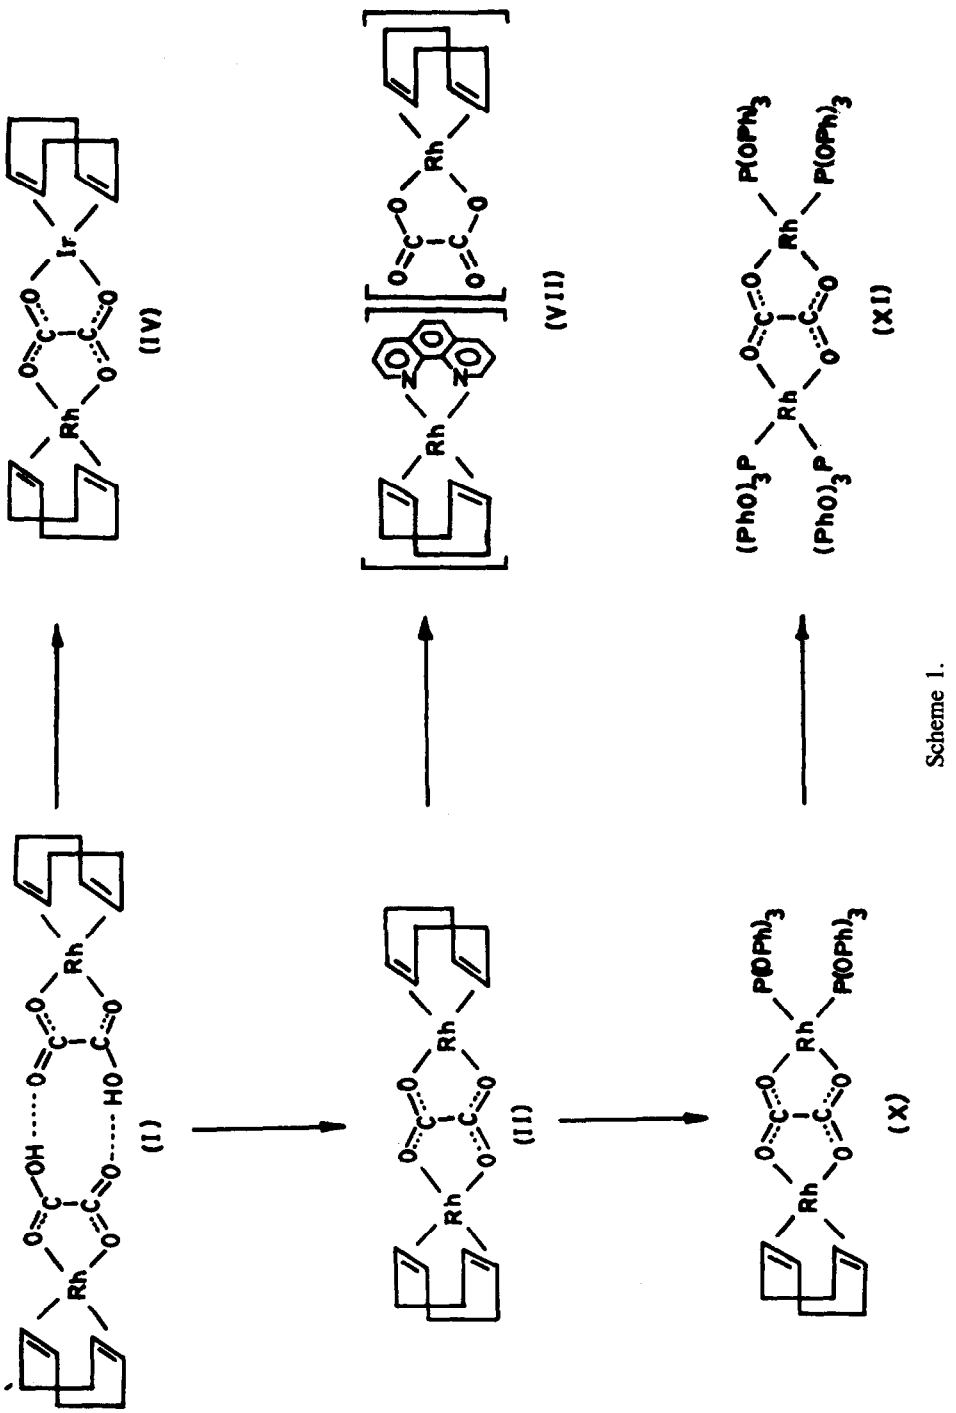
RESULTS AND DISCUSSION

Oxalate diolefin complexes

The reaction of [Rh(acac)(COD)] with a stoichiometric amount of oxalic acid leads to the formation of the yellow microcrystalline compound $[Rh(HC_2O_4)(COD)]$ (**I**). The experimental molecular weight measurements suggest a self-association by hydrogen bonding (Scheme 1). The acidic hydrogen atom in complex **I** can be removed with ease; thus, addition of [M(acac)(diolefin)] derivatives gives dinuclear complexes of formula [(COD)Rh(C_2O_4)Rh(diolefin)] (diolefin = 1,5-cyclooctadiene, COD (**II**) or tetrafluorobenzobarrelene, TFB (**III**)) or the heterodinuclear compound [(COD)Rh(C_2O_4)Ir(COD)] (**IV**).

A direct method of preparing homodinuclear complexes involves the reaction of two moles of [Rh(acac)(diolefin)] with one mole of oxalic acid, according to eqn (1):

$$2[Rh(acac)(diolefin)] + H_2C_2O_4 \cdot 2H_2O \rightarrow [Rh_2(C_2O_4)(diolefin)_2] + 2\,Hacac + 2\,H_2O \quad (1)$$



[diolefin = COD(**II**), TFB(**V**), NBD(**VI**)].

Molecular weight measurements confirm the dinuclear formulation. Scheme 1 shows the suggested structures (five-membered chelate rings).

The $[Rh_2(C_2O_4)(diolefin)_2]$ complexes usually react readily with different ligands. Thus, addition of the bidentate nitrogen donor ligand 1,10-phenanthroline leads to the formation of ionic derivatives of formula [Rh(diolefin)(phen)] – [Rh(C_2O_4)(diolefin)] (diolefin = COD(**VII**) or TFB(**VIII**)). Similarly, complex **V** reacts with 2,2′-bipyridine to give the analogous [Rh(TFB)(bipy)] [Rh(C_2O_4)(TFB)] derivative (**IX**). The electrical conductivities of complexes **VIII**–**IX** show them to be 1/1 electrolytes. In particular the constituent cations of these complexes are reported species[4,5] of high stability.

The stepwise addition of triphenylphosphite to $[Rh_2(C_2O_4)(COD)_2]$ affords the dinuclear derivatives [(COD)Rh(C_2O_4)Rh$\{P(OPh)_3\}_2$] (**X**) and $Rh_2(C_2O_4)\{P(OPh)_3\}_4$] (**XI**), but no further reaction

*Author to whom correspondence should be addressed.

Scheme 1.

was observed by adding excess of triphenylphosphite at room temperature. A similar reaction has been previously reported by Haines[6] by stepwise addition of triphenylphosphite to the compound $[Rh_2Cl_2(COD)_2]$, but the chloride bridges of the $[Rh_2Cl_2\{P(OPh)_3\}_4]$ complex can be cleaved with formation of $[RhCl\{P(OPh)_3\}_3]$. On the other hand, the related complex $[Rh_2(C_2O_4)(PPh_3)_4]$ (**XII**) can be prepared by adding four moles of triphenylphosphine to one mole of complex **II**.

Table 1 lists the analytical data for the isolated complexes.

Oxalate carbonyl complexes

Bubbling carbon monoxide through a dichloromethane solution of complex **II** leads to the displacement of the coordinated diolefin, causing an instantaneous change in colour from yellow to violet, which is followed by the precipitation of violet microcrystals, which were identified as the complex $[Rh_2(C_2O_4)(CO)_4]_x$ (**XIII**). The usual planarity of the oxalate group[7] probably favours the presence of an intermolecular rhodium–rhodium interaction[2a,8] in complex **XIII** as is suggested by the dark colour and dichroism of the compound, along with a complex IR spectrum in nujol mull (2100–1990 cm^{-1} region). Unfortunately, the low solubility of this complex prevents us from molecular weight measurements, but a tetranuclear formulation cannot be completely excluded. Thus, the related dinuclear $[Rh_2(Biim)(COD)_2]$ complex[9] containing the planar biimidazolate dianion forming five-membered rings reacts with carbon monoxide with formation of the tetranuclear red compound $[Rh_4(Biim)_2(CO)_8]$.[9] Furthermore, we have observed that a dinuclear complex of formula $[Rh_2(Biim)(CO)_2(PPh_3)_2]$ is obtained by addition of triphenylphosphine to $[Rh_4(Biim)_2(CO)_8](PPh_3/Rh: 1/1)$.

Addition of triphenylphosphine to solutions of the carbonyl derivative **XIII** leads to the formation of $[Rh_2(C_2O_4)(CO)_2(PPh_3)_2]$ (**XIV**). This product has an IR spectrum exhibiting only one terminal metal carbonyl stretching frequency (1987 cm^{-1}, CH_2Cl_2) suggesting a *trans*-configuration as observed for *trans*-$[Rh_2Cl_2(CO)_2(PPh_3)_2]$.[10] No further reaction was observed by adding excess of triphenylphosphine, although complex **XII** can be obtained by reaction of complex **II** with triphenylphosphine.

The reaction of complex **X** with carbon monoxide leads to the displacement of the coordinated diolefin, yielding to complex $[Rh_2(C_2O_4)(CO)_2\{P(OPh)_3\}_2]$ which was not isolated as a solid, but the presence of one ν(CO) band (2005 cm^{-1}, CH_2Cl_2) suggests a *trans*-configuration as observed for complex **XIV**.

The reaction of one mole of complex **XIII** with two moles of tert-butylisocyanide leads to the formation of *trans*-$[Rh_2(C_2O_4)(CO)_2(t\text{-}BuNC)_2]$ (**XV**) ($\nu C{\equiv}O$: 2010 cm^{-1}, CH_2Cl_2) but an ionic compound analyzing as $[Rh(CO)(t\text{-}BuNC)_3] - [Rh(C_2O_4)(CO)(t\text{-}BuNC)]$ (**XVI**) was obtained when four moles of tert.-butylisocyanide were used.

The [Rh(diolefin)(L–L)][$Rh(C_2O_4)$(diolefin)] complexes (L–L = phen or bipy) react with carbon monoxide with formation of complexes of the type $[Rh(CO)_2(L\text{–}L)][Rh(C_2O_4)(CO)_2]$ (L–L = phen (**XVII**) or bipy (**XVIII**). The complex IR spectra in the carbonyl-stretching frequency region, along with the dichroism and intense colour of the complexes when solids, indicate an ionic chain-like structure involving metal–metal interactions, as reported for related $[Rh(CO)_2(L\text{–}L)][RhCl_2(CO)_2]$ complexes.[8,11] In fact the observed IR absorptions are the result of the superimposed individual *cis*-dicarbonyl bands of $[Rh(CO)_2(L\text{–}L)]^+$ and $[Rh(CO)_2Cl_2]^-$.

The above mentioned ionic derivatives behave as 1 : 1 electrolytes in solution. In general low values of the molar conductivities are found (Table 1), probably due to the low mobility of the relatively bulky ions.

Finally, some oxidative addition reactions have been studied. Thus, complex **XIV** undergoes reactions with iodine or methyl iodide leading to formation of complexes of the type $[Rh_2(C_2O_4)I_2Z_2(CO)_2(Phh_3)_2]$ (Z = I (**XIX**) or Me (**XX**)). The presence of only one terminal ν(CO) band in the dinuclear rhodium(III) complexes at 2095 and 2053 cm^{-1} (CH_2Cl_2) respectively, suggests that a single symmetrical derivative was formed. As expected the ν(CO) vibration of the oxidation products is shifted towards higher energies relative to the parent compound (65–110 cm^{-1}). Table 1 lists some relevant data for the carbonyl derivatives. In general, only a ν(COO) band from the coordinated oxalate anion, in the range 1610–1670 cm^{-1} was unequivocally assigned, due to the presence of several absorptions in the 1300–1350 cm^{-1} range, masking the expected ν(COO) bands.

Malonate complexes

Some dinuclear complexes with the related malonate group have been prepared according to eqn (1), when malonic acid is added to acetone solutions of Rh(acac)(diolefin) complexes. These compounds of formula $[Rh_2\{CH_2(CO_2)_2\}(diolefin)_2]$ (diolefin = COD (**XXI**), TFB (**XXII**), NBD (**XXIII**)) react with carbon monoxide with formation of $[Rh_2\{CH_2(CO_2)_2\}(CO)_4]_x$ (**XXIV**). The latter complex reacts with a stoichiometric amount of

Table 1. Analytical and other data for the compounds

[a]Acetone. [b]Nitrobenzene. [c]Methanol.

triphenylphosphine yielding *trans*-$[Rh_2\{CH_2(CO_2)_2\}(CO)_2(PPh_3)_2]$ (ν(CO): 1970 cm^{-1}, CH_2Cl_2). In the above mentioned complexes, the malonate group is probably acting as bidentate to two rhodium atoms through symmetrical chelate carboxylate bonding (four-membered rings).

EXPERIMENTAL

C, H and N analyses were carried out with a Perkin–Elmer 240-B microanalyzer. IR spectra were recorded on a Perkin–Elmer 599 spectrophotometer over the range 4000–200 cm^{-1}, using Nujol mulls between polyethylene sheets or in dichloromethane solutions between sodium chloride windows, and calibrated with polystyrene. Molecular weights were measured with a Perkin–Elmer 115 osmometer. Conductivity measurements were carried out, with a Philips 9509 conductimeter.

$[RhCl(COD)]_2$, $[RhCl(NBD)]_2$, $[RhCl(TFB)]_2$, $(IrCl(COD)]_2$, Rh(acac)(COD), [Rh(acac)(TFB)], [Rh(acac)(NBD)], [Ir(acac)(COD)], were prepared by published methods.[12–17] Other chemicals were grade reagents and were used without purification.

Preparation of $[Rh(HC_2O_4)(COD)]$ **(I)**

$H_2C_2O_4 \cdot 2H_2O$ (81.24 mg, 0.644 mmol) was added to a solution of Rh(acac)(COD) (200 mg, 0.644 mmol) in dichloromethane (30 cm^3). The suspension was stirred for 30 min and filtered off. The yellow filtrate was vacuum-concentrated to *ca.* 2 cm^3 and addition of ether gave rise to the formation of a yellow solid, which was filtered off, washed with ether and vacuum-dried. Yield: 120.1 mg (62%).

Preparation of $[(COD)Rh(C_2O_4)Rh(TFB)]$. *General method for the synthesis of* **(III)** *and* **(IV)**

[Rh(acac)(TFB)] (75.453 mg, 0.176 mmol) was added to a solution of $[Rh(HC_2O_4)(COD)]$ (52.9 mg, 0.176 mmol) in dichloromethane (20 cm^3). This solution was stirred for 3 hr. Vacuum-concentration and addition of hexane led to the precipitation of the pale yellow complex which was filtered off washed with hexane and vacuum-dried. Yield: 80 mg (72%).

Complex **(IV)** was obtained in a similar way by adding a calculated amount of [Ir(acac)(COD)] (39.9 mg, 0.099 mmol) to a solution of $[Rh(HC_2O_4)(COD)]$ in dichloromethane (30 mg, 0.099 mmol) under nitrogen. Ether was used for the precipitation of this complex.

Preparation of $[Rh_2(C_2O_4)(COD)_2]$. *General method for the synthesis of* **(II)**, **(V)** *and* **(VI)**

To a solution of [Rh(acac)(COD)] (100 mg, 0.322 mmol) in acetone (20 cm^3), was added the stoichiometric amount of $H_2C_2O_4 \cdot 2H_2O$ (20.3 mg, 0.161 mmol). A yellow precipitate was formed immediately. After stirring for 2 hr, it was filtered off, washed with acetone and vacuum-dried. Yield: 70 mg (85%).

Complexes **(V)** and **(VI)** were similarly prepared by the route described above, starting from a calculated amount of [Rh(acac)(TFB)] or [Rh(acac)(NBD)]. The reaction to obtain complex **(VI)** was carried out under nitrogen with deoxygenated solvent.

Preparation of $[Rh(COD)(phen)][Rh(C_2O_4)(COD)] \cdot H_2O$. *General method for the synthesis of* **(VII–IX)**

Addition of 1,10-phenanthroline (7.7 mg, 0.039 mmol) to a solution of $[Rh_2(C_2O_4)(COD)_2]$ (20 mg, 0.039 mmol) in 20 cm^3 of dichloromethane caused a colour change from yellow to red. The solution was stirred for 30 min under nitrogen atmosphere, then the solvent was evaporated off under reduced presure, and addition of ether led to the complete precipitation of a red solid. This was filtered off, washed with ether and vacuum-dried. Yield: 20 mg (74%).

This way, 1,10-phenanthroline and 2,2′-bipyridine reacted with $[Rh_2(C_2O_4)(TFB)_2]$ to give the complexes **(VIII)** and **(IX)**.

Preparation of $[(COD)Rh(C_2O_4)Rh\{P(OPh)_3\}_2]$ **(X)**

$P(OPh)_3$ (41.2 μl, 0.156 mmol) was added to a solution of $[Rh_2(C_2O_4)(COD)_2]$ (40 mg, 0.78 mmol) in dichloromethane (30 cm^3); the colour of the solution changed from yellow to pale yellow. After stirring for 2 hr under nitrogen atmosphere, the solvent was evaporated off under reduced pressure and ether was added to give a pale yellow solid. This was filtered off, washed with ether and vacuum-dried. Yield: 56.4 mg (71%).

Preparation of $[Rh_2(C_2O_4)\{P(OPh)_3\}_4]$. *General method for the synthesis of* **(XI)** *and* **(XII)**

To a stirred suspension of $[Rh_2(C_2O_4)(COD)_2]$ (30 mg, 0.058 mmol) in deoxygenated ether (20 cm^3) was added $P(OPh)_3$ (61.85 μl, 0.235 mmol). The suspension immediately turned into a yellow solution, then a pale-yellow solid was observed. This was filtered off, washed with ether and vacuum-dried. Yield: 60 mg (70%).

Preparation of $[Rh_2(C_2O_4)(CO)_4]_x$. *General method for the synthesis of* **(XIII)**, **(XVII–XVIII)** *and* **(XXIV)**

Bubbling of carbon monoxide through a solution of $[Rh_2(C_2O_4)(COD)_2]$ (55.4 mg, 0.108 mmol) in 20 cm^3 of dichloromethane, for 30 min gave a violet solid. The suspension was vacuum-concentrated to

ca. 4 cm^3 and ether was added. The complex was filtered off, washed with ether and vacuum-dried. Yield: 50 mg (82%).

Methanol was used to precipitate complex (**XXIV**).

Preparation of $[Rh_2(C_2O_4)(CO)_2(PPh_3)_2]$. *General method for synthesis of* (**XIV–XV**) *and* (**XXV**)

A stoichiometric amount of PPh_3 (63.7 mg, 0.242 mmol) was added to a suspension of $[Rh_2(C_2O_4)(CO)_4]$ (49.3 mg, 0.121 mmol) in dichloromethane, and the resulting yellow solution was stirred for 2 hr. Addition of hexane to the concentrated solution (3 cm^3) gave a yellow solid, which was filtered off, washed with hexane and vacuum-dried. Yield: 88 mg (83%).

Complex (**XV**) was prepared under nitrogen atmosphere.

Reaction of (**XIII**) *with* t-*butylisocyanide*

To a suspension of $[Rh_2(C_2O_4)(CO)_4]$ (35.6 mg, 0.087 mmol) in 20 cm^3 of deoxygenated dichloromethane was added *t*-BuNC (38.58 μl, 0.350 mmol) under nitrogen atmosphere. The suspension was stirred for 5 hr giving a yellow solution.

The solvent was evaporated off to 2 cm^3 under reduced pressure, and then ether was added to give a brown solid which was filtered off, washed with ether, and vacuum-dried. This complex analyzed as $[Rh(CO)(t\text{-BuNC})_3][Rh(C_2O_4)(CO)(t\text{-BuNC})]$.

Preparation of $[Rh_2(C_2O_4)I_4(CO)_2(PPh_3)_2]$ (**XIX**)

To a solution of $[Rh_2(C_2O_4)(CO)_2(PPh_3)_2]$ (30 mg, 0.034 mmol) in 30 cm^3 of dichloromethane was added the stoichiometric amount of iodine (17.25 mg, 0.068 mmol); the colour of the solution changed from yellow to brown. The progress of the reaction was followed by IR spectra. After 90 min stirring the solvent was evaporated off to 3 cm^3 and hexane was added to give a dark brown solid. This was filtered off, washed with hexane and vacuum-dried. Yield: 37 mg (79%).

Preparation of $[Rh_2(C_2O_4)I_2Me_2(CO)_2(PPh_3)_2]$ (**XX**)

A suspension of $[Rh_2(C_2O_4)(CO)_2(PPh_3)_2]$ (22 mg, 0.025 mmol) in 30 cm^3 of methyl iodide was stirred. After 5 min, the suspension turned into a yellow solution, then the complex precipitated as a yellow solid. This suspension was stirred for 2 hr, after which time the solvent was evaporated to small volume and the product was filtered off, washed with hexane and vacuum-dried. Yield: 28 mg (96%).

Preparation of $[Rh_2\{CH_2\text{–}(CO_2)_2\}(COD)]$. *General method for the synthesis of* (**XXI–XXIII**)

A stoichiometric amount of $CH_2\text{–}(CO_2H)_2$ (11.7 mg, 0.112 mmol) was added to a solution of [Rh(acac)(COD)] (70 mg, 0.225 mmol) in 20 cm^3 of acetone. The mixture was stirred for 2 hr, during which time the product precipitated as a yellow solid. This was filtered off, washed with acetone and vaccum-dried. Yield: 32 5 mg (55%).

Complex (**XXIII**) is air-sensitive, so it was prepared under nitrogen atmosphere and ether was used as solvent.

Note added in proof: We have been informed about an independent preparation of $[Rh_2(C_2O_4)(CO)_4]$ by P. B. Hitchcock, S. Morton and J. F. Nixon (Paper D26, 2nd International Conference on the Chemistry of the Platinum Group Metals, Edinburgh, July 1984). We thank Dr. J. F. Nixon for useful discussion.

MIXED-LIGAND LANTHANIDE COMPLEXES—II

COMPLEXES OF β-DIKETONE AND HETEROCYCLIC AMINE. SYNTHESIS AND SPECTROSCOPIC STUDIES

K. IFTIKHAR*† and N. AHMAD
Chemistry Department, Aligarh Muslim University, Aligarh 202001 (U.P.), India

(*Received* 12 *October* 1983; *accepted after revision,* 14 *April* 1984)

Abstract—The imidazole adducts of tris(heptafluorooctanedionato)lanthanide(III), [Ln(fod)$_3$ · im] have been synthesized and characterized. The electronic spectra in the visible region have been analysed and spectral parameters ($\bar{\beta}$, $b^{1/2}$, δ and T_λ) and oscillator strengths calculated and discussed. These complexes are more covalent than the analogous [Ln(fod)$_3$ · pz] complexes, pz = pyrazole. The covalency is more in solution than in the solid state. The experimental and the calculated oscillator strengths are in good agreement. The band shape for the hypersensitive transition in the solid and solution spectra is compared with the other known systems and discussed. The difference in the band shape of the hypersensitive transition in the solid and in solution is indicative of solvent molecule coordination. The Mössbauer spectrum of [Eu(fod)$_3$ · im] is reported. The dipolar shift produced in the NMR spectrum of [Eu(fod)$_3$ · im] is upfield in comparison to the signal of the organic moiety itself as well as in its diamagnetic analogues. The coordinated base does not dissociate even in DMSO solution. Due to their poor solubility these compounds are not suitable for use as induced NMR shift reagents.

In the last several years there has been considerable interest in the lanthanide complexes especially concerning specific $f-f$ features of Ln^{3+} spectra in solution to give information regarding structure and composition of the complexes.[1–5] The lanthanide tris β-diketoenolates are being used as induced NMR shift reagents.[6] In the earlier reports we investigated some mixed-ligand lanthanide complexes with β-diketone and nitrogen containing ligands, their electronic spectral features and possible use as pseudo-contact NMR shift reagents.[7–10]†† In this study we report mixed-ligand complexes of most of the lanthanides (except Ce and Pm), yttrium and lanthanum with 1,1,1,2,2,3,3 - heptafluoro–7,7–dimethyl–4,6–octanedione(Hfod) and imidazole(im). Our interest in these newly synthesized adducts is to check their ability as potential shift reagents (the analogous adducts of Ln(fod)$_3$ with pyrazole, (pz), were found to produce larger dipolar shifts in the NMR spectrum of organic moieties,[9] to investigate their electronic spectra for ascertaining the dependence of the hypersensitive bands on the environment about the lanthanide ions and to study the Mössbauer effect in the [Eu(fod)$_3$ · im].

EXPERIMENTAL SECTION

Materials. Lanthanide oxides (Leico Chemicals, U.S.A.) were converted to the corresponding chlorides. Hfod (PCR Chemicals, U.S.A.), imidazole (Fluka, Switzerland) and xylenol–orange (BDH, England) were used in this study. Imidazole was crystallized from chloroform before use. DMSO–d_6 (99.9% d atom) was purchased from Aldrich Chemicals, U.S.A. Spectroscopic grade ethanol (E. Merck) was used for obtaining optical spectra.

Synthesis. The Ln(fod)$_3$ chelates were synthesized by the method of Springer *et al.*[11] The adducts were synthesized by mixing Ln(fod)$_3$ and imidazole (1 : 1 ratio) in ethanol on a hot plate. The products, thus, formed were washed several times with chloroform and hexane and dried *in vacuo* over phosphorus pentoxide.

††Part I of this series is Ref. 8.

Methods. The complexes were subjected to microanalyses for carbon, hydrogen and nitrogen, while the metals were estimated by complexometric titrations with EDTA using xylenol–orange as the indicator. The IR spectra were recorded both in Nujol and KBr on a 621-Perkin-Elmer IR Spectrometer. The magnetic susceptibility was measured by the NMR method using methanol as the solvent at the probe temperature. The NMR spectra of the complexes were recorded on a Varian A-60 machine.

Beckman DU-2 and Cary-17 D spectrophotometers were used, for obtaining optical spectra in solution and in the solid state. The solvent used for the solution spectra was ethanol and the concentration range was between 10^{-2} and 10^{-3}M.

For the measurements of the Mössbauer effect a 10 mCi source of Sm-151 in the form of Sm_2O_3 was used. This source had near natural line-width and an appreciable recoilless fraction (0.38) at room temperature. The absorbers were prepared in the form of pressed disc, the concentration of natural europium being maintained at 100 mg/cm^2 for comparison purposes. Spectra were run at room temperature. The data was computer fitted on a DECK-10 using a non-linear least square curve fitting programme.

Method of calculation is similar to those reported earlier.[8,9]

RESULTS AND DISCUSSION

The $Ln(fod)_3$ complexes are soluble in all common organic solvents but imidazole as well as the adducts of $Ln(fod)_3$ with imidazole are only soluble in polar solvents. This suggests that imidazole coordinates to $Ln(fod)_3$ and maintains its integrity in the adducts. All of the adducts synthesized are new. However, it should be pointed out that analogous mixed-ligand complexes $[Ln(dpm)_3 \cdot im]$ (dpm = dipivaloylmethane) have previously been reported.[7] The complexes, under study, are well defined solids with sharp melting points. The melting points are higher than those of 2,2′-bipyridyl[8](bpy), 1,10–phenanthroline[8](phen) and pyrazole[9] (pz) adducts of $Ln(fod)_3$ but lower than those of $[Ln(dpm)_3 \cdot im]$. These are quite stable and can be handled without any effect of air or moisture, in contrast to the behaviour of $Ln(fod)_3$ and $[Ln(fod)_3 \cdot pz]$ complexes which were found to be very sensitive to moisture. All the adducts behave as non-electrolytes as revealed by their molar conductance in methanol.[12]

The partial decomposition of these complexes starts after melting in the temperature range 220–240°C (Table 2). The total weight loss (5.5–6.5%) in this temperature range is consistent with the loss for imidazole (the theoretical weight loss for imidazole is 6.1–6.3%). One sharp DTA peak is identified in all cases in this temperature range. This indicates the coordinated nature of imidazole. The remaining proportion of the TGA curves, show the same behaviour as reported for the chelates[11] which is quite understandable since the material left after elimination of the imidazole is $Ln(fod)_3$.

The IR spectra of the adducts show presence of coordinated imidazole. The N–H frequency appearing in solid imidazole as a very broad band (2100–3300 cm^{-1})[13] because of intermolecular hydrogen bonding, appears as a comparatively sharp band (3120–3185 cm^{-1}) in the adducts. The observed shift and sharpness in the N–H band suggests a decrease in hydrogen bonding and interaction of ring nitrogen with lanthanide atom. The metal–nitrogen frequency in the analogous pyrazole adducts[9] was observed in the range 290–305 cm^{-1}. The band occurring between 280–290 cm^{-1} in the present complexes, which does not have its equal in the chelate and/or ligand can be assigned to metal–nitrogen frequency.[14] Most of the absorptions of imidazole do not appear, probably these are obscured by chelate absorptions. The absorption peaks occurring in the chelates are also present in the adducts with their positions slightly shifted (Table 3). The metal-oxygen frequencies are lower in the adducts than those of the $Ln(fod)_3$ complexes.

Thus, the adducts on the basis of their elemental analyses molar conductance, magnetic moments (Table 1), thermal analyses (Table 2) and IR spectral studies (Table 3) have been assigned to the general formula, $[Ln(fod)_3 \cdot im]$ where Ln stands for the trivalent lanthanides (except Ce and Pm) yttrium and lanthanum.

Mössbauer effect

The isomer shift is given by the following equation,

$$\text{I.S.} = 4/5\pi \; Ze^2R^2(\delta R/R)[|\psi(0)|^2_{\text{abs.}} - |\psi(0)|^2_{\text{source}}] \quad (1)$$

where all the notations have their usual connotations.[15] The Mössbauer spectra of Eu_2O_3 and $[Eu(Fod)_3 \cdot im]$ are shown in Figs. 1 and 2. The spectrum of $[Eu(Fod)_3 \cdot im]$ shows a definite negative isomer shift (-0.50 mm/sec) relative to Eu_2O_3, since for 21.7 KeV transition in Eu-151, δR (eqn 1) is positive.[16] Any deviation of the shift from zero indicates covalent bonding between the metal and the ligand. The negative isomer shift proves that the *s*-electron density (in europium nucleus) in the complex is lower than the corresponding *s*-electron density in Eu_2O_3. This decrease may be due to transfer of electrons from ligands to unfilled 4*f*

shell and this will involve a change in the configuration from $4f^6 5s^2 5p^6$ (Eu_2O_3) to $4f^{6+x}5s^2 5p^6$ (complex) where $0 < X < 1$. Since this increases the screening of the 5*s* electrons by the 4*f* shell it results in a net decrease in *s*-electron density at the nucleus (*x* will be zero for a purely ionic compound).

Electronic spectra

The electronic spectra of the complexes are recorded in ethanol and in the solid state. The spectra of the complexes show a shift of spectral bands towards lower energy as compared to those of the respective aquoions[17] which is known as nephelauxetic effect. The nephelauxetic parameter ($\bar{\beta}$),[18] the bonding parameter ($b^{1/2}$)[19] and Sinha's covalency parameter (δ)[20] for the complexes of Pr^{3+}, Nd^{3+}, Ho^{3+} and Er^{3+} are presented in Table 4. The nephelauxetic parameter is less than one and $b^{1/2}$ and δ are positive for these complexes which show covalent bonding between the metal and the ligand. The $b^{1/2}$ and δ in these adducts are in the order Pr > Nd > Ho > Er which reveals that for the same ligand covalency decreases as the atomic

Table 4. Covalency parameters

Complexes	$\bar{\beta}$	$b^{\frac{1}{2}}$	δ

[a] ref. 9 ; [b] the values given in parentheses are those calculated from solid state spectra.

number of the lanthanide increases. A comparison of the covalency parameters ($\bar{\beta}$, $b^{1/2}$ and δ) calculated from the solid state spectra with those of values obtained from ethanolic spectra reveals that covalency is more in solution (Table 4). The magnitude of $\bar{\beta}$ is similar to that obtained for the analogous pyrazole adducts,[9] it is perhaps instructive to compare the nephelauxetic effect of the two complexes, for any given metal ion. It is obvious from the Table 4 that, although we are looking for a very small effect, imidazole is a stronger ligand than pyrazole in a nephelauxetic sense and the covalency is higher in the former complexes.

The intensity of the *f–f* transitions of the complexes present interesting features. The experimental and the calculated oscillator strengths are listed in Table 5. The intensity of normal *f-f*-transitions do not show much change whereas hypersensitive transitions (which are very sensitive to the environment) display large changes in the intensity as compared to the corresponding aquo-ions.[17] The oscillator strength of the hypersensitive transitions in Nd^{3+}, Ho^{3+} and Er^{3+} is six, ten and eleven respectively, times higher than the corresponding aquo-ions. It is important to note that the oscillator strength of the hypersensitive transition of imidazole complexes for any given metal ion is higher as compared with those of pyrazole complexes.[9] Imidazole being more basic

Table 5. Oscillator strength

Hypersensitive transitions are enclosed in square brackets.

(pka = 7.1) than pyrazole (pka = 2.52) leads to a greater deal of covalency in its bonding which results in higher oscillator strength.[1,4]

Both changes in line shape and intensity of the hypersensitive transitions can be used as qualitative indication of symmetry.[21] Figures 3–5 show the shape of the hypersensitive bands of Nd^{3+}, Ho^{3+} and Er^{3+} complexes in ethanol solution and solid state. The complexes show remarkable spectral changes on passing from solid to solution states which demonstrate a change in the environment about the lanthanide ion in the two states, thus, indicating that expansion of coordination occurs. However, the band shape of ethanolic spectra of these complexes are quite similar to the band shapes of the eight-coordinate complexes in non-polar solvents or seven-coordinate complexes in polar solvents.[10,21,22] Occurrence of similar spectra is indicative of similar symmetries (i.e. similar coordination number).[23] Thus these complexes which are seven-coordinate take one solvent molecule and behave like eight-coordinate in solution.[10] The reflectance spectra of [Nd(fod)$_3$ · im] and [Nd(fod)$_3$ · pz] do not resemble one another but both acquire the same shape on passing from solid to solution (Fig. 3), thus indicating similar geometrical arrangement in solution but different in the solid states.

The oscillator strength due to the hypersensitive transition of the neodymium complex is higher than the oscillator strengths of other β-diketonate complexes in polar and non-polar solvents.[8,22,23] [Nd(fod)$_3$ · im] have a lower molecular symmetry than the other complexes and low molecular symmetry is usually responsible for higher oscillator strength.[22]

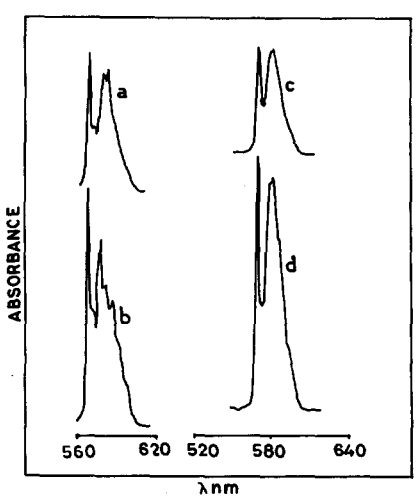

Fig. 3. Spectra of Nd^{3+} $^4I_{9/2} \rightarrow {}^4G_{5/2}$, $^2G_{7/2}$ Transition: (a) [Nd(fod)$_3$ · im] solid; (b) [Nd(fod)$_3$ · pz] solid; (c) [Nd(fod)$_3$ · im] in ethanol; (d) [Nd(fod)$_3$ · pz] in ethanol.

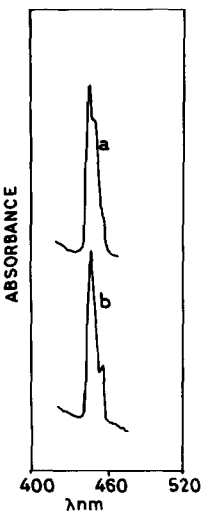

Fig. 4. Spectra of Ho^{3+} $^5I_8 \rightarrow {}^5G_6$ transition: (a) [Ho(fod)$_3$ · im] solid; (b) [Ho(fod)$_3$ · im] in ethanol.

The oscillator strength of the hypersensitive transition in the holmium complex is lower than those of eight- and ten-coordinate complexes.[10] It may be noted that the gradation of hypersensitivity is [Ho(fod)$_3$ · bpy · 2H$_2$O] > [Ho(fod)$_3$ · phen] > [Ho(fod)$_3$ · im]. This trend is in agreement with the conclusion of Henrie *et al.* that hypersensitivity depends upon the number of coordinated ligands.[1] The small difference in the oscillator strength of [Ho(fod)$_3$ · im] as compared to other seven-coordinate complexes reported in the literature[10,21] is due to the change in the nature of ligands present.

The oscillator strength of the hypersensitive transition in the erbium complex is the same as reported for Er(fod)$_3$ in ethanol (in solution Er(fod)$_3$ takes two solvent molecules and becomes eight-coordinate).[22] However, the magnitude is higher than [Er(fod)$_3$ · phen]. The lower value in phen complexes is due to splitting of the hypersensitive band into three.[8] It is instructive to note that the

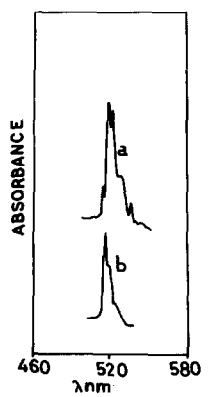

Fig. 5. Spectra of Er^{3+} $^4I_{15/2} \rightarrow {}^2H_{11/2}$ transition (a) [Er(fod)$_3$ · im] solid; (b) [Er(fod)$_3$ · im] in ethanol.

oscillator strength is much lower than some six-coordinate Er^{3+} complexes.[24] The lower value is consistent with a less asymmetric field around the erbium ion, accepting the premise that hypersensitivity depends on the asymmetry of the field on the ion.[23,25]

By the substitution of P_{exptl} and published values of matrix elements[26] in the Judd–Ofelt[27] equation, a set of three parameters (T_2, T_4 and T_6) are obtained. The T_λ parameters along with T_λ parameters of some analogous *fod* complexes[8–10] are collected in Table 6. The change in T_λ parameters show that T_2 is the most sensitive to the change in environment (i.e. change in the ligand). However, it is not true for the Nd^{3+} complexes where there is no trend. Also T_4 is negative in $[Nd(fod)_3 \cdot pz]$ and $[Nd(fod)_3 \cdot bpy \cdot 2H_2O]$ which is meaningless. This is really surprising in view of the fact that the Judd–Ofelt theory accounts reasonably for the other complexes and hence calls for further investigations.

NMR Spectra

The complexes of the diamagnetic trivalent ions La^{3+}, Y^{3+} and Lu^{3+} form a convenient series where ionic radius decrease (1.06, 0.88 and 0.85°A, respectively), while there are no paramagnetic effects to mask the relatively small shifts caused by coordination alone. The NMR spectra of the complexes have been recorded in DMSO-d_6 and spectral data are summarized in Table 7. The NMR signals of the *fod* moiety of the adducts appear at 0.98–1.07 ppm and 5.56–5.76 ppm for the *t*-butyl and the methine protons, respectively, as relatively sharp singlets. These signals of *t*-butyl and methine protons are shifted to high fields in the mixed-ligand complexes as compared to those of their respective chelates.[11] The reason for the high field shift would be the same as given for the analogous complexes.[8,9] Other signals can be assigned to those of the imidazole coordinated to the chelate. The signals of imidazole, in the complex, were found to shift remarkably to lower fields as compared to free imidazole. This deshielding effect of imidazole protons obviously suggests the coordinated nature of heterocyclic amine even in DMSO-d_6 solution. The shift is larger for H-2 (0.59–0.47 ppm) than for H-4 and H-5 (0.19–0.12 ppm). It is interesting to note that the signal for the N–H proton (H-3) is not seen in the spectra of the complex, although an N-H signal is observed in IR spectra.

The NMR spectra of the DMSO-d_6 solution of

[b] in $CDCl_3$; [c] in DMSO-d_6; [d] not observed.

the complexes show no resonance for free imidazole or free β-diketone; no change in signal line width or position is observed even on keeping the solutions for a few hours. This clearly proves that the imidazole as well as the diketone remain coordinated in solution and there is no dissociation even of heterocyclic amine.

The NMR spectrum of $[Eu(fod)_3 \cdot im]$ shows the expected narrow signals. Europium complexes are well known for producing downfield shifts but there are reports in which the $Eu(dpm)_3$ complex was used where upfield shifts were also observed in the substrates.[28,29] It is noteworthy that all of the signals in $[Eu(fod)_3 \cdot im]$ are shifted to upfield with respect to the signal of the organic moiety itself as well as its diamagnetic analogues.

One of the intentions of this study was to examine $[Ln(fod)_3 \cdot im]$ complexes as potential shift reagents. The complexes of praseodymium and europium added to a CCl_4 solution of t-butanol do not show any significant change in the spectrum of 1-butanol. Thus these adducts are not suitable for use as NMR shift reagents in contrast to the analogous pyrazole complexes which produce large dipolar shifts in the NMR spectra of organic moieties.[9]

Abstract—Some new heterobimetallic tetraxanthates of the type $M[Ag(Etxant)_2]_2$ [M = Co(II) or Ni(II), Etxant = ethylxanthate] and their complexes of general formula $M[Ag(Etxant)_2]_2.xL$ [$x = 2$ when L = dimethylsulphoxide (DMSO), triphenylphosphine (PPh_3), pyridine(py) or 2-aminopyridine (2-ampy); $x = 3$ when L = 2,2′-bipyridine (bipy)] have been prepared and characterized by elemental analysis, molar conductance, magnetic susceptibility, infrared and electronic spectral studies. Magnetic and electronic spectral studies indicate square planar geometry around Ni(II) and Co(II) in heterobimetallic tetraxanthates and $Ni[Ag(Etxant)_2]_2.2PPh_3$ and octahedral geometry around the above metal ions in the remaining complexes.

In previous papers[1,2] we reported the synthesis and characterization of heterobimetallic tetraxanthates of the type $MM'(Etxant)_4$ and their complexes with Lewis bases. This work has now been extended to the hitherto uninvestigated heterobimetallic xanthates and their complexes with Lewis bases such as DMSO, PPh_3, py, 2-ampy or bipy in which one of the metal ions is Ag^+ and the other is Ni^{2+} or Co^{2+}. A further point of interest in these studies was to examine whether the Lewis bases bond to Ag(I), Co(II)/Ni(II) or both with or without disrupting the structure of the parent Lewis acids. The synthesis and structural studies of $Co[Ag(Etxant)_2]_2$ and $Ni[Ag(Etxant)_2]_2$ and their complexes with DMSO, py, 2-ampy, bipy and PPh_3 were therefore undertaken and results of these studies are embodied in the present paper.

EXPERIMENTAL

Material and methods. Metal salts and potassium ethylxanthate used in the preparative work were BDH or RIEDEL(LR) grade. The 2-ampy, bipy and PPh_3 were used as such while py, DMSO, and solvents were freshly distilled and dried before use.

Preparation of $M[Ag(Etxant)_2]_2$ *and their complexes with Lewis bases*

$K[Ag(Etxant)_2]$ was prepared in situ by adding with constant stirring, silver nitrate (1 m mole) dissolved in 50 cm^3 water to a 150 cm^3 solution in 80:20 DMF water (v/v) containing potassium ethylxanthate (2 m mole). To the above solution cobalt or nickel nitrate (0.5 m mole) dissolved in 25 cm^3 water, was added gradually with vigorous stirring. The amorphous heterobimetallic tetraxanthates thus precipitated were filtered, washed with ether and dried *in vacuo*.

The complexes $M[Ag(Etxant)_2]_2.xL$ were prepared by mixing together 25 cm^3 dichloromethane suspension containing heterobimetallic xanthates (1 m mole) and 30 cm^3 ethanolic solution of the appropriate Lewis bases (4 m mole). The complexes which precipitated after prolonged stirring and keeping the reaction mixture for several hours were filtered, washed with ethanol and then with ether and dried *in vacuo*.

$Ni[Ag(Etxant)_2]_2\ 2PPh_3$ was prepared by adding $NiCl_2.2PPh_3$[3] (1 m mole) dissolved in 50 cm^3 acetone to a 200 cm^3 solution of $K[Ag(Etxant)_2]$ (2 m mole) in 80:20 DMF-water (v/v). The light orange complex precipitated on stirring the reaction mixture was filtered, washed with acetone followed by ether and dried *in vacuo*. Our attempts to synthesize the analogous Co(II) compound was not successful.

Analysis and physical measurements. The complexes were analyzed for their metal contents applying standard literature procedures.[4] Nitrogen was estimated microanalytically. Sulphur was estimated as $BaSO_4$. The experimental details pertaining to the determination of molar conductance and recording of magnetic susceptibility, x-ray diffraction, IR and electronic spectra were the same as described in our previous paper.[1] The relevant analytical and physico-chemical data are given in Tables 1–4.

RESULTS AND DISCUSSION

The analytical data show the formation of heterobimetallic tetraxanthates $M[Ag(Etxant)_2]_2$ and their complexes $M[Ag(Etxant)_2]_2.xL$ with Lewis bases. All the heterobimetallic xanthates and their Lewis base complexes do not melt but decompose in specific temperature ranges. The two Lewis acids and their complexes are insoluble in water and common organic solvents but slightly soluble in nitrobenzene and dimethylformamide. Very low values of molar conductance of bimetallic xanthates in 10^{-3}M nitrobenzene solution indicate their nonionic[5] nature. However, the molar conductance values for tris-bipy complexes (28.4–34.5 mhos cm^2 mol^{-1}) in the same solvent suggest their 1:1 electrolytic behaviour.

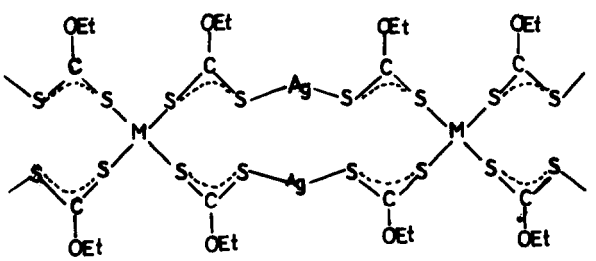
Magnetic and electronic spectral studies. The magnetic moment data given in Table 1 are consistent with square planar geometry around Ni(II)[6] in $Ni[Ag(Etxant)_2]_2$, $Ni[Ag(Etxant)_2]_2.2PPh_3$ and around Co(II)[7] in $Co[Ag(Etxant)_2]_2$ and spin free octahedral geometry[8-11] around Ni(II) and Co(II) in the remaining complexes.

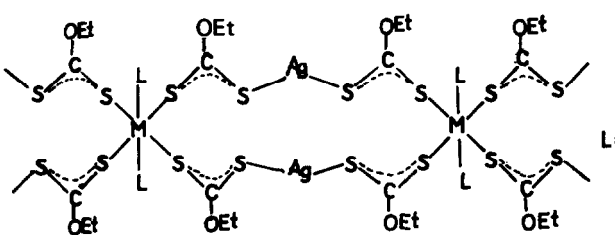
The visible region spectra of $Ni[Ag(Etxant)_2]_2$ and $Ni[Ag(Etxant)_2]_2.2PPh_3$ give three absorption bands which are similar in positions to the bands reported for square planar $Ni(Etxant)_2$ and $NiZn(Etxant)_4$ suggesting square planar[12] geometry around Ni(II) with D_{4h} symmetry. The very similar values 15500 and 16000 cm^{-1} of ν_1 band in $Ni[Ag(Etxant)_2]_2$ and its PPh_3 complex, therefore support the view that the two triphenylphosphine molecules must be bonded to Ag(I) rather than Ni(II). Bonding of the soft PPh_3 molecules to Ag(I) rather than to the borderline Ni(II) is expected on the basis of the HSAB principle.

Py, 2-ampy and DMSO complexes of Ni $Ag(Etxant)_2$ show three d-d transitions which are similar to the ν_1, ν_2 and ν_3 bands reported for a number of octahedral Ni(II) complexes.[10,13] $Ni[Ag(Etxant)_2]_2.3bipy$ exhibits two split bands at 10500 and 125000 cm^{-1} and a shoulder at 19200cm^{-1}. The spectral features suggest distorted octahedral[9,14] environment around Ni(II), in the above complex.



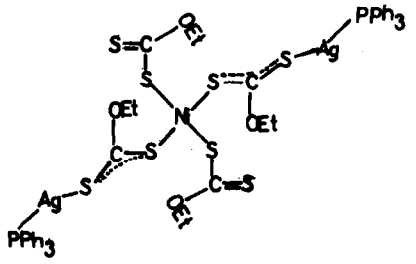
The positions of the *d–d* transitions observed in the electronic spectra of $Co[Ag(Etxant)_2]_2$ and its DMSO, py, 2-ampy and bipy complexes are consistent with square planar geometry around Co(II)[15-17] in the former case and octahedral geometry[13,14] around the above metal ion in the latter complexes. The value of (B = 700 cm^{-1}) for $Co[Ag(Etxant)_2]_2$ has been calculated from the most characteristic band for square planar geometry around Co(II) at 10520 cm^{-1} as suggested by Kida.[17]

IR spectra. The bands observed in the IR spectra of heterobimetallic xanthates in 1250–1260 and 1005–1010 cm^{-1} and in their complexes with Lewis bases in 1150–1205 and 990–1020 cm^{-1} regions are assigned to ν(C–O) and ν(C=S) modes respectively.[1,8,9,18,19] The presence of a single ν(C=S) band in the above complexes and a doublet at 995 and 1000 cm^{-1} due to the above mode in the IR spectra of $M[Ag(Etxant)_2]_2.3bipy$, suggests uninegative bidentate[1,18] behaviour of the xanthate group in the former complexes and its uninegative monodentate[9] behaviour in the latter complexes.



The IR spectra of the heterobimetallic tetraxanthate complexes exhibit bands characteristic of coordinated Lewis bases.[20-23] The coordinated nature of the Lewis bases in the above complexes is further evident from a marked negative shift[24] of about 50–110 cm^{-1} in ν(C–O) frequency.

X-Ray powder diffraction pattern. The $Co[Ag(Etxant)_2]_2$ and $Ni[Ag(Etxant)_2]_2$ have identical X-ray diffraction patterns and also their *d*-spacings are comparable (Table 4) suggesting them to be isostructural.



From the composition and physicochemical studies described above structures **I, II, III** and **IV** are proposed for heterobimetallic tetraxanthates and their complexes with Lewis bases. The disposition of the xanthate groups around Ag(I) is probably non-linear as is common with two coordinated complexes of Ag(I) with sulphur donor ligands.[25,26]

BEHAVIOUR OF α-FUNCTIONAL ORGANOTRANSITION METALS.[1] SYNTHESIS, CHARACTERISATION AND SOME REACTIONS OF 1-ACETOXYALKYL DERIVATIVES OF IRON(II) AND MOLYBDENUM(II)

SUSANNA E. HIMMEL, G. BRENT YOUNG*,
DAWNING C. M. FUNG and CHRISTINE HOLLINSHEAD
Chemistry Department, Imperial College, London SW7 2AY, England

(*Received* 2 *March* 1984; *accepted* 4 *May* 1984)

Abstract—Acetoxyalkyl metal derivatives $M(C_5H_5)(CO)_n[CHROC(O)Me]$[M = Fe, n = 2; M = Mo, n = 3; R = H, Me] are readily prepared by reaction of bromoalkylacetates with the appropriate cyclopentadienylcarbonylmetallate anion. The complexes are characterised by their NMR (^1H and ^{13}C) and IR parameters and by mass spectrometry. The acetoxyethyl species are thermally labile via β-hydrogen transfer. Treatment of acetoxymethyl complexes with protic acids leads to carbon-oxygen cleavage and release of acetic acid; HCl affords chloromethyl complexes, carboxylic acids yield new carboxylatomethyl derivatives, HBF_4 leads to decomposition. The metalloesters are resistant to hydrolysis, transesterification and carboxylate displacement by nucleophiles (HO^-, MeO^-, H_2N^- Et_2N^-). Migratory insertion of CO could not be induced.

There has been considerable interest recently in α-functional organotransition metals, stemming from their implication in a variety of metal-mediated processes. Notable among these derivatives are 1-hydroxyalkyls, which feature as intermediates in the palladium-catalysed oxidative hydrolysis of alkenes (Wacker process)[2] and in the Fischer–Tropsch and related reductions of carbon monoxide catalysed by a variety of metals.[3] Several hydroxymethylmetal complexes have been successfully isolated in investigations aimed at modelling the latter process.[4–6] A variety of ingenious routes have been employed. Acetoxyalkyl ligands seemed attractive as precursors to an assortment of α-functional alkylmetals including hydroxyalkyls, as well as offering a relatively unexplored class of α-functional organometal. An acetoxymethyliron derivative has been described previously, prepared by a less direct route,[4] and has lately found synthetic application.[7] We now report a general, direct synthesis of 1-acetoxyalkyl derivatives of iron and molybdenum, as well as some of their reactivity. A brief report has appeared very recently of analogous ruthenium complexes prepared by this method.[6]

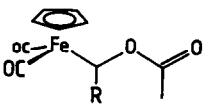
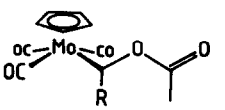
EXPERIMENTAL



General. NMR measurements were performed on Bruker WM250 (^1H, ^{13}C, ^{31}P; FT mode), JEOL FX90Q (^1H, ^{13}C; FT mode) and Perkin–Elmer R32 (^1H; CW mode) instruments. IR data were obtained on a Perkin–Elmer 683 spectrophotometer. Mass spectra were recorded on a VG7070E instrument. All chemical manipulations were carried out in dried, degassed solvents under an atmosphere of purified argon. Diethyl ether and tetrahydrofuran (thf) were distilled under nitrogen from sodium benzophenone anion as were toluene and petroleum ether (40–60° fraction). Dicyclopentadienyltetracarbonyldiiron and dicyclopentadienylhexacarbonyl-dimolybdenum were purchased from Strem Chemicals and were recrystallised prior to use. H.P.L.C. analyses were carried out using an automated Spectra-Physics SP8100 system equipped with SP8440 uv/visible detector and an SP4200 computing integrator. Reaction products were separated on a 25 cm column of ODS bonded on 5μ silica, eluting with methanol and monitoring at 215 nm. Elemental analyses were by Pascher, Bonn.

Preparation of bromomethylacetate.[8]



Paraformaldehyde (12 g, 0.4 mol) was mixed with acetyl bromide (30 cm^3, 0.4 mol) under dry nitrogen. A catalytic amount of $ZnCl_2$ (0.2 g

1.5 mmol) was added. When the considerably exothermic reaction had subsided, the reaction was stirred for a further 3 hr at 90–95°C. Pure bromomethylacetate was recovered from the reaction mixture by distillation (b.p. 132–138°C, 760 Torr). ^{1}H NMR (chloroform-*d*): 5.76 (s, 2H), 2.11 (s, 3H).

1

2

(a) R = H
(b) R = Me

Preparation of 1-*bromoethylacetate*

This was achieved by a modification of the method in Ref. 8; no zinc catalyst was employed. A 25% excess of acetaldehyde (36 cm^3, 35.2 g 0.8 mol) was slowly added to stirred acetyl bromide (38 cm^3 73.8 g 0.6 mol) at 40°C and with exclusion of light. The mixture was stirred for a further 2 hr at 40°C, and the product was purified by distillation at reduced pressure (30°C at 6 Torr). ^{1}H NMR (chloroform-*d*): 6.67 (q, 1H), 2.1 (s, 3H), 2.00 (d, 3H).

Preparation of acetoxymethyl cyclopentadienyl dicarbonyl iron(II)

To a stirred 0.4% sodium amalgam [prepared from 23 cm^3 mercury and 0.96 g (43 mg-atom) sodium] was added a solution of $[Fe(C_5H_5)(CO)_2]_2$ (6.4 g 20 mmol) in thf (80 cm^3). The mixture was stirred for 24 hr. The yellow ethereal solution of $Na[Fe(C_5H_5)(CO)_2]$ was filtered off and to it was slowly added at ambient temperature, bromomethylacetate (5.4 cm^3, 8.82 g, 57.8 mmol). These reagents were stirred for a further 24 hr. The solvent was removed at reduced pressure and the residue extracted with petroleum ether. The supernatant was filtered off and the solvent once more evaporated leaving a red oil, which, from its ^{1}H NMR spectrum, was predominantly the desired product. Purification was achieved by liquid chromatography at 0°C on grade A activated alumina.

Two yellow by-products were eluted first, using petroleum ether and $Fe(C_5H_5)(CO)_2[CH_2OC(O)Me]$ was eluted as a third fraction using 1:1 petroleum ether/diethyl ether. The compound is an orange-red oil at ambient temperature but is crystalline at −20°C. (Yield 7.6g, 76% prior to chromatography.) Found; C, 47.91; H, 4.03; Calc. for $C_{10}H_{10}O_4Fe$: C, 48.04; H, 4.04%.

Preparation of 1-*acetoxyethylcyclopentadienyldicarbonyliron(II)*

A solution of $Na[Fe(C_5H_5)(CO)_2]$ (40 mmol) in thf (100 cm^3) prepared as above was very slowly added to a vigorously stirred sample of 1-bromoethylacetate (6 cm^3, 40 mmol) at −78°C. The mixture was stirred for 4 hours at this temperature, and then allowed to reach ambient. The solvent was evaporated at reduced pressure leaving an oily residue. This was extracted with petroleum, filtered and concentrated under vacuum to a dark red gum. Purification by chromatography at 0°C on alumina as described above afforded a dark red oil. The thermal lability of this compound at ambient temperatures precluded elemental analysis and its identity was established by its spectroscopic characteristics (see Tables 1 and 2).

Preparation of acetoxymethylcyclopentadienyldicarbonylmolybdenum(II)

To $Na[Mo(C_5H_5)(CO)_3]$, in thf (70 cm^3), prepared from $[Mo(C_5H_5)(CO)_3]_2$ (2.0 g 4 mmol) and a 0.2% sodium amalgam (8 cm^3) was slowly added bromomethylacetate (1.2 cm^3, 8 mmol). The mixture was stirred for 24 hr before the solvent was evaporated at reduced pressure. The brown residue was extracted with 40–60 petroleum ether (40 cm^3) the supernatant filtered off and evaporated to dryness, leaving a dun oil, which crystallised on cooling. Recrystallisation from 1 : 1 ether/petroleum ether yielded dark yellow crystals of $Mo(C_5H_5)(CO)_3[CH_2OC(O)Me]$ (yield 2.3 g 91.2%). Found: C, 41.42; H, 3.20. Calc. for $C_{10}H_{10}O_5Mo$: C, 41.53; H, 3.17%.

Preparation of 1-acetoxyethylcyclopentadienyldicarbonylmolybdenum(II)

$Mo(C_5H_5)(CO)_3[CHMeOC(O)Me]$ was prepared by the same procedure as $Mo(C_5H_5)(CO)_3CH_2OC(O)Me$ except that the petroleum extract was purified by chromatography at 0°C on grade A activated alumina. The first (unidentified) product was eluted with 40–60 petroleum ether; the second, and desired, product with 1:1 ether/petroleum ether. This was recovered as red/brown oil (yield 0.4 g, 16%). The high thermal lability even at ambient temperature precluded elemental analyses. Spectroscopic characteristics appear in Tables 1 and 2.

Reaction of $Fe(C_5H_5)(CO)_2[CH_2OC(O)Me]$ *with hydrogen chloride*

Dry, gaseous HCl was passed into a solution of $Fe(C_5H_5)(CO)_2[CH_2OC(O)Me]$ (0.20 g 0.8 mmol) in 40–60 petroleum ether (40 cm^3) for 15 min. The solvent was evaporated at reduced pressure, yielding an orange oil. Orange crystals of $Fe(C_5H_5)(CO)_2CH_2Cl$, identified by its NMR and IR characteristics,[4] were obtained from 40–60° petroleum (yield 0.15 g, 83%).

Reaction of $Mo(C_5H_5)(CO)_3[CH_2OC(O)Me]$ *with hydrogen chloride*

Dry, gaseous HCl was bubbled into a solution of $Mo(C_5H_5)(CO)_3[CH_2OC(O)Me]$ (0.13 g, 0.4 mmol) in 40–60 petroleum ether (30 cm^3) for 20 min. The supernatant was filtered from a small amount of fine brown precipitate. The solvent was evaporated to give $Mo(C_5H_5)(CO)_3CH_2Cl$, pure by NMR (yield, 0.11 g, 93%).

Reaction $Mo(C_5H_5)(CO)_3[CH_2OC(0)Me]$ *with* HBF_4

To a stirred solution of $Mo(C_5H_5)(CO)_3[CH_2OC(O)Me]$ (0.085 g, 0.3 mmol) in diethyl ether (40 cm^3) at ambient temperature was dropwise added an ethereal solution of HBF_4 (1 cm^3 of 0.4 M solution, 0.4 mmol). The mixture was stirred for 30 min and the solvent reduced in volume and cooled. Red crystals of $[Mo(C_5H_5)(CO)_3]BF_4$ were identified from their published characteristics.[9]

(yield 0.076 g, 76%). A violet precipitate, identified as $[Mo(C_5H_5)(CO)_3]_2$ may also be produced on longer stirring. Acetic acid was the major organic byproduct of the reaction, characterised by HPLC analysis of the reaction mixture and by its ^1H NMR spectrum.

Reaction of $Fe(C_5H_5)(CO)_2[CH_2OC(O)Me]$ *with* HBF_4

To a stirred solution of $Fe(C_5H_5)(CO)_2[CH_2OC(O)Me]$ (0.100 g, 0.4 mmol) in diethyl ether (10 cm^3) was slowly added, at ambient temperature, a solution of HBF_4 in the same solvent (3 cm^3 of 0.28 M, 0.84 mmol). A red oil separated immediately. The supernatant was removed by cannula, and the red oil concentrated *in vacuo*. The characteristics of the resulting crystalline material agreed closely with those reported for $[Fe(C_5H_5)(CO)_3]BF_4$.[10] Acetic acid was identified by HPLC and ^1H NMR as the predominant organic by-product.

Carboxylate exchange on $Fe(C_5H_5)(CO)_2[CH_2OC(O)Me]$ *and* $Mo(C_5H_5)(CO)_3[CH_2OC(O)Me]$

These reactions were monitored by ^1H NMR in an appropriate solvent (benzene-d_6) to which the carboxylic acid was added, or in acetic acid-d_4. The appearance of the characteristic signal for the methyl substituent of CH_3CO_2H (2.08 ppm in acetic acid-d_4) was used to monitor the rate and extent of exchange. In addition, the spectroscopic characteristics of the organometallic product were verified.

Carbonyl insertion studies. Two approaches were used (i) The acetoxymethylmetal (*ca.* 3 mmol) was dissolved in acetone (10 cm^3) and maintained at 23°C in a sealed reactor under an atmosphere of CO (120 atm). The mixture was stirred overnight. There was no reduction in gas pressure. The solution was recovered, the solvent removed and the residual material characterised by NMR and IR spectra. (ii) The metalloester (*ca.* 1 mmol) was dissolved in acetone or nonane and a 5-fold excess of tertiary phosphine introduced. The mixture was heated to 50 or 90°C overnight. The solvent was evaporated and the residual material was spectroscopically analysed.

RESULTS AND DISCUSSION

Syntheses

Bromomethylacetate reacts smoothly with sodium cyclopentadienylcarbonylmetallates in tetrahydrofuran (thf) to afford, in good yield, acetoxymethylmetal species via nucleophilic displacement of bromide. The iron(II) complex, **1a,** is a moderately air-sensitive red oil at ambient temperature,[4] but which affords orange-red crystals at −20°C, while the corresponding molybdenum(II) derivative, **2a,** forms dark yellow, air-sensitive crystals. Both compounds are stable indefinitely at −20°C under inert atmospheres. Their identities were established by ^1H and ^{13}C NMR and IR measurements, by mass spectrometry and by elemental analyses.

Reaction of the same organometallic anions with 1-bromoethylacetate proceeds more slowly and in poorer yields. This may in part reflect the sensitivity of a concerted halide displacement to increasing steric obstruction, but it must also derive largely from the high thermal lability of these complexes. Both are prone to decomposition even below 0°C. This feature has made purification (by chromatography) the more difficult, has severely limited the range of reactivity studies and has excluded elemental analysis. Nevertheless, both species have been identified by their characteristic spectra. The 1-acetoxyethyliron(II) complex **1b** is a brown–yellow oil at ambient temperatures; its molybdenum analogue, **2b,** also an oil, is orange–red. Both are extremely air-sensitive.

Spectroscopy

(i) *NMR.* Spectroscopic data for the acetoxyalkylmetals (and some of their reaction products) are presented in Table 1. All four complexes display at least three characteristic resonances in their respective ^1H NMR spectra. One, a singlet, at higher field, derives from the hydrogens of the acetoxyl group; the position of this signal varies little, irrespective of the central metal or the substituents on the α-carbon of the acetoxyalkyl ligand. A second singlet characterises the hydrogens of the η^5-cyclopentadienyl moiety. The chemical shifts are somewhat more sensitive to the metal than to the substitution pattern; C_5H_5 bound to Mo resonates 0.4–0.6 ppm to lower field than in its iron congeners. The same influence by the metal is evident for the α-hydrogen(s) of the acetoxyalkyl group, whose resonance is of particular diagnostic value in these systems. As would be expected, the presence of an α-methyl substituent in **1b** and **2b** induces a downfield shift in the α-H signal, relative to the acetoxymethyl homologues **1a** and **2a** respectively. The other consequence of the α-methyl group is the appearance of the α-hydrogen resonance as a characteristic 1:3:3:1 quartet. The β-hydrogens themselves give rise to a 1:1 doublet at higher field and here again, there is a significant downfield shift for the molybdenum complex relative to iron.

These trends in chemical shifts for hydrogens close to the metal centre, as the metal is varied, must derive in part from the inductive effects of the $M(C_5H_5)(CO)_n$ fragment and also from contributions to shielding by the nonbonding metal *d*-electrons. Although the $Mo(CO)_3$ and $Fe(CO)_2$ moieties are isolobal, without detailed calculations it is not clear to what extent the differing spatial extensions of 3*d* and 4*d* orbitals will be offset by the disparities in metal–ligand bond lengths. The simple view is that the Mo(II) centre is a d^4-species with three powerfully π-acidic carbonyl groups and is likely to be relatively deshielding—either by induction or by more contracted *d*-orbitals—than the corresponding d^6 Fe(II) system with but two carbonyl ligands.

The ^{13}C chemical shifts appear generally less sensitive to the nature of the metal centre; the shifts for the carbon σ-bound to Mo(II) are, in fact, very slightly shielded relative to their iron-bonded counterparts. There is the expected downfield shift of this signal in both of the 1-acetoxyethyl complexes. The resonances ascribed to the CO ligands, on the other hand show no dependence on the alkyl ligand, but occur at significantly lower field in the molybdenum(II) species. Similar downfield shifts have been reported for related compounds and were interpreted as an indication of increasing retrodative M–L π-bonding,[11] consistent with the ^1H NMR shift trends.

(ii) *IR*. A full compilation of characteristic stretching frequencies for complexes 1 and 2 appears in Table 2. Of particular note are the ligand vibrations assigned to ν(C≡O) and ν(C=O). In acetoxymethyl derivatives **1a** and **2a**, the absorption patterns are remarkably similar, given the differing geometries and apparently different extents of M–C π-bonding (*vide supra*). Very strong bands occur at 2010 and 1950 cm^{-1} in the spectrum of **1a** while for **2a**, the corresponding ν(C≡O) appear at 2010 and 1945 cm^{-1}. The strong ester carbonyl absorbtions for **1a** and **2a** are found at 1730 and 1725 cm^{-1} respectively.

The spectra of acetoxyethyl complexes **1b** and **2b**

Table 3. Mass spectroscopic data for acetoxymethylmetal complexes

$Fe(C_5H_5)[(CO)_2CH_2OC(O)CH_3]$

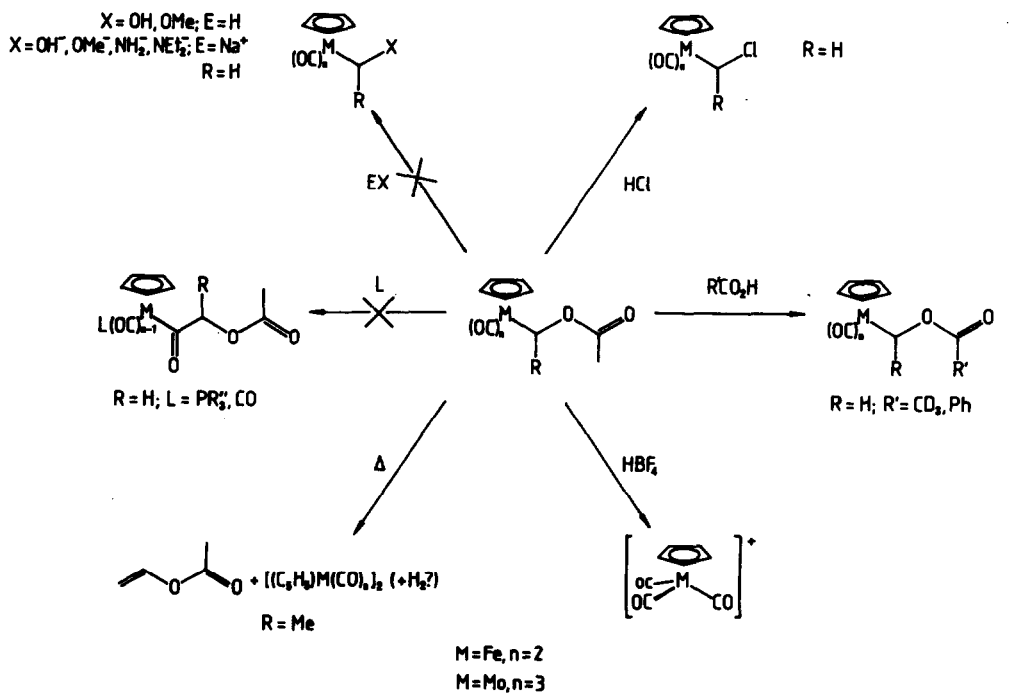
161	68	$Mo(C_5H_5)^+$
96	20	Mo^+

are more complex in the $\nu(C{\equiv}O)$ region. Three bands, at 1990, 1925 and 1980 cm^{-1} arise from **1b**, while five maxima, at 2020, 1995, 1940, 1885 and 1850 cm^{-1} are observed for **2b**.

Mass spectrometry

Only the complexes **1a** and **2a** displayed sufficient thermal stability to allow characterisation by mass spectrometry. The salient features of their very similar fragmentation patterns appear in Table 3. Both species give rise to very weak molecular ions. Stepwise loss of carbonyl ligands occurs readily for both metals and some or all of these fragmentations give rise to metastable peaks. Scission of both of the C–O bonds in the ligand, generating $[(C_5H_5)MCH_2O]^+$ and $[(C_5H_5)MCH_2]^+$ is observed in each case; the former is more apparent for Mo, the latter for Fe. Both systems produce strong ion currents for $[M(C_5H_5)]^+$.



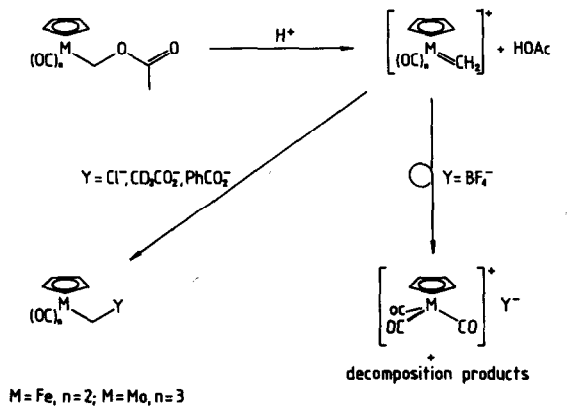
Reactivity (see Scheme 1)

(*i*) *Protic acids.* The thermal lability of **1b** and **2b** (and their organometallic reaction products) precluded satisfactory reaction studies. The ultimate products of reaction of **1a** and **2a** with protic acids are determined by the capacity of the counter "anion" (in HX) to form a covalent bond with the α-carbon. Thus, both complexes react smoothly under mild conditions with dry HCl to yield the chloromethylmetal derivatives.[4] A twofold excess of benzoic acid added to solutions of **1a** and **2a** yields $[Mo(C_5H_5)(CO)_3CH_2OC(O)Ph]$ and $[Fe(C_5H_5)(CO)_2CH_2OC(O)Ph]$ respectively.[12] Acetate metathesis is somewhat faster for molybdenum. Both reactions proceed to the extent of *ca.* 80% conversion over several days at ambient temperature. Acetate *exchange* in the presence of acetic acid-d_4 is immeasurably slow under the same conditions. When, however, **1a** or **2a** are dissolved in acetic acid-d_4 and heated to 60°C, acetic acid-d_1 is slowly liberated to a final extent of 80–90%. The NMR characteristics of the other hydrogens of **1a** or **1b** remain unaffected by the process. Such redistribution reactions are unusual in purely organic esters, but may occur when the carbenium ion of the migrating alkyl moiety forms particularly readily, usually in the presence of a strong acid catalyst.[3] Indeed, when a catalytic amount of HBF_4 is added to a solution of **2a** in acetic acid-d_4, the transcarboxylation reaction proceeds (more rapidly) to completion in less than 24 hr at ambient temperature.

When **1a** or **2a** react with HBF_4 alone, acetic acid is once more the preponderant organic product. NMR analyses revealed complex mixtures of organometallic products from which $[M(C_5H_5)(CO)_3]BF_4$ were the only isolable, identifiable products.[9,10]

There was some indication from NMR observations that excess *p*-toluenesulphonic acid reacts with **1a** and **2a** to give the respective tosylate esters, but attempts to isolate these on a larger scale led only to decomposition.

The acetoxymethyl complexes are similar to



their alkoxymethyl analogues inasmuch as it is the C–O rather than the C–M bond which is the more susceptible to protolytic cleavage.[4] The trans-carboxylation reaction with carboxylic acids is parallelled in aliphatic ester chemistry by the acid catalysed reaction of *tert*-butylacetate, in which the ready formation of the *tert*-butyl carbenium ion is proposed to be crucial.[13] This analogy lends weight to the suggestion[4] that the behaviour of the metalloesters **1** and **2** reflects access to carbenemetal cations of the type $[M(C_5H_5)(CO)_nCH_2]^+$. Thus all the protolytic reactions are envisaged to proceed (Scheme 2) via electrophilic attack on the ester oxygen, causing C–O scission to yield acetic acid. In the presence of a compatible nucleophile (Cl^-, RCO_2^-) the electrophilic carbenemetal species is scavenged. Otherwise (as with BF_4^-), decomposition ensues, via disproportionation and/or oligomerisation. We were not able to detect the carbene intermediate either directly or by its reaction in the presence of cyclohexene.[4] On the other hand, we observed no trace in NMR or IR spectra, of $[M(C_5H_5)(CO)_n(\eta^2\text{-cyclohexene})]^+$[14] which might arise via protolytic M–C cleavage under these conditions.

In contrast with conventional esters, we were unable to achieve either hydrolysis of **1a** and **2a**, to give the hydroxymethyl derivatives nor trans-esterification with methanol to give the known methoxymethylmetals either in the presence or absence of catalytic amounts of acid (HBF_4). In view of the reported ease of related reverse reactions,[4,6] this may indicate a thermodynamic rather than a kinetic impediment.

(*ii*) *Other nucleophiles.* Hydroxymethyl complexes were inaccessible by treatment of **1a** or **2a** in acetone with KOH. Even in presence of 18-crown-6-ether and excess of KOH, the acetoxymethyl complexes were recovered unchanged after 3 days at ambient temperature. **1a** and **2a** were similarly unreactive with NaOMe, $NaNH_2$ and $NaNEt_2$ at temperatures below their own thermolytic limits (Scheme 1).

(*iii*) *Carbonyl insertion.* We were interested to compare the reactivity, in particular of the C—O bond, in **1a** and **2a**, with that in the corresponding acetoxyacetyl derivatives. Hydroxymethyl species have only rarely been sufficiently robust to survive the conditions required to induce migratory insertion of CO to form hydroxyacetylmetals (which is one of the proposed steps in Fischer–Tropsch-type reductive oligomerisation of CO).[5,6] When **1a** and **2a** in acetone were treated with CO (120 atm) at 25°C, no reaction (other than some thermal decomposition) was observed over 16 hr. Addition of Ph_3P or Me_3P also failed to induce insertion at temperatures up to 90°C.

Thermal decomposition. Under dark, anaerobic conditions, the 1-acetoxyethyl complexes **1b** and **2b** decomposed cleanly at ambient temperatures to give vinyl acetate and $[M(C_5H_5)(CO)_n]_2$ in 1:2 ratio. We presume, but did not monitor, concomitant evolution of dihydrogen. Thus, β-hydrogen migration is facile for these systems, and the dimeric products can be ascribed to binuclear elimination of dihydrogen from the intermediate hydridometal complexes. Thermolysis of **1a** and **2a** required much higher temperatures and led to a complex array of organic products, including small amounts of acetic acid. Methyl acetate was not formed. The indications are that, as in the protolysis reactions, the C–O bond is thermally more susceptible than the C–M bond.

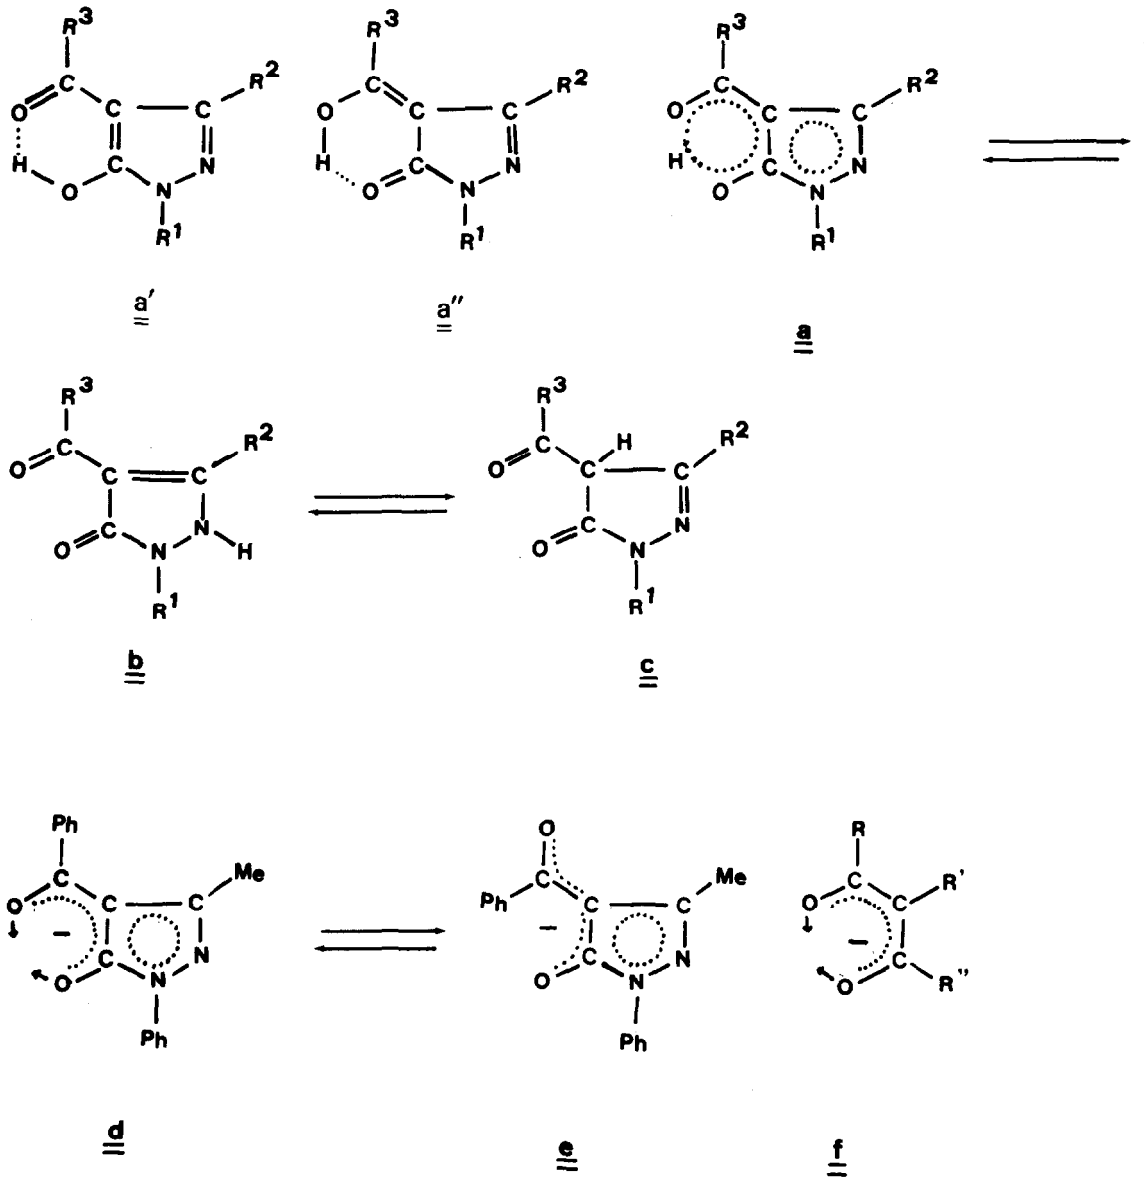
(*Received* 3 *February* 1984; *accepted* 6 *May* 1984)



Abstract—Several (diolefin)M(A) complexes (M = Rh, Ir) were prepared, where AH is 1-phenyl-3-methyl-4-benzoylpyrazolone-5, a very stable asymmetric analogue of acetylacetone. In these complexes the diolefin could be replaced by one mole of $(Ph_2PCH_2CH_2)_2$, two of CO or of PPh_3, or three of $CNBu^t$, while 1,10-phenanthroline displaced the chelating ligand to yield $[(cyclooctadiene)Rh(phen)]^+ (A)^-$. Some compounds X–Y (X–Y = iodine or MeI) added oxidatively yielding the corresponding trivalent species. Using ^{31}P NMR spectra the presence of the expected steric isomers was detected in $(Ph_3P)(CO)Rh(A)$ and in $(Ph_3P)(CO)Rh(A)(X)(Y)$.

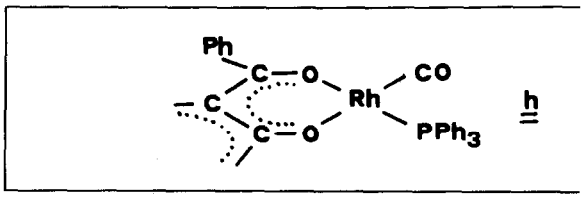
4-Acyl-pyrazolones-5, AH, are a class of potentially bidentate ligands which were originally investigated by Jensen[1] as reagents for radiochemical separations. These molecules are comparable to β-diketones because in both the classes keto-enol tautomerism is possible, the enolic hydrogen may be replaced by a metal ion, and a considerable number of various substituents can be placed on the ligand. In the acylpyrazolones structures such as **a**, **b** or **c** must be considered as possible tautomers, and **a** results from a proton shift between the two oxygen atoms, **a′** and **a″** being the two limiting cases. Structures like **b** are not likely to be important since when $R^1 = R^3 = Ph$ and $R^2 = Me$ protonation takes place at the nitrogen atom only at pH equal or lower than 0.5.[2] In addition, enolic structures should be considered having intermolecular, rather than intra-molecular, hydrogen bonds.

In the case of the molecule AH investigated here ($R^1 = R^3 = Ph$, $R^2 = Me$) two crystalline tautomers can be isolated[1b, 3a, 4a] for which different structural assignments are available. Whichever of these is accepted, the ligand is obtained upon deprotonation, so that -in any case- the deprotonated species, A^-, (**d** or **e**) may be a bidentate, uninegative ligand to be compared with an asymmetric β-diketonate, **f**. The advantage of A^- over the latter will be due to more extended delocalization of the change, so that, even if one or both the phenyl substituents are not involved in it, quite stable compounds are to be expected.

With 1 - phenyl - 3 - methyl - 4 - benzoyl - pyrazolone - 5 several metal derivatives were described including mono- and divalent cations[4b, 3c] or lanthanides;[4c, 4d] its use for the spectrophotometric determination of trace elements[3b] was also reported, but no organometallic derivatives had been investigated before our paper. Therefore, following up our interest in the field of rhodium and iridium compounds we decided to investigate their derivatives containing the A^- ligand; suitable derivatives[5,6] are available for comparison and include also X-ray crystal structures of symmetric or of asymmetric β-diketonates, such as dicarbonyl(acetylacetonato)rhodium(1)[5] or carbonyl(triphenylphosphino)-(thenoyltrifluoroacetato)rhodium(1).[6a]

*Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

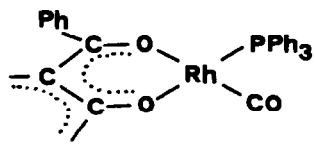


The ligand 1 - phenyl - 3 - methyl - 4 - benzoyl - pyrazolone - 5, AH, reacts with dinuclear rhodium(I) complexes of the type $[RhCl(diolefin)]_2$[7-9] or $[RhCl(monoolefin)_2]_2$,[10,11] in the presence of triethylamine, yielding mononuclear complexes of formula Rh(A)(diolefin)† (diolefin = 1,5 - cyclooctadiene (COD) (I), 2,5 - norbornadiene (NBD) (II), tetrafluorobenzobarrelene (TFB) (III)) or Rh(A)(monoolefin)$_2$ (ethylene (IV), cyclooctene (COE)(V)) Alternatively Rh(A)(diolefin) compounds can be obtained by reacting $[RhCl(diolefin)]_2$ complexes with TlA (VI) (prepared by addition of AH to Tl (acac)). The ethylene ligands can be displaced from complex (IV) by chelating diolefins such as 1,5-cyclooctadiene. In this manner complex (IV) reacts with benzoquinone (BQ) with formation of Rh(A) (BQ) (VII). On the other hand, the polymeric cyclooctatetraene complex $[Rh_2Cl_2(COT)]_n$[13] reacts with AH and NEt_3 yielding the dinuclear $Rh_2(A)_2(COT)$ (VIII) derivative. Similarly the $[RhCl(C_3H_5)_2]_2$ complex[14] affords the Rh(A) $(C_3H_5)_2$ (IX) derivative (Table 1).

The above mentioned complexes have been identified by elemental analyses, IR spectroscopy, molecular weight measurements and in some cases by proton or by $^{31}P\{^1H\}$-NMR spectroscopy. In particular the ^1H-NMR spectrum of Rh(A) (COD) shows resonances at 1.80–1.85 and 2.47–2.52 ppm

†The related Ir(A)(COD) complex (X) was similarly prepared from $[IrCl(COD)]_2$.[12]

($\diagdown$CH$_2$), 4.15 and 4.30 ppm (–CH = CH–) (COD ligand) and 1.70 (Me) and 7–8 ppm (Ph) (A ligand). The inequivalence of the olefinic protons is also observed for the dinuclear $Rh_2(A)_2(COT)$ compound [4.76 and 4.92 ppm (COT); 1.64 (Me) and 7–8 ppm (Ph) (A ligand)]. However in the Rh(A)(BQ) complex only one type of olefinic proton at 5.20 ppm is observed, along with the expected resonances of the A ligand [1.76 (Me); 7–8 ppm (Ph)]. These value are different from those published for the ligand (2.07 and 7.20–8.0 ppm,[4a] or 2.10 and 7.20–8.07[4d]), but are comparable with those of some metal complexes in the same solvent. In these the aryl signal is a multiplet between 7 and 8 ppm, while the methyl singlet is displaced to higher field than in the ligand: namely to 1.73 in $Zn(A)_2 \cdot EtOH$, 2.00 in $Be(A)_2$,[4b] or 2.05 in $Zr(A)_4$[3a].



Attempts to react the free nitrogen atom of the ligand A [complex (I)] with $[Au(PPh_3)S]^+$ (prepared from $AuCl(PPh_3)/AgClO_4$) or $AgClO_4$ were unsuccessful, in accord with the low basicity[2] of the nitrogen atom of ligand A.

h

Complex (I) reacts with two moles of triphenylphosphine or one mole of bis(1,4)-diphenylphosphino)butane (dppb) or excess of *tert*-butyl-isocyanide, with displacement of the cyclooctadiene ligand and formation of Rh(A)$(PPh_3)_2$ (XI), Rh(A)(dppb) (XII) or $Rh(A)(CNBu^t)_3$ (XIII). Since both (XII) and (XIII) were found to be monomers in chloroform solution, in the former the diphosphine must be chelating, rather than bridging, and the rhodium atom is four-coordinated while in the latter it is five-coordinated. Remarkably, the ionic [Rh(COD)-(phen)]A (XIV) complex is obtained by reaction with 1,10-phenanthroline, thus showing that the existence of the A^- anion is possible even though compounds of alkali or of alkaline earth metals, e.g. $Na(A) \cdot 2H_2O$ or $Ba(A)_2 \cdot 2H_2O$,[4b] were reported to have negligible electrical conductance values and, presumably, to be nonionic. Addition of iodine to complexes (I) and (X) produces the rhodium(III)-complex $Rh(A)(I)_2(COD)$ (XV) and the iridium(III) analogue $Ir(A)(I)_2(COD)$ (XVI).

The addition of AH to the solution obtained by refluxing $RhCl_3 \cdot XH_2O$ in dimethylformamide results in the formation of $Rh(A)(CO)_2$ (XVII). The latter complex can also be obtained by carbonylation of Rh(A)(COD), and in the solid state, it exhibits two strong ν(CO) bands (2015 and 2085 cm^{-1}) as expected for *cis*-dicarbonyl derivatives, in contrast with other $Rh(X)(CO)_2$ complexes (HX = acetylacetone, tropolone, Schiff base from salicylaldehyde and an amine): in some of these the complex ν(CO) absorptions observed in the solid state are due to metal–metal interactions.[15,16] These are not possible here if at least one of the phenyl groups does not lie in the plane of the ligand. The position of the two carbonyl stretching frequencies is similar to those of other square planar Rh(I) derivatives such as $(OC)_2Rh$(acetylacetonato) (2083 and 2015 cm^{-1} in petroleum ether)[17] or $(OC)_2Rh(\mu$-pyrazolato-*N*,*N*')BH_2 (2082 and 2013 cm^{-1} in cyclohexane):[18] it is, then, evident that the asymmetric A^- ligand has the same net effect on the groups *trans* to itself as other symmetric O,O'- or *N*,*N*'-chelating ligands.

k

As with the corresponding β-diketonates, triphenylphosphine reacts with the complex (XVII) with displacement of only one CO group and formation of $Rh(A)(CO)(PPh_3)$ (XVIII): this shows only one intense and broad CO stretching vibration in Nujol mull (1985 cm^{-1}) and in dichloromethane solution (1985 cm^{-1}). For the compound (XVIII) two isomers, **h** and **k**, are possible which are likely to show overlapping ν(CO). However their presence can be detected through ^{13}C- or ^{31}P-NMR spectroscopy. Indeed, in the latter case in the $^{31}P\{^1H\}$-NMR spectrum (see Table 2), a stronger and a weaker signal is present, each signal is coupled with ^{103}Rh, and the two ^1J (^{103}Rh–^{31}P) coupling constants are nearly the same. This similarity suggests, in turn, a very similar *trans*-influence of each oxygen donor atom so that the reaction of (XVII) with PPh_3 affords an appreciable quantity of each isomer. On the other side with asymmetric β-diketonates or with other asymmetric ligands (e.g. 8-hydroxyquinolinato) the isolation of a single isomer is reported to be due to a different *trans*-influence of the donor atoms.[6]

The complex (XVIII) undergoes oxidative addition with methyl iodide or with iodine affording (XIX) or (XX), respectively. Since the starting

Table 2. ^{31}P-NMR spectra

Compound	δ_P(ppm)	^1J(Rh-P) (Hz)
Rh(A)(CO)(PPh_3)	45.8[b]	179.9
(XVIII)	49.8	177.0
Rh(A)$(I)_2$(CO)(PPh_3)	24.3[b]	107.3
(XX)	25.9	106.5
Rh(A)(Me)(I)(CO)(PPh_3)	28.0[b,c]	135,140
(XIX)	28.3[c]	108[d]

[a]$CDCl_3$ solution at room temperature. All signals are doublets and lie downfield from reference, external 85% phosphoric acid. [b]more intense signal. [c]this doublet is formed by two overlapping doublets. [d]the difference between the two coupling constants is less than 5 Hz.

material contains the two isomers, addition of X–Y to **h** will give isomers **l** and **m**, while addition to **k** will give **n** and **o**:

Correspondingly the phosphorus NMR spectrum of (**XIX**) (Table 2) contains two pairs of nearly overlapping doublets each being due to two of the four isomers described above with one more abundant than the other (*ca.* 1 : 3), in agreement with the different relative abundance of the isomers **h** and **k** in the starting compound (**XVIII**).

In the special case where X = Y = iodine, then **l** = **m** and **n** = **o**. Correspondingly the spectrum of (**XX**) contains only two doublets, with different relative intensity (*ca.* 1 : 2) as required by the presence of only two isomers with different relative abundance.

Both phosphorus chemical shifts and coupling constants for this type of octahedral isomers are likely to be rather similar, as shown e.g. by the ^1J(Rh–P) values for the P atom *trans* to chlorine in *mer*- or in *fac*-$(Et_3P)_3RhCl_3$: 114 and 112 Hz, respectively.[19] Therefore, while the similarity of the values recorded for our species must correspond to closely related isomers and does not suggest a rearrangement of the ligands during oxidative addition, assignment of each doublet to each isomer is not possible.

Independent confirmation of the presence of the four isomers of (**XIX**) or of the two isomers of (**XX**) might come from their ^{13}C- or ^{1}H-NMR spectra: different chemical shifts or different coupling constants with ^{103}Rh should be observed for the methylrhodium moiety of (**XIX**). Infrared spectral evidence is not conclusive since the carbonyl stretching vibration is likely to be found in the same range as that of the other isomers. Nevertheless, the infrared spectrum of (**XX**) does show two equally intense ν(CO) in Nujol mull: these are

due to solid state splitting since they are not present when the measurement is carried out in dichloromethane solution.

EXPERIMENTAL

The C, H and N analyses were made with a Perkin–Elmer 240-B microanalyzer, the IR spectra were recorded on a Perkin–Elmer 599 spectrophotometer (over the range 4000–200 cm^{-1}) using Nujol mulls between polyethylene sheets or in dichloromethane solutions. Molecular weights were measured with a Perkin–Elmer 115 osmometer. Conductivity was measured in 5×10^{-4}M acetone solutions, with a Philips 9509 conductimeter. The ^{1}H-NMR spectra were recorded on a Varian XL-200 instrument.

The ligand 1 - phenyl - 3 - methyl - 4 - benzoyl - pyrazolone - 5 (m.p. 91°C) was prepared according to the published method.[1b]

Preparation of Rh(A)(COD) **(I)** *and related complexes* **[(II)–(V), (VIII)–(X)]**

(i) $[RhCl(COD)]_2$[7] (246.5 mg, 0.5 mmol) was added with stirring to a solution of the ligand AH (278.3 mg, 1 mmol) and NEt_3 (139.1 μl, 1 mmol) in methanol (25 cm^3). The precipitate formed was stirred for 2 hr and then filtrated off and washed with methanol.

(ii) TlA (240.84 mg, 0.5 mmol) was added to a solution of $[RhCl(COD)]_2$ (123.3 mg, 0.25 mmol) in dichloromethane (25 cm^3). The formed TlCl was filtered off, and the complex was precipitated by the addition of methanol.

The complexes **(II)–(V)** and **(VIII)–(X)** were similarly prepared by the two routes described above, starting from 0.5 mmol of the corresponding dimers $[RhCl(diolefin)]_2$,[8,9] $[RhCl(monoolefin)_2]_2$,[10,11] $[RhCl(C_3H_5)_2]_2$,[14] $(IrCl(COD)]_2$[12] and $[Rh_2Cl_2(COT)]_n$.[13] (Methanol/water (1/1) was used for the precipitation of complex **(IX)**).

Preparation of TlA (VI)

Tl(acac) (151.7 mg, 0.5 mmol) was added with stirring to a solution of AH (139.1 mg, 0.5 mmol) in dichloromethane (25 cm^3). The precipitate formed was filtered off and washed with dichloromethane.

Preparation of Rh(A)(BQ) (VII) *and related complexes* **[(XI)–(XIV)]**

To a solution of $Rh(A)(C_2H_4)_2$ **(IV)** (109.1 mg; 0.25 mmol) in diethyl ether (50 cm^3) under nitrogen, was addeed the stoichiometric amount of benzoquinone (BQ) (27.1 mg, 0.25 mmol). A precipitate formed immediately; which was filtered off, and washed with diethyl ether.

The complexes **(XI)–(XIV)** were obtained in a similar way by adding a calculated amount of the corresponding ligand to a solution of Rh(A)(COD) **(I)** (122.1 mg, 0.25 mmol) in diethyl ether (50 cm^3) under nitrogen. The ionic [Rh(COD)(phen)]A was obtained when 1,10-phenantroline was used.

Preparation of $Rh(A)(CO)_2$ **(XVII)**

(i) Carbon monoxide was bubbled through a solution of Rh(A)(COD) (122.1 mg, 0.25 mmol) in dichloromethane (25 cm^3) for 30 min. The complex was obtained by addition of hexane.

(ii) A mixture of $RhCl_3 \cdot xH_2O$ (100 mg) and an excess of ligand AH (90 mg) in dimethylformamide (10 cm^3) were refluxed for 1 hr. The complex was precipitated by the addition of water and recrystallized from dichloromethane–hexane.

Preparation of $Rh(A)(CO)(PPh_3)$ **(XVIII)**

PPh_3 (65.6 mg, 0.25 mmol) was added to a solution of $Rh(A)(CO)_2$ (109.1 mg, 0.25 mmol) **(XVII)** in dichloromethane (25 cm^3). The complex was separated by the addition of hexane.

Preparation of $M(A)(I)_2(COD)$ M = Rh**(XV)**, Ir**(XVI)**

To a stirred solution of M(A)(COD) (M = Rh(I) (122.1 mg, 0.25 mmol), Ir(X) (144.4 mg, 0.25 mmol) in diethyl ether (50 cm^3) was added dropwise a solution of the stoichiometric amount of iodine in ether (5 cm^3). The resulting precipitate was filtered off, and washed with diethyl ether.

Preparation of $Rh(A)(Me)(I)(CO)(PPh_3)$ **(XIX)**

A solution of $Rh(A)(CO)(PPh_3)$ **(XVIII)** (335.3 mg, 0.5 mmol) in methyl iodide (50 cm^3) was stirred for 1 hr and then, evaporated *in vacuo*. Crystallization was induced by the addition of diethyl ether.

Preparation of $Rh(A)(I)_2(CO)(PPh_e)$ **(XX)**

A solution of $Rh(A)(CO)(PPh_3)$ **(XVIII)** (335.3 mg, 0.5 mmol) in dichloromethane (50 cm^3) was treated with a stoichiometric amount of iodine (126.9 mg, 1 mmol). After stirring for 1 hr the solution was concentrated *in vacuo;* slow addition of ether gave the compound.

(*Received* 3 *January* 1984; *accepted* 23 *June* 1984)

Abstract—Lanthanide(III) chlorosulphates, $Ln(SO_3Cl)_3$ (Ln = La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Ho and Er) have been synthesized by solvolytic reaction of chlorosulphuric acid on the corresponding benzoates. The low conductivity values and the IR spectra of these compounds suggest a cation–anion interaction leading to covalent bonding. The bands observed in the reflectance spectra and the values of magnetic moments may indicate a coordination number of 6 for these metals, with bidentate chlorosulphate groups.

Edwards *et al.*[1] indicated a quantitative comparison of transition metal fluoro- and chlorosulphates obtained by the reaction of halosulphuric acid on corresponding halides with interhalogen or alkali interhalogens. They have shown that the transition metal fluoro- and chlorosulphates are prepared more conveniently by displacement reactions of halosulphuric acid. Later Robinson and Ciruna[2] prepared alkali and alkaline earth metal chlorosulphates with excess of chlorosulphuric acid serving as chlorosulphonating agent as well as the medium of reaction. Recently, there have been several reports of the synthesis of covalent metal chlorosulphates[3–5] and oxychlorosulphates.[6–8] Here we report the synthesis and characterization of lanthanide(III) chlorosulphates.

EXPERIMENTAL

Pure chlorosulphuric acid (Riedel), cerium oxide (BDH), neodymium oxide, gadolinium oxide, samarium oxide, dysprosium oxide, proseodynium oxide, lanthanum oxide (all Indian Rare Earth Ltd) holmium oxide, erbium oxide and terbium oxide (Koch–Light) were used as received.

N,*N*′-dimethyl formamide (E. Merck) was used after drying over KOH followed by distillation. Thionyl chloride (E. Merck) was used after distillation. Sodium benzoate (E. Merck) was used as received.

Preparation of lanthanide benzoate[9]

The metal oxide (2 g) was made into a paste by adding 5 cm^3 water and mixing. The paste was dissolved in 6 cm^3 6.0 *M* HCl. The solution was neutralized to incipient precipitation with 1 *N* NH_4OH adjusted to pH 2 with 1 *M* HCl. The solution was diluted to 200 cm^3, warmed up to near boiling and then treated with 40 cm^3 1 *M* sodium benzoate over a period of 1 h. The mixture was digested for about 4 h, cooled and filtered, washed free from chloride ions and vacuum dried. The product was dehydrated at 85°C.

Synthesis of rare earth metal tris(chlorosulphates) $Ln(SO_3Cl)_3$ (Ln = La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Ho *and* Er)

The dehydrated metal benzoates (~ 5 g) were added in portions to excess chlorosulphuric acid (~30 cm^3) kept in a closed reaction vessel and the temperature of the reaction mixture was not allowed to rise above 40°C. The reaction which was very vigorous was allowed to subside, after which the solution was magnetically stirred for about 6 h. The solid compounds formed were vacuum-filtered, washed several times with chlorosulphuric acid and lastly with thionyl chloride and dried under vacuum at 60–80°C to a constant weight.

The elements chlorine and sulphur were estimated according to usual gravimetric methods,[10] while metals were estimated by EDTA titration using bromopyrogallol red and Eriochrome Black T as indicators.[11]

The IR spectra were recorded on a Perkin–Elmer 621 spectrophotometer as Nujol mulls, contained in envelope cells of thin polyethylene film sealed from all sides.

Diffuse reflectance spectra were taken on a Carl–Zeiss VSU-2P spectrophotometer using MgO as the reflectance standard.

The electrical conductivities of 1 m*M* solutions of the metal chlorosulphate dissolved in DMF were obtained using a Systronic type 302 conductivity bridge thermostatted at 25 ± 0.05°C. The magnetic susceptibility measurements were carried out by using a Model 155 vibrating sample magnetometer at 23°C. All manipulations were done in a dry-box under dry nitrogen.

RESULTS AND DISCUSSION

The results of elemental analyses (Table 1) are in agreement with the proposed composition,

$Ln(SO_3Cl)_3$ (Ln = La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Ho and Er).

The probable structure of and mode of bonding in the present metal chlorosulphates have been proposed after carefully examining the observed frequencies characteristic of the chlorosulphate group in the IR spectra.

The IR spectra (Table 2) show a lowering of the C_{3v} symmetry of the free chlorosulphate ion. This would be sufficient to produce nine normal modes of vibration for SO_3Cl^- irrespective of the mode of coordination of the anion (except Cl coordination).

The observed magnetic moments for a few metal tris(chlorosulphates) at room temperature are comparable with the distorted octahedral rare earth compounds. The results of the magnetic susceptibility measurement and spectral studies indicate a distorted octahedral geometry for those compounds having a coordination number of 6 for the metal, which is unlike that reported[12] for the corresponding fluorosulphates.

STUDIES OF METAL CHELATES WITH THE NOVEL LIGAND 2,2,7-TRIMETHYL-3,5-OCTANEDIONE

THOMAS J. WENZEL,*† ERIC J. WILLIAMS, R. CURTIS HALTIWANGER‡ and ROBERT E. SIEVERS*

Department of Chemistry and Cooperative Institute for Research in Environmental Sciences, University of Colorado, Boulder, CO 80309, U.S.A.

(*Received* 4 *February* 1984; *accepted* 25 *July* 1984)

Abstract—The synthesis of the novel ligand 2,2,7-trimethyl-3,5-octanedione, H(tod), is described, as well as the preparation of some of the transition metal and lanthanide complexes containing the anion of this unsymmetrical beta-diketone ligand. The structure of $Cu(tod)_2$ has been determined by X-ray crystallography to be square-planar with the isobutyl groups *cis* to each other. Thermogravimetric analyses indicate that several of these metal complexes are volatile and thermally stable compounds. Metal complexes containing this ligand also show unusually high solubilities in non-polar solvents such as *n*-hexane. The properties of these compounds indicate that they may be useful for vapour-plating of metals, as fuel additives, and in other applications.

Metal chelate complexes with beta-diketone ligands have been employed for a variety of interesting applications including gas chromatography and trace analysis of metals,[1–13] solvent extraction of metals,[14–18] vapor-plating of metals,[19,20] and fuel additives.[21–25] Metal chelates of the novel ligand 2,2,7-trimethyl-3,5-octanedione, H(tod), have a number of properties that make them ideal candidates for some of the above applications. Several of the metal complexes of this ligand are volatile and thermally stable. These metal chelates are highly soluble in non-polar solvents, even more so than complexes of the isomeric ligand, 2,2,6,6-tetramethyl-3,5-heptanedione, H(thd). In addition, rare earth chelates of H(tod) exhibit antiknock activity and may catalytically eliminate some undesirable combustion products of fuels.[26,27] One final important property of the H(tod) ligand is that the starting materials for its synthesis, neopentanoic acid and methylisobutyl ketone, are much less expensive than those of H(thd) and fluorinated beta-diketones.

In this paper we describe the synthesis of H(tod) and the preparation of the Cr(III), Mn(III), Fe(III), Co(III), Ni(II), Cu(II), Pd(II), La(III) and Ce(IV) complexes with this ligand. The volatility and thermal stability of these chelates have been examined. The molecular structure of $Cu(tod)_2$ is shown, and the solubilities of $Cu(tod)_2$ in a variety of solvents, as well as the partition coefficient between octanol and water, are presented. Finally, an evaluation of some of these chelates for use in fields such as extraction of metal ores, vapour deposition of metals, and fuel combustion modification is discussed.

EXPERIMENTAL

Equipment

Mass spectra were measured with a Varian MAT CH5 single focussing spectrometer. Elemental analyses were performed by Huffman Laboratories (Wheatridge, CO). Reflection information for the crystal structure determination was collected by a Nicolet P1 autodiffractometer using Mo-K_α radiation. The thermogravimetric analyses were performed on a Perkin–Elmer TGS-2 Thermogravimetric Analysis (TGA) System. The sample was kept under a 60 cm^3 min^{-1} flow of dry helium and heated at 10° min^{-1}. Spectrophotometric analyses were performed on a Cary 219 UV-VIS Spectrophotometer or on a Perkin–Elmer Model 360 Atomic Absorption Spectro-

meter. pH values were measured by a Broadley-James pH electrode connected to a Model NX pH meter (Sargent–Welch).

Reagents

All reagents were used as received without further purification. Neopentanoic acid was a gift from Exxon Chemicals (Houston, TX). Sodium hydride and $PdCl_2$ were obtained from Alfa Div., Ventron (Danvers, MA). Methylisobutyl ketone, 1-octanol, hexanes, molecular sieves (3 and 4 Å), the transition metal salts and lanthanum(III) oxide came from Fisher Scientific (Fair Lawn, NJ). Molecular sieves (13X) were obtained from Linde Div. (South Plainfield, NJ). The rare earth chloride mixture was a gift from Molycorp (White Plains, NY). Cerium(III) nitrate hexahydrate, was obtained from Matheson, Coleman, and Bell (Cincinnati, OH). The chloride of La(III) was synthesized by dissolving the metal oxide (La_2O_3) in concentrated hydrochloric acid and evaporating to dryness.

Synthetic procedures

Preparation of 2,2,7-trimethyl-3,5-octanedione, H(tod). Two procedures were used for the synthesis of the ligand. Procedure 1 was used initially in order to obtain the highest purity of H(tod) for further synthetic work. Later, it was determined that procedure 2 would yield product of suitable purity for most purposes but with less time and effort expended. Both procedures are reported here.

Procedure 1

To a 2 l three necked round bottom flask was added a magnetic stirring bar, 67 g of sodium hydride (50% dispersion in mineral oil) and 350 cm^3 of dried (4 Å molecular sieves) toluene. The flask was immersed in a hot water bath atop a stirrer-hot plate and then fitted with a reflux condenser, a pressure-equalizing dropping funnel of at least 100 cm^3 capacity, and a glass inlet for a nitrogen purge gas system (dried by 13X molecular sieves). Ethyl pivalate* (107 cm^3) was added to the flask via one of the necks and methyl isobutyl ketone (88 cm^3) was added to the dropping funnel. Heat was applied to the water bath, stirring was begun and the purge gas was passed through the flask at a low flow rate. When the water bath boiled, the ketone was added at a rate of between 0.5 and 1.0 $cm^3\ min^{-1}$, such that the entire volume was dispensed over the course of about three hours. When the addition was complete, the green–yellow mixture was heated an additional 30 min and then allowed to stir overnight without heat but with the purge gas flowing.

The next day the flask was packed in an ice bath, and, while stirred vigorously with the purge gas flowing, 300 cm^3 of an 18% (6 *M*) aqueous hydrochloric acid solution was *slowly* added (caution: hydrogen evolution). When the neutralization was complete, the mixture was filtered to remove the suspended solids, which were discarded. The mixture was transferred to a separatory funnel, the organic layer was isolated and the solvent was removed by rotary evaporation.

The crude H(tod) was purified first by vacuum distillation (1 torr, 50–80°C) to separate the ligand from high-boiling but organic-soluble impurities. Next, the copper complex was synthesized, as described below, to isolate the beta-diketone from any by-products that are formed by self-condensation of the ketone. Crude $Cu(tod)_2$ (20 g) was placed in a 250 cm^3 separatory funnel with 30 cm^3 of hexane and 150 cm^3 of 10% (1 *M*) aqueous sulphuric acid, and the mixture was shaken until no blue colour remained in the organic phase. The organic solution was isolated and the solvent was removed by rotary evaporation, which left H(tod) of about 97–99% purity.

Procedure 2

To a 1 l round bottom flask to which was fitted a Claisen adaptor containing a reflux condenser and a pressure-equalizing dropping funnel, was added 67 g of sodium hydride, 350 cm^3 of freshly distilled ethyl pivalate, and a Teflon-covered magnetic stirring bar. The flask was fitted with a heating mantle and positioned above a magnetic stirring device. Methyl isobutyl ketone (88 cm^3) was added to the dropping funnel. A ground-glass adaptor, which served as the inlet for a dry helium purge gas system, was fitted to the dropping funnel and a low flow of helium gas (approximately 30 $cm^3\ min^{-1}$) was used to continuously purge the system of air and water vapour. Stirring was begun and heat was applied until the ester came to a low reflux. The ketone was dispensed at a rate such that the entire volume was added over the course of 4–5 h. Heating was continued for an additional 1 h, after which time the green–yellow mixture was left stirring under helium overnight at room temperature.

The next day the flask was packed in an ice bath and 120 cm^3 of absolute ethanol was added via the dropping funnel (caution: hydrogen is evolved and foaming occurs). Following the ethanol, 300 cm^3 of

*Synthesized by the acid-catalyzed condensation of ethanol and neopentanoic acid. Stored over anhydrous magnesium sulfate and distilled prior to use.

an 18% (6 *M*) aqueous hydrochloric acid solution was slowly added. During the neutralization the helium flow was continued and the mixture was stirred as vigorously as possible. When the neutralization was complete, the mixture was filtered through a coarse-pore sintered-glass funnel, the organic layer was isolated, and the bulk of the ester and alcohol was removed by rotary evaporation. The excess unreacted ester, which served as a solvent as well as a reactant, can be recycled in subsequent syntheses. The residue then was vacuum distilled and the fraction coming over at 53–55°C (1 torr) was collected. This pale yellow liquid consists of 90–95% H(tod). Yield: 82 g (61%).

The identity of the ligand was verified by gas chromatographic–mass spectrometric and proton nuclear magnetic resonance analyses. The IR spectrum of a neat sample between NaCl plates showed strong absorbances at 2900, 1600, 1450, 1350, 1300, 1220, 1130 and 950 cm^{-1}.

Preparation of tris(2,2,7-trimethyl-3,5-octanedionato)chromium(III), $Cr(tod)_3$. The $Cr(tod)_3$ complex was prepared by an earlier reported procedure.[28] To a mixture consisting of 67 cm^3 of distilled water and 173 cm^3 of ethanol was added 8 g of $CrCl_3 \cdot 6H_2O$, 15.4 g of H(tod), and 53.3 g of urea. The mixture was stirred and heated under reflux for 20 h. When the mixture had cooled to room temperature 200 cm^3 of distilled water was added, and a dark purple oil formed, which was extracted into hexane. This solution was filtered and the solvent removed by rotary evaporation. Sublimation of the oil gave a solid material that was re-sublimed to yield $Cr(tod)_3$. M.p.: 122–123°C. Found: C, 65.88; H, 9.82. Calc. for $Cr(C_{11}H_{19}O_2)_3$: C, 65.86; H, 9.55%. A molecular ion corresponding to $Cr(tod)_3^+$ is observed in the mass spectrum of this product.

Preparation of tris(2,2,7-trimethyl-3,5-octanedionato(manganese(III), $Mn(tod)_3$. To 100 cm^3 of methanol in an open beaker exposed to oxygen in the air was added 7.7 g of manganese(II) acetate tetrahydrate with stirring. After the solution turned from light pink to brown (about 15 min), 18.4 g of H(tod) was added at once with stirring. The solution was stirred for about 30 min, during which time the pH was brought up to a value of 8 by dropwise addition of 4 *M* aqueous NaOH (about 25 cm^3). After 30 additional minutes the precipitate that had formed was collected by suction filtration, dissolved in hexanes and filtered through a medium porosity sintered glass funnel. The solvent was removed by rotary evaporation and the resulting dark oil solidified on standing overnight. Recrystallization from hot methanol resulted in brown flakes that were collected by filtration. M.p.: 88–90°C. Found: C, 64.89; H, 9.42. Calc. for $Mn(C_{11}H_{19}O_2)_3$: C, 65.54; H, 9.50%. The mass spectrum of this compound shows a molecular ion corresponding to $Mn(tod)_3^+$.

Preparation of tris(2,2,7-trimethyl-3,5-octanedionato)iron(III), $Fe(tod)_3$. To 1 g of $FeCl_3 \cdot 6H_2O$ in 3 cm^3 of distilled water was added 50 cm^3 of a saturated aqueous sodium acetate solution. To this solution was added a mixture of 2 g of H(tod) in 15 cm^3 of ethanol and, the solution was stirred overnight. The bright red solid that resulted was collected by suction filtration and dissolved in hexanes. This solution was filtered and the solvent removed by rotary evaporation. Sublimation gave the bright red $Fe(tod)_3$. M.p.: 78–80°C. Found: C, 65.55; H, 9.64. Calc. for $Fe(C_{11}H_{19}O_2)_3$: C, 65.44; H, 9.49%. The mass spectrum of this product exhibits a molecular ion corresponding to $Fe(tod)_3^+$.

Preparation of tris(2,2,7-trimethyl-3,5-octanedionato)cobalt(III), $Co(tod)_3$. Cobalt(II) nitrate hexahydrate (5.8 g) was dissolved in 60 cm^3 of 50% aqueous ethanol in an open beaker and a solution of 11.0 g of H(tod) in 30 cm^3 of ethanol was stirred in. A solution of 2.6 g of NaOH dissolved in 50 cm^3 of aqueous ethanol was stirred into the above solution, and the combined solution turned bright pink. This solution was warmed to *ca* 50–60°C and stirred for 2 h, over which time the solution turned dark green. After 2 h the solution was filtered through a medium porosity sintered-glass funnel and the filtrate extracted with hexanes. Removal of the solvent by rotary evaporation left a dark green oil which solidified in a vacuum oven (1 torr, 90°C) after 3 h. This solid was dissolved in hexanes, filtered through a medium pore glass funnel and the solvent allowed to evaporate overnight in a hood to dryness. The product, $Co(tod)_3$, was a dark green powder. M.p.: 152–157°C. Found: C, 64.83; H. 9.48. Calc. for $Co(C_{11}H_{19}O_2)_3$: C, 65.11; H, 9.44%. The mass spectrum of this compound shows a molecular ion at *m/z* 608, which corresponds to $Co(tod)_3^+$.

Preparation of bis(2,2,7-trimethyl-3,5-octanedionato)nickel(II), $Ni(tod)_2$. To a solution of 5.0 g of nickel(II) acetate tetrahydrate in 50 cm^3 of hot water was added a solution of 12.0 g of H(tod) in 40 cm^3 of methanol. The pH was adjusted to about 8 by adding concentrated ammonium hydroxide. The solution was stirred for 30 min, then decanted, leaving in the beaker a thick turquoise-coloured oil. This oil was dissolved in 50 cm^3 of hexanes and filtered through a medium porosity sintered glass funnel. Removal of the solvent produced bright green crystals, which were recrystallized from hot methanol. Vacuum sublimation and subsequent drying *in vacuo* at 110°C over P_4O_{10} produced a bright green product. M.p.: 146–148°C. Found: C, 62.12; H, 9.09. Calc. for $Ni(C_{11}H_{19}O_2)_2$: C, 62.14; H,

9.01%. The mass spectrum shows a molecular ion that is characteristic of $Ni(tod)_2^+$, with the isotope pattern expected for ions containing nickel.

Preparation of bis(2,2,7-trimethyl-3,5-octanedionato)copper(II), $Cu(tod)_2$. The $Cu(tod)_2$ complex was synthesized by a previously described procedure for preparing Cu(II) beta-diketonates.[29] To 100 cm^3 of the vacuum-distilled organic residue obtained from the synthesis of the ligand was added 300 cm^3 of methanol. Cupric acetate hydrate (40 g) was added to 500 cm^3 of distilled water and heated to just below the boiling point. The hot solution was filtered directly into the stirred H(tod) solution. The resulting mixture was allowed to stand for 4 h, and the solid that formed was collected by suction filtration and washed with cold methanol. Recrystallization from hexanes gave a purple powder. M.p.: 116–117°C. Found: Cu, 14.47; C, 61.48; H, 8.89. Calc. for $Cu(C_{11}H_{19}O_2)_2$: Cu, 14.77; C, 61.44; H, 8.91%.

Preparation of bis(2,2,7-trimethyl-3,5-octanedionato)palladium(II), $Pd(tod)_2$. $Pd(tod)_2$ was prepared by a modification of a reported procedure.[30] To a suspension of 0.9 g of $PdCl_2$ in a mixture of 25 cm^3 of methanol and 25 cm^3 of distilled water was added a solution of 2.3 g of H(tod) in 10 cm^3 of methanol. After the mixture was stirred for one hour, the solid material which had formed was recovered by suction filtration and dissolved in hexanes. The hexane solution was filtered and the solvent removed by rotary evaporation to yield bright orange–yellow crystals. Sublimation *in vacuo* gave the desired product, $Pd(tod)_2$. M.p.: 152–156°C. Found: C, 56.32; H, 8.74. Calc. for $Pd(C_{11}H_{19}O_2)_2$: C, 55.87; H, 8.10%. The mass spectrum of this product exhibits a molecular ion corresponding to $Pd(tod)_2^+$ with the isotope pattern characteristic of Pd-containing ions. The asymmetry of the ligand causes both *cis* and *trans* isomers of the complex to be formed. The proton NMR spectrum of $Pd(tod)_2$ exhibits distinctive resonances for both isomers, with one of the isomers predominating.

Preparation of tris(2,2,7-trimethyl-3,5-octanedionato)lanthanum(III) dihydrate, $La(tod)_3 \cdot 2H_2O$. The synthesis of this compound was accomplished by a ligand exchange between $LaCl_3 \cdot 7H_2O$ and $Ba(tod)_2$. The $Ba(tod)_2$ was prepared by adding 5.9 g of $Ba(OH)_2$ to 27 cm^3 of water and heating the solution to boiling. The hot solution was filtered directly into a solution of 10 g H(tod) in 10 cm^3 of methanol. After the mixture was stirred overnight, the white $Ba(tod)_2$ that had formed was collected, dried *in vacuo* over P_4O_{10}, and used directly in the ligand interexchange synthesis.

The $La(tod)_3 \cdot 2H_2O$ was prepared by adding a warm solution of 0.5 g $LaCl_3 \cdot 7H_2O$ in 20 cm^3 of ethanol to a warm solution of 1 g $Ba(tod)_2$ in 60 cm^3 of ethanol. A fine precipitate, presumably $BaCl_2$, formed immediately, and the mixture was heated and stirred for 90 min. The solution was filtered through a 5-micron Millipore filter to remove the $BaCl_2$. The ethanol was removed to leave a thick yellow oil that gradually solidified on standing. Recrystallization from hexanes gave an off-white solid. M.p.: 95–97°C. Found: C, 54.01; H, 7.92. Calc. for $La(C_{11}H_{19}O_2)_3 \cdot 2H_2O$: C, 54.69; H, 8.48%. The mass spectrum of this product shows a molecular ion corresponding to anhydrous $La(tod)_3$.

Preparation of tetrakis(2,2,7-trimethyl-3,5-octanedionato)cerium(IV), $Ce(tod)_4$. Ten grams of $Ce(NO_3)_3 \cdot 6H_2O$ was dissolved in 30 cm^3 of methanol. To this solution was added a solution of 17 g of H(tod) in 50 cm^3 of methanol. The solution was stirred and 4 *M* aqueous NaOH was slowly added until pH was approximately 7. During the addition of base, the solution gradually turned a dark red colour and precipitate started to settle out at about pH 6.4. The entire mixture was then added to a separatory funnel: distilled water (100 cm^3) and hexanes (75 cm^3) were added, and the $Ce(tod)_4$ was extracted into the organic phase. This layer was collected, filtered through a medium porosity sintered glass funnel, and the solvent in the filtrate was removed by rotary evaporation. Dark red crystals of $Ce(tod)_4$ (m.p.: 134–136°C) were collected.

When crude H(tod) was used without purification [via $Cu(tod)_2$], a dark red oil was obtained rather than crystals. In this case crystallization was achieved by dissolving the oil in about 100 cm^3 of hexanes and adding this solution to 400 cm^3 of 95% ethanol. Upon standing overnight crystals of $Ce(tod)_4$ formed and were collected by suction filtration. These were dissolved in hexanes and filtered through a medium porosity sintered-glass funnel. The solvent was removed by rotary evaporation, leaving dark red crystals of $Ce(tod)_4$. Found: C, 60.05; H, 8.66. Calc. for $Ce(C_{11}H_{19}O_2)_4$: C, 60.51; H, 8.77%. The mass spectrum of this compound shows a peak at *m/z* 872, corresponding to the molecular ion, $Ce(tod)_4^+$.

Preparation of mixed rare earth chelates of H(tod), $RE(tod)_x$. A mixture of all the hydrated rare earth chlorides was employed. The percent of each metal was governed by the amount occurring in the oxide extract of the ore. In samples of roasted leachates from bastansite ore from the Molycorp (Union Oil Co.) mine at Mountain Pass, CA, the basic composition was found to be 50% cerium, which forms the $Ce(tod)_4$ chelate, and 50% other lanthanides, principally La(III), Nd(III), and Pr(III), which may consist of chelates of the formula $RE(tod)_3$ and $RE(tod)_2(OH)$. One mole of the rare

earth chloride mixture (approximate molecular weight of the hydrated chloride is 356 g mol^{-1}) was mixed with 3.5 moles of H(tod).

To 162 g of the powdered rare earth chloride mixture dissolved in 100 cm^3 of absolute methanol was added 304 g of H(tod) which previously had been dissolved in 300 cm^3 of absolute methanol. The mixture was stirred with an overhead stirring apparatus while 4 *M* aqueous NaOH was slowly added to bring the pH up to 8. As the pH increased, a thick, dark red oil formed and settled to the bottom of the beaker. The methanol–water layer was decanted and the red oil was dissolved in hexanes. This solution was filtered through a medium porosity glass funnel and the solvent was removed by rotary evaporation. Crystallization of the $RE(tod)_x$ mixture, which appeared in the form of a dark red oil, was achieved by dissolving approximately 100 g of the oil in 300 cm^3 of hexanes and adding this solution to 1000 cm^3 of 95% ethanol. This solution was allowed to stand overnight, during which time plate-like crystals and a solid glassy material formed on the bottom of the beaker. The crystals, collected by suction filtration, were dark red in colour while the glassy material was a much lighter rust colour. Both solids were recrystallized from hexanes, and when analyzed for metal content by X-ray fluorescence showed different ratios of lanthanides.[27] The $RE(tod)_x$ mixture exhibits a mass spectrum that is characteristic of a composite of the various metal : tod complexes.

Structure determination

The structure was determined by direct methods. Single crystals in the form of blue plates were prepared by recrystallization of purified $Cu(tod)_2$ from absolute methanol. The unit cell was found to be monoclinic (space group : $P2_1/n$) with dimensions $a = 20.369(4)$ Å, $b = 10.371(2)$ Å, $c = 11.526(2)$ Å, $\beta = 90.04(1)°$, and volume of 2435(1) $Å^3$. The density of $Cu(tod)_2$ was determined in aqueous $ZnBr_2$ solution and was found to be 1.15 g cm^{-3}. Using the value 430.1 g $mole^{-1}$ for the molecular weight, the calculated density for four molecules in the unit cell is 1.17 g cm^{-3}. The least squares refinement yielded $R = 0.065$ and $R_w = 0.080$. Atomic coordinates and thermal parameters and a list of F_o/F_c values has been deposited as supplementary material with the Editor.*

Solubility determinations

The solubilities of $Cu(tod)_2$ and $Cu(thd)_2$ were determined at room temperature and the method used depended on the concentration of the complex at equilibrium. When possible, measured filtered aliquots of a saturated solvent : chelate solution were subjected to gentle heat until the solvent had been removed, as evidenced by constant weight. A spectrophotometric method also was used in which 1 cm^3 filtered aliquots of the equilibrated solution were diluted to 10 cm^3 with hexanes and the visible absorption spectrum obtained over the range 450–900 nm. Standard solutions were made up in an identical fashion and the analytical wavelength used was the absorption maximum at 650 nm. A third method, which was used to evaluate aqueous samples, employed atomic absorption spectroscopy of acidified samples for Cu(II) using standard flame techniques. An extra step in determining the partition coefficient involved centrifuging the aqueous layer to remove any remaining octanol. The extraction isotherm was evaluated at room temperature using distilled water and kerosene.

RESULTS AND DISCUSSION

H(tod) at room temperature is a colourless liquid that shows high solubility in organic solvents, but not in water. The proton NMR spectrum of H(tod) in chloroform shows a doublet (0.90 ppm) and a complex multiplet (2.20 ppm), corresponding to the isobutyl protons, and singlets (1.17, 5.63 and 16.00 ppm), which correspond to tert-butyl protons, a methine proton, and an enol proton, respectively. The enol form of H(tod) is favoured over the keto form in deuterated chloroform by a factor of *ca* 6 to 1. The IR spectrum of H(tod) exhibits absorbances in the region 3000–700 cm^{-1} that are characteristic of the O—H, C—H, C=O and C—O groups, and the mass spectrum is consistent with expected fragmentations.

The metal chelates listed in the experimental section are generally highly coloured, powdery or crystalline materials, and are stable when exposed to air at room temperature. These complexes are highly soluble in organic solvents, but only very sparingly soluble in water. The IR spectra of the compounds are very similar and show broad absorptions with little fine structure.

The mass spectra of these complexes are also quite similar. Table 1 shows the most abundant fragments for all the metal chelates, and it can readily be seen that a number of fragments are common among the mass spectra. For example, all of the compounds show a molecular ion peak. Most of the chelates [except Ni(II)] show a fragment which corresponds to the loss of one ligand; the tris-chelates [except La(III)] exhibit loss of two ligands, as does the tetrakis-chelate of Ce(IV). Also, all of the complexes

* Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

* M = intact molecule: L = ligand.

show fragments that are indicative of the tod ligand, such as *m/z* 127, 85 and 57. Another interesting feature of the mass spectra of these complexes is that the solid probe temperature required to volatilize these compounds into the source of the mass spectrometer was always quite low, of the order of 200°C or less. Thus no special provision for vaporization or ionization, such as fast atom bombardment, is needed to acquire these mass spectra, which makes these chelates quite attractive for such analytical techniques as metal isotope ratio measurements or isotope dilution–mass spectrometry in metal determinations.

Crystal and molecular structure of $Cu(tod)_2$

The structure of $Cu(tod)_2$, shown in Fig. 1 along with the atomic numbering scheme, is similar to that of the isomeric chelate $Cu(thd)_2$, the structure of which had been determined previously.[31] $Cu(tod)_2$ crystallizes in the *cis*-configuration and is monomeric and approximately square planar. There was no evidence of the presence of any *trans* isomer in any of the crystalline samples, but the *trans* isomer may exist in solution and be interconverted as the *cis* isomer .crystallizes. Selected bond angles and distances are given in Table 2.

It is apparent from the edge-on view of the molecule in Fig. 1 that the molecule contains no inversion centre since the two chelate rings are not exactly planar. This geometry is different from that reported for $Cu(thd)_2$[31] and $Ni(thd)_2$,[32] which contain centres of inversion. This difference is likely due to packing stresses induced in the molecule when an isobutyl moiety is substituted for a tert-butyl group in the ligands with subsequent loss of symmetry.

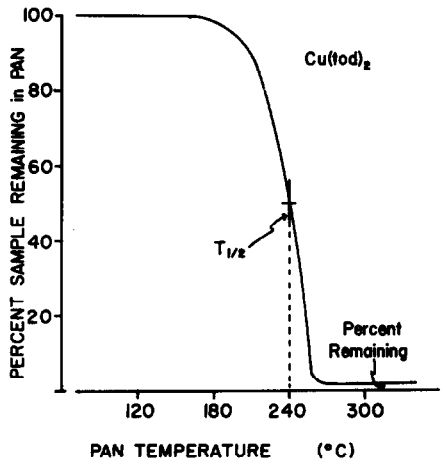

Fig. 2. Thermogram of $Cu(tod)_2$.

Thermogravimetric analyses

In the thermogravimetric analyses the sample was continuously weighed under a flow of helium, while the temperature was increased at 10°C min^{-1}. The important information gained from the analysis includes an estimate of the volatility and the gross thermal stability of the complex. If thermal decomposition is negligible under the conditions required for vaporization, one rapid way to compare volatilities of complexes is to measure the temperatures at which half the sample weight is lost and the amount and appearance of any residue remaining in the pan at the end of the heating (see Fig. 2). The former is a measure of the volatility of a compound and the latter is a measure of the thermal stability.

The results of the thermogravimetric analysis of metal chelates of tod are shown in Table 3. Most of the complexes are reasonably volatile and thermally stable. Some, such as the chelates of Mn(III), Ce(IV) and La(III), show appreciable residue under these heating conditions, though even these samples are partially vaporized without decomposition.

Table 2. Selected bond distances and angles for $Cu(tod)_2$

Bond	Distance (Å)	Bond	Angle (°)
Cu—O1	1.889(7)	O1—Cu—O2	92.7(3)

Solubility and extraction studies

The solubilities of $Cu(tod)_2$ and the isomeric chelate, $Cu(thd)_2$, in various solvents are shown in Table 4. It can be seen from these data that $Cu(tod)_2$ is at least twice as soluble in these solvents as $Cu(thd)_2$.

The partition coefficient of $Cu(tod)_2$ distributed between 1-octanol and water was also determined. This value (normally reported[33] as log P_{oct}), is 3.64 $\pm$0.20; high values such as this have often previously been taken as an indication a compound is likely to be highly soluble in lipids.[33] A qualitative test showed that $Cu(tod)_2$ formed a deep blue clear solution when dissolved in melted bacon fat. While bioavailability of metal ions depends on complex factors, $Cu(tod)_2$ might be useful as a source of Cu(II) for individuals who suffer from copper deficiency diseases, such as Menkes syndrome.[34] Until toxicity data are available care should be taken in handling these compounds in the laboratory. Accidental exposure of $Cu(tod)_2$ under a fingernail resulted in blue staining that did not disappear for several days.

The high solubility of $Cu(tod)_2$ further indicated that this ligand is of potential use in the solvent extraction of metals, such as in the recovery of metals from leached ores. In order to evaluate this potential, an extraction isotherm was determined and is shown in Fig. 3. The isotherm indicates that H(tod) in kerosene will efficiently extract copper from an aqueous solution at pH values greater than 5. Another experiment was conducted to determine the effectiveness of H(tod) in extracting aqueous solutions of high copper concentrations, such as those typically found in ore leachate solutions.[18] A 50% by volume solution of H(tod) in kerosene (100 cm^3 total solution) was used to extract successive 100 cm^3 aliquots of an aqueous ammoniacal solution containing approximately 15 g Cu l^{-1} at pH 11. After five extractions the concentration of copper in the organic phase was 59 g Cu l^{-1}. Assuming stoichiometry of two ligands per metal ion, the theoretical maximum is 77 g Cu l^{-1} and the extraction efficiency is 77%. These experiments indicate that H(tod) is an effective and inexpensive extraction agent.

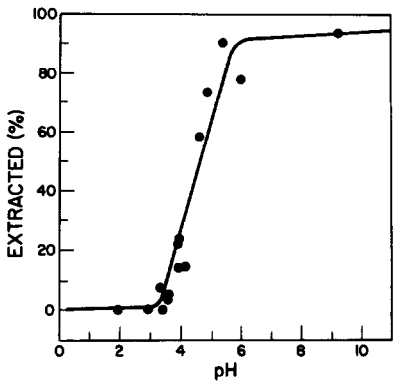

Fig. 3. Extraction isotherm for water: kerosene system using aqueous Cu(II) and H(tod) in kerosene.

Vapour deposition

In vapour deposition experiments the metal chelate was heated under a flow of a gas until it was vaporized and was transported to a target heated at substantially higher temperatures. When the vapours contacted the hot target, a layer of the metal was deposited and the organic by-products swept away by the gas flow. This technique has previously been tested with other metal chelates[19,20] with varying degrees of success. In favourable cases the plated surface has been found to be conducting and of high purity. The process allows good control of the uniformity and thickness of the film, and the metal can be deposited in intricate patterns determined by selective heating. In some of the more successful previous studies, complexes with ligands containing fluorinated substituents, primarily 1,1,1-trifluoro-2,4-pentanedione and 1,1,1,5,5,5-hexafluoro-2,4-pentanedione, were employed. Although the complexes are more volatile, these ligands are relatively expensive while the complexes synthesized from H(tod) offer a much less expensive alternative.

The $Cu(tod)_2$ complex was tested for its utility in vapour-plating. Passage of the vaporized complex in a flow of nitrogen through a glass tube maintained at about 350°C in an oven resulted in a copper deposit on the walls of the tube. In previous studies[19,20] hydrogen was usually used as the carrier gas as well as the metal reducing agent. In those experiments the effluent material was trapped in a cold trap and found to consist of some of the original metal complex and some ligand. In our experiments, since nitrogen is not capable of acting as a reductant, the metal plating is a result of thermal decomposition of

the chelate. The organic products of the thermal decomposition were trapped in a liquid nitrogen cold trap and analyzed by gas chromatography–mass spectrometry. The only peak observed in the chromatogram corresponded to H(tod) ligand. The regeneration of H(tod), which can be used to synthesize more $Cu(tod)_2$, is particularly fortunate because it offers the possibility of cyclic transport and deposition processes. Other decomposition products may not have been readily detectable by gas chromatography–mass spectrometry. In previous studies of the thermal decomposition of metal chelates of 2,4-pentanedione, compounds such as CO_2, methane, acetone and the ligand were observed.[35,36] Our procedure would not detect CO_2 or methane, but ketones, such as methylisobutyl ketone and pinacolone, were not observed.

This technique should be applicable for a wide range of metal complexes of tod, especially those that were shown by thermogravimetric analysis to be volatile and reasonably thermally stable.

Fuel additive studies

In previous studies by Sievers and coworkers[21–24] and Hartle,[25] certain rare earth beta-diketonate complexes were found to possess antiknock activity. The lanthanides are considerably less toxic than presently used lead additives[37] and are less likely to foul noble metal catalysts, a problem associated with lead and manganese fuel additives.

The β-diketonate compounds most studied for their antiknock ability are the rare earth chelates of 2,2,6,6-tetramethyl-3,5-heptanedione. In the earlier studies the Ce(IV) complex was found to be superior to any of the other individual lanthanides, but a mixture of all the rare earth : thd complexes can be used without significant sacrifice in effectiveness. Rare earth ores from the Molycorp mine (the largest supplier of rare earths in the U.S.) yield concentrates in which Ce constitutes about 50% of the metal content. 50% in cerium.

Another potential benefit of using rare earth chelate fuel additives is that their utilization may catalytically eliminate some undesirable combustion products of fuels.[38–40] Rare earth oxides are formed during the combusion of the chelates and, in previous studies, these have been found to catalyze the low-temperature oxidation of organic compounds[41–44] and the decomposition of nitrogen oxides.[45,46] The particles of the rare earth oxides are very finely divided and most are exhausted with the gases : however, some oxides form a coat on the walls of the combustion chamber and exhaust system and may function as surface catalysts.

As most internal combustion engines age, carbonaceous deposits gradually form on the interior engine surfaces. These deposits increase the fuel octane requirement [termed octane requirement increase (ORI)] needed by the engine to maintain a suitable performance level. Such deposits can also lead to "Dieseling" or run-on after turning off the ignition. The rare earth chelates have been shown to catalyze the elimination of these carbon deposits.[45] The elimination of these deposits should enhance the performance of the engine by reducing ORI as well as "Dieseling".

CONCLUSIONS

The beta-diketone, 2,2,7-trimethyl-3,5-octanedione [H(tod)], has been synthesized, and some transition metal and lanthanide complexes with this ligand prepared. H(tod) can be synthesized from methylisobutyl ketone and an ester of neopentanoic acid and is an effective complexing agent for extraction of Cu(II) from aqueous solution into an organic phase. Metal chelates of the beta-diketone exhibit high solubility in non-polar organic solvents and show moderate thermal stability and volatility. The structure of crystalline $Cu(tod)_2$ is *cis*, monomeric and approximately square planar. The properties of these metal chelates make them valuable for applications such as metal ore extraction, vapour-plating of metals and fuel additives.

Abstract—The nitrosation of $Na[W(CO)_5CN]$ using amyl nitrite and sulphuric acid in a two phase water–diethyl ether system gives the trinuclear compound $W_3(\mu CN)_3(NO)_3(CO)_9$. A single crystal X-ray diffraction study showed that the compound contains a nine-membered ring of three tungsten atoms and three bridging cyanide groups. The terminal carbonyl and nitrosyl ligands were not distinguishable.

The three groups CO, CN^- and NO^+ are isoelectronic and so might be expected to have similar bonding properties. However, detailed calculations have revealed[1,2] considerable differences in the electronic requirements of each group when coordinated to a transition metal. It is, therefore, not surprising that few complexes have been prepared which contain all three groups. That the electronic requirements are not completely incompatible is established by the isolation of $K_2[Co(NO)CO(CN)_2]$[3] and $[CpM(CO)(NO)CN]^-$ (M = Cr, Mo, W).[4] In an attempt to prepare a neutral cyanonitrosyl carbonyl we investigated the reaction of $Na[W(CO)_5CN]$ with nitrosating agents.

RESULTS AND DISCUSSION

Preliminary studies showed that $Na[W(CO)_5CN]$ in water reacts vigorously with $NO[PF_6]$ but the reaction proceeded with extensive decomposition. However, by using a two phase water–diethyl ether system an orange yellow product can be obtained from the ether layer. The nitrosation can also be carried out using sodium or amyl nitrite and sulphuric acid. Amyl nitrite and sulphuric acid is the preferred reagent.

The IR spectrum of the product, **I**, shows a strong band at 1713 cm^{-1} indicating that it contains a nitrosyl group. The elemental analysis of the product corresponds to the empirical formula $W(CO)_3(NO)(CN)$. The compound does not sublime *in vacuo*, but was volatile enough to give a mass spectrum which suggested a trimeric structure $[W(CO)_3(NO)(CN)]_3$. The trimeric structure was subsequently confirmed by X-ray crystallography. The formation of the trimer is a consequence of the high lability of carbonyl groups in the presumed intermediate $ONW(CO)_4CN$ [eqn (1)].

$$3[W(CO)_5CN]^- \xrightarrow{NO^+} 3[ONW(CO)_4CN] \xrightarrow{\text{spontaneously}} W_3(\mu CN)_3(NO)_3(CO)_9 + 3CO. \quad (1)$$

Table 1. IR spectrum of $W_3(\mu CN)_3(NO)_3(CO)_9$ in CCl_4

Frequency (cm^{-1})	Intensity
1713	Strong
1996	Strong
2016	Strong
2036	Very strong
2099	Weak
~ 2150	Very weak

Legzdins[5] and coworkers have previously commented on the high lability of carbonyl groups in transition metal carbonyl nitrosyl halides.

The IR spectrum of I in CCl_4 solution in the 2200–1600 cm^{-1} region is given in Table 1.

A detailed examination of the IR spectrum gave very little additional structural information. This was because we could not confidently distinguish the bands due to CN from those due to CO and lack of good precedents in the literature. IR data have been reported[6,7] for the $[W(CO)_5CN]^-$ ion, but the frequencies vary considerably with the counter ion. A value of 2121 cm^{-1} has been reported[7] for the stretching frequency for the bridging cyanide in $PPN[(CO)_5W—C{\equiv}N—W(CO)_5]$. The value is so close to some absorptions in $[W(CO)_5CN]^-$ that there is no reliable guide to enable us to confirm or disprove the presence of bridging cyanide. We therefore decided to undertake an X-ray structural investigation of I.

The task of growing crystals of I suitable for X-ray diffraction was extremely difficult. Although the compound can be recrystallised from ethyl acetate the resulting crystals were crinkled and unsuitable for X-ray diffraction. Using acetone as solvent eventually proved to be satisfactory, but the preparation was repeated over 50 times before a suitable crystal was obtained, and, even then, the crystals were extremely fine, short needles. The structure found is shown in Fig. 1, whilst bond lengths and angles are given in Table 2.

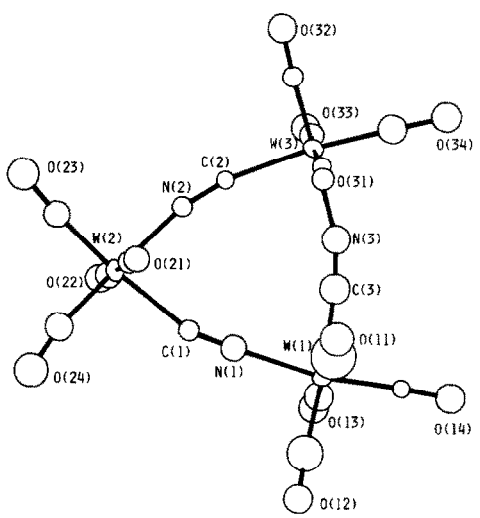

Fig. 1. The molecular structure of $W_3(\mu CN)_3(NO)_3(CO)_9$. For clarity, only the terminal oxygen atoms of the CO/NO groups are labelled.

The compound exists as a trimer with the three tungsten atoms forming an approximate equilateral triangle (W ... W 5.41, 5.34, 5.42 Å) and bridged by cyano groups, thus forming a nine-membered ring. The metal coordination geometry is distorted octahedral, being completed by bonds to a nitrosyl and three carbonyl groups, which were not distinguishable in the structure analysis.

The W—C≡N—W links are bowed outwards from the W—W vector (see Table 2) and the $(WCN)_3$ group is slightly saucer-shaped with all but one atom of the three CN groups lying out of and on the same side of the W_3 plane (Table 3). Analogous features were found in the structure of the $(PdCN)_3$ unit in the complex $[Pd(dppe)CN]_3^{3+}(ClO_4)_3$.[8]

Although, as previously mentioned, the CO and NO groups could not be distinguished, this does not preclude the possibility that there may be some ordering, at least perhaps with regard to equatorial and axial sites. However, we presume that the apparently significant difference between M—X axial and equatorial bonds is more a reflection of a difference in *trans* influences in the two directions rather than an indication of any chemical ordering.

EXPERIMENTAL

All preparative work was carried out in a nitrogen atmosphere using nitrogen saturated solvents and the usual Schlenk procedures. $Na[W(CO)_5CN]$ was made by the method of King[5] using a 1:1 ratio of $W(CO)_6$ and $Na[N(SiMe_3)_2]$ in toluene at room temperature for 40 h.

Synthesis of $W_3(\mu CN)_3(NO)_3(CO)_9$

$Na[W(CO)_5CN]$ (1 g, 2.68 mmol) was introduced into a Schlenk tube with water (25 cm^3) and diethyl ether (50 cm^3). Amyl nitrite (2 cm^3, 1.75 g, 15 mmol) followed by aqueous sulphuric acid (10 cm^3 of 1 m dm^{-3}, 20 mmol of H^+) were added and the mixture stirred with a magnetic stirrer for 20 min at room temperature. The colour quickly changed through green and golden yellow to a dark orange solution in the ether layer. The aqueous layer was removed by pipette, and replaced by water to wash the ether layer. The water was removed by pipette, and the ether layer then dried over anhydrous $MgSO_4$, filtered through silica and concentrated to a small

Table 3. Ring atom deviations from the W_3-plane

Equation of W_3 plane (referred to crystallographic axes):
$6.205x + 0.072y + 77.676z = 3.086$

Deviation (Å): N(1) −0.07, N(2) −0.06, N(3) −0.43, C(1) 0.04, C(2) −0.12, C(3) −0.53

volume *in vacuo*. The residue consisted of a yellow powder and amyl alcohol. Petroleum ether (BP40–60) was added, and the mixture swirled to wash the solid. The liquid was then removed by pipette to give the crude product as an orange yellow powder (~ 230 mg, 26%) which was dried *in vacuo*.

Recrystallisation from ethyl acetate gave yellow orange crystals. Found: C, 15.1; H, 0.1; N, 8.6; O, 19.9; W, 56.2%. $C_{12}N_6O_{12}W_3$ requires C, 14.8; H, 0.0; N, 8.6; O, 19.8; W, 56.8%.

The crystals for the X-ray structure determination were obtained by recrystallising 3 times from acetone, the third recrystallisation being carried out at *ca* 0°C.

X-ray crystallography

The crystal used for data collection had dimensions of $0.15 \times 0.07 \times 0.02$ mm and was carefully mounted inside a Lindemann capillary. All crystallographic measurements were made using a CAD4 diffractometer, operated as described previously.[9] Owing to the weakly diffracting nature of the crystal, the data collection prescan acceptance parameter, $\sigma(I)/I$, normally 0.5–0.667, was set to 1.0.

Crystal data. $C_{12}N_6O_{12}W_3$: $M = 971.88$, monoclinic, $a = 6.753(3)$, $b = 16.305(2)$, $c = 20.590(6)$ Å, $\beta = 91.34(3)°$, $U = 2266.3$ Å^3, $Z = 4$, $D_c = 2.85$ g cm^{-3}, $F(000) = 1728$, space group $P2_1/c$, Mo-K_α radiation, $\lambda = 0.71069$ Å, μ(Mo-K_α) = 146.4 cm^{-1}. Total unique data measured = 2106 ($1.5 < \theta < 20.0°$) of which only 1061 were deemed observed [$I > 1.5\sigma(I)$].

STRUCTURE ANALYSIS AND REFINEMENT

The positions of the three independent tungsten atoms were obtained by manual interpretation of the Patterson map. The rest of the structure was developed, with great difficulty, via repeated least-squares refinements and difference syntheses. In the intermediate stages, all atoms bonded to the tungstens were treated as carbons. Eventually, some indications were given that the bridging C≡N groups were ordered and it was possible to assign one atom on each of two groups as nitrogens, by virtue of their isotropic thermal parameters. The atoms of the third bridging group were not distinguishable, and were assigned on the basis of cyclic repetition. At no stage was it possible to distinguish the nitrosyl groups from the carbonyls. Accordingly the atoms of the terminal groups bonded to the metals were assigned scattering factors for (0.75C + 0.25N)[10] corresponding to complete scrambling of the groups.

In the final stages of the refinement, the metal atoms were assigned anisotropic thermal parameters. The remainder were refined isotropically. An absorption correction was applied at the stage of fully isotropic refinement using the DIFABS procedure.[11] All computations were performed on a DEC VAX 11/750 computer, using standard programs.[12] The final R-value was 0.054 (unit weights). Atomic co-ordinates and thermal parameters and a list of F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are obtainable on request.*

(*Received* 25 *June* 1984; *accepted* 13 *July* 1984)

Abstract—Toluene solutions of $M_2(NMe_2)_6$ and mesitylene thiol react at 80°C to yield $M_2(S\text{-mes})_6$ compounds (M = Mo and W) with the liberation of $HNMe_2$. Similarly $M_2(OBu^t)_6$ in toluene reacts with mesitylene thiol under reflux to yield $M_2(S\text{-mes})_6$ compounds. In all cases the reactions also yield some decomposition products. The compounds $M_2(SBu^t)_2(NMe_2)_4$ react with mesitylene thiol in hexane at room temperature to give $M_2(S\text{-mes})_6$ compounds without significant side reactions. The $M_2(S\text{-mes})_6$ compounds are the first examples of compounds containing triple bonds between molybdenum and tungsten atoms supported exclusively by thiolate ligands. Pertinent bond distances (Å) and angles (°) are: M—M = 2.228(1) (Mo), 2.312(2) (W); M—S = 2.325(2) (Mo), 2.32(1) (W); M—M—S = 96.6(1) (Mo), 97.2(6) (W). The preparations of the new compounds $W_2(SBu^t)_2(NMe_2)_4$ and $W_2(OBu^t)_2(S\text{-mes})_4$ are reported.

Homoleptic compounds of formula $X_3M{\equiv}MX_3$ are known for X = bulky β-elimination stabilized alkyls[1,2] (e.g. CH_2CMe_3 and CH_2SiMe_3), NMe_2[3,4] and OR,[5,6] where R = a bulky alkyl or trialkylsilyl group (e.g. *t*-Bu, *i*-Pr, CH_2-*t*-Bu, $SiMe_3$ and $SiEt_3$). We have wondered for some time whether this series could be extended to include thiolato (mercaptide), SR, ligands and phosphido, PR_2, ligands. Though there was no reason to believe that such ligands could not exist our initial attempts to prepare $(RS)_3Mo{\equiv}Mo(SR)_3$ compounds were thwarted by problems arising from molybdenum's high affinity for sulphur, facile C—S bond cleavages, polymerizations by μ-SR formation and oxidation of the Mo_2^{6+} unit.[7] We were able, however, to attach two SR ligands to the $(Mo{\equiv}Mo)^{6+}$ unit in the preparation of the compounds 1,2-$Mo_2(SR)_2(NMe_2)_4$ [eqn (1)]:[8]

$$1,2\text{-}Mo_2Cl_2(NMe_2)_4 + 2LiSR \rightarrow 1,2\text{-}Mo_2(SR)_2(NMe_2)_4 + 2LiCl \quad (1)$$

where R = Me and Bu^t.

Subsequently, by the use of the bulky aromatic thiol mesitylene thiol we were able to prepare compounds of formula $Mo_2X_2(S\text{-mes})_4$ (mes = mesitylene, 2,4,6-trimethylphenyl) according to eqn (2):[9]

$$Mo_2X_6 + 6HS\text{-mes} \rightarrow 1,2\text{-}Mo_2X_2(S\text{-mes})_4 + 4XH \quad (2)$$

where X = NMe_2, OBu^t, OPr^i and OCH_2Bu^t.

Here the use of an aromatic thiol suppresses the facile C—S bond cleavage reaction and the 2,6-dimethyl substituents on the aromatic ring suppress oligomerization reactions by μ-SR formation. The use of only one methyl substituent in the 2-position (*ortho*) led to polymeric materials, but the use of two methyl groups, one in each of the *ortho* positions in the mesitylene group, led to only partial substitution. It was not clear why only partial substitution occurred in eqn (2). Steric or electronic factors, or both, could be involved. However, we were encouraged in our quest for a successful synthesis of $M_2(SR)_6$ compounds since it seemed that by relatively subtle changes in the steric properties of the aromatic thiol or the leaving group [X in eqn (2)] we could achieve a synthesis of the target compounds. We describe here the fulfillment of this goal.[10]

RESULTS AND DISCUSSION

Syntheses

Previously we had found that the $Mo_2(SR)_2(NMe_2)_4$ compounds, where R = Me and Bu^t, reacted with alcohols (Bu^{t}OH and Pr^{i}OH) in hydrocarbon solvents to give dimolybdenum hexaalkoxides[8] and that these do not react with bulky alkyl thiols such as Bu^{t}SH. However, from eqn (2) it was clear that aromatic thiols would replace alkoxide ligands but it was not clear why the reaction stopped with only partial substitution. Are the M_2X_2(S-mes)$_4$ compounds kinetically or thermodynamically favoured in reaction (2)? If one considers that either an equilibrium $MoOR + R'SH \rightleftharpoons MoSR' + ROH$, or a higher activation energy for the last replacements of the two OR groups on the Mo_2^{6+} centre is at fault then merely increasing the temperature of the reaction and, if necessary, the selective removal of the alcohol by azeotrope distillation, would drive the reaction to the desired $Mo_2(SR')_6$ compounds. Indeed we find that in refluxing toluene, M_2X_2(S-mes)$_4$ compounds do react further with excess mesitylene thiol to give M_2(S-mes)$_6$ compounds. However, under these more forcing conditions some thermal decomposition occurs. Little can be said concerning these decomposition products, though based on a crystallographic study[11] a very minor product, *ca* 2–5% of the sample, obtained in the reaction between $W_2(NMe_2)_6$ and mesitylene thiol, is formulated as the salt $[Me_2\overline{NCH_2CH_2CH_2C}HS\text{-mes}]^+ [WO(S\text{-mes})_4]^-$. Crystallographically there can be little if any doubt concerning the authenticity of the oxo tungsten tetrakismesitylenethiolato moiety and the origin of the oxo group must be questioned. A plausible source is from THF and the cation $[Me_2\overline{NCH_2CH_2CH_2C}HS\text{-mes}]^+$ would appear to also involve the C_4-fragment of THF coupled with the S-mes and Me_2N units.

A cleaner route, one involving milder conditions, involves the reaction shown in eqn (3). The aliphatic thiolate ligands are readily

$$M_2(SBu^t)_2(NMe_2)_4 + 6mesSH \rightarrow M_2(S\text{-mes})_6 + 4HNMe_2 + 2Bu^tSH \quad (3)$$

replaced, along with the NMe_2 groups, by the arylthiolato ligands.

Physicochemical properties

The new M_2(S-mes)$_6$ compounds are orange-red crystalline compounds that are soluble in aromatic hydrocarbon solvents. The compounds are air sensitive and thermally unstable above 80°C. They cannot be purified by sublimation. They are diamagnetic and show ^{1}H NMR data consistent with the observed $X_3M{\equiv}MX_3$ structure. Analytical, IR and ^{1}H NMR data are given in Experimental.

Solid state and molecular structures

The sample of Mo_2(S-mes)$_6$ that was examined was crystallized from toluene/hexane solutions and, in the space group $R\bar{3}$, hexane molecules are contained in the unit cell. The dimolybdenum compound has crystallographically imposed S_6 symmetry. An ORTEP view of the molecule giving the atom number scheme used in the tables is shown in Fig. 1 and a view down the Mo—Mo bond is given in Fig. 2.

The ditungsten compound crystallized from toluene/hexane in the space group $P\bar{1}$. Molecules of W_2(S-mes)$_6$ have a crystallographically imposed centre of inversion. A view of the W_2(S-mes)$_6$ molecule showing the atom number scheme is given in Fig. 3.

As would be expected the Mo_2 and W_2 containing compounds are very similar and this is shown by a comparison of selected pertinent structural parameters in Table 1. A comparison of the structural parameters associated with the central $X_3M{\equiv}MX_3$ units in structurally characterized homoleptic alkyls, amides, alkoxides and thiolates is given in Table 2. The following points are worthy of note.

(1) For related pairs of molecules the W—W distance is longer by 0.08 or 0.09 Å than the Mo—Mo distance.

(2) The M—X distance is, within the 3σ criteria, the same for Mo—X and W—X.

(3) The M—M—X angles span a small range, 96.6–103.7°. The smaller angles seen here for the thiolates are easy to understand in terms of the arrangement of all six mesityl groups which are distal with respect to the central $(M{\equiv}M)^{6+}$ core. In the alkoxide molecule $Mo_2(OCH_2Bu^t)_6$ we see four distal and two proximal arrangements of the $-CH_2Bu^t$ groups leading, respectively, to larger and smaller M—M—O angles.

(4) The M—S distances are essentially the same as were found[9] in the structure of $Mo_2(OPr^i)_2$(S-mes)$_4$. From the arguments previously presented, we conclude that they are shorter by *ca* 0.10–0.15 Å than those expected for a pure MoS σ-bond and this shortening is due to S to M π-bonding.

Concluding remarks

The use of bulky arylthiolato ligands has recently been shown to lead to unusual monomeric compounds. For example, Koch and co-workers[12]

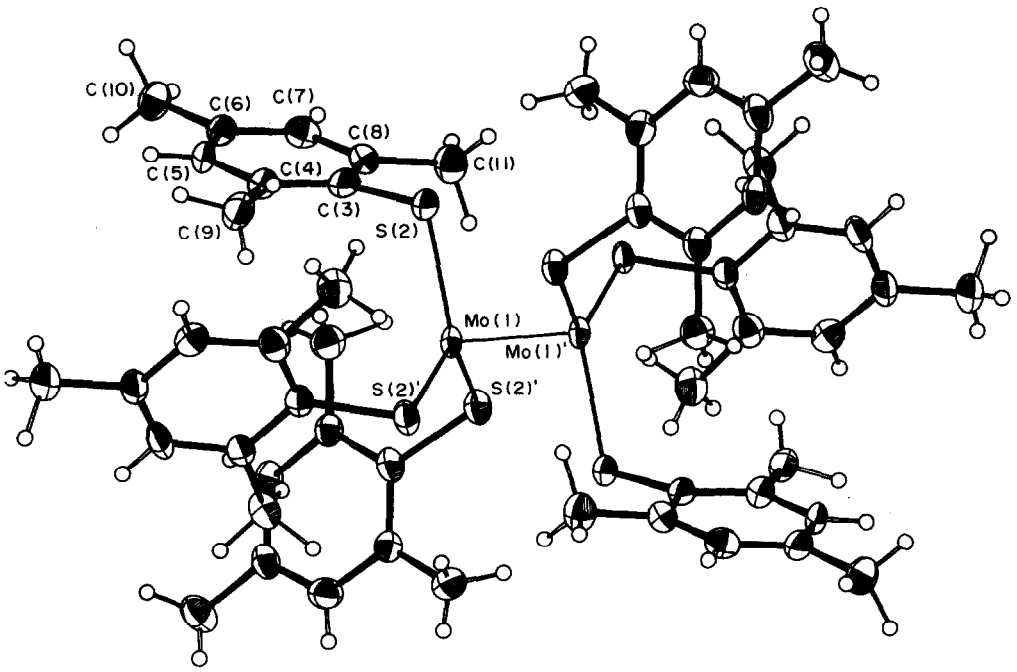

Fig. 1. An ORTEP view of the $Mo_2(S\text{-}mes)_6$ molecule giving the atom number scheme used in the tables.

were able to prepare the first example of a stable Fe(III) tetrathiolate using the metathetic exchange reaction:

$$FeCl_3 + 4LiSC_{10}H_{13} + Et_4NBr \rightarrow [Et_4N][Fe(SC_{10}H_{13})_4] + 3LiCl + LiBr,$$

where $SC_{10}H_{13}$ is the anion derived from 2,3,5,6-tetramethylphenylthiol. Attempts to extend this to Ru and Os gave rise to the first examples of the five-coordinate ruthenium state:

$$M(SC_{10}H_{13})_4(CH_3CN).^{13}$$

Dilworth and co-workers[14] have used the 2,4,6-triisopropylphenylthiolate ligand to obtain some novel carbonyl and nitrosyl mononuclear anionic

complexes of molybdenum(II), e.g.

$$[Mo(CO)_2(SC_6H_2Pr^i_3)_3]^-.$$

We have shown here that by an appropriate synthetic strategy compounds of formula $(RS)_3M{\equiv}M(SR)_3$ can be prepared for molybdenum and tungsten. There exists now the opportunity to compare the chemistry of the $(M{\equiv}M)^{6+}$ unit supported by the closely related alkoxide[15] and thiolate ligands.

Further studies are in progress.

EXPERIMENTAL

General procedures, including the preparations of $M_2(NMe_2)_6$ compounds, where M = Mo and W, $W_2(O\text{-}t\text{-}Bu)_6$ and $Mo_2(S\text{-}t\text{-}Bu)_2(NMe_2)_4$ have been described previously.[9] Mesitylene thiol was prepared from the reaction of mesitylene Grignard reagent and elemental sulphur as described below.

^1H NMR data were obtained from toluene-d_8 solutions using a Nicolet 360 spectrometer. IR spectra were recorded as Nujol mulls using a Perkin–Elmer 283 spectrophotometer. Elemental analyses were obtained from Alfred Bernhard Microanalytical Laboratories (Elbach, F.R.G.).

Preparations

Mesitylene thiol. To a solution of mesitylene magnesium bromide (135 cm^3 of a 1 *M* solution in

THF), elemental sulfur (4.32 g, 0.35 g atoms) was added over a period of 20 min. The solution was hydrolyzed by the addition of H_2O (20 cm^3) followed by the slow addition of 6 *N* HCl (30 cm^3). The THF layer which separated was collected and dried over $MgSO_4$ (12 h). Upon removing the THF at reduced pressure a clear yellow oil remained which was distilled at 50°C, 30 torr yielding 2,4,6-trimethylphenyl thiol (mesitylene thiol) 16.74 g (81% yield). This was then dissolved in THF (15 cm^3) to give a 7.33 *M* solution which was stored over molecular sieves and under an atmosphere of N_2.

$W_2(NMe_2)_2(S\text{-}mes)_4$. $W_2(NMe_2)_6$ (0.46 g, 0.73 mmol) was dissolved in hexane (20 cm^3) to give a clear yellow solution. Mesitylene thiol (0.7 cm^3 of a 7.3 *M* solution in THF, 7 equiv) was added via syringe. The solution was allowed to stir at room temperature for 12 h. A gradual darkening of the solution occurred and a microcrystalline yellow-orange precipitate formed which was collected and dried *in vacuo*: $W_2(NMe_2)_2$ (S-mes)$_4$ (0.71 g, 0.67 mmol, 92% yield). Found: C, 45.01; H, 5.27; N, 2.81; S, 11.98%. Calc. for $W_2(NMe_2)_2(SC_6H_2Me_3)_4$: C, 45.28; H, 5.28; N, 2.67; S, 12.07%.

IR data: 1595 (m), 1290 (m), 1250 (ms), 1170 (m), 1140 (m), 1050 (s), 1025 (s), 935 (s), 885 (m), 840 (s), 800 (m), 730 (ms), 710 (m), 690 (m), 600 (m), 570 (wm), 550 (wm) cm^{-1}.

$W_2(O\text{-}t\text{-}Bu)_2(S\text{-}mes)_4$. $W_2(O\text{-}t\text{-}Bu)_6$ (0.3 g, 0.372 mmol) was dissolved in hexane (15 cm^3). Mesitylene thiol (1.1 cm^3 of a 7.3 *M* solution in THF) was added via syringe at room temperature. The solution was stirred for 24 h. Little colour change was detectable but a reddish precipitate formed which was collected by filtration and dried *in vacuo*. The solids were redissolved in toluene (5 cm^3) warmed to *ca* 50°C. Red-orange crystals were obtained upon cooling to −15°C: $W_2(O\text{-}t\text{-}Bu)_2(S\text{-}mes)_4$ (0.34 g, 82% yield based on W). Found: C, 47.23; H, 5.55; S, 11.45%. Calc. for $W_2(O\text{-}t\text{-}Bu)_2(SC_6H_2Me_3)_4$: C, 47.35; H, 5.72; S, 11.24%.

IR data: 1595 (ms), 1290 (m), 1260 (m), 1235 (m), 1160 (s), 1025 (ms), 965 (vs), 870 (w), 840 (s), 790 (w), 605 (wm), 550 (m), 470 (w), 420 (wm) cm^{-1}.

^1H NMR data at +21°C: O-*t*-Bu, δ = 1.90 (9H); $C_6H_2Me_3$, δ(*p*-methyl) = 2.05 (6H), δ(*o*-methyl) = 2.15 (12H), *meta*-H, δ = 6.4 (δ in ppm relative to Me_4Si).

$W_2(S\text{-}t\text{-}Bu)_2(NMe_2)_4$. $W_2Cl_2(NMe_2)_4$ (0.35 g, 0.57 mmol) was dissolved in toluene (25 cm^3). LiS-*t*-Bu (0.112 g, 1.2 mmol) was added and the reaction mixture was left to stir at room temperature for 48 h. The colour darkened from a yellow-orange to an orange-brown. The solution was evaporated to dryness *in vacuo* and hexane was added. Solids (LiCl and other insoluble materials) were removed by filtration and the hexane soluble filtrate was collected. Cooling to −15°C gave a yellow-green finely divided microcrystalline precipitate: $W_2(S\text{-}t\text{-}Bu)_2(NMe_2)_4$ (0.28 g, 68% yield based on W). Found: C, 26.41; H, 5.79; N, 7.81; S, 8.78%. Calc. for $W_2(S\text{-}t\text{-}Bu)_2(NMe_2)_4$: C, 26.59; H, 5.82; N, 7.65; S, 8.86%. $W_2(S\text{-}t\text{-}Bu)_2(NMe_2)_4$ sublimes with considerable decomposition (80°C, 10^{-2} torr) but does yield a molecular ion in the mass spectrometer: M^+ = 722 based on ^{184}W.

IR data: 1260 (wm), 1245 (ms), 1145 (s), 1039 (m), 1032 (m), 952 (s), 938 (vs), 800 (m), 565 (ms), 535 (m), 340 (wm).

^1H NMR data, 34°C in benzene-d_6: S-*t*-Bu, δ = 1.40 (9H); NMe_2, δ = 3.35 (12H) (δ in ppm relative to Me_4Si).

$M_2(S\text{-}mes)_6$ *compounds.* As noted previously the reaction between $M_2(NMe_2)_6$ compounds, where M = Mo and W, and mesitylene thiol yields $M_2(NMe_2)_2(S\text{-}mes)_4$ compounds when the reaction is carried out in hexane at room temperature. The latter compounds are virtually insoluble in hexane.

However, a similar result is obtained when the reaction is carried out in toluene, for which the M_2(S-mes)$_4$(NMe$_2$)$_2$ compounds are appreciably soluble but when the solution is refluxed for 6–8 h a further reaction with mesitylene thiol occurrs. M_2(S-mes)$_6$ compounds are formed and can be obtained as red crystals by careful recrystallation from toluene. However, the bulk material is contaminated with other products giving poor analytical data which is indicative of the presence of nitrogen containing materials. A better preparative route involves the use of the M_2(S-*t*-Bu)$_2$(NMe$_2$)$_4$ compounds and is given below.

Mo_2(S-*t*-Bu)$_2$(NMe$_2$)$_4$ (0.316 g, 0.58 mmol) was dissolved in hexane (15 cm^3). An excess of mesitylene thiol (2 cm^3 of a 7.33 *M* solution in THF) was added via syringe at room temperature. The solution was stirred for *ca* 10 h during which time some tan-coloured solids precipitated. These were removed by filtration and discarded. The orange-red filtrate was collected and reduced in volume *in vacuo*. The solution was slowly cooled to −5°C yielding a pale-red powder and some larger red crystals: Mo_2(S-mes)$_6$ (0.272 g, 43% yield based on Mo). Found: C, 59.21; H, 5.89; S, 17.61%. Calc. for $Mo_2(SC_6H_2Me_3)_6$: C, 59.01; H, 6.01; S, 17.48%.

IR data: 1598 (m), 1300 (mw), 1260 (ms), 1100 (w, br), 1030 (m, br), 845 (s), 795 (w, br), 610 (w), 550 (m), 415 (wm) cm^{-1}.

^{1}H NMR data, +34°C, benzene-d_6 solvent: *ortho*-methyls, $\delta = 2.15$; *para*-methyl, $\delta = 2.09$; *meta*-H, $\delta = 6.50$ (δ in ppm relative to Me$_4$Si).

W_2(S-mes)$_6$ was prepared in a similar manner, but employing W_2(S-*t*-Bu)$_2$(NMe$_2$)$_4$, and was obtained as a red powder or red crystals from toluene solutions in 35–40% yield based on W. Found: C, 50.53; H, 5.28; S, 15.22%. Calc. for $W_2(S_2C_6H_2Me_3)_6$: C, 50.86; H, 5.18; S, 15.07%.

IR data: 1600 (m), 1300 (m), 1260 (ms), 1180 (wm), 1100 (w, br), 1030 (s), 890 (m), 850 (s), 730 (ms), 610 (w), 555 (m), 470 (mw), 420 (m) cm^{-1}.

^{1}H NMR data, 35°C in benzene-d_6 solvent: *ortho*-methyls, $\delta = 2.18$; *para*-methyls, $\delta = 2.00$; *meta*-H, $\delta = 6.55$ (δ in ppm relative to Me$_4$Si).

Crystallographic studies

General operating procedures and listings of programs have been previously given.[16] Crystal data for the M_2(S-mes)$_6$ compounds are summarized in Table 3.

Mo_2(S-mes)$_6$. A suitable nearly equidimensional fragment was cleaved from a larger cubic shaped crystal which exhibited severe faulting on the faces. Examination of the chosen sample indicated it was crystallographically satisfactory. The sample was transferred to the goniostat using standard inert atmosphere handling techniques and cooled to −162°C for characterization and data collection.

An examination of reciprocal space revealed a trigonal lattice with rhombohedral centring. Subsequent solution and refinement confirmed the space group $R\bar{3}$. The structure was solved by "inspection", in that with $Z = 3$ (yielding a reasonable density), the only permissible location of the molecule was at a 3 site in the lattice. Assuming a Mo–Mo separation of 2.3 Å, a trial Mo was placed along the three-fold axis and a Fourier located the remaining non-hydrogens in the molecule. A difference map phased on the isotropic coordinates of the 11 unique atoms revealed three peaks of intensity 1.6–3.5 e Å^{-3} with all remaining peaks below 0.8 e Å^{-3}. The three larger peaks are apparently due to a disordered hexane solvent along the three-fold axis. When three partial occupancy carbon atoms were placed in these positions, the residual (*R*) dropped from 0.065 to 0.043.

A final difference Fourier after the full-matrix refinement was featureless, the largest peak being 0.4 e Å^{-3}. There was no evidence of hydrogens associated with the hexane. It should be noted that the solvent is poorly defined and the bond distances and angles are quite poor.*

W_2(S-mes)$_6$. A suitable crystal was cleaved to form a nearly equidimensional fragment which was transferred to the goniostat using standard inert atmosphere handling techniques. A systematic search of a limited hemisphere of reciprocal space revealed no systematic absences or symmetry, leading to the assignment of a triclinic space group. Subsequent solution and refinement of the structure (as well as statistical tests) confirmed the centrosymmetric space group $P\bar{1}$.

The location of the unique tungsten atom was achieved by direct methods and all remaining non-hydrogen atoms were located in a difference Fourier phased on the metal parameters. Hydrogen atoms were visible in a difference map phased on the non-hydrogens, and were included in the final stages of refinement (anisotropic thermal parameters for W, S, C; isotropic parameters for H).

* Final atomic positional and thermal parameters and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre. The complete structural reports for Mo_2(S-mes)$_6$ and W_2(S-mes)$_6$, MSC Report Nos. 83046 and 84011, are available in microfiche form only from the Indiana University Library at a cost of $2.50 per report.

(*Received* 3 *January* 1984; *accepted* 16 *July* 1984)

Abstract—The crystal structure of potassium (hydrogen(bismaleato))stannate(II) is reported. It has unit cell data $a = 7.361(12)$, $b = 12.305(3)$, $c = 7.246(8)$ Å, $\alpha = 97.02(6)°$, $\beta = 109.83(28)°$, $\gamma = 87.48(7)°$, $U = 612.77$ Å^3, $Z = 2$, $D_c = 2.096$ g cm^{-3}, $D_m = 2.093$ g cm^{-3} and triclinic space group $P\bar{1}$. The structure consists of layers of discrete $[Sn(CHCO_2:CHCO_2)(CHCO_2:CHCO_2H)]_2^{2-}$ moieties with potassium ions located in holes between the layers. In the discrete unit are two different maleate groups, an anisobidentate maleate ligand and a terminal unidentate monoprotomaleate ligand. The tin atom lies in a trigonal pyramidal environment with three Sn—O distances, to the maleate and monoprotomaleate ligands, of 2.199 and 2.212 Å respectively. These bonds lengths are consistent with the ^{119}Sn Mössbauer data. The preference for tin to exist in a trigonal pyramidal environment, even in the presence of potential chelating ligands is clearly shown in the structure of this complex tin(II) malcate.

Over the past few years the crystal structures of a number of tin(II) derivatives of dicarboxylic acids have been determined. Tin(II) oxalate,[1] tin(II) maleate monohydrate[2] and tin(II) malonate[3] contain tin atoms in distorted four pyramidal environments with two short and two long bonds. This is the expected environment[4] if the dicarboxylate groups are chelating.

Formation of dicarboxylatostannate(II) complexes would be expected to result in a shortening of the average Sn—O bond from those of the parent tin(II) dicarboxylates while retaining the distorted four pyramidal environment. This is certainly the case in the oxalate derivatives, $Na_2[Sn(C_2O_4)_2]$[5] and $K_2Sn(C_2O_4)_2 \cdot H_2O$[6], where the bond lengths are 2.25, 2.25, 2.36, 2.36 and 2.14, 2.20, 2.36, 2.30 Å respectively, in comparison with the bond lengths in tin(II) oxalate of 2.23, 2.23, 2.39 and 2.39 Å.

We have recently shown[7] that in the formation of dipotassium trismalonatodistannate(II) monohydrate from tin(II) malonate, the distorted four pyramidal environment for tin in the parent compound is replaced by a trigonal pyramidal arrangement of nearest neighbour atoms. Unlike the oxalate ions which chelate tin(II) to give the metal distorted four pyramidal environments, the malonate groups, although bidentate, form bridges between different tin atoms. This gives rise to an extended polymeric anionic system $Sn_2[(CH_2C_2O_4)_3]_n^{2n-}$, and not to discrete $Sn(RC_2O_4)_2^{2-}$ ions as found in $Na_2[Sn(C_2O_4)_2]$.

We now report on the crystal structure of a different type of dicarboxylatostannate(II) complex, potassium (hydrogen(bismaleato))stannate-(II), in which one of the ligand maleato groups is monoprotonated.

EXPERIMENTAL

Preparation

Blue-black stannous oxide (0.02 mol, 2.7 g) was refluxed for 1.25 h under an oxygen-free nitrogen atmosphere in a 20% (w/v) aqueous maleic acid solution (50 cm^3) to obtain a clear solution. Potassium carbonate (0.02 mol, 2.7 g) was then added and the mixture refluxed for a further 30 min. The resulting solution was filtered hot and cooled to crystallise out the white product. The crystals were washed with petroleum ether (b.p. 40–60°C) and dried *in vacuo* over pellets of potassium hydroxide. Found: Sn, 31.0; C, 24.8; H, 1.30%. $C_8H_5O_8KSn$ requires: Sn, 30.68; C, 24.84; H, 1.30%.

X-ray crystal structure

Crystal data. $C_8H_5O_8KSn$, $M = 386.9$, space group $P\bar{1}$, $a = 7.361(12)$, $b = 12.305(3)$, $c = 7.246(8)$ Å, $\alpha = 97.02(6)°$, $\beta = 109.83(28)°$, $\gamma = 87.48(7)°$, $U = 612.77$ Å^3, $Z = 2$, $D_c = 2.096$ g cm^{-3}, $D_m = 2.093$ g cm^{-3}, $F(000) = 372$. μ(Mo-K_α) = 22.63 cm^{-1}, $\lambda = 0.70926$ Å, $R = 0.022$, $R_w = 0.024$ for 2051 unique intensity data.

The X-ray data were collected at Queen Mary College, London, as previously described.[7] The position of the tin atom was determined from a Patterson Synthesis and refined by full-matrix least squares. With phasing based on this Sn position, the positions of the K, O, and C atoms were obtained from Fourier syntheses. Anisotropic thermal parameters were assigned to all non-hydrogen atoms. The hydrogen atoms were located but their positions were not refined. All crystallographic calculations were performed using SHELX-76[8] and the diagrams were drawn by CELLPLOT,[9] on a CDC 7600 computer. Final atomic coordinates, bond lengths and angles, together with tables of F_o/F_c have been deposited as supplementary material with the Editor, from whom copies are available on request.

^{119}Sn *Mössbauer spectra*

The Mössbauer spectrum of the material was recorded at liquid nitrogen temperature using a $BaSnO_3$ source by methods described previously.[10]

RESULTS AND DISCUSSION

The structure of potassium (hydrogen-(bismaleato))stannate(II) consists of layers of discrete

$$[Sn(CHCO_2:CHCO_2)(CHCO_2:CHCO_2H)]_2^{2-}$$

moieties with potassium ions located in holes between the layers (Fig. 1).

Each tin atom is bonded to two different types of maleate group, one of which is a bridging bidentate ligand and the other a unidentate monoprotomaleato group. Both maleate groups bridge the two tin atoms in the cell forming a 14-membered ring system with two tin-to-maleate oxygen bonds at each Sn (Fig. 2). A trigonal pyramidal coordination about each Sn is completed by tin-to-monoprotomaleate oxygen atoms. The Sn—O distances to the maleate and monoprotomaleate

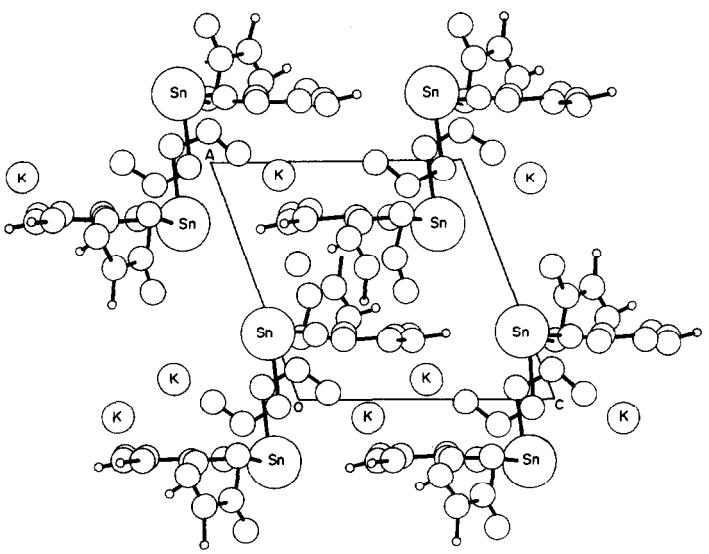

Fig. 1. Projection of the unit cell along the *y* axis.

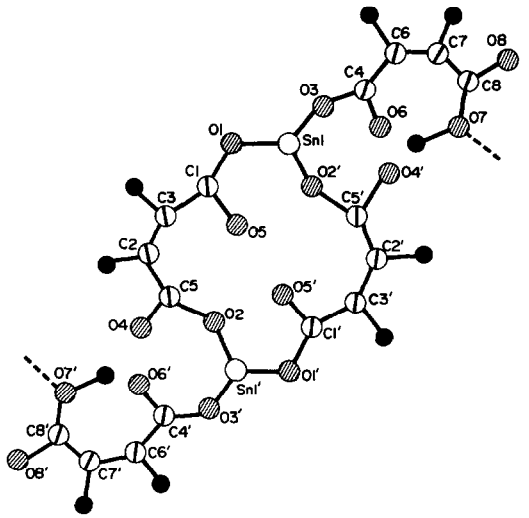

Fig. 2. Diagram showing the 14-membered ring system in $KSn(CHCO_2:CHCO_2)(CHCO_2:CHCO_2H)$.

ligands are 2.199 and 2.212 Å respectively. Three longer contacts to ligand oxygen atoms at 2.642, 2.866 and 2.931 Å complete a distorted octahedral arrangement around the tin atoms (Table 1).

The potassium atom is surrounded by six oxygen atoms with K—O distances of 2.644, 2.728, 2.752, 2.799, 2.932 and 3.052 Å.

Both the protonated and non-protonated maleate groups are structurally very similar. The bond distances and angles are consistent with a regular array of sp^2 hybridised C atoms. The existence of both inter- and intra-molecular hydrogen bonding creates an apparent polymeric chain through the lattice, with discrete anionic

$$[Sn(CHCO_2:CHCO_2)(CHCO_2:CHCO_2H)]_2^{2-}$$

unit being hydrogen-bonded to the next through the H atoms of the terminal maleate groups.

Dipotassium trismalonatodistannate(II) monohydrate was the first example of a complex dicarboxylatostannate(II) derivative shown[7] to have tin in a trigonal pyramidal coordination, in spite of its parent compound, $Sn(CH_2C_2O_4)$, having tin in a four pyramidal environment. This trigonal pyramidal arrangement about the tin in $K_2Sn_2(CH_2C_2O_4)_3 \cdot H_2O$ arises because all three malonate groups must act as bridging bidentate ligands, since the Sn : ligand ratio is 2 : 3.

The tin(II) maleate complex described here also has a trigonal pyramidal arrangement of nearest-neighbour oxygens about the tin atom, although in its parent compound, $Sn(C_4H_2O_4) \cdot H_2O$, the tin atoms lie in four pyramidal sites. In potassium [hydrogen(bismaleato)]stannate(II), however, the trigonal pyramidal arrangement about each tin atom arises, not because of a low tin : dicarboxylate ligand ratio, but, because of the presence of two anisobidentate maleate moieties and one monodentate hydrogen maleate group.

Table 1. Bond lengths (Å) and angles (°) (ESDs in parentheses)

Bond length		Bond angle

C(5)—O(2)	1.284(3)	O(2)—C(1)—O(4)	123.5(2)
		Maleate coordination ($CHCO_2:CHCO_2H$)	
C(4)—O(3)	1.268(3)	Sn—O(2)—O(4)	112.0(2)
C(4)—O(6)	1.240(4)	O(3)—C(4)—O(6)	122.0(2)

It is well known[4] that the most common tin(II) environment is that of a trigonal pyramid in which the tin atom is surrounded closely by three near neighbour ligand atoms, forming three essentially covalent Sn—L bonds. Three more distant ligand atoms with Sn—L bond lengths approaching the sum of the Sn—L van der Waal's radii, complete a distorted octahedral coordination about the tin. This preference for tin to exist in the trigonal pyramidal environment is clearly demonstrated in the structures of the dipotassium trismalonatodistannate(II) monohydrate and potassium (hydrogen(bismaleato))stannate(II) complexes.

The ^{119}Sn Mössbauer parameters for the complex tin(II) maleate ($\delta = 3.22$ mm s^{-1}, $\Delta = 1.65$ mm s^{-1}) show a decrease in chemical isomer shift in going from its parent tin(II) maleate monohydrate ($\delta = 3.31$ mm s^{-1}, $\Delta = 1.76$ mm s^{-1}) to the complex,

Table 2. ^{119}Sn Mössbauer data

Compound	Average Sn—L bond length (Å)	δ* (mm s^{-1})
$Ca[Sn(CH_3CO_2)_3]_2$	2.14	2.90
$KSn(CH_2ClCO_2)_3$	2.16	2.96
$KSn(HCO_2)_3$	2.16	3.08
$K_2Sn_2(CH_2C_2O_4)_3 \cdot H_2O$	2.19	3.15
$KSn(CHCO_2 : CHCO_2)$-$(CHCO_2 : CHCO_2H)$	2.20	3.22
$SnSO_4$	2.26	3.95

* Chemical shift relative to $BaSnO_3$.

which is the expected result for the formation of ligand stannates(II). The data are also consistent with the relationship between chemical shift and tin-to-ligand bond lengths (Table 2), in that the increase in shift from 3.15 to 3.22 mm s^{-1} for $K_2Sn_2(CH_2C_2O_4)_3 \cdot H_2O$ and $KSn(CHCO_2 : CHCO_2)(CHCO_2 : CHCO_2H)$ respectively, parallels the increase in average Sn—O bond length from 2.19 Å for the malonate complex to 2.20 Å for the maleate derivative.

FORMATION OF Cu(II)–DICYANDIAMIDE COMPLEXES IN NEUTRAL AND ACIDIC AQUEOUS SOLUTIONS

URSZULA KOŁODZIEJ* and JAN PRZYŁUSKI

Department of Solid State Technology, Chemical Faculty, Technical University of Warsaw, 00-664 Warszawa, ul. Noakowskiego 3, Poland

(*Received* 9 *March* 1984; *accepted* 16 *July* 1984)

Abstract—This work presents spectroscopic studies and electrochemical characterization of Cu(II)–dicyandiamide (DCDA) complex formation. The range of conditions leading to the precipitation of the complex is significantly larger than that presented in the literature. In all cases the stoichiometry of the compound is: $[Cu(DCDA)_2(SO_4)(H_2O)_5]$. The spectroscopic data suggest that DCDA is a monodentate ligand forming a bond with Cu^{2+} via the nitryl nitrogen. Electroreduction of this complex is a two-step process occurring through a Cu(I)–DCDA intermediate.

The formation of cupric complexes of dicyandiamide (DCDA) was first reported in 1906 and its stoichiometry was established as: $[CuSO_4(DCDA)_2(H_2O)_4]$.[1] In subsequent years a significant revival of interest in the chemistry of these complexes took place due to their catalytic role in the reaction of alcohol addition to the nitryl group of DCDA.[2,3]

The complex studied previously was precipitated from the saturated aqueous solution of $CuSO_4 \cdot 5H_2O$ and DCDA at 273 K and exhibited the formula: $[Cu(DCDA)_2SO_4]$ as determined by elemental analysis. Its structure and bonding were not studied and the only structural information presented was limited to the observation of a 2222 cm^{-1} $\nu(C^1{\equiv}N^3)$ doublet in the IR spectra of the compound. Since this transition is characteristic of DCDA it was concluded that the nitryl group of dicyandiamide does not participate in the complex formation and does not undergo hydrolysis under given conditions.

Cu(II), Ni(II) and Zn(II) complexes of DCDA were prepared in ethanol solutions and have a general formula: $MX_2(DCDA)_2$ or $MX_2(DCDA)_4$, (where X = Cl, Br, NO_3, NCS).[4] In the case of X = ClO_4 the formula $[Cu(DCDA)_4(ClO_4)_2]$ was proposed with ClO_4 as an outershell anion. As determined by IR spectroscopy the 3350–3000 cm^{-1} $\nu(N^{5,6}{-}H)$ bond remains unchanged upon complex formation, but $\gamma(C^1{\equiv}N^3)$ and $\nu(C^1{-}N^4)$ are shifted towards higher and lower wavenumbers respectively. Based on the results presented above it was concluded that the complex is formed via the N^4 nitrogen of the guanidine group, i.e. DCDA is a monodentate ligand. This conclusion can be additionally supported by the existence of the higher local dipole moment at this nitrogen atom,[5] i.e. the guanidine nitrogen should be the most susceptible to form bonds with the cupric ion.

In general in cupric complexes DCDA can act as a ligand in the presence of other ligands of various types. The following complexes have been reported:[6,7] 1-(2-aminoethyl)biguanide(dicyandiamide)Cu(II) sulphate monohydrate:

$$[Cu(C_4H_{12}N_6)(C_2H_4N_4)]SO_4 \cdot H_2O$$

and dichlorodiaquobis(dicyandiamide)Cu(II):

$$[Cu(H_2O)_2(C_2H_4N_4)_2Cl_2].$$

Structural studies of the above complexes showed octahedral coordination of the cupric ion in both complexes. In the former both nitryl nitrogen and the guanidine nitrogen are coordinated to the copper. In the latter case DCDA is a monodentate ligand forming a coordination bond with Cu^{2+} via the N^3 nitrogen of the nitryl group. Our studies of Cu^{2+} electroreduction in the presence of selected derivatives of guanidine led us to study Cu(II)–DCDA complex formation. To date no systematic spectroscopic studies and no electrochemical characterization of these compounds have been presented in the literature.

Exp.	15.2	4.28	11.51	25.41	7.97	24.5

EXPERIMENTAL AND RESULTS

Preparation of complex

Cupric complexes of DCDA were precipitated at room temperature by mixing saturated aqueous solutions of $CuSO_4 \cdot 5H_2O$ and DCDA. In some cases the complexes were precipitated from 0.4 *M* H_2SO_4 or 0.4 *M* K_2SO_4 aqueous solution. The light blue precipitates obtained were repeatedly washed with water and then dried at 323 K in the air. In all experiments reagents of analytical purity and redistilled water were used.

Elemental analysis

C, H, N were determined by combustion analysis using a Perkin–Elmer Microanalyser Model 240. Cupric and additionally cuprous ions were analysed by spectrophotometry. Classical gravimetric analysis was used for sulphate determination. In no samples were cuprous ions detected. In Table 1 results of elemental analysis are presented. The following stoichiometry of the complex was assumed for the calculations: $[Cu(DCDA)_2(SO_4)(H_2O)_5]$.

UV spectroscopy studies

UV spectroscopic studies were carried out for the neutral aqueous and acidic aqueous solutions of Cu–DCDA complexes. A UV–VIS (Karl-Zeiss Jena) spectrometer was used in all experiments. The solutions were loaded into rectangular quartz cuvette of the inner thickness of 1 cm. The results are summarised in Table 2 and Figs. 1–3.

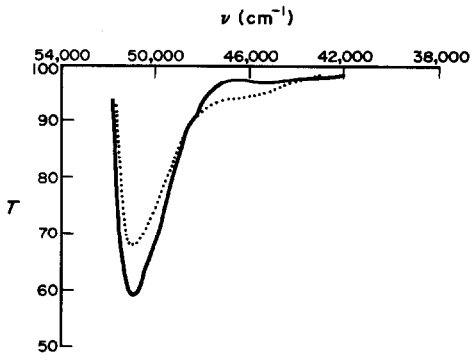

Fig. 1. UV spectrum of DCDA (2×10^{-5} *M* in 0.4 *M* H_2SO_4——) and Cu–DCDA complex precipitated from 0.4 *M* H_2SO_4 (1×10^{-5} *M* in 0.4 *M* H_2SO_4···).

Since guanylurea is the product of DCDA hydrolysis its spectrum was studied for comparison

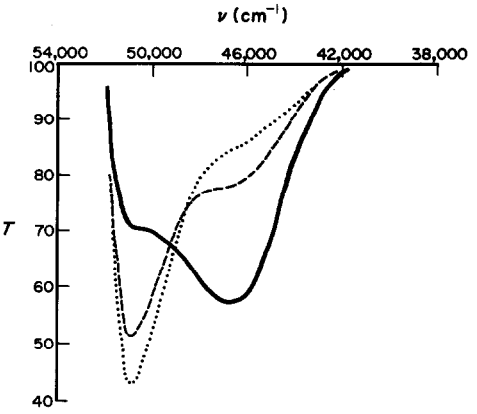

Fig. 2. UV spectrum of Cu–DCDA complex precipitated from 0.4 *M* H_2SO_4 (1×10^5 *M* in 0.4 *M* H_2SO_4——), the same solution after 7 days (– – –), after 12 days (···).

in order to exclude its presence in the reaction products. The appearance of a maximum at $\lambda =$ 197 nm was taken as a criterion for the hydrolysis reaction occurrence simultaneously with the complex formation reaction.

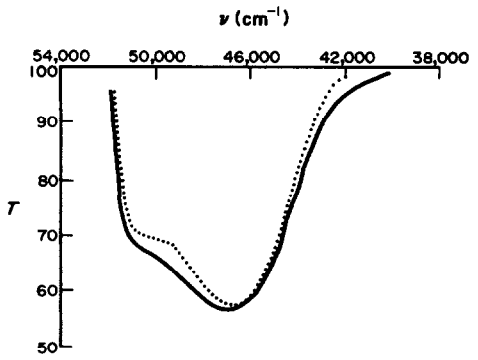

Fig. 3. UV spectrum of guanylurea (1×10^{-5} *M* in 0.4 *M* H_2SO_4——) and DCDA solution (1×10^{-5} *M* in 0.4 *M* H_2SO_4···) after 10 days.

IR spectroscopy studies

A Perkin–Elmer IR Spectrometer was used to examine IR spectra of pure DCDA and Cu–DCDA complexes. KBr pressed pellets method was applied in all cases. Typical spectra, obtained from the acidic solution, are depicted in Fig. 4. All results of IR studies are summarised in Table 3.

Conductivity studies

Specific conductivities of 0.01 *M* aqueous solutions of Cu–DCDA complexes were measured at 291 K using O.K. 102/1 Conductivity Meter (Radelkis). As the reference, conductivities of identical $CuSO_4 \cdot 5H_2O$ and pure DCDA solutions were measured. The results are listed in Table 4.

Polarographic studies

Square-wave Polarograph type OH104 (Radelkis) in two electrode configuration with mercury

dropping electrode and mercury pool as reference electrode was applied to study polarographic behaviour of Cu–DCDA complex. Constant concentration of cupric ions equal to 10^{-5} *M* and varying concentrations of DCDA were employed in the polarographic investigations. 0.4 *M* H_2SO_4 was used as supporting electrolyte. All measurements were performed at 293 K. The list of potentials, at which reduction peaks of the complexed copper ions appear, is presented in Table 5.

DISCUSSION AND CONCLUSIONS

DCDA can form cupric complexes in neutral as well as in acidic aqueous solutions. In both cases identical blue powder of the same stoichiometry are obtained: $[Cu(DCDA)_2(SO_4)(H_2O)_5]$ as shown by elemental analysis. It can be concluded therefore that the range of conditions leading to the precipitation of the complex is significantly larger than that presented previously.[2] This conclusion is highly consistent with the spectroscopic data showing that:

(1) Spectra of the complexes prepared under varying conditions are identical.

(2) Extinction coefficient ratio for "free" and "complexed" DCDA indicates the existence of two DCDA molecules per cupric cation in the complex.

(3) The main changes occurring in the IR spectrum upon coordination can be characterized as follows: the band characteristic of $N^4—C^1{\equiv}N^3$ skeleton observed at 1255 cm^{-1} in "free" DCDA is shifted to 1300 cm^{-1}. On the other hand the band characteristic of $N^{5,6}—C^2{=}N^4$ skeleton is shifted from 1570 cm^{-1} to 1530 cm^{-1}. Additionally the change in the positions of the doublet associated with $C^1{\equiv}N^3$ from 2210, 2160 to 2250, 2210 cm^{-1} can be observed. Finally significant broadening of the bands ascribed to ammine groups is clearly seen. From the above observations it is concluded that DCDA is a monodentate ligand being coordinated to copper via the N^4 nitrogen. This conclusion is consistent with the experimental facts presented before.[5]

The magnitude and direction of the shifts observed in the positions of selected IR bands are in good agreement with the values previously reported.[4] The position of the doublet characteristic of the nitryl group[2] is very similar to the one measured in this work (Fig. 4).

However the conclusions drawn in both papers[2,4] do not necessarily need to be correct especially in view of the fact that the vibrations of $C^1{\equiv}N^3$ group are shifted towards higher wavelength. If a metal acts as a Lewis acid and the coordination of DCDA via the lone pair of the N^3 nitrogen will result in an increase in the frequency of the corresponding IR band.[12] It is therefore probable that DCDA forms a covalent bond with Cu(II) via the N^3 nitrogen.

(4) In UV maxima of the absorption peaks in the "free' and "complexed" DCDA are identical.

(5) The shift of the absorption peak from 216 to 197 nm can be treated as a qualitative test of the hydrolysis leading to the formation of gunylurea.

(6) Existence of the 1740 cm^{-1} vibration mode (Fig. 4) in the IR spectrum additionally confirms the possibility of the hydrolysis of DCDA in acidic solutions. The above-mentioned absorption is characteristic of the carbonyl group of guanylurea.

(7) Polarographic studies of the Cu–DCDA complex led to the determination of its stoichiometry and the mechanism of the reaction occurring at the electrode. In a wide range of DCDA concentrations two one-electron peaks of the reduction could be

Table 5. Polarographic analysis data of Cu–DCDA complex

observed. The potentials at which the above peaks occurred depended linearly on the ligand concentration. The first peak is associated with the Cu(II) + e → Cu(I) reduction process. Its shape and measured half-width seem to suggest that the reduction process is irreversible. Its potential moves towards more positive values if the concentration of the ligand increases. The behaviour of the second peak, corresponding to the second stage of reduction, Cu(I) + e → Cu, is different, its potential moves towards more negative values upon the increase of the ligand concentration. The process is quasi-reversible.

The above collected results seem to indicate that the reduction of Cu(II) in the presence of DCDA can be characterized by the following stages:

(a) Chemical stage—the dissociation of the complex:

$$Cu(DCDA)_2^{2+} \rightarrow Cu^{2+} + 2DCDA.$$

Since in 0.4 *M* H_2SO_4 solution the Cu(II) and DCDA coexist in a form of a well-defined complex and in the polarographic process the simple Cu(II) ion is being reduced, the dissociation of the complex must precede the electrochemical process.

(b) Stage of charge-transfer E1:

$$Cu^{2+} + e \rightarrow Cu^{+}.$$

(c) Stage of the formation of $Cu(DCDA)_2^+$ complex:

$$Cu^{+} + 2DCDA \rightarrow Cu(DCDA)_2^{+}.$$

Since in the second stage of the electroreduction process the cuprous ion, not in the simple but in the complex form, is being reduced, the formation of this complex must follow the stage E1. It is reasonable to believe that this formation occurs at the electrode surface and the adsorbed DCDA molecules participate in this process.

(d) Stage of charge-transfer E2:

$$Cu(DCDA)_2^{+} + e \rightarrow Cu(Hg) + 2DCDA.$$

The stoichiometry of the Cu(I)–DCDA complex and its stability constant $\ln \beta_{CuI} = 6.9 \pm 0.3$ were derived from the relationships described in the literature.[13] In the calculations the experimental values of the potential shifts were assumed to be equivalent to the values of the reversible potentials of the half-wave in accordance with the arguments presented elsewhere.[14]

MAGNETIC AND SPECTRAL STUDIES ON *N*-(THIOPHENE-2-CARBOXAMIDO)SALICYLALDIMINE COMPLEXES OF SOME BIVALENT 3*d* METAL IONS

B. SINGH, * R. N. SINGH and R. C. AGGARWAL
Department of Chemistry, Banaras Hindu University, Varanasi 221 005, India

(*Received* 16 *February* 1984; *accepted after revision* 16 *July* 1984)

Abstract—Metal(II) complexes of *N*-(thiophene-2-carboxamido)salicylaldimine (H_2TCS) of types $M(H_2TCS)_2Cl_2$ [M = Ni, Cu and Zn], M(HTCS)Cl [M = Co, Ni and Cu], $M(HTCS)_2$ [M = Mn, Fe, Co, Ni, Cu and Zn], $M(TCS)\cdot xH_2O$ [M = Mn, Co and Ni, $x = 2$; M = Cu, $x = 0$], $Ni(TCS)py_2$ and Cu(TCS)py have been prepared. Elemental analyses, molar conductance, magnetic moment, electronic, IR and ESR spectral studies have been used to characterize these complexes. The different modes of chelation of the ligand and the stereochemistry of the complexes are discussed.

It was previously reported that studies on coordination properties of aroyl hydrazines and their aromatic Schiff bases, specially those derived from salicylaldehyde may provide a reasonable model for the mechanism of amine oxidase inhibition by many hydrazine derivatives.[1] Recently a number of papers have been appeared on 3*d* metal complexes of *N*-salicylidene acyl hydrazines from our laboratory[2–4] and elsewhere.[5,6] This work has been extended to the hitherto uninvestigated *N*-(thiophene-2-carboxamido)salicylaldimine complexes of 3*d* metal ions because there are as many as five potential donor sites and a possibility of keto–enol tautomerism which may be expected to lead to varied bonding and stereochemical behaviour in the complexes. The results of our investigations on the synthesis and structural studies of Mn(II), Fe(II), Co(II), Ni(II), Cu(II) and Zn(II) complexes with the title ligand are reported in the present paper.

EXPERIMENTAL

All the chemicals used in the present study were of BDH LR grade or of equivalent quality. H_2TCS was prepared as described by Thyssen,[7] m.p. 178–179°C (Lit.[6] 176°C). Found: C, 58.52; H, 4.04; N, 11.42%. $C_{12}H_{10}O_2N_2S$ requires: C, 58.53; H, 4.06; N, 11.38%.

Preparation and analysis of complexes

Dichlorobis-[*N*-(thiophene-2-carboxamido)salicylaldimine]metal(II) complexes, $M(H_2TCS)_2Cl_2$ [M = Ni, Cu and Zn], were prepared by adding ethanolic solution of appropriate metal chloride (1 mmol in 10 cm^3) containing few drops of HCl to the methanolic solution of the ligand (2 mmol in 30 cm^3) at ice-cold temperature. Copper(II) complex precipitated immediately by shaking the reaction mixture while precipitation of the remaining two complexes were effected by adding ether to the reaction mixture.

Monochloro[*N*-(thiophene-2-carboxamido)salicylaldiminato]metal(II) complexes, M(HTCS)Cl [M = Co, Ni and Cu]. The addition of methanolic solution of the ligand (1 mmol in 20 cm^3) to the ethanolic solution of appropriate metal chloride (1 mmol in 10 cm^3) with constant stirring results in the precipitation of the corresponding complexes.

Bis-[*N*-(thiophene-2-carboxamido)salicylaldiminato]metal(II) complexes, $M(HTCS)_2$ [M = Mn, Fe, Co, Ni, Cu and Zn]. These complexes were precipitated by adding boiling aqueous–ethanolic solution of the appropriate metal acetate (1 mmol in 40 cm^3) to methanolic solution of the ligand (2 mmol in 20 cm^3) slowly with constant stirring. The iron(II) complex was prepared by reaction of an aqueous solution of ferrous ammonium sulphate and methanolic solution of the ligand under nitrogen to avoid oxidation.

Diaquo[*N*-(thiophene-2-carboxamido)salicylal-

diminato]metal(II) complexes, $M(TCS)(H_2O)_2$ [M = Mn, Co and Ni] and [*N*-thiophene-2-carboxamido)salicylaldiminato]copper(II), Cu(TCS). An aqueous–ethanolic solution of appropriate metal acetate (1 mmol in 30 cm^3) was added to the methanolic solution of the ligand (1 mmol in 20 cm^3) and the pH of the reaction mixture was raised to ~7 by aqueous NaOH solution. The resulting complexes were digested on a water bath for ~2 h.

Dipyridine[*N*-(thiophene-2-carboxamido)salicylaldiminato]nickel(II), $Ni(TCS)(py)_2$ and monopyridine[*N*-(thiophene-2-carboxamido)salicylaldiminato]copper(II), Cu(TCS)py, were obtained by dissolving the corresponding parent compounds in excess of pyridine and concentrating the solution to incipient crystallization.

All the complexes prepared as above were filtered and repeatedly washed with 50% ethanol, methanol and finally with ether and dried *in vacuo*.

The complexes were analysed for their metal content employing standard literature procedures[8] after decomposing the organic matter at first with a mixture of conc. nitric and hydrochloric acids and then with conc. sulphuric acid. Chloride was estimated as AgCl and nitrogen was determined microanalytically. Hydrazine was estimated volumetrically using KIO_3 after subjecting the complexes to acid hydrolysis for ~ 3 h.

Physical measurements

Molar conductance was measured on a WTW conductivity meter in DMF at 10^{-3} *M* dilution. The magnetic susceptibility of the complexes was determined at room temperature by the Faraday method using $Co[Hg(SCN)_4]$ as calibrant and experimental magnetic susceptibilities were corrected for diamagnetism.[9] The molar conductance and magnetic moment of the complexes are included in Table 1.

The electronic spectra of the complexes were recorded on a Cary 14 spectrophotometer in Nujol. ESR spectra of copper(II) complexes in DMF solution were obtained at 77 K on a Varian E-line X-band ESR spectrometer using TCNE as a *g* marker. The ESR parameters $g_{\|}$, $g_{\perp}$, g_{iso}, $g_{half\,field}$, $A_{\|}$, $A_{\perp}$ and A_{iso} deduced[10] from the analysis of the spectra are given in Table 2. The IR spectra of the complexes and the ligand were recorded on a Perkin–Elmer spectrophotometer Model 621 in Nujol while IR spectrum of the ligand in MeCN was also obtained on Perkin–Elmer Model 257. The important IR bands and assignment thereof are given in Table 3.

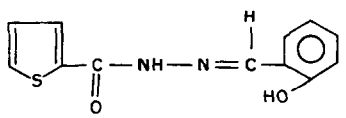

Fig. 1.

RESULTS AND DISCUSSION

The reaction of H_2TCS (Fig. 1) with metal(II) salts yields complexes of different compositions depending on the mode of preparation and metal ions. The complexes are insoluble in water and common organic solvents such as chloroform, ethanol, acetone, benzene and nitrobenzene. With the exceptions of $M(HTCS)_2$ [M = Mn, Co], $M(TCS)(H_2O)_2$ [M = Co, Ni] and $Ni(TCS)(py)_2$, all the complexes are soluble in DMF and DMSO. $Zn(H_2TCS)_2Cl_2$ melts at 190°C. While some of the complexes decompose between 210 and 280°C, the other complexes do not melt or decompose up to 340°C. The hydrated complexes lose water molecules in 130–170°C temperature range yielding anhydrous complexes. The loss of water molecules at higher temperature,[11] the presence of a band in 750–820 cm^{-1} region characteristic[12] of the coordinated water and absence of this band in the corresponding anhydrous complexes show that water molecules are coordinated to the metal ions. The soluble complexes have been found to be non-electrolytes[13] in DMF solution. The insufficient solubility of the complexes in suitable solvents precluded the molecular weight determination and growing of single crystal for X-ray crystallographic studies.

$M(H_2TCS)_2Cl_2$ [M = Ni, Cu *and* Zn] *chelates*

The magnetic moment and electronic spectral studies indicate octahedral geometry[14,15] for nickel(II) complexes. The bands observed at 11,905, 15,385 and 23,000 cm^{-1} in its electronic spectrum are assigned to $^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)(\nu_1)$, $^3A_{2g}(F) \rightarrow 3T_{1g}(F)$ (ν_2) and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$ (ν_3) transitions respectively on the basis of idealized octahedral geometry.[15] Although the μ_{eff} value of the Cu(II) complex is normal as expected for one unpaired electron, a band at 25,000 cm^{-1} in the electronic spectrum and ESR studies suggest it to be a dimer.[16,17] The ESR spectrum gives a band at 1470 G due to the $\Delta M_s = 2$ transition indicating weak intramolecular magnetic exchange interaction[18] in a dimer. Two sets of signals appear in 2680–2980 and 2600–2900 G regions due to zero-field splitting giving an average separation of 60 G ($A_{\|}$), which is half the value expected for a monomer and confirms the dimeric nature of the complex. The Nujol mull IR spectrum of H_2TCS gives bands at 3360, 3200, 1640, 1590, 1530, 1260 and 1025 cm^{-1} which are attributed to ν(OH), ν(NH),

amide I, ν(C=N), amide II, ν_{sym}(C—O) of phenolic group and ν(N—N) modes respectively. The respective bands are observed at 3610, 3270, 1650, 1610, 1520, 1270 and 1040 cm^{-1} in the acetonitrile solution spectrum of the ligand showing thereby that there is intramolecular hydrogen bonding in the solid state. In the spectra of the complexes, amide I, amide II and ν(C=N) suffer a negative shift while ν(N—N) undergoes a positive shift suggesting that carbonyl oxygen and azomethine nitrogen are coordinated to the metal ions. The position of ν(OH) and ν(NH) remains unaltered in the spectrum of complexes indicating their non-involvement in bonding.

M(HTCS)Cl [M = Co, Ni *and* Cu] *chelates*

The anomalous magnetic moment of Cu(II)[19,20] and Ni(II) complexes[21–23] is attributed to metal–metal interaction and/or super-exchange phenomenon while that of Co(II) complex arises presumably due to contribution from high as well as low-spin state of the metal ion.[24] Ni(II) complex shows bands at 11,110, 17,860 and 22,730 cm^{-1} which are assigned to ν_1, ν_2 and ν_3 transitions respectively assuming pseudo octahedral geometry.[15] Three bands observed at 9305, 15,875, and 21,275 cm^{-1} in the electronic spectrum of Co(II) complex are assigned to $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ (ν_1) $^4T_{1g}(F) \rightarrow {}^4A_{2g}(F)$ (ν_2) and $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ (ν_3) transitions respectively assuming octahedral coordination around the metal ion.[15] A band at 12,500 cm^{-1} is attributed to $^2E_g \rightarrow {}^2T_{2g}(D)$ transition suggesting a distorted octahedral[15] geometry for copper(II) complex. IR spectra of the complexes indicate disappearance of ν(OH) and appearance of new bands due to ν_{asym}(C—O) in conjunction with a positive shift in ν_{sym}(C—O) which indicate bonding through phenolic oxygen[25] via deprotonation. A bathochromic shift in amide I, amide II and ν(C=N) together with a hypsochromic shift in ν(N—N) indicates coordination of ligand to the metal ions through carbonyl oxygen and azomethine nitrogen. The ESR spectrum of copper(II) complex yields a band at 1480 G and two sets of bands in 2595–2975 and 2610–2990 G ranges arising from zero-field splitting with an average separation of 63.33 G ($A_{\|}$). The value of $A_{\|}$ being half of the expected value for monomer copper(II) complexes further confirms dimeric[18]/polymeric nature of the complex.

$M(HTCS)_2$ [M = Mn, Fe, Co, Ni, Cu *and* Zn] *chelates*

The pseudo octahedral[15] configuration around the Fe, Co and Ni has been inferred from μ_{eff} values and electronic spectral studies. The lower magnetic moment[19,20] of the copper(II) complex is indicative of metal–metal interaction or super-exchange phenomenon. The manganese(II) complex shows a band at 16,670 cm^{-1} with a split band at 17,390 cm^{-1} and a strong band at 21,050 cm^{-1} which may be due to $^6A_{1g} \rightarrow 4T_{1g}(G)$ and $^6A_{1g} \rightarrow {}^4T_{2g}(G)$ transitions respectively in an idealized octahedral configuration around the metal ion. A band at 9760 cm^{-1} is assigned to $^5T_{2g} \rightarrow {}^5E_g(D)$ on the basis of the idealized octahedral geometry[15] around Fe(II). The Co(II) complex yields two bands at 9300 and 19,050 cm^{-1} assignable to ν_1 and ν_3 transitions respectively while Ni(II) complex gives three bands at 10,810, 17,390 and 22,730 cm^{-1} attributable to ν_1, ν_2 and ν_3 transitions respectively on the basis of pseudo octahedral[15] geometry around these metal ions. The copper(II) complex shows three bands at 14,815, 16,665 and 25,000 cm^{-1}. The first two bands are attributable to *d*—*d* transitions while the third band is due to dimeric/polymeric nature.[16,17] The dimeric[18] nature of the copper(II) complex is further confirmed from signal observed at 1490 G in ESR spectrum, which yields a *g* value of 4.3516. IR spectra of these complexes are similar to those of M(HTCS)Cl type of complexes and show characteristic of coordination through phenolic oxygen via deprotonation, carbonyl oxygen and azomethine nitrogen of the ligand. The magnetic moment[26,27] of Mn(II) complex in conjunction with IR and electronic spectral studies are indicative of octahedral coordination around the metal ion. The high melting or decomposition temperatures and insolubility in common organic solvents suggest a polymeric nature for the $M(HTCS)_2$ complexes.

$M(TCS)\cdot xH_2O$ [M = Mn, Co, x = 2; M = Cu, x = 0] *chelates*

The Ni(II) complex has a normal magnetic moment indicating octahedral geometry[14,15] while that of the Mn(II) complex is indicative of five unpaired spins. A strong band at 23,255 cm^{-1} in the visible spectrum of Mn(II) complex is attributed to $^6A_{1g} \rightarrow {}^4T_{1g}(G)$ transition in an idealized octahedral arrangement of the ligand around the metal ion. The electronic spectrum of Ni(II) complex yields bands at 10,810, 18,180 and 21,050 cm^{-1} assignable to ν_1, ν_2 and ν_3 transitions respectively on the basis of idealized octahedral[15] geometry. The anomalous magnetic moment of Cu(II) complex[19,20] can be explained on the basis of metal–metal interaction and/or superexchange phenomenon while that of Co(II) complex is presumably due to contribution from low- as well as high-spin states of Co(II)[24] in a dimeric structure. Three bands at 9090, 15,750 and

19,050 cm^{-1} observed in the electronic spectrum of Co(II) complex are assigned to ν_1, ν_2 and ν_3 transitions respectively assuming octahedral geometry[12] for the complex. In the spectrum of Cu(II) complex bands at 14,490 and 16,665 cm^{-1} are attributed to *d—d* transitions and a band at 25,640 cm^{-1} is attributed to dimeric[16,17] nature of the complex. A signal at 1520 G in ESR spectrum due to $\Delta M_s = 2$ transition indicates dimeric nature of the complex and thus indicating intramolecular magnetic exchange interaction. It gives two sets of bands in 2620–3050 and 2637.5–3077.5 G regions which can be explained on the basis of zero-field splitting energy. The observed $A_{\|}$ (71.66 G) value is half of the expected value for copper(II) monomers suggesting thereby that the complex is dimer.[18]

The disappearance of ν(OH) and ν(NH) and appearance of ν_{asym}(CO) and ν(NCO) indicate the bonding of carbonyl oxygen and phenolic oxygen via deprotonation. The negative shift in ν(C=N) and positive shift in ν(N—N) is characteristic of coordination through azomethine nitrogen.

Ni(TCS)(py)$_2$ *and* Cu(TCS)py

Magnetic moment and electronic spectral studies of Ni(II) complex are indicative of octahedral[15] geometry suggesting thereby that water molecules are replaced by pyridine molecules without any change in the stereochemistry of the complex. The copper(II) complex is believed to have a 5-coordinate square pyramidal geometry without any change in the dimer entity because Cu(TCS)py has an anomalous magnetic[17,20] moment similar to its parent compound Cu(TCS). The ESR spectrum of Cu(TCS)py gives a half-field signal at 1550 G due to the $\Delta M_s = 2$ transition characteristic of magnetic exchange interaction in dimeric[18] species. Of three bands at 14,715, 16,950 and 25,000 cm^{-1} in the electronic spectrum, the first two bands are attributed to *d–d* transitions and the third band at 25,000 cm^{-1} is due to dimeric nature of the complex. IR spectra have the characteristics of the bonding through carbonyl oxygen and phenolic oxygen in the deprotonated form and azomethine nitrogen similar to their parent compounds.

CONCLUSIONS

The ESR studies indicate that all of the Cu(II) complexes have axial symmetry with the unpaired electron in the $d_{x^2-y^2}$ orbital. The dimeric/polymeric nature of the complexes adduced from electronic spectral studies are supported by the ESR studies.

The IR spectral studies indicate that H_2TCS behaves: (i) as neutral bidentate ligand in $M(H_2TCS)_2Cl_2$ bonding sites being carbonyl oxygen and azomethine nitrogen; (ii) as a mononegative tridentate ligand in $M(HTCS)_2$ and M(HTCS)Cl coordination sites being deprotonated phenolic oxygen, carbonyl oxygen and azomethine nitrogen; and (iii) as a dinegative tridentate ligand bonding through phenolic oxygen, enolic oxygen, and azomethine nitrogen.

The non-ligand bands observed in the 430–335, 380–290 and 320–290 cm^{-1} ranges are tentatively assigned to ν(MO), ν(MN) and ν(MCl) modes respectively.

In all the complexes coordination of the thiophene sulphur to the metal ions is excluded as the ring stretching ($\sim$ 1430 cm^{-1}) CH bending ($\sim$ 1225 cm^{-1}) and C-ring—C-exo ($\sim$ 955) stretching mode of thiophene remain practically unchanged. The poor coordination ability of the thiophene ring sulphur has been attributed to the involvement of the lone pair electrons on sulphur in the aromatic sextet and less capacity of π-orbitals to accept electron pair from the metal.

Acknowledgements—One of us (R.N.S.) is thankful to the UGC, New Delhi, for the award of a Teacher Research Fellowship under the Faculty Improvement Programme. Sincere thanks are also due to RSIC, IIT, Bombay, for providing the ESR spectra of the complexes.

Abstract—The X-ray photoelectron spectra of 14 complexes of Al^{3+}, Cr^{3+}, Fe^{3+}, Co^{3+} and Cu^{2+} with 3-X-2,4-pentanedione (X = H, Cl, Br) were determined to analyse the nature of metal–ligand bonding in these complexes. The trend in the position of *np* photoelectron lines of X-group with a change of metal ion was decided by the relative contribution of metal-to-ligand and ligand-to-metal charge transfer. The analysis of the satellites in the $M(2p_{3/2})$ and $M(2p_{1/2})$ spectra suggested that the metal–ligand bond in the chromium(III) complex had higher covalent character than that in the iron(III) complex. The satellite separations in the O(1*s*) spectra of $M(3\text{-Xptdn})_3$ were in the range 4.0–4.8 eV: these satellites were assigned to a shake-up transition of $L\pi \rightarrow L\pi^*$ character. The O(1*s*) spectra of $Fe(3\text{-Xptdn})_3$ and $Al(3\text{-Xptdn})_3$ displayed an additional strong peak to higher energy than that of the main peak (ΔE = 2.1–3.1 eV) when the samples of complexes were bombarded with argon ions for a longer time.

The metal 2,4-pentanedionates, $M(ptdn)_n$, form an interesting class of compounds which display the characteristic electrophilic reactions[1] of aromatic compounds. The pseudo-aromacity of the chelating ligand and the role of the coordinated metal ion in the ring current are the theme of many papers.[2] The theoretical analysis of the nature of chemical bond in $M(ptdn)_n$ suggests the participation of the metal orbitals in the metal–ligand bonding.[3] The absorption band associated with the charge transfer ($d_\varepsilon \rightarrow \pi_4$) transition in $M(3\text{-Xptdn})_n$ follows the trend of the optical electronegativity of the metal atom.[4] Recently it has been shown from the Szilard–Chalmers reactions of $M(3\text{-Xptdn})_n$ (X = Br, I) that an increasing trend of percentage retention of labelled X follows a decreasing trend of optical electronegativity.[5,6] The former trend obviously depends on the charge at the 3-carbon. The ^1H and ^{13}C NMR spectra of $Co(3\text{-Xptdn})_3$ display the following trend[7] of the coupling constant, $J_{^{13}C-^1H_3}$: $Co(3\text{-Clptdn})_3 > Co(3\text{-Brptdn})_3 > Co(3\text{-Iptdn})_3 > Co(ptdn)_3$. This study suggests the dependence of polarisation of coordinated ligands on the substituent at the 3-carbon. This paper reports the results of such a study of the X-ray photoelectron spectra of complexes with 3-substituted 2,4-pentanedionates.

EXPERIMENTAL

The complexes $M(3\text{-Xptdn})_n$ with X = H, Cl, Br were synthesised and purified by using the established methods.[8–10] The samples were dried in vacuum and were stored under dry nitrogen.

The X-ray photoelectron spectra were recorded on a V.G. Scientific ESCA-3 MK-II electron spectrometer. The Mg-K_α X-ray line (1253.6 eV) was used for photoelectron excitation.

The $Cu(2p_{3/2})$ (E_b 932.8 ± 0.2) and $Au(4f_{7/2})$ (E_b 83.8 ± 0.1) lines were used to calibrate the instrument and $Ag(3d_{5/2})$ (E_b 368.2) was used for cross-checking.[11]

* NCL Communication No. 3568.
† Author to whom correspondence should be addressed.

All the spectra were recorded using the same spectrometer parameters of 50 eV pass energy and 4 mm slit width. The reduced full width at half-maximum (FWHM) for Au($4f_{7/2}$) (E_b 83.8 eV) level under these conditions was 1.2 eV.

The powdered sample was mixed with high purity silver powder to reduce the charging effect. A thin layer of such a sample was pressed on a gold metal gauze which was welded to a nickel sample holder. The Ag($3d_{5/2}$) level (E_b 368.2 eV) obtained from this sample was sharp and did not show any observable shift. Thus the charging of the samples[12] if at all present was negligible.

The samples were cleaned using 10 kV positive argon ion[13] at current of 20 μA cm^{-2} for 3–4 s prior to recording to the PE spectra. The spectra were recorded in triplicate in the regions of interest. In most cases the binding energies were reproducible within $\pm$0.1 eV. The usual least-squares fitting procedure of determining peak positions, line-widths and areas was used.

RESULTS AND DISCUSSION

In the structurally related compounds, M(3-Xptdn)$_n$, the binding energies of X, O and M were expected to be related to the different details of metal–ligand bonding in these complexes. It was therefore possible to correlate these binding energies with the physical properties which were sensitive to the electron density on the respective groups.

Since there was more than one type of carbon in 2,4-pentanedionates, the signals due to C($1s_{1/2}$) were overlapped and one broad signal was obtained. The data of C($1s_{1/2}$) could not be therefore utilised for the structural analysis.

The binding energies of Br in M(3-Brptdn)$_n$ varied considerably and indicated a definite dependence on the central metal atom (Table 1). The following increasing trend for Br($3p_{3/2}$) and Br($3p_{1/2}$) was obtained for the octahedral complexes.

$$Cr < Co < Al < Fe. \quad (1)$$

The observed order of binding energy could be correlated with the polarisation of ligand by the metal ion. 2,4-Pentanedione being a pseudo-aromatic system, the inductive and conjugative effects of 3-Br would be transferred through the metallo-heterocyclic ring. The electronic spectra of these type of complexes in solution[3,14] showed both the ligand-to-metal and metal-to-ligand charge transfer bands. Since the binding energies of Br($3p_{3/2}$) and Br($3p_{1/2}$) in iron(III) complex were the highest, the bromine in this complex was more deshielded suggesting a favourable conjugative effect. Since the binding energies of Br($3p_{3/2}$) and Br($3p_{1/2}$) in chromium(III) complex were the least, the electron density on the bromine in this complex was much higher than that in iron(III) complex. The charge-transfer processes would be of negligible importance in the non-transition metal complexes. Thus the binding energies of Br($3p_{3/2}$) and Br($3p_{1/2}$) for aluminum(III) complex were considered as a reference to analyse the results presented by eqn (1). Since the binding energies of Br($3p_{3/2}$) and Br($3p_{1/2}$) for aluminum(III) complex were definitely less than that for iron(III) complex, the ligand-to-metal charge transfer process seemed to be more important in iron(III) complex. The binding energies of Br($3p_{3/2}$) and Br($3p_{1/2}$) for chromium(III) and cobalt(III) complexes were lower than that for aluminum complex. Thus the metal-to-ligand charge transfer superseded the polarisation effect due to the ligand-to-metal charge transfer in these complexes.

A similar comparison of Cl($2p_{3/2}$) and Cl($2p_{1/2}$) binding energy data for M(3-Clptdn)$_3$ showed the following decreasing order (Table 1):

$$Cr > Co > Fe. \quad (2)$$

This trend was the reverse of that found for Br($3p_{1/2}$) and Br($3p_{3/2}$) binding energies for M(3-Brptdn)$_3$. A reproducible value for the Cl($2p$) binding energy for Al(3-Clptdn)$_3$ could not be obtained and an analysis of these data [eqn (2)] could not be done. One could say with caution that the ligand-to-metal charge-

Br	577.8 (2.4)	589.3 (4.8)	712.4 (4.8)	726.4 (4.8)	781.4 (1.8)	798.5 (1.2)

* Full width at half-maximum (FWHM) of the peak is given in parentheses.

transfer process was more important in these complexes; the extent of charge-transfer in Fe(3-Clptdn)$_3$ was the least.

The observed dependence of binding energy of p-electrons in Br and Cl (eqns (1) and (2)] would be reflected in the binding energies of electrons on oxygen and metal in these complexes.

Unlike the binding energies of np electrons in X, the binding energies of M($2p_{1/2}$) and M($2p_{3/2}$) electrons did not show any significant change with the change of X (Table 2). Thus, the metal–ligand bonding seemed to involve, in effect, a synergistic phenomenon.

The complexes [except Cu(3-Xptdn)$_2$] studied in the present work were of the same symmetry, and the nature of the ligands was closely related. It was therefore envisaged that the metal $2p$ satellite structure would be similar[15] for these complexes.

The present work indicated that the satellite structure in the structurally related complexes did depend on the central metal atom (Fig. 1). The paramagnetic complex Cr(3-Xptdn)$_3$ displayed two (shake-up) satellites in both the M($2p_{3/2}$) and M($2p_{1/2}$) spectra at higher energy separated by about 4.5 and 7.1 eV from the main line. Another paramagnetic complex Fe(3-Xptdn)$_3$ displayed one satellite in both the M($2p_{3/2}$) and M($2p_{1/2}$) spectra at higher energy separated by about 3.9 eV from the main line (Table 3). The satellites in the $2p$ spectra of the diamagnetic complex Co(3-Xptdn)$_3$ were so weak that the analysis could not be done with confidence.

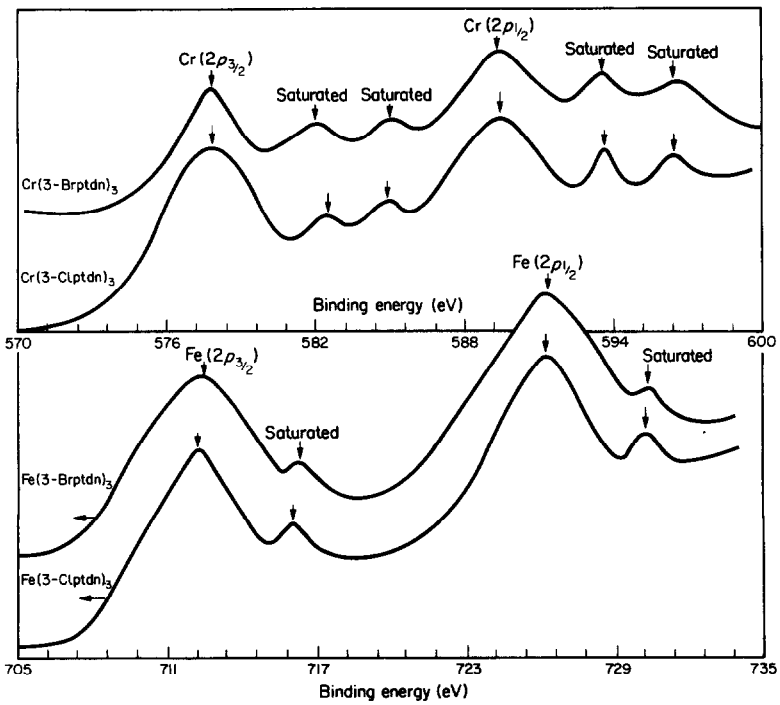

Fig. 1. $2p_{3/2}$ and $2p_{1/2}$ binding energies (eV) and satellites in M(3-Xptdn)$_3$ (M = Cr or Fe, X = Cl or Br).

Fe(3-Brptdn)$_3$	3.9	0.33	3.9	0.37

It was earlier reported that the diamagnetic solid compounds[16,17] did not show the shake-up satellites. The relative intensity of the M($2p_{3/2}$) satellite for diamagnetic complex Ni(ptdn)$_2$ in the vapour state was much lower than that for paramagnetic complex Ni(ptdn)$_2$ in the solid state.[18] There was an interesting report that the 2*p* spectra of the diamagnetic solid complex $K_3Co(C_2O_4)_3$ displayed strong satellites.[19]

The 2*p* satellite spectrum of the first transition metal compounds was interpreted as due to one of the following two types of transitions concurrently associated with the emitted photoelectron: (i) the excitation of a metal 3*d* electron into an unoccupied metal orbital[20] (predominantly 4*s*), and (ii) the ligand-to-metal ($L \rightarrow M$) or metal-to-ligand ($M \rightarrow L$) charge transfer.[21] According to the selection rules the 3*d*–4*s* transition was allowed for the paramagnetic compounds, and was forbidden for the diamagnetic compounds.[22] As regards the second interpretation, an intensity of a satellite associated with a charge transfer ($L \rightarrow M$ or $M \rightarrow L$) would depend on the amount of the total charge transferred through the orbitals of correct symmetry. It would also depend on the magnitude of the central ion component of the ligand orbital before ionization.[19] The analysis of the electronic spectra of Co(ptdn)$_3$ using Hückel LCAO–MO calculations suggested that the metal–ligand bond had a large component.[3] Thus the central metal atom in Co(ptdn)$_3$ was envisaged to have a large ligand orbital component. The nature of the metal–ligand bond in Co(3-Xptdn)$_3$ was expected to be similar to that in Co(ptdn)$_3$. The satellites in the M(2*p*) spectra of Co(3-Xptdn) would be therefore weak. The observed M(2*p*) spectra of Co(3-Xptdn) were in accordance with this prediction.

From the study of the structurally related nickel(II) complexes it was reported that the more covalent the bonding, the larger the satellite separation.[17] The nephelauxetic series of the ligands was correlated with the satellite separations. The present work dealt with the complexes containing similar ligands attached to the different metal ions. The separation between the first shake-up satellite and the main line for chromium(III) complexes was definitely larger than that for the iron(III) complexes. This observation suggested that the metal–ligand bond in chromium(III) complex had a higher covalent character than that in iron(III) complex.

The O(1*s*) binding energies in the complexes studied in the present work showed a small variation with metal (Table 4). The trends observed for O(1*s*) binding energies in M(ptdn)$_3$ and M(3-Clptdn)$_3$ were different from that in M(3-Brptdn)$_3$:

$$\text{M(ptdn)}_3: \text{Al} \leqslant \text{Fe} < \text{Co} < \text{Cr}, \quad (3)$$

$$\text{M(3-Clptdn)}_3: \text{Fe} < \text{Co} < \text{Cr}, \quad (4)$$

$$\text{M(3-Brptdn)}_3: \text{Fe} > \text{Al} > \text{Co} \geqslant \text{Cr}. \quad (5)$$

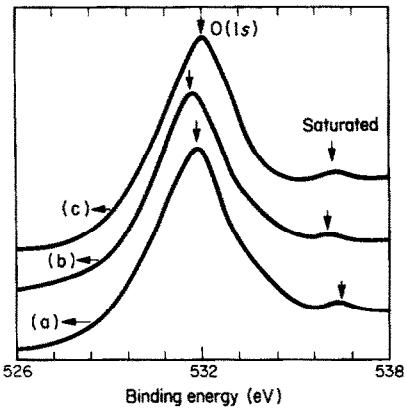

Fig. 2. O(1*s*) binding energies (eV) and satellites in $Co(3\text{-}Xptdn)_3$ [X = H (a), Cl (b) and Br (c)].

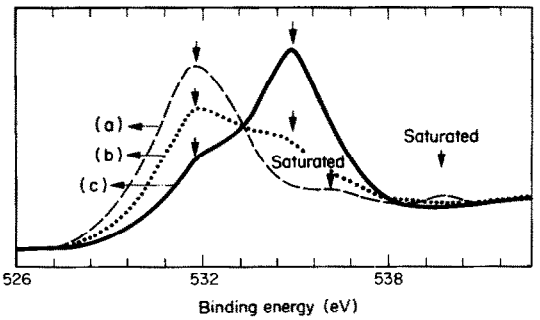

Fig. 3. O(1*s*) spectra of the $Fe(3\text{-}Hptdn)_3$ complex after argon ion bombardment for 3 (a), 10 (b) and 30 sec (c).

These trends were similar to those observed for $X(np_{3/2})$ and $X(np_{1/2})$ binding energies [eqn (1), $n = 3$; eqn (2), $n = 2$]. Thus, the polarization contributions which controlled the bindings energies of $X(np_{3/2})$ and $X(np_{1/2})$ also controlled the O(1*s*) binding energies. This observation was in conformity with the pseudo-aromatic behaviour of the coordinated ligands in these complexes.

The O(1*s*) spectra of all the complexes except that of copper(II) studied in the present work displayed a weak, but definite, satellite at binding energies higher than the main peak (Fig. 2). It was reported that $Cu(ptdn)_2$ vapour also showed a O(1*s*) satellite structure.[18] The observed satellite separations in the O(1*s*) spectra of complexes were in the range 4.0–4.8 eV (Table 4) and were higher than that reported for free 2,4-pentanedione (3.6 eV).[23] This range was equivalent to 32,263–38,716 cm^{-1}.

The analysis of electronic spectra of $M(ptdn)_3$ using the Hückel LCAO–MO calculations suggested that the bands observed in the region 32,400–44,400 cm^{-1} were associated with the $L\pi \rightarrow L\pi^*$ transition.[3] A comparison of the electronic spectra with the satellite separations in the O(1*s*) spectra of $M(ptdn)_3$ would have to be done with caution since the relative energy levels of molecular orbitals could change considerably on core level ionization. The observed satellite separation in the O(1*s*) spectra of $M(ptdn)_3$ was higher than that observed for Hptdn. Due to the polarizing effect of Xptdn it was envisaged that the separation between π and π^* molecular orbitals would be smaller for $M(3\text{-}Xptdn)_3$ as compared to that for $M(ptdn)_3$. It was observed that the satellite separations in the O(1*s*) spectra of $M(3\text{-}Xptdn)_3$ was smaller than that of $M(ptdn)_3$. These observations tempted us to assign the O(1*s*) satellite to a shake-up transition of $L\pi \rightarrow L\pi^*$ character.

As was shown in Experimental the surface of the sample was cleaned by argon ion bombardment. When the samples of $Al(3\text{-}Xptdn)_3$ and $Fe(3\text{-}Xptdn)_3$ were bombarded with argon ions for about 5 s an additional peak was observed in the O(1*s*) spectra. The intensity of this peak was stronger than the main peak when the argon ion bombardment was carried out for about 30 s (Fig. 3). The additional O(1*s*) signal was also associated with a weak satellite at binding energies higher than the additional peak.

The O(1*s*) spectra of other complexes studied in the present work did not show such an additional peak. It has been recognised that many compounds undergo surface decomposition in the X-ray flux of the spectrometer. No compound studied in the present work showed any detectable surface decomposition by X-rays even after exposure over the extended periods. The argon-ion bombardment might also cause structural changes or decomposition of the sample. Recently it was observed that the oxidation state of rhenium[24] in $(ReCl_3)_3$ was changed on the argon ion bombardment from rhenium(III) to rhenium(0). Since the position of the additional peak observed for $Al(3\text{-}Xptdn)_3$ and $Fe(3\text{-}Xptdn)_3$ was to the higher energy than that of main peak, we were tempted to assign it to the keto form of Xptdn (Fig. 4). We were, however, unable to take the reflectance IR spectrum of the irradiated samples to substantiate our prediction. It might be noted here that the stable complexes containing keto form of β-diketone were reported.[25] The forma-

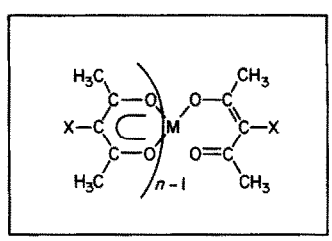

Fig. 4.

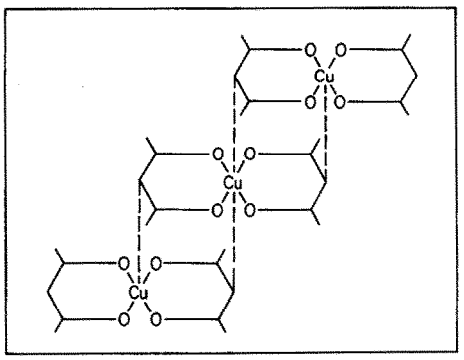

Fig. 5.

tion of such species as intermediates was also suggested from the study of mass spectra[26] of fluorine-substituted-acetylacetonates and (n, γ) reactions[5] of 3-bromo 2,4-pentanedionate of iron(III). Since the additional O(1s) signal was observed for Al(3-Xptdn)$_3$ and Fe(3-Xptdn)$_3$ and not for Cr(3-Xptdn)$_3$, Co(3-Xptdn)$_3$ and Cu(3-Xptdn)$_2$ studied in the present work, the presence of the additional O(1s) signal could be related with the nature of metal–ligand bond. Probably the M—O bond in Al(3-Xptdn)$_3$ and Fe(3-Xptdn)$_3$ had higher ionic character than that in other complexes.

The XPS of copper(II) complexes studied in the present work showed a different behaviour. The positions of the signal due to O($1s_{1/2}$) ionization indicated that the coordinated oxygen had a definite negative charge; but it was much less than that in other transition metal complexes. However, 3p photoelectron line of 3-Br for Cu(3-Brptdn)$_2$ was at a higher energy as compared to that for Cr(3-Brptdn)$_3$. The X-ray diffraction studies of Cu(ptdn)$_2$ showed[27] that the chelates were so packed that there was an interaction of the copper atom of one molecule with the 3-carbon atoms of the chelate ring of the neighbouring molecules (Fig. 5). Such interactions would explain the observed different behaviour of the XPS of copper(II) complexes.

BINUCLEAR SCHIFF-BASE COMPLEXES OF COPPER(II) LINKED BY PHTHALOYL AS A BRIDGING GROUP

K. KASUGA,* T. NAGAHARA and Y. YAMAMOTO
Department of Chemistry, Faculty of Science, Shimane University, Matsue 690, Japan

(*Received* 25 *June* 1984; *accepted* 25 *July* 1984)

Abstract—Binuclear Schiff-base complexes were prepared by bridging an unsymmetrical tetradentate Schiff-base complex of copper(II) with *m*- or *p*-phthaloyl. The complexes were characterized by means of elemental analyses, molecular weights, UV, IR and ^{1}H NMR (for metal-free ligands) spectra. ESR and magnetic susceptibility measurements show that the copper(II)–copper(II) interaction is negligibly small.

There has been considerable interest in the magnetic and spectroscopic properties of binuclear copper(II) complexes.[1] Recently, they have also received attention due to their resemblance to type-III copper proteins.[2] In this paper, we report the new type binuclear copper(II) complexes linked by *m*- or *p*-phthaloyl as shown in Fig. 1.

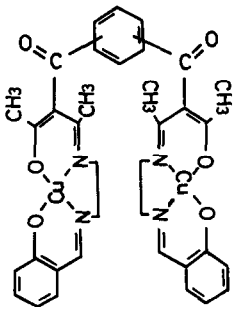

Fig. 1. The abbreviations of the binuclear Schiff-base complexes of copper(II) linked by phthaloyl.

EXPERIMENTAL

Syntheses

[*N*-(1-methyl-3-oxobutylidene)-*N'*-salicylideneethylenediaminato]copper(II), Cu(L—H), was prepared by the method described before.[3]

Preparation of a mononuclear 2-substituted copper(II) *complex.* 4-Nitrobenzoyl chloride (0.40 g, 2.2 mmol) was added to 100 cm^3 of the dichloromethane solution of 0.60 g (2.0 mmol) Cu(L—H), and was refluxed for 1 h. After concentration, the solution was chromatographed on silica gel. The parent complex, Cu(L—H), was first eluted with dichloromethane–acetone [95:5 (v/v)], followed by {*N*-[1-methyl-2-(4-nitrobenzoyl) - 3 - oxobutylidene] - *N'* - salicylideneethylenediaminato}copper(II), Cu(L—$COC_6H_4NO_2$), with dichloromethane–acetone (9:1). Upon recrystallization from acetone, the complex was obtained as bright brown needles (yield 22%). Found: C, 54.93; H, 3.99; N, 9.18%. Calc. for $C_{21}H_{19}N_3O_5Cu$: C, 55.19; H, 4.20; N, 9.19%.

Preparation of the binuclear copper(II) *complexes.* *m*-Phthaloyl dichloride (0.40 g, 2.0 mmol) was added to 100 cm^3 of dichloromethane solution of 1.20 g (4.0 mmol) Cu(L—H). After the solution was refluxed for 3 h, it was concentrated to *ca* 20 cm^3, and then was chromatographed on silica gel. The parent complex, Cu(L—H), was first eluted with dichloromethane–acetone (9:1), followed by the binuclear copper(II) complex, [(CuL)$_2$pht(*m*)], with dichloromethane–acetone (1:1). After concentration of the eluent, the pale brown precipitates of the binuclear complex were obtained by the addition of adequate amounts of hexane (yields 15%). Found: C, 55.78; H, 4.63; N, 6.62%. Calc. for $C_{36}H_{34}N_4O_6Cu_2 \cdot 0.5CH_2Cl_2$: C, 55.61; H, 4.48; N, 7.10%. The binuclear copper(II) complex, [(CuL)$_2$pht(*p*)], was prepared from *p*-phthaloyl dichloride by a similar method to that

described above (yields 10%). Found: C, 55.43; H, 4.10; N, 6.83%. Calc. for $C_{36}H_{34}N_4O_6Cu_2 \cdot 0.5CH_2Cl_2$: C, 55.61; H, 4.48; N, 7.10%.

Measurements

The electronic spectra were measured on a Hitachi 215 spectrophotometer. A Hitachi 115 Vapor Pressure osmometer was used for the determination of molecular weights using dichloromethane as a solvent. ^1H NMR spectra were recorded with a JEOL-MH 100 spectrophotometer at a frequency of 100 MHz. The chemical shifts were determined in ppm, using TMS as the internal standard. A PA 115 Vibrating Sample Magnetometer, operated at 10 kG, was used to measure magnetic susceptibility of the complexes. The ESR spectra (X-band) were measured with a JEOL-1X spectrophotometer.

RESULTS AND DISCUSSION

The results of electronic and IR spectra, and molecular weights are listed in Table 1.

The molecular weight measurements show the formation of the binuclear copper(II) complexes, with the results of elemental analyses. The binuclear complexes exhibit the new IR absorption at 1630 cm^{-1} assignable to νCO of the bridging groups, which also indicates the formation of the binuclear copper(II) complexes. The *d–d* absorption bands (552 nm) for the mononuclear 4-nitrobenzoyl substituted complex and the binuclear complexes are slightly shifted to the shorter wavelengths than that (556 nm) for the parent complex.

Although metal-free bridged ligands, $[(H_2L)_2pht(m)]$ and $[(H_2L)_2pht(p)]$, were not prepared from the direct reaction of *N* - (1 - methyl - 3 - oxobutylidene) - *N'* - salicylideneethylenediamine, $H_2(L—H)$, with *m*- or *p*-phthaloyl dichloride, they were obtained by elimination of copper(II) ion from the binuclear copper(II) complexes by passing gaseous hydrogen sulphide. The results of ^1H NMR spectra for the metal-free ligands are listed in Table 2.

The ^1H NMR signals of the methine proton of the parent ligand, $H_2(L—H)$, disappear in the free bridged ligands, indicating the replacement of the methine proton with the bridging groups. In addition, new ^1H NMR signals appear in the region of aromatic protons, being an indicative of introduction of the bridging groups. The methyl signals of the bridged ligands are somewhat shifted to the higher magnetic fields than that of the parent ligand, probably due to the magnetic anisotropic effect of a carbonyl group and/or benzene ring of the bridging group.

Magnetic properties

The ESR spectra of the binuclear copper(II) complexes were obtained at 77 K in the dichloromethane frozen solutions. The spectra showed axial patterns with $A \simeq 190$ G, which resembles that of the mononuclear copper(II) complex. This suggests that the copper(II)–

Table 2. ^1H NMR data of the metal-free ligands in dimethyl sulphoxide-d_6 (ppm)*

Compound	δCH_3	δCH_2CH_2	δCH	$\delta_{aromatic}$	$\delta_{azomethine}$
$H_2(L—H)$	2.05 (3H, *s*) 2.18 (3H, *s*)	3.96–4.29 (4H, *m*)	5.54 (H, *s*)	7.69–7.89 (2H, *m*) 8.25–8.45 (2H, *m*)	9.67 (H, *s*)
$[(H_2L)_2pht(m)]$	1.88 (6H, *s*) 2.05 (6H, *s*)	3.96–4.29 (8H, *m*)		7.49–7.69 (2H, *m*) 8.02–8.35 (6H, *m*)	9.54 (2H, *s*)
$[(H_2L)_2pht(p)]$	1.87 (6H, *s*) 1.96 (6H, *s*)	3.98–4.30 (8H, *m*)		7.39–7.65 (2H, *m*) 8.01–8.36 (6H, *m*)	9.53 (2H, *s*)

* *s*, singlet; *m*, multiplet.

copper(II) interaction is negligibly weak in the complexes. Magnetic susceptibilities of the binuclear copper(II) complexes were measured on solid samples in the temperature range from liquid nitrogen to room temperature.

The χ_A vs T^{-1} plots for these complexes obey the Curie law. The effective magnetic moments at room temperature and near liquid nitrogen temperature are as follows: 2.21 BM at 293 K and 2.23 BM at 80 K for [$(CuL)_2$pht(*m*)]; 2.15 BM at 293 K and 2.19 BM at 80 K for [$(CuL)_2$pht(*p*)]. The magnetic moments are almost independent of temperature. These results also suggest that the copper(II)–copper(II) interaction of the complexes is very weak.

Furthermore, the catalytic actions of the binuclear copper(II) complexes on a chemiluminescence of luminol and an oxidation of tetramethylphenylenediamine were attempted, but they did not exhibit the activities such as reported by Nishida *et al.*[2]

Acknowledgement—We wish to express our thanks to Dr M. Watanabe for his measurements of magnetic susceptibilities.

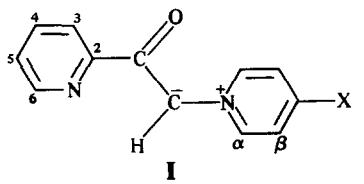
SPECTROSCOPIC STUDIES OF 4-SUBSTITUTED PYRIDINIUM 2-PYRIDYLCARBONYLMETHYLIDE–RHODIUM(I) COMPLEXES AND X-RAY MOLECULAR STRUCTURE OF (1,5-CYCLOOCTADIENE) (4-METHYLPYRIDINIUM 2-PYRIDYLCARBONYLMETHYLIDE)RHODIUM(I) PERCHLORATE

GEN-ETSU MATSUBAYASHI† and SEIGO AKAZAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565, Japan

(*Received* 14 *June* 1984; *accepted* 25 *July* 1984)



Abstract—(1,5-Cyclooctadiene) (4-substituted pyridinium 2-pyridylcarbonylmethylide)-rhodium(I) perchlorates, $[Rh(COD)(C_5H_4NC(O)\bar{C}H\overset{+}{N}C_5H_4X\text{-}4)]ClO_4$ [COD = 1,5-cyclooctadiene; X = $CH_3C(O)$, $CH_3OC(O)$, C_6H_5, CH_3, and H], have been prepared. They are shown to have the geometry with coordination by the pyridyl nitrogen and carbonyl oxygen atoms of the ylide ligands and to exhibit intramolecular rearrangement of co-ordinated COD in chloroform, methanol, and dimethyl sulphoxide based on IR and ^1H NMR spectroscopies. Although the ylides have exhibited fluorescence bands due to an intramolecular charge-transfer transition and phosphorescence bands due to a carbonyl $^3(n\text{–}\pi^*)$ transition, the complexes have given emission bands due to the metal-to-ylide ligand charge-transfer transition. A single crystal X-ray crystal structure has been determined for $[Rh(COD)(C_5H_4NC(O)\bar{C}H\overset{+}{N}C_5H_4CH_3\text{-}4)]ClO_4$. The crystals are monoclinic, space group $P2_1/n$ with cell dimensions $a = 14.887(3)$, $b = 20.274(4)$, $c = 6.966(1)$ Å, $\beta = 96.13(1)°$, and $Z = 4$. The structure has been refined by a block-diagonal least-squares method to final $R = 0.060$ for 2997 independent reflections with $|F_o| > 3\sigma(F)$. The ylide carbon–pyridinium nitrogen bond distance is 1.420(10) Å. The bonded distances from rhodium to the midpoints of the double bonds of COD are 1.982(11) and 2.014(12) Å.

Although reactivities of photo-excited states of organometallic compounds have recently attracted much interest,[1] luminescent properties of ylides and their metal complexes have been little investigated.[2,3] Pyridinium ylides are unique because the carbanion can be stabilized by a vacant π^* orbital of the pyridinium ring.[2] They show an intense absorption band due to the ylide carbon-to-pyridinium nitrogen charge-transfer (CT) transition. We have undertaken to investigate luminescent properties of several pyridinium ylides stabilized by the 2-pyridylcarbonyl group (**I**) and their rhodium(I) complexes as well as configurations of the complexes. Ylides (**I**) are able to interact with platinum(II) and palladium(II) ions through the ylide carbon atom[4,5] and with tungsten(0) and tin(IV) moieties through the carbonyl oxygen atom.[3,6] Thus, the bonding scheme of pyridinium ylides with the rhodium(I) ion is also of interest.

This paper reports luminescent properties of the ylides (**I**) and their rhodium(I) complexes,

$$[Rh(COD)(C_5H_4NC(O)\bar{C}H\overset{+}{N}C_5H_4X\text{-}4)]ClO_4$$

[X = $CH_3C(O)$, $CH_3OC(O)$, C_6H_5, CH_3, and H], and discusses their configurations based on IR and ^1H NMR spectroscopies. The X-ray molecular structure of (1,5-cyclooctadiene) (4-methylpyridinium 2-pyridylcarbonylmethylide)rhodium(I) perchlorate is also described.

EXPERIMENTAL

Preparation of 4-substituted pyridinium 2-pyridylcarbonylmethylides

A benzene (120 cm^3) solution containing 2-(bromoacetyl)pyridine (1.3 g, 6.5 mmol)[7] and pyridine (0.53 g, 6.7 mmol) was refluxed for 4 h to give a white precipitate of *N*-(2-pyridylcarbonylmethyl) pyridinium bromide (1.2 g). To its aqueous (20 cm^3) solution an aqueous (10 cm^3) solution of K_2CO_3 (1.3 g, 9.4 mmol) was added with stirring to afford red solids of crude pyridinium 2-pyridylcarbonylmethylide (Y_H), which were recrystallized from a mixture of dichloromethane and petroleum ether (b.p. 40–60°C) to give red needles of Y_H (0.66 g, 39% yield), m.p. 247°C (dec.). Found: C, 72.58; H, 4.83; N, 14.02. Calc. for $C_{12}H_{10}N_2O$: C, 72.71; H, 5.09; N, 14.13%. 4-Carbomethoxypyridinium (Y_{CM}), 4-acetylpyridinium (Y_{AC}), and 4-phenylpyridinium 2-pyridylcarbonylmethylide (Y_{PH}) were also prepared by the similar procedure. Y_{CM} (63% yield), m.p. 180°C (dec.). Found: C, 65.53; H, 4.71; N, 10.92. Calc. for $C_{14}H_{12}N_2O_2$: C, 66.40; H, 4.78; N, 11.06%. Y_{AC} (39% yield), m.p. 166°C (dec.). Found: C, 68.93; H, 4.79; N, 11.52. Calc. for $C_{14}H_{12}N_2O_3$: C, 69.99; H, 5.03; N, 11.65%. Y_{PH} (55% yield), m.p. 267°C (dec.). Found: C, 40.50; H, 2.15; N, 4.55. Calc. for $C_{18}H_{14}N_2O$: C, 40.39; H, 2.26; N, 4.49%. 4-Methylpyridinium 2-pyridylcarbonylmethylide (Y_{ME}) was prepared as described elsewhere.[5]

Preparation of (1,5-cyclooctadiene) (4-substituted pyridinium 2-pyridylcarbonylmethylide)rhodium(I) perchlorate

To a methanol (20 cm^3) suspension of bis(1,5-cyclooctadiene)dichlorodirhodium(I)[8] (0.125 g, 0.25 mmol) was added a methanol (15 cm^3) solution of Y_H (0.10 g, 0.50 mmol) and the solution was stirred for 10 min at room temperature. To the brown solution was added an aqueous (10 cm^3) solution of $NaClO_4 \cdot H_2O$ (0.056 g, 0.4 mmol) to separate out brown solids. Recrystallization from methanol gave orange needles of $[Rh(COD)Y_H]ClO_4$ (**1**) (0.13 g). The Y_{ME} analogue (**2**) was prepared by the same way and recrystallized from methanol. The Y_{PH}, Y_{CM} and Y_{AC} analogues (**3**–**5**) also were prepared by the same procedure and recrystallized from acetonitrile. Analyses and preparation yields for the ylide–rhodium(I) complexes are summarized in Table 1.

Table 1. Analysis and preparation yields of $[Rh(COD)Y]ClO_4$

No.	Y	Found (Calcd) (%) C	H	N	Yield (%)
1	Y_H	46.95 (47.22)	4.52 (4.36)	5.41 (5.51)	50
2	Y_{ME}	47.81 (48.25)	4.77 (4.63)	5.29 (5.36)	62
3	Y_{PH}	52.90 (53.39)	4.50 (4.48)	4.81 (4.79)	46
4	Y_{CM}	46.56 (46.62)	4.39 (4.27)	4.97 (4.94)	55
5	Y_{AC}	48.07 (47.99)	4.56 (4.37)	5.21 (5.09)	55

Spectral measurements

^1H NMR spectra were measured using a JEOL PS-100 spectrometer equipped with a variable temperature accessory. IR and electronic absorption spectra were recorded on a Hitachi 124 and a Union 401 spectrophotometer, respectively. Total emission spectra were measured on a Hitachi MPF-3 spectrofluorimeter. Spectra of the millisecond component of the emission were obtained on the same fluorimeter using a phosphorescence accessory. Fluorescence lifetimes were determined from decay curves of fluorescence excited by irradiation on N_2 laser pulse (337 nm, $\lesssim$ 5 ns).[9] All the emission measurements were carried out in a degassed methanol/ethanol [1:4 (v/v)] solvent at 77 K.

X-ray crystal analysis

Orange needles of **2** were obtained by recrystallization from methanol. The space group and initial cell parameters were determined from oscillation and Weissenberg photographs. Accurate cell parameters were obtained from the least-squares fit of the angular coordinates of 45 reflections with 2θ values from 25 to 33° which were measured on a computer-controlled Rigaku four-circle diffractometer with Mo-K_α (λ = 0.71069 Å) radiation.

Crystal data

$C_{21}H_{24}N_2O_5ClRh$. M = 522.79. Monoclinic, space group $P2_1/n$, a = 14.887(3), b = 20.274(4), c = 6.966(1) Å, β = 96.13(1)°, V = 2090.2(7) $Å^3$, Z = 4, D_c = 1.6613(6) g cm^{-3}, $F(000)$ = 1064, μ(Mo-K_α) = 9.7 cm^{-1}.

A specimen, approximately 0.12 × 0.12 × 0.25 mm, was used for the data collection on the diffractometer. Intensity data were measured by using graphite-monochromatized Mo-K_α radiation and a ω–2θ scan technique at 2θ scan rate of 2° min^{-1}. They were corrected for Lorentz and polarization effects, but not for absorption. Of the 4789 independent reflections in the range of $2\theta < 55°$,

2997 had structure amplitudes larger than three times their standard deviations. The structure was solved by the conventional heavy-atom technique and the atomic parameters were refined by block-diagonal least-squares method. Anisotropic temperature factors were assigned to all non-hydrogen atoms and isotropic factors to hydrogen. The refinement converged at $R = \Sigma||F_o|-|F_c||/\Sigma|F_o| = 0.066$ and $R_w = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.062$ with the weighting scheme, $1/w = \sigma^2(F_o)+0.0005F_o^2$. The final difference-Fourier map had no positive maxima > 1 e Å^{-3} except in the vicinities of positions of the metal and chlorine atoms. The atomic scattering factors were taken from the usual tabulation.[10] The final atomic coordinates and anisotropic temperature factors together with observed and calculated structure factors have been deposited with the Editor as supplementary materials. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

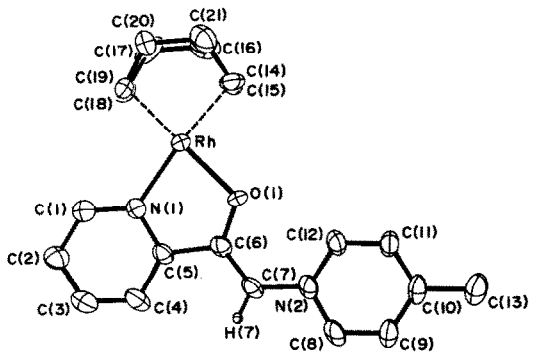
Crystallographic calculations were performed on an ACOS 900S computer at the Crystallographic Research Centre, Institute for Protein Research, Osaka University. Figure 1 was drawn with a local version of ORTEP-II.[11]

RESULTS AND DISCUSSION

Description of the molecular structure of [Rh(COD)($C_5H_4NC(O)\bar{C}H\overset{+}{N}C_5H_4CH_3$-4)]$ClO_4$ (2)

Figure 1 shows the molecular structure of 2 with the atom-labelling scheme. In the crystal structure no unusual intermolecular contacts were found. Pyridyl nitrogen and carbonyl oxygen atoms as well as two olefin carbon–carbon bonds are coordinated to rhodium, forming a square-planar geometry around the metal atom. The perchlorate anion does not participate in the coordination to the rhodium atom. Bond distances and angles with estimated standard deviations are given in Table 2. The Rh—N distance [2.068(6) Å] is very close to that of carbonyl(8-hydroxyquinolinato)(triphenylphosphine)rhodium(I) [2.098(9) Å].[12] The Rh—O distance [2.049(5) Å] is also quite similar to that of this compound [2.042(5) Å] and to that of benzoyl-1,1,1-trifluoroacetonato(1,5 - cyclooctadiene)rhodium(I) [2.050(4), 2.066(5) Å].[13] The COD ligand is coordinated to the metal atom with its customary "tub" conformation, the olefin bonds being orientated approximately perpendicular to the coordination plane. The distances between rhodium and the double bond centres of COD [1.982(11), 2.014(12) Å] are on the short end of the range 2.00–2.16 Å found in heavy-metal complexes with COD.[14] These short distances may result from the *trans* influence of nitrogen and oxygen atoms. On the other hand, the distances of coordinated double bonds, C(14)—C(15) and C(18)—C(19) [1.395(11) and 1.350(12) Å, respectively] are slightly longer than the uncoordinated olefinic C=C distance of 1.34 Å.[15]

All the non-hydrogen atoms of the ylide ligand as well as rhodium are approximately co-planar (±0.08 Å). The C(7)—N(2) bond [1.422(10) Å] is apparently longer than partial double bonds, N(1)—C(1), N(1)—C(5), N(2)—C(8), and N(2)—C(12) (1.346–1.390 Å) and is rather close to the C—N single bond adjacent to the N=C double bond, as was reported for *n*-butyltrichloro(*N'*-phenylpyridine-2-calbaldimine-*N*,*N'*)tin(IV) [1.441(5) Å].[16] This finding may suggest little double-bond character in this



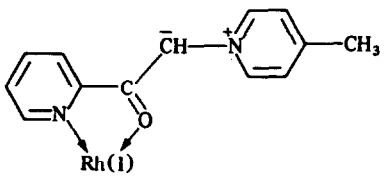


Fig. 1. View of the molecular structure of the cation moiety of [Rh(COD)Y_{ME}]ClO_4 (2) with the atom-labelling scheme. Hydrogen atoms except for H(7) are not illustrated. Thermal ellipsoids are drawn at the 30% probability level.

bond, which is in contrast to the appreciable partial double-bond character of the ylide carbon–nitrogen bond of 4-cyanopyridinium 2-pyridylcarbonylmethylide which was deduced on the basis of ^{1}H NMR spectra.[17] The C(6)—C(7) distance [1.356(11) Å] is significantly short compared with C(5)—C(6) [1.499(11) Å]. Moreover, the ylide carbonyl distance [C(6)—O(1), 1.304(8) Å] is markedly lengthened compared with the C=O distance predicted based on double-bond radii of carbon and oxygen atoms (1.20 Å),[18] and is somewhat longer than the C=O distance of tetracarbonyl(dimethylsulphonium 2-pyridylcarbonylmethylide)tungsten(0) [1.277(9) Å].[19] These findings are explained by assuming the resonance hybrid of canonical structures, **II** and **III**, in the present ylide ligand.

II

III

The IR carbonyl stretching band of **2** is observed at a lower frequency than that of free ligand (Table 3), indicating the contribution of the canonical structure **II**. This is also the same in the other ylide complexes **1**, **3**–**5**. The coordination through the carbonyl oxygen atom in these complexes offers a striking contrast with the ylide carbon–metal bonding in the palladium(II) and platinum(II) complexes with these ylides.[4,5]

Table 3. IR carbonyl stretching frequencies (cm^{-1}) and ^{1}H NMR chemical shifts (δ) for [Rh(COD)Y]ClO$_4$

Y	ν(C=O)[a]	δ H$_6$[b]	δ H$_\alpha$[b]
Y_H	1490 (43)	8.05 (0.45)	9.60 (0.30)
Y_{ME}	1501 (28)	8.12 (0.36)	9.39 (0.45)
Y_{PH}	1480 (35)	c	9.48 (0.51)
Y_{CM}	1501 (26)	8.37 (0.30)	9.59 (0.36)
Y_{AC}	1499 (15)	8.07 (0.48)	9.60 (0.15)

[a] Measured in Nujol mulls. $\nu_{free}-\nu_{complexed}$ in parentheses.

[b] Measured in DMSO-d_6. $\delta_{free}-\delta_{complexed}$ in parentheses.

[c] Not determined precisely owing to complexity of the signals.

* The temperature-dependent ^{1}H NMR spectra were measured for this complex in methanol-d_4 and in chloroform-d, since the solubility of [Rh(COD)Y$_H$]ClO$_4$ was not enough for the measurement. The spectra of both the complexes in these solvents were essentially identical at room temperature.

^{1}H *NMR spectra*

These complexes have shown the ^{1}H NMR signals of protons (H_6) attached to carbons adjacent to the pyridyl nitrogen atoms at considerably higher fields than the free ylides in DMSO-d_6 (Table 3). Generally, these signals are likely to occur at lower fields upon complexation through the pyridyl nitrogen atom with metal ions owing to their inductive effects.[5,6] Signals of *ortho* protons (H_α) of the pyridinium rings of the complexes are also observed at higher fields than those of the free ligands, although the chemical shifts of other protons are not precisely determined owing to their complicated signal occurrences. These unusual upfield shifts of the present complexes may be due to a significant metal-to-ylide ligand CT contribution, as will be described later. The spectra of the complexes in DMSO-d_6 have shown a signal due to the olefinic protons of the ligated COD at room temperature, although these protons are expected to be non-equivalent based on the geometry of these complexes. This indicates some positional rearrangement of ligands around the rhodium atom. The spectra of [Rh(COD)Y$_H$]Cl* in methanol-d_4 and in chloroform-d have shown also a signal due to the non-equivalent olefinic protons of the COD ligand at room temperature. On the other hand, two signals of these protons are observed at lower temperatures (Fig. 2). Both additions of free COD and Y_H to a chloroform-d solution of [Rh(COD)Y$_H$]Cl have not varied the spectrum of the complex. Thus, these findings seem to indicate an intramolecular rearrangement without dissociation of the ligands. The Gibbs free energies of activation of the rearrangement at coalescence temperatures have been estimated 11.8 ± 0.1 kcal mol^{-1} (at -27 ± 2°C) in chloroform-d and 10.6 ± 0.1 kcal mol^{-1} (at -51 ± 2°C) in methanol-d_4, using the approximate equation.[20]

Electronic absorption and emission spectra

Figure 3 shows the absorption spectra of Y_{ME} and the Y_{ME}–Rh(I) complex (**2**) in methanol/ethanol

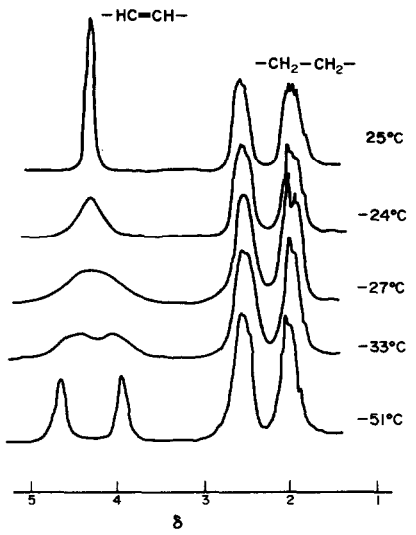

Fig. 2. Temperature-dependent ^1H NMR signals of the COD ligand of $[Rh(COD)Y_H]Cl$ in chloroform-*d*.

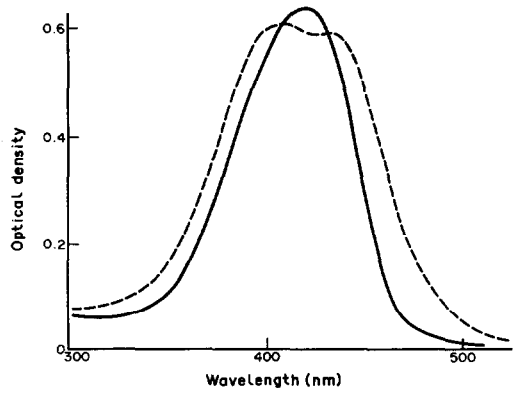

Fig. 3. Electronic absorption spectra of Y_{ME} (6.0×10^{-4} mol dm^{-3}) (——) and $[Rh(COD)Y_{ME}]ClO_4$ (**2**) (2.4×10^{-4} mol dm^{-3}) (– – –) in methanol/ethanol [1:4 (v/v)] at 298 K (1-mm cell).

[1:4(v/v)] at room temperature. The intense band of Y_{ME} at 423 nm is reasonably assigned to an intramolecular CT transition from carbanion to a pyridinium π^* orbital. Generally, pyridinium ylides are known to be stabilized by the carbanion participation in the resonance of the pyridinium ring,[2] which is in contrast with the stabilization by the carbanion delocalization to *d*-orbitals of sulphur and phosphorus atoms in sulphur and phosphorus ylides.[21,22] It is noteworthy that Y_{ME} as well as other pyridinium ylides exhibits the CT band at a longer wavelength than the corresponding triphenylphosphonium- and dimethylsulphonium ylides.[23] An electron-withdrawing substituent of the pyridinium ring would more contribute to this stabilization; the intramolecular CT absorption band of an ylide with a more electron-withdrawing substituent appears at a longer wavelength (Table 4).

Complex **2** shows broad bands at somewhat shorter wavelengths than free Y_{ME}, of which the band at a shorter wavelength is assignable to the intraligand CT transition and the other tentatively to metal-to-ligand CT one, as was observed for $W(CO)_4Y_{ME}$.[3] Coordination to the metal through the carbonyl oxygen atom decreases the intraligand CT contribution of the ylide carbon-to-pyridinium ring, causing to elevate the energy due to the CT transition. The other ylide–Rh(I) complexes have exhibited the same spectral feature (Table 5).

As is summarized in Table 4, the ylides exhibit weak fluorescences with lifetimes of $\lesssim 5$ ns and weak phosphorescences with lifetimes of 200–500 ms in methanol/ethanol [1:4 (v/v)] at 77 K. The excitation spectra which maximize the intensities of fluorescence bands correspond to intramolecular CT absorption bands. On the other hand, the excitation bands of the phosphorescence bands appear at 270–290 nm. On the basis of their lifetimes these emissions are considered to be due to the carbonyl $^3(n\text{–}\pi^*)$ transition. This finding is in contrast with the phosphorescences due to the $^3(\pi\text{–}\pi^*)$

Table 4. Absorption (at 298 K) and emission band maxima (at 77 K) (nm) for 4-substituted pyridinium 2-pyridylcarbonylmethylides in methanol/ethanol [1:4 (v/v)]

Ylide	Absorption[a]	Emission	
		Fluorescence[b]	Phosphorescence[c]

* log [ε (mol^{-1} cm^{-1} dm^3)] in parentheses.

transition observed for several *N*-benzyl-4-substituted pyridinium perchlorates which have 1–3 s as the lifetime.[6]

Figure 4 shows the emission spectrum of **2** in methanol/ethanol [1:4 (v/v)] at 77 K. The complex has shown no phosphorescence with a lifetime in the millisecond range, which is also the same as the other ylide–Rh(I) complexes. Furthermore, no flouresence due to the intraligand CT transition of the ylide has been observed. **2** shows an emission band at a longer wavelength. The excitation band which maximizes the intensity of this band also is close to its absorption band at 430 nm. Thus, the emission is tentatively ascribed to the metal-to-ligand CT transition. The lifetime of this emission has not been determined in the ns and ms regions, but has been estimated to be in the μs region. The other complexes have exhibited an emission band similar to this complex (Table 5). The Stokes shifts of the metal-to-ligand CT emissions are large, indicating markedly prolonged metal-to-ligand bond distances at excited states, as was reported for 1,2-bis(diphenylphosphinoethane)– and *cis*-1,2-bis(diphenylphosphino)-ethylene–Rh(I) complexes.[24]

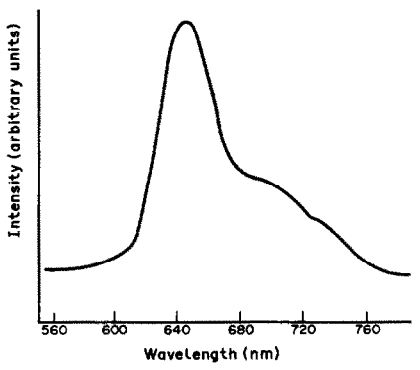

Fig. 4. Emission spectrum of $[Rh(COD)Y_{ME}]ClO_4$ (**2**) in methanol/ethanol [1:4 (v/v)] at 77 K.

Acknowledgements—We wish to express hearty thanks to Professor Toshio Tanaka of Osaka University for his continuous encouragement throughout this study. We thank Professor Kazumi Nakatsu of Kwansei Gakuin University, Nishinomiya, Hyogo, for the use of the X-ray diffractometer and the programs for the structure solution and refinement. We thank Dr Masaaki Yokoyama of Osaka University for the measurement of the fluorescence lifetimes of the ylides.

A NEW COPPER(I) THIOCYANATO THIOCYANOGEN COMPLEX

S. K. TOBIA,* E. R. SOUAYA and W. G. HANNA
Chemistry Department, Faculty of Science, Ain Shams University, Abbassia, Cairo, Egypt

(*Received* 5 *March* 1984; *accepted after revision* 25 *July* 1984)

Abstract—The reaction between Cu^{2+} and SCN^-, in glacial acetic acid at a Cu/SCN ratio, of 1:4, gave a dark red solution that exhibited an absorption band at 496 nm. The colour of the freshly prepared solution was bleached by water with concomitant production of SO_4^{2-} ion. On standing, the stability of the colour towards water is increased and the position of the absorption band shifts to a higher wavelength. It is inferred that the thiocyanogen produced on oxidation of SCN^- by Cu^{2+} is stable in the non-aqueous medium and is coordinated together with SCN^- in a Cu(I) complex. The bleaching action of water is attributed to the hydrolysis of thiocyanogen, mainly to SO_4^{2-}. The presence of thiocyanogen enhanced polymerization and subsequent deposition of an orange-brown solid complex. On the basis of chemical, spectral, and thermal analyses the formula $K[Cu(SCN)_2(NCS—SCN)]$, is assigned to the new compound.

Copper(I) forms an insoluble cyanide as well as a number of soluble cyano-complexes. It also forms an insoluble thiocyanate, but no thiocyanato Cu(I) complexes have been reported previously. On the other hand, copper(II) forms homogeneous thiocyanato complexes as well as mixed ligand complexes. For example, in the presence of organic nitrogen bases, it yields with thiocyanate coloured complexes that have some analytical applications. Other coloured complexes were also obtained by oxidation of colourless redox indicators by Cu(II) in the presence of CN^- or SCN^-. Gregorowicz and Buhl[1] oxidized variamine blue with Cu(II) in the presence of SCN^-. The coloured complex was not characterized but it may be a Cu(I) complex containing SCN^- and the oxidized form of variamine blue.

The SCN^- can also be oxidized to thiocyanogen, but the presence of the latter could only be detected in non-aqueous media because of its ease of hydrolysis. In molten thiocyanate for example, the reduction of Cu(II) to Cu(I) and the oxidation of SCN^- to parathiocyanogen (polymerized thiocyanogen) or to sulphur and cyanogen has been confirmed by a number of investigators:[2]

$$2Cu(II) + 2SCN^- = (NCS—SCN) + 2Cu(I).$$

Thiocyanogen may however, be decomposed to sulphur and cyanogen:

$$(NCS—SCN) = 2S + (CN)_2.$$

Although, these reactions involve Cu(I), SCN^- and (NCS—SCN), the possibility of formation of a complex containing both thiocyanate and thiocyanogen has not been investigated before.

The formation of a complex containing both the pseudohalogen and its oxidation product has been demonstrated before in the Cu^{2+}–CN^- system.[3] Furthermore, a new Fe(II) thiocyanate thiocyanogen complex has been prepared by the reaction of Fe(III) and SCN^- in glacial acetic acid.[4] The present investigation has been undertaken to study the possibility of formation of the corresponding Cu(I) complex when Cu(II) reacts with SCN^- in a non-aqueous medium. Since thiocyanogen is known to be most stable in glacial acetic acid, the latter was used as a reaction medium in this study.

EXPERIMENTAL

Solutions

Stock solutions of Cu(II) and thiocyanate were prepared by saturating a certain volume of glacial acetic acid (AR 99.7) with anhydrous Cu(II) acetate or potassium thiocyanate at 25°C. The concentra-

* Author to whom correspondence should be addressed.

tions of these solutions were approximately 0.08 and 3.0 *M* with respect to Cu(II) and SCN^- ions respectively.

Dilute thiocyanate solutions were prepared by diluting the stock solution with glacial acetic acid, but the copper solution was used without dilution.

Thiocyanogen solution, about 0.1 *M*, was prepared by the action of bromine on silver thiocyanate, in an acetic acid medium as was described by Vanderzee and Quist.[5] The pale yellow solution obtained is known to contain the monomer and was found stable below 15°C.

Preparation of the complexes

The copper solution was run from a burette into the thiocyanate solution contained in a 50-cm^3 conical flask mounted on a magnetic stirrer, and cooled by an ice bath. The compound studied was that obtained at Cu/SCN^- ratio of 1:4. When the dark red solution obtained at this ratio was left overnight, an orange-brown solid was obtained. The latter was separated by filtration, washed with acetic acid, and dried over P_2O_5.

Analytical

The Cu(II) solution was standardized by complexometric titration using EDTA and murexide indicator. The thiocyanate solutions were standardized, after dilution with water, by the Volhard's method.

The solid complex was analyzed as follows.

Since the solid complex is suspected to contain thiocyanate and thiocyanogen, the analytical procedure used allowed for the separate determination of these two species. The procedure adopted involved treatment of the solid with 0.1 *M* NaOH which gave a precipitate containing parathiocyanogen and hydrous copper oxide. The precipitate was separated by filtration, and the filtrate was kept for the determination of SCN^- and K^+. Treatment of the precipitate with dilute HCl dissolved the copper leaving an orange residue of parathiocyanogen which was washed, dried and weighed.

The thiocyanate in the alkaline filtrate was determined by a thiocyanate-sensitive ion-selective electrode. Copper was determined either by iodometric titration or complexometrically using EDTA and murexide. Potassium was determined gravimetrically as cobaltinitrite.

An alternate method for K^+ and Cu^{2+} involved treatment of the solid with concentrated nitric acid and heating to dryness. The residue was taken up by HCl and the resulting solution was used for the determination of those ions.

The percentage of thiocyanogen was also confirmed by subtracting the thiocyanate sulphur from the total sulphur. The latter was determined by a sodium carbonate–potassium nitrate fusion method using a gravimetric finish for the determination of the sulphate formed.

Tests for thiocyanogen in the complex solution and in the solid complex were carried out as described before.[4]

The TG, DTG and DTA graphs were recorded using a Paulik–Paulik–Erdey MOM Derivatograph. Other physical measurements were essentially as described before.[4]

RESULTS AND DISCUSSION

Preliminary experiments indicated that when the thiocyanate solution was added to the copper solution, a dark brown precipitate was obtained when the SCN/Cu ratio reached 2. Chemical analysis of the precipitate showed that it was Cu(II) thiocyanate, $Cu(SCN)_2$. It decomposed on standing into CuSCN and parathiocyanogen. The compound was also insoluble in excess of thiocyanate, and therefore, the investigation of other possible complexes was impossible. For this reason, the copper solution was added to the thiocyanate solution to produce mixtures of any SCN/Cu ratio. In this investigation only the species produced at an SCN/Cu ratio of 4 was studied.

The dark red solution obtained at the above ratio exhibited an absorption band at 495 nm, and was obtained only in the non-aqueous medium. Under these conditions it is possible that the thiocyanogen formed by the oxidation of thiocyanate by copper(II) would be stable and the red colour may be attributed to a thiocyanato thiocyanogen complex of copper(I). The red colour of the freshly prepared solution is almost completely bleached by water with production of sulphate ion, as tested for by Ba^{2+}. This is explained as being due to the hydrolysis of the coordinated thiocyanogen. On standing, however, the red solution was found to gain increasing stability towards water. This suggests that, in the aged solution, the coordinated thiocyanogen must have been protected from hydrolysis, probably by acting as a bridging ligand between the metal ions rather than as a terminal one. This view is supported by a shift in the absorption band from 495 nm in the fresh solution to 500 nm in the aged solution.

The orange brown precipitate obtained when the red solution was left overnight was subjected to chemical and physical tests as described below.

Magnetic measurements showed that the solid is diamagnetic, suggesting the presence of Cu(I) in the complex.

The solid is insoluble in water and most organic solvents. Treatment with NaOH decomposed the solid into a precipitate containing hydrous copper oxide and parathiocyanogen, and alkaline solution containing K^+ and SCN^- ions. The separation of parathiocyanogen is not in itself indicative of the existence of a thiocyanato thiocyanogen complex. The solid may be a mixture of parathiocyanogen and CuSCN, or may contain $Cu(SCN)_2$ which decomposes to CuSCN and parathiocyanogen. However, the following observations provide evidence indicating that the solid is a thiocyanogen Cu(I) complex.

Chemical analysis

The results of chemical analysis are shown in Table 1. For every mole of Cu, there are two moles of SCN^- ion and one mole of NCS—SCN. If these were coordinated to Cu(I), the percent of the potassium counter ion would be 11.67 which is in good agreement with the observed value.

The thiocyanogen produced by Cu(II) would be insufficient for the above stoichiometry, but the extra may be formed by aerial oxidation of the solution standing overnight. The first yield of compound was only about 60% of that expected, but further yields were obtained when the filtrates collected were left exposed to air, until a total of about 85% yield was obtained.

The composition and stoichiometry of the solid compound was further confirmed by chemical synthesis. The same solid was obtained on treatment of a mixture containing equimolar amounts of KSCN and CuSCN, in glacial acetic acid, by a solution of thiocyanogen. A yield, better than 95% was obtained when the number of moles of thiocyanogen was equal to that of copper.

X-ray analysis

The X-ray diffraction pattern was found different from that of CuSCN or $Cu(SCN)_2$. The principal lines are found at 5.7 (100%), 3.69 (55%), 3.09 (80%), 2.95 (60%) and 2.35 (100%).

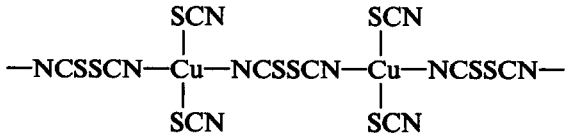
Table 1.

Component Sought	Observed	Calculated from: K $Cu(SCN)_2$(NCS-SCN)
C	13.70	14.35
N	16.50	16.74
S (total)	38.15	38.27
SCN^-	35.29	34.68
(NCS-SCN)	33.86	34.68
Cu	19.00	18.98
K	10.95	11.67

Effect of dry heating

Gentle heating of the solid in a micro test tube gave a sublimate of sulphur and cyanogen gas as indicated by a positive oxine-cyanide test.[6] Parathiocyanogen does not respond to this test.

Thermal analysis



The TGA showed a weight loss occurring in two distinct stages, one between 165 and 371°C, and the other between 371 and 572°C. Each stage corresponded to about 32% loss and was accompanied by an exothermic peak in the DTA graph. The first was strong and sharp centred at 300°C, while the other was broad and complex, probably representing three or more overlapping bands. The two-stage weight loss implies the presence of two different oxidizable ligands that are differently bonded to the metal ion. The theoretical loss in each stage, as calculated from the formula $K[Cu(SCN)_2(NCSSCN)]$ is 34.68%. The difference is due to the retention of some sulphur in the residue which contained potassium sulphate, and a mixture of copper oxide and sulphide. The formation of this product was accompanied by about 6% increase in weight and took place between 572 and 667°C.

IR spectra

In addition to the band at 2080 cm^{-1} assigned to the —C≡N— asymmetric stretching on the SCN^- group, there is a stronger and sharper band at 2160 cm^{-1} assigned to the —C≡N— asymmetric stretching of thiocyanogen. This band exists at 2171 cm^{-1} in free thiocyanogen,[5] and the observed decrease may be attributed to bonding to two copper ions. On heating the solid up to 350°C, the intensity of the thiocyanogen band was decreased by about 50%, while the thiocyanate band was not changed, but it disappeared at a higher temperature. These observations are consistent with those indicated by the thermal analysis.

In the lower frequency range, the C—S stretching is represented by two bands, one at 670 cm^{-1} for thiocyanogen[5] and the other at 745 cm^{-1} for thiocyanate. The effect of thermal treatment on these bands is similar to that observed for the —C≡N— asymmetric stretching, mentioned above. The band at 610 cm^{-1} is assigned to Cu—S stretching. Not only was it maintained on heating up to 500°C, but also became sharper and stronger.

One of the possible structures which may account for all the above observations may be represented as:

in which the copper is bonded to two terminal thiocyanate groups and thiocyanogen acting as a bridging ligand to form an infinite chain polymer. Since —C—S— stretching of the thiocyanate is relatively low, it is possible that the copper is bonded through the thiocyanate sulphur.

EQUILIBRIUM AND KINETIC STUDIES OF THE Fe(III) COMPLEX FORMATION WITH GLYCINEHYDROXAMIC ACID

MOHAMED S. EL-EZABY* and MANSOUR M. HASSAN
Chemistry Department, Kuwait University, Faculty of Science, P.O. Box 5969, Kuwait

(*Received* 8 *May* 1984; *accepted* 25 *July* 1984)

Abstract—Spectrophotometric methods were utilized for stability constant determinations of the Fe(III) interaction with glycinehydroxamic acid (GX) at $I = 0.15$ *M* NaCl and $T = 25°C$. Program SQUAD II was used to assess the absorbance data in the wavelength range 300–520 nm. Four constants were determined for 1:1:1, 1:1:0, 2:1:1 or 3:1:3 and 2:1:0 complex species in the pH range 1.0–7.5. The kinetics of the interactions of Fe(III) with GX were also studied in the pH range 1.0–3.0 by the stopped flow method. The observed rate constant at a given pH was $k_{obs} = A + BT_{GX}$. The parameters A and B are functions of pH in the range 1.7–3.0 and only A is a function of pH in the range 1.0–1.7. The mechanism of complex formation was discussed in the light of the experimental results and the equilibrium study. It has been concluded that $FeOH^{2+}$ is the reactive species in the complex formation of $FeGXH^{3+}$ species while $Fe(OH)_2^+$ is the reactive species in the complex formation of $FeGX^{2+}$ species.

Considerable work has been done in the last decade on hydroxamate chemistry. Aside from their analytical and industrial applications, they serve as metal chelators which may function as growth factors, antibiotics, antibiotic antagonists, tumour inhibitors, antifungal agents and cell division factors.[1–11] The recent interest in hydroxamates lies in the fact that some siderochromes containing hydroxamate groups, such as peptide ferrochrome, form stable complexes with Fe(III).[12] Their specific function is to solubilize iron acting as a mediator for transporting iron from the environment to the cell. Although many hydroxamate complexes of Fe(III) have been reported quite recently,[13–15] few studies have dealt with the kinetics and mechanism of their binary complex formation.[16,17] In addition, ternary complex formation involving hydroxamates as one of the ligands were scarcely investigated.

In an attempt to study kinetically the ternary reaction of Fe(III)-pyridoxol (vitamin B_6 compound) with glycinehydroxamate, prior investigation of the binary system involving Fe(III) and glycinehydroxamate is essential. It has been reported that glycinehydroxamate forms stable monomeric complexes with Fe(III) over quite a wide pH range.[15] The study was carried out by analytical potentiometry. In this work the interaction of Fe(III) with glycinehydroxamate was followed spectrophotometrically in order to define their equilibrium reactions and their reaction kinetics. This kind of work was inevitable to account for iron exchange between its low molecular weight complexes and *apo*transferrin (iron-transport protein), and for the ability of the ligand to extract iron from ferritin (iron storage protein).

EXPERIMENTAL

Solutions of acidic iron(III) chloride (E. Merck) and glycinehydroxamic acid (GX) (E. A. Thomas, > 98%) were obtained by subdilution processes from stock solutions. The concentration of the iron(III) chloride stock solution (~ 0.1 *M* in 0.1 *M* HCl (May & Baker)) was checked by EDTA titration using salicylate indicator, at pH ≈ 1.5.[18] The stock solution of 0.1 *M* GX was prepared by accurate weighing of the required amount (used as provided) and dissolving the respective solid in 0.1 *M* HCl.

Measurements of pH were conducted using Radiometer pH-meter type 63 equipped with Radiometer combined glass electrode type GK 2311C. The pH-meter was calibrated by the two buffers method of known pHs (2 and 4 or 4 and 7) in

* Author to whom correspondence should be addressed.

the pH range used (1–7.5). Spectral measurements were made using Pye–Unicam model 8-100 as well as Schimadzu model 240 spectrophotometers in the wavelength range 250–650 nm. Kinetic measurements were done using a Durrum stopped-flow spectrophotometer D-110. The optical path length was 20.0 mm. The mixing syringes and cuvette were thermostatted at 25°C. The wavelength used was 470 nm.

In the equilibrium studies the ranges of the ligand and metal ion concentrations were $(2.0–4.0) \times 10^{-3}$ M and $(2.0–6.0) \times 10^{-4}$ M, respectively. The pH range was 1.0–7.5. In the kinetic study the ranges of the ligand and metal ion concentrations were $(4.00–40.0) \times 10^{-3}$ M and $(1.0–4.0) \times 10^{-4}$ M, respectively. The pH range was 1.0–3.0. The ionic strength was kept constant in the whole work at 0.15 M NaCl. The temperature was kept constant in the equilibrium study at (25 ± 1)°C. Hydrogen ion concentration was taken to be 10^{-pH}.

The test of the number of absorbing species was carried out using program TRIANG.[19] The computation of the equilibrium constants was made utilizing program SQUAD II.[20]

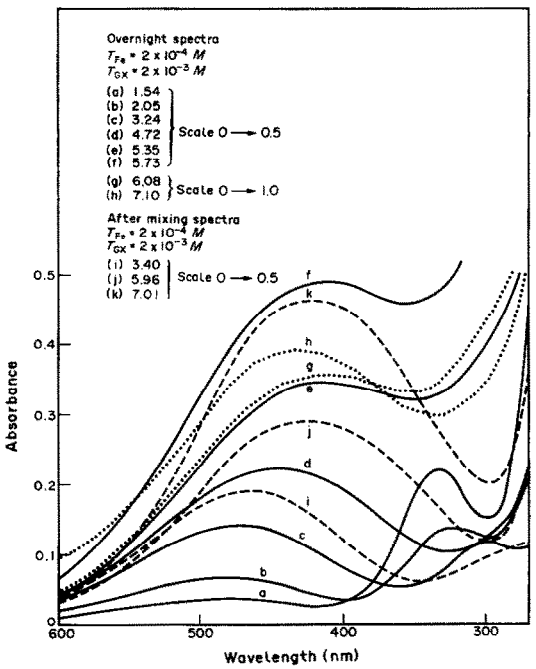

Fig. 1. Typical spectra of Fe(III)–GX system as function of pH (for freshly prepared and overnight solutions).

RESULTS AND DISCUSSION

The spectra of Fe(III)–GX system ($T_{GX} = 10T_{Fe} = 2.0 \times 10^{-3}$ M) were recorded directly after mixing the reactants at various pHs and in another they were recorded after being left overnight. The spectra in both cases were identical only in the pH range 1.0–2.5 but not at other pHs greater than 2.5 where slow spectral changes were observed by time for those taken at time of mixing. These findings were not reported in a previous work.[14] Typical spectra for fresh and overnight solution of Fe(III)–GX at different pHs are shown in Fig. 1, in the wavelength range of 600–270 nm. Although GX has no characteristic spectra in wide wavelength range (600–210 nm) in the pH range ~ 1.0–7.5, iron(III) chloride solution showed some spectral changes under identical experimental conditions. Two major absorption peaks were observed in acidic medium (1.0 M HCl), one at 335 nm and the other at 225 nm. They were appreciably affected by change in pH where both bands lost their identities. This finding was reported previously for iron(III) perchlorate solutions.[21] However, in the presence of GX a major change in the Fe(III) spectra occurred. A new band of probably charge-transfer type centred at ~ 470 nm appeared which showed a hypsochromic shift as well as hyperchromism as the pH was increased from 1.0 to 7.5. The Fe(III) band at 330 nm decreased in absorbance while that at 225 nm increased considerably as the pH was increased from 1.0 to 7.5 relative to those of free Fe(III) spectra. The band at 330 nm vanished at pHs $\geqslant$ 5.0. One should expect that spectral variations with pH serve as good indication of the presence of more than one absorbing species in the wavelength and pH ranges considered. The test for the number of absorbing species[19] indicated the presence of four species if error matrices in the absorbance values were taken in the range of 0.003–0.008 absorbance units. The number of species did not reflect the actual number of species if protonated and nonprotonated species are considered different.

Equilibrium studies

Program SQUAD II[20] has been used to determine the stability constants of various Fe(III)–GX species. The strategy which has been adopted was to separate the data into two sets, one in the pH range 1.0–3.0 and the other in the pH range 3.0–7.5. In both cases the protonation constants of the ligands as well as the hydrolysis constants of Fe(III) were kept constant while varying that of metal ions with ligand. The values of stability constants calculated from the first set were also used as constants in the second set. The constants obtained were invoked in one and the same model for further refinement. Two equilibrium models were obtained which were not easily differentiated. The final log β_{pqr} are listed in Table 1.

The presence of unprotonated species in quite acidic pH range may indicate the involvement of the amino group in complexation of Fe(III). In such a

‡ Ref. 21.

§ Ref. 14.

case the ligand acts as a tridentate species (the octahedral configuration is satisfied in the 2:1:0 complex species). However, a pentacoordinated species may also exist in solution, represented by 2:1:1 complex species. The presence of 3:1:3 species possibly indicates the bidentate nature of the ligand where the amino group or the carbonyl oxygen is not involved in the metal ion complexation (also the octahedral configuration is achieved).

The distribution diagram for the different Fe(III) complexes with GX is shown in Fig. 2. It is clear from this diagram that only two complex species (1:1:1 and 1:1:0 species) together with free Fe(III), $Fe(OH)^{2+}$ and $Fe(OH)_2^+$ coexist in the pH range 1.0–3.0, and actually complex formation occurred at pHs as low as 1.0. However, this conclusion is dependent on the relative concentration of GX to Fe(III).

The log β_{pqr} values obtained in this work are different from those reported previously, using potentiometric methods.[14] This discrepancy may be interpreted on the basis that in this work the equilibrium constants were obtained for solutions which have been kept overnight while those obtained previously were not taken under this condition, specially for pHs greater than 2.5.

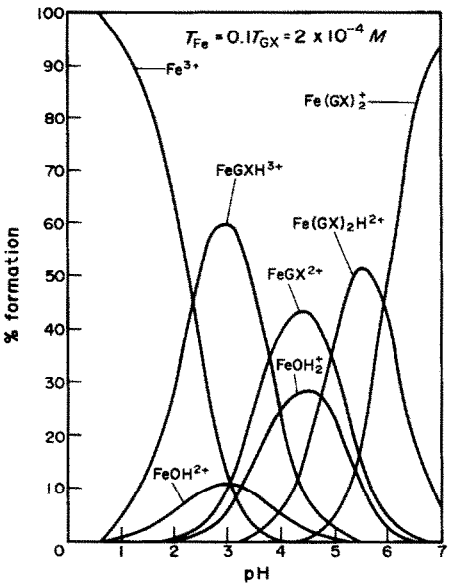

Fig. 2. Distribution diagram of Fe(III)–GX system complex species as function of pH.

Kinetic study

Two rate steps were observed in the kinetic study of Fe(III) reaction with GX in the pH range 1.0–2.5. Both steps are dependent on pH and the initial concentration of the glycinehydroxamate. The slow step was in the hour range while the fast step was in the millisecond range. The fast kinetic step is only considered in this work. It may indicate the involvement of ligand deprotonation step with subsequent formation of a chelated complex of

possibly the following structures:

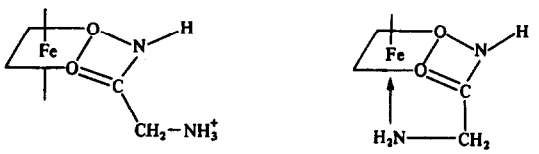

Figure 3 shows the dependence of observed pseudo-first order rate constant, k_{obs}, of the fast step on both pH and total ligand concentration of GX, T_{GX}, when the $T_{GX} > T_{Fe}$. The rate constant was first decreased as pH increased from 1.0 to 1.6, and then increased as pH increased from 1.6 to 3.0. At a given pH the rate constant is a linear function of T_{GX} [Fig. 4(a) and (b)]. Actually, two sets of curves were observed. The first set of curves below pH 1.7 were approximately parallel and of identical slopes but different intercepts [Fig. 4(a)]. The second set of curves above pH 1.6 showed quite significant slopes with small variation in the intercepts [Fig. 4(b)]. The kinetic data represented in Fig. 4(a) and (b) can be empirically expressed as follows:

$$k_{obs} = A + BT_{GX}, \qquad (1)$$

where A and B are the intercepts and slopes of the linear curves shown in Fig. 4(a) and (b), and Table 2. Both A and B are pH dependent at pHs greater than 1.7 and only A at pHs lower than 1.7.

In the pH range used (1.0–3.0) the solution of glycinehydroxamate exhibits only one species, the diprotonated species, GXH_2^+ (Table 1), while that of iron(III) exhibits several chloro complexes of iron(III)

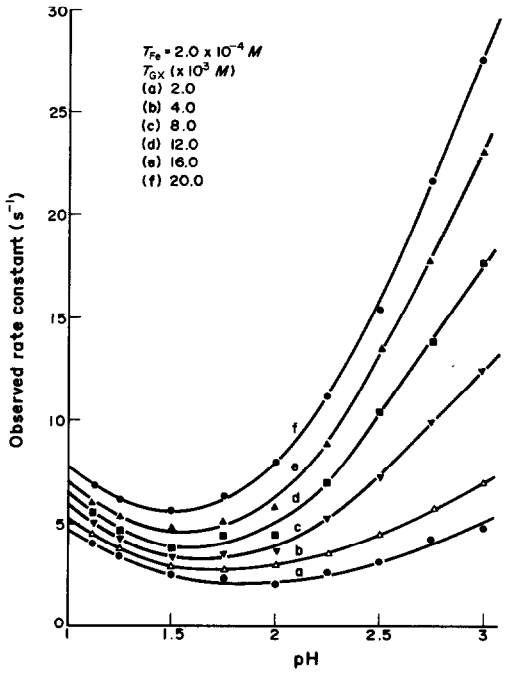

Fig. 3. Observed pseudo first order rate constants as function of pH and T_{GX}.

in addition to the aquated form and hydroxo species (Table 1). The dimeric species of Fe(III) was excluded due to the presence of high relative concentration of chloride ion ($T_{Cl} \gg T_{Fe}$). Besides, it has not been reported that chloride ion bridges two Fe(III) species. The mechanism of Fe(III) interaction with

GX is summarized in the following scheme:

$$Fe^{3+} + GXH_2^+ \rightleftharpoons FeGXH^{3+} + H^+; \qquad k_1, k_{-1} \quad \text{(a)}$$

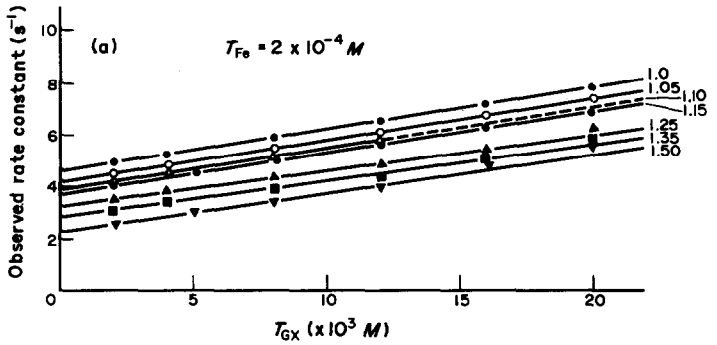
$$K_{1OH} \downarrow\uparrow$$

$$Fe(OH)^{2+} + GXH_2^+ \rightleftharpoons FeGXH^{3+} + H_2O; \qquad k_2, k_{-2} \quad \text{(b)}$$

$$K_{2OH} \downarrow\uparrow$$

$$Fe(OH)_2^+ + GXH_2^+ \rightleftharpoons FeGXH^{3+} + H_2O + OH^-; \qquad k_3, k_{-3} \quad \text{(c)}$$

$$K_{HC} \downarrow\uparrow$$



$$Fe^{3+} + GXH_2^+ \rightleftharpoons FeGX^{2+} + 2H^+; \qquad k_4, k_{-4} \quad \text{(d)}$$

$$Fe(OH)^{2+} + GXH_2^+ \rightleftharpoons FeGX^{2+} + H_2O + H^+; \qquad k_5, k_{-5} \quad \text{(e)}$$

$$Fe(OH)_2^+ + GXH_2^+ \rightleftharpoons FeGX^{2+} + 2H_2O; \qquad k_6, k_{-6} \quad \text{(f)}$$

Scheme 1.*

* For simplicity $Fe(OH)_l Cl_n(H_2O)_{6-n-l}$ species will be represented as Fe^{3+} species or $Fe(OH)_l$ (if $l > 0$).

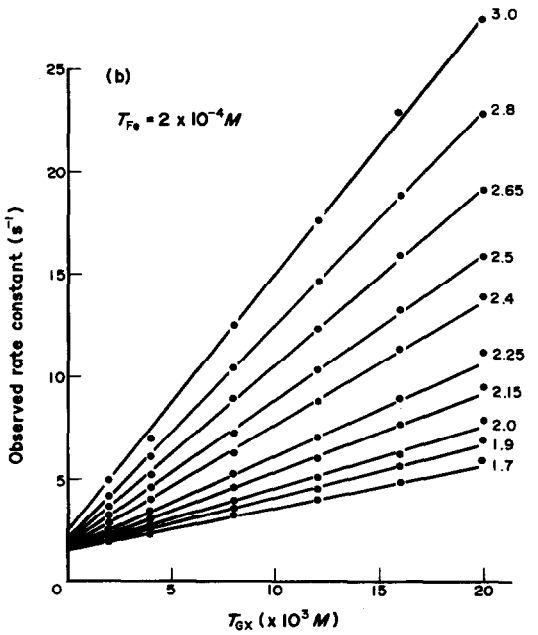


Fig. 4. (a) Observed rate constants as function of T_{GX} at various interpolated pH values in the pH range 1.0–1.50. (b) Observed rate constants as function of T_{GX} at various interpolated pH values in the pH range 1.50–3.00.

where k_i and k_{-i} are the rate constants of forward and backward reactions and K_{1OH},* K_{2OH}* and K_{HC}† are the first and second hydrolysis constants of Fe^{3+}, and the deprotonation constant of FeGXH. At constant pH (when $T_{GX} \gg T_{Fe}$) the rate equation is:

$$Q_2 \frac{d(FeGX)}{dt} = \left[\frac{T_{Fe}-(FeGX)Q_2}{Q_3}\right]\frac{T_{GX}}{Q_1}Q_4 - (FeGX)Q_5, \quad (2)$$

where

$$Q_1 = 1 + K_{1h}/[H^+] + K_{1h}K_{2h}/[H^+]^2$$

(K_{1h} and K_{2h} are the deprotonation constants of GX),

$$Q_2 = ([H^+]/K_{HC}) + 1$$

(K_{HC} is the deprotonation constant of FeGXH),

$$Q_3 = 1 + K_{1OH}/[H^+] + K_{1OH}K_{2OH}/[H^+]^2$$

(K_{1OH} and K_{2OH} are the hydrolysis constants of Fe^{3+}),

$$Q_4 = k_1 + k_2K_{1OH}/[H^+] + k_3K_{1OH}K_{2OH}/[H^+]^2 + k_4 + k_5K_{1OH}/[H^+] + k_6K_{1OH}K_{2OH}/[H^+]^2$$

and

$$Q_5 = [(k_{-3}K_W/K_{HC}) + k_{-6}] + [(k_{-2}/K_{HC}) + k_{-5}][H^+] + [(k_{-1}/K_{HC}) + k_{-4}][H^+]^2.$$

The integrated form of eqn (2) is as follows:

$$\ln \frac{(FeGX)_\infty}{(FeGX)_\infty - (FeGX)_t} = k_{obs}t, \quad (3)$$

where $(FeGX)_\infty$ ($\propto$ absorbance) is the concentration of species at infinite time (t_∞) and $(FeGX)_t$ is at time t and k_{obs} is:

$$k_{obs} = Q_5/Q_2 + Q_4T_{GX}/Q_3Q_1. \quad (4)$$

There is a correspondence between eqns (4) and (1), where

$$A = Q_5/Q_2 = \{k_{-3}K_W/K_{HC} + k_{-6} + [(k_{-2}/K_{HC}) + k_{-5}][H^+] + [(k_{-1}/K_{HC}) + k_{-4}][H^+]^2\}[(H^+)/K_{HC}) + 1]^{-1} \quad (5)$$

and

$$B = Q_4/Q_3Q_1 = (k_1 + k_2K_{1OH}/[H^+] + k_3K_{1OH}K_{2OH}/[H^+]^2 + k_4 + k_5K_{1OH}/[H^+] + k_6K_{1OH}K_{2OH}/[H^+]^2)\{(1 + K_{1OH}/[H^+] + K_{1OH}K_{2OH}/[H^+]^2)(1 + K_{1h}/[H^+] + K_{1h}K_{2h}/[H^+]^2)\}^{-1}. \quad (6)$$

Upon rearrangement of eqns (5) and (6):

$$A\left(\frac{[H^+]}{K_{HC}} + 1\right) = [(k_{-3}K_W/K_{HC}) + k_{-6}] + [(k_{-2}/K_{HC}) + k_{-5}][H^+] + [(k_{-1}/K_{HC}) + k_{-4}][H^+]^2, \quad (7)$$

$$BQ_3Q_1 = (k_1 + k_4) + \frac{K_{1OH}}{[H^+]}(k_2 + k_5) + \frac{K_{1OH}K_{2OH}}{[H^+]^2}(k_3 + k_6). \quad (8)$$

Plotting $A(1 + [H^+]/K_{HC})$ vs $[H^+]$ produced a quadratic relationship [Fig. 5(a)]. The coefficients of eqn (7) have the following values:

$$(K_W/K_{HC})k_{-3} + k_{-6} = 2.84 \pm 2.0, \quad (9a)$$

$$(k_{-2}/K_{HC}) + k_{-5} = (2.13 \pm 0.15) \times 10^3, \quad (9b)$$

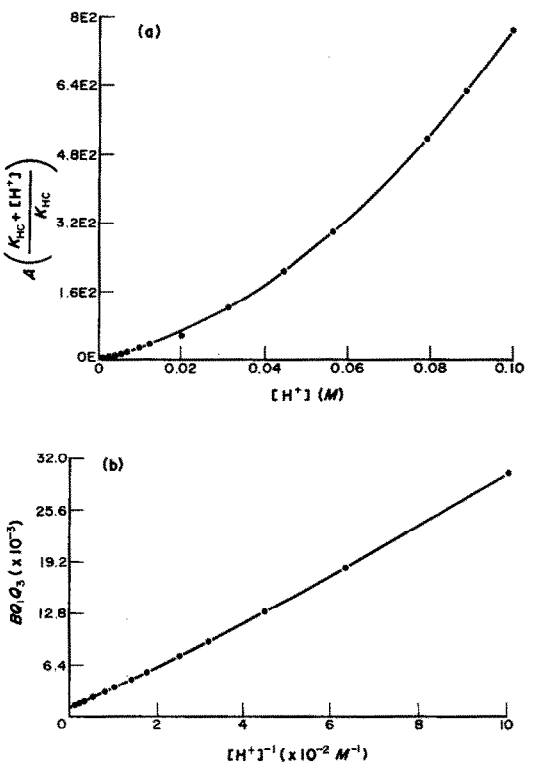

Fig. 5. (a) Plot of $A\{([H^+] + K_{HC})/K_{HC}\}$ vs $[H^+]$. (b) Plot of BQ_1Q_3 vs $[H^+]^{-1}$.

* $K_{1OH} = 9 \times 10^{-4}$ for $Fe^{3+} + H_2O \rightleftharpoons Fe(OH)^{2+} + H^+$; $K_{1OH}K_{2OH} = 4.9 \times 10^{-7}$ for $Fe^{3+} + 2H_2O \rightleftharpoons Fe(OH)_2^+ + 2H^+$.

† K_{HC} for $FeGXH \rightleftharpoons FeGX + H^+$ can be obtained from the equilibrium study.

and

$$(k_{-1}/K_{HC})+k_{-4} = (5.51 \pm 0.16) \times 10^4 \quad (9c)$$

On the other hand, the plot of BQ_3Q_1 vs $[H^+]^{-1}$ is shown in Fig. 5(b). The coefficients of eqn (8) are as follows:

$$k_1 + k_4 = (1.05 \pm 0.08) \times 10^3 \quad (10a)$$

$$(k_2 + k_5)K_{1OH} = (24.14 \pm 0.89), \quad (10b)$$

(or $k_2 + k_5 = 2.7 \times 10^4$)

and

$$(k_3 + k_6)K_{1OH}K_{2OH} = (0.563 \pm 1.50) \times 10^{-3} \quad (10c)$$

(or $k_3 + k_6 = 1.15 \times 10^4$).

In order to determine the values of the different microrate constants, it may be reasonable to assume that at lower pHs (in the pH range 1.0–1.7) the reaction leading to the formation of $FeGX^{2+}$ is much less significant than that leading to the formation of $FeGXH^{3+}$. Moreover, iron present is mainly in the form of free aquated Fe^{3+} species and aquated chloro complexes of iron(III). In other words, the reaction (a) in Scheme 1 is significant in the formation of $FeGXH^{3+}$. This is well confirmed by the pH-independence of the parameter B (or BQ_1Q_3) (Table 2) in the pH range 1.00–1.50. In such a case, eqn (8) is reduced to $BQ_1Q_3 \simeq B \simeq k_1$ which was found equal to 1.50×10^2. From the knowledge of the formation constant of $FeGXH^{3+}$ (Table 1) the backward rate constant can be estimated ($k_{-1} = 1.05 \times 10^2$). In turn, k_{-4} can be calculated from eqn 9(c) ($= 5.51 \times 10^4$) and k_4 from eqn 10(a) (0.9×10^3). The equilibrium constant of the reaction (d) in Scheme 1 is now equal to 1.63×10^{-2}. If $k_{-6} \gg k_{-3}(K_W/K_{HC})$ and $k_6 \gg k_3$ then the equilibrium constant (k_6/k_{-6}) of reaction (f) in Scheme 1 is 4.05×10^3. This will lead to a calculated equilibrium constant (in the log form) for the species 1 : 1 : 0 equal to 14.44 which differs by an amount of 0.30 from that listed in Table 1. This finding showed that the above approximation is twice as much greater than the actual value which indicates that k_3 and $k_{-3}K_W/K_{HC}$ contributes to an extent to the value of the ratio $(k_3 + k_6)/[(k_{-3}K_W/K_{HC}) + k_{-6}]$. However, there is no simple way to separate the involved microrate constants. Besides, the same argument can be employed in the case of the ratio $(k_2 + k_5)/[(k_{-2}/K_{HC}) + k_{-5}]$ ($= 0.13 \times 10^2$). If it is assumed that $k_2 \gg k_5$ and $k_{-2}/K_{HC} \gg k_{-5}$, then $k_2/k_{-2} = 1.86 \times 10^4$ which leads to a calculated equilibrium constant (in the log form) for the 1 : 1 : 1 species equal to 18.37 which is greater by approximately one log unit from the value listed in Table 1. This means that k_2/k_{-2} should be 10 times less than 1.88×10^4. If, on the contrary, $k_5 \gg k_2$ and $k_{-5} \gg k_{-2}/K_{HC}$ then $k_5/k_{-5} = 0.13 \times 10^2$. The calculated equilibrium constant (in the log form) is equal to 15.8 which is still greater by one log unit than that listed in Table 1. This result implies that both reactions (b) and (e) in Scheme 1 may be equally contributing to the formation of $FeGXH^{3+}$ and $FeGX^{2+}$, which indicates an important role played by $FeOH^{2+}$ in the complex formation of iron(III) with GX, a conclusion which was arrived at in a previous report.[17] Furthermore, the discrepancy which was observed between the equilibrium constants obtained from the equilibrium study and the kinetic study may be attributed to the fact that the effect of chloro complexes of iron(III) has been ignored.

CONCLUSION

It has been concluded that reactions (a), (b) and (f) are the most important reactions describing the interaction of iron(III) with glycinehydroxamate, which indicates that $FeOH^{2+}$ is mostly the reactive iron(III) species in the formation of $FeGXH^{3+}$ species and $Fe(OH)_2^+$ is the reactive species in the formation of $FeGX^{2+}$. This finding is interesting since it may be for the first time that $Fe(OH)_2^+$, and not only $FeOH^{2+}$,[17] is also one of the reactive species in the Fe(III) complex formation reaction. This conclusion suggests that the establishment of the first bond (by the loss of first H_2O molecule) initiates rapid ring closure of the bidentate ligand with the metal centre with the loss of a second H_2O molecule in the case of $FeGXH^{3+}$. The further rapid loss of a third H_2O molecule occurs at pHs greater than 1.7 to form $FeGX^{2+}$.

SPECTROPHOTOMETRIC INVESTIGATION OF MONOBROMO AND DIBROMO COMPLEXES OF COPPER(II) IN METHANOLIC MEDIUM

P. G. DAVID
Departamento de Quimica, Universidade de Brasilia, Brasilia, Brazil

(*Received* 18 *June* 1984; *accepted* 16 *July* 1984)

Abstract—Complex formation between copper(II) and bromide in anhydrous methanol was investigated spectrophotometrically. At a constant copper(II) concentration of 3.0×10^{-4} *M*, Cu^{2+} and $CuBr^{+}$ are at equilibrium for $[Br^{-}] < 1.0 \times 10^{-3}$ *M* while $CuBr^{+}$ and $CuBr_2$ exist at equilibrium in the range of $[Br^{-}]$ 2.0×10^{-3}–40×10^{-3} *M*. An isosbestic point at 235 nm indicated the equilibrium of Cu^{2+} and $CuBr^{+}$ while a second isosbestic point at 290 nm showed the equilibrium of $CuBr^{+}$ and $CuBr_2$. Stability constants for the formation of $CuBr^{+}$ and $CuBr_2$ (K_1 and K_2, respectively) were determined as a function of ionic strength in the range 0.01–0.10. Log K_1 and log K_2 values at zero ionic strength were obtained by extrapolation of the plot of log *K* vs ionic strength, the values being 3.97 ± 0.01 and 2.31 ± 0.01.

Colour and spectral changes observed when copper(II) salts are treated with varying concentrations of alkali bromides have been investigated by a number of researchers.[1–8] Kosower *et al.*[2] observed a substantial increase in the formation of copper(II) bromide complexes in alcoholic medium in comparison with aqueous medium, while Barnes and Hume[7] encountered no substantial increase in stability in changing aqueous to alcoholic medium. The former authors have interpreted the spectral changes observed in alcoholic copper(II) perchlorate solution on addition of lithium bromide in terms of successive formation of $[CuBr]^{+}$, $[CuBr_2]$, $[CuBr_3]^{-}$, $[CuBr_4]^{2-}$, $[CuBr_5]^{3-}$ and $[CuBr_6]^{4-}$. However other investigators have interpreted their results in terms of $[CuBr_4]^{2-}$ being the highest copper(II) bromide complex. Determination of the formation constant for $CuBr^{+}$ in aqueous medium and 90% ethanol indicated a low stability in these media.[1,3–7] Matsuo[5,6] determined the formation constants in aqueous media for the succeeding complexes which also showed to have correspondingly lower stabilities. The present work deals with the investigation of the complex formation between copper(II) and bromide ion in anhydrous methanolic medium under conditions at which only $CuBr^{+}$ and $CuBr_2$ are formed: the results indicate an enhancement of the stabilities in this medium in comparison to those in water.

EXPERIMENTAL

Copper(II) perchlorate, lithium perchlorate and lithium bromide were analytical reagent grade chemicals and were dried in vacuum at 100°C for several hours before use. Methanol was distilled over magnesium methoxide; only the middle 50% of the distillate was used. Manipulations of methanolic solutions were carried out in a dry-box in a dry nitrogen atmosphere.

The electronic absorption spectra and absorbance measurements were obtained on a Cary Model 219 recording spectrophotometer. Teflon-stoppered quartz cells were employed. The cells were thermostatted at 25 ± 0.1°C by circulating water through the cell-holders from a constant-temperature water-bath. The absorbance at any wavelength was read directly from the digital display of the spectrophotometer and was reliable within ± 0.0005 units.

The procedure used in preparing solutions for recording the spectra or obtaining absorbance reading at any desired wavelength was as follows. A solution of copper(II) perchlorate [~ 0.0015 *M* (solution A)] was prepared by accurate dilution of a stock solution (~ 0.015 *M*) and was standardized spectrophotometrically as $[Cu(dmp)_2]^{2+}$ (dmp = 2,9-dimethyl-1,10-phenanthroline) following the literature procedure.[9] Also a stock solution of lithium bromide (0.2 *M*) was prepared and was

standardized by the Volhards method.[10] Solutions of lithium bromide [0.05 *M* (solution B) and 0.002 *M* (solution C)] were prepared by accurate dilution of this stock solution. Predetermined volumes of solution A (2.0 cm^3) and 0–5 cm^3 of solution B or C were mixed in a series of 10 cm^3 volumetric flasks followed by a calculated volume of 0.05 or 0.5 *M* methanolic lithium perchlorate solution to adjust the total ionic strength to the desired value within the range 0.01–0.1 and diluted to the mark with anhydrous methanol. The absorbance at the desired wavelength or the absorption curve over the range 200–500 nm was recorded (using a cell of 1-cm path-length) after 3 h within which the solutions were found to reach equilibrium. During this time the solutions were maintained at 25 ± 0.1°C.

RESULTS AND DISCUSSION

When the total concentration of copper(II) in the solution was maintained at 3.0×10^{-4} *M*, a gradual increase in the LiBr concentration from zero to 1.2×10^{-3} *M* exhibited a general increase in the absorption for $\lambda > 235$ nm with a characteristic broad peak centered around 300 nm and a decrease in absorption in the region 235–220 nm. An isosbestic point was observed at 235 nm. Further increase in the concentration of LiBr up to 2.0×10^{-3} *M* showed a general increase in the absorption in the 400–220 nm region without any isosbestic point. When the LiBr concentration was increased further (2.0×10^{-3}–40×10^{-3} *M*) a decrease in the absorption in the region 400–290 nm and an increase for $\lambda > 290$ nm was observed with the existence of an isosbestic point at 290 nm and a characteristic broad peak centred around 245 nm. An increase in the ionic strength of the medium pushed up the lower limit of LiBr concentration at which this isosbestic point at 290 nm was observed. Under the conditions of our investigation this isosbestic point was not observed for ionic strength greater than 0.1. The spectra were constant in the LiBr concentration range 0.04–0.1 *M*.*

Literature data show that a copper(II)–bromo complex occurring at low bromide concentration and exhibiting absorption maximum at around 300 nm has been assigned to[1,2,7] $CuBr^+$. Kosower *et al.*[2] has assigned an absorption maximum at 238 nm in methanolic medium to the $CuBr_2$ complex. However there has been no quantitative investigation hitherto on the successive formation of these two complexes in any medium. Our observation of the existence of an isosbestic point at 235 nm for $[LiBr] \leqslant 1.0 \times 10^{-3}$ indicates that $CuBr^+$ and Cu^{2+} are in equilibrium. We interpret the existence of a second isosbestic point at 290 nm in the LiBr concentration range 2.0×10^{-3}–40×10^{-3} *M* on the assumption that $CuBr^+$ and $CuBr_2$ are at equilibrium. The three species (Cu^{2+}, $CuBr^+$ and $CuBr_2$) are at equilibrium when the concentration of LiBr is in the range 1.0×10^{-3}–2.0×10^{-3} *M*.† The constancy of the spectra at [LiBr] 0.04–0.1 *M* clearly shows that the higher complexes may be ignored in our investigation.

From the constancy of the spectra in the LiBr concentration range 0.04–0.1 *M* we assume that only $CuBr_2$ exists in solution and, hence, it is easy to calculate the molar absorptivity values (ε_2) for this complex at any desired wavelength‡ and to determine the spectra (Fig. 1). The molar absorptivities (ε_1) and the spectra for $CuBr^+$ were determined as follows. Existence of the isosbestic point at 290 nm shows that $\varepsilon_1 = \varepsilon_2$ at this wavelength. This value can be used to calculate the concentration of $CuBr^+$ at equilibrium with Cu^{2+} from any one of the spectra obtained at $[LiBr] \leqslant 1.0 \times 10^{-3}$ *M*, at which only Cu^{2+} and $CuBr^+$ are the copper-containing species.§ Since ε_0, molar absorptivity of Cu^{2+} in methanol at any wavelength is known‖ the same spectrum may be used in calculating ε_1 at any desired wavelength (Fig. 1).‡§

The stability constants

The equilibrium constants for the formation of the complexes may be given by the following equations:

$$K_1 = \frac{[CuBr^+]}{[Cu^{2+}][Br^-]}, \qquad (1)$$

$$K_2 = \frac{[CuBr_2]}{[CuBr^+][Br^-]}. \qquad (2)$$

* The upper limit of LiBr concentration employed in the present investigation was 0.1 *M*.

† The species present are solvated. They probably are $[Cu(CH_3OH)_6]^{2+}$, $[Cu(CH_3OH)_5Br]^+$ and $[Cu(CH_3OH)_4Br_2]$.

‡ The values of ε_0, ε_1 and ε_2 at some selected wavelengths are: 300 nm (first λ_{max} for $CuBr^+$): 489, 1925, 1354; 290 nm (isosbestic point): 592, 1665, 1665; 270 nm: 858, 1299, 2114; 245 nm (λ_{max} for $CuBr_2$): 1655, 1851, 2563; 240 nm (second λ_{max} for $CuBr^+$): 1785, 1932, 2507; 235 nm (isosbestic point): 1854, 1854, 2387 l mol^{-1} cm^{-1}.

§ The equation $A = \varepsilon_0[Cu^{2+}] + \varepsilon_1[CuBr^+] = \varepsilon_0([Cu]_t - [CuBr^+]) + \varepsilon_1[CuBr^+]$ was used in calculating the concentration of $CuBr^+$ or ε_1, the other values being known.

‖ ε_0 values were calculated from the spectrum of $Cu(ClO_4)_2$ in anhydrous methanol.

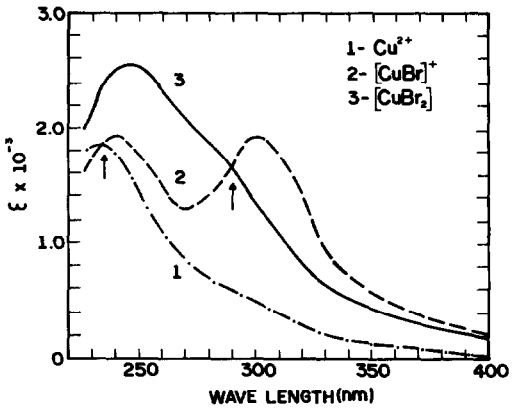

Fig. 1. Electronic absorption spectra of Cu^{2+}, $CuBr^+$ and $CuBr_2$ in methanolic medium. The arrows indicate the isosbestic points.

Since only $CuBr^+$ and Cu^{2+} are at equilibrium at LiBr concentrations 1.0×10^{-3} M and below, and only $CuBr_2$ and $CuBr^+$ at LiBr concentrations 2.0×10^{-3}–40×10^{-3} M, eqns (1) and (2) may be treated independently to determine K_1 and K_2.

If Cu^{2+} and $CuBr^+$ are at equilibrium, the absorbance, A, at any desired wavelength is

$$A=\varepsilon_0[Cu^{2+}]+\varepsilon_1[CuBr^+]. \quad (3)$$

The total analytical concentrations of copper(II) and bromide in solution are

$$[Cu]_t=[Cu^{2+}]+[CuBr^+], \quad (4)$$

$$[Br^-]_t=[Br^-]+[CuBr^+]. \quad (5)$$

Equations (1)–(5) may be solved to arrive at the equation:

$$\frac{(A-\varepsilon_0[Cu]_t)}{(A-\varepsilon_1[Cu]_t)}=-K_1\left\{[Br^-]_t-\left(\frac{A-\varepsilon_0[Cu]_t}{\varepsilon_1-\varepsilon_2}\right)\right\}. \quad (6)$$

In order to determine K_1, the absorbances at 300 nm (wavelength maximum characteristic of $CuBr^+$) were determined at constant $[Cu]_t$ and varying $[Br^-]_t$. Ionic strength was maintained constant for each run. K_1 is determined as the slope by the least square analysis of the data obtained according to the eqn (6). The fit was very good, the correlation coefficient being 0.998 ± 0.001.

If conditions are such that only $CuBr^+$ and $CuBr_2$ are at equilibrium, the absorbance and the total concentrations of copper(II) and bromide may be given by the following equations:

$$A=\varepsilon_1[CuBr^+]+\varepsilon_2[CuBr_2], \quad (7)$$

$$[Cu]_t=[CuBr^+]+[CuBr_2], \quad (8)$$

$$[Br^-]_t=[Br^-]+[CuBr^-]+2[CuBr_2]. \quad (9)$$

From eqns (1), (2) and (7)–(9) we may derive the following equation:

$$\frac{(A-\varepsilon_1[Cu]_t)}{(A-\varepsilon_2[Cu]_t)}=$$

$$-K_2\left\{[Br^-]_t-2[Cu]_t+\left(\frac{A-\varepsilon_2[Cu]_t}{\varepsilon_1-\varepsilon_2}\right)\right\}. \quad (10)$$

The absorbances at three different wavelengths (300, 270 and 245 nm) obtained at constant $[Cu]_t$, ionic strength and varying $[Br^-]_t$ were treated by eqn (10) and the least square analysis provided the K_2 values (Table 1). The fit was very good (correlation coefficient 0.998 ± 0.001) and the K_2 values at the three wavelengths are constant within the experimental error.*

The formation constant K_1 decreases considerably with increase in ionic strength while K_2 is very little influenced (Table 1). A plot of log K vs ionic strength was linear and the Y-intercept provided log K values at zero ionic strength (Fig. 2 and Table 1). The drastic decrease of K_1 values with increase in ionic strength may explain the reason for the absence of an equilibrium involving only $CuBr^+$ and $CuBr_2$ evidenced by the lack of isosbestic point at 290 nm at ionic strengths higher than 0.1. At high ionic strengths the formation of $CuBr_2$ occurs before all Cu^{2+} has been transformed to $CuBr^+$ and, consequently, the three species (Cu^{2+}, $CuBr^+$ and $CuBr_2$) are at equilibrium. The reason for the drastic decrease in K_1 values with increase in ionic strength is not well understood. It is quite probable, being a positively charged species, considerable ion-pair

Table 1. Stability constants for monobromo and dibromo complexes of copper(II) in methanolic medium

Ionic Strength	log K_1 [a]	log K_2 [a] 300 nm	270 nm	245 nm	Average
0	3.97 [b]	....	....	....	2.31 [b]
0.010	3.92	2.29	2.32	2.30	2.30

formation occurs and this may influence the formation constants.

There is a lack of literature values for K_1 and K_2 in non-aqueous solvents that could be compared with our results. Barnes and Hume,[7] working with 90% ethanol, obtained low K_1 values comparable with those in aqueous medium.[1,5] However, since the 10% water can have considerable influence on K_1, their values are of little use for comparison. Also the fact that literature values are obtained at unit ionic strength makes the comparison difficult. However, our results show that the stabilities of $CuBr^+$ and $CuBr_2$ increase in methanol in comparison to aqueous medium, in agreement with the qualitative observations of Kosower *et al.*[2]

THALLIUM-205 NMR STUDY OF Tl(I) MACROCYCLIC COMPLEXES IN NONAQUEOUS SOLVENTS

YANG-CHIH LEE, JOHN ALLISON and ALEXANDER I. POPOV*
Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

(*Received* 10 *April* 1984; *accepted* 21 *August* 1984)

Abstract—Thallium-205 and carbon-13 NMR measurements were used to determine, in nonaqueous solvents, the stabilities of thallium(I) complexes with macrocyclic ligands of different structures but very nearly the same cavity sizes. In a given solvent the complexing abilities of the ligand vary in the order DA18C6 > 18C6 > DC18C6 > DB18C6 > DT18C6. In all cases the stabilities of the complexes varied inversely with the Gutmann donicities of the solvents.

It is well known that the stability of a macrocyclic complex depends on a number of factors. The most emphasized factor is usually the consonance between the cavity size of the ligand and the cationic diameter although its importance has been questioned recently.[1] Other important variables are the number and the nature of heteroatoms in the ring, the flexibility of the ligand, the properties of the anion, the number and the nature of substituent groups on the macrocycle, and physicochemical properties of the solvent such as the solvating ability, the dipole moment and the dielectric constant.

Precise information on the size relationships of the macrocyclic cavities and ions is not available. The former have been estimated from molecular models;[2] Pauling's ionic radii are nearly universally accepted, but it should be noted that his values for the alkali ions have been disputed.[3]

It was of interest to us to investigate the stabilities of Tl^+ complexes with a series of cylic ligands where the cavity size remained very nearly the same. Several such ligands, all with 18-atom cavities, but with different structures, have been described. For this investigation we selected 18-crown-6 (18C6), dibenzo-18-crown-6 (DB18C6), *cis–syn–cis*-dicyclohexano-18-crown-6 (DC18C6), 1,10-diaza-18-crown-6 (DA18C6) and 1,10-dithia-18-crown-6 (DT18C6). As in our previous studies,[4] the formation constants were determined from the variation of ^{205}Tl chemical shift with the [ligand]/[Tl^+] mole ratio. In one case (see below) ^{13}C NMR was used and the chemical shifts of the ligand carbons was followed as the function of the [Tl^+]/[ligand] mole ratio.

The solvents were selected so as to represent as wide a variety of donicities as conveniently possible. However, except for nitromethane, thallium(I) salts and/or thallium(I) complexes were insoluble or very sparingly soluble in solvents of low solvating abilities, and we were unable to make meaningful NMR measurements in these media.

Macrocyclic complexes of the thallium(I) ion are interesting from the point of view of coordination chemistry of this ion; in addition, since the size and the properties of Tl^+ and K^+ ions are very similar, the Tl^+ ion can be used as a probe for the behaviour of the K^+ ion in cases where direct measurements on the latter ion are difficult. This factor is especially important in studies of biological systems[5,6] and, in particular, of ion transport across biological membranes.

Macrocyclic complexes of the Tl^+ ion in nonaqueous solvents, except for methanol, have not been studied very intensively. Formation constants of several complexes in methanol have been determined by various techniques. Those involving 18C6 and its analogues are given together with our results in Table 1. In addition, Srivanavil *et al.*[7] measured *relative* formation constants, $K_{(ML)}/K_{(TIL)}$, of 15C5, 18C6, DB18C6 and DC18C6 complexes: M stands for an alkali ion, ammonium ion and silver(I)

ion. These measurements were made in methanol, dimethylformamide and dimethyl sulfoxide solutions.

EXPERIMENTAL

Salt and ligand purification

Thallium salts were of reagent grade quality. Thallium(I) nitrate (Alfa) and perchlorate (K & K) were purified by recrystallization from deionized distilled water and then dried at 120°C for 2 days.

The crown ether 18C6 (Parish) was purified by the usual technique of converting it to the acetonitrile complex, filtering and driving off acetonitrile under vacuum at 40°C;[8] DB18C6 (Parish) and DA18C6 (Merck) were recrystallized from benzene and heptane respectively, and dried under vacuum; DT18C6 (Parish) was used as received except for vacuum drying at 50°C.

The mixture of DC18C6 isomers (Parish) was separated by the method described by Izatt *et al.*[9] except that the hydrogen sulfide was obtained by a dropwise addition of a 30% phosphoric acid solution to a concentrated aqueous solution of sodium sulfide. Using this method 31% of *cis–anti–cis* and 26% of *cis–syn–cis* isomers were separated. The melting points of the two isomers were identical with the literature values. An attempt was made to separate the two isomers on an alumina column[10] but the method was more tedious and the yields of each isomer were much lower.

Solvents

Nitromethane (NM), (Aldrich), dimethylformamide (DMF) (Mallinckrodt) and dimethylsulfoxide (DMSO) (Fisher), were refluxed over calcium hydride under reduced pressure for 1–3 days. Hexamethylphosphoramide (HMPA) (Aldrich) was refluxed over calcium oxide under reduced pressure for 24 h. Acetone (AC) (Mallinckrodt), acetonitrile (AN) (Mallinckrodt) and tetrahydrofuran (THF) (Baker) were refluxed over calcium hydride. Methanol (Mallinckrodt) was refluxed over magnesium turnings and iodine for 12–24 h. After the above described treatment, the solvents were fractionally distilled, transferred in a dry box under a nitrogen atmosphere and further dried for 4–20 h over freshly activated 3 or 4 Å molecular sieves.

The water content of purified solvents was determined using a Varian Aerograph Model 920 gas chromatograph and was found to be always below 100 ppm. The purity of these solvents was also checked by ^{13}C NMR. No detectable impurities were observed.

The deuterated solvents, chloroform-*d* (Aldrich Gold Label), acetonitrile-d_3, D_2O and methanol-d_4, all from Stohler Isotope Chemicals, were used as received.

NMR measurements

All ^{205}Tl NMR measurements were carried out at 14.09 kG and at 34.61 MHz in F.T. mode, on a highly modified Varian DA-60 spectrometer equipped with a wideband probe capable of multinuclear operation.[11] The external reference was a 1.5 *M* aqueous solution of thallium acetate. The chemical shifts obtained were then related to an infinitely dilute aqueous solution of the Tl^+ ion. A variable temperature probe was used for measurements between room temperature and 95°C.

Carbon-13 NMR measurements were made on a Bruker WM-250 spectrometer at 58.75 KG and 62.89 MHz. The methyl carbon of acetonitrile-d_3 (used as the lock) was used as the external reference.

Both the ^{205}Tl and ^{13}C resonances were corrected for the differences in the bulk diamagnetic susceptibility differences between the aqueous reference and the nonaqueous solvents. Since dilute solutions ($\sim$ 0.01–0.02 *M*) were used in this investigation, no correction was made for the solutes, such correction would have been much smaller than the experimental error. Chemical shifts downfield from the reference are indicated as *positive*.

A series of solutions was prepared for each solvent in an inert atmosphere glove-box. The concentration of the thallium(I) salt was kept constant ($\sim$ 0.02–0.005 *M*, depending on the solvent) while the concentration of the macrocyclic ligand was varied. Thallium-205 chemical shifts were determined for each solution. In all cases the exchange was fast and only one population-averaged signal was obtained. The variation of the chemical shift with the [ligand]/[Tl^+] mole ratio was used to calculate the complexity constant and the chemical shift of the complexed cation. We have shown previously[12] that in the case of fast exchange and a 1 : 1 complex formation the observed chemical shift is given by the equation:

$$\delta_{obs} = [(KC_m^t - KC_l^t - 1) \pm (K^2C_l^{t^2} + K^2C_m^{t^2} - 2K^2C_l^tC_m^t + 2KC_l^t + 2KC_m^t + 1)^{1/2}]\left(\frac{\delta_f - \delta_c}{2KC_m^t}\right) + \delta_c$$

where K is the stability constant, C_l^t and C_m^t represent the stoichiometric concentrations of the ligand and of the metal ion respectively and δ_f and δ_c are the chemical shifts of the free and complexed metal ion respectively.

For most complexes the value of δ_c cannot be obtained directly. Our procedure is to introduce the values of the experimental parameters δ_{obs}, δ_f, C_l^t and C_m^t and to vary K and δ_c until the calculated chemical shifts correspond, within experimental errors, to the experimental values. A nonlinear least squares curve-fitting program KINFIT[13] was used in the calculations. In general, this technique is not applicable if the complexation constants are greater than 10^5 and it can be somewhat marginal if the K_f values are between 10^4 and 10^5.

It is interesting to note that in some solvents, when the [ligand]/[Tl^+] mole ratio is between 0 and 1, the resonance lines are extremely broad due to the exchange between the free and the complexed Tl^+ ion. For example, for the DB18C6–Tl^+ system in HMPA, $W_{1/2}$ (width at half weight) was 1100 Hz at [L]/[M^+] mole ratio of 0.61, and 1760 Hz for the dicyclohexano complex in sulfolane at a mole ratio of 0.55. In NM solutions the ^{205}Tl resonance lines were too broad to be observed when [DB18C6]/[Tl^+] mole ratio was below 0.9. In all of the above cases chemical shifts either could not be measured with good precision, or could not be measured at all. Thus the range of mole ratios at which chemical shifts could be measured was decreased (often substantially), with a resulting decrease in the accuracy of the K_f measurement.

In the case of ^{13}C NMR, the concentration of the crown ether was kept constant at 0.01 *M*, while the concentration of the Tl^+ ion was varied. In this case, of course, the range of chemical shifts was only $\sim$ 1 ppm, but since these could be measured with a precision of $\pm$0.01 ppm, the variation in ^{13}C chemical shifts with the mole ratio was adequate for calculations of K_f values.

RESULTS AND DISCUSSION

Variations in the ^{205}Tl chemical shifts with the ligand/thallium ion mole ratio for the macrocyclic 18C6, DB18C6, DC18C6 in various solvents are illustrated in Figs. 1–3. Very similar behaviour was observed with DA18C6 and DT18C6. It is evident that, in general, the plots can be divided into three groups: (i) plots with a slight (or zero) slope and without any indication of an abrupt change in slope at any given mole ratio; (ii) plots with a pronounced change in curvature at the 1 : 1 mole ratio; (iii) plots formed by two straight lines intersecting at a mole ratio of 1 : 1; beyond this mole ratio the chemical shift remains essentially constant. Qualitatively, these data indicate: (i) very little or no complexation, (ii) significant complexation, (iii) the formation of a stable complex with $K_f > 10^5$, respectively.

These plots clearly illustrate the sensitivity of the ^{205}Tl resonance frequency towards even minor changes in the immediate vicinity of the Tl^+ ion. For example, the difference between the chemical shifts of the free Tl^+ ion in nitromethane and in hexamethylphosphoramide is $\sim$ 900 ppm.

Table 1 summarizes complexation constants

obtained in neat solvents. Some values obtained in previous investigations are also given for comparison. It is easily seen that the stability of Tl^+–macrocycle complexes are very strongly influenced by the nature of the solvents. Since these complexes

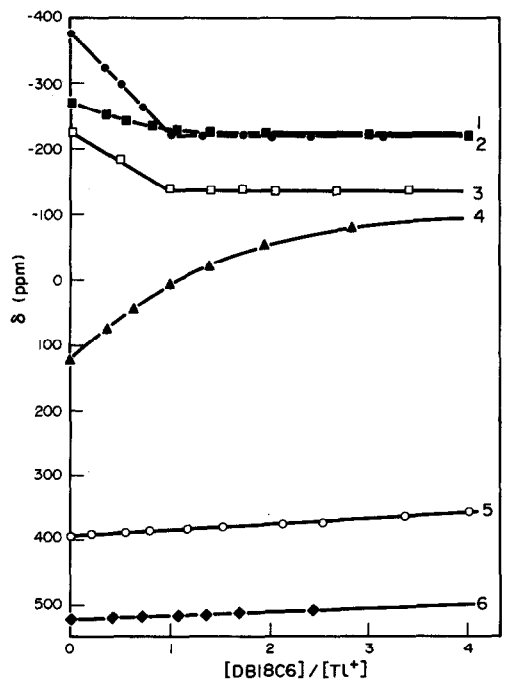

Fig. 2. Thallium-205 chemical shifts as a function of [DB18C6]/[Tl^+] mole ratio in different solvents. 1, Sulfolane; 2, NM; 3, AN; 4, DMF; 5, DMSO; 6, HMPA.

are formed by an ion–molecule interaction, and the ionic strength was < 0.02 *M*, the effect of the dielectric constant of the medium is minimal.[14]

On the other hand, there should be an inverse correlation between the solvating ability of a solvent and the stability of the complex. Unfortunately, at this time, there is no unambiguous way to define and measure this solvent property. A number of empirical classifications have been proposed and a comprehensive review of these systems is given by Griffiths and Pugh.[18] One of the most convenient empirical scales is that proposed by Gutmann[19] which is based on the enthalpy of the reaction between the given solvent and antimony(V) chloride in 1,2-dichloroethane. Gutmann solvent donicities for our solvents are shown in Table 1. It is evident that, in general, the complexes are quite stable in solvents of low donicities and the stability decreases with increasing solvating ability of the solvent. Thus for a given complex the stability decreases in the order NM > AN > AC > sulfolane > DMF > water > DMSO > HMPA.

It should be noted that since the dielectric constants of the solvents are quite elevated, and dilute solutions were used, it seems unlikely that the complex formation had a significant competition from ion pair formation. While measurements of ion pair formation constants for thallium(I) salts in nonaqueous solvents have been rather sparse, Yeager and Kratochvil studied electrical conductance of thallium(I)/perchlorate in AN solutions[20]

and calculate ion pair formation constant value of 32, while similar measurements by Prue and Sherrington in DMF solutions showed the salt to be completely dissociated.[21]

It is seen that in solvents with high donor ability such as DMSO and HMPA, the formation constants are either small or, in the case of DB18C6 and DT18C6 have a value of zero. A seeming discrepancy is observed in aqueous solutions where, despite the high donicity of the solvent, fairly stable complexes are formed. Here the soft–hard interaction plays an important role. Water being a "hard" base will solvate the soft Tl^+ ion less effectively than DMSO or HMPA, and, therefore, will interfere less with the complexation reaction. We observed previously that in pyridine solutions Li^+[22] and Cs^+[23] macrocyclic complexes are more stable than in methanol although the former has a higher donor number, 33 vs 26. Pyridine being a softer base than methanol has a weaker interaction with a hard acid, Li^+ ion than methanol.

In a given solvent, the complexing ability of the ligands vary in the order DA18C6 > 18C6 > *cis–syn–cis*-DC18C6 > DB18C6 > DT18C6. It has been shown previously by Frensdorff[23] that the substitution of two ether oxygens of 18C6 by two >NH groups decreases the stabilities of the alkali and alkaline earth complexes but enhances significantly the stability of the Ag^+ complex. Presumably in our case, since the Tl^+ ion is "softer" than an alkali or an alkaline earth cation,[24] it will interact more strongly with a softer base (NH) than the latter ions. In the case of the DT18C6, although sulphur is a softer base than either oxygen or nitrogen, it is considerably larger and, therefore, the cavity size is probably much smaller than in the oxa- or aza-18C6 macrocycles. In addition, it seems likely that the DT18C6·Tl^+ complex has the same configuration as the DT18C6·$PdCl_2$ complex where the metal ion is coordinated only to the two sulphur atoms and is outside the macrocyclic cavity.[26]

The DB18C6 and DC18C6 complexes are somewhat less stable than those with the unsubstituted ligand. The cyclohexyl and the benzene groups increase the rigidity of the ligand and, in the latter case, decrease somewhat the cavity size.

It is interesting to note that in acetone solutions the chemical shift goes downfield as the ligand is added, passes through a minimum and then shifts upfield. This behaviour is analogous to the one we previously observed for the Cs^+–cryptand 222 system in pyridine and several other solvents[27] and which is indicative of a step-wise formation of ML and ML_2 complexes. The values of K_1 and K_2 are given in Table 1.

(*Received* 13 *July* 1984; *accepted* 21 *August* 1984)

Abstract—Eleven new complexes of the type Ph_3SnX: *o*-$HOC_6H_4CH{=}NR$ (X = Cl, NCS; R = CH_3, *t*-Bu, $PhCH_2$, *n*-C_6H_{13}, *c*-C_6H_{11}, $HOCH_2CH_2$) have been synthesized by the reactions of triphenyltin chloride or isothiocyanate with the *N*-alkylsalicylideneimines. The complexes are non-electrolytes in nitrobenzene. IR, PMR and Mössbauer spectroscopic studies indicate that the ligands are behaving as monodentates via the phenolic oxygen atoms, and that the complexes all have trigonal bipyramidal geometry with the phenyl groups occupying the equatorial positions.

Several reports concerning the Schiff-base complexes of mono- and diorganotin compounds have appeared recently.[1–6] We now wish to report the results of our investigations on the Schiff-base complexes of triorganotin compounds. We have synthesised and characterised a series of new complexes between Ph_3SnX (X = Cl, NCS) and the Schiff bases:

where R = CH_3, *t*-Bu, $PhCH_2$, *n*-C_6H_{13}, *c*-C_6H_{11}, $OHCH_2CH_2$.

EXPERIMENTAL

Triphenyltin chloride was purchased from Alfa Inorganics and used without further purification. Triphenyltin isothiocyanate (m.p. 168–170°C) was prepared from triphenyltin chloride and potassium thiocyanate by the literature method,[7] and recrystallised from benzene before use.

The *N*-alkylsalicylideneimines were synthesised by the condensation of salicylaldehyde with the appropriate primary amine in refluxing benzene, the water formed being removed azeotropically. The Schiff bases were purified by fractional distillation.

The complexes were prepared by refluxing the calculated amounts of ligand and triphenyltin chloride or isothiocyanate in 95% ethanol for 1–2 h. The complexes crystallised out when the solutions were cooled in a refrigerator overnight. They were filtered off and recrystallised from ethanol. Melting points for the complexes are given in Table 1.

Conductance measurements in nitrobenzene were made at room temperature using a Phillips PW 9501 conductivity bridge with a cell constant of 0.71 cm^{-1}. Molar conductances of the complexes are recorded in Table 1.

The IR spectra of the ligands and complexes were recorded in the region 4000–600 cm^{-1} with a Beckmann Acculab '4' instrument either as neat liquid film or Nujol mulls between NaCl plates. For the 600–200 cm^{-1} region, the Beckmann IR4250 spectrophotometer was used and the spectra were recorded as neat liquid or Nujol mulls, CsI discs, or between polythene plates.

PMR spectra were obtained with a Varian CFT-20 spectrometer with deuterochloroform as solvent.

Mössbauer spectra were recorded at the International Tin Research Institute, Greenford, England.

Tin was estimated as SnO_2. Microanalyses were carried out by the Chemistry Department, National University of Singapore, Singapore.

RESULTS AND DISCUSSION

Regardless of the proportions of ligand and triphenyltin compound used, the complexes all crystallised with 1:1 stoichiometry. They were all yellow in colour, thermally stable with sharply-defined melting points and were found to be soluble in the common organic solvents. Microanalytical and conductance data for the complexes are presented in Table 1. The observed molar conductances in nitrobenzene were in the range 1.4–3.0 ohm^{-1} cm^2 mol^{-1}, indicating that the compounds were non-electrolytes and that in each instance, the chloride or isothiocyanate group is bound to the tin atom. (Molar conductances expected for 1:1 and 1:2 electrolytes in nitrobenzene are 25–35 and 44–60 ohm^{-1} cm^2 mol^{-1}, respectively.[8]

Some data from the PMR spectra of the complexes are listed in Table 2. Comparison of the integrated intensities of the ligand and organotin protons confirms the 1:1 stoichiometry of the complexes. The sharp singlet assigned to the azomethine proton[9] of the ligands ($\delta \sim 8.2$ ppm) was found to be unchanged on coordination, indicating that the N-atom is not coordinated to the metal. On the other hand, the peak due to the phenolic proton for each ligand molecule ($\delta \sim 13$ ppm) was significantly broadened on complex formation. As the ring formed by the intramolecular hydrogen bond of the Schiff-base ligand is retained, but distorted in the complexes,[1,3] coordination through oxygen will result in a weakening of the O—H bond, and a strengthening of the C=N···H hydrogen bond, which in turn leads to the observed broadening of the peak due to the phenolic proton. Similar observations have been reported for the dialkyltin chloride complexes of N-arylsalicylideneimines,[4] and of *N,N'*-bis(salicylaldehyde) ethylenediimine.[10]

The IR evidence (Table 3) also suggests that the ligands are behaving as monodentates via the oxygen atoms. A strong band assigned to the C=N stretching vibration[9–11] is observed at 1633–1645 cm^{-1} for the ligands. However, in the complexes, this band shifts slightly towards higher frequency (1645–1660 cm^{-1}). Similar shifts in C=N stretching frequency for ligands of this type have been found to indicate coordination to the tin atom by oxygen.[1–5,10] This has been confirmed by the X-ray

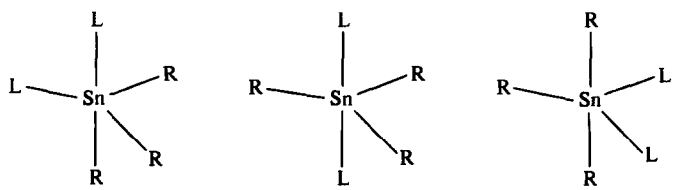
structural analysis of the complex of dimethyltin dichloride with *N,N*-ethylenebis(salicylideneimine).[12]

Due to the strong intramolecular hydrogen bonding present, the stretching vibration of the phenolic O—H is lowered and broadened[13] and the weak, broad bands observed in the spectra of the ligands in the 2600–3000 cm^{-1} range are attributed to these restricted vibrations. For the complexes, these bands are shifted towards higher energies by about 200 cm^{-1}, which is further evidence that the ring formed by the intramolecular hydrogen bond of the ligand although distorted, is still present after complex formation has occurred.[10]



In the case of the ligand

$$o\text{-}HOC_6H_4CH{=}NCH_2CH_2OH,$$

a band at 3350 cm^{-1} is assigned to the alcoholic O—H stretching absorption. This band does not change on complex formation, indicating that the free alcohol group present in this molecule plays no part in the coordination of the ligand to the metal.

In the low frequency IR region, bands observed at ~ 220 and ~ 280 cm^{-1} in all the complexes are assigned to tin–phenyl stretching vibrations. The frequencies of these vibrations are largely unaffected by changes in the coordination number of the tin atom, and occur at almost the same frequencies as in the parent triphenyltin chloride and isothiocyanate.[14] Each of the triphenyltin chloride complexes displayed a band in the region 225–240 cm^{-1}. These are assigned to the Sn—Cl stretching mode, which is sensitive to an increase in coordination round the tin atom, and in each case is shifted downfield by some 100 cm^{-1} from its value in triphenyltin chloride.[14] The strong absorption observed at ~ 2060 cm^{-1} for all the isothiocyanate complexes suggests that the thiocyanate groups are *N*-bonded in each case.[15]

The results so far discussed, including the analytical, PMR, conductivity and IR data, strongly support the assignment of a five-coordinate structure to the complexes. The three possible isomers for trigonal bipyramidal complexes of this type are shown in Fig. 1. It has been shown,[16,17] that each of these three possible isomers would be expected to show a different quadrupole splitting (ΔE_Q) value in the Mössbauer spectrum. For isomers

o-$HOC_6H_4CH{=}NCH_2CH_2OH$: Ph_3SnNCS	1.21	3.42

* The accuracy for all these parameters is ± 0.05 mm s^{-1}.
† Relative to $BaSnO_3$.

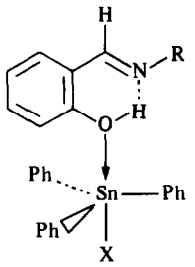

Fig. 2. Proposed structures of the complexes.

of type **I**, the range of ΔE_Q is 1.7–2.3 mm s^{-1}, for **II**, 3–3.9 mm s^{-1} and for **III**, 3.5–4.1 mm s^{-1}. The ΔE_Q values (Table 4) obtained for the complexes described herein fall in the range 3.10–3.42 mm s^{-1}, and thus clearly belong to category **II**.

We believe that the complexes of the *N*-alkylsalicylideneimines with triphenyltin chloride and isothiocyanate have five-coordinate, trigonal bipyramidal structures, with the phenyl groups occupying the equatorial positions and the ligands behaving as monodentates through the phenolic oxygen atoms, as shown in Fig. 2. The assignment of such structures is entirely consistent with the stereochemistry of other triorganotin complexes.[18]

(*Received* 22 *March* 1984; *accepted* 4 *May* 1984)

Abstract—The crystal structure of the acetone adduct of copper(II) (2,4-dichloro-5-methylphenylthio)acetate has been determined by single crystal X-ray diffraction and refined by least squares to 0.051 for 3701 "observed" reflections. Crystals of the compound are triclinic, space group $P\bar{1}$ with one dimer in a cell with $a = 8.357(1), b = 12.502(2), c = 13.721(2)$ Å, $\alpha = 107.20(1)$, $\beta = 96.09(1)$, $\gamma = 104.94(1)°$. The complex is a tetracarboxylate bridged dimer of the copper acetate hydrate type, with a Cu—Cu separation of 2.646(1) Å and a mean Cu—O (equatorial) distance of 1.961(4) Å, while the axial positions of the dimer are occupied by coordinated acetone molecules [Cu—O, 2.206(3) Å]. X-ray crystal data and the results of chemical analyses are also presented, indicating that a second chemical polymorph has both acetone and water molecules, with a similar dimeric structure but having solvated acetone.

The structural systematics of the tetracarboxylate bridged dimeric copper(II) complexes have been of interest to inorganic chemists since 1953 when the crystal structure of copper acetate monohydrate was reported.[2] To date more than 50 of these dimer structures have been determined by X-ray diffraction.[3–7] In $[Cu_2(R \cdot CO_2)_4(L)_2]$ the nature of R varies but the equatorial CuO_4 moieties change little within the series, the largest variation existing in the Cu—L axial distances. So far, the longest Cu—L distances are found for the anhydrous analogues, copper(II) propionate,[8] copper(II) butyrate[9] and copper(II) (2-chlorophenoxy)acetate,[7] in which the axial positions are occupied by oxygens from adjacent carboxylate groups, extending the structures into polymer chains. Other oxygen donor groups found are water [as in the copper(II) acetate monohydrate structure], methanol, ethanol, dimethylsulfoxide, urea, acetic acid, dimethylformamide and 1,4-dioxane while nitrogen base donors include pyridine and substituted pyridines, quinoline, 2-aminopyrimidine, 4-diazobicyclo-[2.2.2]octane and thiocyanate ion. In the present work, compounds prepared from (2.4-dichloro-5-methylphenylthio)acetic acid (DCMPTAH) were found from elemental analyses to have acetone in a formula consistent with dimeric species, $Cu_2(R \cdot CO_2)_4(acetone)_2$ (**1**) and $Cu_2(R \cdot CO_2)_4(acetone)_2(H_2O)_2$ (**2**). Although other molecules analogous to acetone [DMSO and urea] have been found in the axial positions in this

* For Part III see Ref. 1.

† Author to whom correspondence should be addressed.

dimer series no examples involving acetone are known. Furthermore, the occurrence of acetone as a ligand is to date unknown in copper(II) chemistry, although it is commonly found as a molecule of solvation in complexes. The only examples of co-ordinated acetone *per se* among general complexes is in oxochlorobis-[1,2-bis(diphenylphosphino)-ethane]molybdenum(IV) acetonetrichlorozincate(II) acetone (1/1).[10] The present crystal structure of **1** confirms the presence of acetone in the axial position of a stable coordinated copper(II) dimer.

EXPERIMENTAL

Preparation of complexes **1** *and* **2**

$CuCO_3 \cdot Cu(OH)_2$ [0.9 g (4.0 mmol)] was added to a solution of (2,4-dichloro-5-methylphenylthio)-acetic acid (DCMPTAH) [0.5 g (2.0 mmol)] in 70% ethanol/water and the resulting mixture was digested at 50–55°C for *ca* 5 h with continuous stirring. The unreacted carbonate was then removed by filtration and the filtrate allowed to evaporate slowly at room temperature. After several days, a greyish-blue microcrystalline solid was deposited which was subsequently redissolved in acetone. Two different chemical polymorphs were then re-deposited. The first (**1**) forming as dark green prisms in very low yield, was found to have a molecular weight equivalent to $Cu(DCMPTA)_2$(acetone) (precise X-ray cell parameters and measured density). The major product (**2**) formed late in crystallization as light green flat needles for which elemental analysis (C, 38.4; H, 3.47%), X-ray cell parameters and density determination indicated the formula $Cu(DCMPTA)_2(acetone)(H_2O)$. (Calc. for $C_{21}H_{22}Cl_4CuO_6S_2$; C, 39.8; H, 3.46%.)

Crystal data. (**1**) $C_{42}H_{40}Cl_8Cu_2O_{10}S_4$, M_r = 1243.7, a = 8.357(1), b = 12.502(2), c = 13.721(2) Å, α = 107.20(1), β = 96.09(1), γ = 104.94(1)°, U = 1297.1(3) Å^3, D_f = 1.59, D_c = 1.592 g cm^{-3}, Z = 1 (dimer), Mo-K_α radiation, λ = 0.71069 Å, μ(Mo-K_α) = 14.7 cm^{-1}, $F(000)$ = 630, space group $P\bar{1}$.

(**2**) $C_{42}H_{44}Cl_8Cu_2O_{12}S_4$, M_r = 1279.8, a = 8.140(3), b = 9.501(5), c = 18.58(1) Å, α = 90.73(5), β = 99.56(5), γ = 108.72(4)°, U = 1338.6(13) Å^3, D_f = 1.60, D_c = 1.587 g cm^{-3}, Z = 1 (dimer), Mo-K_α radiation, λ = 0.71069 Å, μ(Mo-K_α) = 14.3 cm^{-1}, $F(000)$ = 650, space group $P\bar{1}$ (assumed).

Data collection, structure solution and refinement. For **1**, 4995 reflections were collected from one crystal (0.36 × 0.28 × 0.12 mm) on a Nicolet R3m four-circle diffractometer [graphite crystal monochromatized Mo-K_α radiation, λ = 0.71069 Å; ω–2θ scans at 2.02–8.38 deg min^{-1}; $2\theta_{max}$ = 52°]. Of these, 3701 reflections with $I > 2.5\sigma(I)$ were considered observed and used in structure analysis, after correcting for absorption. The automatic centrosymmetric Σ_2 sign expansion direct methods of SHELX 76[11] failed to locate the Cu atom. It was subsequently located by shifting the Cu atomic co-ordinates found from the first E-map so as to place the inversion centre of the assumed dimer at a crystallographic origin. The structure was then solved by heavy atom and Fourier methods, and refined by blocked-matrix least-squares with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were located in a difference-Fourier synthesis and were included in the refinement at fixed positions with their isotropic U values set invariant at 0.05 Å^2. Final residuals were R [$= \Sigma \|F_o - F_c\| / \Sigma |F_o|$] 0.051 and Rw [$= \Sigma w(\|F_o - F_c\|^2 / \Sigma w|F_o|^2)^{1/2}$] 0.058 with $w = 2.64/(\sigma^2 F_o + 5.3 \times 10^{-4} F_o^2)$ found to be suitable. An analysis of the data indicated that 10 intense low-angle reflections were affected by extinction and were removed before the final cycle of refinement. The maximum peak in the last difference-Fourier was equivalent to 0.18 e Å^{-3}. Neutral atom scattering factors were used,[12] while Cu, Cl and S were corrected for the effects of anomalous dispersion.[12]

Atomic coordinates, thermal parameters, observed and calculated structure factors and intra-ligand bond distances and angles have been deposited with the Editor as supplementary material; copies are available on request from the Editors or the authors. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre. Bond distances and angles about the coordination polyhedron are given in Table 1.

DISCUSSION

Complex **1** forms centrosymmetric tetracarboxylate bridged dimers of the copper(II) acetate monohydrate type[2] (Fig. 1), The four Cu—O (equatorial) distances in the square pyramidal CuO_4L "ends" of the dimer are similar [range 1.958–1.964 Å; mean 1.961(4) Å]. These results emphasize the consistency of this distance among the entire dimer series (1.96 Å mean[3]). The Cu—Cu separation [2.646(1) Å] falls within the quite large range of distances found for the series (2.563–2.886 Å[7]). The value, however, correlates with the out-of-plane distance for the Cu atom, indicating that variation in the Cu—Cu separation is accommodated by a

movement of the Cu atom in and out of the square plane. In this compound, the role of the acetone molecules is of interest since they are coordinated in the axial positions of the dimer [Cu—O, 2.206(3) Å]. The acetones are asymmetrically oriented with the Cu—O—C angle 132.9(4)° roughly consistent with the angle of approach of a lone pair of electrons on the keto oxygen. This is similar to the disposition of the acetone in the tetrahedral (acetone trichlorozincate) ion in $[MoCl\{Ph_2P(CH_2)_2PPh_2\}_2]^+[ZnCl_3(CH_3)_2CO]^- \cdot (CH_3)_2CO$.[10] The Br—O—C angle (125°) in the hydrogen bonded acetone/molecular bromine (1 : 1) adduct shows analogous directional properties in the hydrogen bonding interactions.[13]

The coordinated acetone molecule has seldom been observed in crystalline solids, so that the present example represents a good system for structural observation since it is relatively unperturbed in its mode of attachment and is quite stable under the conditions of the determination. It has both chemical and thermal stability with all atoms of the acetone molecule having normal thermal parameters. This contrasts with the molybdenum zincate complex[10] where the structure analysis was completed at −70°C. The bond distances for the acetone molecule, C=O [1.209(5)

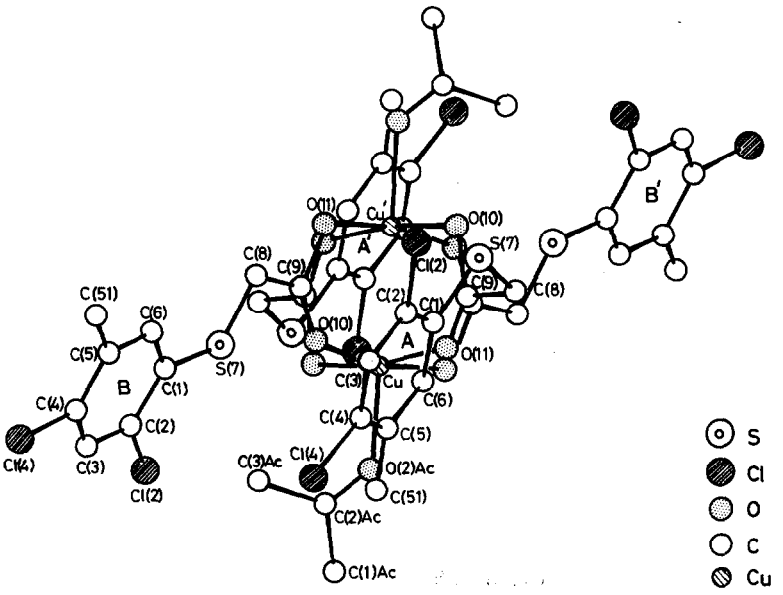

Fig. 1. Molecular stereochemistry and atom naming scheme for $[Cu_2(DCMPTA)_4(acetone)_2]$.

Å] and C—C [1.488(11), 1.504(8) Å] are compared with those for an acetone solvate molecule in the structure of a complex of comparable precision, $[Ba(C_{12}H_8N_2)_2(C_6H_2N_3O_7]\cdot(CH_3)_2CO$, [1.220(5), 1.478(6), 1.499(7) Å].[14] The bond angles C—C—O and C—C—C for (**1**) [121.3(5), 121.8(6)° and 115.9(3)°] are also comparable [120.8(4), 122.8(4)° and 116.4(4)°] indicating distortion away from the repulsive influence of the oxygen lone pairs. The planar nature of the acetone molecule is preserved (intra-angle sum = 360.0°). It would therefore appear that the molecule is not affected significantly on being complexed.

Although it is not altogether surprising to find acetone as a coordinated molecule, or more specifically as an axial ligand in a copper dimer system (considering the number of urea and alcohol examples), the low incidence of examples is probably attributable to steric constraints. In examples where the acid residue is not too bulky, the acetone molecules are able to displace water from the axial sites and coordinate. This process is achieved readily by dissolution of the complex in acetone. In a number of the copper(II) dimers, because of a lack of solubility in this solvent, formation of the acetone adduct is not obtained. In the case of the analogous green phenoxyalkanoic acid complex dimer, $[Cu_2(2,4\text{-}D)_4(H_2O)_2]\cdot 2H_2O$ is readily formed from the monomeric blue complex $[Cu(2,4\text{-}D)_2(H_2O)_4]$ by dissolution in a non-aqueous solvent.[15] The use of acetone results in the deposition of a dark green complex (assumed to be an acetone adduct) but this rapidly reverts in air to the original pale blue form. The probable reason for the forming of stable **1** and not a Cu(2,4-D)-acetone adduct could be due to the greater steric freedom allowed by the longer C—S—C compared to C—O—C chain. This places the bulk of the substituted phenyl ring systems at a more favourable distance from the dimer unit. Therefore, other examples of acetone adducted copper(II) dimers will be found where suitable steric conditions are met to allow this penetration of acetone. Although the structure of compound **2**, $[Cu_2(DCMPTA)_4(acetone)_2]\cdot 2H_2O$ was not determined, analytical evidence indicates that it is a chemical polymorph of **1** differing only in the presence of additional water molecules probably coordinated with lattice acetones.

The substituted (phenylthio)acetate ligands in complex **1** are considerably different conformationally. Whereas ligand B is extended and assumes a relatively planar disposition, the second ligand (A) is convoluted. This is in evidence in the torsion angles for the thioacetate side-chains [C(6)—C(1)—S(7)—C(8), C(1)—S(7)—C(8)—C(9) and S(7)—C(8)—C(9)—O(10)] which are +6.4, −77.4, +109.7 and +5.8, +69.8 and +10.1° for the A and B residues respectively. This difference in conformation is common in other examples of phenoxyalkanoic acid dimers[7,15] and for the (phenylthio)acetic acid (PTAH) dimer, $[Cu_2(PTA)_4(py)_2]$.[16] It is presumably an artifact of the packing efficiency involving dimers which are considerably extended in the peripheral areas because of the acid residues.

Compared to the free (unsubstituted) acid,

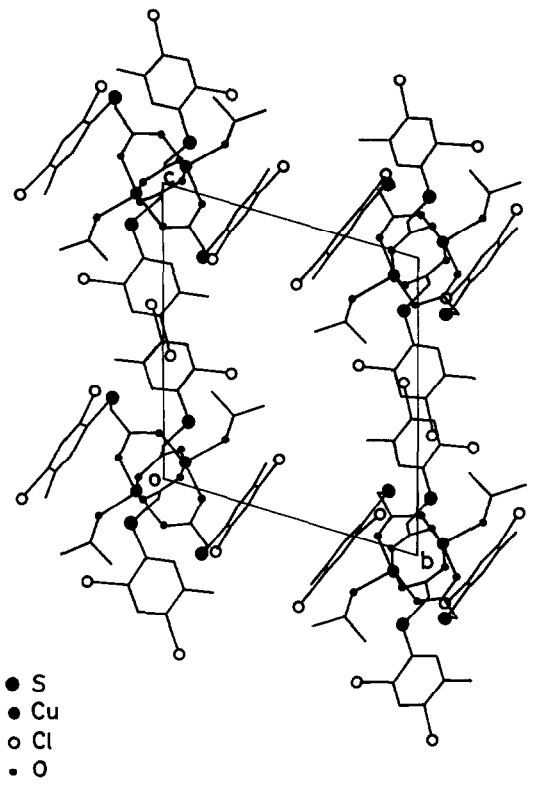

Fig. 2. Molecular packing in the unit cell viewed down *a*.

(phenylthio)acetic acid,[17] and the known complexes of this acid, $[Zn(PTA)_2(H_2O)_2]$,[17] $[Cd(PTA)_2(H_2O)]_n$,[17] $[Cu_2(PTA)_4(py)_2]$.[16] $[Ba(PTA)_2]_n$,[1] $[K(PTA)(PTAH)]_n$,[1] the thioacetate side-chains are also changed conformationally. In **1**, the thioether (S) to carboxyl (O) interactive distances for the individual ligands [3.25 Å (A) and 2.99 Å (B)] are markedly different and different to 2.85 Å for PTAH, 3.03 Å (Zn), 3.01, 3.06 Å (Cd), 3.07, 3.25 Å (Cu), 2.79 Å (Ba) and 2.84, 2.88 Å (K). This inconsistency contrasts with the relatively small spread of values for the O(ether)—O(carboxyl) interactive distances in the phenoxyalkanoic acids,[18] or the metal complexes of these acids,[19] irrespective of side-chain conformation. The reason is probably found in the relatively weaker S—O, cf. O—O interaction for the phenylthio vs the phenoxy acids.

The packing of molecules of **1** in the unit cell (Fig. 2) involves discrete non-interactive dimers. This is the common packing type for such dimers because of the usual non-associative nature of the groups defining the extremeties of the molecules. Exceptions are, of course, those dimers which are sub-units of polymer systems. These form through the axial ligand, either by bi-functional donor molecules (e.g. 1,4-dioxane or pyrimidine) or by the carboxyl oxygens of adjacent dimers (e.g. anhydrous complexes).

(*Received* 5 *December* 1983; *accepted* 9 *May* 1984)

Abstract—The halogen-redistribution reactions between $[AlCl_4]^-$ and $[AlBr_4]^-$ in molten mixtures of $NaAlCl_4$ and $NaAlBr_4$ with widely varying mole ratios have been studied by Raman spectroscopy at 160–300°C and the melting points have been measured. By monitoring the intensities of the totally symmetric stretching a_1-modes of both the parent tetrahalides as well as those of the mixed halides $[AlCl_3Br]^-$, $[AlCl_2Br]^-$ and $[AlClBr_3]^-$ it is concluded that the mixtures equilibrate very fast and consist of an almost random distribution of the five species. $NaAlCl_4$ and $NaAlBr_4$ form an eutectic mixture with a molar ratio near to 4:1, with a melting point of *ca* 142°C.

In the search for low-melting molten salt electrolytes for use in batteries it was deemed of interest to investigate the mixed tetrachloroaluminate–tetrabromoaluminate system. This system is of special interest because of its Lewis-acid neutrality.

This paper is concerned with the equilibrium between sodium melts of $[AlCl_4]^-$ and $[AlBr_4]^-$ and the mixed halides $[AlCl_3Br]^-$, $[AlCl_2Br_2]^-$, and $[AlClBr_3]^-$ which probably are formed rapidly at 200°C, judging from previous studies on mixed solutions in dichloromethane and other solvents at room temperature.[1–3]

The object was to study the halogen-exchange distribution of the species *by means of* their *Raman spectra* as a function of temperature and composition, and to confirm that the redistribution is random and that there is no preference of any of the species. Finally, the melting points of the mixtures were recorded to see if any low-melting eutectic exists in this system.

EXPERIMENTAL

Preparation of samples

Because of the sensitivity to water of the reagents, drybox and vacuum-line techniques were employed. $AlCl_3$ or $AlBr_3$ of highest attainable purities[4] were mixed with an equimolar amount of NaCl or NaBr, respectively, in evacuated Pyrex cells. The sodium halides have previously been purified by recrystallization after flushing with dry hydrogen halide gas. Each of these mixtures was equilibrated in rocking furnaces and recrystallized as described elsewhere.[4] The melting point of the pure $NaAlCl_4$ and $NaAlBr_4$ was 156.7 and 201.5°C, respectively.

Mixtures of various Cl:Br molar ratios were obtained by mixing different weighed proportions of the pure $NaAlCl_4$ and $NaAlBr_4$ compounds in sealed Pyrex tubes. The compositions of the prepared mixtures are given in Table 1.

The Raman spectra were measured as previously,[5] using 488.0 and 514.5 nm argon-ion laser radiation and a JEOL-JRS-400D spectrometer equipped with a four-window accurately regulated furnace. Detection of signals was done with a cooled extended S-20 PM-tube and a photon counting system. The first Raman spectrum of each sample was obtained at 160°C within 5 min after melting the solid mixture by gentle heating in a soft flame and inserting into the preheated furnace.

The melting points of the mixtures were determined visually by slowly heating the Raman cells immersed in a well-stirred oil bath. The temperature accuracy is *ca* 1°C; the small amount of sample did not allow a higher precision. For the neat compounds, an accuracy better than 0.1°C was obtained as described previously.[6]

RESULTS AND DISCUSSION

Raman spectra

Selected Raman spectra of various molten mixtures of $NaAlCl_4$ and $NaAlBr_4$ at 210°C are given in Fig. 1. Similar spectra were obtained at 160 and 300°C using green or blue laser light with no significant change in band positions or relative intensities, and no time dependence. The Raman spectra of the ions $[AlCl_4]^-$ and $[AlBr_4]^-$ are well known, and dominated by a strongly polarized totally symmetric stretching band, the a_1-mode, occurring at *ca* 350 and 210 cm^{-1}, respectively.[2,3,5,7,8] For the mixed species $[AlCl_nBr_{4-n}]^-$ ($n = 1$, 2 or 3) the Raman spectra are equally characterised by a strong polarized a_1-mode attributed to the totally symmetric stretching vibration of the halogen atoms; moving to progressively lower frequencies as bromide replaces chloride in the mixed aluminium tetrahalides.[2,3] The individual a_1-bands due to all five possible mixed tetrahalides can readily be identified in our spectra (Fig. 1) on the basis of their intensity variation with changing chloride content. The positions of the a_1-bands found in this work are shown in Table 2, and as it is seen, in perfect agreement with previous results obtained on solid mixed tetramethylammonium tetrahalide aluminates at room temperature.[2,3]

Halogen-redistribution equilibria

The spectra obtained as soon as possible after melting did not deviate from later spectra. This proves that equilibrium is reached at least within a few minutes at 160°C. This is in accordance with the observation[3] that less than 2 s are needed to obtain equilibrium when organic solutions of $[AlCl_4]^-$ and $[AlBr_4]^-$ are mixed at room temperature, according to ^{27}Al NMR spectra.

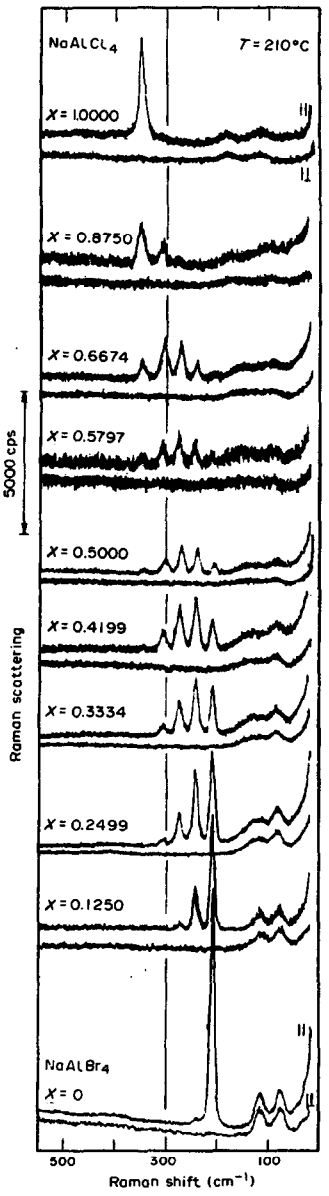

Fig. 1. Raman spectra of mixtures of $NaAlCl_4$ and $NaAlBr_4$ at 210°C as a function of X_{NaAlCl_4}. Excitation 488.0 nm at 300 mW. Resolution 4 cm^{-1}. Scan rate 25 cm^{-1} min^{-1}. || and |⊥ denote polarized and depolarized spectra.[5]

The halogen redistribution among the five possible tetrahaloaluminate ions occur according to the three reactions

$$2[AlCl_nBr_{4-n}]^- \rightleftharpoons [AlCl_{n+1}Br_{3-n}]^- + [AlCl_{n-1}Br_{5-n}]^- \quad (1)$$

Table 2. Raman bands arising from the totally symmetric a_1-vibration of halogen atoms in molten $Na[AlCl_nBr_{4-n}]$ mixtures, $n = 0$–4: band positions* are given in cm^{-1}

§ Relative scattering powers calculated as described in the text.

with $n = 1$, 2 or 3. The equilibrium constants are given by

$$K_n = \frac{(x_{AlCl_{n+1}Br_{3-n}^-}) \cdot (x_{AlCl_{n-1}Br_{5-n}^-})}{(x_{AlCl_nBr_{4-n}^-})^2} \qquad (2)$$

where x denotes concentration or mole fraction.

Similar redistribution reactions have previously been analysed in general,[9] and it has been shown that, for the case of complete randomization, the equilibrium constants take the values $K_1 = K_3 = 3/8$ and $K_2 = 4/9$ and the mole fraction of the individual ions follows a binomial distribution: if X is the formal mole fraction of $[MZ_4]$, the mole fractions of the general species $[MZ_nY_{4-n}]$ are given by X^4, $4X^3(1-X)$, $6X^2(1-X)^2$, $4X(1-X)^3$ and $(1-X)^4$ for $n = 4$, 3, 2, 1 and 0, respectively.

According to this distribution,[9] (i) all five species should occur in appreciable mole fractions (>0.01) when $0.3 < X < 0.7$, (ii) 4 species should occur in appreciable amounts near $X = 0.2$ and $X = 0.8$, (iii) the $[MZ_3Y]$, $[MZ_2Y_2]$ and $[MZY_3]$ species have their maximal mole fractions at $X = 0.75$, 0.50, and 0.25, and (iv) $[MZ_4]$ and $[MY_4]$ have mole fractions of 1/16 at $X = 0.5$.

Qualitatively, these features are nearly what is observed in the spectra (Fig. 1), and hence the distribution of $[AlCl_nBr_{4-n}]^-$ ions are nearly random. This was also found at room temperature in organic solutions.[1–3] The situation is not unique, but has, e.g. also been found in $TiCl_4$–$TiBr_4$ mixtures.[10]

To study the phenomenon quantitatively, Raman a_1-bands of all samples were recorded under as near as possible identical conditions. The stability of the instrumental set-up (of the order $\pm 10\%$) was repeatedly checked by recording of the neat spectra. In this way a set of comparable spectra was obtained from which the relative scattering intensities of the a_1-bands as a function of X_{NaAlCl_4} could be measured. The data are given in Table 3 in arbitrary units (mm on our chart paper), and a graphical representation is shown in Fig. 2. Here, each curve represents the equilibrium mole fraction of the particular

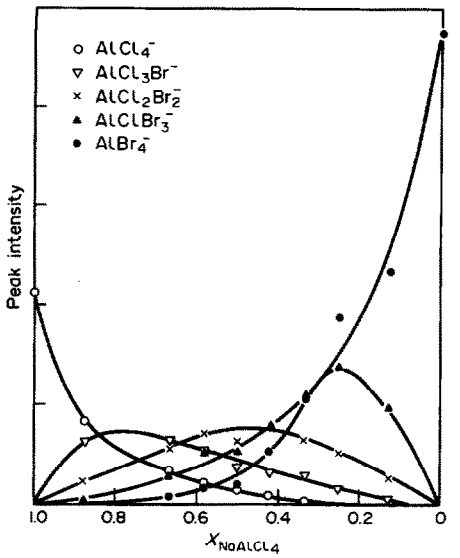

Fig. 2. Raman scattering intensity curves for the individual $[AlCl_nBr_{4-n}]^-$ ions as a function of X_{NaAlCl_4}. Each curve has a different mole fraction scale, depending on the a_1-band scattering power of the particular ion.

$[AlCl_nBr_{4-n}]^-$ ion, but on different scales due to the different scattering power of each ion (the Raman signal is proportional to the concentration*).

The scale of the curves for the ions $[AlCl_4]^-$ and $[AlBr_4]^-$ can easily be obtained, knowing the scattering power of the neat systems. Using the fact that the mole fraction sum must be unity in all mixtures, the scale of the three other curves can be calculated. (We used a graphical technique to avoid the numerical problems due to the scattering of the points. The three curves in Fig. 2 were read off at $X = 0.2$, 0.4, 0.6 and 0.8 to obtain four linear equations in the three scaling parameters. The first and last equation was added to obtain three equations, which were solved.)

From the scaling parameters, the relative scattering powers of the ions shown in the bottom of Table 2 were obtained. The corresponding scaled mole fractions are shown in Table 4 and Fig. 3(A). From the mole fractions in Table 4, the equilibrium constants K_n [equation (2)] were calculated to be $K_1 = 1.0$, $K_2 = 0.4$, and $K_3 = 0.21$ and their uncertainties were estimated to be ~ 0.4, ~ 0.1, and ~ 0.02, respectively.

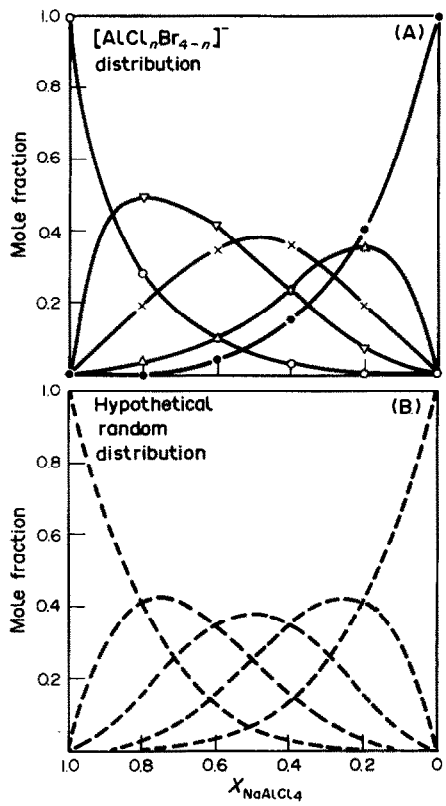

Fig. 3. Distribution curves for the individual $[AlCl_nBr_{4-n}]^-$ ions as a function of X_{NaAlCl_4}. (A) Experimental curves brought to same scale by normalization of the mole fraction sum. (B) The hypothetical, completely random distribution.

The completely random distribution[9] is given in Fig. 3(B) for comparison. It is evident that the $[AlCl_nBr_{n-4}]^-$ distribution is nearly but not totally random, maybe due to steric factors. For example, the formation of $[AlCl_3Br]^-$ seems to be slightly favoured, which is reflected in the small value of K_3, whereas $[AlClBr_3]^-$ doesn't entirely reach the

*The concentration is to a good approximation proportional to the mole fraction since the molar volumes of $NaAlCl_4$ and $NaAlBr_4$ melts at 210°C are *ca* 115 and 136 cm^3 mol^{-1}, respectively, according to available density expressions.[11,12]

statistically predicted mole fraction and K_1 is therefore slightly increased relative to the random value.

The same trend in K_1 and K_3 (0.425 and 0.35) was found by Jones,[3] who however had a higher K_2 value (0.8) for the tetramethylammonium $[AlCl_nBr_{4-n}]^-$ system dissolved in acetonitrile at room temperature.

Melting points

The experimentally determined melting points are given in Table 1. The phase diagram of the binary $NaAlCl_4$–$NaAlBr_4$ system is depicted in Fig. 4. This diagram has not previously been reported. The melting points of $NaAlCl_4$[6] and $NaAlBr_4$[13] are known from the NaX–AlX_3 (X = Cl or Br) phase diagrams to be 156.7 and 201°C, respectively, in good agreement with the results obtained here. Also, the phase diagram of the KCl—$AlBr_3$ system has been studied.[14] At the composition $KAlClBr_3$, a melting point of 171°C was observed. This is 3.5°C lower than our value for $NaAlClBr_3$, which seems reasonable, noting that $KAlBr_4$ melts at 192°C,[13] i.e. 9°C lower than $NaAlBr_4$.

In conclusion, it is seen from Fig. 4 that a soft eutectic exists around 142°C at X_{NaAlCl_4} = ca 0.80. For purposes where one needs a low-melting Lewis-neutral solvent, it is of importance to know that it is possible to lower the melting point from the 156.7°C of an equimolar NaCl–$AlCl_3$ melt[6] down to *ca* 142°C by substituting 20% of the chloride by bromide. Probably, a further reduction in the melting point is possible by substituting some of the sodium by, for example, potassium; it is known that the pure chloride system has an eutectic at *ca* 125°C at a Na/K ratio of *ca* 1/3.[15]

KINETICS AND MECHANISM OF THE INTERACTION OF HEXAAQUOCHROMIUM(III) WITH OCTACYANOMOLYBDATE(IV) IONS

S. I. ALI* and ZAKIR MURTAZA
Department of Chemistry, Jamia Millia Islamia, Jamia Nagar, New Delhi-110 025, India

(*Received* 6 *February* 1984; *accepted* 9 *May* 1984)

Abstract—The kinetics of the interaction of hexaaquochromium(III) ion with potassium octacyanomolybdate(IV) have been studied using conductance and spectrophotometric data. The mechanism of the reaction is discussed and the effect of H^+ ion and the ionic strength on the rate of the reaction determined. The reaction is found to be pseudo-first order with respect to potassium octacyanomolybdate(IV) and inverse first order with $[H_3O^+]$. The rate of the reaction increases with increase in ionic strength and temperature. Activation parameters have been calculated using the Arrhenius equation and have the values $\Delta E^* = 1.3 \times 10^2$ kJ mol^{-1}, $\Delta H^* = 129$ kJ mol^{-1}, $\Delta S^* = -315$ e.u., $\Delta F^* = 2.3 \times 10^2$ kJ and $A = 1.5 \times 10^{-3}$. The mechanism proposed is based on ion-pair formation and the rate equation obtained is given by:

$$k_{obs} = \frac{[kK_E[H_3O^+] + k'K'_Ek_h][Mo(CN)_8^{4-}]}{[H_3O^+] + k_h + [K_E[H_3O^+] + K'_Ek_h][Mo(CN)_8^{4-}]}.$$

The kinetics of the substitution of aquo ligands in hexaaquochromium(III) ion by different ligands has been studied by several workers.[1–6] The ligands which substitute the aquo ligands are oxalate, malonate, citrate and acetate and these reactions follow the S_N1 mechanism. The reaction rates are independent of anion concentration and inversely proportional to hydrogen ion concentration over a particular pH range. Further it has also been found that all the six aquo ligands are not totally substituted but only four are substituted easily to form a complex the diaquo-bis-oxalato chromium(III) and subsequent chelation occurs only when the anion is added in excess to the thoroughly aged corresponding dichelated chromium(III) ion. Similar reactions were studied by others[7–12] using oxalate, malonate, glycinate, 1,10-phenanthroline, 2,2′-dipyridyl and other multidentate ligands. In the study involving substitution by oxalate ion, it has been shown that the substitution proceeds through the mechanism of ion-pair association with the formation of mono-oxalato complex as also in the case of malonate. The reactions in both the cases are found to be first order with respect to chromium(III) and pseudo-first order rate constant increases linearly with increase in anion concentration and the reaction rates are inversely proportional to hydrogen ion concentration. The substitution of aquo ligands by 2,2′-dipyridyl in water–ethanol mixture proceeds through the S_N2 mechanism. Thus, the ligand substitution reactions in the case of chromium(III) do not follow any single mechanism and the reaction path depends on the nature of the incoming ligand and the experimental conditions. In this paper the investigations on the kinetics of the interaction of chromium(III) with octacyanomolybdate(IV) ions have been reported and a mechanism of the reactions has been proposed from which the rate equation has been derived.

MATERIALS AND METHODS

Potassium octacyanomolybdate(IV) was prepared by the methods of Leipoldt *et al.*[13] It was crystallized four to five times from ethanol–water mixture and dried in a desiccator over calcium chloride. Its solution was prepared in distilled water and strength determined by titrating it potentiometrically against ceric sulphate. The solution of chromium(III) nitrate was prepared by dissolving its

* Author to whom correspondence should be addressed.

A.R. crystals in water and strength determined gravimetrically by precipitating it as barium chromate.[14]

Kinetic runs of temperature equilibrated solutions of chromium(III) nitrate and potassium octacyanomolybdate(IV) of desired concentrations mixed in the reaction vessels and kept in a thermostat controlled at the selected temperature within ± 0.1°C were carried out. The course of the reaction was followed by measuring optical density at 380 nm, the wavelength of the maximum absorption of the complex formed by pipetting aliquots of the reaction mixture at definite time intervals and cooled in an ice bath to quench the reaction. The pseudo-first order rate constants for the reaction were obtained by plotting $\ln(O.D._\infty - O.D._0)/(O.D._\infty - O.D._t)$ against time. The pH of the solutions were adjusted with buffer of CH_3COONa–CH_3COOH mixtures, HNO_3 or HCl solutions and ionic strength with KNO_3 solutions.

Optical density measurements were carried out with Spectromom 361 Spectrophotometer using 1 cm cell and pH measurements were made on Elico pH meter model L1-10 using glass electrode EM 60. The conductance measurements were carried out on Toshniwal's digital conductivity meter (S.No. 052, type CL 01/10) with a dip cell (cell constant = 0.981).

RESULTS AND DISCUSSION

The stoichiometry of the reaction between chromium(III) and potassium octacyanomolybdate(IV) was determined[15,16] by the method of continuous variation and was found to be 1 : 1. The same results were obtained by the mole ratio method.[17] No evidence was found for the stoichiometry of 1 : 2 or 2 : 1 in solution. Depending upon the H^+ ion concentration, the reaction can be represented by the following equations:

$$Cr(H_2O)_6^{3+} + Mo(CN)_8^{4-} \rightarrow [Cr(H_2O)_5Mo(CN)_8]^- + H_2O, \quad (1)$$

$$Cr(H_2O)_5OH^{2+} + Mo(CN)_8^{4-} \rightarrow [Cr(H_2O)_4OHMo(CN)_8]^{2-} + H_2O. \quad (2)$$

In the first set of kinetic experiments, the concentration of octacyanomolybdate(IV) ion was varied (3.5–7.5×10^{-2} M) and that of hexaaquochromium(III) ion fixed (5.0×10^{-3} M). In these experiments the ionic strength (1.0 M) and pH (3.42) of the solutions were kept constant. The observed rate constant values at 40°C are 0.37, 2.30, 3.03, 3.22, 3.38, 3.84, 4.25 and 4.76×10^{-4} s^{-1} at 3.5, 5.0, 5.5, 6.0, 6.25, 6.5, 7.0 and 7.5×10^{-2} M concentrations of complex respectively. The rate of the reaction obtained is pseudo-first order with respect to the octacyanomolybdate(IV) ion.

The rate of the reaction is found to increase with decrease in H^+ ion concentration at fixed octacyanomolybdate (5.0×10^{-2} M), hexaaquochromium (5.0×10^{-3} M) and ionic strength (1.0 M). Acetate buffer, nitric acid or hydrochloric acid solutions were used for adjusting the pH of the solution. The rate constant values were found to be the same whether the pH was adjusted with HCl, HNO_3 or acetate buffer solutions. No catalytic effect by NO_3^- ions or coordination by the acetate buffer was observed in the reaction. The plot of $\log k$ vs $\log[H^+]$ is linear with a slope of -1.0 at the lower values of the latter indicating that the reaction has inverse first order dependence on $[H^+]$.

The effect of varying ionic strength on the reaction rate was studied by adding different amounts of KNO_3 at constant hydrated cation and complex anion concentrations. It was observed that increase in ionic strength (0.85–2.0 M) increases the rate of the reaction indicating the easy removal of coordinated water molecules from the ion pair. A plot of $\log k/k_0$ vs $\sqrt{\mu}$ gives a linear curve. The rate of the reaction was studied at six different temperatures (30–50°C) keeping the concentrations of hexaaquochromium(III) (5.0×10^{-3} M) and octacyanomolybdate(IV) (5.0×10^{-2} M) ions constant and maintaining fixed ionic strength (1.0 M) and pH (3.42). It was found that the rate of the reaction increases with increase in temperature. The activation parameters were calculated using the Arrhenius equation, the values are $\Delta E^* = 1.3 \times 10^2$ kJ mol^{-1}, $\Delta H^* = 129$ kJ mol^{-1}, $\Delta S^* = -315$ e.u., $\Delta F^* = 2.3 \times 10^2$ kJ and $A = 1.5 \times 10^{-3}$.

For the system $Cr(H_2O)_6^{3+}$–$Mo(CN)_8^{4-}$, the variation of conductance with concentration was compared with the limiting Onsager equation. A plot of equivalent conductance versus square root of concentration gives a slope which is considerably lower than the theoretical Onsager slope furnishing evidence for the ion-pair formation between hexaaquochromium(III) and octacyanomolybdate(IV) ions. The ion-pair formation between the two reacting species is followed by associative interchange in which bond making plays a significant role. On adding excess nitrate, the water molecules which are coordinated in the ion-pair reorient considerably around nitrate ions through hydrogen bonding. As a result, nitrate ions facilitate the removal of coordinated water molecules from the ion-pair and these water molecules are then engaged in the solvation of nitrate ions. A similar effect of ionic strength was observed by Hamm and coworkers.[6] The two species existing in the hydrogen ion concentration range studied are $Cr(H_2O)_6^{3+}$ and

$[Cr(H_2O)_5OH]^{2+}$, both of which interact and form ion-pairs with $Mo(CN)_8^{4-}$. No evidence has been obtained for the existence of the dimeric species $Cr_2(H_2O)_8(OH)_2^{4+}$ in this system which will require a stoichiometry of 2 : 1 for the reaction instead of 1 : 1. This has not been observed even at high temperatures. The possibility of the formation of protonated species of $Mo(CN)_8^{4-}$ in solution specially at the low pH range was investigated. At the concentration ranges studied, no evidence was found for it. The rate constant values at low pH do not show a marked change. It is inferred from these results that very weak hydrogen bonding between the proton and the nitrogen of CN may exist.

The influence of chromic ions on potassium hexacyanoferrate(II) has been investigated in detail. It has been found that chromic ions catalyse the decomposition of potassium hexacyanoferrate(II) to potassium aquopentacyanoferrate(II):[18]

$$Fe(CN)_6^{4-} + H_2O \xrightarrow{Cr^{3+}} Fe(CN)_5H_2O^{3-} + CN^-.$$

In the case of potassium octacyanomolybdate(IV), no evidence has been found for its catalytic decomposition into potassium aquoheptacyanomolybdate(IV) by chromium(III) ions. As there is no release of CN^- ions in this case, so there is also no possibility for the existence of cyanochromium(III), $CrCN^{2+}$, which has been shown to be formed when an inert cobalt(III) cyano complex oxidizes the labile chromium(II) aqua ion giving an isocyanochromium(III) complex[19,20] which isomerises to the carbon bonded species. Careful measurement of conductance during the progress of the reaction rules out such possibilities.

The dependence of k_{obs} on octacyanomolybdate(IV) and hydrogen ion is consistent with an ion-pair mechanism. The mechanism may be represented considering that both $Cr(H_2O)_6^{3+}$ and $Cr(H_2O)_5OH^{2+}$ (obtained by the ionization of $Cr(H_2O)_6^{3+}$) react with octacyanomolybdate(IV) ions to form the respective complexes. Anation, water exchange and ion-pair[21] formation has also been observed for aquopentaaminechromium(III) ions in acidic aqueous solutions containing chloride or thiocyanate ions and for the systems[22] $Coen_2(H_2O)_2^{3+}$–$C_2O_4^{2-}$ equilibria. Ion-pair formation has also been observed in the case of the interaction of hexaaquochromium(III) with acetate ions[23] when the ion-pairs formed are $Cr(H_2O)_6^{3+}$, $^-OOCCH_3$ and $[Cr(H_2O)_5OH]^{2+}$, $^-OOCCH_3$ which undergo anation reaction, giving out an H_2O molecule and forming the complex.

On the basis of the above results the following ion-pair mechanism has been proposed for the interaction of hexaaquochromium(III) with octacyanomolybdate(IV) ions:

$$Cr(H_2O)_6^{3+} + H_2O \overset{k_h}{\rightleftharpoons} Cr(H_2O)_5OH^{2+} + H_3O^+ \quad (3)$$

$$Cr(H_2O)_6^{3+} + Mo(CN)_8^{4-} \overset{K_E}{\rightleftharpoons} Cr(H_2O)_6^{3+}, Mo(CN)_8^{4-} \quad (4)$$

$$Cr(H_2O)_6^{3+}, Mo(CN)_8^{4-} \overset{k}{\rightarrow} [Cr(H_2O)_5Mo(CN)_8]^- + H_2O \quad (5)$$

$$Cr(H_2O)_5OH^{2+} + Mo(CN)_8^{4-} \overset{K_E}{\rightleftharpoons} Cr(H_2O)_5OH^{2+}, Mo(CN)_8^{4-} \quad (6)$$

$$Cr(H_2O)_5OH^{2+}, Mo(CN)_8^{4-} \overset{k'}{\rightarrow} [Cr(H_2O)_4OHMo(CN)_8]^{2-} + H_2O \quad (7)$$

$$Cr(H_2O)_4OHMo(CN)_8^{2-} + H_3O^+ \xrightarrow{\text{fast}} [Cr(H_2O)_5Mo(CN)_8]^- + H_2O. \quad (8)$$

From the above mechanism the following rate equation is derived:

$$k_{obs} = \frac{[kK_E[H_3O^+] + k'K'_Ek_h][Mo(CN)_8^{4-}]}{[H_3O^+] + k_h + [K_E[H_3O^+] + K'_Ek_h][Mo(CN)_8^{4-}]} \quad (9)$$

or

$$\frac{1}{k_{obs}} = \frac{[H_3O^+] + k_h}{[kK_E[H_3O^+] + k'K'_Ek_h][Mo(CN)_8^{4-}]} + \frac{K_E[H_3O^+] + K'_Ek_h}{kK_E[H_3O^+] + k'K'_Ek_h}. \quad (10)$$

From (10) the plot of $1/k_{obs}$ vs $1/Mo(CN)_8^{4-}$ (Fig. 1) should be linear with an intercept, $K_E[H_3O^+] + K'_Ek_h/kK_E[H_3O^+] + k'K'_Ek_h$ and slope $[H_3O^+] + k_h/kK_E[H_3O^+] + k'K'_Ek_h$. The values of the intercept and the slope are dependent on the hydrogen ion concentration. The mechanism confirms the result of variation of k_{obs} with $[H_3O^+]$ and also the ionic strength. It is based on an eigen mechanism, the rate determining step being the loss of water molecules from the primary coordination sphere. The reaction is associative interchange (I_a) type for the reaction of $Cr(H_2O)_6^{3+}$ and $Mo(CN)_8^{4-}$ and dissociative interchange (I_d) type for $[Cr(H_2O)_5OH]^{2+}$ and $Mo(CN)_8^{4-}$. The final product of the reaction was isolated in the solid state and its composition

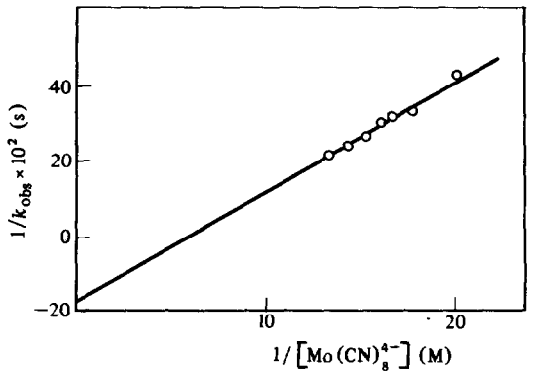

Fig. 1. Plot of $1/k_{obs}$ vs $1/[Mo(CN)_8^{4-}]$.

and structure were determined[17] with the help of elemental and IR analysis. According to the elemental analysis the final product was $KCrMo(CN)_8 \cdot 2H_2O$.

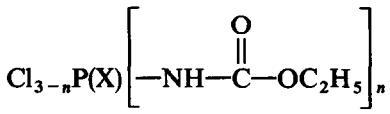
REACTIONS OF PHOSPHORUS HALIDES WITH URETHANE

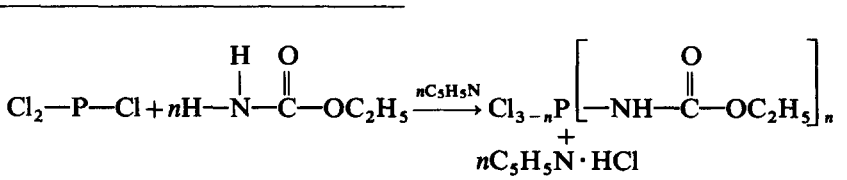


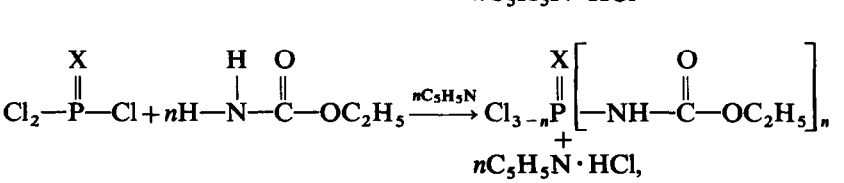
R. P. NARAIN* and MAHTAB Z. SIDDIQUI
Department of Chemistry, University of Gorakhpur, Gorakhpur—273001, India

(*Received* 20 *March* 1984; *accepted* 9 *May* 1984)

Abstract—By the reaction of phosphorus trichloride, thiophosphoryl chloride, phosphorus oxychloride and phosphorus pentachloride with urethane in stoichiometric ratio 1 : 1 or 1 : 2 in benzene, compounds of the type

and





(X = S, O or Cl; n = 1 or 2) have been synthesized. A probable mechanism for their formation has also been suggested.

The reaction between phosphorous acid and alkylurethanes was attempted by Derkach *et al.*[1] in attempts to prepare some insecticidal organophosphorus compounds. The reaction of amido esters of urethanephosphorus acid with acid chlorides in the presence of a base as an acid acceptor has been carried out by Antokhina *et al.*[2] Triaryl phosphine urethane has been synthesized by Gerber *et al.*[3] Semashko has recently reported the herbicidal activity of compounds containing phosphorus-nitrogen linkage and containing phosphorus in trivalent state.[4]

In the present communication we report the facile formation of the compounds having phosphorus–nitrogen linkages, formed by the reaction of phosphorus halides with urethane.

Phosphorus trichloride, thiophosphoryl chloride, phosphorus oxychloride and phosphorus pentachloride were reacted with urethane in molar ratios 1:1 and 1:2 in the medium of benzene containing pyridine. The reactions may be represented by the equations:

where X = S, O or Cl; n = 1 or 2.

It was found that the compound obtained from PCl_3 and urethane in molar ratio 1 : 1 was orange in colour and in molar ratio 1 : 2 it was yellowish

* Author to whom correspondence should be addressed.

whereas the rest of the compounds were light brownish/white coloured crystalline solids. All of them were soluble in alcohol, carbon tetrachloride, chloroform, acetone and acetophenone. They appeared to decompose in their melting point determination.

EXPERIMENTAL

All glass apparatus with interchangeable joints was used throughout and special precautions were taken to exclude moisture.

Benzene, pyridine, ether, acetone and acetophenone were purified by standard procedures.

The phosphorus halides employed were of BDH grade and distilled twice before use.

Urethane (Loba Chemie) was recrystallized before use.

Silica gel G (BDH) was used for TLC and spots were detected by UV lamp, iodine chamber and heating the plates in an oven after spraying with 10% H_2SO_4.

ANALYSIS

Phosphorus was estimated gravimetrically as ammonium phosphomolybdate. Sulphur and chlorine were estimated gravimetrically as barium sulphate and silver chloride.[5]

IR spectra (ν_{max} in cm^{-1}) of compounds were recorded on Perkin–Elmer spectrophotometer model 577 in Nujol and NMR [chemical shifts in τ (ppm)] were recorded on a Perkin–Elmer R-32 instrument (90 Mc) in $CDCl_3$ with TMS as internal standard, both working at the Chemical Laboratories of Central Drug Research Institute, Lucknow, India. The values obtained were interpreted by comparing the absorption bands and τ values with those reported in the literature[6,7] (Table 1).

Molecular weights were determined cryoscopically using acetophenone as a solvent.

Methods of preparation being the same for all the reactions, only one method has been described in detail while a summary of all is given in Table 1.

REACTION OF PHOSPHORUS TRICHLORIDE WITH URETHANE MOLAR RATIO 1:1

To a solution of phosphorus trichloride (4.25 g) taken in benzene (20.00 g) was added urethane (2.75 g) dissolved in pyridine. The reaction was exothermic. The contents of the flask were cooled and stirred during the addition of the reactants. After addition, the contents were subjected to refluxing for 7 h. Benzene was distilled off and the residue was washed several times with dry pyridine to remove the pyridine hydrochloride. Final traces of pyridine hydrochloride were removed by sublimation under reduced pressure. The solid obtained was washed with ether, dried in vacuum and recrystallized from dry acetone. The purity of the compound was checked by thin layer chromatography.

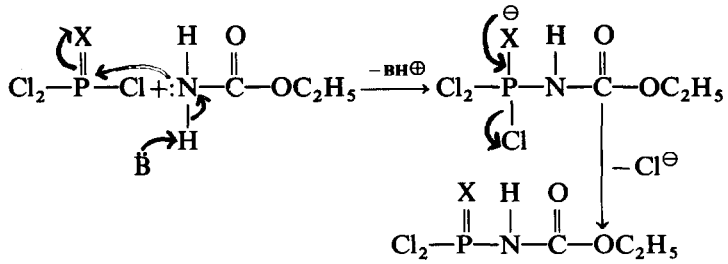
THIN LAYER CHROMATOGRAPHY

The chromatoplate was prepared by applying a uniform layer of silica gel in water, drying first at room temperature for 8 h and then at 100°C for 30 min. A 10% solution of the compound in dry acetone was applied over the plate which was then dried at room temperature for 2 h and at 100°C for 10 min.

The plate was then put in the eluant containing ethyl acetate–benzene mixture 1:2 by volume.

Finally the spots were located in UV light under a UV lamp, as well as in an iodine chamber. A single spot was obtained.

Found: P, 16.24; Cl, 37.28%. $C_3H_6O_2NPCl_2$ requires: P, 16.31; Cl, 37.36%.



RESULTS AND DISCUSSION

Since the urethane molecule has two reacting sites, ethoxy and amino, reactions of urethane with phosphorus halides are therefore possible from both ends. There is also the possibility of removal of both the amino protons with the Cl atoms of phosphorus halides. Since the IR spectra of the compounds showed a peak in the region 820–850 cm^{-1}, characteristic of P—N linkage, the reaction appears to have taken place from the amino end. Further, the presence of a sharp proton as singlet (τ value 2.48) in NMR spectra, could be attributed to —NH group of urethane molecule. This confirms the removal of a hydrogen by a Cl atom of the phosphorus halide, even when the phosphorus halide urethane molar ratio is 1:2.

The reaction is slow due to the $-I$ effect of the keto group and pyridine is needed for the completion of the reaction. The formation of pyridine hydrochloride further confirms that the reaction has taken place from the amino end of the urethane molecule.

The reaction appears to be initiated by the nucleophilic attack of nitrogen of urethane over the phosphorus atom of the halide with the liberation of a proton. This attack is then either followed or accompanied by the elimination of a halide ion.[8] The

entire mechanism may be depicted as follows:

$$BH^{\oplus} + Cl^{\ominus} \longrightarrow BHCl.$$

† s, singlet; m, multiplet; t, triplet.

The catalyst (B) would finally combine with halide ion to give base hydrochloride.

However, in phosphorus trichloride the above mode of attack may be ruled out because of the absence of a double bond attached to the phosphorus atom. Here the nucleophilic attack of the nitrogen of urethane over the phosphorus atom is facilitated by the vacant 3*d*-orbitals and this attack is either followed or accompanied by the elimination of a proton and a halide ion.[9] The entire mechanism may be depicted as:

The reaction provides a convenient route for the establishment of P—N bond.

(*Received* 27 *March* 1984; *accepted* 9 *May* 1984)

Abstract—(1,4,7,10-Tetraazacyclododecane) [diamine or (*S*)-alanine]–cobalt(III) complexes [diamine = ethylenediamine, 2-(aminomethyl)pyridine, (*R*)-1,2-propanediamine, (*R,R*)-1,2-diaminocyclohexane, trimethylenediamine and 2-methyl-1,3-diaminopropane] are prepared and characterized spectroscopically. The ligand field transitions occur at lower energies than those of the corresponding tetraamine analogues. Severe distortions caused by the too small size of the cyclic ligand are one of the origins. The distortions also exert influence upon circular dichroism spectra.

Contrary to a majority of cyclic tetramines which are coordinated in a planar structure[1] the cavity formed by 1,4,7,10-tetraazacyclododecane (cyclen) is too small to accommodate a transition metal ion in the plane of the N_4 donor atoms and then cyclen is, usually, coordinated in a folded *cis*-arrangement (structure **I**). Even in a folded arrangement there

I

are still significant distortions from a regular octahedron as have been revealed for $[Co(cyclen)(NO_2)_2]^+$ and $[Co(cyclen)(acac)]^{2+}$ (acac = acetylacetonate ion). The apical donors, N(1) and N(7), are remarkably deviated from the ideal positions and the angles of N(1)—Co—N(7) are 164.4(2)° for the former and 166.1(3)° for the latter.[2,3] The distortions should be reflected in properties of complexes of cyclen but little is known of cobalt(III) complexes of cyclen.[2–5] To see the effect of the distortions we have studied spectroscopically some new cobalt(III) derivatives of cyclen, $[Co(cyclen)(diamine)]^{3+}$ and $[Co(cyclen)(ala)]^{2+}$. The abbreviations used are given in the footnote of Table 1.

RESULTS AND DISCUSSIONS

The mixed complexes $[CoL(diamine)]^{3+}$ [Table 1 (L represents cyclen)] were easily obtained by the reaction of $[CoLCl_2]Cl \cdot 1.5\text{-}H_2O$ with a diamine in dimethylsulphoxide. These complexes are red despite a "CoN_6" chromophore, for which are usually observed a yellow or an orange colour like the colours of $[Co(en)_3]^{3+}$ and $[Co(NH_3)_6]^{3+}$. The red amino acid complex $[CoL(ala)](ClO_4)_2 \cdot 0.5H_2O$ was similarly prepared. For the complexes of ala and the unsymmetrical diamines two isomers are possible, since the different orientations of the hydrogen atoms on N(4) and N(10) (structure **I**: determined by X-ray analysis for X = Y = NO_2 and X – Y = acac)[2,3] make the two sites of coordination, X and Y, inequivalent.† Attempts to separate the isomers are so far unsuccessful. The ^1H NMR spectra of the complexes (X – Y = pn and ala) show a single methyl doublet at 1.47 ppm(pn) and 1.54(ala), and give no indication of the presence of isomers. This suggests either an accidental coincidence of the methyl chemical shifts between the two isomers or the presence of only one isomer. Attempts to resolve

† The ^{13}C NMR spectrum of $[CoL(en)]^{3+}$ shows that cyclen adopts the configuration of structure **I**: the signals of cyclen are at 59.1, 56.1, 51.6 and 47.3 ppm, and those of en at 46.2 and 45.5 ppm.

Abbreviations: L, 1,4,7,10-tetraazacyclododecane; en, ethylenediamine; pic, 2-(aminomethyl)pyridine; pn, (*R*)-1,2-propanediamine; chxn, (*R,R*)-1,2-diaminocyclohexane; tn, trimethylenediamine; bn, 2-methyl-1,3-diaminopropane; ala, (*S*)-α-alanine.

chiral $[CoL(bn)]^{3+}$ by column chromatography[6] are also wasteful so far.

The absorption spectral data are given in Table 2 and Figs 1–3. Comparison of the data with those of other "CoN_6" type complexes reveals that remarkable red shifts and enhanced intensities of the ligand field transitions are characteristic for the cyclen complexes [cf. $\nu_1(^1A_{1g} \rightarrow {}^1T_{1g}) = 21.30 \times 10^3$ cm^{-1} ($\log \varepsilon = 1.94$) and $\nu_2(\rightarrow {}^1T_{2g}) = 29.40$ (1.90) for $[Co(en)_3]^{3+}$, and 20.96 (1.68) and 29.40 (1.60) for $[Co(NH_3)_6]^{3+}$]. Chelate effect produced by an ethylene chain (a five-membered chelate ring) is completely cancelled out and the transition peaks are at even lower energies than those of $[Co(NH_3)_6]^{3+}$. The apparent weakening of the ligand field strength of cyclen is considered to be due to severe distortions around a cobalt atom caused by an unsuitable size of the cyclic ligand. The

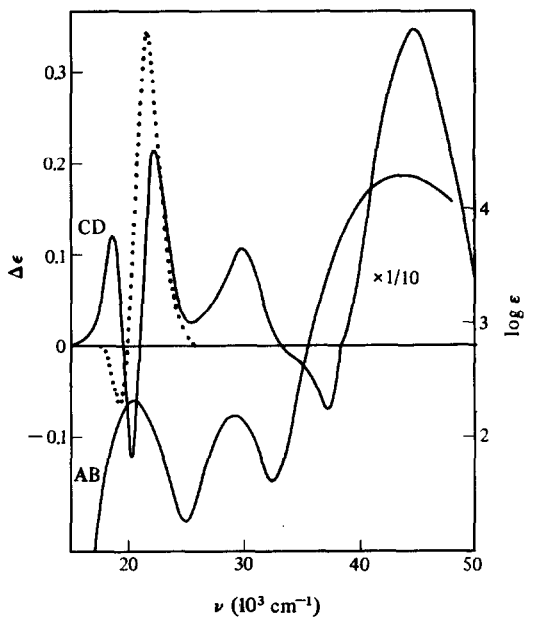

Fig. 1. Absorption and CD spectra of [CoL(pn)] $Br_3 \cdot 4H_2O$ (——) and $[Co(NH_3)_4(pn)]^{3+}$ (····).[8]

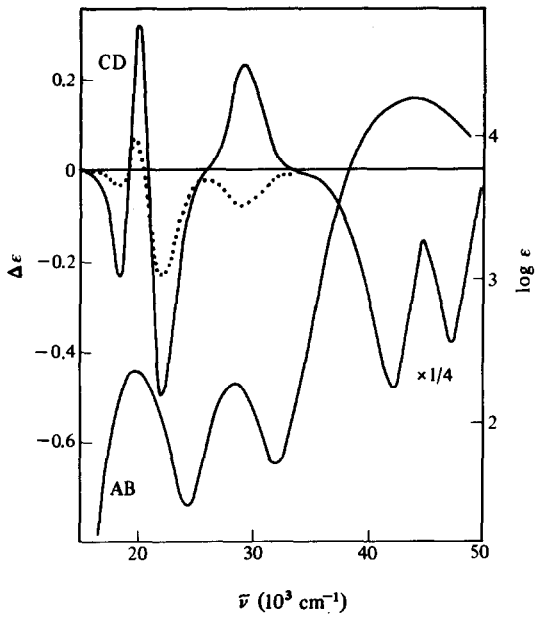

Fig. 3. Absorption and CD spectra of [CoL(ala)] $(ClO_4)_2 \cdot 0.5H_2O$ (——) and $[Co(NH_3)_4(ala)]^{2+}$ (····).[9]

distortions, simultaneously lowering the symmetry of the ligand field, enhance the intensities of the transitions.[7]

Circular dichroism (CD) spectra are a better reflection of fine properties of complexes. The CD spectra of optically active complexes are shown in Figs 1–3, where they are compared with those of the corresponding tetraamine complexes in the $\nu_1(^1A_{1g} \rightarrow {}^1T_{1g})$ region. The CD spectra of $[Co(NH_3)_4(XY)]^{n+}$ (XY = pn, chxn and ala) are induced solely by the vicinal effects of the chiral ligands.[8,9] In the ν_1 region the CD patterns of pn and chxn complexes are significantly varied when $(NH_3)_4$ are replaced by cyclen, while in the case of ala the pattern modification is relatively small and intensities of extremes are altered. The part of cyclen shown in structure I has a plane of symmetry [N(4), N(10), Co, X and Y] but is prochiral. The change of the CD patterns may, on the one hand, be caused by the chiralty induced by the presence of the chiral pn and chxn ligands. Another origin should also be considered. An apparent CD pattern is usually a sum of each component of the split transitions due to a lower symmetry ligand field than an O_h one and the relative energy levels of each split state are disturbed by the severe distortions in the cyclen complexes compared with those of $(NH_3)_4$ complexes.[7] The disturbed energy levels should result in a different CD pattern.

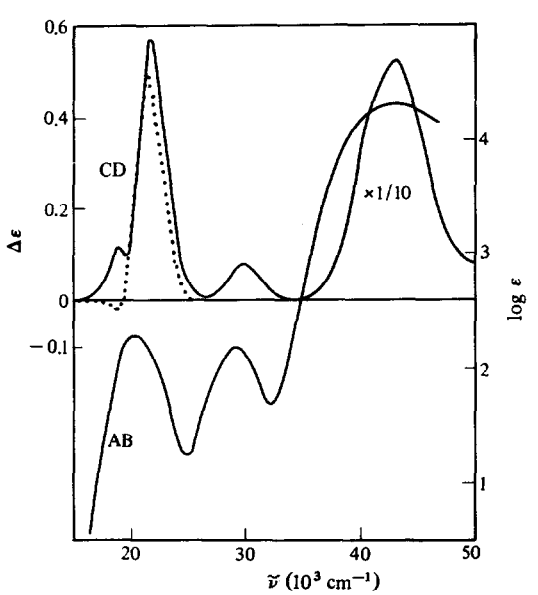

Fig. 2. Absorption and CD spectra of [CoL(chxn)] $Br_3 \cdot 3.5H_2O$ (——) and $[Co(NH_3)_4(chxn)]^{3+}$ (····).[8]

The apparently enhanced CD intensity of $[CoL(ala)]^{2+}$ is not extraordinary if the molar extinction coefficient of the ν_1 band ($\varepsilon = 232$) is taken into consideration (cf. $\nu_1 = 20.3 \times 10^3\ cm^{-1}$ ($\varepsilon = 78$) for $[Co(NH_3)_4(ala)]^{2+}$). The intrinsically low symmetry of the ala complex probably results in the relatively small modification of the CD pattern upon replacement of $(NH_3)_4$ with cyclen.

The above data reveal that the absorption maxima (ν_1) of $[CoL(XY)]^{n+}$ are at an even lower energy than those of the corresponding $[Co(NH_3)_4(XY)]^{n+}$, so there arises a doubt about the absorption maximum reported for $[CoL(acac)]^{2+}$ [$\nu_1 = 2.0 \times 10^4\ cm^{-1}$

($\varepsilon = 200$)],[3] since it is comparable in energy to that for $[Co(en)_2(acac)]^{2+}$ [19.8×10^3 cm^{-1} ($\varepsilon = 159$)].[13] The remeasurement of the spectrum of $[CoL(acac)]^{2+}$ gave the value $\nu_1 = 18.7 \times 10^3$ cm^{-1} ($\varepsilon = 318$). This is consistent with the above results.

EXPERIMENTAL

Measurements

Measurements were carried out by the methods reported previously.[10] ^{13}C NMR spectra were recorded on a JEOL FX-60 spectrometer. The analytical results are given in Table 1.

Synthesis

The ligand cyclen was prepared by the procedure of Richmann and Atkins[11] from diethylenetriamine and diethanolamine. $[CoLCl_2]Cl \cdot 1.5H_2O$ was synthesized by the known method.[5]* $[CoL(diamine)]X_3 \cdot nH_2O$ (X = Cl, Br) (Table 1).

A mixture of 1 mmol of $[CoLCl_2]Cl \cdot 1.5H_2O$ and 1 mmol of a diamine in 50 cm^3 of dimethylsulphoxide was stirred at *ca* 50°C for 1 h and the reaction mixture was diluted with water. The solution acidified with hydrochloric acid was absorbed on a short column of SP Sephadex C-25 and washed with 0.02 N aqueous hydrochloric acid to remove byproducts and the starting material. The main pink band was eluted with 2 N hydrochloric acid and the eluent was evaporated to a small volume under reduced pressure. Upon addition of sufficient ethanol to the concentrated solution the chloride precipitated in a yield of 50–70%. The chloride was recrystallized from aqueous ethanol and dried in air. The bromide was isolated similarly by using hydrobromic acid instead of hydrochloric acid.

* For the preparation of $[CoL(NO_2)_2]Cl$ $NaNO_2$ was used at twice the amount indicated in Ref. 5.

$[CoL(ala)](ClO_4)_2 \cdot 0.5H_2O$

To a solution of 1 mmol of alanine and 1 mmol of 1,8-diazabicyclo(5.4.0)-7-undecene in 30 cm^3 of dimethylsulphoxide was added 1 mmol of $[CoLCl_2]Cl \cdot 1.5H_2O$ and the mixture was stirred at room temperature for one day. The mixture was diluted with water, acidified with hydrochloric acid, and absorbed on a column (3 cm ∅ × 150 cm) of SP Sephadex C-25. The column was eluted with 0.2 M aqueous sodium sulphate and a main red band was collected. The complex was isolated as the perchlorate in the usual manner[6] in a yield of 158 mg.

Acknowledgement—We thank Dr Y. Yoshikawa for measurements of ^{13}C NMR spectra.

SYNTHESIS AND CHARACTERIZATION OF MIXED LIGAND COMPLEXES OF COPPER(II), NICKEL(II), COBALT(II) AND ZINC(II) WITH GLYCINE AND URACIL OR 2-THIOURACIL

MADHU GUPTA and M. N. SRIVASTAVA*
Chemical Laboratories, University of Allahabad, Allahabad, India

(*Received* 15 *November* 1983; *accepted after revision* 22 *May* 1984)

Abstract—Mixed ligand complexes of Cu(II), Ni(II), Co(II) and Zn(II) formed with glycine and uracil or 2-thiouracil have been synthesized and characterized by elemental analysis, conductance, spectral (IR and electronic spectra) and magnetochemical measurements. Results show that glycine is bidentate in all cases; uracil behaves as a bidentate ligand in Cu(II) complex, coordinating through its one carbonyl oxygen and nitrogen, whereas in other cases it is only monodentate, coordinating only through nitrogen. With thiouracil, coordination occurs from carbonyl oxygen and one nitrogen in Cu(II) and Ni(II) complexes, but in the Co(II) complex coordination occurs from thionyl sulphur and nitrogen. In the Zn(II) complex it shows tridentate behaviour, coordinating through oxygen, sulphur and one nitrogen. Mixed Cu(II), Co(II) and Zn(II) complexes of uracil and of Ni(II) and Zn(II) with thiouracil are octahedral, whereas the mixed Ni(II) complex with uracil shows distorted tetrahedral geometry, and the mixed Co(II)–thiouracil complex is square planar. The mixed Cu(II)–thiouracil complex has a binuclear structure, with square planar arrangement around each copper atom.

Mixed ligand complexes are well known to play an important role in biological systems[1] and are being much investigated in solution. Recently Srivastava *et al.*[2] studied potentiometrically the formation of some mixed ligand transition metal complexes in solution, formed with aspartic/glutamic acid and uracil or thymine. The present paper describes the preparation and characterization of some mixed ligand Cu(II), Ni(II), Co(II) and Zn(II) complexes formed with glycine and uracil or 2-thiouracil and their structural studies by spectral (IR and electronic spectra) and magnetochemical measurements.

EXPERIMENTAL

Materials

Glycine (B.D.H.), uracil (Fluka), 2-thiouracil (B.D.H.), cupric chloride (B.D.H., AR) nickel chloride (B.D.H., AR) cobalt chloride (Chemapol) zinc chloride (Merck) and sodium hydroxide (Merck).

Solutions of uracil and 2-thiouracil were prepared by dissolving them in one equivalent of alkali.

Preparation

The metal ion and the two ligand solutions (glycine and uracil/2-thiouracil) were mixed in a molar ratio of 1:1:1, in the order of uracil/2-thiouracil followed by glycine and the pH of the mixture solutions was adjusted to 6–7 by further adding alkali, where necessary. On first adding uracil or 2-thiouracil, precipitates appeared [Cu(II): green; Ni(II): light green; Co(II): pink-violet; Zn(II): colourless] which dissolved on adding glycine to yield clear solutions. The products were obtained by concentration and adding alcohol. They were washed first with 50% alcohol–water mixture, then with absolute alcohol a number of times and finally with ether and dried in an air oven at 50°C. The complexes were also heated in an air oven

*Author to whom all correspondence should be addressed.

successively at 100 and 150°C for about 2 h each time to note any loss of water on heating. It is observed that on heating at 100°C the mixed complexes of Cu(II) and Ni(II) with uracil and of Co(II) with 2-thiouracil lose one water molecule, whilst Co(II) with uracil and of Cu(II) with 2-thiouracil lose two molecules; on the Zn(II) complex with 2-thiouracil there was practically no effect. The mixed Zn(II) complex with uracil loses one water molecule at 100°C and one more on further heating at 150°C. In the mixed Ni(II) thiouracil complex, the loss of water begins from 100°C and is completed by 150°C, the total loss corresponding to one water molecule.

The IR spectra were recorded on a Perkin–Elmer spectrophotometer model 177 covering the range 4000–650 cm^{-1} in KBr discs. The absorption spectra were recorded in aqueous solutions in the range 330–900 nm on a Beckman spectrophotometer model 26. The reflectance spectra of insoluble complexes were recorded in MgO on a spectrophotometer VSU-2P in the range 220–1000 nm.

RESULTS AND DISCUSSION

Given formulae (Table 1) conform to analytical data. Conductance measurements show that the mixed complexes of Ni(II) and Co(II) with uracil are 1:1 electrolytes, whereas the corresponding complexes of Cu(II) and Zn(II) are 1:2 electrolytes. The mixed 2-thiouracil complexes are insoluble in water, as well as in common organic solvents.

IR studies

Some principal IR frequencies of the ligands and their mixed metal complexes are given in Table 2. Results show that the νNH_3^+ of glycine[3,4] (3150 cm^{-1}) disappears on coordination, and instead νNH frequencies appear in the 3400–3200 cm^{-1} region in the metal complexes. $\nu_{as}COO^-$ and ν_sCOO^- frequencies of course appear in their usual region around 1600 and 1400 cm^{-1} respectively. The $\nu C{=}O$ bands of uracil (1712 and 1655 cm^{-1}) are in general little affected in the metal complexes, but in the Cu(II) complex the 1712 cm^{-1} band is considerably lowered in its position to 1670 cm^{-1}. Its $\nu NH + \nu CH$ bands (3130 and 3070 cm^{-1}) appear around 3060 cm^{-1} in the metal complexes.

In 2-thiouracil complexes its secondary amide I band $\nu C{=}O$ (1685 cm^{-1}) is considerably lowered to 1650–1640 cm^{-1} in Cu(II) and Zn(II) complexes, and to 1670 cm^{-1} in the Ni(II) complex, whereas in the Co(II) complex there is little effect. The $\nu NH + \nu CH$ bands (3125 and 3075–3030 cm^{-1}) appear in the 3160–3000 cm^{-1} region in the metal complexes. The thioamide(III) band[5,6] (1150 cm^{-1}) is raised to 1180–1170 cm^{-1} [in the Co(II) complex it is unaffected] whereas the thioamide(IV) band[7] (840 cm^{-1}) (possibly having a major contribution from $\nu C{=}S$)[8,9] is lowered to 830–825 cm^{-1} in Co(II) and Zn(II) complexes, but in Cu(II) and Ni(II) complexes its position remains unchanged.

In addition the metal complexes also show

broad bands in the 3700–3450 cm^{-1} region, attributed to νOH of water or OH^- groups.[10]

It may be thus concluded that glycine is bidentate in all cases, coordinating through $-NH_2$ and COO^- groups. In the Cu(II) complex, uracil acts as a bidentate ligand by coordinating through its one carbonyl oxygen and nitrogen, whereas in the other cases it is only monodentate coordinating through only one nitrogen. It may be however noted that since the Co(II) complex is a 1:1 electrolyte, in it deprotonation from only one uracil occurs, the other one being simply coordinated to the metal ion. With 2-thiouracil, in Cu(II) and Ni(II) complexes coordination occurs from the carbonyl oxygen (C=O) and nitrogen, in the Co(II) complex it is from thiocarbonyl sulphur (C=S) and nitrogen, whereas in Zn(II) complex thiouracil is possibly tridentate, coordinating through carbonyl oxygen, thiocarbonyl sulphur and nitrogen.

Magnetic moments and electronic spectra

The magnetic moment of the Cu(II)–glycine–uracil complex is 1.90 B.M. corresponding to one unpaired electron. Its electronic spectrum shows a charge-transfer band at 29,410 cm^{-1} and one broad asymmetric band with λ_{max} at 710 nm (14,085 cm^{-1}). It thus suggests its distorted octahedral structure. But the corresponding Cu(II)–thiouracil–glycine complex is diamagnetic, suggesting its dimetic nature,[12] which is also supported by spectral evidence. Its electronic spectrum shows three charge-transfer bands at 33,480, 27,780 and 24, 390 cm^{-1}, out of which the band observed at 27,780 cm^{-1} is characteristic of dimeric copper(II) complexes.[13] The main *d–d* absorption band is observed at 15,150 cm^{-1} with a shoulder at 12,500 cm^{-1}. The complex is thus dimeric possibly with a square planar arrangement around each copper atom.

The magnetic moments of nickel(II) complexes are Ni(II)–glycine–uracil (μ_{eff} = 3.03 B.M.) and Ni(II)–glycine–2-thiouracil (μ_{eff} = 2.92 B.M.) suggesting that they have octahedral or distorted tetrahedral geometry.[14] The electronic spectrum of the nickel(II)–glycine–thiouracil complex shows two bands at 17,095 and 28,570 cm^{-1} assigned as ν_2 and ν_3 transitions[11] respectively. Its ν_1 transition, however could not be observed, as it is likely to appear beyond 900 nm. It thus supports its octahedral geometry. But the electronic spectrum of the nickel(II)–glycine–uracil complex shows only one *d–d* absorption band at 13,890 cm^{-1}, and two charge-transfer bands at 28,570(sh) and 33,480 cm^{-1}. It thus suggests a tetrahedral geometry, and the 13,890 cm^{-1} band may be assigned as ν_3 transition.[11] The other two ν_1 and ν_2 transitions would of course appear at much lower frequencies beyond 1000 nm, and hence could not be observed.

The magnetic moment of the Co(II)–glycine–uracil complex is 4.10 B.M. Its electronic spectrum shows a charge transfer band at 26,670 cm^{-1}, the ν_3 transition[11] at 19,765 cm^{-1} and a weak shoulder at 13,715 cm^{-1}, thus suggesting an octahedral geometry. The other two ν_1 and ν_2 transitions are not observed because the ν_2 transition in Co(II) complexes is normally very weak and may or may not be observed, whereas the ν_1 transition is likely to appear at much lower frequencies beyond 1000 nm. The magnetic moment of the Co(II)–glycine–thiouracil complex (μ_{eff} = 2.49 B.M.) suggests it to be a low spin square planar[14] complex. The electronic spectrum shows a charge-transfer band at 28,570 cm^{-1}. The visible *d–d* band[11] is observed at 19,530 cm^{-1}, which may be assigned as a transition from the lower filled orbitals to the empty $d_{x^2-y^2}$ orbital.

SOLVENT COMPLEXES OF THE TYPE $[Fe^{III}(CN)_5L]^{n-}$

GRAŻYNA STOCHEL and ZOFIA STASICKA*
Department of Inorganic Chemistry, Jagiellonian University, 30-060 Kraków, Poland

(*Received* 11 *November* 1983; *accepted* 22 *May* 1984)

Abstract—The title complexes have been prepared *in situ* by photolyzing the $[Fe(CN)_5NO]^{2-}$ ion in some aliphatic alcohols, formamide and its derivatives, pyridine, acetonitrile and dimethylsulphoxide. Characterization of the complexes was made on the basis of three pieces of evidence: (i) the spectral properties, (ii) the presence of the titratable hydrogen in the complexes with protogenic solvents, and (iii) the anation reaction with the N_3^- and NCS^- ions.

The pentacyano(ligand)ferrate(III) complexes have been intensively studied for a long time.[1–12] Nevertheless, we have recently identified some new $[Fe^{III}(CN)_5L]^{n-}$ complexes, where L = solvent or deprotonated solvent molecule.

Moreover, a new way of generation of the iron(III) complexes in photochemical reaction of nitrosylpentacyanoferrate(II) is proposed.

RESULTS AND DISCUSSION

Electronic spectra of the $[Fe^{III}(CN)_5L]^{n-}$ complexes are characterized among others by two intense bands at 23–25 and 28–30 $\times 10^3$ cm^{-1} that are relatively independent of the identity of the ligand L.[2–12] These bands were assigned to the $CN \rightarrow Fe$ LMCT and LF transitions, respectively.[2–7] When ligand L contains acidic proton, i.e. L = L'H, in the spectrum of the deprotonated form, $[Fe^{III}(CN)_5L']^{(n+1)-}$, only one intensive band, relatively independent of the ligand L', is observed[3,8,13] at 22–23 $\times 10^3$ cm^{-1}.

The spectral features characteristic of the $[Fe^{III}(CN)_5 L]^{2-}$ complexes has been revealed by irradiated ($\bar{\nu} > 21 \times 10^3$ cm^{-1}) solutions of $[Fe(CN)_5NO]^{2-}$ in several solvents such as: water, methanol, ethanol, ethylene glycol, formamide, *N*-methylformamide, *N*,*N*-dimethylformamide, pyridine, acetonitrile and dimethylsulphoxide (Table 1). When the exposure was performed in protogenic solvents in the presence of alkalis, the spectra characteristic of the $[Fe^{III}(CN)_5L']^{3-}$ complexes were observed (Table 1).

Photochemical production of the $[Fe(CN)_5H_2O]^{2-}$ and $[Fe(CN)_5OH]^{3-}$ complexes in the aqueous system was substantiated earlier,[9,10,13,14] and the spectrum of the photoproduct generated in pyridine solution is consistent with that of the $[Fe(CN)_5py]^{2-}$ complex obtained by oxidation of the $[Fe(CN)_5py]^{3-}$ one.[4,5] This leads to the conclusion that also in the other cases (Table 1, Nos 2–7, 9, 10, 12–15) the $[Fe^{III}(CN)_5L]^{n-}$ complexes were generated. Among the complexes listed in Table 1 only those with L = H_2O, OH^- and py were recognized earlier,[4,5,9,10,12] whereas those with L = DMSO or CH_3OH were postulated to be generated.[9,13,15,16] The remaining complexes are here reported for the first time. The photochemical method of their generation is expected to operate also in the case of other pentacyano(ligand)ferrate(III) complexes.

The $[Fe^{III}(CN)_5L'H]^{2-}$ complexes, where L'H = MeOH, EtOH, ethylene glycol or formamide, were found to be transformed into the $[Fe^{III}(CN)_5L']^{3-}$ ones by addition of solid or concentrated aqueous alkalis (Fig. 1). The change was reversed by addition of CH_3COOH to the former solution.

The equilibrium constant for the reaction:

$$[Fe(CN)_5CH_3OH]^{2-} + OH^- \overset{K_1}{\rightleftharpoons} [Fe(CN)_5OCH_3]^{3-} + H_2O \quad (1)$$

was evaluated roughly by a spectrophotometric titration of the methanolic complex with OH^- in

aqueous methanol using the relation:

$$\log\left(\frac{A}{A_\infty - A}\right) = \log [OH^-] + \log\left(\frac{K_1}{[H_2O]}\right) \quad (2)$$

as described in Experimental. Plots of log $[A/(A_\infty - A)]$ vs log $[OH^-]$ were found to be linear within the OH^- concentration not higher than 10^{-2}. Above this value the reaction between nitrosylpentacyanoferrate(II) and the OH^- ions[14,17] started to interfere. The average value of K_1 is $(5.1 \pm 2.9) \times 10^1$ at 295 K and $\mu = 0.1$.

The solvent complexes were found to undergo substitution of the solvent molecule by water, N_3^-, SCN^- ions and, in the case of aprotic systems, by OH^- ions. The equilibrium constant for the anation reaction:

$$[Fe(CN)_5CH_3OH]^{2-} + NCS^- \overset{K_3}{\rightleftharpoons} [Fe(CN)_5SCN]^{3-} + CH_3OH \quad (3)$$

was evaluated from plotting the data as suggested by an equation similar to that of (2). The average value of K_3 is $(2.7 \pm 0.9) \times 10^1$ M^{-1} at 295 K and $\mu = 0.1$.

This value was used to assess the affinity of the

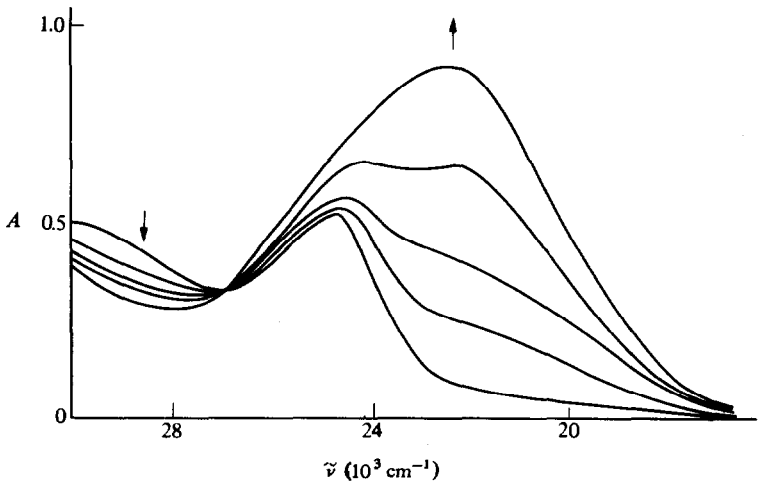

Fig. 1. Spectrophotometric titration of $[Fe(CN)_5CH_3OH]^{2-}$ with NaOH; initial concentration of the complex, $c = 0.927 \times 10^{-4}$ M, $\mu = 0.1$ ($NaClO_4$), $T = 295$ K; arrows show order of spectra with successive increase in the OH^- concentration: $\leq 3.84 \times 10^{-5}$, 3.67×10^{-4}, 7.34×10^{-4}, 1.48×10^{-3} and 3.84×10^{-2} M.

CH_3OH ligand for $[Fe(CN)_5]^{2-}$ relative to displacement of water:

$$[Fe(CN)_5H_2O]^{2-} + CH_3OH \overset{K_4}{\rightleftharpoons} [Fe(CN)_5CH_3OH]^{2-} + H_2O \quad (4)$$

since $K_4 = K_5/K_3$, where K_5 is the equilibrium constant for the reaction:

$$[Fe(CN)_5H_2O]^{2-} + NCS^- \overset{K_5}{\rightleftharpoons} [Fe(CN)_5SCN]^{3-} + H_2O \quad (5)$$

taken from the literature data.[12] The average value of $K_4 = (2.5 \pm 0.9) \times 10^1$ is in unexpected agreement with the value of 4.3×10^1 calculated from the empiric correlation between the association constant of L for $[Fe(CN)_5]^{2-}$, K_f, and pK_a of the ligand (for methanol $pK_a = -2.079$[18]):

$$\log K_f = (0.36 \pm 0.07)pK_a + (2.38 \pm 0.60) \quad (6)$$

formulated by Shepherd *et al.*[3]

EXPERIMENTAL

Reagents

Anhydrous sodium nitrosylpentacyanoferrate(II), $Na_2[Fe(CN)_5NO]$, was prepared by a repeated recrystallization of a commercial dihydrate from aqueous solution and drying of a pulverized sample at 440 K up to the constant weight. Organic solvents were purified by fractional distillation and dried when it was necessary. Alkalis were purified from carbonates, other chemicals were best available commercial reagents used without further purification.

Preparation of complexes

Complexes of the type $[Fe(CN)_5L]^{2-}$ [where $L = CH_3OH$, C_2H_5OH, $HOCH_2CH_2OH$, $HCONH_2$, $HCONHCH_3$, $HCON(CH_3)_2$, C_5H_5N, CH_3CN or $(CH_3)_2SO$] were prepared *in situ* by irradiation of 1×10^{-3} M solutions of anhydrous $Na_2[Fe(CN)_5NO]$ in a proper solvent. Irradiations were carried out using a high-pressure mercury lamp (HBO 200, Narva, D.D.R.), at 295 ± 1 K. Exposure was limited to less than 10% conversion to avoid secondary thermal reactions.[19] Thus the solution studied contained only the $[Fe(CN)_5L]^{2-}$ complex and parent $[Fe(CN)_5NO]^{2-}$, that fortunately did not affect considerably the results. The same method was used to prepare the deprotonated complexes, $[Fe(CN)_5L']^{3-}$ (where $L' = CH_3O^-$, $C_2H_5O^-$, $HOCH_2CH_2O^-$ or $HCONH^-$) except that irradiated solutions contained additionally 1×10^{-2} M NaOH.

Spectrophotometric titrations

Volumetric flasks containing equal amounts of the $[Fe(CN)_5CH_3OH]^{3-}$ complex in methanolic solution (containing 0.1% H_2O) and various amounts of NaOH or KSCN were suspended in temperature bath controlled to ± 1 K for 0.5 h. Ionic strength was maintained at $\mu = 0.1$ using $NaClO_4$ in the former, and $NaNO_3$ in the latter case. The solution spectra were recorded to determine the equilibrium amounts of $[Fe(CN)_5CH_3OH]^{2-}$ and $[Fe(CN)_5OCH_3]^{3-}$ or $[Fe(CN)_5SCN]^{3-}$. Plots of $\log [A/(A_\infty - A)]$ vs $\log [OH^-]$ were made, where A is the absorbance at 20 or 21×10^3 cm^{-1} of the $[Fe(CN)_5OCH_3]^{3-}$ species ($\varepsilon_{20} = 1300$, $\varepsilon_{21} = 1850$) corrected to the minor contributions of the $[Fe(CN)_5NO]^{2-}$ ($\varepsilon_{20} = 9$, $\varepsilon_{21} = 10$) and $[Fe(CN)_5CH_3OH]^{2-}$ ($\varepsilon_{20} = 68$, $\varepsilon_{21} = 100$) complexes at these wave numbers. A_∞ is the value for total conversion of the methanol complex into the methoxo one. In the case of KSCN titrant, the data were analysed at 17.0×10^3 cm^{-1}, where absorbance from the $[Fe(CN)_5SCN]^{3-}$ complex ($\varepsilon = 2680$[11]) exceeded considerably those of $[Fe(CN)_5CH_3OH]^{2-}$ ($\varepsilon = 40$) and $[Fe(CN)_5NO]^{2-}$ ($\varepsilon = 5$).

The electronic spectra were measured using a Specord UV-VIS or VSU 2P spectrophotometer [both C. Zeiss (Jena, D.D.R.)]. All operations were performed in the dark.

COMPLEXES OF *N*-METHYL-4-MERCAPTOPIPERIDINE WITH SOME METAL IONS

W. GAETE* and J. ROS
Departament de Química Inorgànica, Facultat de Ciències, Universitat Autònoma de Barcelona (Bellaterra), Barcelona, Spain

(*Received* 1 *December* 1983; *accepted* 22 *May* 1984)

Abstract—Complexes of *N*-methyl-4-mercaptopiperidine in its zwitterionic form with Co(II) and Zn(II) salts, and in anionic form with Cu(I) and Ag(I) salts have been prepared. Stoichiometry of the complexes, $Co(HRS)_2CoX_4$ (X = Cl and Br), $Co(HRS)_2X_2$ (X = ClO_4, NO_3), $Co(HRS)_3X_3$ (X = NO_3, ClO_4), $Zn(HRS)_2ZnX_4$ (X = Cl and Br), $Zn(HRS)_2(NO_3)_2$, Ag(RS) and Cu(RS), have been established by chemical analysis. The solid complexes have been further characterized by IR and electronic spectra measurements.

As part of our work on the coordination of mercaptoamines to metal ions we have reported the synthesis, properties and structures of some complexes formed by *N*-methyl-4-mercaptopiperidine.[1–5] The observed molecular structures with the ligand in its zwitterionic form $\overset{(+)}{N}H(CH_3)C_5H_9S^-$ (hereafter HRS) are discrete molecules[3] in $Hg(HRS)_2$, dimeric molecules[2,5] in $Zn_2(HRS)_2X_4$ (X = Cl, Br and I) and one-dimensional polymeric chains[1] in $Cd(HRS)_2(ClO_4)_2$. When the ligand is in the anionic form $N(CH_3)C_5H_9S^-$ (RS^-), cyclic tetrameric molecules are formed in[4] $Ni_4(RS)_8$. In all the cases the ligand coordinates only by the sulphur atom.

In continuation of our studies on this type of metal complexes we now report on the synthesis and spectral properties of some metal complexes with the ligand both in its zwitterionic and anionic form.

EXPERIMENTAL

Preparation of the ligand

HRS was synthesized following a previously reported method.[6]

Preparation of the complexes

$Co(HRS)X_2 \cdot \frac{1}{2}H_2O$ (X = Cl *and* Br). In order to prevent oxidation, all reactions and operations were carried under moisture free nitrogen. The complexes were prepared by the addition of a solution of HRS in absolute ethanol to a solution containing the equivalent amount of the cobalt salt in absolute ethanol. The products were separated by filtration, washed with cold absolute ethanol, then dry diethylether and finally vacuum dried at room temperature.

$Zn(HRS)X_2 \cdot H_2O$ (X = Cl *and* Br) *and* $Zn(HRS)_2(NO_3)_2$. Zinc complexes were prepared as described above but without the nitrogen atmosphere. In the $Zn(HRS)Br_2$ preparation the solvent used was methanol. Preparation of $Zn(HRS)_2(NO_3)_2$ involved the addition of a solution of zinc nitrate in ethanol to an ethanolic solution of HRS.

$Co(HRS)_3X_3$ (X = NO_3 *and* ClO_4). Complexes of Co(III) were prepared by the addition of a solution of HRS in water to an aqueous solution of the Co(II) salt. A stream of air was bubbled through the solution during 2 or 3 h. By cooling at 4–5°C the solid compounds precipitated.

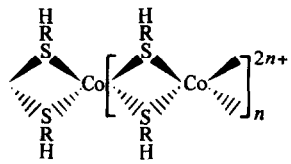
Ag(RS) *and* Cu(RS). These complexes were prepared by the addition of a solution of HRS in water containing some drops of methanol to a solution containing the equivalent amount of $AgNO_3$ or $Cu(NO_3)_2 \cdot 6H_2O$ and NH_3 in water. The products which formed after the reactants had been heated for several minutes, were cooled to room temperature, collected by filtration and washed with ethanol and ether.

Physical measurements

IR spectra (4000–250 cm^{-1}) of complexes were recorded on a Beckman IR-20A spectrophotometer. The samples were either pressed in a potassium

* Author to whom correspondence should be addressed.

halide pellet or run as Nujol mulls between polyethylene plates. Electronic diffuse reflectance spectra at room temperature were recorded on a Beckman ACTA III (800–190 nm) and on a Beckman ACTA VII B spectrophotometer.



RESULTS AND DISCUSSION

The complexes are listed in Table 1 with their elemental analysis. In the hydrated complexes absorptions due to the stretching $\nu_{(O-H)}$ and bending $\delta_{(HOH)}$ vibrations indicate that the water molecules are not coordinated. In the zwitterionic complexes, absorptions due to $\nu_{(N-H)}$ stretching vibrations appear between 2680 and 2710 cm^{-1} indicating hydrogen bond formation.

Complexes with the ligand in zwitterionic form

Co(II) *complexes.* The green complexes are insoluble in common organic solvents. In water and polar solvents they decompose. The solid electronic spectra of the complexes show a strong absorption in the 600–800 nm spectral range assignable to the $^4A_2 \rightarrow {}^4T_1(P)$ transition [7] (ν_3). The shape and bandwidth of these bands are wider than those reported for the $(HRS)_2(CoX_4)$ salts.[8] In the near-IR region, two broad absorptions are observed (1250 and 1660 nm for $Co(HRS)Cl_2 \cdot \frac{1}{2}H_2O$, and 1300 and 1670 nm for $Co(HRS)Br_2 \cdot \frac{1}{2}H_2O$) assignable to the $^4A_2 \rightarrow {}^4T_1(F)$ (ν_2) transition. These facts suggest the existence of two kinds of tetrahedral Co(II) atoms. When the electronic spectra of the $(HRS)_2CoX_4$ compounds and those of the corresponding $Co(HRS)_2X_2$ salts are added, the resulting spectra agree well with those observed, giving support to our assumption.

Based on these observations, a polymeric tetrahedral cation with sulphur-bridging atoms neutralized by CoX_4^{2-} anions is postulated for these Co(II) complexes:

Co(III) *complexes.* The dark brown complexes are insoluble in H_2O and in most organic solvents.

The IR spectrum of the nitrate compound exhibits the characteristically intense ν_3 (1360 cm^{-1}) and moderately strong ν_2 (835 cm^{-1}) bands of ionic nitrate.[9] The presence of the ν_3 (1140–1070 cm^{-1})

* Metal.

and ν_4 (625 cm^{-1}) bands in the IR spectrum of the perchlorate complex suggests this group is not coordinated.[9] The electronic spectra of the two complexes are similar. They show strong absorption at 445 and 580 nm with a broad tail extending up to 800 nm due to $^1A_{1g} \rightarrow {}^1T_{2g}$ (ν_2) and $^1A_{1g} \rightarrow {}^1T_{1g}$ (ν_1) transitions, as expected for spin paired trivalent cobalt complexes in octahedral environment. The calculated ligand field parameters are: $10Dq$ = 18,060 and B = 366 cm^{-1} (β = 0.34). The calculated absorptions for the spin forbidden transitions $^1A_{1g} \rightarrow 3T_{2g}$ (ν_3) and $^1A_{1g} \rightarrow 3T_{1g}$ (ν_4) are 600 and 710 nm. The fourth-derivative curves with the spectrum manually digitized from chart paper[10] reveal that two additional bands are resolved at 600 and 690 nm, in good agreement with the calculated values.

The complexes are probably polymeric octahedrally coordinated cations with sulphur-bridging atoms neutralized by nitrate or perchlorate anions:

Zn(II) *complexes.* In the reaction of HRS with Zn(II) salts two kinds of complexes are obtained depending on the solvent used. When the solvent is water, dimeric molecules of $Zn_2(HRS)_2X_4$ are obtained,[2] but if ethanol or methanol are used, the amorphous complexes $Zn(HRS)X_2$ (X = Cl and Br) and $Zn(HRS)_2(NO_3)_2$ here reported are formed.

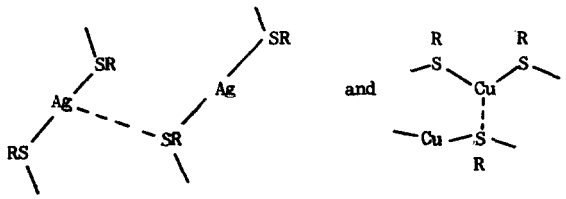
The $\nu_{(Zn-S)}$ stretching vibrations are assigned to the absorptions at 290 and 277 cm^{-1} in the bromide compound and at 282 and 277 cm^{-1} in the nitrate complex and are not observed in the chlorocomplex because they are masked by the strong and broad absorption at 282 cm^{-1}, assignable to the $\nu_{(Zn-Cl)}$ stretching vibration. The proposed structures for these complexes consist of polymeric tetrahedral cations with sulphur-bridging atoms as in the $Cd(HRS)_2(ClO_4)_2 \cdot 2H_2O$ complex[1] neutralized by tetrahalozincate and nitrate anions respectively. When the tetrahalozincates are dissolved in water they decompose, finally becoming the known dimeric complexes $Zn_2(HRS)_2X_4$.

Complexes with the ligand in anionic form

Ag(I) *and* Cu(I) *complexes.* The reactions of formation of these complexes may be written:

$$Ag^+ + HRS + NH_4OH \rightarrow AgRS + NH_4^+ + H_2O$$

and



$$2Cu^{2+} + 4HRS + 4NH_4OH \rightarrow 2CuRS + RS{-}SR + 4NH_4^+ + 4H_2O,$$

where RS—SR is the correspondent disulphide.

The IR spectra of these complexes in the 4000–400 cm^{-1} range are identical with those of the free HRS ligand and of the $Ni_4(RS)_8$ complex whose structure has been well established.[4] The absorptions observed in the 400–250 cm^{-1} range may be assigned to metal–sulphur stretching vibrations. The high number of absorptions may indicate the presence of different kinds of coordination around the metal atoms.

The crystal structure for the silver cyclohexanethiolate has been described[11] as being a one-dimensionally non-molecular solid with some silver atoms approximately linear and others possessing severely distorted trigonal planar stereochemistry. Otherwise several Cu(I) thiolate show polymeric pseudotrigonal structures.[12]

The insolubility in the common organic solvents of the AgRS and CuRS complexes support the hypothesis that they are polymeric in the solid state, with structural fragments such as:

LATTICE ENERGIES OF THE ALKALI METAL BIFLUORIDES, $U(MHF_2)$

JOHN EMSLEY
Department of Chemistry, King's College, Strand, London WC2R 2LS, U.K.

(*Received* 11 *April* 1984; *accepted* 22 *May* 1984)

Abstract—The experimental determination of the hydrogen bond energy of the bifluoride ion makes possible accurate lattice energies of the alkali metal bifluorides, $U(MHF_2)$; see Table 1. From these it is possible to estimate those of NH_4HF_2 and the alkaline earth bifluorides.

From the time when it was discovered that the bifluoride ion harboured a unique hydrogen bond[1] there have been many attempts to evaluate its energy. During the past 25 years over 15 communications have been published offering values ranging from 125 to 262 kJ mol^{-1}.[2] Some were based on the Born–Haber cycle shown below in which $\Delta H_1^{\ominus}$ defined the hydrogen bond energy and $\Delta H_2^{\ominus}$ can be obtained from eqn (1):

$$\begin{array}{ccccc} M^+(g) + F^-(g) + HF(g) & \xrightarrow{\Delta H_1^{\ominus}} & M^+(g) + HF_2^-(g) \\ \uparrow U(MF) & & \uparrow U(MHF_2) \\ MF(s) + HF(g) & \xrightarrow{\Delta H_2^{\ominus}} & MHF_2(s) \end{array}$$

$$\Delta H_2^{\ominus} = \Delta H_f^{\ominus}(MHF_2)(s) - \Delta H_f^{\ominus}(MF)(s) - \Delta H_f^{\ominus}(HF)(g). \quad (1)$$

The weak link in this cycle is $U(MHF_2)$ and attempts have been made to calculate the lattice energies of the alkali metal bifluoride in order to obtain $\Delta H_1^{\ominus}$.[3–5] The best of these efforts led to a $\Delta H_1^{\ominus}$ value of 176 kJ mol^{-1}.[5]

An alternative approach[6] to the problem was to choose a fluoride with a large cation, viz. Me_4NF, and to assume that $U(Me_4NHF_2) = U(Me_4NF)$ so that $\Delta H_1^{\ominus} = \Delta H_2^{\ominus}$. This produced a value of 155 kJ mol^{-1}. Seemingly more realistic was the suggestion[5] that there would be a difference of 30 kJ mol^{-1} between these lattice energies in which case $\Delta H_1^{\ominus}$ would be 185 kJ mol^{-1}.

The recent measurement[7] of $\Delta H_1^{\ominus}$ directly, by ion cyclotron resonance, has settled the issue; $\Delta H_1^{\ominus}$ is 163 $\pm$4 kJ mol^{-1}. This value is supported by *ab initio* calculations employing the largest basis set[2] which gave a value of 169 kJ mol^{-1}.

Using the experimental value for $\Delta H_1^{\ominus}$ it is now possible to return to the Born–Haber cycle and use the bond energy of the bifluoride hydrogen bond to obtain the actual bifluoride lattice energies. These are given in the Table 1. In all cases they are significantly higher by 5–10% than those calculated.[3–5] [The error in $U(MHF_2)$ could not be estimated since some of the published $\Delta H_f^{\ominus}$ data for the fluorides and bifluorides did not include error limits. However the error in $U(MHF_2)$ is probably *ca* $\pm$10 kJ mol^{-1}.]

With reliable $U(MHF_2)$ values for the alkali metals the Kapustinskii equation (2)

$$U \text{ kJ mol}^{-1} = 107{,}900\nu Z_+ Z_-/(r_+ + r_-) \quad (2)$$

can be used to obtain a so-called thermochemical radius for the bifluoride ion,[11] thus $r_-(HF_2^-)$ = 165 pm (using Li^+ = 74 pm); 165 (Na^+ = 102); 160 (K^+ = 138); 163 (Rb^+ = 149) and 167 (Cs^+ = 170).[12] The average radius is 164 pm.* Armed with this it is then possible to compute the lattice energies of the following bifluorides: NH_4HF_2 = 606 kJ mol^{-1} ($r_+NH_4^+$ = 146)[12] which compares fairly well with the reported value of 733 kJ mol^{-1};[14] $Mg(HF_2)_2$ = 2743 kJ mol^{-1} [cf. $U(MgF_2)$ =

* The R(F . . . F) internuclear distance is 226 pm[13] to which the ionic radius of the end fluorine atoms adds *ca* 2 × 133 pm making an overall longitudinal length of 492 pm and a radius of 246 pm. The average of this and the latitudinal radius (133 pm) gives 189 pm. A relationship to the thermochemical radius is not obvious.

Table 1. Lattice energies of the alkali metal bifluorides, $U(MHF_2)$*[a] (all energies in kJ mol^{-1}; 298.15 K)

	Li	Na	K	Rb	Cs
$-\Delta H_f^{\ominus}(MHF_2)(s)$[9]	923.9	906.2	920.4	909.2	904.2
$-\Delta H_f^{\ominus}(MF)(s)$[9]	611.7	569.0	562.8	551.5	545.2
$U(MF)$[10]	1025	903.7	801.2	768.1	715.5
$U(MHF_2)$	903	807	725	692	640
ΔU†	122	97	76	76	75

* $U(MHF_2) = -\Delta H_f^{\ominus}(MHF_2)(s) + \Delta H_f^{\ominus}(MF)(s) - \Delta H_f^{\ominus}(HF)(g) + U(MF) - \Delta H_1^{\ominus}$, where $\Delta H_f^{\ominus}(HF)(g) = 271.1 \pm 2.1$ kJ $mole^{-1}$,[8] and $\Delta H_1^{\ominus} = 163 \pm 4$ kJ mol^{-1}.[7]

† $\Delta U = U(MF) - U(MHF_2)$.

2922 kJ mol^{-1}];[11] $Ca(HF_2)_2 = 2452$ kJ mol^{-1} [cf. $U(CaF_2) = 2597$ kJ mol^{-1}];[11] $Sr(HF_2)_2 = 2312$ kJ mol^{-1} and $Ba(HF_2)_2 = 2158$ kJ mol^{-1}.

Table 1 also spotlights another misconception—that as the cation gets larger the difference between the fluoride and bifluoride lattice energies would decrease. Rather it appears to level off at *ca* 75 kJ mol^{-1}. Yet if $\Delta H_2^{\ominus}$ for Me_4NHF_2 were really 155 kJ mol^{-1} as reported,[6] and $\Delta H_1^{\ominus}$ is 163 kJ mol^{-1}, then $U(Me_4NF) - U(Me_4NHF_2)$ is only 8 kJ mol^{-1}. Perhaps the much larger radius of Me_4N^+ makes this likely but others have argued that, even for this cation, lattice expansion to accommodate the bifluoride ion must occur and that this will be significant.[15]

An alternative explanation would seem to be that this value of $\Delta H_2^{\ominus}$, determined experimentally, is incorrect. Good grounds for suspecting this to be the case lies with the Me_4NF itself. Despite many attempts, this salt has never been obtained anhydrous and recent work has shown that removal of water results in decomposition.[16] This being so, then whatever reaction the original workers[6] thought they were following it almost certainly was not $Me_4NF + HF \rightarrow Me_4NHF_2$. It was merely fortuitous that the value they reported for $\Delta H_2^{\ominus}$ of 155 kJ mol^{-1}, and the assumption made about $U(Me_4NF) - U(Me_4NHF_2)$ being zero was an example of two wrongs almost cancelling each other out.

DIMERIZATION OF COPPER(II) DECANOATE IN 1,4-DIOXANE–WATER MIXED SOLVENTS

YUKIO FUJII,* KAZUSHI JIMBO, HIROMICH YAMADA and MASATERU MIZUTA
Faculty of Engineering, Gifu University, 1-1 Yanagido, Gifu 501-11, Japan

(*Received* 13 *April* 1984; *accepted* 22 *May* 1984)

Abstract—Complex formation of copper(II) with decanoic acid (HA) has been studied by potentiometric measurement in 1,4-dioxane–water mixtures at a constant ionic concentration of 0.1 mol dm^{-3} (Na, H)ClO_4 and at 25°C. The experimental data can be interpreted with the formation of CuA^+, CuA_2 and Cu_2A_4. The dimerization constant formulated as:

$$2CuA_2 \overset{K_{dim}}{\rightleftharpoons} Cu_2A_4$$

was found to be log K_{dim} = 3.75, 4.02 and 4.26 for 0.3, 0.4 and 0.5 mole fractions of dioxane, respectively. Absorbances at 373 and 670 nm are interpreted with the aid of the formation constants determined by potentiometry. Solvent effect on the dimerization of the monomeric copper(II) decanoate is discussed on the basis of selective solvation of CuA_2 and Cu_2A_4 with water molecules.

The cupric alkanoates are well-known to be binuclear in the crystalline and in nonpolar organic solvents.[1] The binuclear (dimeric) structures also persist in solutions such as acetic acid,[2] chloroform[3] and 1,4-dioxane.[4]

Recently, Yamada and others[5,6] have reported on the solvent extraction of copper(II) with decanoic acid into some alkanols. According to their results, the extracted species of copper(II) were not only the dimeric decanoates, Cu_2A_4 and $Cu_2A_4(HA)_2$, but also the monomeric ones, CuA_2 and CuA_2HA. The dimerization constant defined by $K_{dim} = [Cu_2A_4]/[CuA_2]^2$ decreased with increasing water concentration in the organic phase.

More studies are necessary for a full understanding of the formation of both the monomeric and dimeric species in the solvents whose coordinating ability is greater than that of 1,4-dioxane or alkanols but less than that of water.

In the present work we chose binary mixtures of 1,4-dioxane and water. The formation and dimerization of copper(II) decanoates were investigated by potentiometry and spectrophotometry.

EXPERIMENTAL

Reagents

Sodium perchlorate. After the precipitation of heavy metal impurities as hydroxides, the sodium perchlorate was recrystallized from distilled water.

1,4-*Dioxane.* For the preparation of acetal- and peroxide-free 1,4-dioxane, anhydrous tin(II) chloride was added to 1,4-dioxane (R.G.). It was boiled under reflux for 8 h with 5% of its volume of 1 mol dm^{-3} hydrochloric acid. The distillate was stirred with pellets of sodium hydroxide and the aqueous phase was removed. The organic phase was stored over sodium and distilled only when needed.

Copper(II) perchlorate. Copper(II) perchlorate was prepared by dissolving copper metal (99.99%) in hot aqueous perchloric acid solution. The copper(II) perchlorate hydrates crystallized from the solution were dissolved in the mixture of 1,4-dioxane and water. The concentration of copper(II) was determined by complexiometry when necessary.

Sodium hydroxide solution. Carbonate-free sodium hydroxide solution was prepared by electrolysis of 1 mol dm^{-3} aqueous sodium perchlorate solution at a current density about 5 mA

* Author to whom correspondence should be addressed.

cm^{-2} with a couple of platinum electrodes and a salt bridge fitted with a frittered glass membrane to an edge. The alkaline solution was titrated with a standard solution of potassium hydrogen phthalate.

Decanoic acid. Decanoic acid (C.P.) was purified twice by distillation. The middle fraction distilling at 269–271°C was collected. The purity of the purified decanoic acid was 99.5±0.5%, as determined by titration with the standard alkaline solution.

Apparatus

The e.m.f. measurements of the cells were carried out using an Orion research microprocessor ionalyzer Model 901 with a reading accuracy of ±0.1 mV. Orion cupric ion electrode (No. 94-24) and glass electrode (No. 91-01) were used for measurements of cupric and hydrogen ion concentrations, respectively. Spectrophotometric measurements were performed on a Shimadzu double-beam spectrophotometer Model UV 210A using fused silica cells (pass length 10 mm).

Measurements

All titrations were performed at 25.0±0.1°C in a bath which was placed in a room thermostatted at 25 ±1°C. The ionic concentration in the 1,4-dioxane–water mixtures was kept constant at 0.1 mol dm^{-3} (Na, H)ClO_4. The mixtures which contain a definite amount of copper(II) perchlorate and/or decanoic acid were titrated with the sodium hydroxide solution.

We have chosen the Ag–AgCl reference electrode of the Wilhelm type[7] for studies in the 1,4-dioxane–water mixtures. The chemical cell used is depicted by the following scheme:

Ag–AgCl|0.1 mol dm^{-3} NaCl D–W soln (satd AgCl)||0.1 mol dm^{-3} $NaClO_4$ D–W soln|
test soln (0.1 mol dm^{-3} (Na, H)ClO_4 D–W soln)|cupric ion electrode or glass electrode

where D–W denotes the mixture of 1,4-dioxane and water. The e.m.f. of the cells in mV unit gives rise to the following Nernstian responses:

$$E_H = E_H^{\circ\prime} + 59.1 \log [H^+]$$
$$([H^+] \leqslant 10^{-2.5} \text{ mol dm}^{-3})$$

and

$$E_{Cu} = E_{Cu}^{\circ\prime} + 29.4 \log [Cu^{2+}]$$
$$([Cu^{2+}]: 10^{-2.5}\text{–}10^{-5.5} \text{ mol dm}^{-3}),$$

where E_H and E_{Cu} refer to the e.m.f. of the respective electrodes against the Ag–AgCl electrode. The conditional standard potentials, $E_H^{\circ\prime}$ and $E_{Cu}^{\circ\prime}$, were kept constant throughout a series of titrations in a given mixed solvent. The values were $E_H^{\circ\prime} = 449.4$ mV and $E_{Cu}^{\circ\prime} = 362.0$ mV in the mixture of 0.5 mole fraction dioxane–water.

All potentiometric experiments were carried out under an atmosphere of nitrogen gas. A calibrated micropipette equipped with a micrometer (0–0.2 cm^3, 2.5×10^{-4} cm^3/div.) was used for the titration with the alkaline solution. By the titrations, the uncertainty of the total ionic concentration did not exceed 2% as compared with that of original medium, i.e. 0.1 mol dm^{-3}.

RESULTS AND DISCUSSION

Determination of acid dissociation constant of decanoic acid

The acid dissociation equilibrium for decanoic acid is described as:

$$HA \overset{K_a}{\rightleftharpoons} H^+ + A^-,$$
$$K_a = [H^+][A^-]/[HA], \quad (1)$$

where HA and A^- denote decanoic acid and its anion, respectively. The constant K_a was evaluated by potentiometric titration of the acid with standard alkaline solution. The concentration of unionized carboxylic acid in the mixed solvent [HA] is given by:

$$[HA] = C_{HA} - C_{OH}, \quad (2)$$

where C_{HA} and C_{OH} denote the total concentration of the acid and alkali added for the titration, respectively. Assuming that the acid anion does not associate with HA, the concentration of A^- can be equal to C_{OH}. Then eqns (1) and (2) lead to:

$$\log [H^+] = \log K_a - \log C_{OH}/(C_{HA} - C_{OH}). \quad (3)$$

Equation (3) shows that the plot of log $[H^+]$ vs log $C_{OH}/(C_{HA} - C_{OH})$ will give a linear relation with a slope of −1. The plot is shown in Fig. 1. The intercept of the plot (at abscissa = 0) gives the value of log K_a. The numerical pK_a values of the acid in 1,4-dioxane–water mixtures are listed in Table 1.

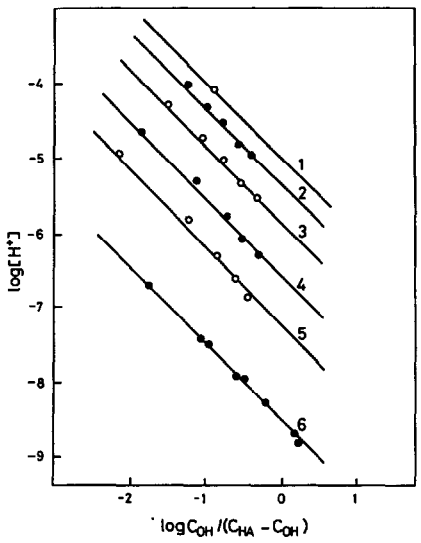

Fig. 1. $\log [H^+]$ against $\log C_{OH}/(C_{HA}-C_{OH})$ for determination of the acid dissociation constant of decanoic acid. The total ionic concentration is 0.1 mol dm^{-3} (Na, H)(ClO_4, A). The numbers refer to solvents listed in Table 1. The slope of the straight line is -1.

The value of K_a decreases with increasing the content of dioxane. This shows that dioxane is a weaker base with regard to decanoic acid than water. It may also be interpreted in terms of dielectric constant of the mixed solvent and hydration of the acid in the mixed solvent.[8,9]

Evaluation of the composition and the stability constant of copper(II) *decanoate*

The chemical species of copper(II) decanoate formed in the mixed solvents being denoted as $CuA_a^{(2-a)+}$ and $Cu_2A_4^{(4-b)+}$, the formation equilibria are written as:

$$Cu^{2+} + aA^- \overset{\beta_{1a}}{\rightleftharpoons} CuA_a^{(2-a)+},$$
$$\beta_{1a} = [CuA_a^{(2-a)+}]/[Cu^{2+}][A^-]^a, \quad (4)$$

$$2Cu^{2+} + bA^- \overset{\beta_{2b}}{\rightleftharpoons} Cu_2A_b^{(4-b)+},$$
$$\beta_{2b} = [Cu_2A_b^{(4-b)+}]/[Cu^{2+}]^2[A^-]^b. \quad (5)$$

Assuming that the perchlorate ion and the acid HA do not associate with any species, the material balance of copper(II) can be written as:

$$C_{Cu} = [Cu^{2+}] + \Sigma[CuA_a^{(2-a)+}] + 2\Sigma[Cu_2A_b^{(4-b)+}]. \quad (6)$$

Substituting eqns (1), (4) and (5) into eqn (6), we obtain the relationship:

$$(C_{Cu} - [Cu^{2+}])/[Cu^{2+}] = \Sigma\beta_{1a}[A^-]^a + 2\Sigma\beta_{2b}[A^-]^b[Cu^{2+}]. \quad (7)$$

The plot of the left-hand side of eqn (7) against $[Cu^{2+}]$ should be linear with an intercept $I = \Sigma\beta_{1a}[A^-]^a$ and a slope $S = 2\Sigma\beta_{2b}[A^-]^b$. Figure 2 shows the relation of $\log [Cu^{2+}]$ to $\log [A^-]$ in 0.5 mole fraction 1,4-dioxane–water mixture (83 w%

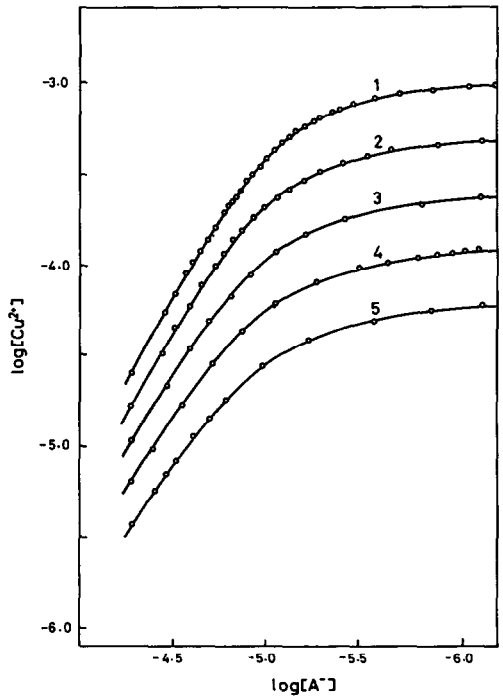

Fig. 2. $\log [Cu^{2+}]$ as a function of $\log [A^-]$. Solvent: 0.5 mole fraction 1,4-dioxane–water mixture. C_{HA} (mol dm^{-3}): 0.050. C_{Cu} (mol dm^{-3}): No. 1, 1.00×10^{-3}; No. 2, 500×10^{-4}; No. 3, 2.50×10^{-4}; No. 4, 1.25×10^{-4}; No. 5, 6.25×10^{-5}. The solid curves are the best fit ones calculated with the equilibrium constants in Table 2.

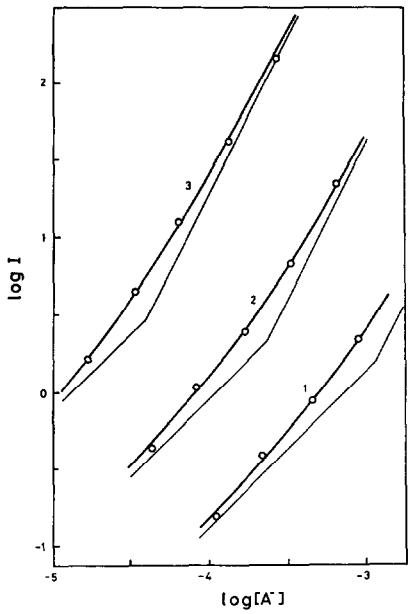

Fig. 3. Relationship between log I and log [A^-]. Solvents (mole fraction of dioxane): No. 1, 0.3; No. 2, 0.4; No. 3, 0.5. The solid curves are normalized ones, i.e. $Y = \log(x + px^2)$ vs $X = \log x$. The straight lines are the asymptotes of the normalized curves.

dioxane). The data was calculated according to eqn (7) and the values of log I and log S were plotted against the value of log [A^-]. In Fig. 3 the plot of log I against log [A^-] is given; the slope of the plot is close to 2 and tends to decrease to unity with decreasing [A^-], i.e. $a = 1$ and 2. The monomeric copper(II) species are therefore CuA^+ and CuA_2, as well as Cu^{2+}.

Figure 4 shows the plot of log S against log [A^-]. The plot lies along a straight line with a slope of 4, i.e.

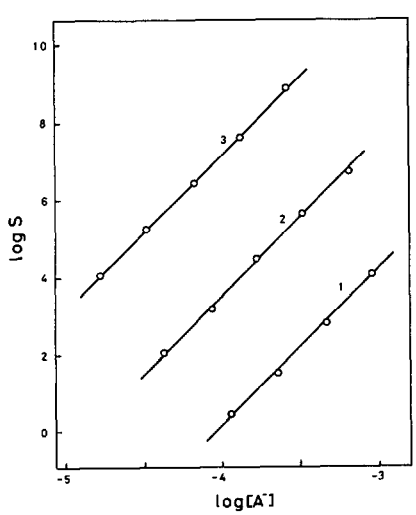

Fig. 4. Relationship between log S and log [A^-]. The numbers correspond to those in Fig. 3. The slope of the straight lines is 4.0.

Table 2. Formation constant of copper(II) decanoates

solvent (dioxane, mf)	log β_{11}	log β_{12}	log β_{24}
0.3	3.11	6.04	15.83
0.4	3.95	7.55	19.12
0.5	4.86	9.28	22.82

$b = 4$, when Cu_2A_4 is the sole dimeric species of copper(II) decanoate. The same species was also found in acetic acid by Cheng and Howald,[2] and Sawada *et al.*[10]

The values of log I and log S were independent of the total concentration of decanoic acid ranging from 0.025 to 0.200 mol dm^{-3}. As can be seen from eqn (7), this evidence strongly suggests that the formation of copper(II) decanoate complexes solvated with the free acid HA can be negligible in these mixed solvents.

The following equilibria are relevant to the formation of copper(II) decanoates:

$$Cu^{2+} + A^- \overset{\beta_{11}}{\rightleftharpoons} CuA^+,$$

$$Cu^{2+} + 2A^- \overset{\beta_{12}}{\rightleftharpoons} CuA_2,$$

$$2Cu^{2+} + 4A^- \overset{\beta_{24}}{\rightleftharpoons} Cu_2A_4.$$

The formation constants evaluated by the curve fitting method for these equilibria are collected in Table 2. The values in Table 2 show that the higher the water concentration in the solvent, the lower the formation constants.

Absorption spectra in the UV and visible regions

The UV and visible spectra of a large number of copper(II) alkanoates and their derivatives have been measured in organic solvents and on single crystals.[1,11] According to the results, these complexes have three bands at about 300, 375 (shoulder) and 700 nm. At about 375 nm, the band which is characteristic of the dimeric copper(II) alkanoates appears both in solution and in crystal. Originally, Tuchida and Yamada[12,13] suggested that the band was a diagnostic property of copper–copper linkage.

Now suppose that the dimeric copper(II) decanoate is responsible for the band at 373, the absorbance (abbreviated as A) can be written as:

$$A_{373} = \varepsilon_{24}[Cu_2A_4] \qquad (8)$$

where ε_{24} denotes the molar extinction coefficient of the dimeric species at a maximum absorbance (373 nm). From eqns (1), (5) and (8) the following

expression is derived:

$$\log A_{373} = \log \beta_{24}\varepsilon_{24}K_a^4 + 4 \log [HA] + 2(\log [Cu^{2+}] - 2 \log [H^+]). \quad (9)$$

As seen from Fig. 5, a plot of $\log A_{373}$ against $\log [Cu^{2+}] - 2 \log [H^+]$ leads to a linear relation with a slope of 2 at a constant [HA]. This fact confirms that the sole species absorbing at this region is the dimeric copper decanoate denoted as Cu_2A_4.

The band at about 700 nm is to be assigned to the normal metal–ligand interaction. The absorbing species and its molar extinction coefficient were evaluated as follows. With the aid of potentiometric results described above, the apparent molar extinction coefficient at 670 nm can be expressed as:

$$\bar{\varepsilon} = \frac{A_{670}}{C_{Cu} - [Cu^{2+}]} = \frac{\varepsilon_{11}[CuA^+] + \varepsilon_{12}[CuA_2] + \varepsilon_{24}[Cu_2A_4]}{[CuA^+] + [CuA_2] + 2[Cu_2A_4]} = \frac{\varepsilon_{11}\beta_{11} + \varepsilon_{12}\beta_{12}[A^-] + \varepsilon_{24}\beta_{24}[A^-]^3[Cu^{2+}]}{\beta_{11} + \beta_{12}[A^-] + 2\beta_{24}[A^-]^3[Cu^{2+}]}, \quad (10)$$

where ε_{11}, ε_{12} and ε_{24} are molar extinction coefficients of the species CuA^+, CuA_2 and Cu_2A_4, respectively, and A_{670} is the absorbance at 670 nm.

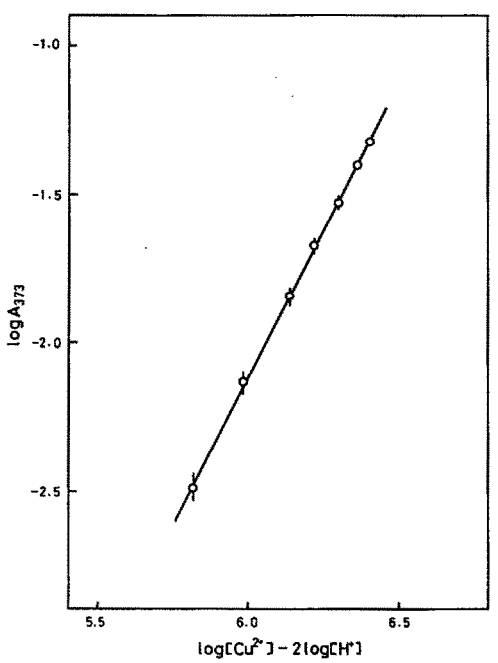

Fig. 5. Correlation between $\log A_{373}$ and $\log [Cu^{2+}] - 2 \log [H^+]$. Solvent: 0.5 mole fraction 1,4-dioxane–water mixture. Total ionic concentration: 0.1 mol dm^{-3} (Na, H)ClO_4. C_{Cu} (mol dm^{-3}), 1.00×10^{-3}; C_{HA} (mol dm^{-3}), 0.050. The solid line is the straight line with a slope of 2.0.

* Calculated from eqn (10); $\varepsilon_{11} < 10$, $\varepsilon_{12} = 195 \pm 10$.

Successive approximations are repeated until the error square sum U, defined as $U = (\bar{\varepsilon} - \bar{\varepsilon}_{cal})^2$, reaches a minimum and the final set of values ε_{11}, ε_{12} and ε_{24} is determined (Table 3). As the dimerization reaction proceeds, the wavelengths of maximal absorption were seen to be shifted from *ca* 740 to 670 nm. This phenomenon can be interpreted by eqn (10). A similar phenomenon was also observed in other systems, such as copper(II) decanoate in 1-octanol[5] and copper(II) acetate in acetic acid.[2,10] Table 3 shows that all these solutions absorb light at about 375 nm (ε = 100–130/two atoms of copper) and 670 nm (ε = 400–460/two atoms of copper).

Solvent effect on the dimerization of copper(II) decanoate

There have been some studies in the monomer–dimer equilibrium of copper(II) alkanoates in donating solvents.[2,5,6,10,14–16] The apparent dimerization constant K_{dim} is given by:

$$2CuA_2 \overset{K_{dim}}{\rightleftharpoons} Cu_2A_4, \quad K_{dim} = [Cu_2A_4]/[CuA_2]^2. \quad (11)$$

The value of K_{dim} may be evaluated by the equation:

$$K_{dim} = \beta_{24}/\beta_{12}^2. \quad (12)$$

Table 4. Dimerization constant of the monomeric copper(II) decanoate in 1,4-dioxane–water mixed solvents

solvent (dioxane, mf)	log[H_2O]	log[dioxane]	log K_{dim}
0.3	1.25	0.88	3.75
0.4	1.11	0.94	4.02
0.5	0.97	0.97	4.26

The values of K_{dim} thus obtained are summarized in Table 4. It is obvious from the table that the dimerization constant decreases with increasing water concentration in the mixed solvent.

The solvent effect on the dimerization equilibrium is considered by:

$$2CuA_2S_2 \overset{K^\circ_{dim}}{\rightleftharpoons} Cu_2A_4S_2 + 2S, \quad (S = \text{solvent molecule}) \qquad (13)$$

$$K^\circ_{dim} = [Cu_2A_4S_2][S]^2/[CuA_2S_2]^2.$$

Then the constant K°_{dim} is related to the apparent constant K_{dim}:

$$K_{dim} = K^\circ_{dim}[S]^{-2}. \qquad (14)$$

With the assumption that the term $[S]^2$ is equal to $[H_2O]^x x[\text{dioxane}]^y$, where $x+y=2$, the following relation is derived:[17]

$$\log K_{dim} = \log K^\circ_{dim} - x \log [H_2O] - y \log [\text{dioxane}]. \qquad (15)$$

Our data fitted with $x = 1.8$, $y \simeq 0$ and $\log K^\circ_{dim} = 6.0$. This finding which was obtained from this rough estimation suggests that the solvent molecules liberated are not dioxane but water at least in the range of the solvent studied. Then we conclude that the reaction is expressed as:

$$2CuA_2(H_2O)_2 \rightleftharpoons Cu_2A_4(H_2O)_2 + 2H_2O.$$

The specific hydration of copper(II) decanoates is attributable to the stronger basicity of water than that of 1,4-dioxane; the latter has lower donor number (DN = 14.8) than that of the former (DN = 18.0).[18]

According to the solvent extraction studies, copper(II) alkanoates have the molecular formula of $Cu_2A_4(HA)_2$ in non-polar organic solvents such as hexane, benzene and carbon tetrachloride, and have those of CuA_2, CuA_2HA, Cu_2A_4 and $Cu_2A_4(HA)_2$ in donating solvents: alkanols and ketones. In the present system, the following species solvated with the free acid were not found: CuA_2HA and $Cu_2A_4(HA)_2$. This shows that the reaction of $Cu_2A_4(HA)_2$ with water results in the species CuA_2 and/or Cu_2A_4.

Acknowledgement—We are grateful to Professor Motoharu Tanaka of Nagoya University for his valuable discussion.

(*Received* 4 *April* 1984; *accepted* 22 *May* 1984)

Abstract—New Pd(II) and Pt(II) 3,6-bis(2′-pyridyl)pyridazine (dppn) mononuclear complexes of the type $M(dppn)Cl_2$ were prepared and characterized. From $M(dppn)Cl_2$, the bimetallic homonuclear complexes $M(dppn)MCl_4$ were prepared by reaction with $Pd(PhCN)_2Cl_2$ or K_2PtCl_4. Bimetallic heteronuclear species of the type $M(dppn)M'Cl_4$ were prepared reacting the mononuclear complexes with the stoichiometric amount of $M'Cl_2$ (M′ = Cu, Co, Ni). All the described reaction give product in high yield. The isolated compounds, almost completely insoluble in most organic solvents, were characterized by elemental analysis, IR, ESR, reflectance spectra, and magnetic moment measurements. On the basis of these data the geometries around the metals are discussed.

Coordination compounds containing two different metal centers are receiving a great deal of interest both as homogeneous catalysts capable of carrying out multistep reactions and as models for surface catalysis.[1–4]

Approaching the synthesis of binuclear complexes by means of ligands capable of binding metals in a nearby and fixed position, the tetranitrogenated compound 3,6-bis(2′-pyridyl)pyridazine (dppn) seems to be a good candidate. Nevertheless, only few examples of binuclear complexes of this ligand with first row transition metals are reported in the literature[5–7] and even less is known on its bimetallic derivatives with second and third row transition metals.[8] The present investigation aims to acknowledge the reactivity of dppn toward Pd(II) and Pt(II), and its ability in mixed complex formation.

* Author to whom all correspondence should be addressed.

RESULTS AND DISCUSSION

In order to obtain bimetallic compounds from dppn, two step synthesis was carried out: preparation of a mononuclear dppn species, followed by reaction with a second metal ion.

Mononuclear complexes

Dppn (1) and $Pd(PhCN)_2Cl_2$, or K_2PtCl_4 (1 : 1 molar ratio), when dissolved in appropriate solvents give in good yields yellow and brown, respectively, diamagnetic solid products whose elemental analyses are in agreement with mononuclear species of formula $M(dppn)Cl_2$ (2: M = Pd; 3 : M = Pt).

IR spectra, in the region characteristic of pyridazine[9] and pyridine[10] ring vibrations (Table 1), show that dppn behaves as a monochelating ligand. The two absorptions in the M—Cl stretching region (Table 1) are consistent with a MCl_2 frame in a

cis arrangement, in agreement with what observed by Durig[11] and Walton[12] in $M(bipy)Cl_2$ (M = Pd and Pt).

On the basis of these results and in analogy with the molecular structure of $Mn(dppn)_2(NO_3)_2$[13] and $[Cu(dppn)_2Cl]Cl \cdot 5H_2O$,[14] the following coordination scheme can be suggested for complexes **2** and **3** in the solid state (Scheme 1):

Scheme 1.

Compound **2** metathesizes with LiX giving the corresponding products **4** and **5** (Table 1) and, when suspended in dichloromethane, quickly reacts with triphenylphosphine giving $Pd(Ph_3P)_2Cl_2$ and dppn in quantitative yields.

Bimetallic homonuclear complexes

When complexes **2** and **3** are reacted in a 1:1 molar ratio with $Pd(PhCN)_2Cl_2$ or K_2PtCl_4 orange, respectively brown, diamagnetic products analyzing for the dinuclear compounds $Pd(dppn)PdCl_4$, **6**, and $Pt(dppn)PtCl_4$, **7**, are obtained.

The reduced number of bands observed above 1000 cm^{-1} in the IR spectra of **6** and **7**, with respect to the parent compounds **2** and **3**, accounts for the change of coordinated nitrogens from two to four (Table 2).

Compound **6** reacts with triphenylphosphine (1:4 ratio) giving two equivalents of $Pd(Ph_3P)_2Cl_2$ and dppn in quantitative yields. This result supports the hypothesis of a structure with two metals coordinated through the four nitrogen atoms, and a *cis* configuration of the dppn ligand. Since a square

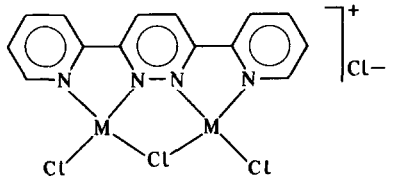
7	$Pt(dppn)PtCl_4 \cdot 0.1dppn$	1601(m)	1045(w); 1040(m)	364sh(m) 340(s); 310sh(m) 291(m)
8	$Pd(dppn)PdCl_2Br_2$	1598(m)	1038(w); 1030(m)	360(m) 341(s); 310(m) 229(m)
9	$Pd(dppn)PdCl_2I_2$	1592(m)	1028(m); 1011(w)	360(m) 342(s); 324sh(s)

* As KBr pellets or Nujol mulls.



planar environment would be expected for the two palladium(II) or platinum(II) centers, whilst an overall planar configuration should be improbable, owing to the steric hindrance between the two internal chlorine atoms, different geometries will be considered. Recently Newkome *et al.*[15] reported for palladium(II) complexes, with either 6,6'-disubstituted bipyridine or 6-monosubstituted bipyridine, a drastic deviation from a wholly planar configuration.

By analogy, the MCl_2 moieties in **6** and **7** could be shifted above and below the dppn plane (Scheme 2):

Scheme 2.

An alternative way of removing the steric hindrance between the chlorine atoms might be the formation of a chlorine bridged binuclear derivative, as formulated by Denti *et al.*[16] for $CuCl_2(\mu\text{-dppn})(\mu\text{-Cl})CuCl(H_2O)$, with an uncoordinated chloride ion (Scheme 3):

Scheme 3.

The assignment of the metal–halide vibrations in compound **6** (Table 2) is in agreement with a terminal Pd—Cl stretching frequency (371 cm^{-1}) and, tentatively, with bridged Pd—Cl—Pd (345 and 320 cm^{-1}).[17] The IR spectra of compounds deriving from the reaction of $Pd(dppn)X_2$ with $Pd(PhCN)_2Cl_2$ show four bands, 360, 341, 310 and 229 cm^{-1} for **8** (X = Br), while three bands are observed for **9** (X = I), 360, 342 and 324 cm^{-1}.

On the basis of the present data the assignment of the actual structure to compounds **6–9** is uncertain, although the presence of bands in the 340–310 cm^{-1} region, tentatively attributed to Pd—Cl—Pd stretching frequencies, seems to suggest a structure as depicted in Scheme 3.

Bimetallic heteronuclear complexes

Synthesis and characterization. The mononuclear compound $Pt(dppn)Cl_2$ (**3**) and a stoichiometric amount of $Pd(PhCN)_2Cl_2$ react to give the brown diamagnetic product **10**, whose analytical data are in agreement with platinum, palladium and dppn in 1:1:1 ratios. The IR spectrum in the regions characteristic of the polydentate ligand (Table 3) is consistent with a twice chelating dppn.

Although elemental analyses do not exclude the possibility that product **10** is a 1:1 mixture of the homonuclear complexes **6** and **7**, its far IR spectrum shows four strong absorptions, none of these overlapping with bands of complexes **6** or **7** (Tables 2 and 3): complex **10** can then be regarded as

Table 3. Selected IR absorption bands* of bimetallic heteronuclear complexes in the regions: (a) 1610–1540, (b) 1050–970 and (c) 400–200 cm^{-1}

* Description in the text.

† Values lower than spin only value could be due to the presence of a variable quantity of a clatrated molecule in the paramagnetic unities.

a bimetallic heteronuclear species having a probable coordination scheme like 3.

Complexes **2** and **3** react with a number of metal(II) chlorides (1:1 ratio) in the appropriate solvents to give compound **11–16** for which the analytical data (see Experimental) are in agreement with the proposed stoichiometry or their solvated forms. IR absorptions in the 1610–1540, 1050–970 and 400–200 cm^{-1} regions (Table 3) are consistent with bimetallic heteronuclear complexes.

Electronic and magnetic properties. Bimetallic heteronuclear complexes, beside to play an important role as models of heterogeneous metal catalysts, may be an elucidative test of the structure of the reported compounds. Actually some of coordination centers like Cu(II), Co(II), Ni(II) are spectroscopic and magnetic active centres and can be useful structural probes when they substitute Pt(II) and Pd(II) in bimetallic compounds.

Pd/Cu *and* Pt/Cu *compounds* (**11**, **12**) contain Cu(II) as paramagnetic center (magnetic moment values in Table 4). The values of g components $g_{\parallel} > g_{\perp} > 2$ (Table 4) account for the well known d^9 configuration with the unpaired electron mainly in the $d_{x^2-y^2}$ orbital. Axial symmetry of the g tensor is in agreement with this ground state configuration. No hyperfine coupling with Cu(II) nucleus was observed.

By using the Figgis equations[18]

$$g_{\parallel} = 2.00 + \frac{8k_{\parallel}^2\lambda_0}{\Delta_1} \qquad \Delta_1 = E_{x^2-y^2} - E_{xy}$$

$$g_{\perp} = 2.00 + \frac{2k_{\perp}\lambda_0}{\Delta_2} \qquad \Delta_2 = E_{x^2-y^2} - E_{xz,yz}$$

$$\lambda_0 = 828 \text{ cm}^{-1}$$

and assuming for Δ_1 and Δ_2 values the energies of the *d–d* transitions observed in the diffuse reflectance spectra (Table 5), the best fit was obtained for the higher energy absorption corresponding to the Δ_1 energy difference. The results of such a calculation are reported in Table 4.

The ESR spectra of **11** and **12** account either for a tetragonal elongated octahedral geometry or for a compressed tetrahedral geometry, both consistent with the tetracoordinated paramagnetic centres present in these complexes. Actually the energy of the observed *d–d* transition is more consistent with the compressed tetrahedral geometry.

Table 5. Electronic diffuse reflectance data*

No.	Compound	ν_1	ν_2	ν_1'	ν_2'	ν_3'	ν_1''	ν_2''	ν_3''
11	$Pd(dppn)CuCl_4$	7143	12,200						
12	$Pt(dppn)CuCl_4$	5882	11,500						
13	$Pd(dppn)CoCl_4$						7407	11,100	16,660
14	$Pt(dppn)CoCl_4 \cdot 0.5CH_3CN$						7400	11,100	16,660
15	$Pd(dppn)NiCl_4 \cdot 2H_2O$			8690	14,280	21,740			
16	$Pt(dppn)NiCl_4 \cdot H_2O$			8330	12,500				
17	$[IrCl(PPh_3)_2(\mu\text{-dppn})(\mu\text{-NO})CuCl][PF_6]_2$	14,800	7143						

* Symbols are in agreement with O_h symmetry: ν_1' ($^3A_{2g} \rightarrow {}^3T_{2g}$), ν_2' [$^3A_{2g} \rightarrow {}^3T_{1g}(F)$], ν_3' [$^3A_{2g} \rightarrow {}^3T_{1g}(P)$], ν_1'' ($^4T_{1g} \rightarrow {}^4T_{2g}$), ν_2'' ($^4T_{1g} \rightarrow {}^4A_{2g}$), ν_3'' [$^4T_{1g} \rightarrow {}^4T_{1g}(P)$].

In order to obtain additional data to support one of the two possible symmetries, we have investigated the heterobimetallic compound $[Ir(PPh_3)_2Cl(\mu\text{-dppn})(\mu\text{-NO})CuCl][PF_6]_2$,[17] which is related to **11** and **12** for what concerns dppn coordination and whose crystal structure shows an overall planar coordination around the copper atom.[8] The best fit between the g values of **17** and the experimental energies of the observed d–d transitions (Tables 4 and 5) was obtained for the higher energy absorption corresponding to Δ_2. Moreover the parallel component of the hyperfine coupling with the Cu nucleus was observed ($A_{\parallel} = 150\ cm^{-1}$ 10^4).

The higher value of Δ_2 exhibited by compound **17** with respect to **11** and **12** is probably attributable to an enhanced back-donation from the $d_{xz,yz}$ Cu(II) orbitals toward dppn and NO π^* orbitals, due to the overall planar geometry of the $[IrCl(\mu\text{-dppn})(\mu\text{-NO})CuCl]^{2+}$ moiety. Where the bridged NO group is not present (**11** and **12**), the energy trend which fits the magnetic parameters changes from $\Delta_2 > \Delta_1$ to $\Delta_1 > \Delta_2$. This leads us to suggest for complexes **11** and **12** a field geometry around the Cu(II) centres quite different from that present in **17** and assignable more to a compressed tetrahedral symmetry than to an elongated octahedral one.

Pd(Pt)/Co(Ni) *compounds* (13–16)

Co(II) and Ni(II) are well known to be very sensitive probes for assigning the planar ligand field since they change their spin state even by small displacement of the metal from the ligand plane.

Pd/Co and Pt/Co compounds (**13**, **14**) are both high spin complexes, with ESR spectra interpretable in terms of $S' = 1/2$ fictitious spin state. Though the resonance lines of the polycrystalline sample show broad shape, even at 4.2 K, differences of symmetry between the Pd/Co derivative and the Pt one can be observed. The Pd derivative shows rhombic symmetry ($g_1 = 4.32, g_2 = 2.45, g_3 = 1.85$) whilst an axial symmetry is displayed by the Pt derivative ($g_1 = 3.70, g_2 = 1.62$).

Electronic diffuse reflectance spectra of Pd/Co and Pt/Co are very similar and both spectral patterns are characteristic of a distorted octahedral symmetry (Table 5). Such a distortion is not enough to change the spin state of Co(II) and even if definitive conclusions about the molecular structure are difficult to be drawn, we can assume that the cobalt ion cannot lie in the plane of the surrounding groups. Pd/Ni and Pt/Ni compounds (**15**, **16**) are paramagnetic high spin complexes. ESR spectra of the polycrystalline sample at −160°C are peculiar to the $S = 1$ spin state: the strong resonance lines at 1500 G are assignable to the $\Delta M_s = \pm 2$ transition; the lines of $\Delta M_s = \pm 1$ transition, centred at 3000 G, are broad and unresolved.

Electronic diffuse reflectance spectra are characteristic of a distorted octahedral geometry.

The magnetic behaviour of Ni(II) compounds excludes an overall planar geometry around the d^8 coordination centre.

In view of the results reported for Co(II) and Ni(II) heterobimetallic compounds, as well as from the comparison with the Ir/Cu derivative, it seems definitively confirmed that in Cu(II) compounds **11** and **12**, the copper atom and the ligands are not coplanar.

Concluding remarks

The satisfactory yields obtained and the very mild conditions used in the reported syntheses confirm that dppn is a good assembler for mixed complexes when the mononuclear compounds $Pd(dppn)Cl_2$ or $Pt(dppn)Cl_2$ are used as starting materials.

However the steric requirements of the dppn ligand are not always strong enough to fix both metal centers in the same coordination geometry. While in bimetallic Pt/Pt, Pd/Pd and Pd/Pt complexes both metal centres show the same coordination symmetry, in the other reported bimetallic compounds each centre seems to display an independent coordination geometry. Indeed the Cu centre has the same planar field geometry as the Ir centre in the Ir nitrosyl compound **17**, but an overall planar geometry cannot be proposed in the Pd(Pt)/Cu complexes **11** and **12**, which do not contain the additional steric requirements of the NO bridging ligand. In the same way Co and Ni centres show coordination geometry quite different from that of the other centre (Pd or Pt) present in the same molecule. Although the geometrical properties of the two metal centres in most mixed compounds are independent, magnetic properties indicate that a sort of influence of one centre on the other is present. Indeed the magnetic moment values of the paramagnetic Pt containing derivatives are all lower than those of the corresponding Pd ones. This aspect has a different meaning depending on the partner of Pt and Pd. For Cu compounds the variation of the magnetic moment value should correspond to an increased distortion of the tetrahedral symmetry on switching from Pd to Pt. This is consistent with the increase of the difference between the covalence of the "in plane" and "out of plane" ligands ($\Delta K = |K_{\parallel} - K_{\perp}|$) on going from Pd to Pt; it seems that Pt induces higher compression of the tetrahedral symmetry of the Cu centre than Pd does. The

highest ΔK value was observed in the wholly planar Ir/Cu compound.

For Ni compounds the distortion from the octahedral symmetry decreases on switching from Pd to Pt: for Co compounds it increases.

Therefore for Ni and Cu compounds Pt is likely to display a higher ability than Pd to force the metal partner into a planar geometry.

EXPERIMENTAL

IR spectra were recorded with a Perkin–Elmer 180 (4000–200 cm^{-1}) spectrometer. The solid samples were run as KBr pellets or Nujol mulls. ESR spectra were recorded on a Varian E.109 spectrometer, operating at the X-band frequency, equipped with a Varian temperature control and an Oxford liquid helium cryostat.

Electronic diffuse reflectance spectra were recorded on a Beckman K-2A spectrophotometer. Elemental analyses were performed by the microanalysis Laboratory of the Istituto di Farmacia dell'Università di Pisa, Italy.

The ligand 3,6-bis(2'-pyridyl)pyridazine (dppn) and the starting complex $Pd(PhCN)_2Cl_2$ or K_2PtCl_4 were prepared as described in the literature.[19–21]

Preparation of $Pd(dppn)Cl_2$ (**2**)

To a solution of 0.23 mmol of dppn (25 cm^3) in acetonitrile, was added a solution (25 cm^3) containing 0.23 mmol of $Pd(PhCN)_2Cl_2$ in acetonitrile. The mixture was stirred at room temperature for 12 h. The yellow precipitate was filtered, washed with dichloromethane, ethanol, diethyl ether and dried under vacuum: yield 98%. Found: C, 41.50; H, 2.33; N, 13.23%. Calc. for **2** ($C_{14}H_{10}Cl_2N_4Pd$): C, 40.85; H, 2.45; N, 13.61%.

Preparation of $Pt(dppn)Cl_2$ (**3**)

To a solution of 0.25 mmol of K_2PtCl_4 in 10^{-1} N hydrochloric acid (200 cm^3) was added 0.25 mmol of dppn. The mixture was stirred under reflux for 30 min. After cooling the brown precipitate was filtered, washed with water, ethanol, diethyl ether and dried under vacuum: yield 95%. Found: C, 31.38; H, 2.07; N, 10.33%. Calc. for **3** ($C_{14}H_{20}Cl_2N_4Pt \cdot 2H_2O$): C, 31.35; H, 2.63; N, 10.45%.

Preparation of $Pd(dppn)X_2$ [X = Br (**4**); X = I (**5**)]

To a suspension of 0.2 mmol of **2** in acetonitrile (15 cm^3) was added 5 mmol of appropriate LiX. The mixture was stirred at room temperature for 10 days. The orange or deep red precipitate was filtered, washed with water, ethanol, diethyl ether and dried under vacuum: yield 97% (**4**), 88% (**5**). Found: C, 33.90; H, 1.95; N, 10.80%. Calc. for **4** ($C_{14}H_{10}Br_2N_4Pd$): C, 33.60; H, 2.01; N, 11.19%. Found: C, 28.46; H, 1.64; N, 9.42%. Calc. for **5** ($C_{14}H_{10}I_2N_4Pd$): C, 28.29; H, 1.69; N, 9.42%.

Reaction of **2** *with triphenylphosphine*

To a suspension of 0.17 mmol of **2** in dichloromethane (10 cm^3), a solution (10 cm^3) containing 0.40 mmol of triphenylphosphine in dichloromethane was added. The mixture was stirred at room temperature for 1 h. The yellow precipitate was filtered, washed with a few millilitres of diethyl ether and dried under vacuum. $Pd(PPh_3)_2Cl_2$ was recovered in quantitative yield. From the mother liquor free dppn was detected by TLC.

Preparation of $Pd(dppn)PdCl_2X_2$ [X = Cl (**6**); X = Br (**8**); X = I (**9**)]

In a typical preparation to a suspension of 0.1 mmol of the appropriate species (**2**, **4** or **5**) in 10 cm^3 of dichloromethane an acetonitrile solution (10 cm^3) containing 0.1 mmol of $Pd(PhCN)_2Cl_2$ was added. The mixture was stirred at room temperature for 4 h (**6**) or 18 h (**8** and **9**). The yellow (**6**) or orange (**8**) or brown (**9**) precipitate was filtered, washed with ethanol, diethyl ether and dried under vacuum: yield 95% (**6**), 96% (**8**), 95% (**9**). Found: C, 28.84; H, 1.64; N, 9.49%. Calc. for **6** ($C_{14}H_{10}Cl_4N_4Pd_2$): C, 28.55; H, 1.71; N, 9.51%. Found: C, 25.59; H, 1.54; N, 8.30%. Calc. for **8** ($C_{14}H_{10}Br_2Cl_2N_4Pd_2$): C, 24.81; H, 1.64; N, 8.39%. Found: C, 21.61; H, 1.26; N, 6.74%. Calc. for **9** ($C_{14}H_{10}Cl_2I_2N_4Pd_2$): C, 21.79; H, 1.31; N, 7.26%.

Preparation of $Pt(dppn)PtCl_4$ (**7**)

In a typical preparation to a suspension of 0.2 mmol of **3** in 10^{-1} N hydrochloric acid (200 cm^3), 0.20 mmol of K_2PtCl_4 were added. The mixture was stirred under reflux for 1 h. After cooling the brown precipitate was filtered, washed with water, ethanol, dichloromethane and dried under vacuum yield 95%. Sometime this compound retains small amounts of free dppn. The best analytical data were obtained after washing it many times with dichloromethane. Found: C, 23.48; H, 1.50; N, 7.97%. Calc. for **7** ($C_{14}H_{10}Cl_4N_4Pt_2 \cdot 0.1$dppn): C, 23.42; H, 1.40; N, 7.80%.

Reaction of **6** *with triphenylphosphine*

To a suspension of 0.19 mmol of **6** in dichloromethane (10 cm^3), a dichloromethane solution (10 cm^3) containing 0.97 mmol of triphenylphosphine was added. The mixture was stirred at room temperature for 5 h. The yellow precipitate was filtered, washed with a few millilitres of diethyl ether and dried under vacuum. The precipitate, identified as $Pd(PPh_3)_2Cl_2$ by comparison with an authentic sample, was recovered in quantitative yield. From the mother liquor free dppn was detected by TLC.

Preparation of $Pt(dppn)PdCl_4$ (**10**)

To a suspension of 0.2 mmol of **3** in 15 cm^3 of dichloromethane an acetonitrile solution (15 cm^3) containing 0.2 mmol of $Pd(PhCN)_2Cl_2$ was added. The mixture was stirred at room temperature for 48 h. The brown precipitate was filtered, washed with ethanol, diethyl ether and dried under vacuum: yield 96%. Found: C, 23.82; H, 1.40; N, 7.90%. Calc. for **10** ($C_{14}H_{10}Cl_4N_4PdPt$): C, 24.82; H, 1.49; N, 8.27%.

Preparation of $M(dppn)M'Cl_4$ (**11**: M = Pd, M' = Cu; **12**: M = Pt, M' = Cu; **13**: M = Pd, M' = Co; **14**: M = Pt, M' = Co; **15**: M = Pd, M' = Ni; **16**: M = Pt, M' = Ni)

In a typical preparation to a suspension of 0.3 mmol of **2** or **3** in acetonitrile (10 cm^3) an ethanolic solution (10 cm^3) containing 0.3 mmol of the appropriate MCl_2 (M = Cu, Co, Ni) was added. The mixture was stirred at room temperature for 24 h. The precipitate was filtered, washed with ethanol, diethyl ether and dried under vacuum. **11**: brown, yield 98%. Found: C, 30.90; H, 1.80; N, 10.27%. Calc. for $C_{14}H_{10}Cl_4CuN_4Pd$: C, 30.80; H, 1.84; N, 10.26%. **12**: brown yellow, yield 94%. Found: C, 26.84; H, 1.63; N, 8.73%. Calc. for $C_{14}H_{10}Cl_4CuN_4Pt$: C, 26.49; H, 1.59; N, 8.83%. **13**: green, yield 95%. Found: C, 31.05; H, 2.01; N, 10.73%. Calc. for $C_{14}H_{10}Cl_4CoN_4Pd$: C, 31.06; H, 1.86; N, 10.35%. **14**: greenish, yield 76%. Found: C, 28.84; H, 1.69; N, 9.66%. Calc. for $C_{14}H_{10}Cl_4CoN_4Pt \cdot 0.5CH_3CN$: C, 27.69; H, 1.78; N, 9.68%. **15**: pale yellow, yield 85%. Found: C, 29.09; H, 2.01; N, 10.42%. Calc. for $C_{14}H_{10}Cl_4N_4NiPd \cdot 2H_2O$: C, 29.13; H, 2.45; N, 9.71%. **16**: yellow-green, yield 93%. Found: C, 26.30; H, 1.85; N, 8.64%. Calc. for $C_{14}H_{10}Cl_4N_4NiPt \cdot H_2O$: C, 25.96; H, 1.87; N, 8.65%.

(*Received* 1 *May* 1984; *accepted* 22 *May* 1984)

Abstract—The compound [μ-2,7-(SCSNEt$_2$)-7-(PMe$_2$Ph)-*nido*-7-PtB$_{10}$H$_{11}$] has been obtained in a yield of 52% from the reaction of [7,7-(PMe$_2$Ph)-*nido*-7-PtB$_{10}$H$_{12}$] and [AuBr$_2$(S$_2$CNEt$_2$)], and identified by single crystal X-ray diffraction analysis and multi-element single and double resonance NMR spectroscopy. The yellow-orange compound crystallizes in the monoclinic space group $P2_1/n$ with a = 1179.2(2), b = 1244.9(5), c = 1641.4(2) pm, β = 95.45(1)°, Z = 4, and the structure (R = 0.0209, R_w = 0.0211 for 3719 observed reflections) is that of a *nido*-7-platinaundecaborane with an exopolyhedral *N*,*N*-diethyldithiocarbamate ligand bridging the Pt(7) and B(2) positions to give a Pt–B–S–C–S five-membered ring. The *tetrahapto* platinum-to-borane bonding has a considerable twist distortion relative to other *nido*-7-platinaundecaboranes which do not possess this cyclic feature. The NMR parameters exhibit no anomalies and are consistent with the crystal molecular structure. A plot of $\delta(^{11}B)$ vs $\delta(^1H)$ for directly bound *exo*-terminal hydrogen atoms shows good correlation with the slope 16:1.

We have become interested in the incidence of cyclic exopolyhedral metal-to-cluster linkages in polyhedral metalloborane compounds, and have reported the synthesis of both five-membered and six-membered rings during the course of our recent work on metallaboranes of the heavier transition metals.[1–6]

Currently the best represented of these exopolyhedral cyclisation processes is that of *ortho*-cycloboronation; this occurs with P-phenyl ligands on the metal centres and leads to five-membered M–P–C–C–B rings.[1–3,6] Known incidences include six-vertex *closo* clusters,[1] and ten-vertex *nido*,[3,6] *isonido*,[2] *isocloso*,[3] and *arachno*[7] clusters (see Fig. 1). In most of these the *ortho*-cycloboronation usually occurs at reasonably low temperatures and is generally concerted with other processes. Recently, however, it has been reported that it can be induced to occur independently of these processes, although high temperatures of 220–250°C are then required.[7]

The other examples of exopolyhedral linkages include an acetate linkage on a *closo* ten-vertex system, which gives a five-membered Ir–O–C–O–C ring to the carbon atom of an iridacarborane cage; this is obtained in low yield in an obscure reaction process.[4] By contrast, an *ortho*-oxyphenylene linkage on a *nido* eleven-vertex system, which results in a six-membered Pt–P–C–C–O–B ring, can be obtained in a quantitative yield in a designed synthesis.[5]

Here we now report a further type of exopolyhedral cyclisation process resulting in a five-membered Pt–S–C–S–B ring on an eleven-vertex *nido*-platinaundecaborane cluster [Fig. 1(a)]; this presumably occurs *via* a ligand-exchange-type process from the reaction of [7,7-(PMe$_2$Ph)$_2$-*nido*-7-PtB$_{10}$H$_{12}$] with [AuBr$_2$(SCSNEt$_2$)] prior to the formation of a boron–sulphur bond.

An ORTEP drawing of the molecular structure of the exopolyhedral heterocyclic platinaundecaborane [μ-2,7-(SCSNEt$_2$)-7-(PMe$_2$Ph)-*nido*-7-Pt$_{10}$H$_{11}$] is shown in Fig. 2. Selected interatomic distances and selected angles between interatomic vectors are given in Tables 1 and 2 respectively. The gross heavy-atom structure of the cluster can be seen

to be that of an open-faced eleven-vertex cluster based on an icosahedron with one vertex removed and is thus similar to related species such as $[B_{11}H_{13}]^{2-}$,[8] and $[Me_2TlB_{10}H_{12}]^-$.[9] The title compound was prepared from $[7,7\text{-}(PMe_2Ph)_2\text{-}nido\text{-}7\text{-}PtB_{10}H_{12}]$ and comparable boron–boron and boron–hydrogen bond lengths[10] and associated interatomic angles for the two related compounds are, within experimental error, in close agreement. The Pt(7)–P(1) bond length of 234.6(3) pm is directly comparable to other known Pt–P bond lengths in platinaborane clusters.[11] The Pt(7)–S(2) bond length

* The two columns in (a), (b) and (c) compare pairs of distances that would be identical if the molecule had C_s symmetry about the Pt(7)–B(1)–B(5) plane.

is very similar to the Pt(7)–P(1) bond length at 235.6(3) pm, and the angle S(2)–Pt(7)–P(1) of 95.7° is again very similar to the P–Pt–P angle of 95.4° in the related compound [7,7-(PMe$_2$Ph)$_2$-*nido*-7-PtB$_{10}$H$_{12}$]. A view of the platinum bonding environment looking down the plane containing S(2), Pt(7) and P(1) towards the four boron atoms to which the platinum atom is directly bonded is shown in Fig. 3. Here it can be seen that the platinum tetragonal bonding plane, as defined by the S(2), Pt(7) and P(1) plane, is set at an angle of *ca* 36° to that expected for an undistorted dsp^2 hybridization involving two-electron three-centre Pt(7)–B(2)–B(11) and Pt(7)–B(3)–B(8) bonds. Indeed, the observed geometry is with P(1) approximately *trans* to B(2) {P(1)–Pt(7)–B(2) angle 174.2(1)°} and S(2) approximately *trans* to B(8) {S(2)–Pt(7)–B(8) angle 174.9(11)°} indicating a "quasi conical" three-orbital four electron contribution rather than a square-planar two-orbital two-electron contribution of the Pt to the cluster bonding. The angle of twist (36°) is greater than that in the related [7,7-(PMe$_2$Ph)-*nido*-7-PtB$_{10}$H$_{12}$] cluster compound (21°) and this can be partly attributed to the constraints placed upon the metal centre by the exopolyhedral Pt–B–S–C–S five-membered ring. The platinum–boron bond lengths of the title compound of 216.9(6) B(2), 226.8(7) B(11), 218.2(6) B(3) and 223.5(6) B(8) are significantly shorter than the corresponding platinum–boron distances in the related compound [7,7-(PMe$_2$Ph)$_2$-*nido*-7-PtB$_{10}$H$_{12}$] of 223.1(10) B(2), 232.5(11) B(11), 223.5(9) B(3), and

S(1)–C(1)–S(2)	123.3(3)		
S(2)–C(1)–N(1)	120.0(4)	S(1)–C(1)–N(1)	116.8(4)
S(2)–Pt(7)–B(2)	90.1(2)	S(1)–B(2)–Pt(7)	112.3(3)
Boron–platinum–boron			
B(8)–Pt(7)–B(3)	48.4(2)	B(11)–Pt(7)–B(2)	47.9(2)
B(8)–Pt(7)–B(2)	86.3(3)	B(11)–Pt(7)–B(3)	85.9(3)
B(8)–Pt(7)–B(11)	90.7(3)		
B(3)–Pt(7)–B(2)	49.8(2)		

232.3(11) B(8), and this may also be due to the bond distances and angles of the five-membered exocyclic ring; a further factor may be the effective electronegativity differences between the S and P ligands on platinum and between S and H on boron. The boron–sulphur bond length B(2)–S(1) of 189.7(6) pm indicates a bond order of one between the two atoms and is consistent with the bond length of other sulphur–boron single bonds such as in the *arachno*-[6,9-(Me$_2$S)$_2$B$_{10}$H$_{12}$] cluster compound (192 ± 1 and 193 ± 1 pm)[12] and the *arachno*-[4-(Me$_2$S)-7-MeOB$_9$H$_{12}$] cluster (194 pm).[13] The interatomic distances and angles together with the conformation of the *N*,*N*-diethyldithiocarbamate ligand are all essentially identical with those reported[14,15] for the polyhedral [(SCSNEt$_2$)AuC$_2$B$_9$H$_{11}$] and [(SCSNEt$_2$)$_2$Au$_2$B$_8$H$_{10}$] cluster compounds.

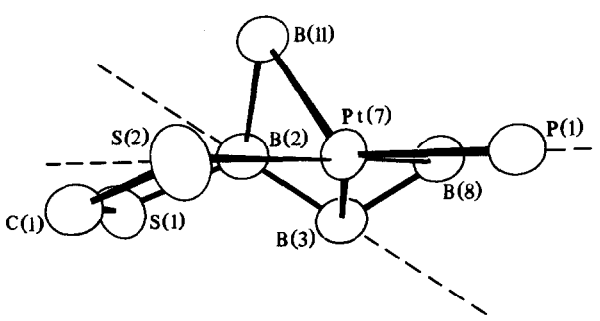

Fig. 3. View of the Pt(7)–P(1)–S(2) plane of the platinum and circumjacent atoms of [μ-2,7-(SCSNEt$_2$)-7-(PMe$_2$Ph)-7-PtB$_{10}$H$_{11}$]. The twist angle θ (between the hatched lines as defined in Ref. 10) is *ca* 36°. The dihedral angle between the Pt(7)–P(1)–S(2) and B(2)–B(3)–B(8)–B(11) planes is 72.8°, and the five-membered Pt(7)–S(2)–C(1)–S(1)–B(2) ring has the "opened envelope" configuration with the angle between the S(2)–C(1)–S(1)–B(2) and S(2)–Pt(7)–B(2) planes being 22.1°.

The NMR properties that we have been able to measure are summarized in Table 3, and are consistent with the structure, confirming that the crystal used for X-ray diffraction is representative of the bulk sample. The boron-11 NMR spectrum is similar to those obtained in these laboratories for a variety of substituted *nido*-7-platinaundecaboranes.[5,16–18] Satellites arising from coupling $^1J(^{195}\text{Pt}–^{11}\text{B})$ were not resolved under the conditions used, and so specific peak assignments are hindered. The substituted site B(2) is readily identified, however, and the highest field resonances will be due to B(4) and B(6). There seem to be no large anomalous cluster-nucleus-shielding effects associated with the large (36°) twist of the formal platinum bonding axes as discussed above, which implies that the twist does not perturb the intracluster bonding to any great extent which would be consistent with a "quasi-conical" contribution of three platinum bonding orbitals to the cluster bonding scheme.[19] The phosphorus parameters $\delta(^{31}\text{P})$ and $^1J(^{195}\text{Pt}–^{31}\text{P})$ are also in normal ranges for the {Pt(PMe$_2$Ph)$_2$} unit in polyhedral platinaboranes.[5,11,20–23]

The proton chemical shifts also show no abnormalities. There is a good general linear relation

between the shieldings of the terminal protons and the shielding of the nuclei of the boron atoms to which they are directly bonded, with a slope of $\delta(^{11}B):\delta(^1H)$ of *ca* 16:1 (Fig. 4) as observed for a variety of other platinaboranes and related species.[16–18,23] The difference in shielding between the two bridge protons is perhaps somewhat larger than expected, and may arise from aromatic anisotropic shielding contributions which could occur in the liquid state from a platinum–phosphorus bond rotamer which has the phenyl group above the open face. Of some interest is that, because of the fixed Pt–S–C–S–B ring, each of the two protons in each of the two ethyl *N*,*N*-diethyldithiocarbamate methylene groups is chemically distinct and therefore together these afford a

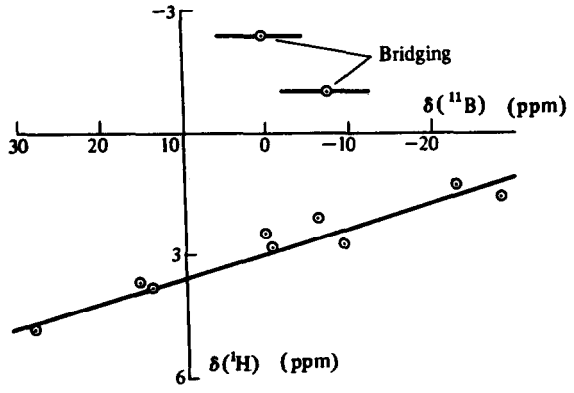

Fig. 4. Proton vs boron-11 nuclear shielding correlation plot for [μ-2,7(SCSNEt$_2$)-7-(PMe$_2$Ph)-7-PtB$_{10}$H$_{11}$]. The line drawn has slope $\delta(^{11}B):\delta(^1H)$ 16:1.

complex spectrum which consists of the AB parts of two overlapping ABX_3 systems (at δ *ca* +3.9).

EXPERIMENTAL

General

The *nido*-platinaundecaborane cluster compound $[(PMe_2Ph)_2PtB_{10}H_{12}]$ and the gold(III) complex $[AuBr_2(SCSNEt_2)]$ were prepared according to published methods.[10,24] CH_2Cl_2 was refluxed over and distilled from CaH_2 before use, and AnalaR benzene and 60°–80° light petroleum were used as supplied without further purification. Nitrogen gas was dried by passing through conc. H_2SO_4 and then over KOH pellets. Preparative thin layer chromatographic techniques have been described elsewhere.[10]

Preparation of $[SCSNEt_2)(PMe_2Ph)PtB_{10}H_{11}]$

To a solution of $[(PhMe_2P)_2PtB_{10}H_{12}]$ (0.2 mmol, 0.120 g) in dry CH_2Cl_2 (25 cm^3) under an atmosphere of dry N_2 was added via a tipper tube solid $[AuBr_2(SCSNEt_2)]$ (0.2 mmol, 0.120 g). The reaction mixture was stirred under a N_2 atmosphere at room temperature (20°C) for 2 days and then the solvent was removed under reduced pressure (water pump/25°C). Subsequent manipulations were carried out in air. The solid residue was chromatographed on silica preparative TLC plates with 100% CH_2Cl_2 as the eluant. An orange-yellow band at R_f 0.8 (the title compound) was removed from the silica and purified further by preparative TLC using 50/50 CH_2Cl_2/60°–80° light petroleum (R_f 0.5) and then 100% benzene (R_f 0.5) as the eluants. The compound was obtained as yellow-orange crystals, by evaporation of a solution in CH_2Cl_2/60°–80° light petroleum, in *ca* 52% yield (0.060 g). A single crystal suitable for an X-ray diffraction analysis was grown by diffusion of solvents (CH_2Cl_2/60°–80° light petroleum) at 4°C.

Crystallographic studies

All crystallographic measurements were made on a Syntex $P2_1$ diffractometer operating in the ω–2θ scan mode using graphite monochromatised Mo-K_α radiation (λ = 71.069 pm) following a standard procedure described in detail elsewhere.[25] The data set was corrected for absorption empirically.[26]

Crystal data. $C_{13}H_{32}B_{10}NPPtS_2$, M = 600.69, monoclinic, a = 1179.2(2), b = 1244.9(5), c = 1641.4(2) pm, β = 95.45(1)°, U = 2.400(1) nm^3, space group $P2_1/n$ (= $P2_1/c$, No. 14), Z = 4, D_c = 1.66 g cm^{-3}, μ(Mo-K_α) = 58.38 cm^{-1}, $F(000)$ = 1172, T = 290 K. 4727 data were collected, 3719 were considered observed [$I > 2\sigma(I)$]. Scans from 1° below $K_{\alpha 1}$ to 1° above $K_{\alpha 2}$, scan speeds = 2.0–29.3° min^{-1}, $4.0 < 2\theta < 50.0°$.

Structure determination and refinement. The structure was determined by standard heavy atom procedures and refined by full-matrix least squares using the SHELX program system.[27] All non-hydrogen atoms were assigned anisotropic thermal parameters with the phenyl rings refined as rigid bodies with hexagonal geometry (C–C = 139.5 pm). All of the hydrogen atoms were located experimentally and refined freely with individual isotropic thermal parameters. A weighting scheme of $\omega = 1/[\sigma^2(F_o) + 0.0001(F_o)^2]$ was used at the end of refinement to give a flat analysis of variance with increasing sin θ and $[F/F_{max}]^{1/2}$. Final R values were R = 0.0209 and R_w = 0.0211.*

NMR spectroscopy

100-MHz ^1H, ^1H-{^{11}B} and ^1H-{^{31}P}, 32 MHz ^{11}B and ^{11}B-{^1H}, and 40-MHz ^{31}P-{^1H} NMR experiments were carried out on a JEOL FX-100 pulse (F.t.) NMR spectrometer. High field (128 MHz) ^{11}B and ^{11}B-{^1H} NMR experiments were performed as part of the SERC service at Sheffield on a Bruker WH-400 pulse (F.t.) NMR spectrometer. Solutions and conditions are specified in Table 1. Chemical shifts are given in ppm to high frequency (low field) of $[SiMe_4]$ for ^1H, in ppm to high frequency (low field) of $[BF_3 \cdot OEt_2]$ in $CDCl_3$ [Ξ 32,083,971 Hz][23] for ^{11}B, and in ppm to high frequency (low field) of 85% H_3PO_4 [Ξ 40,480,730 Hz] for ^{31}P.

HYDRATES OF SODIUM THIOSULPHATE

D. A. EDWARDS* and A. A. WOOLF
School of Chemistry, University of Bath, Bath BA2 7AY, U.K.

(*Received* 22 *March* 1984; *accepted* 9 *May* 1984)

Abstract—Dehydration of sodium thiosulphate pentahydrate with organic solvents produces mixtures of the anhydrous salt and dihydrate for compositions up to $2H_2O$ and of di- and pentahydrates above this composition, with occasional traces of monohydrate present. This confirms the stable compounds in the Na_2S_2O–H_2O system. The constituents in mixtures were identified qualitatively and semi-quantitatively by Raman spectroscopy. X-ray powder diffractometry is much inferior for identification purposes. Correlations between vibrational frequencies and structure are suggested.

The $Na_2S_2O_3$–H_2O system is difficult to study experimentally because of marked supercooling and superheating phenomena. The two most detailed studies differ considerably. Burke and Young[1] isolated various hydrates after heat treatment of solutions and determined their solubilities over a temperature range. Intersections of solubility curves were identified with transitions between hydrates. In this way twelve hydrates were classified into five systems. Picon[2] after heat treating his solutions observed the temperatures at which all crystalline material had dissolved and plotted liquidus curves intersecting at transition points. He claimed only eight distinct hydrates, two of which had not been obtained by Burke and Young, a primary set of 10, 5, 2, and 1 hydrates and a secondary set of 12, 6, 5 and 1 hydrates. Members of the secondary series could be converted by seeding into members of the primary series but not vice versa. The various hydrates were identified by their crystalline appearance and by thiosulphate analysis. These analyses, apart from that for the pentahydrate, only approximated the suggested compositions because of the difficulty in freeing the crystals from the adherent viscous mother liquors.

Recently the dehydration of the solid pentahydrate and thiosulphate solutions with organic solvents has been examined in order to prepare anhydrous thiosulphate for use as a primary volumetric standard.[3] Any composition between 0 and $5H_2O$ can be obtained under appropriate conditions and hence alternative preparations of some of the above hydrates in a pure form seemed possible. Raman spectroscopy was explored as the main method for identifying the solid phases produced.

EXPERIMENTAL

Aqueous thiosulphate solutions can be partially dehydrated and precipitated by shaking with MeOH or CH_2OHCH_2OMe at room temperature whereas EtOH, Me_2CHOH, Me_2CO and MeCN reprecipitate the pentahydrate from solution. The crystalline pentahydrate is completely dehydrated in refluxing MeOH, $Me_2C(OMe)_2$ or CH_2OHCH_2OMe and partly dehydrated with Me_2CO, EtOH, MeCN or $O(CH_2CH_2OMe)_2$. Methanol, ethanol and acetone, or their mixtures, were chosen as the most suitable solvents because of their ease of removal from any solid phase. A number of different techniques were investigated to produce compositions between 0 and $5H_2O$. These compositions were measured from the water loss at 130°C after at least a 12 h heating.

Method 1. $Na_2S_2O_3 \cdot 5H_2O$ (5g) were heated under reflux for 2.5 h with various volumes of acetone. Compositions were generally reproducible to ± 0.1 H_2O. Some results are collected in Fig. 1. The Me_2CO/H_2O ratios are based on the total water present in the original pentahydrate and solvent, and not on the final solution composition.

Method 2. $Na_2S_2O_3$ (3.5 g) was equilibrated with methanol–water mixtures (50 cm^3) for 2 days. The solid compositions with mole ratios $MeOH/H_2O$ of 2/1, 3/1 and 6/1 were 3.86, 1.85 and $0.09H_2O$. Another set of results using $Na_2S_2O_3$ (5.0 g) with

* Author to whom correspondence should be addressed.

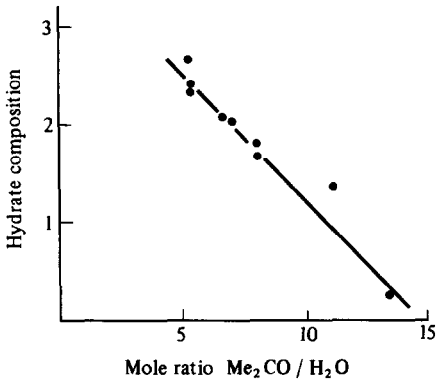

Fig. 1. Dehydration of $Na_2S_2O_3 \cdot 5H_2O$ with acetone–water mixtures.

MeOH–H_2O mixtures (50 cm^3) and shaking for 7 h gave compositions 4.31, 1.59 and 0.36H_2O at mole ratios of 2/1, 3/1 and 5/1 respectively.

Method 3. 5 cm^3 aliquots of a 5.92 molal $Na_2S_2O_3 \cdot 5H_2O$ aqueous solution were injected into 50 cm^3 of MeOH–EtOH mixtures. The compositions 2.13, 2.18, 2.91 and 4.25H_2O were precipitated from 100%, 80%, 60% and 50% MeOH mixtures.

Method 4. 10 cm^3 aliquots of a 6.00 molal $Na_2S_2O_3 \cdot 5H_2O$ aqueous solution were mixed with different volumes of MeOH at 22°C. At mole ratios MeOH/H_2O of 8.26, 4.13 and 2.07 the hydrated compositions were 1.12, 1.48 and 4.61H_2O respectively. The effect of raising the temperature (20–50°C range) at a fixed MeOH/H_2O ratio was to decrease the water of hydration. The composition was also variable to a small extent with the method of mixing and the geometry of the container. Hence to obtain reproducible compositions the exact experimental conditions need to be specified as illustrated for the dihydrate.

Preparation of the dihydrate

$Na_2S_2O_3 \cdot 5H_2O$ (8.00 g) were shaken with 50 cm^3 of MeOH in a boiling tube (20 cm × 2.54 cm diam.) held horizontally for 6 h at room temperature (24–25°C). The filtered solid was held over H_2SO_4 aq. (density 1.402) in a desiccator overnight and checked for weight constancy over a longer period.

The composition reached was $Na_2S_2O_3 \cdot 1.994H_2O$. Another experiment using 7.50 g of pentahydrate with 50 cm^3 of MeOH gave $Na_2S_2O_3 \cdot 1.999H_2O$. With 6.00 g the composition had dropped to 0.641H_2O.

Examination of hydrates

X-ray powder diffractometry. X-ray films taken on conventional cameras (Straumanis and Guinier–De Wolff mountings) were difficult to measure because of the complexity of the patterns and large number of weak lines. A graphical output (1° of θ = 2 cm) from a Philips goniometer diffractometer (PW 1050) linked to an Xe proportional counter (PW 1965) and single channel analyser (PW 4620) enabled mixed powder patterns to be separated. Specimens were contained in planchettes covered with adhesive tape and since they were not rotated the relative intensity values of peaks were not on an absolute scale. The patterns for the 0 and 5 hydrates have been tabulated previously.[4]

The d spacings observed from the dihydrate over a θ range 4.5–32° using Cu-K_α radiation were

9.678, 9.732, 5.695, 5.588, 5.412, 4.832, 4.695, 4.448, 4.396, 4.222, 4.084, 3.802, 3.693, 3.576, 3.507, 3.440, 3.414, 3.305, 3.255, 3.193, 3.079, 2.944, 2.881, 2.831, 2.792, 2.747, 2.739, 2.705, 2.683, 2.655, 2.629, 2.613, 2.543, 2.492, 2.456, 2.424, 2.356, 2.313, 2.279, 2.260, 2.249, 2.227, 2.214, 2.115, 2.049, 2.015, 1.999, 1.965, 1.933, 1.909, 1.863, 1.689, 1.590, 1.523, 1.495, 1.445.

The better defined thirty reflections were used to obtain a unit cell by means of a systematic computer fitting.[5] The best cell was monoclinic with a = 11.431, b = 4.452, c = 20.368 AU, β = 93.79° and cell volume 1034.4 AU^3. A value of Z = 6 was calculated from a measured density of 1.88 g cm^{-3}.

The powder patterns of the hydrates prepared from organic solvents were then examined. Only the lines of the 0, 2 and 5 hydrates were observed. Compositions with less than 2H_2O were mixtures of the 0 and 2 hydrates, and compositions above 2H_2O consisted of mixtures of 2 and 5 hydrates.

However in two instances a few additional weak lines were observed which were identified as belonging to the monohydrate. An impure specimen of this hydrate (composition 1.50H_2O) was made by Picon's method.[2] Anhydrous thiosulphate was added to water to give the composition $Na_2S_2O_3 \cdot 4.10H_2O$. After dissolution above 80°C the solution was held at 58–59°C for two days and the liquid decanted from the crystals after cooling to 35°C. The crystals were mixtures of the mono- and dihydrates.

An insufficiency of suitable lines prevented a unit cell being obtained for the monohydrate.

Heat of solution of hydrates. It was hoped to detect hydrates by breaks or non-linearities in the heat-composition curve. Samples (0.1–0.2 g) were injected into 50–100 cm^3 water in a conventional isoperibol calorimeter and the heat change measured. The results are summarized in Fig. 2.

Raman spectra. These were obtained on solid samples in "Pyrex" capillary tubes using the 514.5

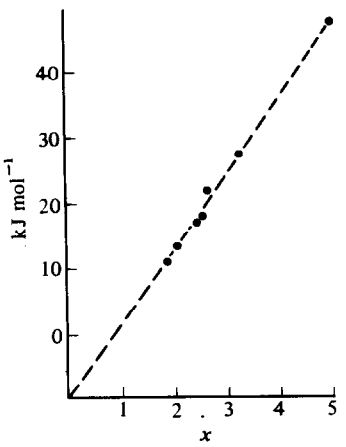

Fig. 2. Heats of solution of $Na_2S_2O_3 \cdot xH_2O$ compositions.

and 488 nm lines from an Ar^+ laser. The scattered radiation was resolved on a double monochromator (Spex 1401). Relative intensities were not corrected for frequency variation of the monochromator–photomultiplier detector response. Band frequencies, apart from those of the broadest peaks, were accurate to within ± 2 cm^{-1}. The Raman spectra characterized the individual compounds $Na_2S_2O_3 \cdot xH_2O$ ($x = 0, 1, 2, 5$) and enabled mixtures to be rapidly identified. By using the relative peak heights of the symmetric ν(SO) bands it was possible to calculate a mixture composition in close agreement with the gravimetric composition.

DISCUSSION

Dehydration of sodium thiosulphate pentahydrate, or hydration of the anhydrous salt, with organic solvents produce only the stable species in the $Na_2S_2O_3$–H_2O system, i.e. 0, 1, 2 and 5 hydrates or mixtures thereof. Picon[2] by careful heat treatment obtained the 1 and 2 hydrates from pentahydrate solutions but noted that if the dehydrations were rapid or brusque then only the dihydrate resulted. He obtained the same dihydrate, admixed with the anhydrous salt, from vacuum or desiccant dehydration. Recent Russian work using DTA and DSC techniques confirms the latter observation and an X-ray powder identification of the dihydrate was given without any analytical composition.[6] We were able to prepare the pure dihydrate for the first time, without adherent solution or enclosed anhydrous material, by simply shaking the pentahydrate with methanol at the correct $MeOH/H_2O$ ratio. The main evidence that it was a distinct species, rather than an accidental mixture of the correct composition, was provided by the Raman spectra. All the solid thiosulphates give more than the expected six Raman active bands ($3A_1 + 3E$) of the $S_2O_3^{2-}$ ion because of lattice splittings of the E modes (Table 1). The S—S stretch is the most intense for all compounds but cannot be used alone for identification because only the pentahydrate's frequency is different from the rest. However the other A_1 fundamentals (the S—O stretches and bends) are diagnostic. A 1–2% impurity in the dihydrate could be detected.

It is difficult to rationalize changes in Raman bands as the anhydrous salt becomes hydrated, no doubt because of irregularities in the sequence of structures. Only full structures of $Na_2S_2O_3 \cdot 5H_2O$ and $Na_2S_2O_3$ are available. For example one would

	936.0[4]	1.753	141.5(3)

have expected the ν(S—O) stretch to weaken as hydration and hence hydrogen bonding increased rather than the irregular sequence found, $1H_2O > 5H_2O > 0H_2O > 2H_2O$. However the difference in the ν(S—S) stretches between the pentahydrate and the other solids may simply reflect differences in hydrogen bonding to sulphur. In the solid pentahydrate the water molecules are non-equivalent.[7,8]

The ten OH groups form hydrogen bonds, two to adjacent water molecules, four to oxygens on thiosulphate ions and four to sulphurs on thiosulphate ions. It is the latter set which would weaken the ν(S—S) stretch. In the other compounds either no hydrogen bonding occurs, or only OH...O interactions are present and hence ν(S—S) would remain invariant.

The crystallographic data (Table 2) confirm the irregularity in the structural sequence. All unit cells were monoclinic but the dihydrate with the peculiar number of six molecules per cell must have units in special positions. (A search for alternative hexagonal or trigonal cells failed.) A comparison of molecular volumes shows that the pentahydrate contracts by about 10% compared with the sum of anhydrous salt plus water volumes whereas the dihydrate molecular volume is about 1% greater than the molecular volume sum. This is compatible with the ν(S—O) sequence found in the Raman spectra (i.e. $5H_2O > 0H_2O > 2H_2O$). Thermal data also indicate a weakening of hydrogen bonding in the dihydrate compared with the pentahydrate. In Fig. 3 heats of solution are given with respect to (a) the infinitely dilute solution, and (b) the previously reported heats of fusion or melting with respect to the molten state.[13] If one assumes the differences in disruption heats of the hydrated lattices are mainly due to differences in hydrogen bonding then on a purely statistical basis the expected dihydrate levels should be at 4/10 of the pentahydrate levels as indicated by the dotted lines. In each case the dihydrate is destabilized with respect to these hypothetical levels.

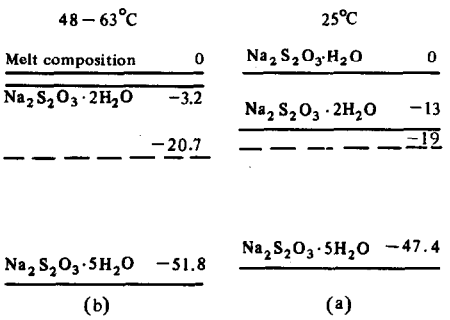

Fig. 3. Heats of melting and heats of solution (kJ mol^{-1}).

Although we were unable to isolate metastable phases by treatment with organic solvents we have established that Raman spectroscopy would be the most favourable technique to follow the *in situ* equilibration of phases from the metastable part of the $Na_2S_2O_3$–H_2O system.

PREPARATION AND CRYSTALLOGRAPHIC INVESTIGATION OF THE SPINEL SERIES: $Mn_{1+2s}Cr_{2-3s}Sb_sO_4$ ($0.05 \leqslant s \leqslant 0.30$)

P. GARCÍA CASADO

(*Received* 3 *January* 1984; *accepted* 14 *April* 1984)

Abstract—$Mn_{1+2s}Cr_{2-3s}Sb_sO_4$, a new series of spinels, have been prepared and studied using X-ray powder data. For s going from 0.05 to 0.30, a gradually increases from 8.441(1) to 8.472(1) Å, and u slightly decreases, from 0.262 to 0.258. Interatomic distances are given. The $Mn_{1+2s}Cr_{2-3s}Sb_sO_4$ ($0.05 < s < 0.30$) series may be conceived as the result of partial substitution of Cr^{3+} by $2/3Mn^{2+} + 1/3Sb^{5+}$ in the normal spinel, $MnCr_2O_4$.

The spinels are usually formulated as AB_2X_4, A and B being metals and X oxygen or chalcogen. AB_2O_4 is the composition of the most abundant group of spinels, i.e. those constituted by metals in oxidation states II–III or II–IV. Other stoichiometries such as $Co_{7/3}Sb_{2/3}O_4$, $Li_{4/3}Ti_{5/3}O_4$, $Cu_{1/2}Fe_{5/2}O_4$ and $CrMnNiO_4$, are also known. All of these non-deficient compounds could be formulated as M_3X_4. For two metals, M and M′, in oxidation states m and m' respectively, the following compounds are possible: $M_bM'_cX_4$, where $b = (3m' - 8)/(m' - m)$ and $c = (8 - 3m)/(m' - m)$. For three metals, M, M′ and M″, and oxidation states m, m' *and* m'', the series $M_sM'_dM''_eX_4$, where $d = (8 - 3m'' - ms + m''s)/(m' - m'')$ and $e = (3m' - 8 + ms - m's)/(m' - m'')$ could exist when s, d and e are positive.

In attempts to study new mixed oxides of antimony, we have prepared 12 samples of the series $Mn_{1+2s}Cr_{2-3s}Sb_sO_4$ ($0.05 \leqslant s \leqslant 0.60$). For $s >$ 0.30, a mixture of phases was obtained; for $0.05 \leqslant s \leqslant 0.30$, six polycrystalline spinels resulted, in which a gradual variation of a, the unit-cell parameter, was observed. The aim of this paper is to report how the mentioned series was prepared and to establish the cell dimension, a, the positional parameter, u, for oxygen atoms, and the distribution of cations for six samples ($0.05 \leqslant s \leqslant 0.30$) of the series.

EXPERIMENTAL

The samples were prepared from mixtures of analytical grade Mn metal, Cr_2O_3 and Sb_2O_3, molar ratios $Mn:Cr:Sb = (1+2s):(2-3s):s$ ($s = 0.05$, 0.10, ... 0.30), which were heated in air at 1073, 1273, 1473, 1573 and 1623 K during 1 day. After each thermal treatment the materials were quenched and ground. Additional experimental details were as indicated elsewhere.[1] The unit-cell parameters were refined from the 2θ values of the last eight reflections; the arbitrarily chosen Debye–Waller factors, B_j, for the calculation of the intensities were 0.30 and 0.80 Å^2 for Sb and O atoms respectively; the values 0.62 and 0.63 for Mn and Cr were obtained from these two by interpolation of the respective atomic masses between those of O and Sb. Intensities were calculated for u, the oxygen positional parameter, equal to 0.255, 0.256, . . . 0.269, and assuming $Mn_{1.00}$ at tetrahedral (a) sites.

RESULTS AND DISCUSSION

The six $Mn_{1+2s}Cr_{2-3s}Sb_sO_4$ ($0.05 \leqslant s \leqslant 0.30$) samples were obtained as polycrystalline powders, coloured from medium brown to black, which gave

good X-ray diffraction patterns. The a values showed a gradual slight variation, confirming the existence of the series. The observed, d_o, and calculated, d_c, interplanar spacings are included in Table 1. Thus, $Mn_{1+2s}Cr_{2-3s}Sb_sO_4$ $(0.05 \leqslant s \leqslant 0.30)$ is a series of cubic spinels, space group $Fd3m$ (No. 227), $Z = 8$, and the a, U and D_c values shown in Table 2.

The observed, I_o, and calculated, I_c, intensities which gave the best discrepancy factors,

$$R = (\sum |I_o^{1/2} - I_c^{1/2}|)/\sum I_o^{1/2},$$

are also included in Table 1. Those calculated were obtained for the distribution of cations and u values—origin at centre $(\bar{3}m)$—of Table 2, where the resulting R factors are also shown. The observed a and u values are comparable to those established by Raccah *et al.*[2] for $MnCr_2O_4$ $(s = 0)$: $a = 8.43$ Å, $u = 0.264$.

The observed M—O and O—O distances and the average M—O distances calculated from Shannon[3] ionic radii are included in Table 3. The observed and calculated octahedral M—O distances are practically identical, but the observed tetrahedral M—O distances are slightly shorter than those calculated.

The observed M—O distances of Table 3 have been determined as functions of the experimental a and u values, $M—O = a(3u^2 - 2u + 3/8)^{1/2}$ at octahedral sites, and $M—O = a3^{1/2}(u - 1/8)$ in the tetrahedral sublattice. For u values typical of spinels, $0.241 \leqslant u \leqslant 0.269$, if a is increased, both distances increase; and when u is reduced, the octahedral distance is enlarged where the tetrahedral one diminishes.

Trends in a, u and M—O distances of Tables 2 and

COMMUNICATION

ON A CONVENIENT SYNTHESIS OF $WOCl_4$ AND THE QUESTION OF THE EXISTENCE OF Cp_2WOCl_2

ROBERT H. CRABTREE* and GREGORY G. HLATKY

Sterling Chemistry Laboratory, 225 Prospect Street, New Haven, Connecticut, U.S.A.

(*Received* 10 *April* 1984; *accepted* 5 *July* 1984)

Abstract—$WOCl_4$ is synthesised from tungstic acid in refluxing $SOCl_2$. The literature report of the synthesis of Cp_2WOCl_2 from $WOCl_4$ and cyclopentadiene could not be confirmed.

We were attracted to the report of Multani *et al.*[1] on a synthesis of a material described as Cp_2WOCl_2 by simple reflux of $WOCl_4$ with cyclopentadiene in benzene. This seemed an unexpectedly simple entry into the "Cp_2W" series. Although the product is a 20-electron molecule as written, ways exist to reduce the electron count, e.g. $(\eta^3\text{-Cp})(\eta^5\text{-Cp})WOCl_2$ or $[(\eta^5\text{-Cp})_2WO]Cl_2$.

The reported synthesis appears to be quite general, a whole range of unprecedented organometallic compounds being formed, e.g. $(C_7H_7)MOCl_2$[2] from $MOCl_4$ and cycloheptatriene (M = Mo or W) and $(C_8H_7)_2MoOCl_2$[3] from $MoOCl_4$ and cyclooctatetraene. Related Ti, Zr and Hf complexes are also reported.

We were unable to repeat the synthesis of Cp_2WOCl_2 and the recent report by Deacon *et al.*[4] on their failure to confirm other work by Multani *et al.*[1] prompts us to report our results. The reported synthesis of Cp_2WOCl_2 requires $WOCl_4$ and in the course of this work, we discovered a new and much more convenient synthesis of this compound, which we report here.

$WOCl_4$ has been synthesised by several methods, all of which require relatively forcing conditions. The best ones previously available were chlorination of WO_3 with $SOCl_2$ for 6–12 h at 200°C,[5] with Cl_2–CCl_4 for 3 h at 200°C,[6] or with C_5Cl_8 for 10 min at 290°C.[7] In contrast, the corresponding molybdenum complex, $MoOCl_4$, can be readily prepared from MoO_3 in refluxing $SOCl_2$[8] (79°C). WO_3 does not react at all under these conditions. The closely related hydrated oxide, tungstic acid,[9] $WO_3 \cdot xH_2O$ does react, when freshly prepared, and 65% yields of $WOCl_4$ can be isolated by sublimation. These are the mildest conditions yet reported for the synthesis of this compound.

On refluxing the $WOCl_4$ so obtained with dry cyclopentadiene by the method of Multani *et al.*[1] we obtained a tan solid that seemed to be a mixture of oxyhalides but did not appear to contain any organic material (^1H NMR) and could not be recrystallised. We could not obtain any characterisable organometallic product *via* the alternative route described by Multani *et al.*[1] from NaC_5H_5 and $MoOCl_4$.[1,10] Since the IR spectra and physical properties of our materials were quite different from those reported for Cp_2WOCl_2, we clearly did not obtain the previously reported material. We cannot, of course, exclude the possibility that some subtle but important differences in experimental technique are responsible for our failure to obtain Cp_2WOCl_2.

We also tried to repeat the synthesis of $(C_7H_7)MoOCl_2$[2] and $(C_7H_7)_2ZrCl_2$[3] by refluxing cycloheptatriene with $MoOCl_4$ and $ZrCl_4$, again without success.

EXPERIMENTAL

Solvents and reagents (Aldrich Chemical Co.) were distilled before use. Metal halides were purchased (Alfa) except for $WOCl_4$, which was synthesised. Reactions were carried out under dry

N_2. IR spectra were recorded on a Nicolet 7000 FT-IR.

Tungsten oxytetrachloride

Tungstic acid (1 g, obtained by Morley's[9] method A from ammonium or sodium tungstate and 1 N HCl) was placed in a widemouth Schlenk tube fitted with a reflux condenser. $SOCl_2$ (20 cm^3) was added and the mixture refluxed for 6 h under dry air or nitrogen. The Schlenk tube was cooled, and the volatiles removed *in vacuo* (care should be taken to prevent damage to the vacuum pump by the HCl present in the flask, by interposing an NaOH acid-trap after the cold trap). Pure $WOCl_4$ was then sublimed *in vacuo* as glistening red needles on to a cold finger inserted into the Schlenk tube. Yield: 0.65 g (65%) of a red product, m.p. 208°C (lit.:[7] 210°C). Found: Cl, 41.28%. Calc. for Cl_4OW: Cl, 41.5%. It was instantly decomposed by water and slowly decomposed by atmospheric moisture.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry. Ti—Organotitanium Compounds. Part 4: Mononuclear Compounds 4, Cumulative Index for Parts 1 to 4. Published by Gmelin Institute for Inorganic Chemistry of the Max Planck Society for the Advancement of Science, Springer, Berlin, 8th edition, 1984, 17 illustrations, ix + 242 pp., DM851, approx. $330.20.

The growth of organotitanium chemistry over the past decade is appropriately recognised in the publication of this, the fourth in a series of volumes concerned with organotitanium chemistry. It covers the literature in detail up to the end of 1979, a few later references also being included. The volume continues the treatment of titanium compounds with two ^{5}L-groups (^{5}L being the symbolism used to represent a ligand bound to titanium by five carbon atoms), and concludes with a discussion of complexes containing ^{n}L-ligands where $n > 5$. Some examples of compounds treated in this volume are $(\pi\text{-}C_5H_5)_2Ti(CO)_2$, the titanacyclic compounds $(\pi\text{-}C_5H_5)_2Ti([CH_2]_4)$, $(\pi\text{-}C_5H_5)_2Ti([CH_2]_5)$ and $(\pi\text{-}C_5H_5)_2Ti(C_6H_5C{=}C_6H_5]_2)$, the π-allyl complex $(\pi\text{-}C_5H_5)_2TiC_3H_5\text{-}\pi$, compounds with arene ligands such as $(\pi\text{-}C_6H_6)_2Ti$ and $\pi\text{-}C_6H_6Ti(Cl_2AlCl_2)_2$, as well as the compounds $\pi\text{-}C_7H_7TiC_5H_5\text{-}\pi$, $\pi\text{-}C_8H_8TiC_5H_5\text{-}\pi$ and $(\pi\text{-}C_5H_4(CH_2)_2C_5H_4\text{-}\pi)TiCl_2$ which contain ^{7}L-, ^{8}L- and ^{10}L-ligands, respectively. The volume is authoritative and beautifully produced, and many data are contained in well-arranged tables. There is also an empirical formula index and a very large (85 pp.) ligand formula index which should assist readers greatly. The cost is, of course, immense and one only hopes that libraries can continue to afford to buy quality productions such as this undoubtedly is.

FAR-IR SPECTRA OF CHARGE-TRANSFER COMPLEXES BETWEEN IX (X = Cl, Br OR I) AND *TRANS*-1,2-BIS(4-PYRIDYL)ETHYLENE, 1,2-BIS(4-PYRIDYL)ETHANE AND 4,4′-BIPYRIDYL

KOYO AIDA, KANJI YOSHIDA* and KEIKO KATO†
Department of Engineering Science, Faculty of Engineering, Tohoku University, Sendai, Japan

(*Received* 6 *April* 1984: *accepted* 9 *July* 1984)

Abstract—Far-IR spectra of charge-transfer complexes of *trans*-1,2-bis(4-pyridyl)ethylene (Bpe), 1,2-bis(4-pyridyl)ethane (Bpa) and 4,4′-bipyridyl (4,4′-Bpy) with IX (X = Cl, Br or I) have been measured as solids. Assignments for the modified IX stretching and the intermolecular NI stretching vibrations are proposed. The force constants for these vibrations have been calculated assuming a linear triatomic model, putting a donor molecule as a point mass. It is concluded that the donor tendency towards the halogens is in the order Bpe > Bpa > 4,4′-Bpy.

Numerous studies have been reported on the vibrational spectra of charge-transfer (CT) complexes between halogens or interhalogens and pyridine (Py) or substituted Pys.[1–9] With regard to 4,4′-bipyridyl (4,4′-Bpy) as a donor, Yagi *et al.*[2] have reported far-IR frequencies of its ICl and IBr complexes. 4,4′-Bpy is a weak base consisting of two Py rings joined together at the 4-position on each ring. *trans*-1,2-Bis(4-pyridyl)ethylene (Bpe) and 1,2-bis(4-pyridyl)ethane (Bpa) are analogous compounds in which two Py rings are separated by C=C and C—C bonds, respectively. It is of interest to measure the far-IR spectra of their IX (X = Cl, Br or I) complexes and to investigate their donor ability towards halogens in comparison with that of 4,4′-Bpy.

EXPERIMENTAL

Bpe and Bpa from Aldrich Chemical Co. were purified by recrystallization from benzene and a benzene–cyclohexane (1 : 3) mixed solvent, respectively. Bpe: m.p. 152°C (lit.,[10] 151–152°C). Bpa: m.p. 110°C (lit.,[10] 110–111°C). 4,4′-Bpy from Wako Chemical Co. was used without further purification, m.p. 112.5°C (lit.,[11] 111.8–120°C). I_2 was purified by sublimation under vacuum. ICl and IBr from Nakarai Chemical Co. were used without further purification. CCl_4 was dried with $CaCl_2$ and then distilled twice.

Complexes were prepared by slowly mixing CCl_4 solutions (~0.05 *M*) of the two components. Complexes were obtained in the form of fine needles with light yellow (ICl complexes), yellow (IBr complexes) and dark orange (I_2 complexes), except for the I_2 complex of Bpa, which was obtained in the form of red brown plates. The products were filtered, washed with CCl_4 and dried in *vacuo*. Analytical results are given in Table 1 and are in good agreement with those values calculated for 1 : 2 complexes. Decomposition points for these complexes are also included in the table.

Far-IR spectra (400–50 cm^{-1}) were recorded on a Hitachi FIS-III spectrophotometer which was evacuated to remove atmospheric water vapor. Samples were measured in Nujol mulls spread on polyethylene plates.

RESULTS AND DISCUSSION

Hassel and Rømming[12] have reported an X-ray study on the structure of the Py·ICl complex and have shown that the ring nitrogen atom forms a donor–acceptor bond with the iodine atom, resulting in a linear N—I—Cl arrangement. It seems quite reasonable to assume the same arrangement for each nitrogen atom with IX in the present complexes. Then, we can expect three vibrational

modes for this portion, the modified interhalogen IX stretching, the intermolecular NI stretching and the NIX bending vibrations. These vibrations are expected to appear in the far-IR region. The far-IR spectra for these CT complexes are shown in Fig. 1, together with those for free donor molecules.

It is well established that the IX stetching vibration decreases in frequency and increases in intensity upon complex formation. For instance, Yarwood[6] has reported the ICl stretching frequency in the Py·ICl complex to be near 270 cm^{-1}, which is lower than that of "free" ICl at 384 cm^{-1}.[13] He has also assigned absorptions near 175 and 80 cm^{-1} to the intermolecular NI stretching and the NICl bending vibrations, respectively.

As Fig. 1 shows, two new bands appear upon complex formation in each case. Taking their positions into consideration, these absorptions can

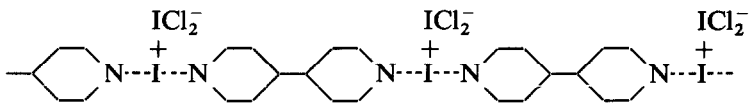
be assigned to the modified IX stretching and the intermolecular NI stretching vibrations, respectively. A possible NIX bending vibration could not be clearly identified in each case. They are probably too weak to be observed. The fact that only one absorption appears for each stretching vibration suggests that the vibrational coupling between two NIX groups must be very small.

The proposed assignments are summarized in Table 2, together with those for 4,4'-Bpy, 2,2'-Bpy and Py reported by Yagi *et al.*[2] The splitting of the IBr stretching frequency in the 4,4'-Bpy·2IBr complex has already been discussed by Yagi *et al.*[2] and the present results are in good agreement with theirs.



The results for 4,4'-Bpy·2ICl are of some interest in view of its structure. Popov *et al.*[11] have proposed the following polymeric structure for this complex

because of its high decomposition point starting at 230°C, higher than usual for a monomeric CT complex such as 2,2′-Bpy·2ICl, which has a decomposition point starting at 140°C.[11] However, the present ICl complex of 4,4′-Bpy has a decomposition point starting at 145°C, almost the same decomposition point as those of the other complexes, as Table 1 shows. Moreover, if the ICl complex has the above polymeric structure, then we can expect a strong absorption near 230 cm^{-1}, which is assigned to the ν_3-vibration of the ICl_2^- ion. However, there is no absorption near 230 cm^{-1} in the far-IR spectrum of 4,4′-Bpy·2ICl, as Fig. 1 shows. These facts suggest that the present ICl complex of 4,4′-Bpy is not the same complex as that of Popov *et al.*[11] Considering the spectra shown in Fig. 1 and the decomposition points listed in Table 1, it is most likely that these CT complexes, including 4,4′-Bpy·2ICl, have a monomeric structure with the usual donor–acceptor bonds.

As halogens are sacrificial acceptors, increasing electron transfer is accompanied by a progressive weakening of the interhalogen bond. Thus, the relative change in the interhalogen stretching force constant can be used to measure the extent of donor–acceptor interaction. Several attempts have been made to calculate the force constants for the halogen complexes with nitrogen donors under the assumption of a linear triatomic model, putting a donor molecule as a point mass.[2,4] It is not certain whether the same assumption holds in the present complexes, as there are two NIX groups in each of the present complexes. However, as was pointed out before, the vibrational coupling between these two NIX groups seems to be very small. In the case of *p*-dithian·2IX (X = Br or I), the calculation has been made under the assumption of a linear triatomic model, with no vibrational coupling between two SIX groups, and the results were found to be reasonable. Therefore, it is worthwhile to make the same calculation under this simple assumption.

An additional assumption is necessary about the interaction constant, k_{12}, because there are three force constants for two observable stretching frequencies. So far, $k_{12} = 0.40$ N cm^{-1} has been widely used by previous authors for many halogen complexes of nitrogen donors.[2,4,6] Adopting the same value for k_{12}, the force constants were calculated with a linear D—I—X model, where D represents the whole donor molecule. The results are given in Table 3.

In order to verify the aforementioned treatment,

the force constant for the "pure" dative structure, $D^+—I^-$, k^o_{DI}, has been calculated. Yarwood[14] has shown that k^o_{DI} is about 2.5 N cm^{-1} for halogen complexes of Py. From Table 3, it is seen that this value is nearly 2.5 N cm^{-1} for each complex and this probably suggests that the treatment is reasonable.

Table 3 shows that the relative change in the interhalogen stretching force constant, W, defined by $(k^o_{IX} - k_{IX})/k^o_{IX}$, where k^o_{IX} denotes the force constant calculated from the gas-phase frequency, increases in the order I_2, IBr and ICl for each donor molecule. Also, the intermolecular stretching force constant, k_{DI}, which directly reflects the strength of the donor–acceptor bond, increases in the same order. This is in agreement with what might be expected from the strength of acidity of halogens.

For the same acceptor molecule, W increases in the order 4,4′-Bpy, Bpa and Bpe. With regard to 4,4′-Bpy and Bpe, this is in agreement with their pK_a value. The pK_a value for Bpa is not known, but from Table 3 it is expected to be close to that of Bpe, i.e. somewhere around 5.5. In conclusion, the donor tendency towards the halogens is in the order 4,4′-Bpy < Bpa < Bpe.

CATALYTIC ISOMERISATION OF ALKENES BY $Fe(CO)_4$

V. V. KANE, J. R. C. LIGHT* and M. C. WHITING
Dyson Perrins Laboratory, Oxford, U.K.; and Chemistry Department, The University, Bristol BS8 1TS, U.K.

(*Received* 17 *May* 1984; *accepted* 27 *July* 1984)

Abstract—Photolysis of alkene solutions of iron dodecacarbonyl at wavelengths greater than 500 nm causes dissociation into $Fe(CO)_4$. With ethylene and propene the latter forms (alkene)$Fe(CO)_4$ complexes. With higher alkenes it promotes isomerisation of terminal to internal alkenes. This isomerisation is non-sequential.

Preliminary observations on the isomerisation of *n*-octenes by photolysed $Fe_3(CO)_{12}$ have been published,[1] and the full details of this are presented here, together with evidence that $Fe(CO)_4$ is the catalytic agent. The participation of $Fe(CO)_4$ has been suggested in other reactions,[2] produced from $Fe_3(CO)_{12}$ thermally or by IR irradiation of $Fe(CO)_5$, and the existence of discrete $Fe(CO)_4$ has been demonstrated in frozen gas matrices[3] and in a polymer matrix.[4]

RESULTS AND DISCUSSION

Formation of $Fe(CO)_4$

The electronic spectrum of iron dodecacarbonyl has a maximum at 450 nm overlapping the tail of strong absorption in the UV region. There is a more pronounced maximum at 605 nm, and the radiation used was filtered to ensure absorption in this region only. At 373 K the thermal decomposition of $Fe_3(CO)_{12}$ to $Fe(CO)_5$ in hexane solution is appreciable but at 293 K formation of $Fe(CO)_5$ was immeasurable in the dark.

Irradiation of solutions of $Fe_3(CO)_{12}$ at 293 K under nitrogen produces $Fe(CO)_5$ in 96% yield according to the equation

$$5Fe_3(CO)_{12} \rightarrow 12Fe(CO)_5 + 3(Fe),$$

where (Fe) represents iron bound in the uncharacterised precipitate. Similar results were obtained under argon and hydrogen atmospheres. Replacement of the nitrogen by carbon monoxide, however, led to all the iron being converted to $Fe(CO)_5$:

$$Fe_3(CO)_{12} + 3CO \rightarrow 3Fe(CO)_5$$

and no initial precipitate was formed, although of course $Fe(CO)_5$ itself decomposes slowly giving a brown precipitate.

These results suggested that the photodissociation was simply

$$Fe_3(CO)_{12} \rightarrow 3Fe(CO)_4.$$

Reaction with ethylene

Irradiation of iron dodecacarbonyl solutions in the presence of ethylene gave a solution having a complex IR spectrum in the metal–carbonyl stretching region (Table 1). Bands due to $Fe(CO)_5$ and $(C_2H_4)Fe(CO)_4$ were detected, and the PMR spectrum[5] confirmed the presence of $(C_2H_4)Fe(CO)_4$. The presence of other species was suspected because of variations in relative peak heights and half-widths, and of small shifts in the position of maxima in IR spectra obtained from different experiments. These variations did not appear to be produced by differences in concentration, temperature or length of irradiation. Small differences resulted from the use of non-purified hydrocarbon solvents, and large ones from the use of halogenated solvents, or unfiltered radiation.

The solutions were stable at 195 K in the dark, but decomposed to $Fe_3(CO)_{12}$ in sunlight. They were moderately sensitive to oxygen, but not at all to hydrogen, carbon monoxide, propene or propyne. Addition of cyclopentadiene appeared to displace some ethylene.

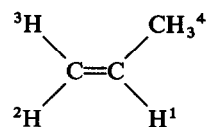
Reaction with propene

Solutions similar to, but much less stable than, those obtained with ethylene were obtained with propene.

The PMR spectrum of $C_3H_6Fe(CO)_4$ was obtained in $CFCl_3$ at 203 K and at temperatures up to 243 K showed no appreciable change, but thereafter the rate of decomposition of the complex increased and was rapid at 273 K.

The measured parameters of the spectrum are compared with literature values[6] for propene itself in Table 2. The value of zero given to J_{23}, J_{24} and J_{34} is only approximate, there being considerable peak broadening in the spectrum, probably due to suspended particles of iron produced by decomposition of the complex. However, double irradiation experiments confirmed the values obtained, and showed no signs of J_{23}, J_{24} or J_{34} coupling.



As expected the chemical shifts of protons attached to carbon atoms interacting directly with the metal are shifted to higher field. The methylene protons have a similar chemical shift to those in the ethylene complex, but the relative values of the shifts of the protons *cis* and *trans* to the lone proton are reversed with respect to the free propene, assuming that the protons have been correctly assigned (on the basis of the *trans* coupling being greater than the *cis*). The chemical shift of the methyl protons remains effectively the same.

A discussion of the significance of the value of J_{23} in terms of the bonding in the complex would not be helpful in view of the uncertainty in the value of J_{23}, and the doubts which have been expressed about the validity of correlations between coupling constants and bond angles. The reduction of coupling constants in going from the free propene to the complex is paralleled in other π-alkene complexes of iron tetracarbonyl such as $(H_2C{=}CHCOOCH_3)Fe(CO)_4$.[7]

Isomerisation of alkenes

The preceding experiments demonstrate that $Fe(CO)_4$ is formed by dissociation of $Fe_3(CO)_{12}$ resulting from absorption of light at 605 nm, and that it forms complexes with ethylene and propene. It seemed likely that it might catalyse the isomerisation of alkenes, as has since been reported to occur when alkenes were treated with various iron carbonyl species.[8] This photochemical route seemed to be a particularly clean way of preparing (alkene)$Fe(CO)_4$ species, since they would not absorb light of such wavelengths. Using hex-1-ene under the conditions

* By least-square extrapolation.

described above it was shown that extensive isomerisation occurred, giving up to 96% of internal hexenes; that the presence of alkene inhibited the disproprotionation reaction (no immediate precipitate); that carbon monoxide inhibited the isomerisation; and that no reaction takes place in the absence of light. Using oct-1-ene it was found that no reduction to octane occurred.[9] When the mixtures obtained after varying degrees of reaction were analysed ("method B")[10] and the ratios of the products to *trans*-oct-3-ene (chosen arbitrarily) were extrapolated to zero conversion,[22] the initial product-mixture from oct-1-ene was shown already to contain substantial amounts of the oct-3-enes and oct-4-enes. Indeed, its composition did not differ greatly from that of an equilibrium mixture of the *n*-octenes.[12]

It is quite possible that the equilibrium coefficients for the six internal octenes as $Fe(CO)_4$ complexes are very similar to those for the octenes themselves, and

(1 = oct-1-ene etc.)

$k_{CO} > k_{C_2H_4} > k_1 > k_d > k_{t2}, k_{c2}, k_{H_2}\ k_{N_2}$

$k_{1\rightarrow c2}$ etc. $> k_{-c2}$ etc.

Scheme 1.

that (oct-1-ene)$Fe(CO)_4$ rapidly converts to this equilibrium mixture, before the much slower equilibration between these alkenes and their complexes makes significant progress. Alternatively, the rate of dissociation of the complexes may be slower than that of the isomerisation processes but not much slower than the slowest of these, perhaps $k_{t3\rightarrow c4}$. In that case the kinetic product mixture will be distorted from the hypothetical equilibrium mixture. The marked delay in the precipitation of iron (or iron sub-carbonyl species) when hex-1-ene is present suggests that the complexing rate of a terminal alkene, k_1, compares favourably with that of disproportionation, k_d, and this was confirmed when oct-1-ene and $Fe_3(CO)_{12}$ were irradiated in a *ca* 700 : 1 molar ratio, when at least 270 mol of oct-1-ene were isomerised per mol of $Fe_3(CO)_{12}$. However, the similar isomerisation of *cis*- and *trans*-oct-4-enes could not be examined in detail, because the disproportionation process in this case proved to be relatively too fast. Evidently complexing rates for disubstituted alkenes are much lower than for terminal alkenes and the $Fe(CO)_4$ complexes much less stable.

We may summarise the behaviour of $Fe(CO)_4$ in the scheme shown; its properties are reminiscent of those of a reactive intermediate of moderate stability, like CCl_2, and could in principle be explored quantitatively, using visible-light photolysis of $Fe_3(CO)_{12}$ as a cleaner source of this species than, e.g. thermolysis of $Fe_2(CO)_9$. This would require more rigorous exclusion of unwanted reactants (oxygen, impurities in solvents etc.) than was attempted here. Our work has no bearing on the mechanism of the isomerisation reaction. It has been suggested[13] that it occurs via an intermediate of the type $(CO)_3Fe(alkene)_2$ and our results are consistent with this view, providing the intermediate can be generated by some such process as the following:

$$(CO)_4Fe(alkene) + Fe(CO)_4 \rightleftharpoons (alkene)Fe(CO)_3 + Fe(CO)_5,$$

$$(alkene)Fe(CO)_3 + alkene \rightleftharpoons (alkene)_2Fe(CO)_3.$$

EXPERIMENTAL

In pilot experiments using commercial solvents unexpected peaks were obtained in the metal–carbonyl stretching region of the IR spectra. These were due to alkene impurities in the hydrocarbons (*n*-heptane, iso-octane, methylcyclohexane and cyclopentane) compexing the $Fe(CO)_4$ formed during irradiation. They were eliminated by carefully purifying the solvents (stirring for 1 week with acid potassium permanganate solution, separating, drying and filtering through two silica gel columns).

Iron dodecarbonyl was prepared both from iron pentacarbonyl[14] and di-iron nonacarbonyl.[15]

General procedure

Solutions of iron dodecacarbonyl were prepared by stirring the solid in the solvent and filtering under nitrogen and with as much protection from daylight as possible. The concentration of the solutions was calculated from the absorbance of the 605 nm absorption in the VIS (using a Unicam SP800 spectrophotometer; molar absorption coefficient of $Fe_3(CO)_{12} = 2505\ m^2\ mol^{-1}$). 25–50 cm^3 portions of the solutions in glass tubes fitted with gas inlet and outlet were immersed in a cooling bath maintained at 283–293 K by circulating the coolant through ice. The coolant contained sodium dichromate (4 g dm^{-3}), a 1 cm thickness of which was sufficient to absorb all radiation of shorter wavelength than 500 nm. Light was provided by a 2 kW xenon arc lamp. The products were examined by IR spectroscopy in 1 mm solution cells (NaCl) on a Perkin–Elmer 257 over the range 4000–650 cm^{-1}. Concentrations of $Fe(CO)_5$ were determined from the optical densities of the two major peaks by comparison with a calibration graph. Vapour phase chromatograms were run on a Perkin–Elmer F11 using a 2 m long $\frac{1}{8}''$ diameter stainless steel column packed with 25% M. & B. Embaphase silicone oil on 60–80 mesh Diatoport-S at 298 K using a flame ionisation detector, except for the analysis of octene mixtures, where method B of ref. 10 was used.

Thermal stability of $Fe_3(CO)_{12}$

A solution of $Fe_3(CO)_{12}$ in *n*-heptane was protected from the light and heated to 373 K in a stream of nitrogen. The issuing gas was passed through a trap at 195 K. Several samples were collected in succession and all contained $Fe(CO)_5$ (IR).

In a related experiment at 293 K a little $Fe(CO)_5$ was obtained initially (presumably from prior decomposition) but, thereafter, none. Thus decomposition of $Fe_3(CO)_{12}$ is appreciable at 373 K but not at 293 K.

Photolysis of $Fe_3(CO)_{12}$ *under nitrogen*

A solution of $Fe_3(CO)_{12}$ (5.67×10^{-5} mol) in *n*-heptane was irradiated at 293 K for 75 min in a slow stream of N_2. The amount of $Fe(CO)_5$ carried forward in the gas stream (8.20×10^{-8} mol) was

negligible compared to that remaining in solution (1.30×10^{-4} mol). The intense green of the $Fe_3(CO)_{12}$ had given way to the pale straw-colour of $Fe(CO)_5$, and a black precipitate had formed (5.1 mg). On the basis of carbonyl groups the yield of $Fe(CO)_5$ was 96%. The precipitate had a broad absorption at 2000 cm^{-1} and contained 57% iron (determined by dissolution in conc. HCl, reduction with $SnCl_2$, and titration against standard potassium dichromate). Qualitatively similar results were obtained under argon and hydrogen.

Photolysis of $Fe_3(CO)_{12}$ *under carbon monoxide*

A solution of $Fe_3(CO)_{12}$ (2.20×10^{-5} mol) in *n*-heptane was irradiated for 30 min in a slow stream of CO. A clear pale-yellow solution of $Fe(CO)_5$ was obtained (6.44×10^{-5} mol; 98% of the iron used) but no precipitate.

Photolysis of $Fe_3(CO)_{12}$ *under ethylene*

Passage of a slow stream of C_2H_4 through a solution of $Fe_3(CO)_{12}$ in *n*-heptane during irradiation gave a pale yellow solution, and no precipitate. The solution appeared to contain $(C_2H_4)Fe(CO)_4$ (IR, Table 1). It slowly decomposed, depositing a brown precipitate, but in sunlight some $Fe_3(CO)_{12}$ (IR, UV–VIS) was reformed. At low temperature in the dark the solution was stable for at least 2–3 weeks.

PMR spectrum of $(C_2H_4)Fe(CO)_4$

The IR spectra of solutions obtained from the irradiation of $Fe_3(CO)_{12}$ with C_2H_4 in *n*-heptane and in $CFCl_3$ were different. However, when the two solutions were diluted each with an equal volume of the other solvent (i.e. *n*-heptane with $CFCl_3$; $CFCl_3$ with *n*-heptane) the resulting solutions had identical spectra. This suggests that the differences in the spectra are a solvent effect and that the species present are in fact the same. Solutions in CCl_4 paralleled the behaviour of those in $CFCl_3$. The slow decomposition of the complex, on the other hand, is probably different in the two types of solvents, since in hydrocarbons a brown precipitate is formed, whereas in the chlorinated solvents it is white.

$Fe_3(CO)_{12}$ (0.379 g) was stirred with $CFCl_3$ in a current of C_2H_4 and irradiated for 80 min. The solution was concentrated by vacuum evaporation of the solvent at 195 K and separated from solid matter by allowing it to evaporate in vacuum at 293 K and condensing the evaporate. The PMR spectrum (100 M.c. Varian HA100 NMR spectrometer) of the solution was compared with one of C_2H_4 in $CFCl_3$. There was an additional sharp singlet at δ 2.31 (relative to TMS), attributed to the complex.[5]

Reactions of $(C_2H_4)Fe(CO)_4$

A solution of the complex in *n*-heptane was prepared as before. After bubbling H_2, CO, propene and propyne through separate portions of the solution no change was found in the IR spectrum of the metal–carbonyl region. Bubbling oxygen through reduced the intensity of the spectrum.

Reactions of $Fe(CO)_4$ *with cyclopentadiene*

A solution of $Fe_3(CO)_{12}$ in *n*-heptane was irradiated for 5 min in the presence of C_5H_6. The solution became colourless and had a characteristic spectrum (Table 1). After 24 h a brown precipitate had formed.

Reaction of $(C_2H_4)Fe(CO)_4$ *with cyclopentadiene*

A solution of the ethylene complex was prepared in the usual way. C_5H_6 was added. The IR spectrum of the solution (2087, 2047, 2007, 2001, 1982, 1975 cm^{-1}) had the appearance of a mixture of the ethylene and cyclopentadiene complexes. After 24 h a brown coating had appeared on the tube, and after 48 h the IR spectrum of the solution had reverted almost completely to that of the ethylene complex, but was less intense.

Photolysis of $Fe_3(CO)_{12}$ *under propene*

This was effected in the same way as for ethylene. A mixture of $Fe(CO)_5$ with the $(CH_3CHCH_2)Fe(CO)_4$ complex was obtained, and the propene complex identified by its PMR spectrum as described above. The propene complex was much less stable than the ethylene analogue, but could be kept satisfactorily at 195 K in the dark. It did not react with H_2.

Isomerisation of 1*-hexene*

A solution of $Fe_3(CO)_{12}$ (7.97×10^{-5} mol), 1-hexene (1 cm^3) and *n*-octane (1 cm^3) in *n*-heptane (50 cm^3) was irradiated for 35 min. A heavy precipitate was produced and the solution was pale yellow.

The trap contained $Fe(CO)_5$ (2.55×10^{-7} mol). After standing, the characteristic green of $Fe_3(CO)_{12}$ returned (VIS showed 6.79×10^{-6} mol), and the solution also contained $Fe(CO)_5$ (1.97×10^{-4} mol). After 16 h the concentration of $Fe_3(CO)_{12}$ had increased to 1.06×10^{-5} mol. The ratio of internal

hexenes to 1-hexene was 41:1 (VPC). The IR spectrum indicated a trace of some compound other than $Fe(CO)_5$, presumably a hexene complex.

A solution of $Fe_3(CO)_{12}$ was divided into three 25 cm^3 portions (3.89×10^{-5} mol in each) and 1 cm^3 1-hexene was added to each. The first was kept dark, and no reaction occurred. The second was irradiated under N_2 and gave $Fe(CO)_5$ (1.06×10^{-4} mol; IR peak ratios and the presence of an additional small peak indicated some undecomposed hexene complex). The ratio of internal hexenes to 1-hexene was 1.44 to 1. The third solution was irradiated under CO. No isomerisation occurred, but a little alkene complex appeared to be present in the $Fe(CO)_5$ (1.15×10^{-4} mol).

Isomerisation of oct-1-ene

The $Fe(CO)_4$ was produced in these experiments by light from a tungsten–iodine lamp (3400 K) filtered through a Kodak No. 8 yellow filter, and the solvent was light petroleum. 25 cm^3 of $Fe_3(CO)_{12}$ solution (2 mg dm^{-3}) and 80 mg of oct-1-ene were irradiated. 30 mg of octene isomerised, i.e. 274 mol of oct-1-ene per mol $Fe_3(CO)_{12}$. In a similar experiment, the product ratios of the internal octenes were measured by VPC at 90 s intervals throughout the irradiation (Table 3). In further experiments, *cis*-oct-4-ene isomerised less than 1% after 24 min and *trans*-oct-4-ene about 2% in 23 min.

(*Received* 4 *January* 1984; *accepted* 9 *May* 1984)

Abstract—A Cu(II) complex has been prepared with *N*-cyano-*N'*-methyl-*N''*-[2-{(5-methyl-1*H*-imidazol-4-yl)-methylthio}ethyl]guanidine, cimetidine (CM), at 1 : 3 metal to ligand ratio with the formula $Cu(CM)_2(ClO_4)_2$. Magnetic moment, IR, diffuse reflectance and EPR spectra of this compound have been recorded and discussed. The structure of $Cu(CM)_2(ClO_4)_2$ has been determined by X-ray crystallography and refined to $R = 0.042$ for 1265 observed reflexions. Cimetidine acts as a bidentate ligand through N(2) and S atoms. Cu^{2+} ions are six coordinated with a distorted octahedral environment. The cation and the perchlorate ions are linked by N—H . . . O, hydrogen bonds.

Cimetidine (CM) which has been widely studied as histamine H_2-receptor antagonist[1,2] has the structure:

and may be regarded as being composed of three main structural moieties: 4,5-disubstituted imidazole, cysteamine and the *N*-cyanoazomethine derivative. Cimetidine can act either as a bidentate ligand by formation of a 5-membered ring through N (imidazole) and S or as a tridentate ligand by coordination through N (imidazole), S and the N atom from the nitrile group.

An extensive literature exists on the metal complexes of imidazole.[3,4] mercapto-[5] and cyano[6,7]-type ligands. The study of these compounds is rapidly expanding owing to the fact that the interaction between such ligands and metal ions plays an important role in a variety of biological systems.[8]

Patel *et al.*[9] and Güven *et al.*[10] have carried out a colorimetric determination of cimetidine based on complex formation with Cu(II) acetate; however, no characterization of this complex has been reported.

It should be emphasized that complex formation between metal ions and active drugs could modify the therapeutic action of the latter.

* Author to whom correspondence should be addressed.

Our work reports the preparation, spectral and crystal structure determination of the copper(II) complex of cimetidine.

EXPERIMENTAL

Preparation of the complex

A methanolic solution of cimetidine (7.5 mmol in 50 cm^3) was slowly added to a stirred clean methanolic solution of $Cu(ClO_4)_2$ (3 mmol in 20 cm^3). A green solution was obtained; on keeping this solution open to the atmosphere at room temperature, green crystals separated within 24 h. The crystals were washed with methanol and stored under vacuum. A yield of 95% of green crystals that melt at 203°C was recovered.

Single crystals suitable for X-ray diffraction were grown in gel media by the standard technique.[11]

Analyses

The composition of the compounds was determined as follows: copper volumetrically by the iodide–thiosulphate method and C, H, N, and Cl were carried out by an elemental analyzer M.O.V. Carlo Erba.

Found: C, 31.80; H, 4.36; N, 21.93; Cu, 8.21; Cl, 9.27%. Calc. for $Cu(C_{10}H_{16}SN_6)_2(ClO_4)_2$: C, 31.29; H, 4.17; N, 21.91; Cu, 8.28; Cl, 9.24%.

Molar conductances in aqueous solution were measured using a Radiometer CDC 304 electrode (cell constant 1.0 cm) in conjunction with a radiometer CDM 83 conductivity bridge.

Spectroscopic measurements

IR spectra were taken on a Perkin–Elmer model 577 spectrophotometer as Nujol mulls (below 400 cm^{-1}) and KBr discs.

X-band EPR spectra of powder samples were recorded at room temperature on a JEOL MES-3X spectrometer. The microwave frequency was determined using DPPH as a reference and the magnetic field calibrated with a Newport Instruments NMR magnetometer.

Solid reflectance spectra were made with a Perkin–Elmer Hitachi 200 spectrophotometer, with reflectance attachment fitted.

Magnetic susceptibility measurements were made by the Gouy method with $[Ni(en)_3]S_2O_3$ as calibrant.[12]

Diamagnetic corrections were estimated from the Pascal constants.[13]

X-ray analysis

Crystal data are: $Cu(C_{10}H_{16}N_6S)_2(ClO_4)_2$, $M_r = 767.12$, $D_x = 1.51$ g cm^{-3}, monoclinic, $P2_1/c$, $a = 12.306(3)$, $b = 8.576(3)$, $c = 15.995(4)$ Å, $\beta = 94.48(2)°$, $V = 1683(1)$ $Å^3$, $Z = 2$, $\lambda(\text{Mo-}K_\alpha) = 0.71069$ Å, $\mu(\text{Mo-}K_\alpha) = 9.9$ cm^{-1}. Four-circle diffractometer, graphite monochromator, $\omega/2\theta$ scan, $\theta_{max} = 30°$, 4838 independent reflexions, 1265 observed with $I > 3\sigma(I)$, no crystal decomposition, no absorption corrections. Scattering factors[14] for neutral atoms and anomalous dispersion corrections for Cl, S and Cu. Structure solution with MULTAN,[15] anisotropic refinement[16] with full-matrix least-squares, unit weights, H-atoms found on a difference map and included in the refinement as isotropic fixed contribution. Final disagreement indices are $R = 0.042$ and $wR = 0.046$.

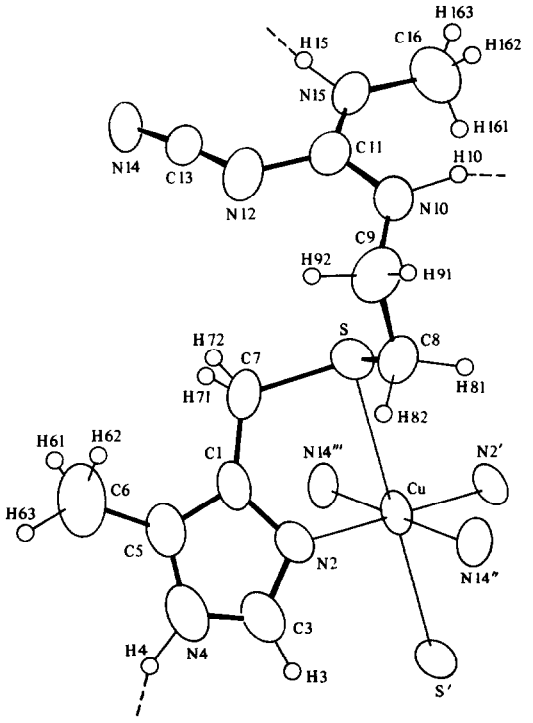

Fig. 1. Perspective drawing[17] of the cimetidine molecule together with the Cu^{2+} environment. The metal atom lies on a symmetry centre. For symmetry codes, see Table 2. Thermal ellipsoids at the 50% level. Dashed lines represent the hydrogen bonds with the perchlorate group.

* Atomic coordinates, thermal parameters, full lists of bond lengths and angles, and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS

X-ray analysis

Figure 1 shows a perspective drawing of the molecular structure. The perchlorate group is not shown. The distribution of bond lengths and bond angles (Table 1) indicate some degree of electronic delocalization (Fig. 2) around Cu(II) and within the pentagonal ring, which does not deviate significantly from planarity.

The Cu^{2+} ions, which lie on centres of symmetry, are six coordinated from two chelating (S and imidazole N) and two cyanonitrogen atoms from neighbouring molecules. The geometrical features around Cu^{2+} are in Table 1.

The cimetidine molecules are connected to the perchlorate groups by N—H ... O (ClO_4) hydrogen bonds (Table 2). One of the oxygen atoms of the ClO_4^- group, O(3), is not involved in the hydrogen bonds and shows the smallest distance Cl—O = 1.412(9) Å.

Molar conductance in 10^{-3} M aqueous solution at 25°C is 191 ohm^{-1} mol^{-1} cm^2. This value is slightly below the range expected for 1:2 electrolytes,[19] probably due to H-bond formation

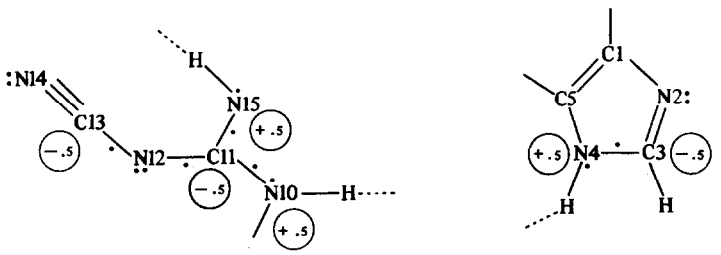

Fig. 2. Major electronic distribution according to Linnett's[18] model in two parts of the cimetidine molecule.

Table 2. Hydrogen bonds: ESDs in parentheses

between ClO_4^- and cimetidine, as shown by X-ray data.

IR spectra

A comparison of the IR spectrum of the ligand with those of the complex reveals the following important features. The IR spectrum of the complex shows three well-characterized bands located at 3360, 3280 and 3160 cm^{-1} assigned to the stretching vibrations of the N—H group. In the ligand, however, only two bands appeared at 3220 and 3140 cm^{-1}, which might be due to the presence of hydrogen bonds in the complex.[20] This is consistent with the proposed structure for X-ray. The —C≡N stretching band in the complex is found at 2200 cm^{-1}, this band appears slightly shifted compared to the corresponding vibration in free ligand. This is in agreement with the coordination of this group.[21] The peaks at 1582 and 1451 cm^{-1} of imidazole group assigned to the antisymmetric and symmetric C=N—C=C stretching vibration respectively are shifted to 1605 and 1440 cm^{-1} in the complex which indicates the involvement of this group in the coordination.[22] The complex shows two bands at 1095 and 630 cm^{-1} which supports a T_d symmetry for ClO_4^- groups.[23] The C—S stretching vibration which in the free ligand appears at 680 cm^{-1} is shifted to 710 cm^{-1}.

The broad band at 300 cm^{-1} may be assigned to M—S[5] and M—N[24] (nitrile) stretching vibration. The band at 260 cm^{-1} can be assigned to νM—N (imidazole).[25]

The EPR spectrum obtained from a solid sample shows the parallel component (at about 2.20) overlapping the perpendicular one ($g_\perp = 2.08$). The fact that this value is greater than 2.04 are in good agreement with the values expected for copper in an elongated tetragonal octahedral environment.[26]

The electronic spectrum of the compound in the visible region shows a band at 16,000 cm^{-1} with a shoulder at about 12,000 cm^{-1} and a band at 27,030 cm^{-1}. The first band and shoulder may be assigned to *d–d* transitions of Cu(II) ions. The last band is a charge transfer transition.

The magnetic behaviour was studied at room temperature. The μ_{eff} value is 2.11 B.M.

The *d–d* spectrum[27] and the magnetic moment confirms a pseudooctahedral stereochemistry around Cu(II).

THE EXTRACTION OF MOLYBDENUM(VI) FROM PERCHLORIC ACID SOLUTION BY TRI-*n*-BUTYL PHOSPHATE

J. J. CRUYWAGEN* and T. RYPSTRA
Department of Chemistry, University of Stellenbosch, Stellenbosch 7600, Republic of South Africa

(*Received* 13 *March* 1984; *accepted* 9 *May* 1984)

Abstract—The extraction of molybdenum(VI) by tri-*n*-butyl phosphate (TBP) from 1 M $NaClO_4$ medium has been investigated as a function of molybdenum concentration (10^{-4}–10^{-2} M) in the pH_c range 0.7–3.2. At molybdenum(VI) concentration $\gtrsim 5 \times 10^{-4}$ M a polynuclear species, which has been identified as the $Mo_6O_{19}^{2-}$ ion, predominates in the TBP phase. At very low molybdenum(VI) concentration ($< 10^{-4}$ M) mononuclear species predominate. A conditional formation constant for the hexanuclear species in the organic phase (0.15 M $HClO_4$) has been determined, i.e. $K = (1.3 \pm 0.4) \times 10^{20}$.

Depending on the conditions, molybdenum(VI) is extracted quite effectively by tributyl phosphate (TBP) from aqueous acid solutions.[1–7] At relatively high hydrogen ion concentrations cationic species of molybdenum(VI) occur which can form extractable complexes with suitable ligands. For example, large distribution ratios are observed when molybdenum(VI) is extracted from $\gtrsim 3$ M hydrochloric acid solution and it has been shown that the major species in the TBP phase is the solvated chloro-complex $MoO_2Cl_2 \cdot 2TBP$.[1–3] At pH ~ 1.5 conditions are again relatively favourable for the extraction of molybdenum(VI) provided its concentration is not too low.[2,5,7] The extraction behaviour of molybdenum(VI) at this pH, however, is very complex, because various mono- and polynuclear species, cationic as well as anionic, can exist in simultaneous overlapping equilibria. At very high dilution (~ 5×10^{-5} M) monomeric molybdic acid, $Mo(OH)_6$, is the predominant species, in equilibrium with the ions $HMoO_4^-$ and $Mo(OH)_5(H_2O)^+$.[8] The polynuclear species which occur at higher molybdenum(VI) concentrations in the pH range 1–3 are still incompletely characterised. Interpretation of the distribution data is therefore very difficult and the extraction system not well understood. Although it has been concluded[3,7,9] that polymeric species are extracted into TBP, virtually nothing is known about the nature of these species. The situation for other solvents is much the same as that for TBP.[10]

In this study the distribution of molybdenum(VI) between TBP and perchloric acid has been determined as a function of both pH and molybdenum(VI) concentration. The UV spectra of equilibrated TBP phases at various acid and molybdenum concentrations have also been measured. The objective was to obtain data that could lead, firstly, to a better understanding of the extraction system and, secondly, to the identification of molybdenum(VI) species in the TBP phase.

EXPERIMENTAL

All reagents were of analytical grade (Merck p.a.) and solutions were prepared with de-ionised distilled water. Sodium molybdate, $Na_2MoO_4 \cdot 2H_2O$, was purified and recrystallised as described by Sasaki and Sillén.[11] The stock solution, standardised gravimetrically by precipitation of molybdate as $PbMoO_4$,[12] was kept in a polythene bottle. Sodium perchlorate solution was prepared from recrystallised $NaClO_4$ and standardised by drying samples to constant weight at 130°C. Perchloric acid was standardised indirectly against potassium hydrogen phthalate by titration with sodium hydroxide. The TBP used was purified as described elsewhere.[13]

Equilibrations were carried out by shaking equal volumes (usually 10 cm^3) of "wet" TBP and aqueous solution in a centrifuge tube for 18 h in a constant temperature room at 25 ± 1°C. The time needed for equilibration depended on both molybdenum and acid concentration. Preliminary experiments

* Author to whom correspondence should be addressed.

showed that under certain conditions at least 6 h were needed to establish equilibrium. The molybdenum concentration in each phase was determined by atomic absorption[14] using a Varian Techtron Model AA-120 instrument in conjunction with a Vitatron UR400 recorder. An air–acetylene flame was used. The lamp current was set at 5 mA and absorbances were measured at 313.3 nm. A series of standard solutions were prepared for each phase. The molybdenum concentrations of the standard solutions were checked colorimetrically by the Tiron method.[15]

The equilibrium concentration of perchlorate ions in the aqueous phase was kept constant at 1.0 M, using sodium perchlorate. Since the extraction of perchloric acid and sodium perchlorate is interdependent and a function of the concentration of their ions in solution the initial perchlorate ion concentration had to be varied with variation in pH to maintain a constant perchlorate ion concentration in the aqueous phase. The hydrogen ion concentration of the aqueous phase was measured to within 0.01 pH units with a Metrohm E300 pH meter using a glass and calomel combination electrode. The potassium chloride solution of the electrode was replaced by a saturated sodium chloride solution to prevent precipitation of potassium perchlorate. Solutions with the compositions (0.10 M $HClO_4$ + 0.90 M $NaClO_4$), (0.01 M $HClO_4$ + 0.99 M $NaClO_4$) and (0.001 M $HClO_4$ + 0.999 M $NaClO_4$) were used as standards for $-\log[H^+]$ 1.0, 2.0 and 3.0 respectively. For brevity $-\log[H^+]$ will be represented by pH_c.

Absorption spectra of TBP phases were measured with a Zeiss Model PMQII spectrophotometer, using calibrated quartz cuvettes of suitable pathlengths ranging from 0.01 to 2.00 cm. The cuvette compartment was kept at 25°C by circulating water from a thermostat bath.

RESULTS AND DISCUSSION

Distribution behaviour of molybdenum(VI)

The results of the extraction of molybdenum(VI) by TBP from 1 M perchlorate solution in the pH_c range 0.7–3.7 are shown in Fig. 1. The initial molybdenum(VI) concentration in the aqueous phase was varied from 10^{-4} to 10^{-2} M. At the lowest molybdenum concentration, 1×10^{-4} M, where polynuclear species are present only in very small amounts,[9] the extraction is rather poor. With increase in concentration, condensation of molybdenum(VI) becomes significant and the extraction at $pH_c < 3$ improves. This shows that one or more

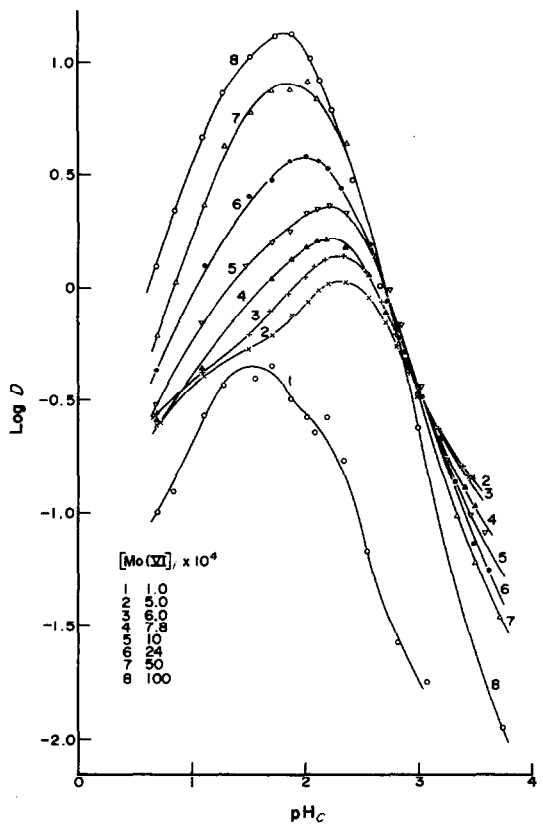

Fig. 1. The distribution of molybdenum(VI) between TBP and aqueous perchloric acid as a function of pH_c at various initial molybdenum(VI) concentrations.

polynuclear species are extracted into the TBP phase. Further, from the increase in the distribution ratio, D, with increase in molybdenum(VI) concentration at $pH_c \lesssim 3$ it may be concluded that the weight average degree of condensation is greater in the TBP phase than in the aqueous phase.[16] At $pH_c \gtrsim 3$ just the opposite applies; D decreases with increasing molybdenum(VI) concentration. In this pH_c region the major condensed species are the hepta- and octamolybdate ions[17] $Mo_7O_{24}^{6-}$, $HMo_7O_{24}^{5-}$, $H_2Mo_7O_{24}^{6-}$ and $Mo_8O_{26}^{4-}$, which apparently do not extract. As the molybdenum(VI) concentration increases, the relative concentrations of these species increase, thereby causing a decrease in extraction.

It is seen that all the distribution curves show a maximum. The pH_c at which maximum extraction occurs, depends on the molybdenum(VI) concentration, a feature which again illustrates the complexity of the extraction system. At molybdenum(VI) concentrations above $\sim 5 \times 10^{-4}$ M the TBP phase showed a distinct yellow colour which happened to be most intense at the pH_c values where maximum extraction takes place. This pointed to the presence of a species predominating in the

TBP phase but which does not occur in significant concentrations in the aqueous phase.

Species in the TBP phase

The yellow species in the organic phase could be identified from its UV spectrum. The spectrum of the yellow molybdenum containing TBP phase (Fig. 2) showed three prominent absorption bands at wavelengths 222, 257 and 325 nm which is characteristic of the hexamolybdate ion $Mo_6O_{19}^{2-}$. Although this polyion does not appear to exist in significant concentrations in aqueous solution it can be prepared[18] by precipitation from aqueous solution as the yellow compound $[(C_4H_9)_4N]_2Mo_6O_{19}$. This compound, however, was found to be insoluble in TBP but its UV spectrum can be measured by dissolving it in acetonitrile.[19] The molar absorptivities measured at wavelengths 222, 257 and 325 nm for the hexameric ion in acetonitrile namely 23.1×10^3, 13.9×10^3 and 6.8×10^3 agreed satisfactorily (within 5%) with those obtained for the yellow molybdenum(VI) species extracted by TBP. The possibility of course still exists that on dissolution in acetonitrile a conversion of the hexameric ion to some other polyanion might occur and that the observed peaks belong to this polyanion. This was ruled out by measuring the spectrum of a very thin compressed transparent disk of the solid $[(C_4H_9)_4N]_2Mo_6O_{19}$ mixed with potassium chloride. The spectrum of the solid was practically identical to that of the hexameric ion in solution.

A systematic survey of the spectra of TBP extracts in the pH_c range 0.7–3.7 at various molybdenum(VI) concentrations indicated (Figs 2 and 3) that no other polynuclear species were present in significant amounts. If such ions do extract they are converted to the more stable (in TBP) hexanuclear species. At very low molybdenum(VI) concentrations ($< 1 \times 10^{-4}$ M) the absorption bands at wavelengths 222, 257 and 325 are practically absent and the spectrum (Fig. 2) resemble that of the mononuclear species $[Mo(OH)_5(H_2O)]^+$ in aqueous solutions.[8]

Only when molybdenum(VI) is extracted from an aqueous phase of pH_c lower than ~ 0.7 did the spectra of the TBP phase clearly indicate the presence of another polynuclear species. For example when the pH_c of the aqueous phase is 0.53 (total acid concentration in the organic phase 0.56 M) and the molybdenum(VI) concentration in the TBP phase relatively low, i.e. $\sim 1.5 \times 10^{-3}$ M, a shoulder in the spectrum is observed at ~ 246 nm. Since in aqueous solution, dimeric cationic species show a strong absorption band at this wavelength,[20] it may be concluded that a dimeric cation, most likely the singly charged ion $HMo_2O_6^+$, is extracted as an ion pair $HMo_2O_6^+ClO_4^-$(org), at low pH_c. In fact when a TBP solution, containing the yellow hexanuclear species, is mixed with another strongly acidified TBP solution (0.7 M in $HClO_4$) the yellow colour completely disappears after some time and the spectrum of this solution then showed only the strong absorption band at 246 nm characteristic of the dinuclear cations.

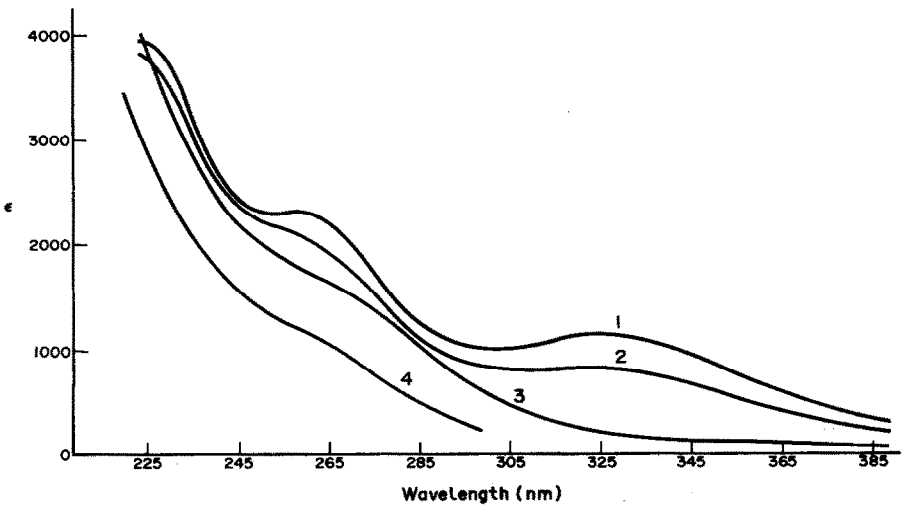

Fig. 2. UV absorption spectra of TBP extracts of molybdenum(VI) at $pH_c = 2.0$: 1, $[Mo(VI)]_{org} = 1.98 \times 10^{-3}$ M; 2, $[Mo(VI)]_{org} = 2.48 \times 10^{-4}$ M; 3, $[Mo(VI)]_{org} = 5.7 \times 10^{-5}$ M; 4, spectrum of $[Mo(OH)_5(H_2O)]^+$ in aqueous solution.[8]

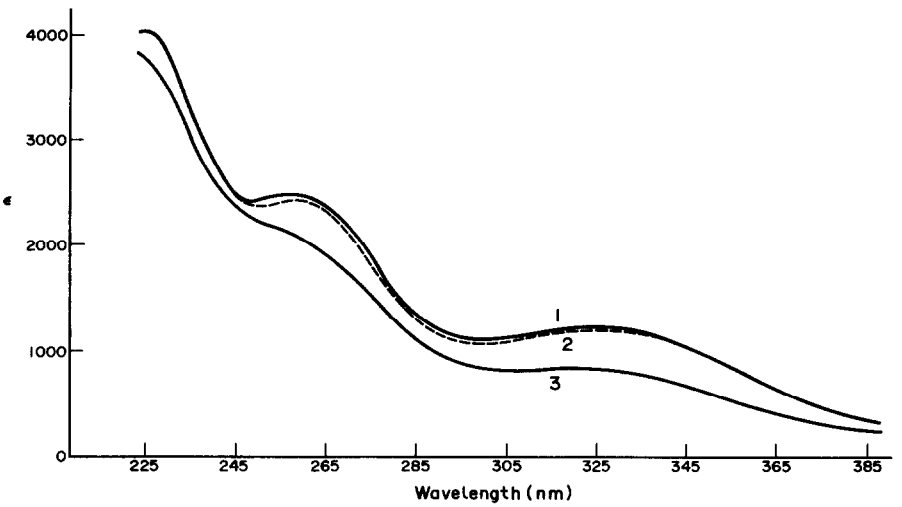

Fig. 3. UV absorption spectra of TBP extracts of molybdenum(VI) at different pH_c values: 1, $[Mo(VI)]_{org} = 4.61 \times 10^{-2}$ M; $pH_c = 1.2$; 2, $[Mo(VI)]_{org} = 4.27 \times 10^{-3}$ M; $pH_c = 2.65$; 3, $[Mo(VI)]_{org} = 2.48 \times 10^{-4}$ M; $pH_c = 2.00$.

Equilibria in the TBP phase

From the results discussed earlier it is evident that the distribution behaviour of molybdenum(VI), in the pH_c range 0.7–3.2 at concentrations above $\sim 10^{-4}$ M, is to a large extent governed by the stability of the $Mo_6O_{19}^{2-}$ ion in the TBP phase. The slight shoulder at $pH_c \sim 2$, shown by the distribution curve for molybdenum(VI) concentration 1×10^{-4} M (Fig. 1) suggests that hexamolybdate ions already start to form at extremely low concentration in the TBP phase. To obtain a quantitative measure of the thermodynamic stability of the hexanuclear species in the TBP phase a conditional equilibrium constant for its formation at perchloric acid concentration 0.15 M was determined spectrophotometrically. A concentration of 0.15 M in perchloric acid is obtained in the TBP phase when the aqueous phase has a pH_c of 2.0 and a perchlorate ion concentration of 1.0 M after equilibration. The conditional equilibrium constant, K, is defined as follows:

$$K = C_h/C_m^6, \qquad (1)$$

where C_h and C_m denote the concentrations of the hexanuclear and mononuclear species respectively in the TBP phase. It seems reasonable to assume that the hexamolybdate is present as an ion pair in the organic phase, tentatively formulated as the complex $[H^+_{(org)}]_2[Mo_6O^{2-}_{19(org)}]$. At relatively high and constant perchloric acid concentration the possible ionisation of the complex can be ignored. Very little is known about the nature of the monomeric molybdenum(VI) species in TBP, but the spectrum of an extremely dilute (5×10^{-5} M) solution at perchloric acid concentration 0.15 M is very similar to that of $[Mo(OH)_5(H_2O)]^+$ in aqueous solution (Fig. 2). Presumably this species is extracted as the ion pair $[Mo(OH)^+_{5(org)}][ClO^-_{4(org)}]$.

The molar absorptivity, ε, of a solution containing the above-mentioned species is given by:

$$\varepsilon = \frac{A}{Bd} = \frac{\varepsilon_m + \varepsilon_h K C_m^5}{1 + 6KC_m^5}, \qquad (2)$$

where A is the absorbance measured in a cuvette of pathlength d cm; B is the total molybdenum(VI) concentration: ε_m and ε_h are the molar absorptivities of the monomeric and hexanuclear species respectively.

The molybdenum(VI) concentration was varied over the range 2×10^{-2}–1×10^{-4} M by appropriate dilution of a TBP extract obtained at $pH_c = 2.0$. The perchloric acid concentration of the TBP used for dilution was 0.15 M. The absorbance of the various solutions was measured at wavelength 325 nm and used to solve eqn (2) employing a package computer programme BMDX85.[21] Provision was made in a subroutine for an iterative computation of C_m from the total molybdenum(VI) concentration, B, for each data point using the equation:

$$B = C_m + 6KC_m^6. \qquad (3)$$

The values for the parameters thus computed were:

$$K = (1.3 \pm 0.4) \times 10^{20}, \quad \varepsilon_m = 0,$$

$$\varepsilon_h = (7.3 \pm 0.1) \times 10^3.$$

The value of zero for ε_m is in agreement with the

practically negligible absorption of the monomeric species in aqueous solution[8] at 325 nm. The large value of K makes it impossible in practice to measure the absorbance of a TBP solution containing practically exclusively monomeric species. For example, using K, it can be calculated that, at a concentration as low as 5×10^{-5} M, approximately 10% of the molybdenum(VI) is already in the hexanuclear state.

The remarkable stability of the $Mo_6O_{19}^{2-}$ in TBP, in contrast with its practical absence in aqueous solution can be ascribed to its very compact structure and low charge density. The structure[22] can be visualised as comprising of six MoO_6 octahedra arranged in such a way that they all share a common vertex, resulting in an octahedral array of molybdenum atoms.

The compactness of the hexamolybdate ion's structure is most probably also the reason for its exceptional kinetic stability in TBP. For example, on dilution depolymerization of the hexamer takes place very slowly and equilibrium is established only after about 10 h. Even if the TBP phase is equilibrated with strongly alkaline solution, it can take up to 6 h before the hexamer is completely converted to MoO_4^{2-}. Its formation is also rather slow. Only under conditions where the hexamolybdate did not occur in the TBP phase had extraction equilibrium been established within a few minutes.

CONCLUSION

The distribution behaviour of molybdenum(VI) between TBP and aqueous perchlorate solution in the pH_c range 0.7–3.0 is essentially determined by the remarkable thermodynamic and kinetic stability in the TBP phase of a polynuclear ion which has been identified as the hexamolybdate ion, $Mo_6O_{19}^{2-}$. These findings provide a much better understanding not only of this particular extraction system but also of various other molybdenum(VI) extraction systems previously investigated.[3,5,7,10]

For example, when 1×10^{-3} M molybdenum(VI) in perchloric acid solution is equilibrated with propylene carbonate,[23] the shape of the extraction curve obtained is similar to that of curve 5 in Fig. 1. The spectrum reported for the propylene carbonate phase showed three absorption maxima at the wavelengths now known to be characteristic of the $Mo_6O_{19}^{2-}$ species. However, an incorrect assumption about the equilibria in the aqueous phase led to the conclusion that the condensed species in the organic phase consisted of 13 molybdenum atoms. In view of the results of the present investigation the possibility of studying by solvent extraction the hitherto incompletely characterized molybdenum(VI) equilibria in aqueous solution in the pH_c range 1–3 now appears to be very promising. Such an investigation is currently being conducted in this laboratory.

Finally, considering the kinetic stability of $Mo_6O_{19}^{2-}$ in TBP, an interesting possibility for the separation of molybdenum(VI) from other elements by solvent extraction presents itself. Molybdenum(VI) can be extracted by TBP from an aqueous mixture at $pH_c \sim 2$. Other species that co-extract can be separated by rapid back-extraction at a suitable pH, leaving behind in the TBP phase most of the molybdenum(VI) as the stable hexamolybdate. The molybdenum(VI) can then be recovered completely as MoO_4^{2-} by equilibrating the TBP phase for some time with an alkaline solution.

SYNTHESIS AND CHARACTERIZATION OF NEUTRAL LIGAND-BRIDGED BINUCLEAR DIALKYLCOBALT(III) COMPLEXES

ALBERT W. HERLINGER* and K. RAMAKRISHNA
Department of Chemistry, Loyola University of Chicago, Chicago, IL 60626, U.S.A.

(*Received* 22 *July* 1983; *accepted in revised form* 22 *May* 1984)

Abstract—A series of neutral ligand-bridged binuclear dialkylcobalt(III) chelates has been prepared. Chelate systems based on monoanions of dimethylglyoxime (dmgH) and cyclohexanedionedioxime (chdH) and dianions of bis(acetylacetone)ethylenediimine (BAE) and bis(salicydaldehyde)ethylenediimine (SALEN) are employed. Symmetric complexes RCo(chel)LCo(chel)R, where R = CH_3 or CH_2Cl and chel = dmgH, chdH, BAE or SALEN, were obtained by addition of a bidentate ligand L to a solution of the anhydrous RCo(chel) complex. The bridging ligands were pyrazine (pyz), 4,4′-bipyridine (bpy), 4,4′-trimethylenebipyridine (tbpy), *p*-dithiane (dth) and 1,2-bis(diphenylphosphino)ethane (diphos). A single step direct synthesis of the dialkyl complexes was also achieved by reacting a cobalt(I) chelate, prepared *in situ*, with the appropriate alkyl halide in the presence of the bridging ligand. The isolated products were characterized by elemental analysis, magnetic susceptibility, ^1H NMR, and UV–visible spectroscopy. The water molecule *trans* to the alkyl group in RCo(chel)OH_2 complexes may be displaced by bidentate ligands. Depending upon reaction stoichiometry, mononuclear RCo(chel)L or binuclear RCo(chel)LCo(chel)R compounds are obtained. The mononuclear complexes function as ligands and provide a convenient synthetic route to unsymmetric bridged complexes RCo(chel)LCo(chel′)R. Reaction of bis(acetylacetonato)cobalt(II) with $CH_3Co(dmgH)_2$tbpy yields the ligand-bridged compound $CH_3Co(dmgH)_2$tbpy$Co(acac)_2$. Magnetic susceptibility measurements establish the paramagnetic character of this mixed-valent complex. The effective magnetic moment is 4.84 B.M. at 19.2°C.

The study of cobalt chelates as models for vitamin B_{12} and B_{12} coenzyme is well documented.[1–3] Special aspects of the chemistry of these compounds such as unusually stable cobalt–carbon bonds and remarkable rapid ligand substitution reactions make them interesting in their own right. Ligand-bridged complexes are of particular interest in view of the role they play as reaction intermediates in inner-sphere electron transfer processes.[4] Reports of cyano- and azido-bridged anionic organocobaloximes,†[5] neutral cyano-, thiocyanato- and selenocyanato-bridged dicobaloximes,[6] and doubly alkylated binuclear cobalt complexes with bridging carbonyls[7] have appeared. To our knowledge, however, no such compounds containing long chain non-linear bridging ligands have been prepared.

We wish to report here the synthesis and characterization of neutral ligand-bridged binuclear dialkylcobalt(III) compounds containing pyrazine (pyz), 4,4′-bipyridine (bpy), 4,4′-trimethylenebipyridine (tbpy), *p*-dithiane (dth) or 1,2-bis(diphenylphosphino)ethane (diphos) as the bridging ligand L. The bridging groups were chosen so as to include a variety of ligand types, i.e. nitrogen heterocycles with extended π-electron systems, a nitrogen heterocycle with conjugated π-systems separated by a saturated alkyl chain, a saturated sulfur heterocycle, and a bulky phosphine. Except for diphos, the ligands which have two donor sites are restricted by their geometry to function either as a monodentate or a bridging ligand. Both symmetric RCo(chel)LCo(chel)R and unsymmetric RCo(chel)LCo(chel′)R complexes (where R = CH_3 or CH_2Cl and chel = dmgH, chdH, BAE or SALEN) have been prepared. The methods used to prepare the ligand-bridged complexes appear quite general and

† Cobaloxime is the trivial name for complexes with the bis(dimethylglyoximato)cobalt unit, $Co(dmgH)_2$.

provide synthetic routes to a series of complexes in which portions of the complex may be systematically varied. Such a series is amenable to a study of structure–reactivity relationships and some of our preliminary findings have been reported.[8]

EXPERIMENTAL

Spectral studies

Electronic spectra of the complexes were recorded in the 200–550 nm region using a Perkin–Elmer Coleman 575 spectrometer. The spectra were obtained from dry CH_2Cl_2 solutions that were approximately 5×10^{-5} M in complex.

^{1}H NMR spectra were recorded on a Varian A-60A spectrometer operating at 36°C or a Varian EM-360 spectrometer operating at 28°C. The spectra of the diamagnetic complexes were obtained from d_1-chloroform solutions. In one case, d_6-DMSO was added to increase the solubility of the SALEN complex which is only slightly soluble in $CDCl_3$. All spectra were referenced to TMS as internal standard.

Magnetic susceptibility measurements

Magnetic susceptibility measurements for paramagnetic compounds were obtained at room temperature by the Gouy method using mercury tetrathiocyanocobaltate(II) as calibrant.[9] The apparatus employed a Sartorius 2442 electrobalance and an Alfa model 7500 electromagnet operating at 10,000 G. Molar susceptibilities were corrected for diamagnetic contributions of all atoms with Pascal's constants and converted to values expressed in Bohr magnetons using the standard equation:

$$\mu_{eff} = 2.84(\chi_m T)^{1/2} \text{ B.M.},$$

where T is the absolute temperature.[9]

Elemental analysis

Satisfactory elemental analyses were obtained for all compounds. Analysis for carbon, hydrogen and nitrogen were performed by Micro-Tech Laboratories, Inc. (Skokie, IL).

Preparation of complexes

All reagents were purchased from Aldrich Chemical Co. and used without further purification. The Schiff bases BAE and SALEN were prepared by literature methods.[10] Solutions containing alkylcobalt compounds were protected from direct exposure to light. Solvents were refluxed over P_2O_5 and distilled under dry N_2 prior to use.

The complexes

$$CH_3Co(dmgH)_2OH_2,^{11}$$

$$CH_2ClCo(dmgH)_2OH_2,^{11}$$

$$CH_3Co(SALEN)OH_2^{12}$$

and

$$CH_3Co(BAE)OH_2^{13}$$

were also prepared by methods reported in the literature. These complexes were dehydrated by heating *"in vacuo"*. The BAE and SALEN aquo complexes yield monomeric five coordinate complexes when heated at ~80°C for 12 h. By contrast, the dmgH complexes require heating to ~110°C and yield six coordinate dimeric compounds.[14]

The syntheses for

$$CH_3Co(dmgH)_2L,$$

$$CH_3Co(BAE)L,$$

$$CH_3Co(SALEN)L$$

for L = py, bpy and tbpy were by procedures published for analogous compounds.[9] This involves displacement of the axial water molecule from the corresponding aquo complex by stoichiometric quantities of the base L.

$RCo(dmgH)_2LCo(dmgH)_2R$

Complexes of this formulation were prepared by mixing equimolar amounts of the bridging ligand L and the $[RCo(dmgH)_2]_2$ dimer in dichloromethane solutions for R = CH_3 or CH_2Cl and L = dth, pyz, bpy, tbpy or diphos. In a typical synthesis 0.26 g (0.42 mmol) of $[CH_3Co(dmgH)_2]_2$ and 0.051 g (0.42 mmol) of *p*-dithiane were placed in a dry Schlenk reaction vessel and 50 cm^3 of freshly distilled CH_2Cl_2 was added under a purge of dry dinitrogen. The reaction mixture was stirred at room temperature until all of the reactants dissolved. Addition of 40 cm^3 of anhydrous ether caused the yellow complex to precipitate from solution. The product was collected by filtration, washed with anhydrous ether, and dried *in vacuo* at room temperature. The yield was approximately 90%.

The diphos bridged complexes were prepared by this procedure except that product isolation was affected by evaporation of the reaction mixture to dryness. Satisfactory elemental analyses were obtained for all reported compounds. These results are reported in Table 1.

Table 1. Analytical data

Complex	% C (calc.)	% H (calc.)	% N (calc.)
$CH_3Co(dmgH)_2dthCo(dmgH)_2CH_3$	36.20 (36.27)	5.71 (5.77)	15.44 (15.38)

$CH_3Co(dmgH)_2tbpyCo(BAE)CH_3$	52.63 (52.49)	6.56 (6.51)	14.03 (14.05)
$CH_3Co(dmgH)_2tbpyCo(acac)_2$	50.38 (50.60)	5.72 (5.92)	11.07 (11.06)

$CH_3Co(BAE)bpyCo(BAE)CH_3$

The synthesis of the compound was carried out in a darkened room under dry conditions using a Schlenk reaction vessel under a purge of N_2. Typically 0.31 g (1.04 mmol) of $CH_3Co(BAE)$ and 0.10 g (0.52 mmol) of 4,4′-bipyridine were dissolved in 30 cm^3 of freshly distilled CH_2Cl_2 with stirring. After several minutes the solution was evaporated to dryness and a dark brown solid isolated. The solid was suspended in 50 cm^3 of anhydrous ether, collected by filtration, washed with anhydrous ether and air dried.

$CH_3Co(SALEN)bpyCo(SALEN)CH_3$

In a typical synthesis, 0.50 g (1.47 mmol) of anhydrous $CH_3Co(SALEN)$ and 0.142 g (0.735 mmol) of 4,4′-bipyridine were dissolved in 30 cm^3 of freshly distilled CH_2Cl_2 under a dry N_2 purge. After stirring for several minutes, the resulting dark red solution was evaporated to dryness. The red powder was suspended in absolute ethanol and collected by filtration. The isolated product was washed with anhydrous ether and dried *in vacuo* at room temperature.

$CH_3Co(chdH)_2tbpyCo(chdH)_2CH_3$

This procedure closely follows that reported for the synthesis of [RCo(BAE)],[2] [RCo(SALEN)][3] and [$RCo(dmgH)_2L$] complexes.[1,11] The method permits the direct preparation of symmetric ligand-bridged binuclear dialkylcobalt(III) complexes. All [$RCo(dmgH)_2LCo(dmgH)_2R$] compounds reported in Table 1 were also obtained by this route. The method is particularly useful for the preparation of complexes for which the aquo complex required in the previously described syntheses is unobtainable. Our attempts to prepare the aquo isopropyl complex $C_3H_7Co(dmgH)_2OH_2$, for example, were unsuccessful. The ligand-bridged isopropyl complex $(C_3H_7)Co(dmgH)_2bpyCo(dmgH)_2(C_3H_7)$, however, can be readily obtained by this procedure.

In a typical synthesis, 0.50 g (3.5 mmol) of 1,2-cyclohexanedionedioxime and 0.42 g (1.8 mmol) of $CoCl_2 \cdot 6H_2O$ were placed in a Schlenk reaction vessel and 50 cm^3 of methanol was added under a N_2 purge. The mixture was stirred until the cobalt salt dissolved. An aqueous solution of 0.14 g (3.4 mmol) of NaOH and an ethanolic solution of 0.17 g (0.88 mmol) of 4,4′-trimethylenebipyridine were added to the reaction mixture. The mixture was cooled to −20°C and aqueous solutions containing 0.14 g (3.4 mmol) of NaOH and 0.03 g (0.8 mmol) of $NaBH_4$ were added while the stirring continued. Subsequently, 1.0 g (7.0 mmol) of CH_3I was added and the reaction mixture slowly returned to room temperature. The mixture was filtered, and upon addition of 200 cm^3 of H_2O to the filtrate orange-red crystals separate from solution upon standing. These were collected by filtration, washed with anhydrous ether, and dried *in vacuo* at room temperature. The yields based on $CoCl_2$ were generally 30–40%.

$CH_3Co(dmgH)_2tbpyCo(acac)_2$

For the preparation of this mixed-valent complex, 0.650 g (1.07 mmol) of $[CH_3Co(dmgH)_2]_2$ and 0.420 g (2.14 mmol) of 4,4′-trimethylenebipyridine were dissolved in 30 cm^3 of dry freshly distilled CH_2Cl_2 in a Schlenk reaction vessel under a purge of dry N_2. To this solution, 0.550 g (2.14 mmol) of anhydrous bis(acetylacetonato)cobalt(II), dissolved in 25 cm^3 of freshly distilled CH_2Cl_2 were added with stirring at room temperature. The solution was concentrated by means of a rotary evaporator and precipitation occurred. The yellow product was collected by filtration, washed with anhydrous

ether, and dried *in vacuo* at room temperature. The compound is air stable in the solid state, but slowly undergoes oxidation in solution.

$CH_3Co(dmgH)_2tbpyCo(BAE)CH_3$

This compound was prepared by essentially the method described above for the mixed-valent complex. $CH_3Co(dmgH)_2tbpy$ was prepared from the corresponding aquo complex by reaction with tbpy. A mixture of 0.60 g (1.2 mmol) of $CH_3Co(dmgH)_2tbpy$ and 0.35 g (1.2 mmol) of $CH_3Co(BAE)$ was placed in a Schlenk reaction vessel and 30 cm^3 of freshly distilled CH_2Cl_2 was added under a purge of N_2. The reaction mixture was stirred until all reagents dissolved. The solution was concentrated under reduced pressure and anhydrous ether added to induce precipitation. The yellow product was collected by filtration, washed with anhydrous ether, and dried *in vacuo* at room temperature.

RESULTS AND DISCUSSION

Syntheses

The syntheses of the ligand-bridged binuclear dialkylcobalt(III) compounds RCo(chel)LCo(chel)R for various combinations of akyl groups, equatorial chelate systems, and bridging ligands are described in the Experimental Section. One general method of preparation involves the addition of stoichiometric quantities of a suitable bidentate ligand to an anhydrous RCo(chel) complex. Alternatively, the bridged complex may be prepared from the aquo complex by ligand displacement with the bridging ligand. The dialkyl ligand-bridged compounds may also be obtained directly by reacting a cobalt(I) chelate, prepared *in situ*, with alkyl halides in the presence of the bridging ligand. All compounds are light sensitive, particularly in solution.

Alkyl groups are known to exert large *trans* effects in metal complexes.[15] This has been demonstrated in vitamin B_{12} derivatives[16] and cobaloxime analogues.[17] *Trans*-labilization by the alkyl group makes dehydration of $RCo(chel)OH_2$ complexes relatively facile and stable "ligand free" anhydrous $[RCo(dmgH)_2]_2$, RCo(BAE) and RCo(SALEN) compounds readily form. The dmgH complexes are dimeric and hexacoordinate in solution[14] while the BAE[2] and SALEN[3] complexes are monomeric and pentacoordinate. These "ligand free" materials provide a convenient synthetic route to hexacoordinate alkylcobalt(III) compounds since they exhibit Lewis acidity towards many ligands. Depending upon reaction stoichiometry, addition of bidentate ligands to the anhydrous complexes yields mononuclear RCo(chel)L or binuclear ligand-bridged compounds. The reactions proceed according to eqns (1) and (2):

$$RCo(chel) + L \rightarrow RCo(chel)L. \quad (1)$$

$$2RCo(chel) + L \rightarrow RCo(chel)LCo(chel)R. \quad (2)$$

The isolated mononuclear complexes have one donor site of a coordinated ligand which is not bound. Thus, mononuclear complexes may function as Lewis bases and provide a synthetic route to mixed-valent complexes and unsymmetric ligand-bridged complexes [RCo(chel)LCo(chel')R]. To illustrate the utility of the mononuclear complexes, the mixed-valent complex

$$[CH_3Co(III)(dmgH)_2(tbpy)Co(II)(acac)_2]$$

and the bridged complex

$$[CH_3Co(dmgH)_2(tbpy)Co(BAE)CH_3]$$

were prepared. The reaction scheme has the advantage of offering a common route to a variety of products using a common intermediate.

The axial position *trans* to the alkyl group in

$$[RCo(dmgH)_2X], \quad [RCo(BAE)X]$$

and

$$[RCo(SALEN)X]$$

complexes is labile to ligand substitution.[18] Simple ligand displacement reactions are restricted to this site since the equatorial ligand and the alkyl group are substitution inert under mild conditions. The property of having a single labile coordination site introduces an element of synthetic control in the reaction of $[RCo(chel)(H_2O)]$ complexes with potentially chelating ligands. The axial water molecule of these aquo complexes is easily displaced by bidentate ligands; and depending upon reaction stoichiometry, either mononuclear [RCo(chel)L] or ligand-bridged binuclear [RCo(chel)LCo(chel)R] complexes are obtained.

The final method of preparation of ligand-bridged dialkylcobalt complexes utilizes a strongly nucleophilic Co(I) species generated by pre-reduction of the Co(II) chelate with $NaBH_4$. The procedure is similar to that used to prepare $[RCo(dmgH)_2X]$,[1,11] [RCo(BAE)][2] and [RCo(SALEN)][3] complexes. The nucleophilicity of Co(I) in cobaloximes has been discussed, and it is generally assumed that the high energy $(e_g)^2$ electrons outside a $(t_{2g})^5$ core of the metal ion attack the electrophilic carbon of the alkyl halide.[19] The reaction is essentially oxidative-

addition of an alkyl halide to a d^7 metal complex. This method is particularly useful for the synthesis of [RCo(chel)LCo(chel)R] compounds for which the [RCo(chel)(H_2O)] precursor required in the ligand displacement route is difficult to prepare.

Characterization

The isolated products were characterized by elemental analysis, magnetic susceptibility, ^1H NMR and UV–visible spectroscopy. Analytical results for the compounds reported here are consistent with the indicated stoichiometries. The electronic spectra of the ligand-bridged binuclear dialkylcobalt(III) complexes and some related mononuclear complexes are reported in Table 2. The ^1H NMR spectral data reported in Table 3 indicate that, for the bidentate ligands used in this study, the [$RCo(dmgH)_2LCo(dmgH)_2R$] complexes are undissociated in chloroform solution. The measured magnetic susceptibility of the mixed-valent complex [$CH_3Co(dmgH)_2tbpyCo(acac)_2$] yields an effective magnetic moment of 4.82 B.M. at 19.2°C. The oxygen atoms of the acac ligands and a nitrogen atom from tbpy provide a square-pyramidal crystal field environment for the metal ion. Cobalt(II), in this configuration, should be in a high spin state. Magnetic moments for similar complexes have been observed in the 4.1–4.7 B.M.[20–22] range and that for $Co(acac)_2$ is 4.93 B.M.

Electronic spectra

The electronic spectra of all complexes are quite similar. The similarity is most evident between mononuclear and bridged complexes containing the same equatorial chelates and bidentate ligand L, but it also extends to complexes having different in-plane ligands. The spectra generally consist of a distinct intense band at *ca* 240 nm, several ill-resolved bands in the 250–400 nm region, and a weak low energy absorption in the visible region between 400 and 500 nm. These general spectral characteristics resemble those of the closely related cyano-bridged dicobaloximes.[6]

If there are no interactions between metal centers, a symmetrical ligand-bridged complex may be viewed as two RCo(chel)X units. With tbpy as the bridging ligand, the conjugated π-electron systems of the pyridine rings are separated by a saturated alkyl chain. Metal–metal interactions are not expected to be transmitted across such a ligand bridge. Thus, the electronic spectra of the pyridine complex

$$[CH_3Co(dmgH)_2(py)]$$

and

$$[CH_3Co(dmgH)_2(tbpy)Co(dmgH)_2CH_3]$$

should be quite similar. Consistent with this expectation, a comparison of the spectral data in

Table 2 for these two compounds shows that their electronic spectra are virtually identical.

The most intense and highest energy absorption band in the electronic spectrum of the binuclear complexes is relatively insensitive to the nature of the bridging ligand. In all cases, this band appears at *ca* 240 nm. In the absorption spectrum of related mononuclear complexes, a band in this region has been assigned on the basis of molecular orbital calculations[23,24] to a $\pi \rightarrow \pi^*$ transition of the equatorial ligand. By analogy, then, the 240 nm band is empirically ascribed to an inter-π-electron transition of the equatorial chelate ligand system.

The overlapping of absorption bands in the 260–400 nm region makes assigning these bands difficult. Further, both the bridging ligands and the cobalt chromophore absorb in this spectral region. Specific assignment of these bands was not attempted.

The lowest energy band is sensitive to both axial and equatorial ligands. In the spectra of related mononuclear[24] and dinuclear[7] complexes, a band in the 400–500 nm region with extinction coefficient of *ca* 10^3 has been assigned on the basis of a molecular orbital calculation as a Co—C charge transfer transition. This band has been used as a diagnostic tool to indicate a covalently bonded alkyl group.[24] Tetragonal cobalt(III) complexes are also expected to exhibit *d–d* transitions in this spectral region.[25,26] Electronic bands in the spectra of *trans*-diacidotetraaminecobalt(III) complexes[27] and *trans*-diacidobis(diamine)cobalt(III) complexes[25] for example have assigned as ligand field transitions consistent with a D_{4h} symmetry model. The *d–d* transitions observed for these classical complexes are, however, generally of lower intensity ($\varepsilon < 50$) than the charge transfer band observed in the alkylcobalt complexes.[6,24] Except for the

$$[CH_3Co(dmgH)_2diphosCo(dmgH)_2CH_3]$$

complex, a band ($\varepsilon \sim 10^3$) in this spectral region is observed for all bridged complexes. In view of the intensity of this band and the fact that it is not observed in the spectrum of

$$[Co(dmgH)_2(py)_2](ClO_4),^6$$

it is assigned by analogy to a Co—C charge transfer transition. In the spectrum of the diphos complex, a very broad band at 310 nm obscures this region. It is evident, however, from the ^{1}H NMR spectrum of the diphos complex (*vide infra*) that the cobalt bonded methyl group is present.

The spectra of

$$[CH_3Co(dmgH)_2tbpyCo(BAE)CH_3]$$

and

$$[CH_3Co(dmgH)_2tbpyCo(acac)_2]$$

appear to be a simple superposition of the spectra of the two complexes which formally form these binuclear compounds. The conjugated π-electron systems of tbpy are separated by a saturated alkyl chain and metal–metal interactions are not expected to be transmitted via this ligand. The spectra are compatible with an interpretation involving two separate isolated metal centers and assignments are on this basis. In the spectrum of

$$[CH_3Co(dmgH)_2tbpyCo(BAE)CH_3],$$

the absorption band at 239 nm is the π–π^* transition of the equatorial ligands and the weak band at 420 nm is assigned as the Co—C charge transfer transition. Two poorly resolved bands at 205 and 300 nm and a weak band at 350 nm are attributed to metal *d–d* and/or bridging ligand transitions. Bands appearing close to these wavelengths in the electronic spectrum of the mixed-valent tbpy bridged complex are assigned similarly. The 282 nm band, however, is undoubtedly of complex origin since both $Co(acac)_2$ and

$$[CH_3Co(dmgH)_2tbpyCo(dmgH)_2CH_3]$$

absorb strongly at this wavelength. For $Co(acac)_2$ a band at 283 nm is assigned to a π–π^* transition of the acac ligand, while in the symmetric tbpy bridged complex a band at this wavelength is associated with either metal *d–d* and/or bridging ligand transitions.

Proton NMR spectra

^{1}H NMR data for the ligand-bridged dialkylcobalt complexes are reported in Table 3. An examination of the data reveals that the spectra have the following features in common: (1) a high field resonance due to a cobalt-bound alkyl group, (2) bridging ligand resonances, and (3) signals associated with the equatorial chelate system. The dmgH and chdH complexes exhibit an additional very low field resonance characteristic of the strongly hydrogen bonded protons remaining on the oxime oxygens of these ligands.[18,28] This signal, which is not reported in Table 3, generally appears in the $\tau - 8.4$ to -8.8 ppm range.

The ^{1}H NMR spectral data indicates that both donor atoms of L are coordinated and the complexes are best formulated as two RCo(chel) units symmetrically bridged by a bidentate ligand located *trans* to the alkyl groups. Evidence for this comes by comparison of the spectra of binuclear complexes with those of the mononuclear compounds and signal intensity ratios. Small differences in the chemical shifts of protons located close to the donor atoms of L are expected if only one end of the bidentate ligand is coordinated. While these

differences are observed for the mononuclear complexes, no such splittings are apparent in the spectra of symmetric binuclear complexes. In every case, a single resonance was observed for each type of proton of the bridging ligand. A comparison of signal intensities also confirms the presence of the bridged complexes in solution. The intensity ratios of signals arising from the chelate ligand system (chel) or the axial alkyl group to signals associated with L in the bridged complexes are twice these ratios in the corresponding mononuclear compounds.

The association of alkylcobaloximes in solution is readily disrupted by many coordinating ligands to form stable six-coordinate complexes as illustrated in eqn (3):

$$[CH_3Co(dmgH)_2]_2 + 2L \rightleftarrows 2[CH_3Co(dmgH)_2L]. \quad (3)$$

In nearly all cases the equilibrium favoring formation of the adduct is essentially complete and only the mononuclear complex is observed.[18] For the bidentate ligands used in this investigation, no signals attributable to free ligand, mononuclear complex, or "ligand free' RCo(chel) species were observed in the ^1H nuclear magnetic resonance spectra of the bridged compounds. The $[RCo(dmgH)_2LCo(dmgH)_2R]$ complexes are essentially undissociated in chloroform solution. However, equilibria involving appreciable concentrations of all these species are possible for weakly coordinating and/or severely sterically hindered ligands.*

The situation is different for SALEN[2] and BAE[3] complexes where the equilibrium involving adduct formation may be incomplete and exchange is rapid on the NMR time scale. $CH_3Co(BAE)$ and $CH_3Co(SALEN)$, for example, do not bind a sixth ligand as strongly as "ligand free" $[CH_3Co(dmgH)_2]_2$,[30,31] and $[CH_3Co(BAE)py]$ does not exhibit slow exchange in solutions containing excess ligand at $-90°C$.[18] The ^1H NMR spectrum of

$$[CH_3Co(SALEN)tbpyCo(SALEN)CH_3]$$

recorded in $CDCl_3$ with d_6-DMSO added to increase its solubility is substantially different from that of the

$$[CH_3Co(SALEN)DMSO]$$

complex.[32] Thus the tbpy bridged complex must be more stable than the DMSO adduct. No quantitative studies of chemical shift as a function of ligand concentration were conducted so the quantitative extent of adduct formation is not known. However, based on our observations with the DMSO complexes and a comparison of base strengths, it appears that the stability of the tbpy bridged $CH_3Co(BAE)$ and $CH_3Co(SALEN)$ complexes are comparable to the corresponding pyridine complexes.[32]

The NMR spectrum of

$$[CH_3Co(dmgH)_2dthCo(dmgH)_2CH_3],$$

shown in Fig. 1, is representative of that observed for the binuclear complexes. Assignments were made by comparison with the spectra of related mononuclear complexes, characteristic group chemical shifts, and signal intensities.[14,18] The highest field resonance in the spectrum occurs at τ 8.89 ppm relative to TMS and is assigned to the cobalt bonded methyl group. The intense singlet at τ 7.79 ppm is within the range of chemical shifts expected for the dmgH—CH_3 resonance in alkylcobaloximes[18] and it is assigned accordingly. The remaining signal at τ 7.45 ppm is 0.30 ppm upfield from the resonance for the methylene protons in uncomplexed *p*-dithiane. This upfield shift of the protons adjacent to the donor sulfur atom which occurs upon complexation is somewhat greater than that observed in the related thioxane mononuclear complex ($\Delta\tau$ = 0.22 ppm).[18] A single observed resonance for the bridging ligand indicates both donor atoms are coordinated. The intensities of the signals shown in the figure are in the ratio expected for a symmetrically bridged dithiane complex, i.e. 3:12:4. An additional signal arising from the oxime oxygen protons of the dmgH ligands not shown in Fig. 1 appears at $\tau - 8.6$ ppm.

The spectral changes which occur upon varying the axial alkyl group from —CH_3 to —CH_2Cl are exemplified by the dithiane and pyrazine bridged chloromethyl-compounds. In the spectra of $[CH_2ClCo(dmgH)_2LCo(dmgH)_2CH_2Cl]$ complexes, the signal associated with the alkyl group shifts to substantially lower fields and the intensity reflects the decreased number of protons. The chemical shift of the —CH_2Cl group in the dithiane complex is τ 6.14 ppm and it is found at τ 5.10 ppm in the pyrazine complex. The intensity ratios for the signals are as expected. The aromatic protons of pyrazine are shifted *ca* 0.42 ppm from the free ligand value and appear at τ 1.44 ppm as a singlet as expected for a symmetrical bridged binuclear compound. The chemical shift of the dithiane protons appears at identical positions in the methyl- and chloromethyl-complexes.

* The formation constant for the equilibrium involving the formation of the binuclear complex $CH_3Co(dmgH)_2LCo(dmgH)_2CH_3$, where L = triethylenediamine, is sufficiently small that both "ligand free" and bridged complexes are observed.[29]

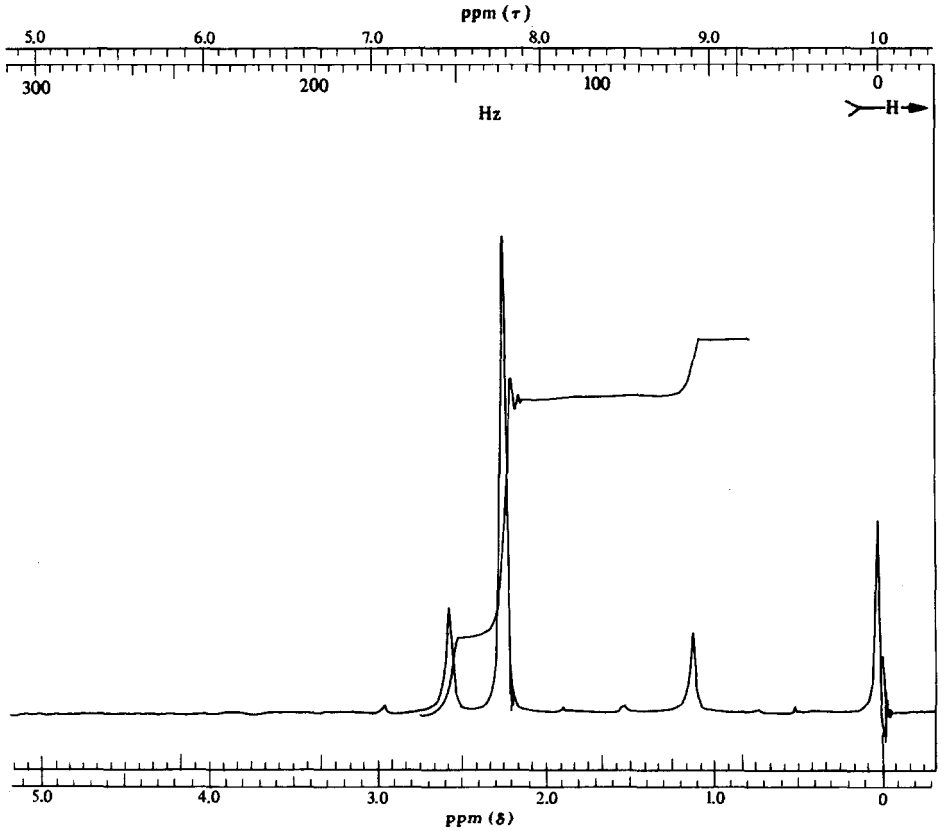

Fig. 1. The ^{1}H NMR spectrum of $[CH_3Co(dmgH)_2dthCo(dmgH)_2CH_3]$.

The dmgH—CH_3 resonance in the binuclear dimethylglyoximato-complexes is sensitive to the nature of the axial alkyl group. This resonance shifts to slightly higher fields as the alkyl group becomes more electron donating. The order which is most clearly seen in the bipyridine bridged complexes listed in Table 3 is chloromethyl < methyl < isopropyl. This can be interpreted simply in terms of increased electron density on cobalt being transmitted to the methyl hydrogens thereby causing a greater shielding. These results are qualitatively in agreement with previous NMR work on the *cis*-effect in cobaloximes. A correlation between the proton resonances of the in-plane hydrogens and the Hammett σ para-function of the axial ligand has been demonstrated.[32,33]

The bridged alkylcobaloximes typically exhibit a singlet in the τ 7.72–8.22 ppm range due to the dmgH–CH_3 protons and another singlet due to protons of the cobalt bound alkyl group. In methyl-complexes the alkyl resonance is found in the τ 8.89–9.15 ppm range. With diphos as the bridging ligand these resonances are expected to split into doublets in the region of slow exchange through a spin interaction with ^{31}P. Whereas in the fast exchange region, rapid ligand dissociation would cause the doublets to collapse to singlets. Doublets with scalar coupling constants of 3 Hz are observed in ^{1}H NMR spectra of both diphos bridged complexes in the dmgH—CH_3 resonance region. In the methyl-complex, the ^{1}H–^{31}P coupling to the axial alkyl group is sufficient to give rise to a doublet (J = 4 Hz), but the splitting is not apparent in the chloromethyl-complex. These observations are similar to those for related mononuclear complexes containing phosphorus ligands. It has been reported that the scalar interactions of protons of axial haloalkyl groups with ^{31}P is considerably smaller than that of axial alkyl groups and in some cases may not be observed.[34]

The aromatic protons of the bridging diphos ligand appear as a complex doublet centered at *ca* τ 2.76 ppm. This chemical shift is close to the value observed for this resonance in the free ligand. The ethylene protons which appear as a triplet (J = 5 Hz) at τ 7.90 ppm in diphos are shifted slightly upfield in the bridged complexes. The center of the triplet lies under the dmgH—CH_3 resonance and appears as a shoulder at *ca* τ 8.1 ppm on this latter signal.

The ^{1}H NMR spectra of the 4,4′-bipyridine complexes, $[CH_3Co(chel)bpyCo(chel)CH_3]$, as expected are quite similar to analogous $[CH_3Co(chel)py]$ complexes.[34,35] The conjugation in these systems can be disrupted by a twisting of the

aromatic rings with respect to each other. The rings generally are not coplanar and conjugation does not extend between ring systems. The bridging bpy ligand shows a characteristic "para" pattern when the nitrogens are equivalent. For the free ligand, the $AA'XX'$ spin system produces two sets of doublets (J = 6 Hz) centered at τ 2.49 and 1.29 ppm. Each peak shows an additional splitting of 1 Hz arising from magnetic non-equivalence of the hydrogens. The bridged complexes show a similar pattern of doublets at chemical shifts close to free ligand values. The lowest field aromatic resonance which shows the greatest shift upon complexation is ascribed to the bpy protons adjacent to the nitrogens. Splitting arising from magnetic non-equivalence which is evident in the spectra of dmgH complexes is not as apparent for the BAE and SALEN complexes. The lowest field aromatic resonance in the spectrum of the BAE complex, for example, is substantially broadened and shows no splitting.

The axial methyl resonance in

$$[CH_3Co(BAE)bpyCo(BAE)CH_3]$$

occurs 0.24 ppm to lower fields than in the base free $CH_3Co(BAE)$ complex. At 60 MHz, the —CH, $—CH_2$, and $—CH_3$ proton resonances of the BAE ligand in the bpy bridged complex appear as singlets at τ 4.97, 6.78 and 8.00 ppm, respectively. The shifts of these resonances upon addition of a sixth ligand to the base free $CH_3Co(BAE)$ complex is analogous to that which is observed for the pyridine complex.[35] However, the non-equivalence of the BAE methyl groups and the splittings of the methylene proton resonance which are apparent at 100 MHz[32,35] were not observed.

The spectrum of

$$[CH_3Co(SALEN)bpyCo(SALEN)CH_3]$$

is complicated somewhat by the presence of d_6-dimethylsulfoxide which was added to increase the solubility of this complex in chloroform. The coordinating properties of DMSO make displacement of the bridging bpy ligand possible; but the observed chemical shifts are substantially different from values for the DMSO complex.[32] We have not attempted to analyse the spectra of the SALEN aromatic hydrogens which is a broad multiplet τ (3.77–2.67 ppm), but singlets at τ 2.11 and 6.47 ppm are due to the methine and methylene protons, respectively. The non-equivalence of the methylene hydrogens previously observed at 100 MHz[32] was not apparent under the spectral conditions used here.

The chemical shift of the axial methyl group in $[CH_3Co(chel)L]$ complexes depends upon electronic effects of both axial and equatorial ligand systems.[18,32] Similar effects are observed for the bridged complexes. The axial methyl resonance, for example, occurs at lower fields when the bridging ligand contains sulfur or phosphorus donor atoms as compared to oxygen or nitrogen atoms. The equatorial ligand also has a substantial effect on this resonance. A comparison of the bipyridine complexes shows this nicely. In the dmgH complex this resonance appears at τ 9.15 ppm, whereas it shifts to lower fields in the BAE and SALEN complexes, i.e. τ 7.50 and 7.44 ppm, respectively. The results are comparable to those observed in the pyridine complexes,[35] but not as large as those reported in methylatocobalt(aeitoporphyrin).[36] In the latter complex a substantial shielding from the porphyrin ring current is expected and the axial methyl resonance occurs at τ 15.15 ppm. The down-field shift in the BAE and SALEN complexes compared to the dmgH complex (in which there is no ring current) may also be due to an equatorial ring current.[35] In the present situation however, the ring current would have a deshielding effect on the axial methyl group since it is now situated at the edge of the ring rather than in the center.

The spectra of the 4,4′-trimethylenebipyridine bridged complexes are very similar to the bpy bridged complexes; i.e. the resonances due to the axial alkyl groups and equatorial chelate systems appear at nearly identical chemical shifts. There is no conjugation between the aromatic rings which are separated by a saturated alkyl chain. The tbpy ligand also shows a characteristic "para" pattern when the nitrogens are equivalent. The aromatic hydrogens produce two sets of doublets (J = 6 Hz) centered at τ 2.73 and 1.42 ppm which show additional splitting of *ca* 1 Hz from magnetic non-equivalence. Again, this splitting is much less evident in the bridged complexes. The trimethylene chain gives rise to a complex triplet (J = 8 Hz) centered at τ 7.30 ppm and a quintet at τ 7.90 ppm. This latter resonance is partially obscured by a signal arising from the equatorial ligand systems in the complexes and these lie too close together to integrate as separate peaks.

Except in the aromatic region, the ^1H NMR spectrum of $[CH_3Co(dmgH)_2tbpyCo(BAE)CH_3]$ appears to be a composite of the spectra of two $CH_3Co(chel)X$ units which form this unsymmetric complex. Singlets at τ 9.20 and 7.60 ppm arise from protons of the axial methyl groups of $[CH_3Co(dmgH)_2X]$ and $[CH_3Co(BAE)X]$, respectively. The methyl resonance of BAE in the bridged complex appears as a singlet at 8.00 ppm. The dmgH—CH_3 singlet is at τ 7.85 ppm. The BAE methine and methylene proton resonances are at chemical shifts close to their values in $[CH_3Co(BAE)bpyCo(BAE)CH_3]$. The spectrum

in the aromatic region is more like that observed for the mononuclear $[CH_3Co(dmgH)_2tbpy]$ complex. This is not unexpected since in both cases the nitrogen atoms of tbpy are not equivalent. The highest field aromatic signal, a doublet at τ 2.83 ppm of intensity four, arises from tbpy ring protons farthest from nitrogen. The ring protons adjacent to the coordinated nitrogens give rise to two signals of equal intensity (2), i.e. a doublet and a broad absorption band at slightly lower fields. By comparison with the spectra of symmetric complexes, the signals are empirically assigned to protons closest to the $CH_3Co(dmgH)_2$ and $CH_3Co(BAE)$ bound nitrogens, respectively.

In the spectrum of

$$[CH_3Co(chdH)_2tbpyCo(chdH)_2CH_3],$$

the aromatic resonances of tbpy appear as described for the other symmetrically bridged tbpy complexes. The methylene proton resonances lie under the very broad complex absorbance envelope of the 1,2-cyclohexanedionedioxime equatorial ligand. The saturated cyclohexane ring hydrogens give rise to two broad, poorly resolved bands at τ 8.37 and 7.30 ppm. The protons farthest from the oxime nitrogen atoms overlap the proton resonance of the central methylene group of tbpy. Similarly, the lower field resonance which is associated with the protons adjacent to the oxime nitrogens overlaps the resonance signal of the methylene groups attached to the pyridine rings.

Abstract—The reactions of the complexes $[CpFe(CO)_2]_2[\mu\text{-}(CH_2)_n]$ with Ph_3CPF_6 yield cationic di-iron complexes of the type $\{[CpFe(CO)_2]_2[\mu\text{-}(C_nH_{2n-1})]\}^+$ (n = 3–6). The ^1H NMR spectra for the cationic complexes where n = 4–6 and the variable temperature spectra for the cation where n = 3 are reported and discussed.

The reaction of $[CpFe(CO)_2]_2[\mu\text{-}(CH_2)_3]$ with Ph_3CPF_6 is known to give the cationic complex $\{[CpFe(CO)_2]_2[\mu\text{-}C_3H_5]\}^+PF_6^-$ (I).[1] The structure and low temperature ^1H NMR spectrum of this cationic complex have been reported[2] as well as a detailed discussion of the energies involved in the fluxional processes occurring in solutions of $\{[CpFe(CO)_2]_2[\mu\text{-}(C_3H_5)]\}^+PF_6^-$.[3]

We now find that reactions of the complexes $[CpFe(CO)_2]_2[\mu\text{-}(CH_2)_n]$ (where n = 4–6) with Ph_3CPF_6 in dichloromethane give yellow crystalline complexes

$$\{[CpFe(CO)_2]_2[\mu\text{-}(C_nH_{2n-1})]\}^+PF_6^-.$$

These cationic complexes show four strong ν(CO) bands in their IR spectra and two singlet resonances for the cyclopentadienyl protons in their ^1H NMR spectra. These data are consistent with structures for these complexes where one iron atom is π-bonded and the other σ-bonded to the alkenyl chain, e.g. for n = 4:

Fp = $CpFe(CO)_2$

I

These cationic complexes are formed as a result of hydride abstraction from the β-carbon atom of $[CpFe(CO)_2]_2[\mu\text{-}(CH_2)_n]$. An alternative route to the BF_4^- salt of the cation where n = 5 has been reported by the reaction of

$$[CpFe(CO)_2(CH_2{=}CH_2)]^+$$

with

$$CpFe(CO)_2(CH_2CH{=}CH_2)$$

and some related cations have also been prepared by this method.[4]

In the ^1H NMR spectrum of I at room temperature we observe a singlet at δ 5.50 ppm for the 10 cyclopentadienyl protons and a low field quintet at δ 6.80 ppm due to the CH proton (H_X); the CH_2 protons (H_A and H_B) (see Fig. 1) are coalesced into the base line at this temperature. On cooling to below −10°C the spectrum sharpens and four resonances are observed: the cyclopentadienyl protons remain unchanged as a singlet at δ 5.50 ppm, the H_X proton is observed as a triplet of triplets at δ 6.80 ppm, $^3J(H_AH_X)$ 14.0, $^3J(H_BH_X)$ 6.0 Hz and H_A and H_B

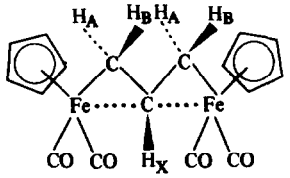

Fig. 1.

* Author to whom correspondence should be addressed.

protons as two doublets of doublets at δ 2.92 ppm, $^3J(H_BH_X)$ 6.0, $^2J(H_AH_B)$ 2.8 and δ 2.35 ppm, $^3J(H_AH_X)$ 14.0, $^2J(H_AH_B)$ 2.8 Hz. The ^{1}H NMR spectrum of I did not change further on cooling to -70°C. This low temperature limiting spectrum is consistent with an A_2B_2X spin system of a rigid η^3-allyl group.[5] On heating the solution of I, the low field triplet of triplets (assigned to H_X) broadened and became a binomial quintet at δ 6.80 ppm, which became sharp above 25°C. The two doublets of doublets (assigned to H_A and H_B) coalesced at 37 $\pm$2°C and then sharpened to a doublet at δ 2.65 ppm, $^3J(H_{A,B}H_X)$ 10 Hz.

Similar changes in the ^{1}H NMR spectrum of the BF_4^- salt of I and some related compounds have been reported although these authors interpreted their results in terms of unsymmetrical hybrid structures.[6] We interpret our ^{1}H NMR results as follows: at low temperature, a symmetrical carbonium ion static structure for I is present, as is found in the solid state.[2] On heating the solution, rotation about the CH_2—CH bonds of the allyl group in I occurs thus equilibrating protons A and B of the A_2B_2X spin system to give an A_4X system.

EXPERIMENTAL

The compounds $[CpFe(CO)_2]_2[\mu\text{-}(CH_2)_n]$ (n = 3, 4, 5 or 6)[7] and

$$\{[CpFe(CO)_2]_2[\mu\text{-}(C_3H_5)]\}^+PF_6^-$$ [1]

were prepared by literature methods. IR spectra were recorded on a Perkin–Elmer 180 spectrophotometer, ^{1}H NMR spectra at 60 MHz were recorded on a Perkin–Elmer R12 spectrometer and the variable temperature ^{1}H NMR spectra of $\{[CpFe(CO)_2]_2[\mu\text{-}(C_3H_5)]^+\}^+PF_6^-$ were obtained using a Bruker WH-270 spectrometer operating in FT mode. All NMR spectra were recorded on d_6-acetone solutions with internal tetramethylsilane as reference standard. Conductivity measurements were made on approximately 10^{-3} M solutions in nitrobenzene. Melting points were determined on a Kofler hot-stage microscope and are uncorrected. Solvents were dried and saturated with nitrogen before use and all reactions were carried out under an atmosphere of nitrogen.

Preparation of $\{[CpFe(CO)_2]_2[\mu\text{-}(C_4H_7)]\}^+PF_6^-$

A solution of $[CpFe(CO)_2]_2[\mu\text{-}(CH_2)_4]$ (0.45 g, 1.10 mmol) in dichloromethane (5 cm^3) was added to a solution of Ph_3CPF_6 (0.48 g, 1.24 mmol) in dichloromethane (10 cm^3) and the reaction mixture allowed to stand for 17 h. The solution was filtered and diethyl ether added to precipitate the product as yellow microcrystals (0.20 g 33%), decomp. without melting > 115°C. Found: C, 38.76; H, 3.13; F, 18.65%. $C_{18}H_{17}F_6Fe_2O_4P$ requires: C, 39.03; H, 3.09; F, 20.58%. IR (CH_2Cl_2) $\nu_{(CO)}$ 2073s, 2036s, 2007s, 1950s cm^{-1}; molar conductance 30.9 ohm^{-1} cm^2 mol^{-1}; ^{1}H NMR δ 5.89 ppm (5H, s, C_5H_5) 5.36 ppm (1H, broad, m, =CH), 5.03 ppm (5H, s, C_5H_5), 3.96 ppm (1H, d, $=CH_2$, J = 8.2 Hz), 3.53 ppm (1H, d, $=CH_2$, J = 14.3 Hz), 1.64 ppm (2H, m, CH_2), 1.24 ppm (2H, m, CH_2Fe).

Preparation of $\{[CpFe(CO)_2]_2[\mu\text{-}(C_5H_9)]\}^+PF_6^-$

This was prepared similarly from $[CpFe(CO)_2]_2[\mu\text{-}(CH_2)_5]$ (0.50 g, 1.19 mmol), Ph_3CPF_6 (0.46 g, 1.18 mmol) and dichloromethane (16 cm^3). The product was obtained as yellow microcrystals (0.33 g, 49%), decomp. without melting 115–128°C. (*Received* 13 *April* 1984; *accepted* 22 *May* 1984)

Abstract—The crystal structure of 2Li picrate.dibenzo-36-crown-12.2H_2O was determined by X-ray diffraction methods. The 2:1 (metal:ligand) complex crystallises in the monoclinic system, space group $P2_1/c$ with $a = 9.748(2)$, $b = 22.559(4)$, $c = 12.474(2)$ Å, and $\beta = 107.05(1)°$. The Li^+ ions are 5-coordinated within a distorted trigonal bipyramidal geometry to *one* water molecule, *two* crown ether oxygen atoms, and the *phenoxide* and *nitro* group oxygen atoms of a picrate counterion. The picrate ions are nearly parallel to the benzo rings in the host with a minimum inter-group separation of 3.37 Å. However, ^1H NMR spectroscopy of a range of DB3*n*C*n* (n = 9–12) hosts in CD_2Cl_2 reveals little if any interaction between picrate and benzo-rings in solution.

Dibenzo-crown ethers of the general type DB3*n*C*n* (n = 6–12) form[1,2] stable adducts in solution with $[Pt(bipy)(NH_3)_2][PF_6]_2$, not only by virtue of the expected electrostatic interaction and [N—H---O] hydrogen bonding, but also as a result of charge transfer between the bipyridyl (bipy) ligand (π-acceptor) in the complex and the benzo-rings (π-donors) of the host. Stability constant measurements indicated[2] optimum binding (free energy of complexation of 7.2 kcal mol^{-1} in MeCN) when n = 10, and X-ray crystal structures of the 1:1 adducts where n = 8 and 10 confirmed that, when n = 10, the macrocycle is sufficiently large and flexible to allow both benzo-rings to enter into stabilising charge transfer interactions with the bipyridyl ligand such that the platinum complex is completely encapsulated by DB30C10 in a U-shaped cavity. Subsequently, an X-ray crystallographic investigation of the 1:1 complex formed between $[Diquat][PF_6]_2$ and DB30C10 revealed[3,4] very similar gross structural features for this complex. Intermolecular charge transfer interactions combine with Coulombic (ion-dipole) forces and weak [C—H---O] hydrogen bonding to stabilise the complex. Stability constant measurements once again indicated[3,4] optimum binding (free energy of complexation of 5.8 kcal mol^{-1} in Me_2CO) when n = 10 in the range (n = 9–12) of DB3*n*C*n* hosts examined. These observations are summarised (cf. ref. 4) diagrammatically in Fig. 1. They led us to speculate that it might even be possible to stabilise, by a similar charge transfer interaction, organic anions, such as picrate, which carry several electron withdrawing groups. The idea we set out to test is presented diagrammatically in Fig. 2. We were encouraged to carry out some experiments in the knowledge that, although the crystal structures of some metal picrate (pic) complexes (e.g.

$[K(pic).(B15C5)_2]$,[5] $[Na(pic).B15C5]$[6]

and

$[TlMe_2(pic).DB18C6]$[7])

* Author to whom correspondence should be addressed.

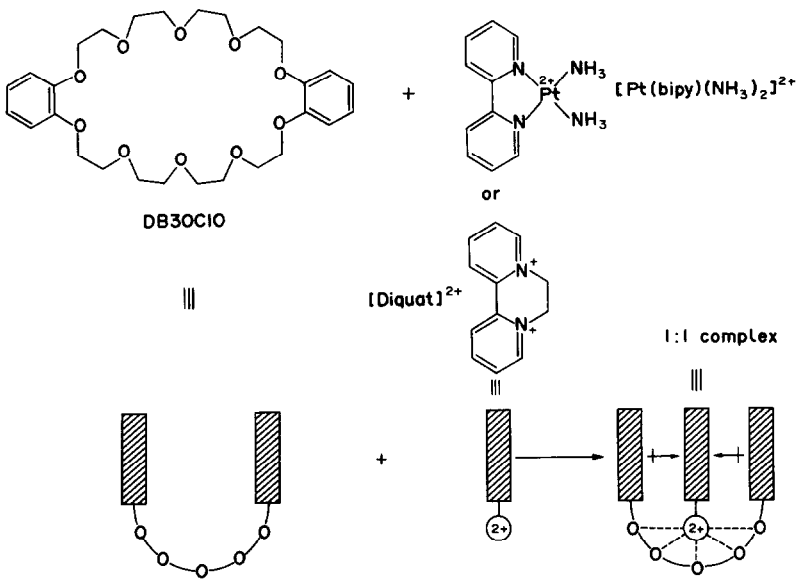

Fig. 1. The formation of 1:1 complexes between DB30C10 and either $[Pt(bipy)(NH_3)_2]^{2+}$ or $[Diquat]^{2+}$ dications. The schematic representation shows the pole–dipole (----) and charge transfer (↔) interactions.

with benzo- and dibenzo-crown ethers show no near approaches between the picrate and the catechol rings of the hosts, others (e.g.

$$[Ba(pic)_2.DB24C8.2H_2O],^{8}$$

$$[Ca(pic)_2.B15C5.3H_2O]^{9}$$

and

$$[Li(pic).B15C5.2H_2O]^{10})$$

reveal the stacking of the picrate rings alongside the catechol rings. 3,5-Dinitrobenzoate (dnb) rings have also been found (e.g. in $[Ca(dnb)_2.(B15C5)_2.3H_2O]$)[11] lying parallel to catechol rings in solid state structures of crown ether complexes.

The main reasons for choosing lithium picrate as the guest salt in our investigations were the following: (i) being a monocation, lithium only associates with one picrate anion; (ii) being a hard cation, lithium is strongly anionophilic; and (iii) the tendency of lithium ions to coordinate to water molecules (see later) renders it highly flexible in its adaptation to a crown ether cavity.

This paper describes the isolation of

$$3Li(pic).2DB30C10.5H_2O$$

and

$$2Li(pic).DB36C12.2H_2O$$

and an X-ray structural investigation of

$$2Li(pic).DB36C12.2H_2O.$$

Comparisons are drawn between the conformation of DB36C12 in this 2:1 complex and the host conformations in $2NaPF_6.DB36C12$[12] and

$$2[Rh(cod)(NH_3)_2PF_6].DB36C12.$$[13]

The nature of the first coordination sphere of the lithium ion is compared with that in complexes involving other crown ethers and synthetic ionophores. Finally, ^1H NMR spectroscopic data for some 1:1 complexes between Li(pic) and

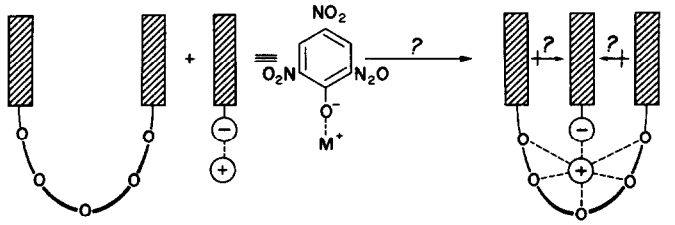

Fig. 2. A schematic representation of the proposed 1:1 complex formation between DB30C10 and alkali metal picrates.

DB3*n*C*n* ($n = 9$–12) ethers are interpreted with reference to previous investigations of the analogous 1:1 complexes involving $[Pt(bipy)(NH_3)_2][PF_6]_2$ and $[Diquat][PF_6]_2$ as guests.

EXPERIMENTAL

The crown ethers 18C6 and DB24C8 were obtained from Aldrich. The stepwise syntheses of DB27C9, DB30C10, DB33C11 and DB36C12 have been described briefly elsewhere.[1] A full account of their synthesis will be published shortly.[4] ^{1}H NMR spectra (tetramethylsilane as lock and internal standard) were recorded on a Perkin–Elmer R34 (220 MHz) spectrometer.

Isolation of 3Li picrate.2DB30C10.5H_2O

Lithium picrate monohydrate (25.3 mg, 0.1 mmol) and DB30 C10 (53.6 mg, 0.1 mmol) were dissolved in acetonitrile (3 cm^3). This solution was layered firstly with ether and then with light petroleum (b.p. 60–80°C). After 48 h, the mixture contained a fibrous micro-crystalline material, m.p. 73–76°C, which was isolated by filtration. ^{1}H NMR spectroscopy (CD_2Cl_2) revealed (cf. Table 4) the presence of the following signals: δ 2.92 (6H, s, $2CH_3CN$), 3.50–3.80 (19H, m, γ- and δ-OCH_2 protons and H_2O), 3.87 (8H, m, β-OCH_2 protons), 4.10 (8H, m, α-OCH_2 protons), 6.80 (8H, m, catechol ring protons) and 8.81 (3H, s, picrate protons). This spectrum is, therefore, consistent with a stoichiometry of 3:2:3 for Li picrate:DB30C10:H_2O. The sample was dried under high vacuum. Yield 49 mg, 80%; IR data (Nujol): 3570 m, 3490 m (ν_{OH}), 1560s, 1330s (ν_{NO_2}), 1125s (ν_{CO}) cm^{-1}.

Found: C, 47.1; H, 5.3; N, 6.6%. $C_{74}H_{98}O_{48}N_9Li_3$ (i.e. 3Li picrate.2DB30C10.5H_2O) requires: C, 46.7; H, 5.2; N, 6.6%.

Isolation and X-ray structural analysis of 2Li picrate.DB36C12.2H_2O

On standing overnight, the CD_2Cl_2 solution of DB36C12 containing 1.0 equivalent of lithium picrate, which had been used to record ^{1}H NMR spectra, deposited a small crop of pale yellow needles. IR data (Nujol): 3560 m, 3440 m (ν_{OH}), 1365 s, 1325 s (ν_{NO_2}) cm^{-1}. From these, a single crystal was chosen for X-ray study.

Crystal data. $C_{32}H_{48}O_{12}.Li_2C_{12}H_4O_{14}N_6.2H_2O$, monoclinic, $a = 9.748(2)$, $b = 22.559(4)$, $c = 12.474(2)$ Å, $\beta = 107.05(1)°$, $U = 2622$ Å^3, space group $P2_1/c$, $Z = 2$, $M = 1129.9$, $D_c = 1.44$ g cm^{-3}, μCu-K_α 10 cm^{-1}.

Measurements. Refined unit cell parameters were obtained by centering 18 reflections on a Nicolet R3m diffractometer. 3624 Independent reflections ($\theta < 55°$) were measured with Cu-K_α radiation (graphite monochromator) using the omega scan measuring routine. Of these, 3280 were unique, and 2995 had $|F_o| > 3\sigma(|F_o|)$ and were considered observed. Lorentz and polarisation corrections were applied. No absorption correction was applied.

Structure analysis. The structure was solved by direct methods. An *E* map computed with 418 *Es* > 1.62 for the phase solution with the highest "figure of merit" gave the positions of all non-hydrogen atoms. A ΔF map revealed disorder to be present in the macrocycle associated with O(4), C(5) and C(8) [and, of course, with the symmetry related O(4′), C(5′) and C(8′)]. These atoms were assigned two alternative sites in each case, with occupation factors of 0.65 and 0.35. All the ordered non-hydrogen atoms and the major (0.65) sites associated with the disorder were refined anisotropically. The minor site atoms were refined isotropically. The hydrogen atoms were placed at idealised positions (C—H = 0.96 Å), assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$, and allowed to ride on their parent carbon atoms. The hydrogens belonging to the minor (0.35) fraction of the disorder were disregarded. Refinement was by block cascade full matrix least squares to $R = 0.055$, $R_w = 0.068$ [$w^{-1} = \sigma 2(F) + 0.006F^2$]. Computations were carried out on an Eclipse S140 computer using the SHELTXL program system.[14] Scattering factors were taken from the *International Tables for X-Ray Crystallography*.[15]

Final atomic coordinates, including those of the hydrogen atoms, and thermal parameters have been deposited with the Editor as supplementary data.*

RESULTS AND DISCUSSION

Tables 1 and 2 record the bond lengths and bond angles respectively for 2Li(pic).DB36C12.2H_2O. Torsional angles for the C—C and C—O bonds on the macrocyclic ring are listed in Table 3 together with those for $2NaPF_6$.DB36C12[12] and 2[Rh(cod)$(NH_3)_2PF_6$].DB36C12[13]. In common with both the sodium and rhodium complexes, the macrocycle (Figs 3 and 4) possesses a crystallographic centre of symmetry and binds the guest species in a displaced manner to opposite faces of the host. There is disorder associated with O(4), C(5) and O(8)—and of course, with the symmetry related O(4′), C(5′) and O(8′)—in the polyether chain. Not surprisingly, in such a large and flexible macrocycle,

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

there are significant differences in the conformations of the polyether chains in the three different complexes. However, in the region of the macrocycle between O(16′) and C(11) via C(6) there are, with two exceptions—O(1)C(2)C(3)O(4) in $2NaPF_6$.DB36C12 and O(7)C(8)C(9)O(10) in $2[Rh(cod)(NH_3)_2PF_6]$.DB36C12—gross similarities between the torsional angles in the polyether chains of the three complexes.

The five-fold coordination geometry of the Li^+ ion is that of a distorted trigonal bipyramid with the [Li^+---O] bonds to the ether oxygen O(7) [2.234(5)] and the phenoxide oxygen O(23) [1.936(5)] forming the apices, and those to the ether oxygen O(10) [1.983(5)], the *ortho*-nitro group oxygen O(22) [2.067(6)] and the oxygen of the water molecule O(24) [1.962(6)] Å the equatorial components. The angles at the Li^+ ion to the equatorial ligands are 129.0(3), 120.2(3) and 109.7(2)° respectively with the lithium atom being slightly displaced (0.12 Å) from the plane of O(10), O(22) and O(24) towards O(23). This coordination has also been found[16] in the crystal structure of the 1:2 complex of an 18,18′-spirobi-(19-crown-6) derivative with lithium iodide dihydrate. Square pyramidal geometry has been observed more frequently in crystalline complexes between crown ethers and lithium ions (e.g. in

[LiSCN.12C4],[17] [LiSCN.12C4],[18]

[LiSCN.DB14C4],[19] [LiSCN.B13C4][20]

and

[$LiN(SiMe_3)_2$.12C4][21]).

In the complexes involving the thiocyanate counterion, the nitrogen atom of the anion provides the fifth coordination site for the cation. In some cases, namely with [$LiNO_3$.B14C4][22] and with an analogous complex[23] involving a chiral dimethyl derivative of benzo-14-crown-4, although the cation is hexacoordinated, the geometry of the coordi-

* The values in italics in parentheses indicate how strongly the respective signals are shifted relative to either Li(pic).18C6 in the case of the picrate protons, or the free crowns in the case of the C_6H_4 and OCH_2 protons. The OCH_2 protons are labelled α, β, γ etc. in the shorter polyether chain, and α', β', γ' etc. in the longer polyether chain, both starting from the benzo-rings.

† No attempt was made to dry the solvent (CD_2Cl_2) or the salt [Li(pic)]. Significantly, therefore, broad signals, which were assigned to H_2O, were observed at δ 4.20, 3.60, 3.62, 3.53 and 3.26 for the complexes involving 18C6, DB27C9, DB30C10, DB33C11 and DB36C12, respectively.

The water molecule is involved in intracomplex hydrogen bonding with the disordered O(4) and forms a bifurcated hydrogen bond to O(13′) and O(16′). This situation is portrayed graphically in Fig. 5. All three nitro groups are rotated out of the plane of the picrate ring. The rotations are 45.2, 5.7 and 12.5°, for the groups associated with N(1), N(2) and N(3), respectively.

In view of the observation of a near-parallel (9.9° between the mean planes) overlap and close approach [3.37 Å between C(19′) and the C(26)—N(2) bond] of the picrate and catechol rings, it was decided to find out if there was any evidence for this stacking phenomenon in solution. In the crystal structures of

$$[Pt(bipy)(NH_3)_2(PF_6)_2.DB30C10.0.6H_2O]^{1,2}$$

and

$$[Diquat.(PF_6)_2.DB30C10],^{3,4}$$

the near parallel guest and host aromatic rings were separated by *ca* 3.5 and 3.4 Å, respectively. Evidence was obtained[1–4] for charge transfer stabilisation of both these supramolecular structures in solution by spectroscopic (^{1}H NMR and UV) methods. In the event, it was only just possible to dissolve 1.0 molar equivalent of lithium picrate in CD_2Cl_2 solutions containing the DB3*n*C*n* (*n* = 9–12) ethers. In Table 4, the chemical shifts of guest and host protons are compared with those for [Li(pic).18C6] and the free host, respectively. The changes (0.01–0.09 ppm) in chemical shifts were extremely small compared with those observed previously[1–4] for the dicationic complexes. It was, therefore, concluded that, even in the most favoured situation (DB30C10), any charge transfer stabilisation of the picrate anion by benzo-rings in DB3*n*C*n* ethers is very small in solution if indeed it exists at all. It has to be remembered that in the one case (DB36C12), where we have unequivocal structural information, it is for 2:1 stoichiometry in the solid state. Also, all the solution work has been carried out—and had to be—with a 1:1 stoichiometry. The possibility exists that, even in the solid state, the stacking of host and guest aromatic rings does not arise because of charge transfer. Moreover, there is no evidence in the appropriate region (300–400 nm) of the UV spectra of 1:1 complexes of DB30C10 and DB36C12 with lithium picrate in acetonitrile of a charge transfer band. Thus, we believe it is more likely that, although ion pairing does occur between the picrate anion and the lithium cation in CD_2Cl_2 solution, this electrostatic interaction, together with three electron withdrawing nitro groups, is not sufficient to annul the effect of the negative charge on the anion and render this aromatic ring system a π-acceptor towards the electron rich π-donating catechol units. In summary, although lithium picrate complexes with DB3*n*C*n* ethers in solution, it appears to do so without any appreciable ordering of guest and host aromatic ring systems.

EFFECT OF INORGANIC AQUEOUS ANIONS ON THE SYNERGIC EXTRACTION OF CADMIUM AND ZINC WITH 1-PHENYL-3-METHYL-4-BENZOYL-PYRAZOL-5-ONE (HPMBP) AND LIPOPHILIC AMMONIUM SALTS

Laboratoire de Chimie Minérale E.N.S.C.S., Associé au C.N.R.S. (E.R.A. 468), 1, rue Blaise Pascal, 67008 Strasbourg Cedex, France

(*Received* 9 *March* 1984; *accepted* 9 *May* 1984)

Abstract—As a part of a systematic study of the synergic extractions of metals with mixtures of acidic chelating extractants and lipophilic anion-exchangers (B, X with X^- = inorganic anion), the extractions of M = Cd and Zn from perchlorate, nitrate and sulphate media with 1-phenyl-3-methyl-4-benzoyl-pyrazol-5-one (HL) and tri-*n*-octylammonium salts (TOAH.X) or aliquat 336 (TOMA.X) in toluene have been investigated. Three key equilibria describe the extractions:

(a) $$M^{2+} + 2\overline{HL} \rightleftharpoons \overline{ML_2} + 2H^+.$$

(b) $$\overline{B.X} + \overline{HL} \rightleftharpoons \overline{B.L} + H^+ + X^-$$

with B efficiency TOMA < TOAH and X efficiency $ClO_4 < NO_3 < SO_4$.

(c) $$\overline{ML_2} + \overline{B.L} \rightleftharpoons \overline{B.ML_3}$$

with B efficiency TOMA > TOAH and Ni ~ Co > Cd > Zn.

As a consequence of the conflicting orders of efficiencies of TOMA and TOAH in equilibria b and c, TOAH.X is a better synergic extractant from perchlorate medium than TOMA.X whereas the inverse is observed from nitrate and sulphate media. Equilibrium c is independent of the inorganic anions. Constants of equilibria a, b and c are given. $B.ML_3$ species are not extracted in 1-octanol.

Metal cations M^{m+} with a usual coordination number $N_c > 2m$, are extracted in a water-immiscible organic solvent containing a chelating acidic extractant HL as hydrated complexes following:

$$M(H_2O)_x^{m+} + m\overline{HL} \rightleftharpoons \overline{ML_m(H_2O)_y} + mH^+.$$

If HL is associated with a solvating extractant S, the coordinated water molecules in the extracted species may be substituted by S, forming more lipophilic complexes and, then, a synergic extraction is observed following:

$$M(H_2O)_x^{m+} + m\overline{HL} + y\overline{S} \rightleftharpoons \overline{ML_mS_y} + mH^+.$$

Another fact which may limit the extraction efficiency is the formation of $ML_{(m+1)}^-$ inextractable anions.[1] This difficulty, together with the substitution of water molecules in the extracted species, may be solved by using lipophilic ammonium salts (B.X) as co-extractants. Then, the extraction is partly described by the following equilibrium

$$ML_{(m+1)}^- + \overline{B.X} \rightleftharpoons \overline{B.ML_{m+1}} + X^-$$

(X^- = inorganic anion). A great number of papers are now available that describe synergic metal extractions with combinations of acidic chelating extractants and lipophilic anion-exchangers.[1–7] However, if the stoichiometry of the extracted species is generally well-known the role of the inorganic anions has been poorly investigated.[3,4,6] This paper tries to elucidate this aspect in relation to the extraction of divalent cations (Zn, Cd in comparison with Ni, Co) with mixtures of HPMBP (noted HL) and lipophilic ammonium salts (B.X) (with $B^+ = TOAH^+$ = tri-*n*-octylammonium or

* Author to whom correspondence should be addressed.

B^+ = $TOMA^+$ = methyl-tri-*n*-alkyl ammonium = aliquat 336 cation) from perchlorate, nitrate and sulphate aqueous media.

EXPERIMENTAL

Reagents and solutions

HPMBP was prepared as described previously[8] and purified by several recrystallizations in a 1:10 toluene–ethanol mixture. Fluka chemicals (aliquat 336; tri-*n*-octylamine = TOA) were used to prepare the extractant solutions: for solutions containing HL + TOMA.X, the Cl^- anions of the commercial aliquat 336 were eliminated by several washings with a 1 M solution of the appropriate inorganic acid (0.33 M for H_2SO_4) until traces of Cl^- were no longer detected by $AgNO_3$ tests on the washing solutions. A similar treatment was used for HL + TOA solutions with a view to protonating TOA and to form the appropriate tertiary ammonium salt. The ammonium salts initial concentrations in toluene or 1-octanol were varied from 0 to 0.1 M (0 to 0.05 for HPMBP). Organic solutions were systematically pre-equilibrated against an aqueous solution, free of extractable metal, of the same composition as the one that is used in the corresponding metal extraction procedure. The total aqueous inorganic anion concentrations were kept equal to 1 M (ClO_4^-, NO_3^-) or 0.33 M (SO_4^{2-}). The initial total metal concentrations were $1–2 \times 10^{-3}$. pH was adjusted by 0.1 M NaOH solutions of suitable compositions.

Extraction and analytical procedures

The distribution measurements were performed in a thermostatted vessel (25.0 ± 0.2°C) using a batch technique. Equal volumes of the organic and aqueous phases were shaken for at least 10 minutes, which was generally sufficient to reach equilibria, and then separated by gravity. For each experimental point, aliquots of each phase were withdrawn and analysed by atomic absorption using a IL 453 spectrometer.

RESULTS AND DISCUSSION

Extractions with HPMBP alone

The extractions of divalent transition metals, M, with HPMBP (noted HL) have been accurately described by Zolotov,[12–14] Navratil[9,10] or Lambrev[11] and their collaborators. Nevertheless, new experiments were needed because of the different experimental conditions of the present paper i.e. metal concentration, nature of diluents (toluene, octanol) and inorganic anions (perchlorate, nitrate, sulphate) and ionic strength (1 M).

In all cases, plots of log D_M *vs* pH ($D_M = [\overline{M}][M]^{-1}$) (at constant $[\overline{HL}]$) and log D_M *vs* log $[\overline{HL}]$ (at constant pH) are straight lines of slope 2 showing that the extractions are well described by equilibrium (1) where the solvating molecules (H_2O, 1-octanol) have been omitted (overlined symbols refer to the organic phase):

$$M^{2+} + 2\overline{HL} \overset{K_1}{\rightleftharpoons} \overline{ML_2} + 2H^+. \qquad (1)$$

The corresponding equilibrium constants K_1 are given in Table 1.

If toluene is the diluent, divalent metals are extracted following Cu > Zn > Ni ~ Co > Cd; this order agrees with the usual order of distribution constants of the hydrated metal chelates.[16,17]

If 1-octanol is the diluent, a synergic effect is observed. It is due to the substitution of water solvating molecules by 1-octanol in the extracted species. Then, a new selectivity order is observed: Cu > Ni ~ Co > Zn > Cd that is the order usually followed by the formation constants of the corresponding β-diketonates.[15,16]

Extractions of Cd *and* Zn *with mixtures of* HPMBP *and* TOAH.X *or* TOMA.X *in 1-octanol*

As previously observed for Co and Ni,[3] no synergic effect on the extractions of Cd and Zn is observed by addition of amines or ammonium salts to HPMBP in 1-octanol. On the contrary,

antagonistic effects occur for TOA and $X = SO_4$ due to "$\overline{TOA} + \overline{HL} \overset{k}{\rightleftharpoons} \overline{TOAH.L}$" that decreases $[\overline{HL}]$ by formation of $\overline{TOAH.L}$ ($\log k = 2.15$).[3]

Behaviour of mixtures of HPMBP *and* TOAH.X *or* TOMA.X *in liquid–liquid systems (diluent = toluene)*

With a view to understanding the extractions of metals from various aqueous media with mixtures of HPMBP and amines or ammonium salts, a preliminary work has been performed to point out the equilibria that occur if the liquid–liquid system is free of extractable metals. They are summarized in Table 2.

It shows that the anionic exchanges between ammonium salts ($\overline{TOAH.X}$, $\overline{TOMA.X}$) and $\overline{HPMBP}$ follow the orders $ClO_4^- < NO_3^- < Cl^-$, order of the hydratation heats of the anions in water (inverse order of their extractabilities by amines[18]) and TOAH > TOMA.

The formation of the ammonium pyrazolonate compound is most probably favoured with tertiary ammoniums because of intramolecular hydrogen bonds.

If inorganic anions in the aqueous phase are sulphate ones, under the herein experimental conditions ($[SO_4] = 0.33$ M; pH > 3), $\overline{TOAH.L}$ and $\overline{TOMA.L}$ are approximately the only ammonium species in the organic phases.

Synergic extractions from perchlorate medium (organic: toluene + HPMBP + ammonium salts)

As previously observed for Co and Ni[3], the addition of TOA enhances the extraction of Cd with HPMBP (Fig. 1). The slopes of the experimental curves $\log D_{Cd}$ vs pH ($[\overline{HL}]_i$ and $[\overline{TOA}]_i$ constant, (i denoting initial concentrations) increase from 2 ($[\overline{TOA}]_i = 0$) to 2.5 approximately. By comparison to the extractions of Co and Ni in the same experimental conditions,[3] equilibrium (5) is assumed to describe the synergic extraction of Cd.

$$M^{2+} + 3\overline{HL} + \overline{B.ClO_4} \overset{K_5}{\rightleftharpoons} \overline{B.ML_3} + 3H^+ + ClO_4^- . \quad (5)$$

Taking into account the ratios of reagents involved in the organic metal species and equilibrium (4), the experimental curves can be corrected. According to equilibrium (5), after suitable corrections, curves $\log D_{Cd}$ vs pH or $\log [\overline{HL}]$ become straight lines of slope 3 whereas $\log D_{Cd}$ vs $\log [\overline{TOAH.ClO_4}]$ have a slope of 1 which is in good agreement with equilibrium (5). Assuming arbitrarily that the ammonium salts are

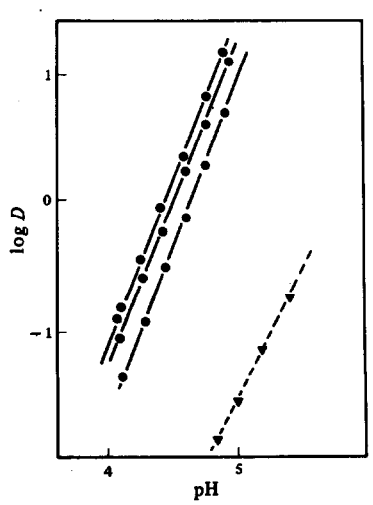

Fig. 1. Extraction of Cd from ClO_4^- medium $[ClO_4^-] = 1$ M; $[\overline{HPMBP}]_i = 0.02$ M; from the right to the left $[\overline{TOA}]_i = 0, 0.0066, 0.04, 0.1$ M; diluent: toluene.

* From Ref. 3.

monomers and taking log $[ClO_4^-] = 0$, constants of equilibria (5) K_5 have been calculated (Table 3).

As it is shown on Fig. 2, the synergic effect is less important for Zn than for Cd under the same experimental conditions. Slopes of experimental plots log D_{Zn} vs pH remain lower than 2.3 with increasing $[\overline{TOA}]_i$ which shows that $\overline{TOAH.ZnL_3}$ and $\overline{ZnL_2}$ are co-extracted. An iterative calculation using log $K_1(Zn, ClO_4) = -4.85$ (Table 1) fits with log $K_5 = -5.2 \pm 0.1$.

The synergic extractions of Cd, Zn, Co and Ni with HPMBP and TOMA.ClO_4 in toluene have been also performed. The results are not very different from the ones with TOAH.ClO_4. A like analysis of the experiments has been realized. The corresponding extraction constants are given in Table 3.

The synergic extractions follow the order Ni > Co > Zn > Cd that is the one observed for extractions with HPMBP alone in *n*-octanol. Similar conclusions can be drawn out, i.e. the ML_3^- formation constants are here determinative.

Though the opposite is generally observed, the extractions are more effective with the tertiary ammonium salt ($\overline{TOAH.ClO_4}$) than with the quaternary one ($\overline{TOMA.ClO_4}$). In fact, equilibrium (5) may be considered as the summation of equilibrium (1) (extraction of M with $\overline{HL}$ alone), (4) (anionic exchange between $\overline{B.X}$ and $\overline{HL}$) and (6):

$$\overline{ML_2 aq.} + \overline{B.L} \overset{K_6}{\rightleftharpoons} \overline{B.ML_3} \qquad (6)$$

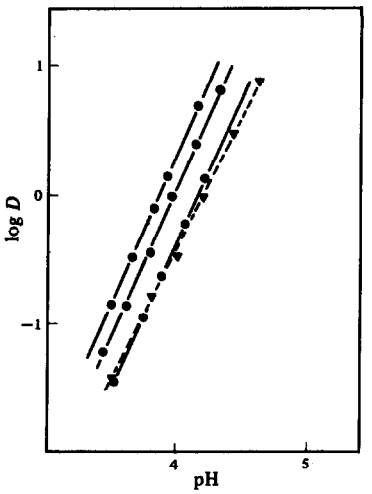

Fig. 2. Extraction of Zn from ClO_4^- medium $[ClO_4^-] = 1$ M; $[\overline{HPMBP}]_i = 0.02$ M; from the right to the left $[\overline{TOA}]_i = 0, 0.0066, 0.04, 0.1$ M; diluent: toluene.

K_6 are given in Table 4. The formation of $\overline{B.ML_3}$ is favoured with quaternary ammonium salts (log K_6(TOMA) − log K_6(TOAH) ~ 2.6) whereas the $\overline{B.L}$ formation by anionic exchange [equation (4)] is favoured with tertiary ammonium salts (log K_4(TOAH) − log K_4(TOMA) ~ 3).

Synergic extractions from sulphate medium (organic: toluene + HPMBP + ammonium salts)

Typical experimental extraction curves log D_M vs pH at constant $[\overline{HL}]_i$, $[\overline{TOA}]_i$ or $[\overline{TOMA.L}]_i$ (*i* denotes initial concentrations) are shown in Figs. 3 and 4 (Cd and Zn extractions, respectively).

The addition of TOMA.L to HL in toluene enhances greatly the extractions of Cd and Zn from sulphate medium. After suitable corrections that take into account the quantities of extractants involved in the organic metal species, log–log plots

Table 4. log K_6 (± 0.2) ($\overline{ML_2} + \overline{B.L} \rightleftharpoons \overline{B.ML_3}$)

B	TOAH			TOMA		
X	ClO_4	NO_3	SO_4	ClO_4	NO_3	SO_4
Cd	5.50	5.55	5.50	8.15	8.20	8.20
Zn	3.60	4.05	3.90	6.15	6.60	6.00
Co	6.30*	—	6.10*	9.15	—	—
Ni	6.40*	—	—	8.85	—	—

* From Ref. 3.

show that the extractions are well described by equilibrium (7).

$$M^{2+} + 2\overline{HL} + \overline{B.L} \overset{K_7}{\rightleftharpoons} \overline{B.ML_3} + 2H^+ \qquad (7)$$

(M = Cd, Zn; B = TOMA).

The difference between equilibria (7) and (1) gives the synergic equilibrium (6) with $\log K_6 = 8.2 \pm 0.2$ and 6.0 ± 0.2 respectively for M = Cd and Zn. These values are closed to the ones determined from perchlorate medium (Table 4) showing that equilibrium (6) does not depend on the nature of the inorganic anions.

A smaller synergic effect is observed with TOA (Fig. 3 and 4). It is maximum for the ratio $[\overline{HL}]_i : [\overline{TOA}]_i = 3$ which corresponds to the stoichiometry of the extracted species $\overline{TOAH.M(PMBP)_3}$. With an excess of TOA, an antagonistic effect may be observed that is due to an excessive formation of $\overline{TOAH.PMBP}$ and a simultaneous missing of $\overline{HPMBP}$ following equilibrium (3) (Zn extraction, Fig. 4). Equilibrium (3) has to be considered for a quantitative explanation of the experimental curves, particularly at high pH. For each experimental point, K_6 can be determined by using the equations:

$$K_1 = [\overline{ML_2}][H^+]^2[M^{2+}]^{-1}[\overline{HL}]^{-2}$$

$$K_3 = [\overline{TOAH.L}][\overline{TOA}]^{-1}[\overline{HL}]^{-1}$$

$$[\overline{TOA}]_i = [\overline{TOA}] + [\overline{TOAH.L}] + [\overline{TOAH.ML_3}]$$

$$[\overline{HL}]_i = [\overline{HL}] + [\overline{TOAH.L}] + 3[\overline{TOAH.ML_3}] + 2[\overline{ML_2}]$$

$$[\overline{M}] = [\overline{ML_2}] + [\overline{TOAH.ML_3}]$$

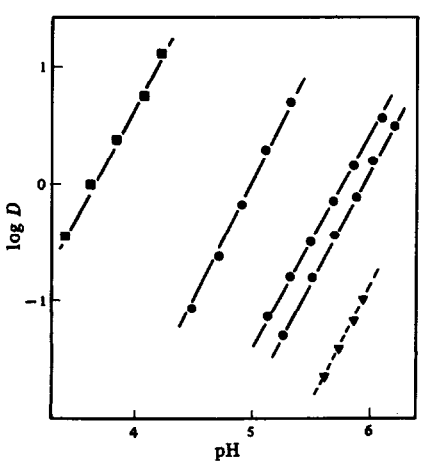

Fig. 3. Extraction of Cd from SO_4^{2-} medium; $[SO_4^{2-}] = 0.33$ M; $[\overline{HPMBP}]_i = 0.02$ M; dashed line: HPMBP alone; continuous lines: from the left to the right $[\overline{TOMA}]_i = 0.0066$ M, $[\overline{TOA}]_i = 0.0066$, 0.04, 0.1 M; toluene.

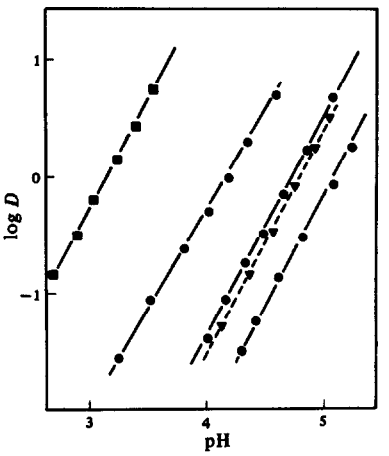

Fig. 4. Extraction of Zn from SO_4^{2-} medium; $[SO_4^{2-}] = 0.33$ M; $[\overline{HPMBP}]_i = 0.02$ M; dashed line: HPMBP alone; continuous lines: from the left to the right $[\overline{TOMA}]_i = 0.0066$ M, $[\overline{TOA}]_i = 0.0066$, 0.04, 0.1 M; toluene.

and

$$K_6 = [\overline{TOAH.ML_3}][\overline{ML_2}]^{-1}[\overline{TOAH.L}]^{-1}.$$

Calculations give $\log K_6 = 5.50 \pm 0.2$ and 3.90 ± 0.2 for Cd and Zn respectively which is in good agreement with calculated values from perchlorate medium (Table 4).

Synergic extractions from nitrate medium (organic: toluene + HPMBP + ammonium salts) and conclusions

The quantitative study of the synergic extractions of Cd and Zn from perchlorate and sulphate media has shown that the magnitude of the synergism is mainly dependent on the nature of inorganic anions because of equilibrium (4) which determines the formation of the synergic agent $\overline{B.L}$. Equilibrium (4) constants for $X = NO_3$ (Table 2) are intermediate between the ones for $X = ClO_4$ or SO_4. Then, an intermediate synergic effect is expected. Consequently, synergic extractions of Cd and Zn by mixtures of $\overline{HPMBP}$ and $\overline{TOAH.X}$ or $\overline{TOMA.X}$ from nitrate medium have been performed with a view to checking the thermodynamic pattern obtained from the other media. Using the constants of equilibria, 1, 2, 3 and 4 determined for a nitrate aqueous medium (Table 2) and mass-balance equations, $\log K_6$ has been determined for each experimental point. The results are given on Table 4 by comparison to the other aqueous media. The good fit of the results, particularly for the cadmium synergic extractions, strongly supports the conclusions drawn from the results in perchlorate and sulphate media:

The magnitude of the synergisms mainly results from two equilibria—the anionic exchange equilibrium (4) that determines the concentration of the real synergic agent $\overline{B.L}$ (ammonium acylpyrazolonate) with the orders of efficiencies TOAH > TOMA and $SO_4 > NO_3 > ClO_4$, and the synergic equilibrium (6) that determines the formation of the extracted synergic species $\overline{B.ML_3}$ with TOMA ≫ TOAH. As a consequence of these conflicting orders, the tertiary amines are better (or equivalent) synergic agents than quaternary ammonium salts for extractions performed from perchlorate medium whereas the inverse is observed for the extraction performed from nitrate and sulphate media (with a maximum of divergence for the latter).

REDUCTIVE NITROSYLATION OF TETRAOXOMETALLATES—XI. MOLYBDATE HYDROXYLAMINE REACTION IN THE PRESENCE OF CYANIDE: SYNTHESIS OF MONO- AND DINITROSYL CYANOMOLYBDATES AND THEIR 2,2′-BIPYRIDINE AND 1,10-PHENANTHROLINE DERIVATIVES DIRECTLY FROM MOLYBDATE

RAMGOPAL BHATTACHARYYA,* GOBINDA PRASHAD BHATTACHARJEE and ALOK MOHAN SAHA

Department of Chemistry, Jadavpur University, Calcutta 700 032, India

(*Received* 17 *November* 1983; *accepted* 9 *May* 1984)

Abstract—The new molybdenum cyanonitrosyl complexes, $R_2[Mo(NO)(CN)_5]\cdot 2H_2O$ (R = Ph_4P and Bu_4N) and $[Mo(NO)(CN)_3(L\text{–}L)]\cdot H_2O$ [L–L = 2,2′-bipyridine (bipy) or 1,10-phenanthroline (phen)] were synthesized directly from $[MoO_4]^{2-}$ in aqueous-alkaline (pH ~ 8) and aerobic media, either by using the counter ions (R) or L–L ligands. However, the same reaction if conducted at a lower pH (~ 5) in the presence of a further excess of $NH_2OH\cdot HCl$, dinitrosylation occurs and hitherto unknown

$(Ph_4P)_2[Mo(NO)_2(CN)_4]\cdot 2H_2O$ and $[Mo(NO)_2(CN)_2(phen)]\cdot 2H_2O$

complexes were obtained. The mononitrosyl series show a single ν_{NO} vibrational mode in their IR spectra at 1650–1700 cm^{-1} region whilst the *cis*-dinitrosyl species show two such bands one around 1650 and the other around 1780 cm^{-1}. The presence of lattice-water molecules in the complexes have been corroborated from thermoanalytical studies. The anionic complexes show 2:1 electrolytic behaviour and the neutral species are non-electrolyte and monomeric. The diamagnetic complexes grossly show a single MLCT ($d \rightarrow \pi^*NO$) transition.

Reductive nitrosylation of $[MoO_4]^{2-}$ using NH_2OH and CN^- in an alkaline medium and generation of $\{Mo(NO)\}^{+}$ moiety as $[Mo(NO)(CN)_5]^{4-}$ has been known for many years,[2,3] but until our recent preliminary communication,[4] such a reaction converting $[MoO_4]^{2-}$ to $\{Mo(NO)_2\}^{2+}$ was unknown. Also, though, the paramagnetic $[Mo(NO)(CN)_5]^{3-}$ anion containing $\{Mo(NO)\}^{2+}$ moiety has been recently characterized,[5] the corresponding dianion, $[Mo(NO)(CN)_5]^{2-}$ is still unknown. The present paper describes for the first time a direct conversion of $[MoO_4]^{2-}$ to $\{Mo(NO)\}^{3+}$ moiety representing a missing link in the series of isostructural anions, $[Mo(NO)(CN)_5]^{n-}$ ($n = 4$–2) using KCN and NH_2OH in an alkaline medium as evidenced by synthesizing the hitherto unknown $R_2[Mo(NO)(CN)_5]^{2-}$ species (while writing out the manuscript we noticed that the phosphonium salt has been recently reported by Wieghardt *et al.*[6]) and its 2,2′-bipyridine (bipy, L–L) and 1,10-phenanthroline (phen, L–L) derivatives of the types $[Mo(NO)(CN)_3(L\text{–}L)]$ in an aerobic condition. We also describe here, a further reductive conversion of MoO_4^{2-} to the $\{Mo(NO)_2\}^{2+}$ stage, and the synthesis of so far unknown products[4] $[Mo(NO)_2(CN)_4]^{2-}$ and $[Mo(NO)_2(CN)_2(phen)]$.

EXPERIMENTAL

Materials and methods

All reagents were of reagent grade and used without further purification. For physicochemical

measurements, the solvents were further purified using literature methods.[7] IR spectra were recorded as KBr discs in a Perkin–Elmer 597 spectrophotometer calibrated with polystyrene. Solution conductances were measured with a Wayne–Kerr Autobalance Precision Bridge B 331 and the electronic spectra (800–200 nm) were taken using a Pye Unicam SP8–150 UV–VIS spectrophotometer. Magnetic susceptibilities were measured with a Gouy balance using $Hg[Co(NCS)_4]$ as a calibrant. T.G.A. curves were recorded in a Shimadzu (Japan) DT-30 Thermoanalyser. A Knauer vapour pressure osmometer was used for the molecular weight determination. The elements C, H and N were analysed microanalytically and Mo and P by standard methods.[8]

Preparation of the complexes (for complexes **1–4**)

A mixture of $Na_2MoO_4 \cdot 2H_2O$ (0.5 g; 2.0 mmol) and KCN (2.0 g; 30 mmol) in water (25 cm^3) was stirred at 60–70°C for 5 min. To the resulting solution, $NH_2OH \cdot HCl$ (2.2 g; 32 mmol) was added with constant stirring at 60–70°C when a red solution was obtained. Stirring and heating was continued for another 30 min and the clear solution (pH ~ 11) was cooled to room temperature and the pH of the solution was reduced to 8 with 6 M HCl (*solution A*).

Tetraphenylphosphonium pentacyanomononitrosyl molybdate(II) *dihydrate*

$\{(Ph_4P)_2[Mo(NO)(CN)_5] \cdot 2H_2O\}$ (**1**).

An aqueous (40 cm^3) solution of Ph_4PBr (1.4 g; 5.7 mmol) was added to the solution A with stirring at 40–50°C when the solution became turbid. The turbid solution was cooled to 0°C and the yellow solid obtained was filtered off, washed with H_2O, EtOH, Et_2O and dried over fused $CaCl_2$ at a reduced pressure. The compound was crystallised from CH_3CN–Et_2O mixture as yellow microcrystals. Yield: 1.39 g; 65%. Found: C, 66.0; H, 4.3; N, 8.5; P, 6.1; Mo, 10.3; H_2O, 3.4%: $C_{53}H_{44}N_6P_2O_3Mo$ requires: C, 65.6; H, 4.5; N, 8.7; P, 6.4; Mo, 9.9 and H_2O, 3.7%. IR: ν_{CN} 2160(s), 2120(sh); ν_{NO} 1650(s); ν_{MoN} (NO) 610(w); ν_{MoC} 350 (w) cm^{-1}. UV–VIS: ν_{max} (cm^{-1}) 23,260 (90). Λ_M = 235 ohm^{-1} cm^2 mol^{-1} (in CH_3CN).

Tetrabutylammonium pentacyanomononitrosyl molybdate(II) *dihydrate*

$\{(Bu_4N)_2[Mo(NO)(CN)_5] \cdot 2H_2O\}$ (**2**).

The same procedure as described under complex **1** was followed using tetrabutylammonium chloride as the precipitating agent instead of Ph_4PBr. Yield, 0.96 g; 63%. Found: C, 57.6; H, 9.6; N, 14.0; Mo, 12.7; H_2O, 4.3%: $C_{37}H_{76}N_8O_3Mo$ requires: C, 57.2; H, 9.8; N, 14.4; Mo, 12.4; H_2O, 4.6%. IR: ν_{CN} 2160(s), 2120(sh); ν_{NO} 1680(s); ν_{MoN}(NO) 620 (w); ν_{MoC} 355(w) cm^{-1}. UV–VIS: ν_{max} (cm^{-1}) 27,780(100). $\Lambda_M(CH_3CN)$ = 242 ohm^{-1} cm^2 mol^{-1}.

Tricyano - unis{2,2′ - *bipyridine*}*mononitrosyl molybdenum*(II) *monohydrate*

$\{[Mo(NO)(CN)_3(bipy)] \cdot H_2O\}$ (**3**).

Solution A was added to a hot aqueous solution (25 cm^3) of bipy (0.5 g; 3.2 mmol) with stirring at the room temperature and the pH of the solution was adjusted to 3.5–4. The separated yellow solid was filtered off, washed with H_2O, EtOH, Et_2O and dried over fused $CaCl_2$ at a reduced pressure. The compound was crystallised from DMF–Et_2O mixture as a bright yellow solid. Yield, 0.54 g; 69%. Found: C, 41.7; H, 2.2; N, 21.9; Mo, 25.8; H_2O, 4.6%; mol. wt (DMF, osmometric) 347: $C_{13}H_{10}N_6O_2Mo$ requires: C, 41.3; H, 2.6; N, 22.2; Mo, 25.4; H_2O, 4.8%. Mol. wt 378. IR: ν_{CN} 2160(s), 2130(sh); ν_{NO} 1690(s); ν_{MoN} (NO) 615(w); ν_{MoN}(L–L) 390(w); ν_{MoC} 355(w) cm^{-1}. UV–VIS: ν_{max} (cm^{-1}) 26,600 (80).

Tricyano - unis{1,10 - *phenanthroline*}*mononitrosyl molybdenum*(II) *monohydrate*

$\{[Mo(NO)(CN)_3(phen)] \cdot H_2O\}$ (**4**).

The same procedure was followed as described under complex **3** using phen instead of bipy to get a yellow compound. Yield, 0.5 g; 60%. Found: C, 45.1; H, 2.4; N, 20.5; Mo, 24.6; H_2O, 4.4%; mol. wt (DMF, osmometric) 388: $C_{15}H_{10}N_6O_2Mo$ requires: C, 44.8; H, 2.5; N, 20.9; Mo, 23.9; H_2O, 4.5%. Mol. wt 402. IR: ν_{CN} 2160(s), 2130(sh); ν_{NO} 1700(s); ν_{MoN} 610(w); ν_{MoN} (L–L) 400(w); ν_{MoC} 360(w) cm^{-1}. UV–VIS: ν_{max} (cm^{-1}) 26,320(75).

Complexes **5** *and* **6**

A mixture of $Na_2MoO_4 \cdot 2H_2O$ (0.5 g; 2.0 mmol) and NaOH (0.5 g; 12.5 mmol) in water (25 cm^3) was stirred at 80°C for 10 min. To the resulting solution, first KCN (2.4 g; 37 mmol) and then $NH_2OH \cdot HCl$ (3.8 g; 55 mmol) were added with stirring at 80°C when an orange red solution was obtained. To this solution, 5–6 drops of 12 M HCl were added and stirred for 5 min when the colour of the solution became red. The solution was stirred for another 5 min and then cooled (pH ~ 7.5). The pH of the solution was then reduced to 5.5 with 6 M HCl (*solution B*).

Tetraphenylphosphonium tetracyanodinitrosyl molybdate(0) *dihydrate*

$\{(Ph_4P)_2[Mo(NO)_2(CN)_4] \cdot 2H_2O\}$ (**5**).

The same procedure as described under complex **1** was followed using the solution B when a greenish yellow solid was separated out and recrystallised as described under complex **1**. Yield, 1.0 g; 50%. Found: C, 63.8; H, 4.0; N, 8.4; P, 6.1; Mo, 10.0; H_2O, 3.9%: $C_{52}H_{44}N_6O_4P_2Mo$ requires: C, 64.1; H, 4.5; N, 8.6; P, 6.4; Mo, 9.8 and H_2O, 3.7%. IR: ν_{CN} 2140(sh), 2110(s); ν_{NO} 1792(s), 1658(s); $\nu_{MoN}(NO)$ 610(w); ν_{MoC} 345(w) cm^{-1}. UV–VIS: ν_{max} (cm^{-1}) 22,800(945). $\Lambda_M(CH_3CN) = 232$ ohm^{-1} cm^2 mol^{-1}.

Dicyano - unis{1,10 - phenanthroline}dinitrosyl molybdenum (0) *dihydrate*

$$\{[Mo(NO)_2(CN)_2(phen)]\cdot 2H_2O\} \quad (6).$$

A hot aqueous solution (40 cm^3) of phen (0.7 g; 3.5 mmol) was added to solution B with stirring at 50°C. The separated yellow solid was filtered off, washed with H_2O, EtOH, Et_2O and dried at a reduced pressure over fused $CaCl_2$. The compound was crystallised from CH_3CN–Et_2O mixture as golden yellow needles. Yield, 0.35 g; 40%. Found: C, 39.5; H, 2.7; N, 19.5; Mo, 22.4; H_2O, 9.0%; mol. wt (CH_3CN, osmometric) 400. $C_{14}H_{12}N_6O_4Mo$ requires: C, 39.6; H, 2.8; N, 19.8; Mo, 22.6; H_2O, 8.5%. Mol. wt 424. IR: ν_{CN} 2150(s), 2130(s); ν_{NO} 1780(s), 1665(s); ν_{MoN} 620(w); ν_{MoN}(L–L) 400 (w); ν_{MoC} 350(w) cm^{-1}. UV–VIS: ν_{max} 23,000 (2960) cm^{-1}.

The anionic complexes are soluble in acetone, acetonitrile and nitromethane but insoluble in methanol, ethanol, benzene and ether. Also, whilst compound **3** is soluble only in DMF or DMSO (and moderately in acetonitrile), **6** is also soluble in acetone, acetonitrile or nitromethane.

RESULTS AND DISCUSSIONS

It is quite interesting to note that, in the presence of an excess of $NH_2OH\cdot HCl$ (as the source of NO group) and CN^-, it is the actual pH of the finally prepared solution (A or B) which decides whether the reaction will be stopped at $\{Mo(NO)\}^{3+}$ stage or can progress further furnishing $\{Mo(NO)_2\}^{2+}$ moiety. While the facile conversion to the former proceeds at a relatively higher pH ($\sim$ 8), the latter requires a slightly acidic medium (pH $\sim$ 5). Interestingly, in a drastically alkaline condition and in the presence of a limited amount of NH_2OH and an excess of CN^-, such a reaction produces $\{Mo(NO)\}^+$ system (see Ref. 2). It may, however be recalled here, that the pH sensitivity of the analogous nitrosylation reaction using NCS^- is extremely acute.[9] In this connection mention may be made that the complex $[Mo(NO)_2(CN)_4]^{2-}$ was alleged to be obtained by the treatment of $[MoCl_2(NO)_2(py)_2]$ with KCN/MeOH, but no details regarding the preparation and characterization were reported.[10]

The IR data (see Experimental) indicate that irrespective of the nature of the complexes, ν_{CN} band is always split and centred around the same region. Of course, as usual,[9] the mononitrosyl species show a single ν_{NO} band and the dinitrosyl species, having *cis*-configuration with respect to each other, show two bands.

Considering the NO^+ formalism[11] the mononitrosyl complexes possessing $\{Mo(NO)\}^{3+}$, $[\{Mo(NO)\}^4]$ moiety should have the central metal ion in the +2 oxidation state and in the dinitrosyl species $[\{Mo(NO)_2\}^{2+}$, i.e. $\{Mo(NO)_2\}^6]$, the same is in the zero valent state, which are further confirmed by the observed diamagnetism of all the isolated complexes. Assuming that, apart from the complexes **1** and **2**, the L–L derivatives, viz. **3** and **4** may also be described by a similar MO picture to that applicable to[11] C_{4v} cases, the single electronic absorption band obtained in these cases may be designated as $e \rightarrow b_2$[11] transition. Another possible transition $e \rightarrow e$, otherwise observable in the thiocyanato complexes[9] around 30 kK, is not observed here due possibly to its occurrence at a still higher energy where it is masked by intense intraligand transition bands. If the symmetry species of the dinitrosyl complexes are approximated as C_{2v} then their MO configuration may be $(a_2)^2$ $(a_1)^2$ $(b_2)^2$ (see ref. 11) and accordingly three electronic transitions ($b_2 \rightarrow a_1$, $b_2 \rightarrow b_1$ and $b_2 \rightarrow b_2$) should be observed.[11] However, only a very intense band (possibly due to $b_2 \rightarrow b_1$ transition, $b_2 \rightarrow a_1$ is expected[11] at a lower energy) is observed in both the cases. Others are either unobserved or concealed by the absorption due to the organic moieties. It is noteworthy that the dinitrosyl complexes of the present cyano series absorb more intensely than their mononitrosyl analogues, as was also observed in the cases of the thiocyanato complexes.[9]

The neutral complexes are non-electrolytes and the anionic ones are 2:1 electrolytes[12] in CH_3CN. The lattice held water molecules in the mononitrosyl complexes can be removed at a lower temperature than the dinitrosyl complexes where the two water molecules are rather strongly held as evidenced from their TGA and DTA curves. This fact indicates that in the dinitrosyl complexes, the water molecules are possibly more strongly hydrogen bonded to the NO^+ and CN^- ligands, as structurally characterized in the cases of some other cyanonitrosyl species.[13,14]

THE THERMAL DECOMPOSITION, IR SPECTRUM AND CRYSTAL STRUCTURE OF AMMONIUM MANGANESE(II) TRIS(HYDROGENSELENITE), $NH_4Mn(HSeO_3)_3$

JUSSI VALKONEN* and SIRPA JALKANEN
University of Jyväskylä, Department of Chemistry, 40100 Jyväskylä 10, Finland

(*Received* 24 *February* 1984; *accepted* 9 *May* 1984)

Abstract—The compound $NH_4Mn(HSeO_3)_3$ has been prepared and its IR spectrum and thermal behaviour have been investigated. It crystallizes in the monoclinic space group with cell dimensions $a = 13.716(5)$ Å, $b = 7.678(2)$ Å, $c = 9.416(3)$ Å and $\beta = 98.51(2)°$. The space group is $P2_1/c$. The structure is a three-dimensional network. The manganese atom is six coordinated by oxygen atoms, which form bridges between selenium and manganese atoms.

Manganese forms several compounds with the selenium(IV) anions: selenite, SeO_3^{2-}, hydrogenselenite, $HSeO_3^-$, and diselenite, $Se_2O_5^{2-}$. The hydrogenselenite has been reported only for manganese(III).[1,2,14] The known manganese(II) selenites are $MnSeO_3$, $MnSeO_3H_2O$, $MnSeO_3D_2O$, $MnSeO_32H_2O$ and $MnSe_2O_5$,[3–7] and the double selenites

$$Na_2Mn(SeO_3)_22H_2O, \quad K_2Mn_2(Se_2O_5)_33H_2O$$

and

$$(NH_4)_2Mn(SeO_3)_2.$$[8,9]

The structures of the double selenites are unknown and the aim of this investigation was to investigate the structure of ammonium manganese(II) selenite.

EXPERIMENTAL

Synthesis

The compound was synthesized as described for $(NH_4)_2Mn(SeO_3)_2$,[9] but it can also be crystallized from an aqueous solution containing manganese selenite and ammonium selenite in molar ratio 1 : 15. Crystals are well-formed, light-coloured prisms. Manganese and selenium were analyzed with a Perkin–Elmer 5000 AAS-spectrophotometer and ammonium was analyzed by distillation and titration. The results of analyses are NH_4: 3.7% (3.9), Mn: 12.1% (12.0) and Se: 52.9% (51.8), calculated values for $NH_4Mn(HSeO_3)_3$ in parentheses.

Thermal analysis

The thermoanalytical investigation was carried out with a Perkin–Elmer Thermogravimetric System TGS-2. The sample size was about 10 mg, the heating rate 4° min^{-1} and the atmosphere was air with a flow of 50 cm^3 min^{-1}.

IR spectrum

The IR spectrum was recorded with a Perkin–Elmer 283 IR spectrophotometer. Scan range was from 4000 to 200 cm^{-1}, scan time 12 min and the method KBr pellet technique.

Data collection

Conditions for unit cell determination and data collection are given in Tables 1 and 2. Semi-empirical absorption corrections were made on the bais of a ϕ-scan with five different 2θ values. The largest measured relative reduction in intensity was from 1.00 to 0.51.

The structure was solved by direct methods using the program package Multan.[10] The refinement was carried out with the program XRAY,[11] using the scattering factors of Cromer and Mann[12] for neutral atoms. The picture was drawn with the program ORTEP, which is a part of the XRAY system.

μ(Mo-K_α) = 123.30 cm^{-1}

Refinement was based on structure factors and unit weights.

RESULTS AND DISCUSSION

Thermal analysis

The thermal behaviour of $NH_4Mn(HSeO_3)_3$ is shown in Fig. 1 and Table 3.

The first stage is the liberation of selenium dioxide.

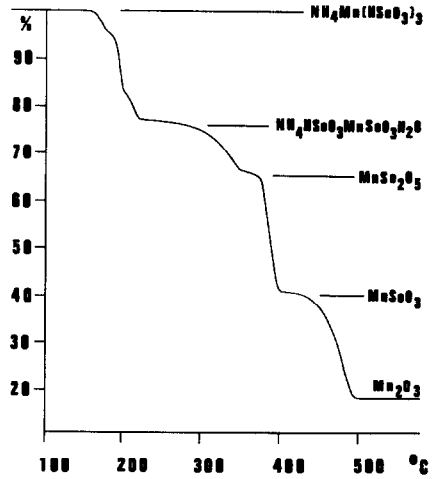

Fig. 1. The thermal decomposition of $NH_4Mn(HSeO_3)_3$.

The composition of the reaction product is not clear: it is either a mixture of ammonium hydrogen selenite and manganese selenite or a double salt. The next stage is the formation of manganese diselenite. In the third stage selenium dioxide is again liberated, this time with the formation of manganese selenite. In the fourth stage, manganese selenite decomposes to manganese(III) oxide, which converts to Mn_3O_4 at high temperature. The decomposition of the hydrogenselenite to diselenite and normal selenite is in good agreement with the literature.[13]

IR spectrum

The IR spectrum is shown in Fig. 2 and Table 4. The IR spectra of the selenite and hydrogenselenite are quite similar. The main differences between the spectra of the selenite and hydrogenselenite ions are the peaks at 2405 and 1237 cm^{-1} for hydrogenselenite.

The ammonium ion causes a strong peak at wavenumber 1425 cm^{-1} as well as at wavenumbers above 2900 cm^{-1}, where also the peaks of hydrogen bonds of OH group are situated. The results agree

Crystal structure

The crystal data are given in Table 2, interatomic distances in Table 5 and the picture of the structure in Fig. 3.*

The structure of ammonium manganese tris(hydrogenselenite) forms a three-dimensional network, which can be thought to consist of two very similar layers oriented in the *yz*-plane. The first layer consists of Mn(1), Se(1), O(1), O(2) and O(3) atoms and the *x*-coordinate has value close to 0. The second layer consists of Mn(2), Se(2), O(4), O(5) and O(6) atoms and the *x*-coordinate is about 0.5. Layers are connected together through the selenite group containing the selenium atom Se(3), which is located between the layers.

The manganese atoms lie in special positions with fixed coordinates, each surrounded by six oxygen atoms forming an elongated octahedron. The oxygen–manganese–oxygen angles are 180° or vary between 86.4 and 93.6°.

Selenite groups form trigonal pyramids with selenium atoms at the apex. One selenium–oxygen distance is elongated in each selenite group, which is characteristic of the hydrogenselenite. This elongation is caused by hydrogen atoms, which draw oxygen atoms toward themselves. All manganese–oxygen and selenium–oxygen distances are in good agreement with other manganese selenites.[2,5–7]

Nitrogen atoms of the ammonium group are located in holes between the layers. The hydrogen atoms could not be found, but possible hydrogen bond distances less than 3.2 Å are listed in Table 5.

* Atomic coordinates have also been deposited with the Institut für Anorganische Chemie, Bonn, F.R.G. for inclusion in their Data Base.

FORMATION AND TRANSFORMATION OF Pb_2SiO_4

OSAMU YAMAGUCHI,* HIROSHI OKA and KIYOSHI SHIMIZU
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kyoto 602, Japan

(*Received* 12 *December* 1983; *accepted* 11 *May* 1984)

Abstract—A new modification of Pb_2SiO_4 was formed by the simultaneous hydrolysis of lead and silicon alkoxides, followed by washing and drying. It has a hexagonal unit cell with $a = 9.928$ Å and $c = 7.184$ Å. The IR spectra indicate that this modification contains $[SiO_4]^{4-}$ and $[Si_2O_7]^{6-}$ groups in the structure. The transformation process is examined by high-temperature X-ray diffraction.

Lead orthosilicate, Pb_2SiO_4, exists in at least three polymorphic modifications: L(low)-, M(medium)- and H(high)-forms. The system PbO—SiO_2 has a wide glass-forming range extending beyond the orthosilicate composition; therefore, almost all studies on the formation and transformation of Pb_2SiO_4 have been carried out by the crystallization from the glass.[1–7] However, there has been conflicting information in the literature concerning the identities and names of the modifications.

In the present study, a new modification of Pb_2SiO_4 was formed by the simultaneous hydrolysis of lead and silicon alkoxides, followed by washing and drying. On the basis of this result, the characterization and transformation of alkoxy-derived Pb_2SiO_4 were examined by differential thermal analysis, high-temperature X-ray diffraction, and infrared spectrum analysis.

EXPERIMENTAL

Silicon ethoxide, $Si(OC_2H_5)_4$, was a pure grade. Lead amyloxide, $Pb(OC_5H_{11})_2$, was synthesized by the reaction of anhydrous lead acetate with sodium amyloxide in the presence of an excess amount of isoamyl alcohol.[8,9] The mixed alkoxides prepared in the mole ratio $Pb^{2+}:Si^{4+} = 2:1$ were refluxed for 10 h at 131°C and then hydrolyzed by adding distilled water at 25°C. The hydrolysis product was separated from the suspension by filtration, washed repeatedly with hot water, and dried at 80°C under

reduced pressure. The average particle size of the resulting starting powder, determined by electron microscopy, was *ca* 450 Å.

Differential thermal analysis (DTA) was conducted in air at a rate of 10°C min^{-1}; α-alumina was used as a standard material. The starting powder was examined by X-ray diffraction using nickel-filtered Cu–K_α radiation. The goniometer scanning speed of 1/4° min^{-1} was selected so as to achieve accurate *d* spacings. The diffractometer was calibrated with high purity silicon. The specimens obtained in the heating and cooling processes at a rate of 10°C min^{-1} were identified by high-temperature X-ray diffraction. Infrared spectroscopy (IR) was performed on a dispersion in potassium bromide, using the pressed disk technique.

RESULTS AND DISCUSSION

The identities and names of the modifications of Pb_2SiO_4 were inconsistent due to contradictory results. Because the present results were in general agreement with those of Furukawa *et al.*,[7] their nomenclature was used in the description of the present results.

Table 1 shows the X-ray diffraction data of the starting powder; these diffraction data are different from those of the modifications of Pb_2SiO_4 reported previously. Many compounds have been reported in the system PbO—SiO_2. As will be described, lead silicates other than Pb_2SiO_4 and free species were not observed throughout the heating process. Therefore, the starting powder can be considered to be a compound corresponding to Pb_2SiO_4. The diffraction pattern was indexed as a hexagonal unit cell with $a = 9.928$ Å and $c = 7.184$ Å.

A DTA curve in the heating process revealed small and sharp endothermic peaks at 570–625°C and 720–760°C, respectively. High-temperature X-ray diffraction analysis confirmed that the first endothermic peak (at 570–625°C) is due to the transformation of the hexagonal phase (starting powder) into H—Pb_2SiO_4, and the second endothermic peak (at 720–760°C) to the melting of H—Pb_2SiO_4. The melting temperature (at 744°C) was in agreement with the reported one.[10] In the cooling process from H—Pb_2SiO_4 (at 625–720°C), a small exothermic peak was observed at 490–530°C, corresponding to the transformation of H— into M—Pb_2SiO_4; however, H—Pb_2SiO_4 transformed sluggishly into M—Pb_2SiO_4. Thus, pure M—Pb_2SiO_4 was difficult to obtain under the present conditions; the X-ray diffraction pattern of the mixture of M— and H—Pb_2SiO_4 (M ≫ H) was

* Absorption bands resulting from H—Pb_2SiO_4.

observed at room temperature. This result is in agreement with that reported by Furukawa *et al.*[7] On the other hand, pure H—Pb_2SiO_4 was easily obtained at room temperature by rapid quenching from the temperature between 625 and 720°C. No L—Pb_2SiO_4 phase, being always the first product crystallized from the $2PbO \cdot SiO_2$ glass, could be recognized in the present study.

Table 2 shows the IR data of the starting powder, M—Pb_2SiO_4, and H—Pb_2SiO_4. Goetz *et al.*[5,6] showed that H—Pb_2SiO_4 ("M" in their nomenclature) is constructed from $[Si_4O_{12}]^{8-}$ rings, that M—Pb_2SiO_4 ("H" in their nomenclature) is a polysilicate chain structure, and that L—Pb_2SiO_4 is a pyrosilicate with $[Si_2O_7]^{6-}$ units; these results suggesting that all modifications of Pb_2SiO_4 contain the oxygens which are not bonded to silicons. Furukawa *et al.*[7] supported the silicate structures proposed by Goetz *et al.*[5,6] The IR data of M— and H—Pb_2SiO_4 in the present study were consistent with their data.[5–7] On the other hand, the spectrum data of the starting powder are in good agreement with those of phase X crystallized from $5PbO \cdot 3SiO_2$ and $3PbO \cdot 2SiO_2$ glasses.[7] According to the data for phase X, there are two types of silicon in the structure, $[SiO_4]^{4-}$ and $[Si_2O_7]^{6-}$ groups. It is evident therefore that the starting powder contains both silicate anions, so that the crystal-chemical formula is represented by $Pb_6O(SiO_4)(Si_2O_7)$.

BI- AND TRIHETERONUCLEAR COMPLEXES OF URANIUM AND GROUP VI TRANSITION METALS

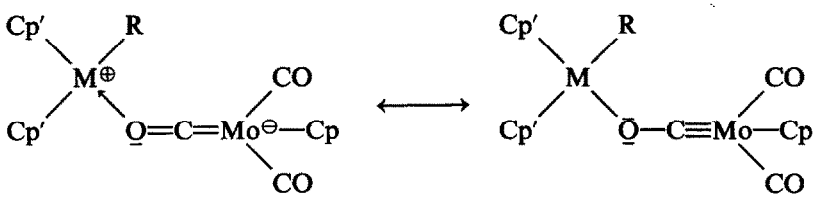
ALAIN DORMOND* and CLAUDE MOISE
Laboratoire de Synthèse et d'Electrosynthèse Organométalliques Associé au CNRS (LA 33), Faculté des Sciences, 6 Bd Gabriel 21100 Dijon, France

(*Received* 27 *March* 1984; *accepted* 19 *May* 1984)

Abstract—The new heterobimetallic compounds $Cp_3U[OCM(CO)_2Cp']$ containing uranium and group VI transition metals are synthesized from Cp_3UCl and $Na[M(CO)_3Cp']$ or from Cp_3UCH_3 and $H[M(CO)_3Cp']$ (M = Mo, W; Cp = C_5H_5; Cp' = C_5H_5 or C_5Me_5). In a same manner, the trimetallic $Cp_2U[OCMo(CO)_2Cp]_2$ is obtained starting from $Cp_2U(NEt_2)_2$ and $H[Mo(CO)_3Cp]$. All these complexes exhibit low CO stretching frequencies characteristic of isocarbonyl linkages between uranium and Mo or W atoms.

There is now a great interest in heterobimetallic complexes incorporating both early and late transition metals; this increase of interest is due to their potential importance in catalysis[1,2] and organic synthesis.[3] Among heterobinuclear complexes reported to date are compounds containing both group IV (Ti, Zr) and group VI (Mo, W) metals. In these compounds, the two metal atoms are not directly bonded but are linked by a bridging carbonyl ligand.[4–8]

In cyclopentadienyllanthanide series, the reaction with some group VI metallate anions has been described,[9] but, at this time, there is no report on analogous investigations in actinide series. In an effort to develop the chemistry of cyclopentadienyluranium compounds, we have studied the condensation reactions of metallate anions $[M(CO)_3Cp']^-$ (M = Mo, W; Cp' = C_5H_5 or C_5Me_5) with Cp_3UCl and the elimination reactions between the hydrides $H[M(CO)_3Cp']$ and Cp_3UCH_3, Cp_3UNEt_2 and $Cp_2U(NEt_2)_2$. We report in this paper the synthesis and characterization of new bi- and triheteronuclear systems incorporating both uranium and group VI transition metal atoms.



RESULTS AND DISCUSSION

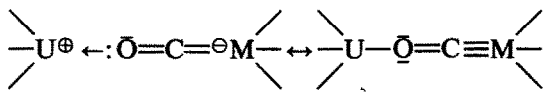
In THF solution at −50°C, Cp_3UCl reacts readily with $Na[Mo(CO)_3Cp]$ in the molar ratio 1:1. The solution turns deep red and NaCl deposits. After removal of the solvent, **1** can be isolated in quantitative yield as a reddish brown compound but always containing small amounts of NaCl [equation (1)]

$$Cp_3UCl + Na[Mo(CO)_3Cp] \xrightarrow[-NaCl]{THF} Cp_3U[OCMo(CO)_2Cp]. \quad (1)$$

1

If pentane is added to the THF solution, **1** deposits immediately as a brown microcrystalline compound. Moreover, **1** is quantitatively obtained by a methane elimination reaction[10] from Cp_3UCH_3 and $H[Mo(CO)_3Cp]$ in heptane or toluene solutions at −50°C. In a similar manner, the bimetallic

M = Ti, Zr; Cp = C_5H_5; Cp' = C_5H_5 or C_5Me_5



* Author to whom correspondence should be addressed.

complexes **2** and **3** are obtained with high yields [equation (2)].

$$Cp_3UCH_3 + H[M(CO)_3Cp'] \xrightarrow{-CH_4} Cp_3U[OCM(CO)_2Cp'] \quad (2)$$

1: M = Mo; Cp′ = Cp
2: M = Mo; Cp′ = C_5Me_5
3: M = W; Cp′ = Cp

The IR solid spectra of these compounds exhibit a very low carbonyl stretching frequency at *ca.* 1640 cm^{-1} indicative of an isocarbonyl linkage between U and Mo (or W) atoms.[4,5,7–10,11]

These complexes may be considered formally to consist of the acid–base adducts of the Lewis acid Cp_3U^+ and the metallate anions $[M(CO)_3Cp']^-$. The formation of an isocarbonyl bridge preferentially to a direct metal–metal bond may be rationalized in terms of the preference of the "hard" uranium centre to form a bond with the "hard" oxygen site rather than the "soft" molybdenum or tungsten centres. This trend reflects the well known oxophilic character of actinides (or early transition metals) in relatively high oxidation state.[12]

Compounds **1**, **2** and **3** are poorly soluble in non coordinating solvents such as toluene or hydrocarbons: all attempts at recrystallization lead to the formation of the hydrides $H[M(CO)_3Cp']$ and of unidentified uranium byproducts. A similar hydride formation has been observed with analogous titanium (or vanadium) heterobimetallic systems.[11] All these complexes are highly soluble in THF; the NMR spectra of the deep red solutions show a sharp C_5H_5 singlet at *ca* −3.2 ppm (C_5H_5 resonance of Cp_3UCl in THF occurs at −3.4 ppm); the IR spectra exhibit strong CO stretching peaks which are quite identical to those of the free carbonyl anions $[M(CO)_3Cp']^-$, thereby suggesting a substantial dissociation corresponding to an ionic structure: the companion cation is presumably $[Cp_3U(THF)]^+$ [equation (3)].

$$Cp_3U[OCM(CO)_2Cp'] \xrightarrow{THF} [Cp_3U(THF)]^+ + [M(CO)_3Cp']^- \quad (3)$$

These complexes react with anhydrous HCl or CCl_4 affording in a quantitative yield Cp_3UCl and respectively $H[M(CO)_3Cp']$ and $Cl[M(CO)_3Cp']$ (identified by NMR and IR spectroscopy). Such cleavage reactions cannot thus be used as a diagnostic tool of metal–metal bonds in heterobimetallic complexes as it has been previously claimed[6,13] but seems to be a general feature of "early–late" transition metal binuclear compounds.[5,8,11]

The bisdialkylamido derivative $Cp_2U(NEt_2)_2$ reacts quantitatively in heptane solution at −70°C when mixed with $H[Mo(CO)_3Cp]$ in a 1:2 ratio. A red powder deposits and no remaining hydride or Cp_2UNEt_2 are present in the colourless supernatant heptane. This red powder is very thermally unstable and decomposes readily at room temperature affording $H[Mo(CO)_3Cp]$ and intractable uranium products. This instability precludes recrystallization and elemental analysis. Its IR spectrum shows only three intense CO absorptions at 1900, 1740 and 1640 cm^{-1}.

The stoichiometry of the reaction and the IR data are in agreement with the trimetallic structure **4** [equation (4)].

$$Cp_2U(NEt_2)_2 + 2H[Mo(CO)_3Cp] \rightarrow Cp_2U(O{-}C{\equiv}Mo(CO)_2Cp)_2 \quad (4)$$

4

If dissolved in THF, even at low temperature, **4** evolves immediately with formation of $H[Mo(CO)_3Cp]$ and of the compound **1** identified by IR and NMR spectroscopy.

1 can be also obtained from Cp_3UNEt_2 in toluene or THF [equation (5)] and from the biscyclopentadienyl Cp_2UNEt_2 when performed in THF medium [equation (6)]

$$Cp_3UNEt_2 + H[Mo(CO)_3Cp] \xrightarrow[\text{or toluene}]{THF} \mathbf{1} + HNEt_2 \quad (5)$$

$$Cp_2U(NEt_2)_2 + \tfrac{2}{3}H[Mo(CO)_3Cp] \xrightarrow{THF} 1 + HNEt_2 + ? \quad (6)$$

This ligand redistribution is indicative of the greater stability of a triscyclopentadienyl versus a biscyclopentadienyl uranium moiety. This is a general trend in actinide series which reflects the tendency of the cyclopentadienyl ligands to saturate the actinide coordination sphere.[14,15]

These studies provide further examples which illustrate the similar properties of actinides and IVA transition metal cyclopentadienyl derivatives. Both series give closely related bimetallic systems which exhibit an isocarbonyl linkage. Nevertheless, it has been recently related a series of Zr–Fe and Zr–Ru complexes[16] which adopt metal–metal bonded

Table 1. Analytical and IR data

	Compound	Found (required) % C	H	M	U	νC≡O (cm^{-1}) Nujol mulls (THF solution)		
1	$Cp_3U[OCMo(CO)_2Cp]$	39.99 (40.70)	3.06 (2.95)	13.93 (14.16)	35.35 (35.10)	1900 (1899	1740 1794	1634 1744)

structures; it seems therefore to be of interest to examine if similar attachment mode is possible in the actinide series and further work in this field is in progress.

EXPERIMENTAL

Microanalysis were by Service Central d'Analyse, CNRS (Lyon). Spectrometers: IR Perkin–Elmer 580B; spectra in nujol mulls or in THF solutions (NaCl cells), NMR Hitachi Perkin–Elmer R24 (protonated solvents) or Jeol FX100. ^1H data references to Me_4Si. All operations were performed under argon and all solvents were distilled from sodium/benzophenone under argon immediately before use.

The following complexes: Cp_3UCl,[17] Cp_3UCH_3,[18] Cp_3UNEt_2,[19] $NaM(CO)_3Cp'$,[20] $HM(CO)_3Cp'$[20] were prepared according to literature methods.

Analytical and IR data were collected in Table 1.

Preparation of $Cp_3U[OCMo(CO)_2Cp]$

Method A: to a stirred solution of Cp_3UCl (1.56 g) in THF (40 cm^3) at −50°C was added dropwise a solution of $Na[Mo(CO)_3Cp]$ (0.89 g) in THF (20 cm^3), the reaction mixture develops immediately a deep red colour and white NaCl deposits. The solution was allowed to rise to room temperature, filtered, concentrated to *ca* 10 cm^3 and pentane (30 cm^3) was added. The reddish-brown powder was collected, washed with pentane and dried. Yield 2.15 g (96%).

Method B: to a stirred solution of Cp_3UCH_3 (1.12 g) in toluene (20 cm^3) at −50°C, was added a solution of $H[Mo(CO)_3Cp]$ (0.615 g) in heptane (20 cm^3). The mixture was allowed at −25°C and brown crystals deposit within *ca* 1 h. Yield 1.64 g (97%). Compounds (2) $\{Cp_3U[OCMo(CO)_2(C_5Me_5)]\}$ and (3) $\{Cp_3U[OCW(CO)_2Cp]\}$ were obtained in an identical manner.

Method C: to a stirred solution of Cp_3UNEt_2 (1.1 g) in toluene (20 cm^3) at −50°C was added $H[Mo(CO)_3Cp]$ (0.57 g) in heptane (10 cm^3) and the mixture was allowed to rise to room temperature. **1** crystallises readily. Yield 1.1 g (81%).

If the reaction was performed in THF, the IR spectrum of the solution showed two strong peaks at 1898 and 1787 (very broad) cm^{-1}. The same spectrum was recorded when a small amount of $HNEt_2$ was added to a THF solution of **1**.

Cleavage of $Cp_3U[OCMo(CO)_3Cp]$

HCl: To a suspension of **1** (0.5 g) in toluene (10 cm^3) at −70° was added slowly a dilute solution of HCl in toluene (10 cm^3). After 1 h, the brown solution was allowed to room temperature, evaporated to dryness and $H[Mo(CO)_3Cp]$ was extracted by sublimation. The brown residue was Cp_3UCl and a very small amount of $Cl[Mo(CO)_3Cp]$.

CCl_4: In the same manner, after similar treatment, the residue contains a mixture of Cp_3UCl and of $Cl[Mo(CO)_3Cp]$ in equimolecular amounts.

Preparation of $Cp_2U[OCMo(CO)_2Cp]_2$ (4)

To a stirred solution of $Cp_2U(NEt_2)_2$ (1.02 g) in heptane (20 cm^3) at −70° was added $H[Mo(CO)_3Cp]$ (0.95 g) in heptane (20 cm^3). A red powder deposits readily. Yield 1.1 g (91%). **4** may be stored 24 h at −70°C without noticeable decomposition. At room temperature under argon it decomposes within *ca* 10 minutes affording quantitatively $HMoCO_3Cp$ and an unidentified black powder.

Reaction of $Cp_2U(NEt_2)_2$ *with* $H[Mo(CO)_3Cp]$ *in* THF

To a solution of $Cp_2U(NEt_2)_2$ (1.02 g), 2×10^{-3} mol in THF (10 cm^3) at room temperature, was

added dropwise a 10^{-3} mol solution of $H[Mo(CO)_3Cp]$ in THF; the consumption of the hydride solution (1.4 cm^3) was monitored by IR. After filtration, concentration and addition of pentane (30 cm^3) moderately pure **1** was isolated. Yield 0.5 g (56%).

Acknowledgement—We thank Mr D. Arnoult for his technical assistance.

SYNTHESIS AND BASE HYDROLYSIS OF CHLORO(N-(2-PYRIDINYLMETHYLENE)-N′-[3-[(2-PYRIDINYLMETHYLENE)AMINO]-PROPYL]-1,3-PROPANEDIAMINE)COBALT(III) PERCHLORATE

GEOFFREY A. LAWRANCE
Department of Chemistry, The University of Newcastle, N.S.W. 2308, Australia

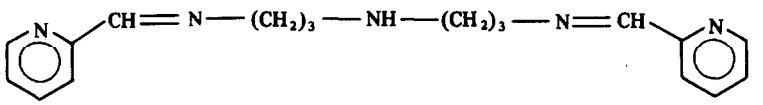
(*Received* 10 *April* 1984; *accepted* 22 *May* 1984)

Abstract—Synthesis of $[Co(pyDPT)Cl](ClO_4)_2$ from pentadentate ligand and cobalt(II) yields one *cis* isomer. Hydrolysis in base is extremely rapid (k_{OH} 1.8×10^6 M^{-1} s^{-1} at 25°C) in this complex, where the geometry and ligand character fix the single site for conjugate base formation as *cis* to the leaving group.

Studies of the base hydrolysis of haloamine complexes have been extensive in recent years.[1–4] At least for cobalt(III), the dissociative conjugate base (S_N1cb) mechanism appears to operate

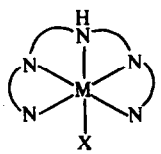
$$Co(ligNH)X_n^{m+} + OH^- \rightleftharpoons Co(ligN^-)X_n^{(m-1)+} + H_2O$$
$$\downarrow$$
$$Co(ligNH)X_{(n-1)}(OH)^{m+} \xleftarrow[\text{fast}]{OH_2} Co(ligN^-)X_{(n-1)}^{m+} + X^-$$

where ligNH represents an N-donor ligand with at least one available site for deprotonation.



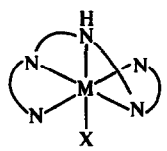
With certain unsaturated multidentate ligands such as N-(2-pyridinylmethylene)-N′-[3-[(2-pyridinylmethylene)amino]-propyl]-1,3-propanediamine (pyDPT, **I**)[5] the available sites for conjugate base formation when complexed is limited to one.

Provided the coordinated geometry of the ligand is established, the disposition of the site of deprotonation to the leaving group is firmly established. In general, such pentadentate ligands can form a number of geometrical isomers (**II–V**), although all need not occur. In this paper the synthesis, characterization and base hydrolysis of one isomer of the chlorocobalt(III) complex of **I** is reported.

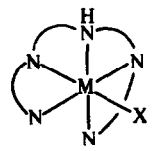


EXPERIMENTAL

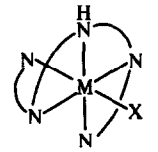
Synthesis of $[Co(pyDPT)Cl](ClO_4)_2$



A solution of 1,7-diamino-4-azaheptane (5.2 g, 0.05 mol) in methanol (200 cm^3) was reacted with



I



II

III

IV

V

pyridine-2-aldehyde (10.7 g, 0.1 mol) essentially as previously described.[5] A solution of $CoCl_2 \cdot 6H_2O$ (11.9 g, 0.05 mol) in methanol (100 cm^3) was added, and air bubbled through the solution for 1 h. Concentrated HCl (40 cm^3) was added to the dark brown solution, producing an immediate deep red colour. Solid $LiClO_4$ was added with stirring until precipitation commenced. After cooling in an icebath, the purple precipitate was collected on a frit and dried at the pump. The crude material was dissolved in a minimum volume of warm aqueous HCl (1 M, ~60°C), filtered, and solid $NaClO_4$ added with stirring until precipitation commenced. After ice cooling, the purple product was collected, washed with ethanol and ether, and dried in a vacuum desiccator. (Yield 7.3 g.) Found: C, 36.1; H, 3.8; N, 11.5. Calc. for $C_{18}H_{23}N_5Cl_3CoO_8$: C, 35.87; H, 3.85; N, 11.62%. Visible absorption maxima (λ, nm (ε, M^{-1} cm^{-1}) in 1 *M* HCl: 539 (78), 453 (51).

Hydrolysis kinetics. The kinetics of base hydrolysis were followed at 325 nm using a Varian 635 spectrophotometer and a thermostatted (±0.1°C) cell holder. Succinate buffers (pH 4.5–6.0) were employed, with ionic strength (0.1 M) controlled with $NaClO_4$. Complex concentrations of $2 \rightarrow 5 \times 10^{-4}$ M were employed. Rate constants were determined by standard Guggenheim methods, with first order behaviour observed for at least three half-lives.

Physical methods. IR spectra were recorded as KBr discs on a Perkin–Elmer 300 spectrometer, while visible absorption spectra were recorded with a Varian 635 spectrophotometer. ^1H and ^{13}C NMR spectra were recorded using Varian HA-100 and Jeol FX-60 spectrometers respectively, with NaTPS and dioxan as internal references respectively.

RESULTS AND DISCUSSION

The synthesis described yields predominantly one isomer, since the recrystallized product behaves as a single species when it is chromatographed on various cation exchange resins. That the condensation has proceeded as expected is clear from the ^1H NMR and IR spectra. The IR shows an NH stretch at 3210 cm^{-1}, a C=N stretch at 1628 cm^{-1} and pyridine ring vibrations at 1600, 1570, 1480 and 1445 cm^{-1}, analogous to positions observed in the cobalt(II) complex of **I**.[5] Integration of the ^1H NMR spectrum indicates the presence of two imine protons, eight pyridine ring protons and a single amine proton (Fig. 1), in addition to methylene resonances. The ^1H NMR is not consistent with a symmetrical *trans* stereochemisty; rather, an unsymmetrical *cis* stereochemistry exists. This was confirmed by ^{13}C NMR, where resonances assignable to six methylene carbons (14.8, 21.9, 30.1, 34.1, 41.5, 42.8 ppm *vs* dioxan) were observed in addition to multiple resonances in the pyridine ring region (87.0, 84.8, 76.1, 64.5, 63.9 ppm) which are split slightly under higher resolution. Further, two imine carbon resonances at 110.9 and 108.8 ppm were observed, and support the assignment of resonances at 9.28 and 9.44 ppm in the ^1H NMR spectrum to nonequivalent imine protons.

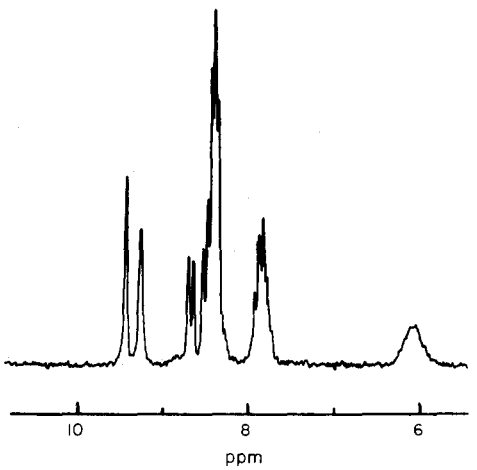


Fig. 1. Section of the ^1H NMR spectrum of $[Co(pyDPT)Cl](ClO_4)_2$ in DCl, showing the nonequivalent imine proton resonances (left of figure), pyridine ring proton resonances, and the single amine proton resonance (right of figure).

The NMR spectroscopy shows that *trans* isomers **II** and **III** are not the product. A *cis* isomer **IV** or **V** is the isolated species, and Dreiding models indicate that isomer **V** with the central saturated tridentate amine component in the *mer* geometry is less strained, and this is the proposed structure for the isolated complex.

Hydrolysis in base is extremely rapid. To determine the kinetics of hydrolysis, it was necessary to employ succinate buffers where the pH is below 6. The observed rate constants displayed a first order dependence with respect to hydroxide ion concentration over the range studied (Table 1), with the second order rate constant at 25°C 1.8×10^6 M^{-1} s^{-1}. Activation parameters for the process are $\Delta H^{\neq}$ 58 kJ mol^{-1} and $\Delta S^{\neq}$ +70 J K^{-1} mol^{-1}. From the rapid disappearance of the amine proton signal in the ^1H NMR spectrum of the complex in acid buffers in D_2O, the proton exchange rate was estimated to be of the order of 10^8 M^{-1} s^{-1}. Although limited solubility did not permit an accurate rate constant to be determined, clearly base abstraction is not rate determining in this system.

‖ $I_{buffer} = 0.05$ M.

The observed second order rate constant for hydrolysis is much larger than those usually observed for ammine and saturated amine complexes, but is of the same order of magnitude as rate constants reported for unsaturated and multidentate amine ligand complexes, including macromonocyclic ligand complexes.[1] The activation entropy is consistent with a conjugate base mechanism, where a large positive contribution due to the preequilibrium deprotonation applies. The single site available for the deprotonation fixes the geometry of the leaving group as *cis* to the conjugate base in this case, and it is apparent that this arrangement is appropriate for the S_N1cb mechanism to operate. Experiments investigating the site of deprotonation have inferred that sites both *cis* and *trans* to the leaving group may be effective in the S_N1cb mechanism.[6–9] With appropriate ligand design and favourable geometrical isomer formation, N-donor complexes with a single fixed deprotonation site can be prepared. Isolation of a complex with a single *trans* site to complement this study will be pursued.

(*Received* 30 *May* 1984; *accepted* 7 *June* 1984)

Abstract—The interaction of iron(II) acetate in presence of bis(dimethylphosphino)methane (dmpm) with dimethyl- and diethylmagnesium leads to *cis*-$FeMe_2(dmpm)_2$ and $(\eta^2$-$C_2H_4)Fe(dmpm)_2$, respectively; $(PhCH_2)_2Mg$ gives the *trans*-dibenzyl while *o*-$C_6H_4(CH_2MgCl)_2$ gives $C_6H_4(CH_2)_2Fe(dmpm)_2$. On the basis of NMR spectra the latter is best formulated as an "olefin" complex with both uni- and bidentate dmpm ligands. Also described are $[M(dmpm)_3]X_2$, M = Fe, Ru, X = Cl, PF_6; $Fe(dmpm)_3$, which has one unidentate ligand; *cis*-$Fe(CO)_2(dmpm)_2$; $Fe(CO)(dmpm)_2$; $[RuH(dmpm)_3]PF_6$ and $[FeH(dmpm)_3]BF_4$. The X-ray crystal structures of $Fe(\eta^1$-dmpm)$(dmpm)_2$ and the *trans*-$[RuH(\eta^1$-dmpm)$(dmpm)_2]^+$ ion as its PF_6^- salt have been determined. Both complexes contain one unidentate and two bidentate dmpm ligands. The iron complex has square pyramidal geometry with the two chelating dmpm ligands spanning basal edges [Fe—P = 2.161(3) Å] and the unidentate ligand bonding at the axial site [Fe—P = 2.165(3) Å]. The ruthenium complex has an analogous arrangement of dmpm ligands: [Ru—P(chel) = 2.318–2.338(4) Å, Ru—P(uni) = 2.348(4) Å], with the Ru—H bond [1.68(5) Å] *trans* to the Ru—P(unidentate) bond. Crystals of *cis*-$FeMe_2(dmpm)_2$ have also been examined, but severe rotational disorder has precluded the determination of any meaningful geometrical data.

Although many transition metal complexes of bis(diphenylphosphino)methane (dppm) acting as a uni or bidentate ligand or as a bridging group are well known,[1] relatively few studies have been made using the methyl analogue, bis(dimethylphosphino)methane (dmpm),[2] probably because this ligand is more difficult to make.

We now describe some complexes of iron and ruthenium with uni- and bidentate dmpm ligands. ^1H and ^{31}P—$\{^1H\}$ nuclear magnetic resonance data are collected in Table 1. The X-ray crystal structures of $Fe(dmpm)_2(\eta^1$-dmpm), and *trans*-$[RuH(\eta^1$-dmpm$)(dmpm)_2]PF_6$ have been determined.

RESULTS AND DISCUSSION

Alkylation of iron(II) acetate

Me_2Mg. Treatment of $Fe(O_2CMe)_2$ with Me_2Mg in the presence of dmpm in thf led to an air-sensitive orange crystalline compound $FeMe_2(dmpm)_2$ which is readily soluble in hydrocarbons. The compound was also isolated but in lower yield in the reaction of $[Fe(dmpm)_3]Cl_2$ (see later) with methyllithium.

The ^1H NMR spectrum shows a multiplet for the Fe-methyl groups at −0.03 ppm. The ^{31}P–$\{^1H\}$ NMR spectrum shows a complex 12-line pattern centred at 13.6 ppm from the dmpm ligands as expected for a *cis*-configuration for the compound.

An attempt to confirm this assignment via an X-ray structure determination has not been completely successful. The compound crystallises in the cubic system with extensive orientational disorder of the molecule (see Experimental) and we have not been able to extract from the structure analysis any meaningful geometrical parameters.

Et_2Mg. When $Fe(O_2CMe)_2$ was treated with Et_2Mg in the presence of dmpm in thf a golden yellow crystalline compound of stoichiometry $(C_2H_4)Fe(dmpm)_2$ was isolated. The compound is air- and moisture-sensitive and is very soluble in hexane. No metal-hydride stretch was observed in

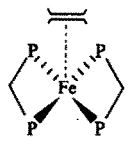
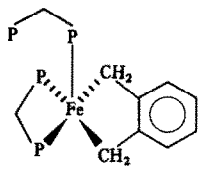
the IR spectrum. In the ^1H NMR spectrum, other than the resonance due to dmpm, there is a quintet [J(P—CH_2) = 9.0 Hz] centred at 1.84 ppm for the protons of bound ethylene indicating that the C_2H_4 group protons are equivalent and are coupled to four equivalent P atoms. The ^{31}P—$\{^1H\}$ spectrum shows only a singlet at 1.24 ppm for the dmpm ligands. The spectroscopic data is thus consistent with a square pyramidal geometry (**I**) earlier, where the η^2-ethylene occupies the axial site.



The ethylene complex is doubtless formed via the diethyl intermediate, *cis*-$Et_2Fe(dmpm)_2$, which undergoes β-hydride transfer with elimination of ethane. A similar mechanism has been invoked for the formation of $(\eta^2\text{-}C_2H_4)Ru(PMe_3)_4$.[3]

$(PhCH_2)_2Mg$. Alkylation of the acetate leads to a dark red compound which is slightly soluble in saturated hydrocarbons but very soluble in toluene. The ^1H NMR spectrum shows a broad multiplet at 0.12 ppm for the benzyl methylene protons while the ^{31}P—$\{^1H\}$ spectrum shows a singlet at 1.67 ppm for dmpm. Spectroscopic and analytical data confirm the formulation *trans*-$(PhCH_2)_2Fe(dmpm)_2$.



o-$C_6H_4(CH_2MgCl)_2$. In this case alkylation leads to a dark red hexane soluble compound, $C_6H_4(CH_2)_2Fe(dmpm)_2$. The ^1H NMR spectrum shows a broad singlet at 2.31 ppm and a broad doublet (J = 12.6 Hz) at −1.60 ppm for the methylene protons of the *o*-xylidene moiety. The ^{31}P–$\{^1H\}$ spectrum shows a broad singlet, a doublet (J = 11.1 Hz), and a broad singlet (relative intensities 1:2:1) at 41.9, −11.5 and −60.5 ppm, respectively. This indicates the presence of both uni- and bidentate dmpm. The resonances at 41.9 and −60.5 ppm can be assigned respectively to the coordinated and the uncoordinated phosphorus atoms of the unidentate ligand.

There are two possible structures for the compound having either a σ-bonded or a π-bonded *o*-xylidene (**IIa** and **IIb**). For σ-bonded *o*-xylidenes the ^1H chemical shifts of the methylene protons are at 1.91 and 1.66 ppm for $Fe(CH_2C_6H_4CH_2)(dmpe)_2$[4] and at 3.28 ppm for $Pt(CH_2C_6H_4CH_2)(COD)$, whereas for π-bonded *o*-xylidenes they are at 2.49 and −0.39 ppm for $W(CH_2C_6H_4CH_2)_3$[6] and at 1.89 and −0.13 ppm for $Ru(CH_2C_6H_4CH_2)L_3$,[7] (L = PMe_3, PEt_3, PMe_2Ph). The high chemical shift of the methylene protons at −1.60 ppm in the present compound is consistent with a π-bonded *o*-xylidene group. Further, the presence of a unidentate dmpm with an uncoordinated phosphorus atom is in accord with an 18-e species (**IIb**) rather than a 16-e species (**IIa**). Unfortunately single crystals suitable for X-ray work were not obtained.

Synthesis and reactions of [M(dmpm)$_3$]X_2; M = Fe, Ru, X = Cl, PF_6

Iron. Treatment of $FeCl_2$ with excess dmpm in refluxing ethanol produces high yields of a pale yellow compound of stoichiometry $Fe(dmpm)_3Cl_2$ which is a 1:2 electrolyte in methanol. The ^1H NMR spectrum shows a multiplet and a doublet (J = 14.8 Hz) of relative intensity 1:6 at 3.6 and 1.78 ppm for the methylene protons and the methyl protons of the dmpm moiety, respectively. The ^{31}P–$\{^1H\}$ spectrum shows a singlet at −2.9 ppm. The compound is thus $[Fe(dmpm)_3]Cl_2$, with octahedral Fe^{II}.

Reduction of $[Fe(dmpm)_3]Cl_2$ with excess sodium amalgam in thf gave an extremely air-sensitive, dark red crystalline compound of stoichiometry $Fe(dmpm)_3$ which is monomeric in benzene. This complex has been mentioned also in a recent paper.[2b] The ^{31}P–$\{^1H\}$ NMR spectrum shows a doublet of quintets (J = 26.6 Hz, 6.5 Hz), a doublet (J = 6.5 Hz), and a doublet (J = 26.6 Hz) of relative intensities 1:4:1 at 18.4, −12.2 and −61.0 ppm. The resonances at 18.4 and −61.0 ppm correspond respectively to the coordinated and uncoordinated phosphorus of unidentate dmpm. The data are consistent with a square pyramidal geometry (**III**) where the unidentate dmpm occupies the axial site and there is free rotation about the Fe—P bond of this ligand in solution at room temperature.

Thus in solution, the equatorial phosphorus P_E should be dynamically equivalent, and the ^{31}P–$\{^1H\}$ NMR spectrum for **III** should exhibit a

doublet of quintets for P_A (coupled to P_X and four P_E, a doublet for P_E (coupled to P_A), and a doublet for P_X (coupled to P_A) of relative intensities 1:4:1, respectively. Based on the coupling pattern and intensity ratio, the resonances at 18.4, −12.2, and −61.0 ppm can be assigned to P_A, P_E and P_X respectively.

The square pyramidal geometry is confirmed by a single crystal X-ray diffraction study. A diagram of the molecular structure is given in Fig. 1, whilst selected bond lengths and angles are given in Table 2. The molecule lies on a crystallographic mirror plane which bisects the two bidentate dmpm ligands which form the base of the square pyramidal co-ordination geometry. However, the unidentate dmpm ligand is disordered and adopts two mirror symmetry related conformations; this places the uncoordinated phosphorus and the bridge methylene carbon slightly off the plane, with a concommitant orientational disorder of the two methyl carbons. The "free" end of this unidentate ligand is oriented so that the Fe—P(3) and C(3)—P(4) bonds have a mutually *trans* configuration. Perhaps the most significant feature of the structure is that the axial and based Fe—P bonds are equal within the limits of experimental error.

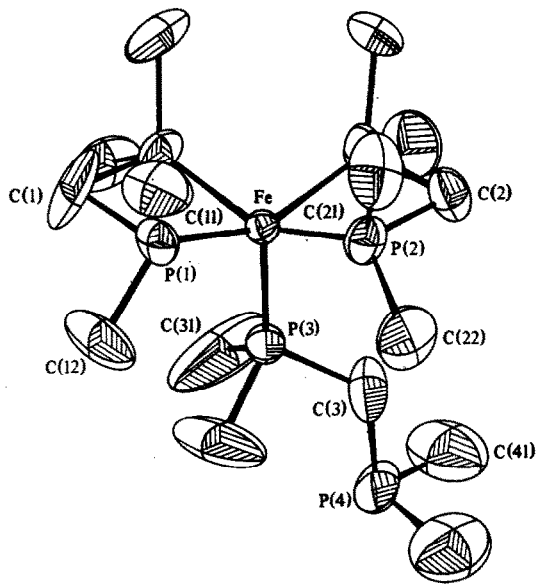

Fig. 1. The structure of $Fe(\eta^1\text{-dmpm})(dmpm)_2$.

The interaction of $[Fe(dmpm)_3]Cl_2$ with excess Na/Hg under CO pressure in thf gave *cis*-$Fe(CO)_2(dmpm)_2$ and $Fe(CO)(dmpm)_2$ (see below).

Ruthenium. Treatment of $RuCl_2(PPh_3)_3$ with excess dmpm in refluxing ethanol gave a white crystalline compound, $[Ru(dmpm)_3]Cl_2$, which is a

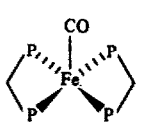
Key to symmetry operations relating designated atoms to reference atoms at (*x*, *y*, *z*): (a) 1.0-*x*, *y*, *z*.

1 : 2 electrolyte in methanol. It is the analogue of the above iron compound and the NMR spectra (Table 1) are similar. The PF_6^- salt can be prepared quantitatively by metathesis of the chloride with excess NH_4PF_6 in methanol.



Interaction of $[Ru(dmpm)_3](PF_6)_2$ with excess Na/Hg in thf gave a white crystalline compound of stoichiometry $[RuH(dmpm)_3]PF_6$. The compound is insoluble in hexane, toluene and Et_2O, but readily soluble in acetone and thf; it decomposes slowly in air. The IR spectrum shows a metal-hydride stretch at 1828 cm^{-1} and the ^1H NMR spectrum a complex pattern for the dmpm ligands plus a metal-hydride resonance at −7.64 ppm as a doublet of quintets (J = 62.7 Hz, 23.0 Hz). The $^{31}P-\{^1H\}$ spectrum shows a quintet of doublets (J = 26.6, 22.2 Hz), a doublet (J = 26.6 Hz), and a doublet (J = 22.2 Hz) of relative intensities 1 : 4 : 1 centred at 2.1, −25.3, and 54.6 ppm. The spectroscopic data are consistent with an

IV

V

VI

octahedral geometry (IV) where a unidentate dmpm ligand and the hydride are *trans* and there is free rotation about the Ru—P bond of the unidentate ligand in solution at room temperature.

In solution, the equatorial phosphorus atoms P_E should be dynamically equivalent; the ^1H NMR spectrum should exhibit a doublet of quintets for the hydride (coupled to P_A and four P_E). The $^{31}P-\{^1H\}$ spectrum should exhibit a quintet of doublets for P_A (coupled to four P_E and P_X), a doublet for P_E (coupled to P_A), and a doublet for P_X (coupled to P_X) of relative intensities 1 : 4 : 1, respectively. Thus the resonances at 2.1, −25.3, and −54.6 ppm can be assigned to P_A, P_E and P_X respectively.

The structure of the cation is shown in Fig. 2; selected bond lengths and angles are given in Table 3. The metal has essentially octahedral geometry with the Ru—H bond *trans* to the phosphorus of the unidentate dmpm. The arrangement of the dmpm ligands in this complex is different from that found in the iron complex described above. Although the two bidentate dmpm ligands have, themselves, a pseudo mirror-like arrangement, the "chain" of the unidentate ligand does not lie even approximately along this direction but is oriented close to the direction of the Ru—P(4) bond. Steric pressure arising from this feature may well account for the length of the Ru—P(4) bond, which is the longest of the four, quite variable, "equatorial" Ru—P bonds which could be expected to have very similar lengths. The "axial" Ru—P bond, *trans* to the Ru—H bond, is longest and indicates a small *trans* influence for the H ligand.

Reactions of $Fe(dmpe)_3$

Carbon monoxide. When $Fe(dmpm)_3$ was treated with CO (60 psi), yellow (major product) and orange (minor product) compounds were isolated. The yellow compound, which is readily soluble in hydrocarbons, is $Fe(CO)_2(dmpm)_2$. Both compounds were identical to those obtained from $[Fe(dmpm)_3]Cl_2$ as above. The $^{31}P-\{^1H\}$ NMR spectrum of the yellow complex shows a multiplet, a doublet (J = 17.7 Hz) and a broad singlet of relative intensities 1 : 2 : 1 at 46.4, −6.3 and −58.7 ppm, which can be respectively assigned to the P atoms of the coordinated unidentate ligand, the bidentate ligand and the uncoordinated P atom of the unidentate ligand. The IR spectrum in hexane shows two terminal CO stretches at 1902 and 1848 cm^{-1} indicating a *cis*-dicarbonyl configuration. Thus, the yellow compound is trigonal bypyramidal *cis*-$Fe(CO)_2(\eta^2$-dmpm$)(\eta^1$-dmpm) (V).

The orange compound has a terminal CO stretch at 1887 cm^{-1} and the $^{31}P-\{^1H\}$ NMR shows a singlet at 47.3 ppm; the compound is evidently $Fe(CO)(dmpm)_2$ with a square pyramidal structure (VI).

Methyl iodide. When $Fe(dmpm)_3$ was treated with excess methyl iodide, a pale yellow crystalline compound of stoichiometry $[Fe(dmpm)_3]I_2$ was isolated. The compound is insoluble in hydrocarbons and thf but readily soluble in alcohols and in methanol is a 1 : 2 electrolyte. The ^1H and ^{31}P NMR spectra are similar to those of the chloride.

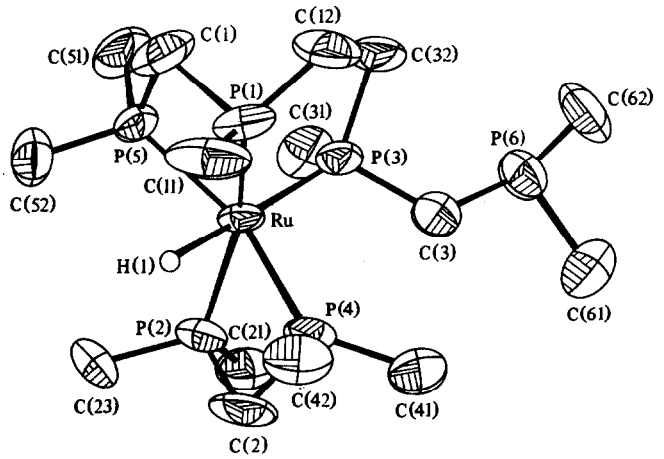


Fig. 2. The structure of the cation *trans*-$[RuH(\eta^1\text{-dmpm})(dmpm)_2]^+$.

Fluoroboric acid. When $Fe(dmpm)_3$ was treated with one equivalent of HBF_4 in diethyl ether at $-78°C$, a yellow crystalline compound of stoichiometry $[FeH(dmpm)_3]BF_4$ was isolated. The compound is insoluble in hydrocarbons, toluene and thf. The IR spectrum shows a metal-hydride stretch at 1823 cm^{-1}. The ^1H NMR spectrum shows a complex pattern for the dmpm ligands, and a metal-hydride resonance as doublet of quintet at -9.18 ppm ($J = 48.9$ and 10.3 Hz). The $^{31}P\text{-}\{^1H\}$ spectrum shows a multiplet, a doublet ($J = 35.4$ Hz) and a multiplet of relative intensities 1:4:1 at 28.7, 7.0 and -53.1 ppm can be assigned to P_A, P_B and P_X, respectively. The structure is thus the same as the ruthenium analogue (IV).

EXPERIMENTAL

Microanalyses were by Pascher (Bonn). IR spectra were obtained on a Perkin–Elmer 683 spectrometer; data given in cm^{-1} for Nujol mulls unless otherwise specified. NMR spectra were recorded on a JEOL FX90Q; data in δ ppm referenced to $Me_4Si(^1H)$ and 85% $H_3PO_4(^{31}P)$. Conductivities were measured using a Data Scientific PT1-18 conductivity meter. Molecular weights were determined cryoscopically in benzene.

All operations were carried out under argon or *in vacuo*. All chemicals used were of reagent grade. Solvents were dried by standard procedures, distilled, and deaerated prior to use. Melting points were taken in sealed capillaries and are uncorrected. $RuCl_2(PPh_3)_3$[8] and $Fe(O_2CMe)_2$[9] were made by standard methods. Bis(dimethylphosphino) methane was prepared by first, synthesis of $Cl_2AlCH_2AlCl_2$ from Al and CH_2Cl_2, reaction of this with PCl_3 to give $Cl_2PCH_2PCl_2$ and finally methylation of the latter with MeMgCl.[10]

cis-*Dimethylbis*[*bis*(*dimethylphosphino*)*methane*]*iron*(II)

Dmpm (0.35 cm^3, 2.3 mmol) and Me_2Mg (3.8 cm^3 of 0.56 *M* solution in Et_2O, 2.1 mmol) were added to a suspension of $Fe(O_2CMe)_2$ (0.33 g, 1.9 mmol) in thf (40 cm^3) at $-78°C$ and the mixture allowed to warm slowly to room temperature and stirred for additional 12 h. The dark red solution was evaporated under vacuum and the residue extracted with hexane (2×30 cm^3). The solution was filtered, concentrated to *ca* 10 cm^3, and cooled to $-20°C$ to give red-orange crystals. Yield: 0.5 g, 73%; m.p. 108°C (decomp. with gas evolution). [Found (required): C, 40.6 (40.2); H, 9.5 (9.5); P, 35.0 (34.6)%.] IR. 1422m, 1410m, 1354w, 1284m, 1269s, 1172w, 1146m, 1058s, 942s, 924vs, 912vs, 856s, 829m, 716s, 687s, 671m, 643m, 456w, 416s.

η^2-*Ethylene bis*[*bis*(*dimethylphosphino*)*methane*]*iron*(0)

Dmpm (0.8 cm^3, 5.3 mmol), Et_2Mg (3.5 cm^3 of 0.61 *M* solution in Et_2O, 2.1 mmol) and $Fe(O_2CMe)_2$ (0.36 g, 2 mmol) in thf (50 cm^3) were warmed from $-78°$ to room temperature and stirred for 12 h. The solvent was removed under vacuum and the residue extracted with hexane; the solution was filtered, concentrated to *ca.* 5 cm^3 and cooled to $-78°C$ to give yellow microcrystals. Yield 0.23 g, 30%; m.p. 120°C (decomp. with gas evolution). [Found (required): C, 41.0 (40.4); H, 9.1 (9.0); P, 34.4 (34.8)%.] IR 1420m, 1416m, 1407m, 1279m, 1267s,

trans-*Bis(benzyl)bis[bis(dimethylphosphino)-methane]iron*(II)

As earlier but using dmpm (1.8 cm^3, 12 mmol), $(PhCH_2)_2Mg$ (16.5 cm^3 of 0.38 *M* solution in Et_2O, 6.3 mmol) and $Fe(O_2CMe)_2$ (1 g, 5.7 mmol) in thf (100 cm^3). The hexane extract was concentrated to *ca.* 10 cm^3 and cooled to −20°C to give dark-red crystals. Yield: 0.29 g, 10%; m.p. 92°C decomp. [Found (required): C, 57.0 (56.5); H, 8.3 (8.2), P, 23.9 (24.3)%.] I.R. 3072w, 3055w, 1590s, 1496w, 1482s, 1428m, 1419w, 1410m, 1302w, 1292m, 1284m, 1272m, 1200m, 1174w, 1150w, 1082m, 1073m, 1027m, 989m, 943vs, 924s, 863m, 834m, 794m, 747s, 723s, 696s, 670w, 652m, 553s, 530m.

Benzo(6) buten-1,4-diylbis[bis(dimethylphosphino)-methane]iron(II)

As earlier but from dmpm (1 cm^3, 6.6 mmol), *o*-$C_6H_4(CH_2MgCl)_2$ (90 cm^3 of 0.073 *M* solution in thf; 6.6 mmol) and $Fe(O_2CMe)_2$ (0.57 g, 3.3 mmol) in thf (50 cm^3). The hexane extract was concentrated to *ca* 30 cm^3, and cooled to −20°C to give dark red crystals. Yield: 1.0 g, 75% m.p. 78–79°C. [Found (required): C, 49.8 (50.0); H, 8.3 (8.3); P, 28.5 (28.7)%. *M*, 460 (432).] IR 3040w, 3020w, 3002w, 1430m, 1420m, 1341m, 1285m, 1271m, 1150w, 1130w, 1072m, 1065m, 1021w, 980w, 940vs, 925vs, 890s, 860m, 830s, 811w, 770w, 748s, 720s, 700s, 685s, 665m, 655m, 630w, 590m, 490w, 460w, 423m.

Tris[bis(dimethylphosphino)methane]iron(II) *dichloride*

Dmpm (5.5 cm^3, 36.3 mmol) and $FeCl_2$ (1.4 g, 11.2 mmol) in ethanol (100 cm^3) were refluxed for 14 h. The pale yellow solid precipitated on cooling to 20°C was collected, washed with diethyl ether (2 × 50 cm^3) and crystallized from methanol to give white microcrystals. Yield: 5.7 g; 95%; m.p. 264°C. [Found (required): C, 33.8 (33.6); H, 8.1 (7.9); P, 34.2 (34.7); Cl, 13.0 (13.3)%.] Conductivity: Λ_M = 130 ohm^{-1} cm^2 mol^{-1} (10^{-3} M in MeOH). IR 1430m, 1420m, 1405m, 1355w, 1300m, 1288m, 1280m, 1090m, 920vs, 875w, 850w, 842w, 833w, 735s, 720m, 692w, 660w, 409m.

Tris[bis(dimethylphosphino)methane]iron(0)

A suspension of $[Fe(dmpm)_3]Cl_2$ (3.0 g, 5.6 mmol) in tetrahydrofuran (150 cm^3) was transferred to a flask containing sodium amalgam (0.5 g, 21.7 mmol Na in 15 cm^3 Hg) and the mixture was stirred for 7 d. The dark red solution was filtered, evaporated and the residue extracted into hexane (3 × 40 cm^3). The filtered solution was concentrated to *ca* 30 cm^3 and cooled to −20°C to give red crystals. Yield: 1.9 g, 75%, m.p. 76°C. [Found (required): C, 38.9 (38.8); H, 9.2 (9.1); P, 40.3 (40.1)%. *M*, 440 (464)] IR 1425m, 1405w, 1350w, 1275m, 1260m, 1054m, 920vs, 905vs, 882s, 843m, 831m, 809w, 760w, 720m, 681s, 645s, 458m, 430m.

Dicarbonylbis[bis(dimethylphosphino)methane]-iron(0)

Method A. A suspension of $[Fe(dmpm)_3]Cl_2$ (0.8 g; 1.5 mmol) in thf (70 cm^3) with sodium amalgam (0.3 g, 13 mmol of Na in 10 cm^3 Hg) was pressurized with CO (60 psi) in a pressure bottle. The mixture was heated at 70°C with stirring for 3 d. The orange solution was filtered, evaporated and the residue extracted with hexane (2 × 40 cm^3). The filtered extract was concentrated to *ca* 25 cm^3 and cooled to −20°C to give pale yellow crystals and a small amount of orange crystals which can be easily separated by hand. For the yellow compound: yield, 0.4 g, 70%; m.p. 69°C. [Found (required): C, 37.6 (37.5); H, 7.3 (7.3); P, 32.0 (32.3); O, 8.3 (8.3)%. *M*, 370 (384).] IR (hexane) 1902s, 1848s. For the orange crystals: IR (hexane) 1887s.

Method B. A solution of $Fe(dmpm)_3$ (0.23 g, 0.5 mmol) in hexane (50 cm^3) was pressurized with CO (60 psi) in a pressure bottle. After 2 d at 20°C the orange solution was filtered, evaporated under vacuum and the residue extracted with hexane (2 × 30 cm^3). The filtered solution was concentrated to *ca* 10 cm^3 and cooled to −20°C to give yellow crystals together with a trace amount of orange crystals identical with those obtained in method A.

Tris-[bis(dimethylphosphino)methane]iron(II) *diiodide*

To a solution of $Fe(dmpm)_3$ (0.39 g, 0.84 mmol) in hexane (50 cm^3) was added methyl iodide (1.0 cm^3, 1.8 M in ethyl ether), when a white solid formed immediately. The mixture was stirred for 16 h, the solid filtered, washed with diethyl ether (2 × 40 cm^3) and recrystallized from methanol to give pale yellow micro-crystals. Yield: 0.5 g, 85%; m.p. 315–318°C (decomp.). [Found (required): C, 25.0 (25.1); H, 5.9 (5.9); P, 25.8 (25.9); I, 35.2 (35.4)%.] Conductivity: Λ_M = 140 ohm^{-1} cm^2 mol^{-1}, (10^{-3} *M* in MeOH). IR 1420m, 1405m, 1307m, 1290m, 1285m, 1019w, 921vs, 875m, 845m, 740s, 721m, 670m, 405m.

Hydridotris[bis(dimethylphosphino)methane]-iron(II) tetrafluoroborate

To a solution of $Fe(dmpm)_3$ (0.23 g, 0.5 mmol) in Et_2O (50 cm^3) at −78°C was added dropwise 0.5 cm^3 of aqueous HBF_4 (65%) *ca.* 6 mmol cm^{-3} to give a yellow precipitate. After stirring at −78°C for 1 h the solid was collected and dissolved in thf. The solution was evaporated under vacuum and the residue extracted into CH_2Cl_2 which was concentrated to *ca* 2 cm^3. On addition of Et_2O (*ca* 2 cm^3) until yellow crystals began to precipitate and cooling to −20°C yellow crystals were obtained. Yield: 0.19 g, 70%; m.p. 198°C decomp. [Found (required): C, 32.3 (32.7); H, 7.7 (7.8); P, 33.3 (33.8); F, 13.4 (13.8)%.] IR 1823m, 1422m, 1292m, 1279m, 1136w, 1084s, 1048vs, 1030s, 922vs, 893m, 872m, 854w, 843m, 816w, 762w, 728m, 716m, 705m, 684w, 687w, 428m, 412m.

Tris[bis(dimethylphosphino)methane]-ruthenium(II) hexafluorophosphate

A solution of dmpm (0.7 cm^3, 4.7 mmol) and $RuCl_2(PPh_3)_3$ (1.3 g, 1.4 mmol) in EtOH (50 cm^3) was refluxed for 12 h. After cooling to room temperature, a solution of NH_4PF_6 10.7 g, 4.3 mmol) in H_2O (30 cm^3) was added and the solution concentrated until crystals started to deposit when it was cooled at 0°C to give white crystals. Yield: 1 g, 90%; m.p. 320°C. [Found (required): C, 22.7 (22.5); H, 5.4 (5.3); P, 30.6 (31.0); Cl, 0.5 (0)%.] Conductivity: Λ_M = 140 ohm^{-1} cm^2 mol^{-1} (10^{-3} M in MeOH). IR 1428m, 1307s, 1293m, 1120m, 936vs, 885s, 850vs.br, 756m, 739m, 710w, 685w, 568s.

Hydridotris[bis(dimethylphosphino)methane]-ruthenium(II) hexafluorophosphate

A suspension of $Ru(dmpm)_3(PF_6)_2$ (0.8 g; 1 mmol) and Na/Hg (0.1 g, Na in 10 cm^3 Hg) in thf (50 cm^3) was stirred at room temperature for 2 d. The pale yellow solution was filtered and evaporated under vacuum. The residue was washed with petroleum (2 × 30 cm^3), toluene (2 × 30 cm^3) and diethylether (2 × 30 cm^3) then extracted into thf (2 × 30 cm^3). The filtered thf solution was concentrated to *ca* 5 cm^3 and cooled to −20°C to give white crystals. Yield: 0.5 g, 76%; m.p. 216–220°C. [Found (required): C, 27.7 (27.5); H, 6.6 (6.6); P, 32.6 (33.1)%.] IR 1828m, 1428m, 1296w, 1100m, 928s, 898s, 878m, 856m, 836vs, 768w, 732m, 721m, 708w, 686w, 660w, 569s.

Crystallographic studies

Crystals of the three compounds examined were sealed under argon in glass capillaries for the X-ray work. Following initial, photographic, crystal quality checks, all subsequent X-ray measurements were made using a CAD4 diffractometer and graphite monochromated Mo-K_α radiation (λ = 0.71069 Å). Cell dimensions were determined, and intensities measured using standard procedures.[11]

The structures of the $Fe(dmpm)_3$ and $[RuH(dmpm)_3]PF_6$ complexes were determined and refined routinely, although in the case of the iron complex some problems arose due to disorder. Whilst a structure in which the molecule conformed exactly to the space-group requirements of mirror symmetry refined to an R value of 0.046, some of the atoms of the unidentate dmpm ligand showed very high anisotropic "thermal motion". Attempts were made to model this, in terms of 50/50 disorder of two mirror related conformations of the ligand, in which the bridging methylene carbon and the non-coordinated phosphorus atom lay just off the crystallographic mirror plane, and the pairs of methyl groups on each phosphorus had lost their mutual mirror relationship by virtue of torsions in the Fe—P, P—C and C—P bonds away from values which would give the ideal geometry. However, following refinement using this model, some of the resulting geometry parameters were quite unacceptable. Accordingly we have used the simpler model and assume that the high apparent thermal motion is either real, or represents a continuous disorder between the two "off-mirror" conformations.

For both structures, all heavy atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in idealised positions and assigned an overall isotropic thermal parameter for each group.

Crystal data, details of the intensity measurements and refinements are given in Table 4. Atomic co-ordinates, thermal parameters, complete lists of bond-lengths and angles and tables of F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request.*

Crystals of the complex *cis*-$FeMe_2(dmpm)_2$ were also examined, but were found to belong to a cubic space group, probably I432, with orientational disorder of the molecule such that the Fe–ligand bonds lay along the crystallographic axes. Although attempts are being made to arrive at a model for this structure, the results, which will be reported elsewhere, are not likely to be very significant, geometrically. Accordingly only details of the crystal

* Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

THE CRYSTAL AND MOLECULAR STRUCTURE OF DINITRATOBIS(2-METHYLMERCAPTOANILINE)Cd(II) MONOHYDRATE: A TRIGONAL BIPYRAMIDAL $CdSN_2O_2$ POLYHEDRON WITH AN ADDITIONAL WEAKLY BOUND SULFUR

E. A. H. GRIFFITH, N. G. CHARLES, P. F. RODESILER and E. L. AMMA*

(*Received* 11 *October* 1983: *accepted after revision* 7 *June* 1984)

Abstract—The single crystal X-ray structure determination of dinitratobis-(2-methylmercaptoaniline) has been carried out. The structure consists of neutral molecules separated by ordinary van der Waals distances with the water molecules of hydration simply filling holes. The geometry about Cd^{2+} may be best described as trigonal bipyramidal $CdSN_2O_2$ with an additional weakly bound sulfur. The two oxygen ligands are from different nitrate groups and one of the 2-methylmercaptoaniline ligands contributes a nitrogen and a sulfur to the coordination polyhedron while the other contributes only an aniline nitrogen, i.e. one of the normally chelating ligands is nitrogen bonded to the metal with only weakly bound sulfur. The bonded distances are: Cd—S, 2.715(3), Cd—N, 2.369(8), 2.33(1); Cd—O, 2.3887(9), 2.353(9) Å and a long Cd—S of 3.118(3) Å. Diffraction data: monoclinic, $P2_1/n$; $a = 12.268(2)$ Å, $b = 7.909(1)$ Å, $c = 24.631(4)$ Å, $\beta = 103.4(2)°$, $D_M = 1.54(2)$ g cm^{-3}, $D_C = 1.52$ g cm^{-3}; $Z = 4$, $\lambda = 0.71073$ Å. The structure was refined by full matrix least squares including anisotropic temperature factors, absorption corrections and anomalous dispersion corrections to a final conventional R of 0.057.

The binding of sulfur, nitrogen and oxygen to metal is of considerable importance in a number of biological processes of metalloenzymes. This is particularly true for the case of Zn metalloenzymes.[1] For example, the structural site of horse liver alcohol dehydrogenase (LADH) is accepted as a more or less tetrahedral ZnS_4 site.[2] The catalytic site of this enzyme is a ZnS_2NO location.[3,4] Enzymatic sites in some other metalloenzymes are: carboxypeptidase, ZnO_2N_2;[5] carbonic anhydrase, ZnN_3O;[6] alkaline phosphatase, ZnN_3O;[7] superoxide dismutase ZnN_3O;[8] and metallothionein Zn_xS_y(clusters).[9] In a number of these enzymes the replacement of Zn^{2+} by Cd^{2+} decreases, but does not destroy, enzymatic activity,[1,10] and this coupled with the recent developments in ^{113}Cd NMR spectroscopy has led to the observation and interpretation of ^{113}Cd NMR of these and other Cd substituted enzymes.[11–35]

We have been actively synthesizing model compounds for these and other Cd substituted enzymes, determining crystal structures and measuring solution and solid state cross polarization magic angle spinning (CP/MAS) ^{113}Cd NMR[36–45] in an attempt to correlate structure, metal stereochemistry and metal coordination with ^{113}Cd NMR chemical shifts. Clearly, one is interested in synthesizing $CdS_xN_yO_z$ type systems observing their solution and solid state (CP/MAS) ^{113}Cd NMR and correlating the solid state structure and solid state and solution NMR. A relatively straightforward synthesis problem along these lines is offered by the ligand 2-methylmercaptoaniline which should bind to Cd^{2+} via S and N to form cadmium-(2-methylmercaptoaniline)$_2^{2+}$ a $CdS_2N_2^{2+}$ system. Although Cd^{2+} binds two ligands, one binds via S and N as expected, but the other binds only via the nitrogen atom and Cd prefers to bind to oxygen of nitrate rather than a sulfur atom. Unfortunately, the ^{113}Cd NMR in this case is beset by technical problems; nevertheless, the stereochemistry and coordination polyhedron of the metal is interesting and unusual and we report the structure at this time and shall report the ^{113}Cd NMR solid and solution results at a later time.

EXPERIMENTAL

A methanol solution (50 cm^3) of 2-methylmercaptoaniline [Aldrich] (2.78 g, 0.02 mol) was added to a solution of 3.08 g, 0.01 mol of $Cd(NO_3)_2 \cdot 4\ H_2O$ [Mallinckrodt] in 100 cm^3 of methanol/water (1/1) with stirring and gentle heating (40°C). After approximately 15 min the solution was allowed to evaporate slowly at ambient temperature. Diffraction quality crystals appeared in 4–5 days.

X-RAY DATA AND STRUCTURE ANALYSIS

The crystals were found to be air and light sensitive and were sealed into thin walled glass capillaries. Data collection and refinement parameters are enumerated in Table 1. The structure was solved by standard heavy atom methods. The atom parameters, B_{eq}, anisotropic temperature factors and F_o, F_c tables have been deposited. The interatomic distances, angles and least squares planes are found in Table 2.

DESCRIPTION OF STRUCTURE AND DISCUSSION

The structure may be described as isolated uncharged molecules of dinitratobis(2-methylmercaptoaniline) Cd(II) (Fig. 1), separated by ordinary van der Waals distances between molecules. The water molecules of hydration seem only to fill interstices. The shortest oxygen of water of hydration O(7)–O, distance is greater than 4 Å. The

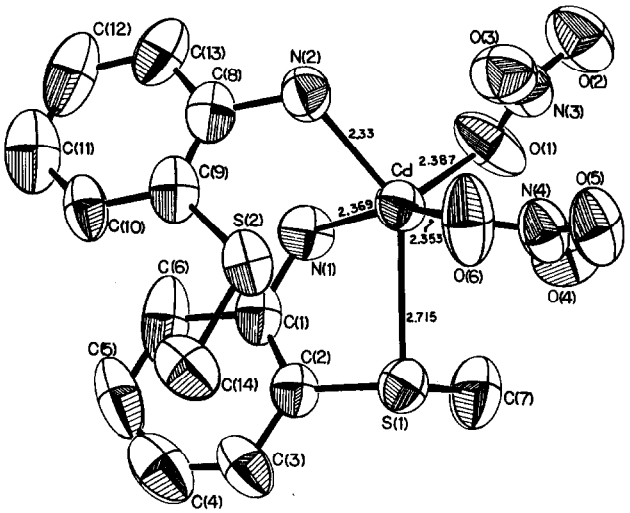

Fig. 1. An ORTEP[58] view of an isolated molecule of dinitratobis(methylmercaptoaniline)Cd(II). The bonded distances to Cd are shown, but the others are deleted for simplicity. The notation is consistent with the tables. The ellipsoids are drawn at the 50% probability level.

environment about the Cd atom may be described as distorted trigonal bipyramidal, with N(1) and O(6) being the axial ligands, or as a distorted square pyramid with O(1) as the apical atoms. In either description there seems to exist a weak Cd—S(2) interaction at 3.118(3) Å. The relative merits of these two descriptions may be seen from the sum of the angles around Cd. In what would be the equatorial plane in the TBP description, the sum is 353° (Table 2) and the analysis of the least squares plane of the equatorial plane atoms shows that (Table 2) Cd is displaced toward O(6) by 0.26 Å whereas the other three atoms are ~0.1 Å toward N(1). The N(1)—Cd—O(6) angle is 161.4(4)° rather than the ideal value of 180°. In the square pyramid description, N(2) and S(1) are ~ 0.2 Å on one side of the best least squares plane of N(1), N(2), S(1) and N(1) and O(6) are ~ 0.2Å on the other side with Cd 0.57 Å from the plane on the same side as N(1) and O(6). There is some preference for the trigonal bipyramidal description of the Cd environment. Trigonal bipyramidal Cd(II) has also been previously observed[46–49,52] and tetragonal pyramidal Cd(II) has also been observed.[50,51]

The most surprising feature of the structure is the fact that S(2) at 3.118(3) Å is only weakly bonded to Cd! The orientation of the mercapto group supports this view of little Cd—S covalent bonding. Considering cadmium's preference for sulfur coordination, this is most unusual. However, two other cases of non-sulfur bonding[53,54] have been reported but these involve carboxylate groups which are much better complexing agents than the nitrate ion. The shortest Cd—O(NO_3) distances of 2.387(9) and 2.353(9) Å are somewhat longer than those observed in tetrahedral dinitratobis(tetramethylthiourea)Cd(II)[41] at 2.290(4), 2.299(4) Å but shorter than the 2.42(1) Å average in dinitratobis(α,α'-dipyridyl)Cd(II).[39] The next closest set of Cd—O distances are Cd—O(3) 2.517(9) and Cd—O(4) 2.71(1) Å. The latter must have very little covalent bonding associated with it and arises primarily from the orientational packing properties of that nitrate group. On the other hand, considering the Cd—O(3) distance of 2.517(9) Å, although longer by 0.13 Å than the longest of the Cd—O "bonded" distances in this structure, its exclusion from the coordination sphere is somewhat arbitrary. However, it no doubt contributes to the distortion of the N(1)—Cd—O(6) angle from the ideal value of 180°. It is to be noted that the next longest Cd—O distances in dinitratobis(tetramethylthiourea) are at 2.68 (1) Å.[41]

The angle between the normal to the C(2), S(1), C(7) plane and Cd—S(1) of 14.8(3)° is close to the 19° expected for the utilization of a pure sulfur sp^3 lone pair in forming the Cd—S bond. In fact, one would expect this angle to be somewhat less than 19° due to repulsions between lone pair electrons. The analogous angle for the C(9)—S(2)—C(14) normal and the Cd—S(2) line is 41.1(3)°.

Unfortunately, although we originally made the compound to study ^{113}Cd NMR of sulfur nitrogen coordinated Cd complexes, the solution NMR spectra is difficult to observe due to exchange processes. The CP/MAS ^{113}Cd NMR is complex and beset with technical problems at this time.

Nevertheless, the structure is of some interest, particularly since in this case Cd prefers coordination to oxygen of nitrate rather than to the sulfur atom.

Acknowledgements—We wish to thank the PHS for research support with Grant GM-27721 and the NSF-supported regional NMR center at the University of South Carolina (CHE 78-18723) and Colorado State University (CHE 78-18581) for their help, discussions and assistance with the ^{113}Cd NMR data.

ALKALI-METAL TETRAFLUOROMANGANATE(III) MONOHYDRATES, $AMnF_4 \cdot H_2O$ (A = Rb OR Cs)

M. N. BHATTACHARJEE, M. K. CHAUDHURI,* H. S. DASGUPTA and A. KATHIPRI

Department of Chemistry, North-Eastern Hill University, Shillong 793 003, India

(*Received* 4 *August* 1983; *accepted after revision* 7 *June* 1984)

Abstract—Deep brown crystalline $AMnF_4 \cdot H_2O$ have been synthesized from the reactions of $KMnO_4$ with AHF_2 (A = Rb or Cs) and 40% HF at *ca* 100°C, and also from the reaction of MnO(OH) with AHF_2 and 40% HF. Characterisation and assessment of molecular structure of the compounds were made.

We have reported recently[1,2] the synthesis and structural assessment of A_2MnF_5 (A = NH_4, Na, K or Cs) compounds. In this paper we report the synthesis of $AMnF_4 \cdot H_2O$ (A = Rb or Cs) achieved from the reaction of MnO_4^- or MnO(OH) with AHF_2 and 40% HF, at relatively higher temperatures, without making use of any reducing agent or MnF_3.

EXPERIMENTAL

All chemicals were of reagent grade. MnO(OH)[3] and AHF_2[4] were prepared by the literature methods.

Magnetic susceptibility, IR and reflectance spectral measurements were made by the methods described in one of our previous papers.[5]

Synthesis

Since the two methods developed for the synthesis of the title compounds are general, only two typical procedures are described.

Method 1. Finely powdered $KMnO_4$ (6.3 m mol) and AHF_2 (12.6 m mol) were separately dissolved in 40% HF (total 400–500 m mol) by slightly warming over a steam-bath, and then mixed together. The resulting dark pink solution was heated on a steam-bath first until crystals began to appear, and then for an additional 2 h. The reaction container was cooled in a freezer for *ca.* 7 h. The deep brown crystallized $AMnF_4 \cdot H_2O$ was separated by decanting and dried by placing between folds of a filter paper, and then stored in a sealed polythene capsule. The yield of $RbMnF_4 \cdot H_2O$ was 88% and that of $CsMnF_4 \cdot H_2O$ was 79%.

Method 2. This method of synthesis was similar to that of the method 1 except that freshly prepared MnO(OH) was used instead of $KMnO_4$. The yields of $RbMnF_4 \cdot H_2O$ and $CsMnF_4 \cdot H_2O$ obtained by this method were 82% and 81% respectively.

Found: Rb, 36.51; Mn, 23.57; F, 32.53%. $RbMnF_4 \cdot H_2O$ requires: Rb, 36.46; Mn, 23.44; F, 32.42%. IR (cm^{-1}): ν_{Mn-F}, 600 m; ν_{Mn-F}, 530 s; ν_{O-H}, 3465 s; δ_{H-O-H}, 1640 m. Reflectance spectral data (cm^{-1}): $^5B_{1g} \rightarrow {}^5A_{1g}$, 12,100; $^5B_{1g} \rightarrow {}^5B_{2g}$, 18, 400; $^5B_{1g} \rightarrow {}^5E_g$, 21,700. μ (299 K), 4.9 BM.

Found: Cs, 47.29; Mn, 19.54; F, 26.85%. $CsMnF_4 \cdot H_2O$ requires: Cs, 46.15; Mn, 19.49; F, 26.96%. IR (cm^{-1}): ν_{Mn-F}, 600 m; ν_{Mn-F}, 535 s; ν_{O-H}, 3460 m; δ_{H-O-H}, 1642 m. Reflectance spectral data (cm^{-1}): $^5B_{1g} \rightarrow {}^5A_{1g}$, 12,000; $^5B_{1g} \rightarrow {}^5B_{2g}$, 18,850; $^5B_{1g} \rightarrow {}^5E_g$, 22,800. μ(299 K), 5.1 BM.

Elemental analyses and chemical determination of oxidation state of manganese were accomplished by standard methods.[5]

RESULTS AND DISCUSSION

In the course of our previous studies,[1,2] we observed that the heating of 40% HF solutions of A_2MnF_5 (A = NH_4, Na, K or Cs) at *ca.* 100°C, in order to concentrate, reproduced the crystalline A_2MnF_5 compounds only when the cation A^+ was NH_4^+, Na^+ or K^+ but not Cs^+. Instead the Cs^+ salt gave a deep brown crystalline compound with the atomic ratio Mn : F as 1 : 4. Accordingly, the reaction of $KMnO_4$ or MnO(OH) with AHF_2

* Author to whom correspondence should be addressed.

(A = Cs or Rb) and 40% HF at *ca.* 100°C produced deep brown crystalline compounds of the type $AMnF_4 \cdot H_2O$.

The compounds can be stored undecomposed in sealed polyethylene capsules. The chemically estimated oxidation states of manganese lie between 2.9 and 3.1, and the room temperature magnetic moments of $RbMnF_4 \cdot H_2O$ and $CsMnF_4 \cdot H_2O$ were found to be 4.9 and 5.1 B.M. respectively in conformity with those reported for the salts of the alleged tetrafluoromanganate(III) ion.[6,7] The IR spectra of the two salts resemble each other very closely with their most prominent feature being the absorptions at 600 and $\sim 530\,cm^{-1}$ which have been assigned to manganese–fluorine vibrations.[8–10] The typical pattern implies the presence of an octahedral or a distorted octahedral environment around manganese(III) in the complex ion (cf. the analysis of ν_{M-F} in MF_6^{n-} complexes).[1,2,8] The two extra vibrations at *ca.* 1640 and *ca.* 3460 cm^{-1} resemble in their shapes and positions those observed for the $K_2MnF_5 \cdot H_2O$[11] enabling us to infer that each of the newly synthesized compounds contains one molecule of uncoordinated water. The reflectance spectra of the compounds exhibit bands at $\sim$ 12,000, $\sim$ 18,500 and $\sim$ 22,000 cm^{-1} which have been assigned to the transitions $^5B_{1g} \rightarrow {}^5A_{1g}$, $^5B_{1g} \rightarrow {}^5B_{2g}$ and $^5B_{1g} \rightarrow {}^5E_g$ respectively[12] owing to the appreciably large splitting of ^5E_g ground state of Mn^{3+} in the complex ion as a consequence of Jahn–Teller effect. Thus it is evident that the effective field around manganese(III) in the complex ion is most probably D_{4h} which it attained through a polymeric structure involving *trans*-linked —F—Mn—F— chains.

(*Received* 4 *October* 1983; *accepted after revision* 7 *June* 1984)

Abstract—Kinetic effects of various 1–1 electrolytes on the $CoClL_n^{2+} + Hg^{2+}$ reaction (L_n: neutral ligands) were studied with varying concentrations of the added electrolytes (0.025–1.0 mol dm^{-3}). Unusual deviations from the expected primary salt-effects have been observed in the reactions of the complexes containing bipyridine or phenanthroline in the presence of simple organic sulphonate ions. The results were interpreted in terms of the Guggenheim equation for the activity coefficients of the reactants and the activated complexes, and the specific effects were attributed to the hydrophobic interactions between the complex cations and the sulphonate anions.

The rate of a second-order reaction between two cations or two anions generally increases with increasing ionic strength according to the primary salt effect.[1] In the presence of long-chained alkane sulphonates and polyalkanesulphonates, the Hg^{2+}-assisted aquation of $[CoCl(NH_3)_5]^{2+}$ is drastically accelerated and this extreme case in the salt effects can be attributed to the large negative potentials on the polyanions.[2,3] On the other hand, the polysulphonate anions are much less effective on the electron-transfer reaction between $[Co(phen)_3]^{2+}$ and $[Co(phen)_3]^{3+}$.[4] This unusual effect was attributed to the hydrophobic interaction between the phenanthroline complexes and the polyanions.

No studies have been reported, however, for the effects of simple organic electrolytes on the reactions between cations. The present paper reports the study of the specific effects of simple organic sulphonate ions on the Hg^{2+}-assisted aquation of *cis*-$[CoCl(OH_2)(bpy)_2]^{2+}$ and of *cis*-$[CoCl(OH_2)(phen)_2]^{2+}$, comparing them with the effects of these anions on similar reactions of $[CoCl(NH_3)_5]^{2+}$, *cis*-$[CoCl(NH_3)(en)_2]^{2+}$, and *cis*-$[CoCl(py)(en)_2]^{2+}$. The specific effects of the added anions will reveal the specific interactions between the complex cations and the added anions during the reaction.

EXPERIMENTAL

Cobalt(III) complexes

The complexes, $[CoCl(NH_3)_5](ClO_4)_2$, *cis*-$[CoCl(NH_3)(en)_2](ClO_4)_2$, *cis*-$[CoCl(py)(en)_2](ClO_4)_2$, and *cis*-$[CoCl(OH_2)(phen)_2](ClO_4)_2$ were prepared by the published methods.[5–8] The complex *cis*-$[CoCl(OH_2)(bpy)_2](ClO_4)_2$ was obtained from *cis*-$[CoCl_2(bpy)_2]Cl \cdot 2H_2O$ in a manner similar to that for the preparation of the corresponding phenanthroline complex.

A preparation of *cis*-$[CoCl(NH_3)(bpy)_2](ClO_4)_2$ was made as follows. To a solution of *cis*-$[CoCl_2(bpy)_2]Cl$ (1 g) in methanol (50 cm^3) was added dropwise a concentrated aqueous ammonia (2–3 cm^3) at −20°C until the colour of the solution changed from purple to red. Perchloric acid (*ca* 10 mol dm^{-3}) was added (2–3 cm^3) to control the pH value to 1–2. When the solution was left at room temperature, a fine crystalline precipitate separated out which was assigned to $[CoCl(NH_3)(bpy)_2](ClO_4)_2 \cdot 2H_2O$ by elemental analysis. Found: C,

* Author to whom correspondence should be addressed.

36.21; H, 3.39; N, 10.29%. Calc: C, 36.4; H, 3.49; N, 10.6%. Absorption maximum, 522 nm ($\log \varepsilon = 1.75$).

Chemicals

Sodium methanesulphonate was prepared by neutralizing methanesulphonic acid with a sodium carbonate solution. The crystalline product was then obtained in a rotating evaporator. Found: C, 10.41; H, 2.54%. Calc. for CH_3SO_3Na: C, 10.17; H, 2.56%. Sodium benzenesulphonate, an extra pure reagent of Nakarai Chemicals Ltd., was recrystallized from water–methanol solution and dried at 80°C. Methanol was dried through a column of Molecular Sieve Type 3A and then distilled. Sodium perchlorate was prepared by neutralizing perchloric acid with a sodium hydroxide solution.

Kinetic runs

Each kinetic run was carried out under a pseudo-first-order condition with a solution containing 1.13×10^{-2} mol dm^{-3} $Hg(ClO_4)_2$ and 1.0×10^{-3} mol dm^{-3} of a cobalt(III) complex.[9]* The kinetic measurements were made at 25 ± 0.1°C with a Shimadzu UV-210A spectrophotometer. The pH values of the reaction solutions were controlled to 2.0 ± 0.2. (The pH values were slightly changed with the addition of the salts.) The reaction showed no pH dependency in this region.

The spectra of the final reaction solutions agreed with those of the aquated complexes (with aqua substituted for chloro ligand), and no by-products were detected by SP-Sephadex column chromatography. The decrease in the concentration of the chloro cobalt(III) complex was followed at 270 nm for $[CoCl(NH_3)_5]^{2+}$, at 290 nm for *cis*-$[CoCl(NH_3)(en)_2]^{2+}$, at 310 nm for *cis*-$[CoCl(py)(en)_2]^{2+}$, at 550 nm for *cis*-$[CoCl(OH_2)(bpy)_2]^{2+}$, and at 410 nm for *cis*-$[CoCl(OH_2)(phen)_2]^{2+}$.

RESULTS AND DISCUSSION

Fundamental kinetic studies have already been reported[9–11] for the reactions studied here except for those of *cis*-$[CoCl(OH_2)(bpy)_2]^{2+}$, *cis*-$[CoCl(OH_2)(phen)_2]^{2+}$, and *cis*-$[CoCl(NH_3)(bpy)_2]^{2+}$. The reactions, *cis*-$[CoCl(OH_2)(bpy)_2]^{2+} + Hg^{2+}$ and *cis*-$[CoCl(OH_2)(phen)_2]^{2+} + Hg^{2+}$, go to completion in about 3 h when $[Hg^{2+}] = 10^{-2}$ mol dm^{-3}, and the spectrum changes with isosbestic points at 502 and 428 nm for the former reaction and at 513 and 445 nm for the latter. All the reactions studied here can then be expressed as follows.

$$CoClL_n^{2+} + Hg^{2+} \xrightarrow[H_2O]{k} CoOH_2L_n^{3+} + HgCl^+$$

$$-\frac{d[CoClL_n^{2+}]}{dt} = k[CoClL_n^{2+}][Hg^{2+}] \quad (1)$$

$$k_{obs} = k[Hg^{2+}] \quad (2)$$

where L_n is the neutral ligands.

The *cis*-$[CoCl(NH_3)(bpy)_2]^{2+} + Hg^{2+}$ reaction proceeds very slowly and the spectrum of the reaction solution showed no detectable change in several days even when $[Hg^{2+}] = 0.1$ mol dm^{-3}.† Therefore, kinetic salt effect could not be studied for this reaction.

Figures 1–3 show the effects of the various reagents on the reactions. In explaining the results, we notice the following facts. Firstly both the methanesulphonic acid and the benzenesulphonic acid are strong acids and their salts are completely dissociated into ions in the present pH regions. Secondly no cobalt(III) complexes with the methanesulphonate or benzenesulphonate ligand were detected throughout the reactions. Then, these sodium sulphonates can be considered to be simple and inert 1–1 electrolytes. According to the Debye–Brønsted equation, simple 1–1 electrolytes largely accelerate 2+–2+ reactions and the pseudo-first-order rate constant (k_{obs}) can be expressed as a

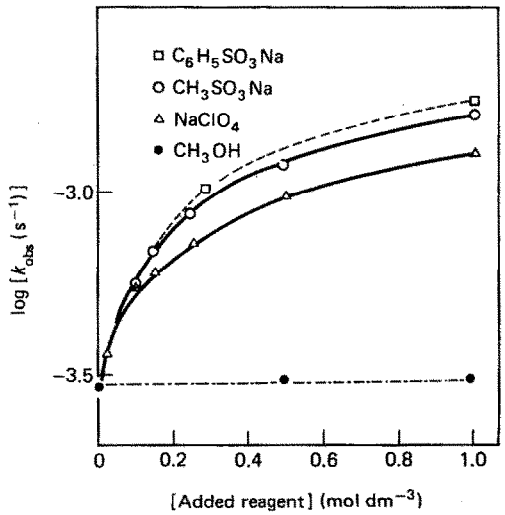

Fig. 1. Effects of the added salts (and methanol) on the $[CoCl(NH_3)_5]^{2+} + Hg^{2+}$ reaction.

* As the solubility of the phenanthroline complex is less than 1.0×10^{-3} mol dm^{-3} when $NaClO_4$ is present in more than 0.5 mol dm^{-3}, the concentration of the complex was around 5×10^{-4} mol dm^{-3} in such cases.

† The complex rapidly hydrolysed in an ammoniacal solution (pH 9) and the final reaction solution contained free chloride ions equimolar with the cobalt(III).

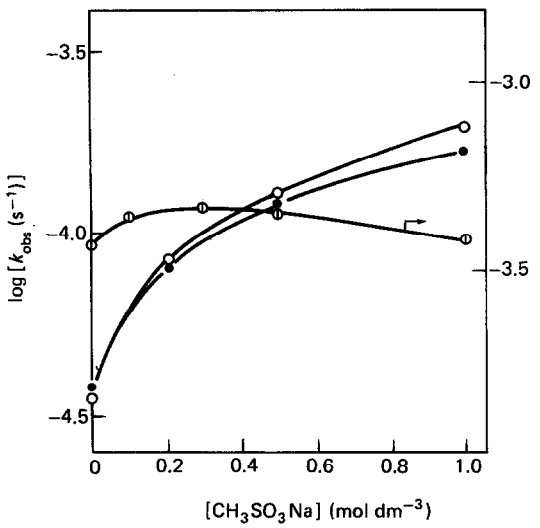

Fig. 2. Effects of CH_3SO_3Na on the *cis*-$[CoCl(NH_3)(en)_2]^{2+}+Hg^{2+}$ (○), the *cis*-$[CoCl(py)(en)_2]^{2+}+Hg^{2+}$ (●), and the *cis*-$[CoCl(OH_2)(bpy)_2]^{2+}+Hg^{2+}$ (◑) reactions.

function of the concentration (c) of the added salts, i.e.

$$\log k_{obs} = \log k_0 + 8A\frac{\sqrt{c}}{1+\sqrt{c}} \quad (3)$$

where k_0 is the rate constant at infinite dilution and A is the Debye–Hückel parameter (0.521 at 25°C, in water). The effects of 1–1 electrolytes qualitatively followed equation (3); the effects of the sulphonate anions on the *cis*-$[CoCl(OH_2)(bpy)_2]^{2+}+Hg^{2+}$ and *cis*-$[CoCl(OH_2)(phen)_2]^{2+}+Hg^{2+}$ reactions are exceptions. The anomalous effect of the sulphonates may be attributed to hydrophobic interaction between the organic sulphonate ions and the coordinated bpy or phen. However, the fact that methanol had no substantial effect on the reactions shows that the effect of the sulphonate ions cannot be attributed to a simple hydrophobic interaction, but can be understood to arise from cooperative hydrophobic and electrostatic interactions.

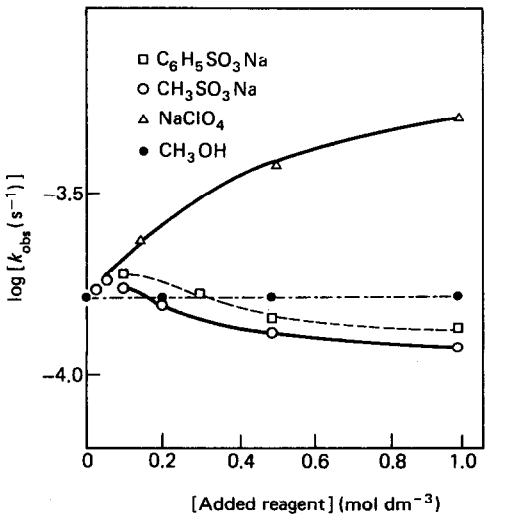

Fig. 3. Effects of the added reagents on the *cis*-$[CoCl(OH_2)(phen)_2]^{2+}+Hg^{2+}$ reaction.

In order to numerically express the specific effects of the anions we use the Guggenheim equation for the activity coefficients (y_i):

$$\log y_i = -Az_i^2\frac{\sqrt{c_j}}{1+\sqrt{c_j}} + \sum_j B_{ij}c_j \quad (4)$$

where z_i is the charge number of the ith ion and B_{ij} is the coefficient of specific interaction between the ith and jth ions.

As the sizes of the complex cations used here are widely ranged and the contribution of the reactants to the ionic strength cannot be neglected, the following equation will be appropriate in the place of equation (4),

$$\log y_i = -Az_i^2\frac{\sqrt{c_j+0.037}}{1+Ba\sqrt{c_j+0.037}} + \sum_j \beta_{ij}c_j \quad (5)$$

where a is the closest distance of approach of the complex cation with the added anion, B is the Debye–Hückel B parameter, and β_{ij} is the refined coefficient of specific interaction between the i and j ions. The rate constants of the reaction between M cations and N cations can be expressed as:

$$\log k_{obs} = \log k_0 + \frac{8A\sqrt{c_A+0.037}}{1+Ba\sqrt{c_A+0.037}} + (\beta_{MA}+\beta_{NA}-\beta_{XA})c_A \quad (6)$$

where β_{MA}, β_{NA}, and β_{XA} are the specific interaction coefficients of the M cation, the N cation, and the activated complex with the supporting A anion, respectively. In the present case, the M cation denotes the cobalt(III) complex and the N cation the mercury ion, respectively. We can assume that β_{NA} is nearly zero and that the value of β_{XA} can be approximated as a function of only β_{MA}, because it seems no remarkable specific interaction between Hg^{2+} and the anions used here. Then, β_{XA} is taken as $\lambda\beta_{MA}$ where λ is a constant.

Equation (6) is reduced to equation (7)

$$\log k' = \log k_{obs} - \frac{4.17\sqrt{c_A+0.037}}{1+0.329\mathring{a}\sqrt{c_A+0.037}} = \log k_0 + (1-\lambda)\beta_{MA}c_A \quad (7)$$

where $\mathring{a}$ is defined as $a/10^{-10}$ m.

The value of $\mathring{a}$ in equation (7) can be estimated

Table 1. Specific interaction coefficients, $(1-\lambda)\beta_{MA}$, between the cobalt(III) complexes (M^{2+}) and the anions (A^-)

Complex cation	A^-		
	ClO_4^-	$CH_3SO_3^-$	$C_6H_5SO_3^-$
$[CoCl(NH_3)_5]^{2+}$	−0.12	0.04	0.06
cis-$[CoCl(NH_3)(en)_2]^{2+}$		−0.04	
cis-$[CoCl(py)(en)_2]^{2+}$		−0.07	−0.23
cis-$[CoCl(OH_2)(bpy)_2]^{2+}$		−0.7±0.1	
cis-$[CoCl(OH_2)(phen)_2]^{2+}$	−0.02±0.1	−1.6±0.2	−1.4±0.2

from the ionic radii of the metal complexes and that of Hg^{2+}. It seems reasonable to take $\mathring{a} = 6$ for $[CoCl(NH_3)_5]^{2+}+Hg^{2+}$, *cis*-$[CoCl(NH_3)(en)_2]^{2+}+Hg^{2+}$, and *cis*-$[CoCl(py)(en)_2]^{2+}+Hg^{2+}$ systems, and $\mathring{a} = 7$–9 for *cis*-$[CoCl(OH_2)(bpy)_2]^{2+}+Hg^{2+}$ and *cis*-$[CoCl(OH_2)(phen)_2]^{2+}+Hg^{2+}$ systems. The values of the left-hand side of equation (7) are plotted against c_A as in Figs 4–6 and so the slope of the linear part of the plot gives $(1-\lambda)\beta_{MA}$. The results are listed in Table 1. As all the reaction systems are of the same type, including a dipositive complex ion, a uninegative anion, and an Hg^{2+} ion, the value of $\lambda\beta_{MA}$ reflects the specific interaction between the anion and the complex ion. Large negative values of $-\lambda\beta_{MA}$ seem to indicate that the hydrophobic interaction between the metal complexes and the added anions will prevent the metal complexes from contacting with the mercury ions.

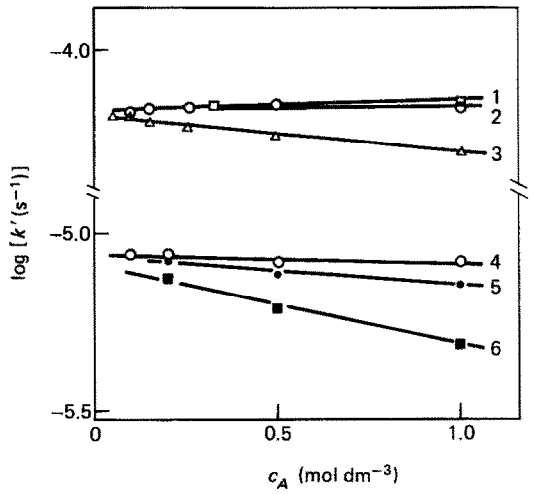

Fig. 4. Determination of $(1-\lambda)\beta_{MA}$ from log k' vs c_A plots. (I) $[CoCl(NH_3)_5]^{2+}+Hg^{2+}$ in the presence of $C_6H_5SO_3Na$ (1), CH_3SO_3Na (2), and of $NaClO_4$ (3); $[CoCl(NH_3)(en)_2]^{2+}+Hg^{2+}$ in the presence of CH_3SO_3Na (4); *cis*-$[CoCl(py)(en)_2]^{2+}+Hg^{2+}$ in the presence of CH_3SO_3Na (5), and of $C_6H_5SO_3Na$ (6).

In order to clarify the specific role of the sulphonate ions we have determined the activation parameters of the *cis*-$[CoCl(OH_2)(phen)_2]^{2+}+Hg^{2+}$ reaction in the presence of $CH_3SO_3^-$ or ClO_4^- by changing temperatures, 25–45°C. Table 2 shows the results. Addition of sodium perchlorate greatly decreases both the activation enthalpy and the activation entropy. It can be explained as is the case for the anion effects on the $[CoF(NH_3)_5]^{2+}+Al^{3+}$ reaction.[12] That is, the presence of ClO_4^- is electrostatically advantageous to the approach of the two reactant cations to each other and so the

1 mol dm^{-3} $NaClO_4$	55±3	−122±15
1 mol dm^{-3} CH_3SO_3Na	99±4	10±18

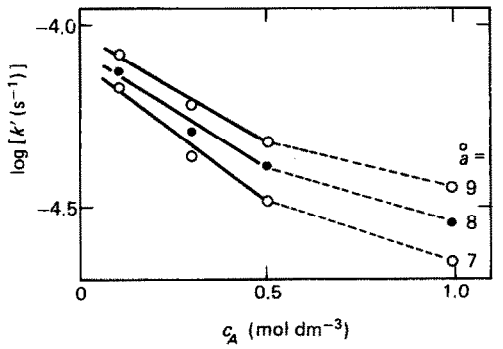

Fig. 5. Determination of $(1-\lambda)\beta_{MA}$ from log k' vs c_A plots. (II) *cis*-$[CoCl(OH_2)(bpy)_2]^{2+}+Hg^{2+}$ in the presence of CH_3SO_3Na.

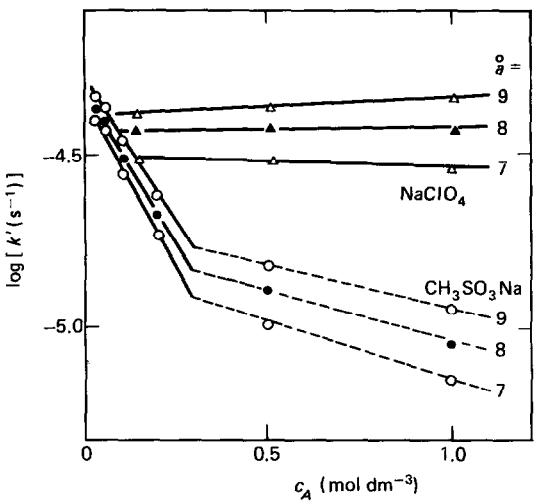

Fig. 6. Determination of $(1-\lambda)\beta_{MA}$ from log k' vs c_A plots. (III) *cis*-$[CoCl(OH_2)(phen)_2]^{2+} + Hg^{2+}$ in the presence of $NaClO_4$ and of CH_3SO_3Na.

activation enthalpy is depressed, while the activation entropy is decreased as a result of ClO_4^- sterically hindering the reactant cations from contacting each other.

When $CH_3SO_3^-$ is present, the effect on the activation parameters becomes appreciably smaller. The activation entropy shows that the probability to form the activated complex containing $CH_3SO_3^-$ is higher than in the case of ClO_4^-. On the other hand, the larger value of the activation enthalpy in the former case reveals that the activated complex containing the anion is more unstable than in the latter case. This tendency gives the following information on the structure of the activated complex with considering the hydrophobic interaction between the metal complexes and $CH_3SO_3^-$ (Fig. 7): $CH_3SO_3^-$ will predominantly be present in the part of the phenanthroline ligand of the cobalt(III) complex by the hydrophobic interaction and will not so largely prevent Hg^{2+} from approaching to the chloride ligand in the cobalt(III) complex as is the case of ClO_4^-. This entropic effect will result in making the two reactant cations approach more closely, and therefore, the electrostatic repulsion between the two cations makes the activated complex more unstable. This enthalpic disadvantage overcomes the entropic advantage and then the reaction rate becomes significantly smaller than the case where ClO_4^- is added.

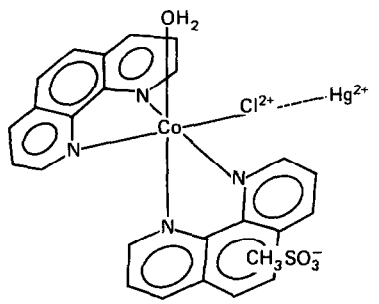

Fig. 7. A proposed structure of the activated complex for the *cis*-$[CoCl(OH_2)(phen)_2]^{2+} + Hg^{2+}$ reaction in the presence of $CH_3SO_3^-$.

In conclusion, we revealed that even the simple organic sulphonate ions such as $CH_3SO_3^-$ and $C_6H_5SO_3^-$ specifically affect the reaction containing the bipyridine or the phenanthroline complex as a reactant and it can be attributed to the hydrophobic interaction between the added anions and the metal complexes.

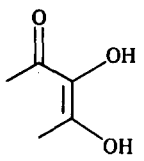
(*Received* 27 *February* 1984; *accepted* 7 *June* 1984)

Abstract—Reaction of 5,6-diamino-1,3-dimethyluracil (DDU) with iron(III) ion gave a fine blue colouration due to the formation of $Fe[(DDU—H)_3]\cdot 2HClO_4$. An oxidation product (7), $C_{12}H_{12}N_6O_4$, was also isolated from the reaction mixture.

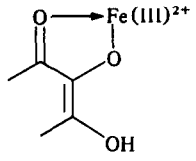
Since von Euler and Martius[1] reported a strong reducing agent named reductone in 1933, many reducing agents have been reported as this kind of von Euler's reductone. The structure of the reductone is characterized as enediol conjugated with carbonyl group (Scheme 1). Some of enediamines, enedithiols, enaminols, and enaminothiols have also been reported to be reducing agents like enediols.[2] One of features of the reductone is a fine blue colouration which is unstable and brought about by iron(III) ions.[3] However, there is no report of such a blue colouration on enediamine reductones. In the course of synthesizing purine analogues from uracil derivatives,[4] we found that DDU as enediamine reductone reacted with iron(III) ions to bring about a fine blue colouration accompanied by oxidation. Although the blue substance in the colouration is very unstable in the solutions like that of enediol reductone, we were able to isolate the blue substance as a powder.

EXPERIMENTAL



All organic chemicals except **4** were synthesized. Elementary analyses (C, H, N) were carried out on a Perkin–Elmer 240B instrument. The X-ray fluorescence analyses (Cl, Fe) were performed on a Rigaku Geiger Flex 3063P instrument by the method of Kawashima and Matsumoto.[5]† Iron and nitrogen were also determined on a Shimadzu Atomic Absorption/Flame Emission Spectrophotometer (AA-630-02), and by the method of Kjeldahl, respectively. The IR spectra were run on a Shimadzu IR-G spectrophotometer.

Synthesis of the blue complex: tris(5,6-diamino-1,3-dimethyl-1,2,3,4-tetrahydropyrimidin-2,4-dionato) iron(III) *diperchlorate* (**6**)



A solution of $Fe(ClO_4)_3\cdot 6H_2O$ (0.8 g, 1.7 mmol) in 10 cm^3 of ethanol was added to a solution of DDU monohydrate (0.3 g, 1.6 mmol) in 50 cm^3 of ethanol with stirring at room temperature. After 8 min, a blue powder precipitated was collected by filtration, washed with small volume of ethanol, and dried in a vacuum desiccator. Yield 60 mg (14.7%), mp > 300°C. The above filtrate was allowed to stand for 3 days to precipitate crystals of compound **7** in 37% yield (90 mg). [The blue complex **6** was also obtained in similar yield when the reduced amount of $Fe(ClO_4)_3\cdot 6H_2O$ (0.1 g, 0.2 mmol) was employed in the above experiment.] Found: C, 28.18; H, 3.57; N, 21.81%. Calc. for $C_{18}H_{29}Cl_2Fe_1N_{12}O_{14}$: C, 28.29; H, 3.82; N, 22.0%. The blue complex **6** (about 20 mg)

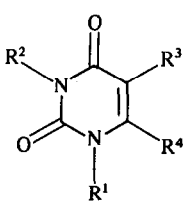
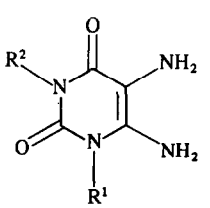
was dissolved in 5 cm^3 of both water and 0.1 N HCl solution in order to determine the elemental ratio between Cl and Fe, and between Fe and N, respectively, using the analytical methods described above. Fe: Cl: N = 1.00: 2.06: 11.9.

RESULTS AND DISCUSSION



Colouration

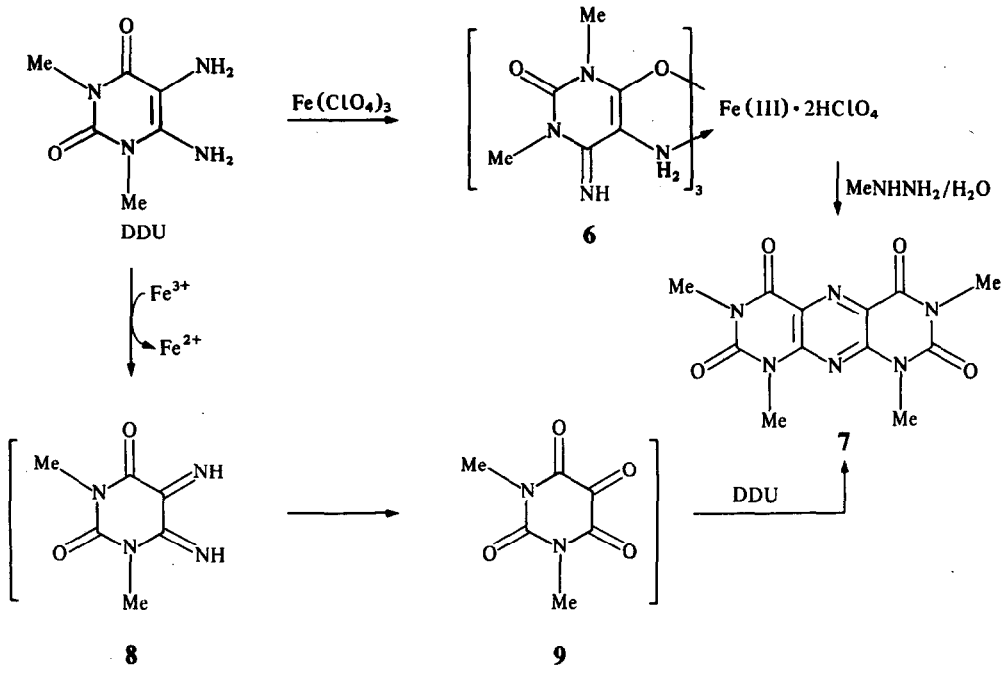


When a solution of DDU in water was treated with iron(III) chloride, a fine blue (λ_{max} 656 nm) appeared simultaneously, and the colour disappeared gradually. This blue colouration was independent of counter anions of the iron(III) salts. The blue colouration was not observed in the solution of DDU both above pH 8 and below pH 3. In general, the blue complex is somewhat more stable in organic solvents such as alcohols, acetonitrile, and tetrahydrofuran than in water, and the decolourizing rate in water is dependent on pH values of the solutions, the higher, the faster. Namely, the blue complex becomes somewhat stable in an acidic solution which is adjusted below pH 3 after the colouration. Iron(II) salts such as chloride, sulphate and perchlorate gave no colouration with DDU. When excess of hydrogen peroxide was added to the mixed solution of DDU and iron(II) salts, the blue colour developed immediately: addition of 1 drop of hydrogen peroxide (30%) to a mixed solution of DDU (0.01 g) and iron(II) sulphate (0.01 g) in 2 cm^3 of water brought about a fine blue colouration. When iron(III) salts were added to a solution of DDU in the presence of excess amount of ascorbic acid in water, the blue colouration did not occur. These results indicate that iron(III) ions are essential for the blue colouration with DDU.

In order to study the relation between structure and colouration, several uracil derivatives were reacted with iron(III) ions (Scheme 2). 5-Amino-1,3,6-trimethyluracil (**1**), 6-amino-1,3-dimethyluracil (**2**) and 6-amino-5-*N*-(2′,2′-dicyanovinyl)amino-1,3-dimethyluracil (**3**) did not show any colouration with iron(III) ions, however, 5,6-diamino-3-methyluracil (**5**) reacted with iron(III) ions to give a blue colouration. Hydrochloride salts of DDU and **5** did not afford the blue colouration but a red colouration in water. Similarly, when hemisulphate of 5,6-diaminouracil (**4**) reacted with iron(III) ions in water, a red colour gradually developed. These results indicate that free enediamine in DDU is essential for the blue colouration with iron(III) ions. This strongly corresponds to the fact that enediols conjugated with carbonyl group mostly show a blue colouration with iron(III) ions.[3]

Composition of the blue substance

Although the blue colouration is very unstable in its various solutions, we found that when DDU reacted with iron(III) perchlorate in ethanol, a small amount of blue powder was immediately precipitated from the blue coloured solution. The precipitates were collected, washed with a small volume of ethanol, and dried in a vacuum desiccator. Hereupon, it is worth noting that 1,3,6,8-tetramethyl - 2,4,5,7(1*H*,3*H*,6*H*,8*H*)pyrimido[5,4 - g]pteridine-



1 $R^1 = R^2 = R^4 = CH_3$, $R^3 = NH_2$
2 $R^1 = R^2 = CH_3$, $R^3 = H$, $R^4 = NH_2$
3 $R^1 = R^2 = CH_3$, $R^3 = -CH = C(CN)_2$, $R^4 = NH_2$

(DDU) $R^1 = R^2 = CH_3$
4 $R^1 = R^2 = H$
5 $R^1 = H$, $R^2 = CH_3$

Scheme 3.

tetrone (7) was only precipitated as crystals from the filtrate after a few days (Scheme 3). Compound 7 was identified by comparison with the authentic sample prepared by the method of Yoneda and Nishigaki.[6] The molecular formula of the blue substance was determined as $C_{18}H_{29}Cl_2Fe_1N_{12}O_{14}$ on the basis of the results of elementary analyses which were performed by the methods described in Experimental. It should be noted that the blue substance is very hygroscopic. The mass spectrum could not be obtained because of its non-volatility. The ^1H NMR spectrum showed signals at 3.33 and 3.43 ppm which might be attributed to methyl protons, although the resolution was very poor because of the iron(III) ion's paramagnetism.* The IR spectrum is shown in Fig. 1, where characteristic

*The spectra were run on a Varian T-60 (60 MHz) spectrometer with $(CD_3)_2SO$ as the solvent and $(CH_3)_4Si$ as the internal standard.

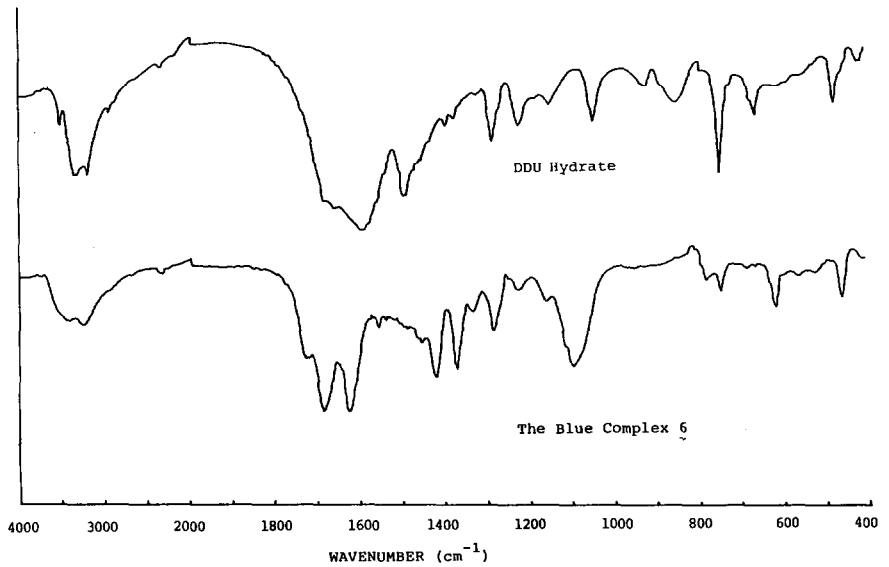

Fig. 1. The IR spectra of the blue complex (6) and DDU hydrate (in KBr pellet).

absorption bands for carboxamide amidine moiety [—C(=O)NMe— and —C(=NH_2^+)NMe—] were observed at 1685 and 1625 cm^{-1}.* The absorption bands of ferric perchlorate [$Fe(ClO_4)_3 \cdot 6H_2O$] at 1142 (strong), 1115 (s), 1090 (s), 638 (medium) and 628 (m) cm^{-1} may be due to the hydrogen bonded O—Cl bond whose absorption bands were observed at 1115 (s), 1099 (s) and 1070 (s) as a broad line, and 630 (weak) and 619 (m) cm^{-1} in the case of the blue substance. The shift to the lower wavelength of these absorption bands of the blue substance might be due to the hydrogen bonded O—Cl bond such as Cl—O···H—N. In addition to the above analytical results, the blue substance was hydrolyzed to determine its ligand. The blue substance was treated with methylhydrazine at room temperature to give **7** which did not afford any colouration with iron(III) ions. Since DDU itself is able to be converted to **7** by its self-condensation,[8] we propose DDU as the ligand of the blue complex, and determined it as $Fe[(DDU—H)_3] \cdot 2HClO_4$ (**6**).

Conclusion

As an enediamine reductone, DDU reacted with iron(III) ions like enediol reductones to give the blue complex **6** and compound **7**. The molar ratio of iron(III) ion to the ligand in **6** is 1 to 3. This is an interesting result since the blue colouration by the reaction of iron(III) ions with enediol reductone is due to the formation of a complex of which the molar ratio of iron(III) ion to the ligand is reported as 1 to 1.[2,3] The formation of **7** may be rationalized as shown in Scheme 3. DDU is oxidized with iron(III) ion to **8** which is further hydrolyzed to **9**. DDU, then, reacts with **8** and/or **9** to give **7** by loss of ammonia and/or water, respectively.

* A number of carboxamide–alkylamidine derivatives, R-$CONH(CH_2)_n$-$C(=NH_2^+)NH_2 \cdot Cl^-$ ($n = 1, 2$), were synthesized and their IR spectra were measured.

EPR AND ELECTRONIC ABSORPTION STUDIES OF Mn^{2+} ION IN $3CdSO_4 \cdot 8H_2O$ SINGLE CRYSTALS

N. SATYANARAYANA
Department of Physics, Indian Institute of Technology, Madras 600 036, India

(*Received* 27 *February* 1984; *accepted* 7 *June* 1984)

Abstract—EPR and electronic absorption spectra of the Mn^{2+} ion in $3CdSO_4 \cdot 8H_2O$ crystals have been studied at 300 K and 80 K. The EPR spectra have been analysed using the spin Hamiltonian for rhombic symmetry. The spin Hamiltonian g, A, B_2^0, B_4^0 and B_4^2 parameters were evaluated from the EPR analysis. The site symmetry of the Mn^{2+} ion in the lattice was also suggested for the two observed magnetic complexes. The characteristic features of the absorption spectrum showed splitting and better resolution of the absorption bands at 80 K than 300 K. By solving energy matrices corresponding to octahedral symmetry, band positions have been calculated. A good fit was obtained between the observed and calculated band positions for $Dq = 700\ cm^{-1}$, $B = 835\ cm^{-1}$, $C = 2982\ cm^{-1}$ and $\alpha = 76\ cm^{-1}$ values. By evaluating the above parameters, crystal field transitions were also assigned.

The EPR and electronic absorption spectra of the Mn^{2+} ion introduced into various crystalline materials have been the subject of a number of recent studies. Mn^{2+} (high spin system) is one of the most studied transition metal ions because of many interesting reasons.[1–5] The advantage of studying this ion is that it can easily exist in any of several symmetries and ligand environments. The EPR and electronic absorption spectra of Mn^{2+} ion can be observed at room temperature, because of large spin–lattice relaxation time. Since the Mn^{2+} ion has electron spin of 5/2, one would observe the zero field splitting. The zero field splitting parameter is highly sensitive to the local symmetry and ligand field environment. Using the Mn^{2+} ion as a probe and EPR as the experimental tool, one can study fairly accurately the symmetry of host lattices.[6–9]

In the high spin case, the ground state of Mn^{2+} will become $t_{2g}^3 e_g^2 ({}^6S)$ level. In the free ion state, the d^5 ion gives rise to a number of quartet and doublet excited levels and the transitions between these levels are spin forbidden. In octahedral symmetry one can get all the transitions from the sextet level to quartet and doublet levels. Generally, spin forbidden bands are weak in intensity and hence, the electronic absorption studies become interesting.[10,11] We have, therefore, attempted to study the EPR and electronic absorption of Mn^{2+} ion in the $3CdSO_4 \cdot 8H_2O$ lattice.

EXPERIMENTAL

Good quality single crystals of pure and Mn^{2+} ion doped $3CdSO_4 \cdot 8H_2O$ with well-defined morphology were grown by the slow evaporation method from the saturated aqueous solution. In order to get the impurity doped crystals a small amount (0.2 mol. to 4 mol. wt %) of $MnSO_4 \cdot H_2O$ (AR grade BDH company) powder was added to the saturated aqueous solutions. All Mn^{2+} doped crystals were pale pink in colour. Morphology of the host lattice did not change on increasing the concentration of the dopant. Single crystals of $3CdSO_4 \cdot 8H_2O$ were verified by X-ray diffractometer. The crystallographic $\bar{a}$, $\bar{b}$ and $\bar{c}$ axes were identified by taking oscillation photographs.

The $3CdSO_4 \cdot 8H_2O$ crystals belong to monoclinic system with space group $C_{2/c}$.[12] There are two chemically distinguishable Cd(Cd_I and Cd_{II}) atoms per unit cell and its unit cell dimensions are $a = 9.44$ Å, $b = 11.87$ Å, $c = 16.49$ Å and $\beta = 117°2'$. According to crystal structure, Cd_I (two) sites are at the special positions (1/4, μ, 0) while the Cd_{II} (four) atoms are at the general positions in the lattice; x, y, z; $x + 1/2, \bar{y}, z$; $x, y + 1/2, \bar{z}$; $\bar{x}, \bar{y}, z$. The Cd_I atoms at the special positions are completely equivalent, whereas the other Cd_{II} atoms at the general positions are inequivalent, thus, showing two magnetically inequivalent Cd_{II} atoms present in the lattice. In

the $3CdSO_4 \cdot 8H_2O$ lattice, Cd_I is surrounded by six oxygen ligands (two from the two water molecules and four from the four sulphate molecules) forming an approximately octahedral symmetry. Cd_{II} is also surrounded by six oxygen ligands but the symmetry is highly distorted octahedron.

EPR MEASUREMENTS

The EPR spectra were recorded at ambient temperature (300 K) on a VarianE-4 Spectrometer operating at X-band frequencies at about 9.45 GHz with a 100 kHz field modulation. The crystals were mounted at the end of the single circular goniometer which can fit onto the EPR rectangular cavity operating in TE_{102} mode. The EPR spectra were recorded about the three orthogonal $\bar{a}$, $\bar{b}$ and $\bar{c}^*$ axes in turn with an accuracy of $\pm 2°$ and spectra were recorded at every 10° for rotation about the three axes. Very little quantity of DPPH powder was used as a g-marker.

Electronic absorption spectra were recorded on a Cary-14 spectrophotometer. A cold finger type cryostat was used for recording the absorption spectra at low temperature (80 K). Complete calculations were made using the IBM 370/155 computer for the analysis of EPR and electronic absorption spectra.

EPR THEORY

The different crystal field effects on Mn^{2+} ion can be expressed in terms of different spin Hamiltonians.[13] In the present case, the symmetry of the spin Hamiltonian has been assumed to be rhombic. The spin Hamiltonian for rhombic symmetry is of the form;

$$\mathcal{H} = g\beta\bar{H}\cdot\bar{S} + B_2^0O_2^0 + B_2^2O_2^2 + B_4^0O_4^0 + B_4^2O_4^2 + A.\bar{I}.\bar{S} \quad (1)$$

where, B_n^m ($n = 0, 2, 4$ and $m = 0, 2, 4$ for d-orbitals) forms a set of empirical coefficients which can be calculated from the experimentally observed results. The crystalline electric field can be expressed as a series of terms of the spin operators (O_n^m) as described by Stevens.[14,15] In equation (1), the last term describes the hyperfine interaction and the first term gives the Zeeman energy of the Hamiltonian. When the molecular z-axis coincides with the external magnetic field, the off-diagonal terms in the energy matrix are small. Hence, we get the symmetric EPR spectrum about the $1/2 \rightarrow -1/2$ transitions as described by the first three terms in the spin Hamiltonian equation (1). However, when the magnetic field is along the molecular X and Y directions, the EPR spectrum will not be symmetric about $1/2 \rightarrow -1/2$ transitions. In these directions, the off-diagonal terms cannot be neglected as compared to the Zeeman splittings.[16] The energy level expressions have been derived using the second order perturbation theory for the allowed $M = \pm 1$ transitions.[17] The transition fields due to the hyperfine corrections are[18]

$$H_{Mm} = H_M - \frac{A_m}{g\beta} - \frac{A^2}{4g\beta} \times \left[\frac{F(M)f(-m)}{E_M - E_{M-1}} + \frac{F(-M)-f(m)}{E_M - E_{M+1}} - \frac{F(M-1)f(-m)}{E_{M-1} - E_{M-2}} - \frac{F(M+1)f(m)}{E_{M-1} - E_M}\right] \quad (2)$$

where E_m denotes energy level of M and

$$F(M) = (S+M)(S-M+1);$$

$$f(M) = (I+M)(I-M+1).$$

EPR STUDIES

Results

The EPR spectra of Mn^{2+} ion in $3CdSO_4 \cdot 8H_2O$ crystals at room temperature (300 K) have been recorded at regular intervals of 10° rotation about the three crystallographic orthogonal $\bar{a}$, $\bar{b}$ and $\bar{c}^*$ axes with an accuracy of $\pm 2°$. Figures 1–3 show the EPR spectra of Mn^{2+} ion recorded when the magnetic field ($\bar{H}$) is parallel to molecular Z-, Y- and X-axes respectively. These axes were found by searching directions corresponding to the maxima in the spread of the spectra in the three $\bar{a}\bar{b}$-, $\bar{b}\bar{c}^*$- and $\bar{c}\bar{a}^*$-planes. The direction in which the fine structure of five sextet lines has maximum separation is denoted as Z-axis spectrum. Similarly, the next consecutive maxima in the spectra were assigned to Y- and X-axes, spread in the X-axis spectrum found to be minimum and was approximately half of the spread of the Z-axis spectrum, which is perpendicular to ZY-plane. The Y-axis is perpendicular to ZX-plane and the spread of the spectrum was found to be three fourths of the spread of the Z-axis spectrum.

The observed angular variation spectra showed the existence of two different types of Mn^{2+} sites in the lattice with different intensity ratio (20:1). The lines with higher intensity correspond to site 1 and those with low intensity correspond to site 2. Site 2 could not be analysed because of the weak intensity of the lines. Complete analysis has been done only for the high intensity lines (site 1). Site 1 did not split but showed single site in all three planes.

Figure 4 shows the angular variation plot for the extreme sets of observed hyperfine lines (i.e. $M_s =$

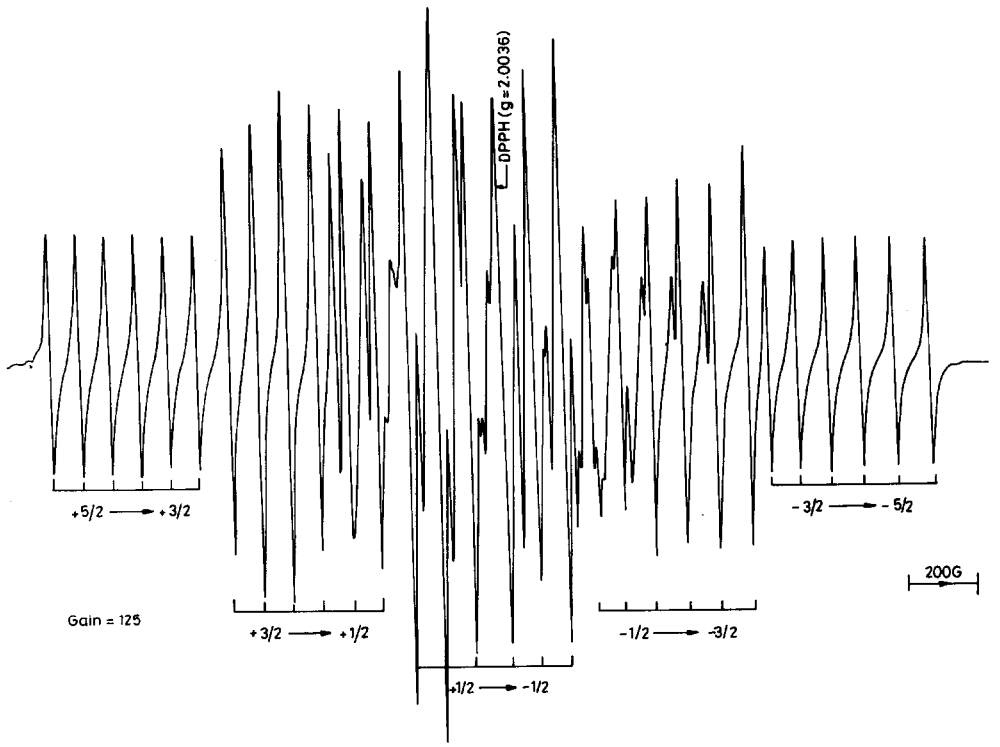

Fig. 1. EPR spectrum of $3CdSO_4 \cdot 8H_2O : Mn^{2+}$ crystal recorded at 300 K, where $\bar{H}$ is parallel to Z-axis in the ac^*-plane.

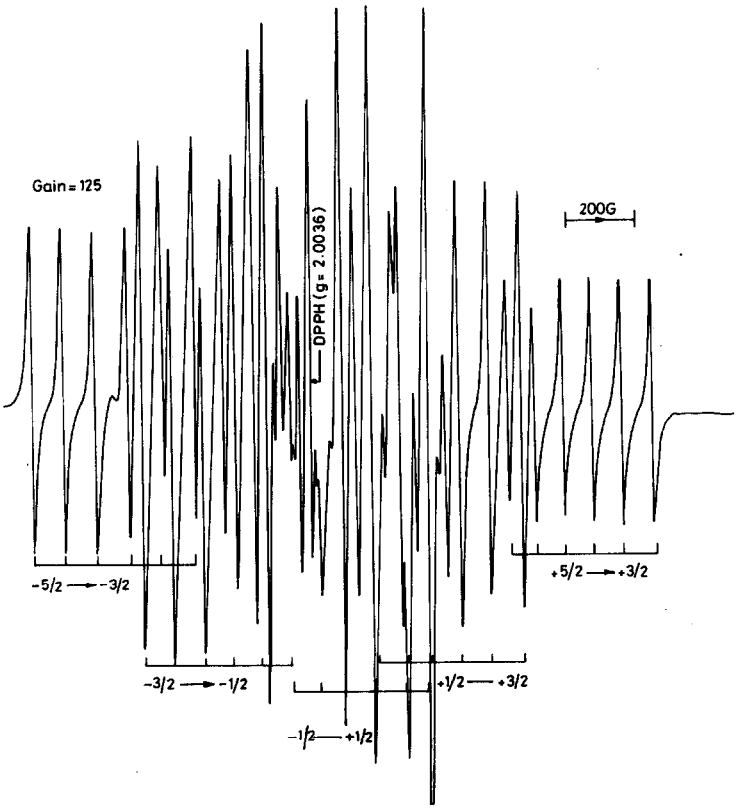

Fig. 2. EPR spectrum of Mn^{2+} doped $3CdSO_4 \cdot 8H_2O$ crystal recorded when $\bar{H}$ is parallel to Y-axis in the ab-plane.

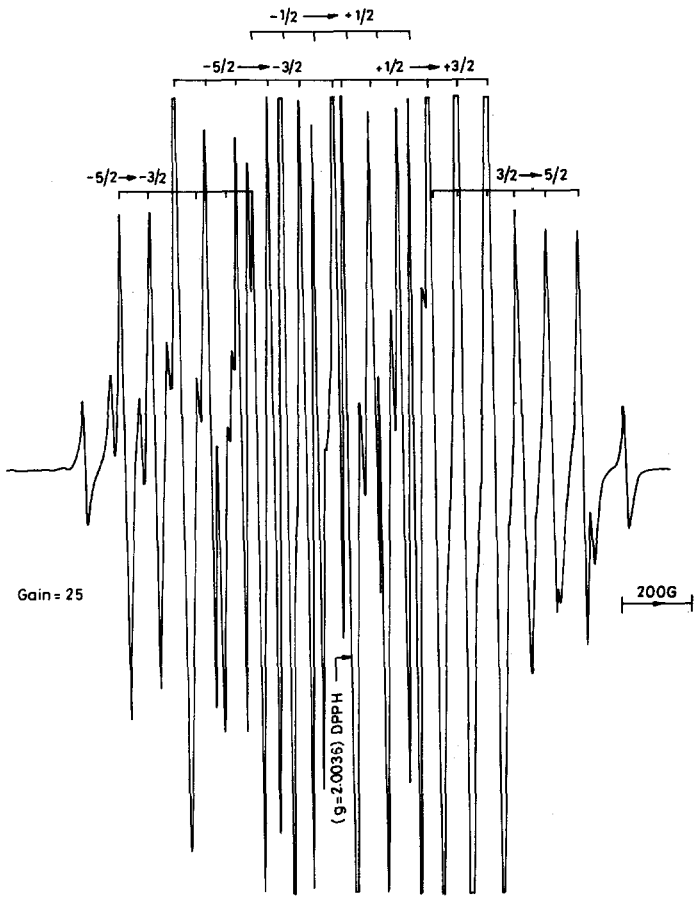

Fig. 3. EPR spectrum of Mn^{2+} ion in $3CdSO_4 \cdot 8H_2O$ crystal recorded when $\bar{H}$ is parallel to X-axis in the ac^*-plane.

$\pm 5/2 \rightarrow \pm 3/2$) in the ZX-plane of Mn^{2+} ion for site 1 in $3CdSO_4 \cdot 8H_2O$ lattice. The angular variation of the high field side resonance lines correspond to $M_s = -5/2 \rightarrow -3/2$, $M_I = 5/2, 3/2, 1/2, -1/2, -3/2$ and $-5/2$ transitions while the angular variation of low field side lines correspond to $M_s = +5/2 \rightarrow 3/2$, $M_I = 5/2, 3/2, 1/2, -1/2, -3/2$ and $-5/2$. The two extreme sets of six hyperfine lines are found to cross each other at about 54° and at 90° (along x-axis), the two transitions are completely reversed, i.e. low field set reached the high field side and the high field side hyperfine set reached the low field side. Again after 90°, the above two sets of six hyperfine lines were merged at 126°. Finally, at 180°, the two sets appear as observed at 0°. A similar behaviour of angular variation seen in the case of fine structure transitions (i.e. $M_s = 5/2 \rightarrow 3/2$, $3/2 \rightarrow 1/2$, $1/2 \rightarrow -1/2$, $-1/2 \rightarrow 3/2$ and $-3/2 \rightarrow -5/2$) and are shown in Fig. 5.

CALCULATION OF SPIN HAMILTONIAN PARAMETERS

Since the total spread of the EPR spectrum of Mn^{2+} is different in three directions, the observed angular variation spectra were analysed using rhombic spin Hamiltonian of the form given in equation (1) which is expressed in terms of Stevens operators. In order to evaluate the spin Hamiltonian parameters from the EPR spectra, the following iterative procedure has been used.

The fine structure positions from each set of six hyperfine lines are found, by taking the mean of the extreme hyperfine lines. The centre field (H_0) position of the spectrum has been calculated from the five fine structure field positions. The centre field has been eliminated by taking the pair of equations involving $\pm M_s$ transitions of each group. So, we get two equations which were in terms of B_2^0 and B_2^2 parameters. By solving the two equations, the values of B_2^0 and B_2^2 were obtained. Similarly, we can get other parameters B_4^0 and B_4^2 by substituting the B_2^0 and B_2^2 values in Y- and X-axes spectra respectively. By substituting the B_2^0, B_2^2, B_4^0 and B_4^2 values in the second order energy expressions, magnetic field positions were generated for all resonance lines. If the calculated magnetic fields do not coincide with the observed spectrum, another set of calculated field

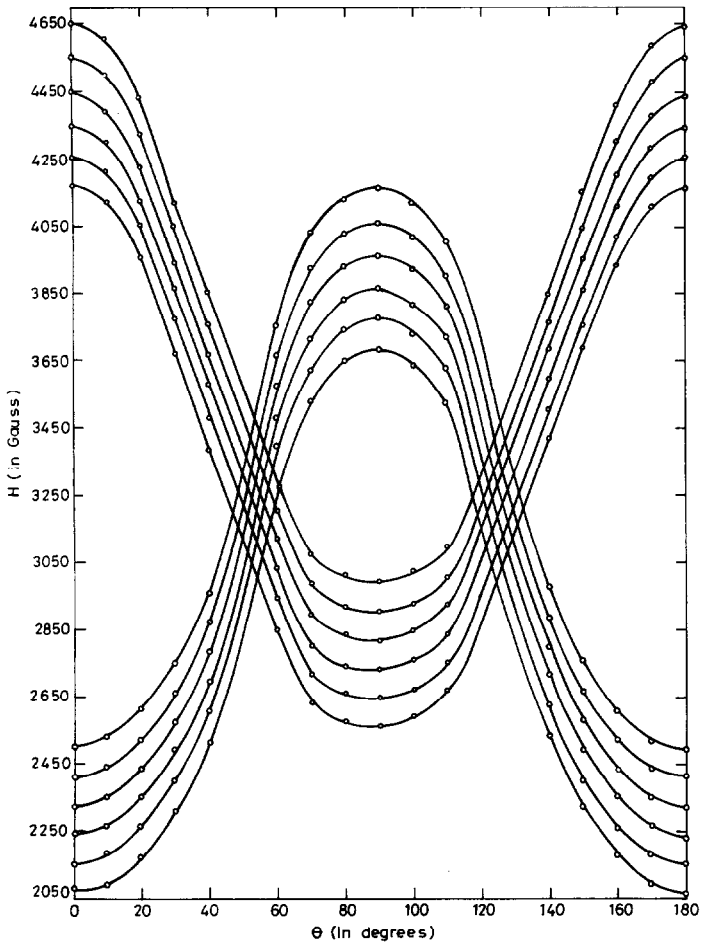

Fig. 4. An angular variation of the lowest and highest field hyperfine corresponding to the transitions ($M_s = \pm 5/2 \rightarrow \pm 3/2$) for Mn^{2+} ion in $3CdSO_4 \cdot 8H_2O$ crystal recorded when the magnetic field is varied in the ZX-plane.

positions are generated by taking the new set of B_2^0, B_2^2, B_4^0 and B_4^2 values. This procedure was repeated until a best fit between the observed and calculated resonance field positions is obtained. The best fit for the spin Hamiltonian parameters are given in Table 1. The principal g_{xx}, g_{yy}, g_{zz}, A_{xx}, A_{yy} and A_{zz} parameters have been obtained directly from the EPR spectra recorded along the three principal X-, Y- and Z-axes. The above measured parameters are found to be almost isotropic and are given in Table 1. Table 2, gives the observed and calculated resonance

Table 1. Spin-Hamiltonian parameters obtained from the EPR spectra of Mn^{2+} ion in $3CdSO_4 \cdot 8H_2O$ lattice

		$B_2^0 = 89.06$ G
$g_{zz} = 2.0095$	$A_{zz} = 90$ G	
		$B_2^2 = 24.66$ G
$g_{yy} = 2.0004$	$A_{yy} = 89.8$ G	$B_4^0 = -0.024$ G
$g_{xx} = 2.0065$	$A_{xx} = 90$ G	$B_4^2 = -0.185$ G

line positions for all the transitions, i.e. $M_s = \pm 5/2$, $\pm 3/2$ and $\pm 1/2$ along the Z-axis. Similarly, we have also calculated the resonance field positions for all transitions along the X- and Y-axes.

DISCUSSION

Since the Mn^{2+} ion has 5/2 spin, the five electrons will give rise to fine structure EPR lines and these arise because of the transition between the spin levels. The interest in the EPR spectra of Mn^{2+} is due to the spin transitions which are highly angular dependent and the angular variation follows the $(3\cos^2\theta - 1)$ rule. In Fig. 5, the five fine structure transitions become a single transition when the magnetic field is making an angle 54° to the Z-axis, i.e. at 54°56′ the $(3\cos\theta^2 - 1)$ term becomes zero. Hence, we get an almost merged single spectrum of six lines at 54°56′ which is shown in Fig. 4. At this angle all the spin or dipolar contributions along the

	4650	4642			

magnetic field are zero. The angular variation of five fine structure lines is shown in Fig. 5, which also behaved in a similar way as discussed. The observed EPR spectra can be interpreted on the basis of crystal structure of the host lattice. In the lattice, there are two chemically inequivalent cadmium atoms. If the Mn^{2+} ion enters the Cd_1 site, the EPR spectra should show single site in all orientations, whereas if it enters in Cd_2 site, the EPR spectra should show two sites, in general orientations and single site along the three crystallographic axes. Suppose, Mn^{2+} ion enters both the sites with equal population, then it will be highly complicated EPR spectrum as it has been observed in the case of VO^{2+} ion (high concentration) doped $3CdSO_4 \cdot 8H_2O$ lattice. In the present case, the site I did not show any splittings in any orientations and hence, the observed site is due to the replacement of Cd_1 site by Mn^{2+} ion in the lattice as observed in the case of VO^{2+} ion (low concentration) in $3CdSO_4 \cdot 8H_2O$ crystals.[18] Site 2 which appear in Z-axis spectrum, could be due to the substitution of Cd_2 site, because in other orientation, the above site was splitting, thus showing very small intensity of lines. Hence, site 2 could not be examined.

RELATIVE SIGNS OF A AND B_2^0

The relative signs of A and B_2^0 can be derived by correlating the observed hyperfine coupling separation in the high and low field sides. In the present case, the separation of the hyperfine coupling constant was found to be larger at high field (95.6 G) than that at low field side (85.2 G). Assuming A to be $-$ve, and B_2^0 to be $+$ve and vice versa, the resonance field positions have been calculated from the resonance field expressions given by Low[2] and compared with the observed field positions. In the present lattice, the observed spacing between the hyperfine lines coincide well with the calculated ones for $-$ve A and $+$ve B_2^0 values. Hence, the signs of A and B_2^0 are taken to be $-$ve and $+$ve respectively.

COVALENCY OF THE METAL–LIGAND BOND

The nature of bonding between the Mn^{2+} ion and its surroundings can be found by calculating the hyperfine coupling from the EPR spectrum. It has been reported that the hyperfine coupling constant decreases with increase in the degree of covalency.[19] In the present case, the average hyperfine coupling constant was found to be 90.5 G. The average covalency per bond for the complex has been estimated from the curve given by Simanek and Muller[20] and was found to be $\approx 7\%$ for the $Mn—O_w$ bond.

ELECTRONIC ABSORPTION STUDIES

The Mn^{2+} ion (d^5) has five unpaired electrons in the valency shell distributed in the t_{2g} and e_g orbitals in O_h symmetry. In the free ion state, it will give rise to a number of free ion terms with the increasing order of energy $^6S, {}^4G, {}^4P, {}^4D, {}^2I, {}^2G, {}^2H, {}^4F, {}^2D, {}^2F, {}^2F, {}^2S, {}^2D, {}^2G, {}^2P$ and ^2D. These levels can split further when the d^5 ion is placed into different crystal field environments.

The electronic absorption spectrum of the Mn^{2+} ion in $3CdSO_4 \cdot 8H_2O$ crystal has been studied at room temperature (300 K) and liquid nitrogen temperature 80 K in the region 6000–2500 Å which is shown in Fig. 6. The above figure has the characteristic features of Mn^{2+} ion in octahedral symmetry and showed eight absorption bands. On cooling down to liquid nitrogen temperature, the above spectrum was resolved and showed twelve absorption bands at 19,231, 23,255, 24,752, 24875, 27,472, 27,932, 28,169, 29,585, 32,467, 38,095, 38,855 and 43,478 cm^{-1} and almost all the bands showed small blue shifts. The above weak intensity bands are spin forbidden. In the present case, in octahedral symmetry all the optical transitions occur from sextet $^6A_{1g}$ ground state to all quartet and doublet levels. The observed spectrum was analysed assuming octahedral site symmetry. The energy matrices for octahedral symmetry were given by Orgel and Tanabe and Sugano.[21,22] These matrices involved the crystal field parameter Dq and the interelectronic repulsion parameters B and C. As can be seen in Fig. 6, some of the bands at 24,752, 24,875 and 29,585 cm^{-1} are sharp in intensity. The above sharp intensity bands are observed due to $^4A_{1g}(G)$, $^4E_g(D)$ and $^4E_g(G)$ energy level transitions respectively, because of their energy expressions are independent of Dq parameter. These transitions are useful to calculate the interelectronic repulsion B and C parameters.

In order to evaluate the crystal field parameter (Dq) and interelectronic repulsion parameters (B and C) diagonalisation method has been used to solve the energy matrices. To get the best fit, between experimentally observed and calculated energy positions a new parameter (α) has been introduced into the energy matrices as an element and called Trees correction.[24] The complete energy matrices inclusive of Trees correction have been given by Mehra.[25] First B and C parameters were calculated from the energy matrix corresponding $^4E_g(G, D)$ levels. The solved expressions for B and C from the

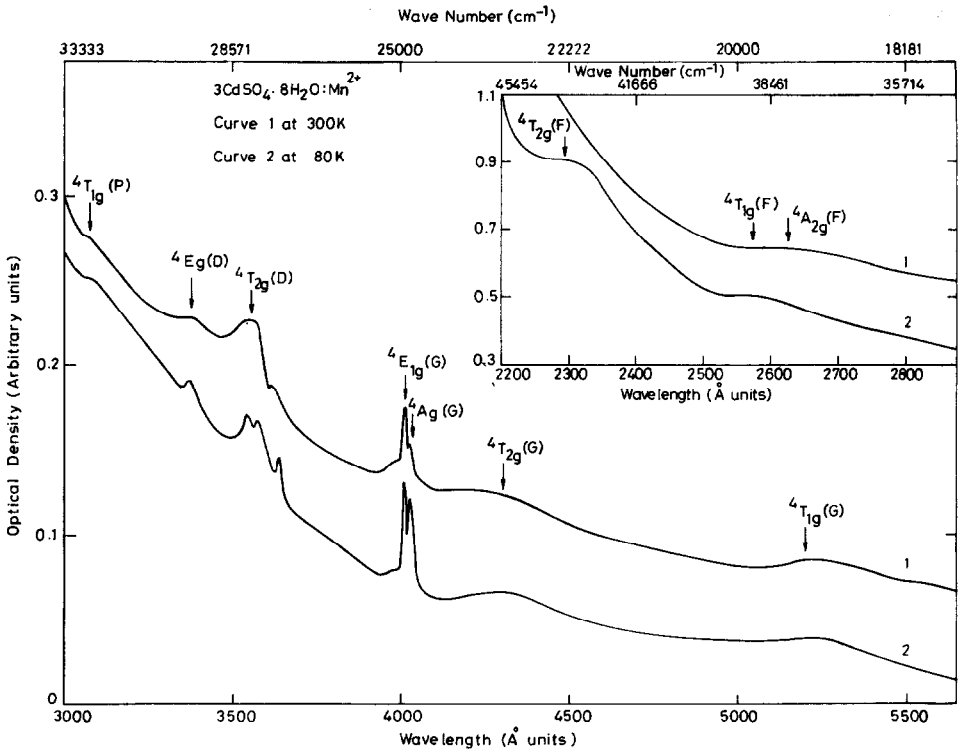

Fig. 6. The electronic absorption spectrum of Mn^{2+} ion in $3CdSO_4 \cdot 8H_2O$ crystal recorded in the visible and UV regions. Curve 1 recorded at 300 K: Curve 2 recorded at 80 K.

above levels are as follows:

$$B = \frac{94 \pm \sqrt{49(E_1 - E_2)^2 - 76S\alpha^2}}{49},$$

$$C = (E_1 + E_2 - 278 - 26)/10,$$

Table 3. Band positions and their assignments of transitions of Mn^{2+} ion in $3CdSO_4 \cdot 8H_2O$ lattice: $Dq = 700\ cm^{-1}$, $B = 835\ cm^{-1}$, $C = 2982\ cm^{-1}$ and $\alpha = 76\ cm^{-1}$

S. No.	Band position (cm^{-1}) Observed at 80 K	Calculated	Assignment of transition
1.	19,231	19,201	$^6A_{1g} \rightarrow {}^4T_{1g}(G)$
2.	23,255	23.124	$\rightarrow {}^4T_{2g}(G)$
3.	24,752	24,753	$\rightarrow {}^4A_{1g}(G)$
4.	24,878		$\rightarrow {}^4E_g(G)$
	27,472		
5.	27,932	28,049	$\rightarrow {}^4T_{2g}(D)$
	28,169		
6.	29,585	29,587	$\rightarrow {}^4E_g(D)$
7.	32,256	32,058	$\rightarrow {}^4T_{1g}(P)$
8.	38.095	38,226	$\rightarrow {}^4A_{1g}(E)$
9.	39,215	40,891	$\rightarrow {}^4T_{1g}(F)$
10.	43,478	43,323	$\rightarrow {}^4T_{2g}(F)$

where E_1 and E_2 are the respective transition energies of $^4E_g(D)$ and $^4E_g(G)$ levels. Using the experimentally observed energy values E_1 and E_2, B and C parameters have been evaluated to be 835 and 2982 cm^{-1} respectively. Using the B, C and α (for a free ion $\alpha = 76\ cm^{-1}$) values in the energy matrices, the band positions were calculated by diagonalisation method for different Dq values. Exact Dq value has been fixed from the good fit of the experimentally obtained band positions with the calculated ones and Dq value was found to be 700 cm^{-1}. Exact crystal field transitions were also assigned for all the observed bands. Table 3, gives the observed and calculated band positions along with their crystal field transitions.

The energy difference between the split components (27,472, 27,932 and 28,169 cm^{-1}) of the band at 28,049 cm^{-1} is compared with the calculated spin–orbit couplings for different transitions. The experimentally observed band splittings agree well with the calculated ones for $^2T_{2g}(D)$ level. Hence, the resolved fine structure is attributed to the spin–orbit splittings of the $^2T_{2g}(D)$ level at 80 K. The observed spin–orbit splittings are shown in a schematic energy level diagram (Fig. 7).

EPR results proved that the Mn^{2+} ion has substituted the Cd_1 site in the $3CdSO_4 \cdot 8H_2O$ lattice. In this case, the site symmetry of the ion

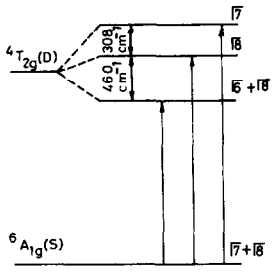

Fig. 7. The observed spin–orbit splittings of $^6A_{1g}(S) \rightarrow {}^4T_{2g}(D)$ band.

is expected to be approximately octahedral, but, although the observed electronic absorption spectrum could be fitted to octahedral, the electronic absorption bands could not be resolved further. This is purely because of weak intensity nature of the bands, which are all due to spin forbidden transitions. Hence, the electronic absorption results also suggest that the Mn^{2+} ion has entered the Cd_I site in the $3CdSO_4 \cdot 8H_2O$ lattice.

Abstract—The preparation of the complex species $[Cd(TDPS)_4](ClO_4)_2$ and $[Zn(TDPS)_4](ClO_4)_2$ (TDPS = tris(dimethylamino)phosphine sulphide) is described; their solutions in CD_2Cl_2 have been examined by ^{31}P and ^{35}Cl NMR. The ligand exchange mechanism for both complexes was found to be of the interchange type and the corresponding values for the rate constant and the activation parameters are $k(25°C) = (1.36 \pm 0.34) \times 10^5$ and $(1.35 \pm 0.35) \times 10^4$ s^{-1}; $\Delta H^{\neq} = (36.4 \pm 1.3)$ and $(40.9 \pm 2.5$ (kJ mol^{-1}; $\Delta S^{\neq} = (-24.6 \pm 5.8)$ and (-28.8 ± 10.3) J mol^{-1} K^{-1}; for the Cd and Zn complex respectively.

Information about the ligand substitution on Zn^{2+} and Cd^{2+} ions is relatively rare as a consequence of the great lability of their complexes in solution.[1] These ions however, particularly Zn^{2+}, are of great importance biologically. In their complexes Zn^{2+} and Cd^{2+} are commonly characterized by coordination numbers of 4, 5 and 6.[2] In the classification of Lewis acids,[3] Cd^{2+} is considered as soft and Zn^{2+} as "borderline". The Zn^{2+} ion therefore forms kinetically stable complexes with the hard Lewis bases hexamethylphosphoramide (HMPA),[4] nonamethylimidodiphosphoramide (NIPA)[5] and octamethylpyrophosphoramide (OMPA),[6] all containing the P=O group, as well as with soft bases like thiourea.[7] Ligand exchange kinetics could also be studied in the case of Cd^{2+} with the ligands NIPA[5] and OMPA.[6] It seemed interesting to compare the behaviour of the complexes of Zn^{2+} and Cd^{2+} with HMPA to those with thio-HMPA, tris(dimethylamino) phosphine sulphide (TDPS), in order to evaluate the influence of the substitution of the "hard" O-atom by the "soft" sulphur.

In this paper we describe the preparation of the complexes $ZnL_4(ClO_4)_2$ and $CdL_4(ClO_4)_2$ (L = TDPS) and the kinetics of the ligand exchange reactions in solution. Only a few complexes of TDPS are reported in the literature,[8] especially of Co(II), Ni(II), and Cu(I) perchlorates showing equally tetracoordination. Zirconium(IV) and tin(IV) chlorides form adducts with the ligand.[9]

EXPERIMENTAL

Materials

Tris(dimethylamino)phosphine sulphide (TDPS) was prepared by refluxing tris(dimethylamino) phosphine with a stoichiometric amount of sulphur in benzene.[10] The purity of the product was controlled by ^1H and ^{31}P NMR. The solvents used in the experiments are Fluka "puriss" grade nitromethane, Prolabo "normapur grade" dichloromethane, C.E.A. (Service des molécules marquées) deuterated CD_2Cl_2 and CD_3NO_2. The complexes were synthesized starting from $Cd(ClO_4)_2$, $6H_2O$ and $Zn(ClO_4)_2$, $6H_2O$ (Alfa Ventron) according to a

* Author to whom correspondence should be addressed.

method described by Van Leeuwen *et al.*[11] The precipitation of the complex $Cd(TDPS)_4(ClO_4)_2$ takes place immediately. The preparation of the $Zn(TDPS)_4(ClO_4)_2$ complex provides in a first step an oil which is washed several times with anhydrous ether until the precipitation of a solid occurs. These products should be handled with utmost care! During the manipulation of the very dry Zn-complex a violent explosion happened. Therefore all further attempts to synthesize this salt were abandoned. Found: C, 26.4; H, 6.71; P, 11.12; S, 11.68; Cd, 10.35%. Calc. for $Cd(TDPS)_4(ClO_4)_2$: C, 26.4; H, 6.6; P, 11.36; S, 11.7; Cd, 10.3%. Found: C, 27.48; H, 7.09; P, 11.68; S, 12.02; Zn, 6.48%. Calc. for $Zn(TDPS)_4(ClO_4)_2$: C, 27.5; H, 6.9; P, 11.9; S, 12.25; Zn, 6.25%.

All solutions were prepared by weight; all manipulations were carried out under purified argon in a glove box.

NMR spectroscopy

NMR spectra were taken on Bruker WP 80 and WH 90 spectrometers and on a 250 MHz Cameca apparatus. ^{31}P NMR was performed at 32.44 MHz (100–800 scans of 4K/8K points over a frequency range of 2 kHz) with 85% H_3PO_4 in H_2O as an external reference and CD_2Cl_2 as an internal lock substance. All ^{31}P spectra are broad band decoupled from proton.

Line-shape measurements

Theoretical line shapes are computed using a matrix formalism due to Anderson,[12] Kubo[13] and Sack[14] and the program ECHGN.[15]

In the case of the Zn complex the site exchange occurs between two singlets. The population vector **P** and the exchange matrix are therefore

$$\mathbf{P} = r, 1$$

and

$$\mathbf{E} = \begin{vmatrix} -1 & 1 \\ r & -r \end{vmatrix} \times k\left(r = \frac{[TDPS]_{bound}}{[TDPS]_{free}}\right).$$

The ^{31}P NMR spectrum of the ligand molecules bound to Cd^{2+} consists of three signals of relative intensities 12.5, 75 and 12.5 (see below) leading to $\mathbf{P} = 0.125r, 0.75r, 0.125r, 1$ and

$$\mathbf{E} = \begin{vmatrix} -1 & 0 & 0 & 1 \\ 0 & -1 & 0 & 1 \\ 0 & 0 & -1 & 1 \\ 0.125r & 0.75r & 0.125r & -r \end{vmatrix} \times k.$$

All calculations were performed on a Texas Instruments 980A mini-computer equipped with a Hewlett–Packard 7280 Å digital plotter.

RESULTS AND DISCUSSION

Stoichiometry of the complexes in solution

The solid complexes $Cd(TDPS)_4(ClO_4)_2$ and $Zn(TDPS)_4(ClO_4)_2$ retain their stoichiometry on dissolution in an inert solvent. This was proven by comparing the areas of the ^{31}P NMR signals of free and bound TDPS stemming from a solution of known quantities of complex and added free TDPS in CH_2Cl_2 at low temperature (−90°C). The calculated ratio r was confirmed experimentally in both cases.

Generally, ion pair formation is favoured in solvents of low dielectric constant[16] such as dichloromethane ($\varepsilon_{20} = 9.08$).

Therefore the dissociation of the salts is incomplete in this solvent. A ^{35}Cl NMR study of the Cd^{2+}-complex at 30°C shows clearly the presence of ion pairs. In the liquid state the predominant mechanism for the relaxation of the ^{35}Cl nucleus is quadrupolar relaxation and its rate therefore depends on the intensity of the electric field gradient at the nucleus.

The relaxation time T_2 is related to the width of the NMR line at its half-height, $\Delta\nu_{1/2}$, by $\Delta\nu_{1/2} = 1/\pi T_2$.

When the solvation shell of the perchlorate ion is highly symmetrical the field gradient at the chlorine nucleus is zero. $Cd(ClO_4)_2$ in D_2O, e.g. yields a ^{35}Cl NMR signal of a width of 6.5 Hz proving a very symmetrical arrangement of the solvent molecules around the anion.

For ClO_4^- in contact with a counterion however the field gradient is large and the resulting NMR signal very broad. In fact the observed line is always an averaged signal due to a rapid exchange of the ClO_4^- ion between the bound site and a "free" site in the bulk of the solution.

Therefore, in our case, the observed linewidth indicates that a fraction of the anions is associated with the complex ion $Cd(TDPS)_4^{2+}$.

A solution of the complex CdL_4^{2+}, $2ClO_4^-$ alone gives rise to a ^{35}Cl NMR signal of 155 Hz line-width. Upon addition of excess TDPS the width reduces to 85 Hz ($C_{complex} = 0.1$ M, $C_{free} = 0.256$ M). Further addition of ligand lowers the signal width to 64 Hz. Addition of nitromethane, a solvent of a much higher dielectric constant ($\varepsilon_{20} = 38.6$) than dichloromethane, to the initial solution produces the same effect.

The results corroborate the hypothesis of ion-pair formation in the system studied. It is however impossible to decide whether the perchlorate anion

forms a contact ion-pair with the cation or an outer-sphere complex, $[CdL_4, ClO_4]^+$.

NMR parameters

The ^1H signals corresponding to the methyl groups of the ligands in both the cadmium and zinc complexes appear at lower field than those of the non-bonded molecules. The effect is more important for the zinc complex ($\Delta\delta = 0.18$ ppm) than for the Cd^{2+}-complex ($\Delta\delta = 0.11$ ppm). These observations suggest a predominant deshielding effect of the electrical field created by the cation.[17,18] It may also be noticed that the coupling constant $^3J_{P-H}$ increases from 10.5 to 11.5 Hz when TDPS is coordinated. Complexation of TDPS shifts the $^{31}P\{^1H\}$ signals to higher fields for the two complexes: $\Delta\delta = -7.25$ ppm for CdL_4^{2+} and -3.97 ppm for ZnL_4^{2+}. For the complex $Zn(HMPA)_4(ClO_4)_2$ Lincoln and Tkaczuk[4] found a low field shift ($\Delta\delta \simeq 2.5$ ppm). This example shows once more that the sign and the amplitude of the difference between the ^{31}P chemical shifts of free and bound organophosphorus ligands cannot be explained in a simple manner as it had been noticed before in reports[5,6,19] on the coordination of these molecules.

The ^{31}P signal of the cadmium complex consists of one main line (75% of the total intensity), accompanied by two satellites of equal intensities ($\sim$ 12.5% each). Cadmium has two magnetically active isotopes, ^{111}Cd and ^{113}Cd, of closely similar abundance (12.75 and 12.26%), both with spin $I = 1/2$. As their gyromagnetic ratios are identical within 4%, only one coupling constant is observed, $^2J_{^{31}P-Cd} = 30.75$ Hz.

Kinetic measurements

When excess TDPS is added to a solution of the complex ML_4^{2+}, two ^{31}P NMR signals are observed at low temperature (-94°C for M = Cd, -70°C for M = Zn) as mentioned above.

On increasing the temperature, coalescence of the lines occurs (Fig. 1). A complete line-shape analysis of the spectra of six solutions for the Cd complex and two solutions for the Zn compound yields the rate constants $k_{NMR} = \tau_c^{-1}$, where τ_c represents the mean lifetime of TDPS coordinated to the cation,

$$TDPS_{bound} \overset{k_{NMR}}{\rightleftharpoons} TDPS_{free}.$$

Enthalpies and entropies of activation are calculated from a set of k_{NMR} values determined at different temperatures. The variation of k_{NMR} with the concentration of free TDPS allows us to draw some

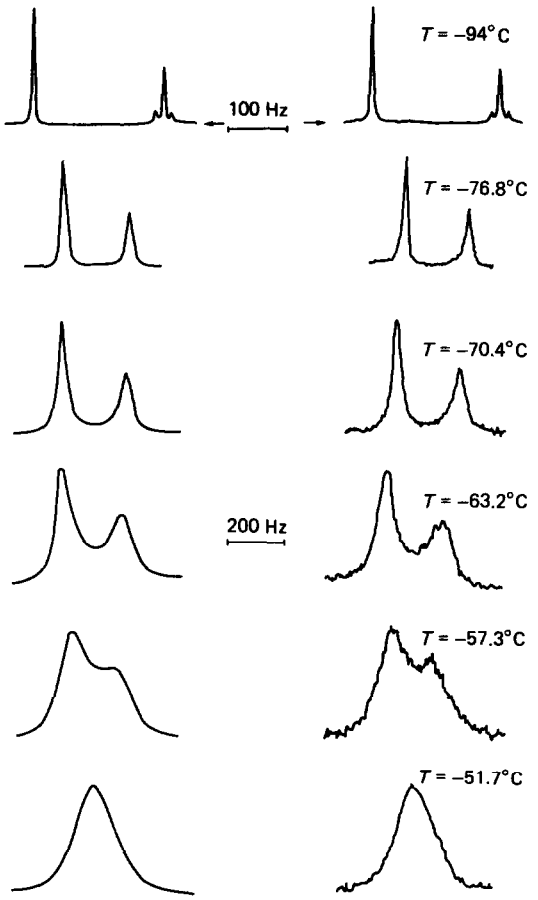

Fig. 1. Calculated (left) and experimental (right) $^{31}P\{^1H\}$ NMR spectra at different temperatures for the system $Cd(TDPS)_4^{2+}/TDPS/CD_2Cl_2$. $[TDPS]_{bound} = 0.275$ and $[TDPS]_{free} = 0.33$ mol l^{-1}.

conclusions concerning the mechanism of the exchange process. The results are summarized in Tables 1 and 2.

A better precision could have been obtained for the system Zn—TDPS by increasing the number of solutions differing in concentration of free ligand but all further experiments have been abandoned when the hazards of explosion of this product became evident (see Experimental).

As it can be seen from Table 1, the values of k_{NMR} at -73°C and of k_{NMR} at 25°C are not rigorously constant for different concentrations of free ligand but do not depend either in a simple manner on this parameter. The relative dispersal of the k_{NMR} values cannot be explained in terms of the ion-pair formation mentioned before and is attributed to experimental errors. We conclude that the rate constants are independent of free ligand for the exchange on the CdL_4^{2+} complex. The same conclusion holds for the Zn complex (Table 2).

The mean values for the exchange parameters

Table 1. Solution compositions and kinetic parameters for TDPS exchange on the $Cd(TDPS)_4^{2+}$ complex ion in CD_2Cl_2

$[TDPS]_{bound}$* (mol l^{-1})	$[TDPS]_{free}$† (mol l^{-1})	k_{NMR} (25°C) (s^{-1})	k_{NMR} (−73°C)§ (s^{-1})	ΔH^* (kJ mol^{-1})	ΔS^* (J mol^{-1} K^{-1})
0.275	0.33	1.5×10^5	85.0	36.1	−24.2
0.275	0.175	1.9×10^5	72.4	37.9	−16.5
0.545	0.625	1.4×10^5	51.1	37.9	−19.4
0.205	0.45	1.1×10^5	55.2	36.4	−25.9
0.41	0.256	0.9×10^5	58.7	35.3	−31.3
0.10	0.20	1.4×10^5	95.2	34.7	−30.0

are $k(25°C) = (1.36 \pm 0.34) \times 10^5$ s^{-1}; $\Delta H^* = (36.4 \pm 1.3)$ kJ mol^{-1}; $\Delta S^* = (-24.6 \pm 5.8)$ J mol^{-1} K^{-1} for $Cd(TDPS)_4^{2+}$ and $k(25°C) = (1.35 \pm 0.35) \times 10^4$ s^{-1}; $\Delta H^* = (40.9 \pm 2.5)$ kJ mol^{-1}; $\Delta S^* = (-28.8 \pm 10.3)$ J mol^{-1} K^{-1} for $Zn(TDPS)_4^{2+}$.

The mechanism of a ligand exchange reaction independent of the free ligand concentration can be of the dissociative (D) or interchange (I) type.[20] In the first case it is assumed that the intermediate ML_3^{2+} (M = Zn or Cd) is formed in the initial step. This mechanism should be characterized by a high activation enthalpy and a strongly positive value of the activation entropy. This is obviously not the situation encountered here. An interchange mechanism implies the formation of an outer-sphere complex (OSC)

$$ML_4^{2+} + L^* \overset{K_{OSC}}{\rightleftharpoons} (ML_4 \ldots L^*)^{2+},$$

$$(ML_4 \ldots L^*)^{2+} \overset{k_I}{\rightleftharpoons} (ML_3L^* \ldots L)^{2+} \rightarrow ML_3L^{*2+} + L.$$

The observed rate constant k_{NMR} in this case is

$$k_{NMR} = \frac{k_I K[L]}{1 + K[L]}.$$

For high values of K ($K[L] \gg 1$) k_{NMR} becomes equal to k_I and is therefore independent of the concentration of free ligand.

This mechanism is compatible with the values of the observed ΔH^*, intermediate between those obtained for a purely associative (A) mechanism (e.g. exchange on $Zn(HMPA)_4^{2+}$)[4] and a pure D mechanism (e.g. exchange on $Zn(S{=}C[NMe_2]_2)_4^{2+}$][7] by Lincoln and co-workers and those of ΔS^* which are only slightly negative.

For all these reasons the interchange mechanism appears more likely than a pure dissociative pathway.
