The molar conductances of these complexes in DMF solutions show that they are non-electrolytes, as expected[1] (see Table 1). The water soluble complex *cis*-(S-MeCys)platinum(II) dichloride as well as the *cis*-(S-EtCys)platinum(II)dichloride has a molar conductance[1] of 280 ohm^{-1} cm^2 $mole^{-1}$, in aqueous solutions. This may be explained by their easy aquation, especially at the position *trans* to the sulphur atom,

$$[PtLCl_2] + H_2O \rightarrow [PtL(H_2O)Cl]Cl \xrightarrow{+H_2O} [PtL(H_2O)_2]Cl_2 \quad (7)$$

and the ionization of the free carboxylate group.[1,14,15] A 10^{-3} M aqueous solution of the complexes has a pH ~ 3. On the other hand, the complex $[Pt(MtH)Cl_2]$, with MtH = methionine has a $pK_a = 2.3$, of the same order with the hydrochloric acid salt of methionine (MtH·HCl), while the $[Pd(MtH)Cl_2]$ presents $\Lambda_M = 365$ ohm^{-1} cm^2 $mole^{-1}$.[5,15]

In the IR spectra of all these complexes, there is a strong band at ~ 1720 cm^{-1} which is assigned to the $\nu_{as}C{=}O$, of a free carboxylate group. For the ionized free carboxylate group, this vibration occurs in the range of 1550–1620 cm^{-1}, while for a coordinated one, it is seen at 1580–1660 cm^{-1}.[1,12,13] This suggested an S, N coordination in the case of *cis*-(S-EtCys)platinum(II)dichloride complex, which was confirmed with its X-ray crystal structure determination[1] and suggests the same, for all the similar $PtLCl_2$ complexes, isolated in the present study.

The amino group participation in the bonding with Pt(II) is confirmed here also from the examination of the νNH_2 and the δNH_2 frequencies of the complexes, identified with deuteration at ~ 3200 and ~ 1600 cm^{-1}, respectively (see Table 2). The observed frequencies compare favorably with the ones of other similar complexes like, $Pt(MtH)Cl_2$, $Pt(L–H^+)_2$, where L = CysOEt,

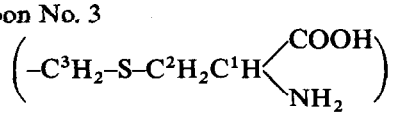
br = broad.



etc.[7,8,12,14,15] Also, the $\delta_t(NH_2)$ twisting motion of the free S-EtCys which occurs at 1120 cm^{-1} is seen at 1085 cm^{-1} in its complex with Pt(II), while the $\delta_r(NH_2)$ rocking motion at 535 and 600 cm^{-1} respectively, identified with deuteration. The negative shift of the former and the positive one of the latter, once again confirm the amino group participation with Pt(II).[16] All the complexes present also two Pt–Cl bands, confirming their *cis* configuration.

The ^1H NMR spectra of the complexes are useful for assigning the bonding sites and confirming the existence of two diastereoisomers in all the complexes. They were recorded either in D_2O or DMSO-d_6 according to their solubilities. All the protons near the bonding sites (N, S) of the ligands are shifted down- or up-field upon complexation with Pt(II), while the observed two sets of protons for the various methylene or methine protons, confirm the existence of the two diastereoisomers[1] (see Table 3). Similar results were also found in the work of Erickson *et al.*[17] on the interaction of Pt(II) with S-

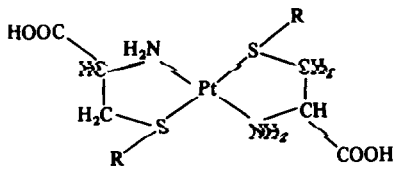
MeCys and others.[18,19] It is worthwhile mentioning that the down-field chemical shifts of the protons at the carbon No. 3

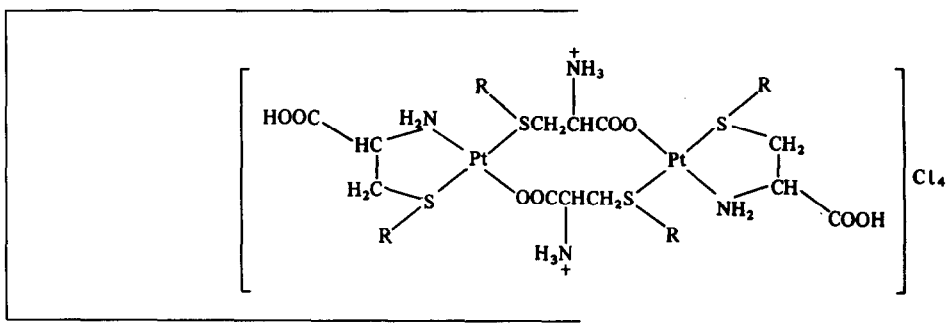
are larger in the complexes with S-BzlCys and S-DpmCys than in the other ligands, due to the large shielding constants of the phenyl groups (see Table 3).



The conclusion of the ^1H NMR spectra was further reconfirmed more clearly with the ^{13}C NMR spectra of the ligands S-methyl and S-EtCys and their complexes with Pt(II)[1] and this was also in agreement with the results of Kozlowski *et al.*[2,3,9,20]

2. PtL_2Cl_2 type complexes

The molar conductances of these complexes in aqueous solutions, range from 650 to 700 ohm^{-1} cm^2 mole^{-1}, much higher than the values for the 1:2 electrolytes (~ 200). This is obviously due to the ionizations of the two free carboxylate groups. A 10^{-3} M aqueous solution of the complexes has a pH ~ 2.5. This compares favorably with the pH ~ 2.9 for the complex $[Pt(MtH)_2]Cl_2$ found by Chernova *et al.*,[14] as well as the values of the Λ_M for the same complex, which is found[14] near 600 ohm^{-1} cm^2 mol^{-1}.



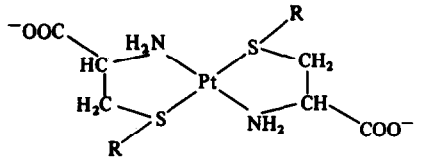
From the IR spectra of these complexes, which closely resemble those of the $PtLCl_2$ series, it is again concluded that the carboxylate groups are free, as the strong band at ~ 1730 cm^{-1} assigned to the $\nu_{as}C{=}O$, shows. The amino groups are coordinated with Pt(II), since the νNH occurs at 3100–3200 cm^{-1} and the δNH at 1580–1585 cm^{-1} (see Table 2), identified with deuteration. The characteristic feature in the far IR spectra of these complexes, is the absence of the doublets observed at 300–330 cm^{-1} in the $PtLCl_2$ series, indicating ionic chloride ions, in this case.

Since the PtL_2Cl_2 series is easily prepared from the $PtLCl_2$ series and the S and N atoms are the coordination sites in the latter and taking into account the large *trans* influence of the sulphur atom, the observations of free carboxylate groups and coordinated amino groups as well as the absence of Pt–Cl bonds in the former, the following structures for them are suggested.

(a) (b)

The insoluble products of the reactions (2) and (3) which correspond to the same empirical formulae, present a strong band at 1630–1640 cm^{-1}, which may be assigned to the νC=O of a coordinated carboxylate group (–COO–Pt), beside the other νC=O strong band at 1730 cm^{-1}. These observations suggest an oligomeric or polymeric structure for these materials.

Similar polymeric structures cannot be excluded. Similar oligomeric or polymeric structures were also found in the complexes $Pt(Cys)_2$ and $Pd(Cys)_2$,[12,21] as well as the $Pt(MtH)_2Cl_2$.[14]



The ^1H NMR spectra in these series of complexes further shows the S, N coordination with Pt(II). The protons near the coordination sites shift downfield by 0.2–0.7 ppm (see Table 3). Several diastereoisomers are expected theoretically in the PtL_2Cl_2 series of complexes. However, taking into account that in the crystal structure of *cis*-Pt(S-EtCys)Cl_2, we found only two diastereoisomers, namely the S and R around the chiral sulphur centre, with the chelate ring in the λ conformation[1] and if we assume that the second chelate ring takes also a λ configuration, then the expected isomers will be only the R(λ)R(λ), R(λ)S(λ) and S(λ)S(λ) combinations.

A detailed analysis, however, of all the diastereoisomers formed cannot be done with certainty in the present case, like in the case of other similar Pd(II) complexes,[9] due to the low solubility of most of the complexes of the PtL_2Cl_2 series. Most of the proton resonances are broad and not well resolved in an 80 MHz spectrometer and may

suggest the presence of more than one diastereoisomer (see Table 3).

3. $Pt(L–H^+)_2$ *type complexes*

Since the complexes are prepared according to the reactions (4) and (5), their expected structures are

These complexes are non-electrolytes in water solutions, with molar conductances ranging from 8–16 $ohm^{-1}\ cm^2\ mole^{-1}$ (Table 1), as expected.

The structures **III** are further substantiated from their IR spectra, where we observe the νNH of a coordinated amino group, in the range 3020–3280 cm^{-1} and the δNH of the same at $\sim$ 1580 cm^{-1}, both identified with deuteration. Also with the absence of the characteristic band near 1730 cm^{-1} assigned to the νC=O of a free and protonated carboxylate group. There is instead a strong absorption near 1620 cm^{-1} not removed upon deuteration, assigned to the νC=O of a free ionized carboxylate group. [1,12,13] This was substantiated from the IR spectra of the residue of a sample of a $Pt(L–H^+)_2$ in 0.1 N HCl aqueous solution, obtained after evaporation, which showed again the band at 1730 cm^{-1} and not the one at 1620 cm^{-1}. Obviously, the HCl addition is reversible and the following reaction occurred:

$$Pt(L–H^+)_2 + 2HCl \rightarrow PtL_2Cl_2. \qquad (8)$$

The structure **III** was also proposed by Chernova *et al.*[14] for the complex $Pd(Mt)_2$, with Mt = the methionine anion, which showed the νC=O at 1575 cm^{-1} and the νNH at 3150 and 3004 cm^{-1}. In these complexes again, the νPt–Cl bands, are not observed in their far IR spectra, as expected.

The ^{1}H NMR spectral data have been included in Table 3. These indicate once again as coordination sites the S and N atoms (shift of the adjacent protons). Only the methine protons of C_1 are shifted to a larger extent here than in the other series of complexes, shielded by the adjacent $-COO^-$ group. The broadness of the observed ^{1}H NMR resonances also suggests several diastereoisomers here, as in the PtL_2Cl_2 series.

4. $PtL(nucl)_2Cl_2$ *type complexes*

The nucleosides used for the preparation of these complexes, according to reaction (6), were guanosine = Guo and inosine = Ino. These complexes have molar conductances in aqueous solutions ranging from 300–400 $ohm^{-1}\ cm^2\ mole^{-1}$ (see Table 1), due to the ionization of the free carboxylate group of the amino acids.

The IR spectra of these complexes are quite complicated, due to the presence of the nucleosides and it is not easy to identify the νNH and δNH motions of the amino-acids or the nucleosides, whenever present, because they overlap in several cases. The only observation worth mentioning is that the νC=O motions of the free carboxylate groups of the amino acid complexes without nucleosides, occurring near 1730 cm^{-1}, are now observed near 1700 cm^{-1} as broad bands, obviously coupled with the νC=O of the carbonyl groups of the nucleosides guanosine and inosine. Also there are no bands assignable to νPt–Cl in the far IR spectra of the complexes, as expected.

The ^{1}H NMR spectral data are given in Table 4. The H_2 and H_8 aromatic proton resonances of free inosine, appearing at 8.07 and 8.17 ppm respectively,[22] shift to higher fields and show two resonances for each proton near 8.30 and 9.00 ppm, in the complexes (see Table 4). The larger shift of the H_8 resonance (near 9.00 ppm) suggests an N_7 coordination with Pt(II), as expected.[23] The two sets of resonances observed for each proton are most probably due to the inequivalence of the two inosine molecules, in the $[PtL(Ino)_2]Cl_2$ complexes, the one being *trans* to a sulphur atom, with a higher *trans*-influence than the other, *trans* to a nitrogen atom. The protons less shifted to higher fields are assigned to the inosine molecule coordinated through N_7, *trans* to the sulphur atom. Similar behaviour was also observed in the complex Pt(Cys–

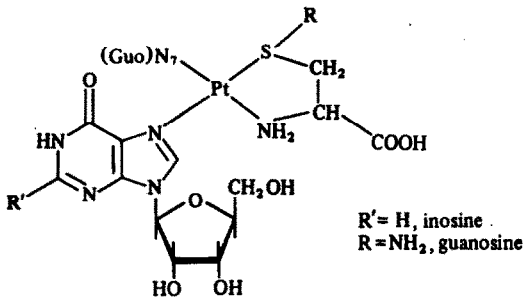


Table 4. ^{1}H NMR chemical shifts of the nucleosides in the complexes $PtL(nucl)_2Cl_2$ in ppm

Compound	H_2	H_8	H'_1	H'_2	H'_3	H'_4	H'_5
$[Pt(S\text{-}Me\text{-}L\text{-}Cys)(Guo)_2]Cl_2$	—	8.56, 8.35	5.92	4.65	4.41	4.28	3.86

$[Pt(S\text{-}Et\text{-}L\text{-}Cys)(Ino)_2]Cl_2$	8.30 (doublet)	8.98, 8.81	6.12	4.65	4.34	4.34	3.90

OMe)(Ino)Cl[13] where the H_8 proton of inosine opposite to the sulphur atom, was shifted only by 0.28 ppm, while in the *cis*-$Pt(Ino)_2Cl_2$[23] the same proton was shifted by 0.62 ppm.

The same behaviour is also found in the complexes with Guo, $[PtL(nucl)_2]Cl_2$, e.g. two resonances for the H_8 protons (see Table 4). The ^{195}Pt–H coupling satellites are also seen in the spectra of the complexes, although not well enough resolved to allow measurements of the coupling constants.

The ^{13}C NMR spectral data finally, are given in Table 5 and Fig. 1. The chemical shifts of the carbons of the amino acids are shown as doublets and this indicates that the S, N coordination and the two diastereoisomers of the starting complexes are retained also in the complexes $[PtL(nucl)_2]Cl_2$. The chemical shifts of the nucleoside carbon resonances on the other hand, confirm once again the N_7 coordination, in both Ino and Guo (see Table 5). The C_2 and C_4 resonances of the nucleosides are the more sensitive in the different Pt–N_7 bond strength, and are shown up as doublets, like in the ^1H NMR spectra. The two diastereoisomeric forms of the starting complexes would result also in two different isomers in the complexes with the nucleosides. However, the chemical shifts, both in the ^1H NMR and the ^{13}C NMR spectra of the nucleosides due to the two isomers are exactly the same. The only differentiation comes out from the different Pt–N_7 bond strengths of the nucleosides *trans* to sulphur or nitrogen atoms. The suggested structures for these complexes are

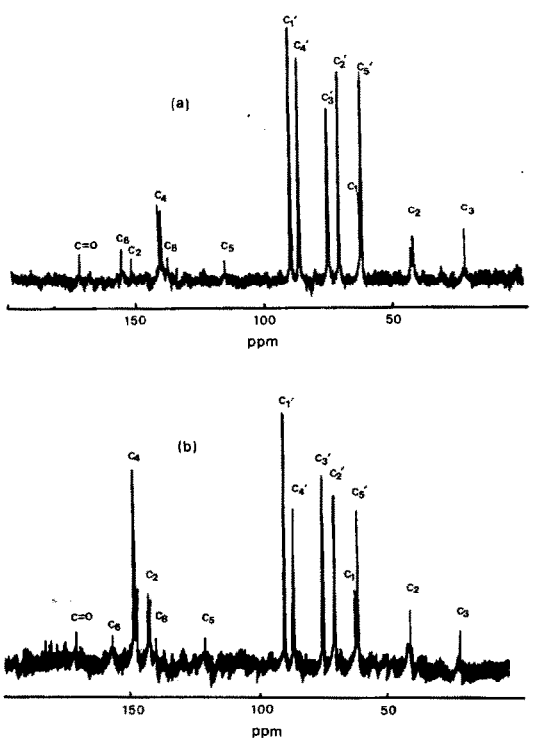

Fig. 1. ^{13}C NMR spectra of the complexes (a) [Pt(S-Me-Cys)$(Guo)_2$]Cl_2 and (b) [Pt(S-Me-Cys)$(Ino)_2$]Cl_2, in D_2O.

EXPERIMENTAL

Materials. S-Ethyl-L-cysteine, S-methyl-L-cysteine and S-benzyl-L-cysteine were purchased from Aldrich Chem. Comp, Fluka A.G. and ICN Pharmaceuticals Inc. A part of S-benzyl-L-cysteine together with S-*p*-nitro-benzyl-L-cysteine, S-trityl-L-cysteine, S-diphenyldimethyl-L-cysteine and S-4',4'-dimethoxyphenyl-methyl-L-cysteine were prepared in our laboratory, according to known methods.[24,25] The nucleosides guanosine and inosine were also from Fluka A.G.

Potassium tetrachloplatinate(II) was from Johnson Matthey and Mallory Ltd., Fluka A.G. and Ventron GmbH.

Methods. (1) The elemental analysis of Pt and Cl were performed in our laboratory, while those of C, H, N, and S in the laboratories of F. Hoffman–La Roche and Co., Basel, Switzerland.

(2) The IR spectra were recorded in a Perkin–Elmer model 283 spectrophotometer, covering the region of 4000–200 cm^{-1} in KBr pellets, Nujol mulls and CaF_2 cells in D_2O solutions.

(3) The ^1H NMR and ^{13}C NMR spectra were recorded using a Varian F.T.80A spectrometer, with TMS as internal standard.

(4) The conductivity measurements were performed in an E365B Conductoscope, Metrohm Ltd., Herisau, Switzerland.

Preparation of the complexes

1. $PtLCl_2$ *type complexes.* (a) In the case of the amino acids, S-Me-L-Cys, S-Et-L-Cys, S-Bzl-L-Cys and S-(*p*-NO_2-Bzl)-L-Cys, soluble in 0.1–0.5 N HCl, the reactions with K_2PtCl_4 were carried out in this solvent, by using equimolar amounts (1 mmol) of each, either at room temperature or in the water bath at 40–50°C for the first two aminoacids or in the

water bath for the other two. The reactions with the first two aminoacids could also be performed in aqueous solutions, in the water bath.

The heating in the water bath at 40–50°C lasted for 4–5 h, whereupon standing at room temperature, yellow crystals of the complexes of Pt(II) with the first two aminoacids were obtained. The other two aminoacids produce yellow powders. Yellow powders are also obtained in the reactions carried out in aqueous solutions, overnight. The yellow crystals or powders are filtered off by suction, washed with small quantities of ice cold water, ethanol and finally with ether. They are first dried in a desiccator at room temperature and then at 110°C under vacuum, until constant weight. The complexes with the first two aminoacids could also be obtained after evaporation of the reaction mixtures until dryness, dissolution of the residue in THF, filtration from the insoluble KCl and precipitation with excess of ether. Yields 70–80%.

(b) In the case of the insoluble S-Dpm-L-Cys, the reaction is carried out in the same solvent (0.1 N HCl) with equimolar amounts of the reactants (1 mmol), by suspending the aminoacid in the solvent and heating in the water bath, at 40–50°C and 3–4 h time. After one day the precipitate is obtained with filtration, using the same procedure as in (a). The reaction is facilitated by using a small excess of K_2PtCl_4 (5–10%). Yield 80%.

(c) In the case of the aminoacids S-Trt-L-Cys and S-Dmb-L-Cys and using the same procedure as in (a), the obtained final products corresponded to the empirical formula $Pt_2L_2Cl_2$, where L = cysteine anion[12] with a platinum content of 58.5%. It seems that the bulky trityl and dimethoxydiphenylmethyl groups hydrolyze after metal complexation with sulphur and this is verified with the TLC identification of the corresponding carbinoles, Trt–OH and Dmb–OH, in the washing liquids of the complexes after filtration.

2. PtL_2Cl_2 *type complexes.* (a) Using equimolar amounts (0.5 mmol) of the $PtLCl_2$ complexes, prepared above, and the corresponding aminoacids (L), in the minimum amount of water or 0.1 HCl and heating in the water bath at 40–50°C for 30 min, in the case of S-Me-L-Cys and S-Et-L-Cys or at 70–80°C for 2–3 h, in the case of the other aminoacids, the solutions become colourless. The complexes are obtained upon evaporating the solutions to dryness, in quantitative yields. They are dried first at room temperature and then at 110°C under vacuum.

(b) The same complexes could also be obtained, starting with K_2PtCl_4 and the corresponding aminoacid (L) in 1:2 molar ratio, in water or 0.1 N HCl solutions upon slight heating (40–70°C) in the water bath. In this case however, it is difficult to isolate pure complexes without KCl, due to their high water solubility. Only in the case with S-Me-L-Cys, where the complex is soluble in DMF, can it be separated from the insoluble form in this solvent, KCl.

Note. In the case of the complexes with the aminoacids, S-Bzl-L-Cys, S-(*p*-NO_2-Bzl)-L-Cys and S-Dmp-L-Cys and upon heating at 70–80°C in the water bath, small amounts of a yellow precipitate is obtained, which is not further soluble in the reaction mixture. This is filtered off, prior to the evaporation of the solutions to dryness. To this insoluble precipitate, which corresponds to the same elemental analysis, an oligomeric or polymeric structure was assigned (Structure **III**).

3. $Pt(L–H^+)_2$ *type complexes.* (a) These complexes were obtained by reacting the PtL_2Cl_2 type complexes with freshly prepared Ag_2O in (1:1.95) molar ratios, in aqueous solutions. The Ag_2O is prepared with titration of 0.1 N $AgNO_3$ solutions

Table 5 (*continued*).

87.6	70.4	74.2	85.6	61.4	—	—	—	—	—	DMSO-d_6

with 0.1 N NaOH, filtration and drying of the precipitate at 110°C under vacuum, in the dark. After stirring the PtL_2Cl_2 and Ag_2O mixtures for 30 min at room temperature, in the dark, the AgCl precipitate formed, is filtered off and the resulting solution is evaporated to dryness. The complex is then obtained by dissolving the residue in a small amount of MeOH or EtOH, filtering and adding excess of ether. After filtration and drying at 110°C under vacuum, the yields of the hygroscopic products, were of the order of 50%.

(b) The same compounds can also be obtained upon neutralization of 10^{-3} M solution of the PtL_2Cl_2 complexes with 0.1 N NaOH and evaporation to dryness, or from the starting materials (K_2PtCl_4 and L) in 1 : 2 molar ratios and pH = 9.5. However, the complexes obtained in these ways, were not 100% pure, containing amounts of KCl or NaCl salts.

4. $[PtL(nucl)_2]Cl_2$ *type complexes.* These complexes were prepared from the $PtLCl_2$ complexes and the corresponding nucleosides (inosine or guanosine) in 1 : 2 molar ratios, in aqueous solutions. The solutions were stirred with heating at 50–60°C over night and they became colourless. After evaporation to a small volume of the resulting colourless solutions, the complexes were precipitated by adding an excess of acetone. They were then filtered and dried first at room temperature and then at 110°C in vacuum, in the presence of P_2O_5. The yields were quantitative.

5. *Deuterated complexes and ligands.* The deuterated complexes were prepared according to the above described corresponding method in D_2O, instead of H_2O solutions, or by equilibrating in an atmosphere saturated with D_2O, in a desiccator.

The ligands were dissolved in D_2O and reprecipitated with excess of acetone.

(*Received* 8 *August* 1984; *accepted after revision* 18 *December* 1984)

Abstract—The thermal decomposition of triphenyltin hydroxide in the temperature range 25–400°C has been studied. The decomposition products formed at each stage have been isolated and characterised. A decomposition scheme involving a reductive-elimination reaction is proposed. The proportions of this reaction and the accompanying reaction are dependent on the mode of heating.

The literature contains very few reports on the thermal decomposition of organotin(IV) compounds. The interpretation of pyrolysis reactions involved in the decomposition of a series of organotin(IV) adducts and carbohydrate derivatives has been shown to be difficult[1] because of the lack of information on the thermal decomposition of simple organotin(IV) compounds. This is particularly true of organotin–oxygen-containing derivatives and for this reason we have investigated the thermal behaviour of a number of relatively simple oxygen-containing compounds by simultaneous thermogravimetry and differential thermal analysis (TG/DTA).

Triphenyltin hydroxide was chosen as the first example for a detailed thermal analytical study including the identification of the product(s) formed at each stage of the decomposition by the use of appropriate techniques including IR, UV and ^{119}Sn Mössbauer spectroscopy, thin layer chromatography, X-ray powder diffraction data and elemental analyses.

EXPERIMENTAL

The thermal decompositions were carried out under a N_2 atmosphere in a vertical electrically heated furnace (temperature control ±5°C). The sample was contained in a small pyrex dish and a glass probe, which could be cooled if necessary, was inserted into the furnace such that the bottom tip of the probe was about 5 mm above the sample. The slow stream of N_2 gas issuing from the furnace was passed through a trap cooled in liquid nitrogen to collect any volatile products. The sample was heated stepwise at 85, 310 and 400°C and maintained at each temperature for 2.5 h. After each heating stage the furnace was cooled to room temperature, the volatile product on the probe was collected and a sample of the non-volatile product removed for analysis.

The TG/DTA data were recorded using a Stanton Redcroft STA 780 simultaneous thermal analyser, IR data, as KBr discs, on a Perkin–Elmer 599 IR Spectrophotometer and UV spectra, in absolute ethanol, using a Perkin–Elmer 402 UV/visible Spectrophotometer. ^{119}Sn Mössbauer data were recorded at 78 K using a $BaSnO_3$ source as previously described.[2]

RESULTS AND DISCUSSION

The TG/DTA data show that Ph_3SnOH decomposes in three stages as detailed in Table 1, and the decomposition products identified are listed in Table 2.

From the percentage weight loss data, the first decomposition corresponds to the reaction

$$2Ph_3SnOH \xrightarrow{75°C} Ph_3SnOSnPh_3 + H_2O \quad (1)$$

and the second to

$$nPh_3SnOSnPh_3 \xrightarrow{290°C} (Ph_2SnO)_n + nPh_4Sn. \quad (2)$$

* Author to whom correspondence should be addressed.

Table 1.

Decomposition reaction	Temperature (°C)	Weight loss (%)	DTA feature
1	75	2.5	Endothermic
2	290	59.5	Endothermic
3	362	16.5	Endothermic

However, no simple decomposition reaction can be inferred from the percentage weight loss recorded in the third decomposition. In order to determine the products formed in the third decomposition, and to confirm the products postulated in the reactions (1) and (2), the pyrolysis of approximately 0.2 g Ph_3SnOH was carried out stepwise at temperatures slightly in excess of those recorded in Table 1 with product isolation and characterisation at each stage.

The IR and C, H analysis of (**I**) and the TG data are consistent with reaction (1) being the first decomposition step. The O–H bands at 3610 and 895 cm^{-1} in the IR spectrum of Ph_3SnOH are absent in (**I**); the percentage weight loss of 2.5 is close to that required (2.45). Characterisation of the non-volatile product (**II**) by IR and C, H analysis, and of the volatile product (**III**) by IR and UV spectroscopy identified them as $(Ph_2SnO)_n$ and Ph_4Sn respectively. For reaction (2) the percentage weight loss required is 59.3, and that found is 59.5.

The third decomposition reaction gives three final products, a non-volatile residue (**IV**), whose IR spectrum shows the absence of any organic species, and two volatile fractions (**V**) and (**VI**) of different volatility. Component (**VI**) was identified as Ph_4Sn from its IR spectrum. The IR spectrum of (**V**) was similar to that of (**VI**), but with one extra band at 749 cm^{-1}. The absorption band λ_{max} 250 nm in the UV spectrum of (**V**) suggested the presence of Ph–Ph. A TLC study using a 100:50:5 mixture of *n*-butanol:water:acetic acid[3,4] showed that (**V**) consisted of Ph–Ph with a small amount of Ph_4Sn, whereas (**VI**) consisted mostly of Ph_4Sn with a small amount of Ph–Ph (Ph–Ph, R_f 1.00; Ph_4Sn, R_f 0.00).

^{119}Sn Mössbauer spectroscopy on the non-volatile residue (**IV**) gave the following data, a Sn(II) doublet ($\delta = 2.76 \pm 0.02$ mm s^{-1}, $\Delta = 1.41 \pm 0.02$ mm s^{-1}), assignable to SnO, and a Sn(IV) singlet ($\delta = 0.12 \pm 0.01$ mm s^{-1}) assignable to SnO_2.

Table 2.

Temperature (°C)	Non-volatile product	Volatile product
85	$(Ph_3Sn)_2O$ (**I**)	H_2O
310	$(Ph_2SnO)_n$ (**II**)	Ph_4Sn (**III**)
400	Tin oxide (**IV**)	Ph–Ph*: Ph_4Sn (**V**)
		Ph–Ph: Ph_4Sn* (**VI**)

* Major component of (**V**) > (**VI**).

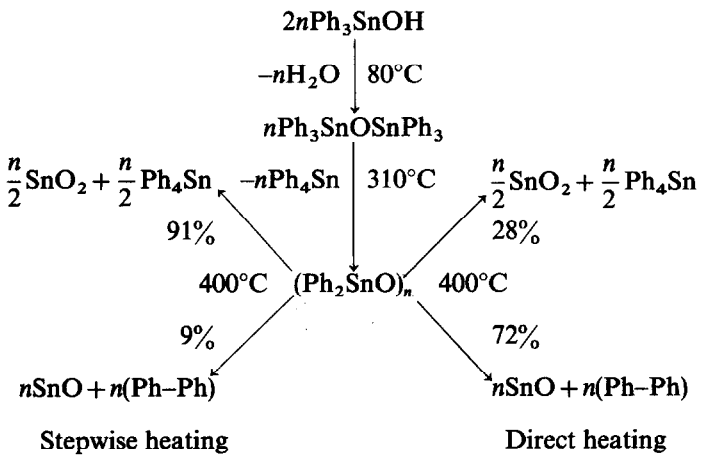

Fig. 1.

The volumetric determination of Sn(II) in the residue using ceric sulphate showed that the Sn(II) : Sn(IV) ratio was approximately 1 : 5.

When a sample of Ph_3SnOH was heated directly to 400°C more Ph–Ph and SnO were produced than when it was heated stepwise to the same temperature. By titrimetry the Sn(II) : Sn(IV) ratio in the residue in this case was approximately 5 : 1.

Thus for the third decomposition reaction, the contribution of the reductive elimination reaction

$$(Ph_2SnO)_n \xrightarrow{400°C} n(Ph\text{–}Ph) + SnO$$

to the overall decomposition of $(Ph_2SnO)_n$ when Ph_3SnOH is heated stepwise to 400°C is less than when it is heated directly to the same temperature.

The results show that the thermal decomposition of Ph_3SnOH by the two modes of heating are as shown in Fig. 1.

The results clearly show that the products of the thermal decomposition of even a simple compound such as Ph_3SnOH do depend on the exact conditions of pyrolysis.

Acknowledgement—The authors thank the International Tin Research Institute for the generous gift of organotin(IV) compounds.

C^3-BONDED HETERO-β-DIKETONATES OF PALLADIUM(II)

G. C. DASH, R. C. MISHRA, D. PANDA and B. K. MOHAPATRA*
Department of Chemistry, B.J.B. College, Bhubaneswar-14, India

(*Received* 24 *July* 1984; *accepted* 4 *January* 1985)

Abstract—Reactions of PdL_2 complexes, where LH = benzoylacetone, dibenzoyl methane, or dipivaloyl methane, with pyridine and neat β-diketones (L^1H trifluoroacetylacetone, hexafluoroacetylacetone, thenoyltrifluoroacetone and pivaloyltrifluoroacetone) in toluene resulted in the formation of central carbon (C^3) bonded hetero-β-diketonate complexes of the formula [Pd(L)(C^3-L')py]. These were characterized by microanalyses, IR and ^1H NMR spectral data.

As a part of the general programme of "studies on the linkage modes of β-diketones in transition metal complexes" the chelation of the terminal carbon (C^1) bonded acetylacetonato complex [Pd(C^1-acac)Cl · bpy] to form bi- and tri-nuclear complexes with another metal ion involving the bridging of the terminal carbon bonded acetylacetone dianion has been reported by us.[1] The ionic C^3-bonded acetylacetonato complex K[PtCl(acac)$_2$] reacts[2] with several divalent metal ions to form neutral complexes of the type [MPtCl(acac)$_2$]. On the otherhand, the neutral palladium(II) [Pd(acac)(C^3-acac)(γ-pic)][3] contains the central carbon bonded acetylacetone molecule in the keto form. Such a compound can have ketonic coordination with other metal ions or form O,O'-chelate if the proton at the C^3-atom can be abstracted. Reaction of this compound with divalent metal halides and acetates results in the cleavage of the Pd–C bond, but reaction with [Pd(hfac)bpy]Hfac produces[4] a mixed β-diketonate like [Pd(acac)(bpy)]Hfac and a central carbon bonded β-diketonato complex. Reaction of similar compounds [Pd(acac)(C^3-acac)py] and [Pt(acac)(C^3-acac)py] with substitution labile compounds like Pd(tfac)$_2$, Pd(hfac)$_2$ resulted[5] in the formation of central carbon bonded hetero β-diketonate complexes like [M(acac)(C^3-X)py] where M is Pd(II) or Pt(II) and XH is trifluoro- or hexafluoroacetylacetone. Such compounds are also produced by reaction with neat β-diketones. It has also been observed that the Pt–C bond of [Pt(acac)(C^3-acac)(PPh_3)] is cleaved[6] on treatment with either an organic halide or $NaBH_4$ (in the presence of PPh_3). The results suggested that the C^3-acac ligand is more labile than the chelate acac ligand towards electrophilic attack. Yamamoto *et al.* studied the reactions of complexes [M(acac)(C^3-acac)(PPh_3)], where M = Pd(II) or Pt(II), with a series of β-diketones and found that some β-diketones replaced the chelated acac ligand selectively, leaving the C^3-acac ligand intact. Thus three kinds of products, i.e. [Pt(acac)(C^3-dik)(PPh_3)], [Pt(dik)(C^3-dik)(PPh_3)] and [Pt(dik)(C^3-acac)(PPh_3)] were obtained depending on the nature of the β-diketones employed. To study further about these selective replacement reactions, this communication describes the reaction of Pd(bzac)$_2$, Pd(dbm)$_2$ and Pd(dpm)$_2$ with a number of halogen substituted β-diketones to produce C^3-bonded hetero β-diketonate complexes of palladium(II).

EXPERIMENTAL

To warm aqueous solution of potassium tetrachloro palladate(II) methanol solutions of the respective β-diketones, i.e. benzoylacetone, dibenzoylmethane and dipivaloylmethane in 1 : 2 proportion were added, followed by dropwise addition of aqueous sodium acetate solution. The solution was stirred for 30 min and the precipitate filtered, washed with ethanol followed by ether and dried in vacuum.

PdL_2 (1 mmol) was dissolved in 3 cm^3 dichloromethane, 5 cm^3 of dichloromethane solutions of L'H (more than 3 mmol) and pyridine (1 mmol) were added to it, followed by 10 cm^3 of toluene. The resulting orange–yellow solutions were stirred magnetically for 3 h at 40°C in a closed vessel. Volume of the solution was reduced to 3 cm^3 by a

RESULTS AND DISCUSSION

Complexes reported have the general composition [Pd(L)(L')py] where LH is benzoylacetone, dibenzoylmethane or dipivaloylmethane and L'H is trifluoroacetyetone, hexafluoroacetylacetone, thenoyltrifluoroacetone or pivaloyltrifluoroacetone. These are yellow–brown crystalline solids. Acetone solution of the complexes have low molar conductance values indicating non-electrolytic nature.

The IR spectra of the compounds reveals the presence of two types of carbonyl frequencies in two different regions. Comparison of these with those of PdL_2 and the C^3-bonded β-diketonate complexes of palladium(II)[8–10] and platinum(II) [11–13] made the assignments easier. In all the compounds three bands were observed around 1580–1590, 1525–1545, and 1500–1520 cm^{-1} regions attributable to ν(C=O) + ν(C–C) modes of the O,O'-chelated β-diketones (L). The other set of bands were observed around 1715–1730 and 1660 cm^{-1} regions assignable to the ν(C=O) modes of the central carbon (C^3) bonded β-diketones (L'). Hence the infrared spectra show the presence of the β-diketone (L) in the O,O'-chelated form and the fluorine substituted β-diketones (L') in the central carbon (C^3) bonded form. The characteristic band of pyridine is observed in the 1610–1618 cm^{-1} region. The other important band due to pyridine ring vibrations undergoes a marked shift and is observed at 635 cm^{-1}. In the far IR region ν(Pd–O), ν(Pd–C) and ν(Pd–N) are observed at 470, 500 and 330 cm^{-1} confirming the bonding of the respective ligand donor atoms.

The presence of chelated β-diketone (L) and central carbon bonded β-diketone (L') has been corroborated by ^1H NMR spectra. Two types of CH proton signals of the β-diketones have been observed (Table 2). One is ascribed to the methine proton signal of the oxygen bonded β-diketone (L) and the other to the methine proton signals of the central carbon bonded β-diketones (L'). These assignments have been made by comparison with the methine proton signals of the chelated β-diketones (L) and the central carbon bonded β-diketones (L') in earlier reported[9–11] compounds.

Methine protons of pyridine resonate in the 7–8.5 ppm region. Factors governing such selectivity of the β-diketones to be present in the O,O'-chelated or carbon bonded form is the keto-enol character of these compounds. A great difference in the keto-enol character of each β-diketone was observed and the diketones may be divided into two categories. One is a highly keto predominant type such as Htfac, Hhfac, Htta, Hpta and the other is rich in enol form such as Hbzac, Hdbm, or Hdpm. Keto-predominant β-diketones replace the chelated β-diketones either by a direct attack of the carbanion (dik^-) to the metal centre or by the process involving the ionic intermediate in which the β-diketonate anion is coordinated to the complex in the outer sphere.[14]

(*Received* 15 *March* 1984; *accepted after revision* 4 *January* 1985)

Abstract—The reactions of the Schiff-base N,N-ethylenebis-(isonitrosoacetylacetoneimine), (H_2L), with Ni(II) acetate led to the formation of the yellow–orange complex LNi (**I**) in water and the red complex LNi (**II**) in ethanol. Both oximato groups in **I** are coordinated to the metal through the oximino-oxygen whereas in **II** one group is similarly coordinated while the other is coordinated through the oximino-nitrogen. Complex **I** was converted to complex **II** by boiling in chloroform and the conversion was reversed by reacting complex **II** with either piperidine or ethylenediamine. H_2L neutralized by ammonia reacted with Ni(II) chloride (1 : 1) and the complex formed was characterized as the red square planar bis-(4-iminopentane-2,3-dione 3-oximato)Ni(II); (**III**). This *trans* complex reacted with piperidine (1 : 4) to produce its *cis* configuration (**IV**). Complex **III** reacted with ethylenediamine (2 : 1) and 1,3-diaminopropane (1 : 1) to produce complexes **II** and **V** respectively of the identical structure. Attempted similar reaction (1 : 1) with either 1,4-diaminobutane or 1,5-diaminopentane led to the formation of the binuclear complexes **VI** and **VII** in which two molecules of complex **III** are linked together by $-(CH_2)_4-$ and $-(CH_2)_5-$ moieties respectively. The suggested structures of the square planar Ni(II) complexes are based on analytical, spectral and magnetic moment evidence.

Recently the versatile chemistry of square planar Ni(II) complexes was subjected to extensive studies based on two main aspects. The first one deals with the geometrical interconversions of the metal complexes of the Schiff-bases N-substituted salicylaldiminates[1] through the effect of heat or reactions with organic solvents. The second aspect concentrates on linking two of the square planar bis(α-dioximato) nickel(II) complexes by linking reagents to produce binuclear complexes whereby the metal ions are not in one plane.[2] These observations prompted us to pursue our interest in the chemistry of square planar complexes of the metal ion[3,4] by investigating the possible interconversions and linking in the Ni(II) complexes of the Schiff-base N,N′ - ethylenebis - (isonitrosoacetylacetoneimine) and the related ligand 4-iminopentane-2,3-dione 3-oxime taking into consideration the above mentioned two points in addition to the interesting isomeric linkage behaviour of the latter ligand.[5] This phenomenon had resulted from the ability of the oximato group to coordinate through either the oximino-oxygen or the oximino-nitrogen forming thereby six- and five-membered chelate rings respectively.[6]

EXPERIMENTAL

Reagent grade chemicals were used. The ligands N,N′ - ethylenebis - (isonitrosoacetylacetaneimine)[3] and authentic sample of bis-(4-iminopentane-2-3-dione 3-oximato)nickel(II)[7] were prepared by published methods. The IR spectra of the metal complexes were measured as KBr pellets using a Perkin–Elmer 683 spectrophotometer. The electronic spectra were obtained using a Pye–Unicam S.P. 8000 spectrophotometer. ^1H NMR spectra were obtained in $CDCl_3$ solution using a Varian EM 390 spectrometer at 25°C. Chemical shifts are reported in

ppm relative to internal tetramethylsilane (τ = 10.00). Magnetic susceptibilities were measured at 25°C by the Gouy method. Mercuric tetrathiocyanotocobaltate(II) was used as the magnetic susceptibility standard. Diamagnetic corrections were effected by employing Pascal's constants.[8] The magnetic moments were calculated from the equation $\mu_{eff} = 2.84\sqrt{\chi_M^{Corr.} \cdot T}$. Carbon, hydrogen and nitrogen analyses were determined at the analytical unit of our department. A standard method was used for the determination of the metal ion. The metal complexes were dried under vacuum over phosphorus pentoxide.

Preparation of the Ni(II) *complexes*

1. *Reaction of the ligand* (H_2L) *with* $Ni(OAc)_2 \cdot 6H_2O$. (a) Complex **I**. The filtered aqueous solution (50 cm^3) of the metal acetate (0.0071 mol) was added, while stirring, to a suspension of the equimolar concentration of the powdered ligand in water (100 cm^3). The warmed reaction mixture was stirred for 3 h, filtered, and washed several times with water. The same complex was obtained when the molar ratio of the metal acetate to the ligand was varied from 1 : 1 up to 5 : 1.

(b) Complex **II**. This red complex was prepared as described in (a) using absolute ethanol as a solvent instead of water. The same complex was obtained on changing the molar ratio of the metal acetate to ligand from 1 : 1 up to 5 : 1.

2. *Reaction of complex* **I** *with chloroform to produce complex* **II**. A suspension of the powdered complex **I** (0.003 mol) in chloroform (100 cm^3) was boiled for 2 h whereby the solvent turned red. The unreacted complex **I** (yellow–orange) was filtered off and complex **II** was obtained from the filtrate by evaporating the solvent.

3. *Reaction of complex* **II** *with piperidine or ethylenediamine to produce complex* **I**. This reaction was carried out by refluxing the chloroform solution (100 cm^3) with either piperidine (1 : 4 molar ratio) or ethylenediamine (1 : 1 molar ratio) for 1 h. The precipitated yellow–orange complex was filtered off and washed with chloroform.

4. *Reaction of the ligand* (H_2L) *with* Ni(II) *ion in the presence of ethylenediamine.* This reaction was carried out in absolute ethanol using the molar ratios for NiX_2 (0.0071 mol; X = chloride, nitrate or acetate) ethylenediamine and the ligand of 2 : 4 : 1, 2 : 1 : 1, 4 : 2 : 1 and 1 : 2 : 1. The ethylenediamine was added to the ethanol solution (100 cm^3) of the metal ion and the resulting amine complex was added to the warmed suspension of the ligand in ethanol (100 cm^3). The reaction solution was stirred for 2 h and the precipitated yellow material was filtered off and washed with ethanol. The crude product was boiled in water (50 cm^3) for 1 h in order to separate complex **I** from the water soluble organic amine salts formed in the reaction. The yellow complex **I** was filtered off, washed with water and dried.

5. *Reaction of the neutralized ligand with* $NiCl_2 \cdot 6H_2O$. The powdered suspension of the ligand (0.014 mol) in water (150 cm^3) was neutralized by dil. ammonia to pH 9 and added to the aqueous solution (50 cm^3) of the equimolar concentration of the metal chloride. The reaction solution was warmed for 3 h. The precipitated complex was filtered off, washed with ethanol and crystallized from chloroform (complex **III**).

6. *Reactions of complex* **III**. (a) With piperidine. The chloroform solution (50 cm^3) of the base (0.028 mol) was added to the red chloroform solution (100 cm^3) of the Ni(II) complex (0.007 mol) and the resulting reaction solution was refluxed for 5 h. A dark brown precipitate was formed on cooling which was filtered off, washed with benzene and dried (complex **IV**).

(b) With ethylenediamine. The chloroform solution (30 cm^3) of the base was added to that of the Ni(II) complex (0.014 mol) in the same solvent (100 cm^3). The molar ratios of the base to Ni(II) complex were either 1 : 1, 2 : 1, 3 : 1 or 4 : 1. The reaction solution was refluxed for 2 h to precipitate the yellow complex **I**. This was filtered off, washed with benzene and dried. The orange–red complex **II** was formed when the molar ratio of the base was lower than that of the Ni(II) complex (1 : 2). Mixtures of complexes **I** and **II** were obtained from the other molar ratios with shorter reaction times.

(c) With either 1,3-diaminopropane, 1,4-diaminobutane or 1,5-diaminopentane (1 : 1 molar ratio). These reactions were carried out as described in (b). The reaction solution was boiled for 2 h in the case of 1,3-diaminopropane to precipitate complex **V**. The formation of complexes **VI** and **VII** from the reaction with 1,4-diaminobutane and 1,5-diaminopentane respectively, had required boiling the reaction solutions for 12 h. The unreacted complex **III** was precipitated from shorter reaction times.

RESULTS AND DISCUSSION

The reactions of the ligand N,N′-ethylenebis-(isonitrosoacetylacetoneimine) with Ni(II) ion and the reactivity of the formed complexes are schematically represented in Fig. 1. Thus, the analytical (Table 1) and spectral data (Tables 2 and 3) are compatible with regarding the reaction of the ligand with Ni(II) acetate in water to produce the yellow–orange complex **I** which is structurally

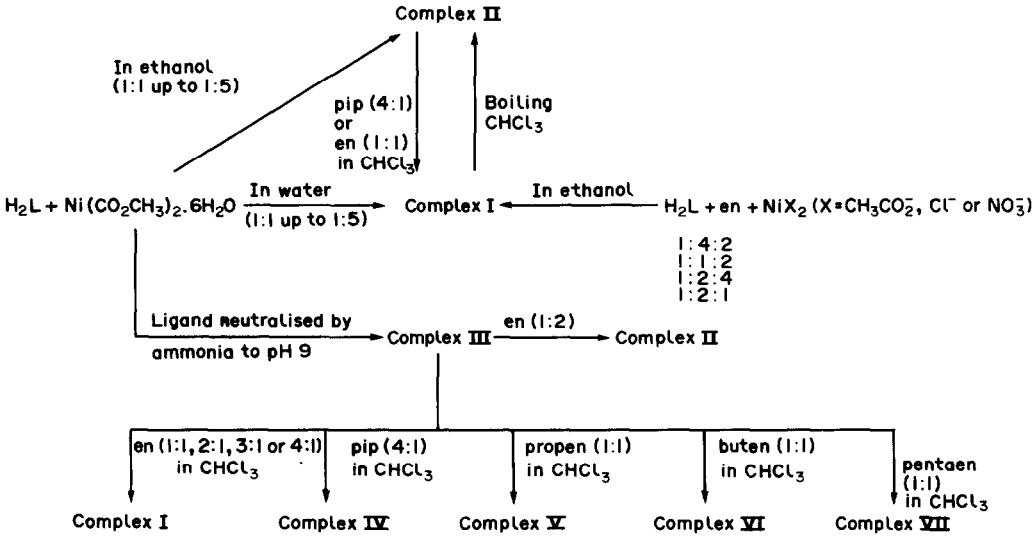

Fig. 1. Schematic representation for the reactions of the ligand (H_2L) with Ni(II) and the reactivity of the metal complexes (en = ethylenediamine, propen = 1,3-diaminopropane, buten = 1,4-diaminobutane, pentaen = 1,5-diaminopentane and pip = piperidine).

different from the red complex **II**, obtained when the same reaction was carried out in absolute ethanol (Fig. 2), although they have the same analytical data.

The IR spectrum of complex **I** revealed the presence of a splitting ν(C=O) in the 1670–1690 cm^{-1} region. This band is located at comparable frequency to that observed from the ligand itself which indicated that the carbonyl group is not coordinated to the metal atom. Furthermore, this region for ν(C=O) is associated[9] with the six-membered chelate ring in the Ni(II) complexes of vicinal oxime-imine ligands which implied, in turn, coordination of the oxime group through the oximino-oxygen. Since there are no other vibrational frequencies in this region, as well as in the frequency region (1660–1630 cm^{-1}) ascribed to the five-membered chelate ring in the vicinal oxime-imine Ni(II) complexes,[9] it is suggested therefore that

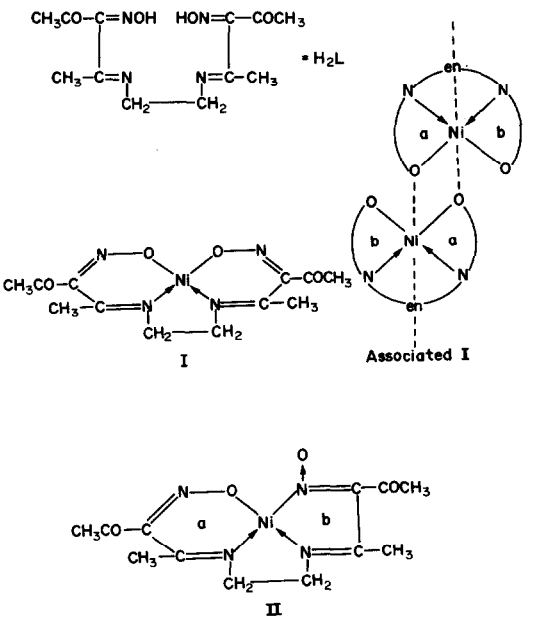

Fig. 2. Suggested formulation for complexes I (and its associated form) and II.

both chelate rings in complex I are six-membered. The 1153 and 1145 cm^{-1} bands in the IR spectrum of this complex are assigned to ν(N–O) of the oxygen-bonded oxime group (shifted from the 1060–975 cm^{-1} bands of the ν(N–O) in the hydrogen bonded –NOH group[3] to the imino-nitrogen of the ligand). These bands are located at lower frequency than the 1200 cm^{-1} band of the oximino-nitrogen coordination in the Ni(II) complex of pyridine-2-aldehyde oxime and could be compared with those reported for the ν(N–O) in the oximino-oxygen coordination in the mononitrosation product of N,N′-ethylenebis-(acetylacetoneimine)Ni(II) (ν(N–O) 1171 cm^{-1})[11] and the Cu(II) complex[12] (ν(N–O) 1143 cm^{-1}); see Fig. 3. for complexes **B** and **C**. The structure of the Ni(II) complex was investigated by isotopic labelling of the oxygen and nitrogen atoms of the oximato group in isomers **A** and **B** whereas that of the Cu(II) complex was determined from X-ray structural data.

Coordination by the oximino-oxygen would lead to more single bond character for the N–O bond and therefore lower the frequency of the stretching vibration.[13] This splitting of the ν(N–O) band to two bands (separated by 8 cm^{-1}) is compatible with the non-equivalence of the two six-membered chelate rings in the square planar structure of the complex.

This behaviour could be explained by the possible weak molecular association in the solid state as a result of side coordination of the oxygen of chelate ring (a) to the metal ion of adjacent molecules. This bridging behaviour is expected to increase the constraint on the N–O bond in chelate ring (a) relative to that in chelate ring (b) and should produce ν(N–O) with higher frequency [1153 cm^{-1} for chelate ring (a)] in a similar manner to

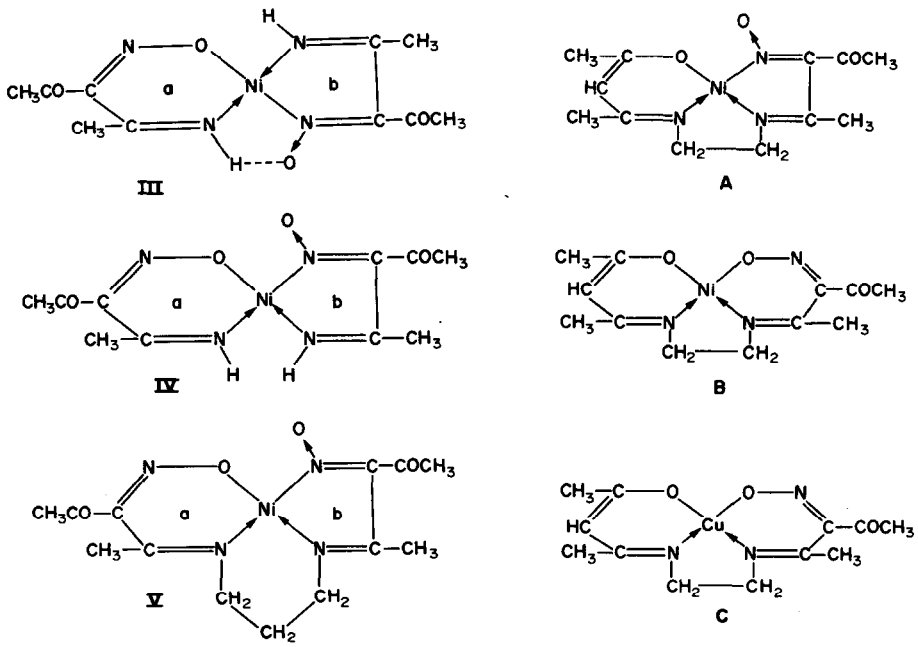

Fig. 3. Suggested formulations for complexes III, IV and V and their relation to the formulated mononitrosation products (complexes A, B and C) of the Ni(II) and Cu(II) complexes of N,N′-ethylenebis-(acetylacetoneimine).

that reported[14] for the ν(C–O) with the oxygen bridging coordination in the adducts of either N,N′-ethylenebis-(salicylideneimine)Ni(II) or N,N′-ethylenebis-(acetylacetoneimine)Ni(II) with transition and non-transition metal ions.

The insolubility of complex **I** in organic solvents (ethanol, chloroform, methylenedichloride) is consistent with the molecular association suggested in this case. This formulation is compatible with the formation of complex **II** from complex **I** by refluxing the chloroform suspension of the latter complex. Under such conditions, molecular dissociation of complex **I** on dissolution in chloroform should produce a separated reactive molecule, allowing thereby for the rearrangement of the coordination mode of the oximato group of chelate ring (a) from the oxygen cordination of complex **I** to the isomeric nitrogen coordination in complex **II** (see Fig. 2). Two distinct ν(C=O) vibrations were observed from complex **II** at the higher (1680 cm^{-1}) and lower (1640 cm^{-1}) regions. The higher frequency vibration is assigned[9] to the ν(C=O) in the six-membered chelate ring (a) and the lower frequency vibration is ascribed to ν(C=O) in the five-membered chelate ring (b) (see Fig. 2). This implied coordination for the oximato group through the oximino-oxygen and the oximino-nitrogen in chelate rings (a) and (b) respectively. Consequently, those bands at 1127 and 1188 cm^{-1} in complex **II** which replaced the ν(N–O) band in complex **I**, are associated with the ν(N–O) in chelate rings (a) and (b) of the former complex. Since the N–O bond of chelate (b) (N-coordination) is expected to have more double bond character than the corresponding bond for chelate ring (a) (O-coordination) it is, therefore, suggested that the higher frequency band (1188 cm^{-1}) is associated with ν(N–O) of oximino-nitrogen coordination of chelate ring (b) and the lower frequency band (1127 cm^{-1}) is attributed to ν(N–O) of the oximino-oxygen coordination in chelate ring (a).

Complex **II** (soluble in chloroform) was converted to complex **I** (insoluble in chloroform) through its reaction with piperidine or ethylenediamine, Fig. 1. This reaction involves the change in the coordination mode of the oximato group in chelate ring (b) of complex **II** from the oximino-nitrogen to oximino-oxygen followed by molecular association of the formed complex to produce the associated form of complex **I**. A process of this type should involve the dissociation of the Ni–N bond (oximato-nitrogen) of chelate ring (b), in the presence of piperidine or ethylenediamine, followed by charge redistribution in the oximato group to allow for the coordination through the oximino-oxygen. The formation of complex **I** in this reaction, is related to the suggested weak molecular association as a stabilizing factor.

Complex **II** was also prepared from the reaction of the ligand with Ni(II) acetate (1 : 1 up to 1 : 5 molar ratios) in ethanol. Under this condition a clear red reaction solution was obtained before the precipitation of complex **II** whereas the yellow complex **I** was formed from the suspension of the ligand in water. The formation of either complexes is thus related to the dissociation of the dimeric ligand in the solvent as well as to the hydrolyses of the monomeric ligand itself to isonitrosoacetylacetone and ethylenediamine in a similar manner to that suggested[15] for N,N′-ethylenebis-(acetylacetoneimine). In order to investigate this and other possible template reactions, several reactions were carried out, in ethanol, for the ligand with NiX_2 (X = acetate, chloride or nitrate) in the presence of ethylenediamine; see Fig. 1 for molar ratios. These reactions led to the formation of complex **I** instead of complex **II** which is formed in the absence of ethylenediamine. The formation of the latter complex is explained by either the shift of the dissociation equilibrium by the presence of the diamine or the reaction of the diamine with the complex **II** to form complex **I**.

The reaction of the hydrolysed ligand (by ammonia to pH 9) with Ni(II) chloride produced a red complex which was characterized by analytical and spectral evidence as the previously reported[3] square planar bis-(4-iminopentane-2,3-dione 3-oximato)Ni(II), complex **III** (Fig. 3). This complex comprises chelate rings (a) and (b) of complex **II** with the oximato group in the *trans* position rather than the *cis* position of complex **II**. The reaction of the red complex **III** with piperidine (1 : 4 molar ratio) led to the formation of a dark brown complex **IV**. These two complexes have the same analytical data. The IR spectrum of the latter complex is identical with that of complex **III** except that a new band appeared at 1232 cm^{-1} in addition to the weakened vibration at 1202 cm^{-1} which was assigned[11] to the coupled ν(N–O). This spectral feature is reproducible after crystallization from boiling chloroform in which the complex is sparingly soluble in contrast with the soluble complex **III**. Complex **IV** is formulated as the *cis* structure of the *trans* complex **III** and the band at 1232 cm^{-1} is assigned to the pure ν(N–O) of the oximino-nitrogen coordination in chelate ring (b). It is of interest to note that the coupled ν(N–O) band at 1202 cm^{-1} of complex **III** was broad which is not the case in complex **IV**. It could be safely assumed, therefore, that the band at 1202 cm^{-1} in the case of complex **IV** is associated with the pure ν(N–O) of the oximino-oxygen coordination of chelate ring (a) in complex **IV**.

The visible spectra of complexes **I**, **II** and **IV** are similar to that of complex **III**, which is known to be square planar,[5] and other square planar Ni(II)

complexes[6] (Table 3). Furthermore, these complexes are spin-paired which is additional evidence for the square planar structure. It is assumed therefore that 180° rotation of either chelate rings (a) or (b) of complex **III** to the fixed position of the other one produced the *cis* complex **IV**. The action of piperidine in this process should involve (i) breaking of the hydrogen bonding between the two chelate rings and (ii) dissociation of one of the coordinate bonds between the metal and the imino-nitrogen, in order to allow for the free rotation of one of the chelate rings to the position of the other one. Reaction of piperidine with the metal in the axial position, as an intermediate step, is less probable.[16] The location of ν(N–H) is identical in both complexes **III** and **IV** which implied that the hydrogen bonding between chelate rings (a) and (b) is weak and therefore had insignificant effect on the ν(N–H). However, this weak hydrogen bonding had observable influence on the ν(N–O) of the chelate ring (b) to the extent that the ν(N–O) of both chelate rings were coupled in complex **III** and the removal of the hydrogen bonding had separated the ν(N–O) vibrations of the oximino-nitrogen from the oximino-oxygen. The locations of ν(C=O), ν(C=N) and ν(Ni–N) are identical in complexes **III** and **IV** as expected since the 180° rotation of one of the chelate rings does not involve them. The reaction of piperidine with complex **III**, that led to the formation of complex **IV**, produced no change when attempted with bis-(dimethyl glyoximato)Ni(II) of the established[17,18] hydrogen bonding [ν(O–H ... O) at 2300 cm^{-1}]. The stability of the latter complex in the presence of piperidine appears to be compatible with the known square planar structure of this complex with the added stability of the hydrogen bonding and the layer structure of the complex.[18]

The conversion of the *trans* complex **III** to *cis* complex **IV** as well as the suggested coordination modes in chelate rings (a) and (b) of complexes **I** and **II** are substantiated from the reaction of complex **III** with aliphatic diamines. These reactions are based on the following factors: (i) The conversions of complexes **II** to **I** and **III** to **IV** were effected through the reaction of complexes **II** and **III** with the basic nitrogen of piperidine, (ii) The reactions of ethylenediamine with complex **II** did not lead to condensation with the carbonyl group of the chelate rings in the complex but produced, instead, a change in the coordination mode of the oximato group (from the oximino-oxygen to the oximino-nitrogen) in one of the chelate rings, and (iii) The mode of coordination of the oximato groups in chelate rings (a) and (b) of complex **III** are identical with those suggested for complex **II** and therefore transamination of the latter complex with ethylenediamine should provide direct evidence for its suggested structure as well as for the role of the basic nitrogen in converting complex **III** to complex **IV** before allowing for the transamination reaction.[16] Thus, the 1:2 molar ratio reaction of ethylenediamine with complex **III** led to the formation of complex **II** which was characterized by analytical and spectral data and compared with complex **II** prepared from the reaction of Ni(II) acetate with the ligand N,N′-ethylenebis-(isonitrosoacetylacetoneimine) in ethanol. The formation of this complex could only take place through satisfying the requirements of factor (iii) and provided, thereby, a conclusive evidence for the structure of complex **II** (and indirectly complex **I**) in addition to clarifying the role of basic nitrogen of ethylenediamine in converting complex **III** to complex **IV** (in a similar manner to the conversion produced by piperidine) which is the preceding step to the transamination reaction. Moreover, the 1:1, 2:1, 3:1 and 4:1 molar ratio reactions of ethylenediamine with complex **III** led to the formation of a mixture of complexes **I** and **II** after a reaction time of 1 h. The IR spectrum of the product was a superimposition of the IR spectra of both complexes. However, complex **I** was the only product when the reaction time was increased to 3 h. This observation is explained by the reaction of the formed complex **II** with the unreacted ethylenediamine which is present in the reaction solution in higher molar ratio than complex **III** in accordance with factors (i) and (ii).

It is note-worthy in this connection that Bose *et al.* had reported[19] the reaction of ethylenediamine with complex **III** using the molar ratio 1.5:1, and the proposed structure was that of both chelate rings of complex **II** to be five-membered with the oximato group coordinated to the metal through oximino-nitrogen. This structure was based on the similarity of their IR spectrum of the complex with those of authentic samples prepared by either the direct[13,20] nitrosation of N,N′-ethylenebis-(acetylacetoneimine)Ni(II) or by the condensation[13,21] of isonitrosoacetylacetone with ethylenediamine in the presence of Ni(II) acetate. This suggestion[19] assumes that the mode of coordination of the oximato group in chelate ring (a) of complex **III** had changed from the oximino-oxygen to the oximino-nitrogen coordination in the reaction of complex **III** with ethylenediamine. An investigation of the reported IR spectrum[13,20] showed that it is identical with that of complex **I**. Furthermore, the ν(N–O) of the complex reported by Bose *et al.*[19] was located around 1150 cm^{-1} and not around 1200 cm^{-1} used by the same authors[19] for the N-coordinated oximato group in vicinal oxime-imino complexes of Ni(II) with ligands of isomeric linkage. Accordingly, it is suggested that

the structure of the Ni(II) complex reported[19] by Bose *et al.* is identical with that of complex I (Fig. 2) and resulted from the reaction of ethylenediamine with the initially formed complex II and not the proposed structure with the two five-membered chelate rings. The same structure of complex I is also applicable to the complex prepared from the nitrosation[13,20] of N,N'-ethylenebis-(acetylacetoneimine)-Ni(II) or from the condensation of isonitrosoacetylacetone with ethylenediamine in the presence of Ni(II) acetate (2:2:1 molar ratio) in methanol. The presence of ethylenediamine in the latter reaction in a higher molar ratio than required by condensation reaction produced the conversion of complex II to complex I. Attempted similar reaction with a molar ratio of 2:1:1 in water or ethanol led to the formation of a mixture of complexes I and II.

The reaction of complex III with aliphatic diamino ligands was extended to include the 1:1 molar ratio reactions with either 1,3-diaminopropane, 1,4-diaminobutane or 1,5-diaminopentane. The reaction with 1,3-diaminopropane in chloroform produced complex V. The analytical and spectral data (Tables 1, 2 and 3) are compatible with the suggested formulation in Fig. 3. Thus, two ν(C=O) bands are located at comparable locations to those of complexes II, III and IV indicating the presence of two carbonyl groups attached to a six-membered [higher ν(C=O)] and five-membered chelate rings[9] [lower ν(C=O)]. Two bands were detected at 1185 and 1127 cm^{-1} corresponding to those of complex II and are assigned accordingly to ν(N–O) of the oximino-nitrogen (five-membered chelate ring) and oximino-oxygen (six-membered chelate ring) respectively. The ν(Ni–N) band is located near 600 cm^{-1} as in complex II which accords with the formulation shown in Fig. 3. The alternative formulation which comprises linking two molecules of complex III by $-(CH_2)_3-$ moiety after the transamination reactions appears to be energetically less favourable than the chelate ring formation of the diamine suggested in Fig. 3.

The analytical and spectral data are consistent with regarding the products of the reaction (1:1 molar ratio) between complex III and either 1,4-diaminobutane or 1,5-diaminopentane to be formulated as shown in Fig. 4. This formulation considers that the transamination reaction had involved the imino group of the five-membered chelate rings and led to linking two molecules of complex III through the $-(CH_2)_n-$ moiety (n = 4 or 5 for complexes VI and VII respectively). Thus, ν(C=O) of the six-membered and five-membered chelate rings in complex VI and VII are located at comparable locations to those of complexes II–V (Table 2). The splitting of these bands in the latter

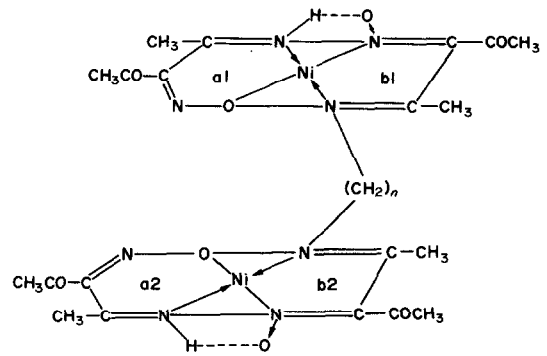

Fig. 4. Suggested formulations for complexes VI (n = 4) and VII (n = 5).

complexes was identical with those observed from complexes VI and VII (Table 2). The ν(NO) bands observed from complexes II and V (Figs. 2 and 3 respectively), which are ascribed to oximino-oxygen [chelate ring (a)] and oximino-nitrogen [chelate ring (b)], have their counterparts in complex VI and VII. Under such conditions the higher frequency band is associated with the N-coordination and the lower frequency is related to the O-coordination. The splitting of each of these bands to two bands in complexes VI and VII is indicative of the presence of steric interactions between the linked square planar mononuclear Ni(II) complex III. This suggestion accords with the observed decrease of the extent of separation between the ν(N–O) bands of the same mode of coordination as the linking moiety is increased from $-(CH_2)_4-$ in complex VI to $-(CH_2)_5-$ in complex VII (compare values of Δ for ν(N–O) in Table 2).

It seems that these steric interactions did not allow linking with the $-(CH_2)_3-$ moiety (and consequently $-(CH_2)_2-$) and led to the more stable complex V. The formulation of complexes VI and VII assumes that linking takes place between the imino-nitrogen of chelate ring (b-1) and the imino-nitrogen of chelate ring (b-2) which allows for the least possible steric interactions and consequently accounts for the absence of another link between the imino-nitrogen of chelate ring (a-1) and that of chelate ring (a-2) although the reaction solution (1:1 molar ratio) of complex III and the diamine was refluxed for 12 h. The ν(N–H) vibrations of complexes VI and VII are another evidence for the steric interactions between the linked square planar Ni(II) complex III. Thus, two well resolved ν(N–H) vibrations (separated by 150 cm^{-1}) were detected from complex VI of the higher steric interactions whereas only one of these bands was detected from complex VII.

The ^1H NMR spectra of complexes VI and VII are diagnostic for the linked imino-nitrogen. Thus, two

NH proton resonances were detected from complex **III** at $\tau = 1.35$ and $\tau = 2.32$ where the downfield resonance is associated[9] with the hydrogen bonded –N–H and the second resonance is attributed to the –N–H of the six-membered chelate ring. In the case of complexes **VI** and **VIII** a downfield resonance ($\tau = 1.23$) only was observed, indicating, therefore, that the hydrogen bonded –N–H (Fig. 4) of chelate rings (a1) and (a2) was not involved in the transamination reaction. The absence of the higher field –NH proton resonance ($\tau = 2.32$) indicated, thereby, that the two molecules of the square planar Ni(II) complex **III** are linked together through the imino-nitrogen of the five-membered chelate rings [(b1) and (b2) in Fig. 4] of each molecule. The proposed structures for complexes **VI** and **VII** are useful for locating the rotating chelate ring in the conversion of complex **III** to **IV**. Thus, the suggestion that the unreacted molecule of either 1,4-diaminobutane or 1,5-diaminopentane (in the 1 : 1 molar ratio reaction of complex **III** with diamines) did not lead to rotation of either chelate ring (a1) or (a2) implied that the imino-nitrogen of the five-membered chelate ring (b) in complex **III** is the reactive site not only for the transamination reaction (complexes **VI** and **VII**) but also for the rotation of chelate ring (b); complexes **IV**, **II** and **I**. The latter step could not occur after the transamination reaction that led to complexes **VI** and **VII**.

The electronic spectra of the metal complexes as Nujol mulls and in chloroform are summarized in Table 3. The observed peaks in the visible region are typical *d–d* transition peaks of square planar Ni(II) complexes.[22] There are slight shifts from the positions of the absorption maxima when comparing the spectra of Nujol mulls with those in chloroform. Furthermore, the intensities of the maxima are somewhat higher than expected.[22] This is accounted for by the intermolecular interactions which are operative in the solid state as well as the intramolecular interactions taking place between the mononuclear square planar units of complexes **VI** and **VII**. Accordingly, it could be suggested that the *d–d* transitions have been overlapped by some charge-transfer absorption peaks. This observation, which is most noticeable in the spectra of complexes **VI** and **VII**, is consistent with our interpretation for their IR spectra regarding steric interactions and accords with similar behaviour reported[13] for the Cu(II) analogue of complex **I** (intermolecular interactions).

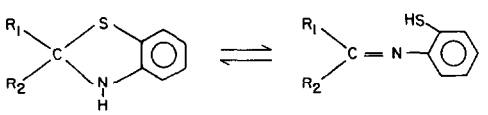
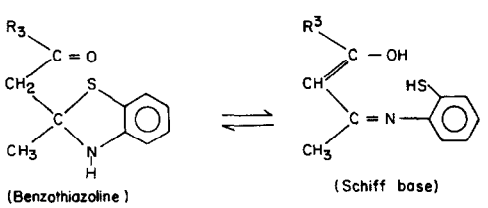
COORDINATION BEHAVIOUR OF BENZOTHIAZOLINES TOWARDS STANNOUS ION



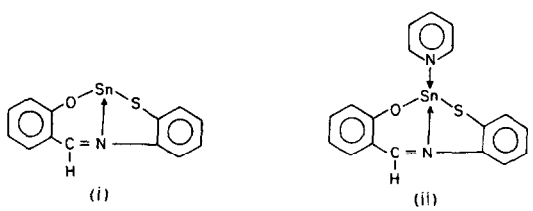
ANIL VARSHNEY and J. P. TANDON*
Department of Chemistry, University of Rajasthan, Jaipur-302004, India

(*Received* 19 *October* 1984; *accepted* 4 *January* 1985)



Abstract—Equimolar reactions of tin(II) methoxide with benzothiazolines result in the isolation of a new series of tin(II) complexes, which further undergo 1 : 1 adduct formation with pyridine. The electronic, IR and ^{1}H NMR spectral studies indicate coordination of tin to the oxygen, azomethine nitrogen and sulphur of the ligand moiety.

The condensation of a *o*-aminothiophenol with a carbonyl compound does not normally lead to the isolation of the corresponding Schiff-base, but a benzothiazoline is formed.[1,2] However, in the presence of a metal ion, the cyclic structure of thiazoline or benzothiazoline rearranges to give the Schiff-base metal chelate quantitatively.[3,4] During the course of the present investigations, an attempt has been made to synthesize tin(II) derivatives by interacting tin(II) methoxide with benzothiazolines derived by the condensation of salicylaldehyde (**I**), 2-hydroxy-1-naphthaldehyde (**II**), *o*-hydroxy acetophenone (**III**), acetylacetone (**IV**) or benzoyl acetone (**V**) with *o*-aminothiophenol.



The benzothiazolines used can be structurally depicted as follows:

I, R_1 = C_6H_4OH and R_2 = H (H_2SSP)
II, R_1 = $C_{10}H_6OH$ and R_2 = H (H_2NSP)
III, R_1 = C_6H_4OH and R_2 = CH_3 ($H_2A'SP$)

IV, R_3 = CH_3 (H_2ASP)
V, R_3 = C_6H_5 (H_2BSP)

EXPERIMENTAL

Tin(II) methoxide was prepared by the reaction of anhydrous $SnCl_2$ with an excess of triethylamine in methanol as described by Gsell and Zeldin.[5] The ligands were prepared by the condensation of aldehydes/ketones with *o*-aminothiophenol as described earlier.[6,7] These were purified by recrystallization from ethanol.

The complexes were analysed as reported earlier[8] and the infrared spectra were recorded on a Perkin–Elmer 577 IR spectrophotometer in the region, 4000–200 cm^{-1} using KBr optics. The electronic spectra (in methanol) were taken on a Toshniwal spectrophotometer. A Perkin–Elmer (Model RB-12) spectrometer was used for obtaining the PMR spectra employing DMSO-d_6 as the solvent and TMS as the internal standard. Molar conductance measurements were made in anhydrous dimethylformamide at 36 ± 1°C using a Systronics Conductivity Bridge Model-305. Molecular weight determinations were carried out by the Rast Method.

Synthesis of tin(II) complexes

To a weighed amount of tin(II) methoxide was added the calculated amount of the ligand in 1 : 1 molar ratio using methanol as the reaction medium

in an oxygen-free nitrogen atmosphere. Immediately, the colour of the solution changed and it was then stirred magnetically for *ca* 2 h. The excess of the solvent was removed and the compound finally dried *in vacuo* at a bath temperature of 35 ±5°C after being repeatedly washed with dry cyclohexane.

Synthesis of 1 : 1 *adducts*

To a weighed amount of tin(II) complex was added the calculated amount of pyridine in 1 : 1 molar ratio in methanol under an oxygen-free nitrogen atmosphere. The above solution was stirred magnetically for *ca* ½ h. The excess solvent was removed and the compound finally dried *in vacuo* after being repeatedly washed with dry cyclohexane.

RESULTS AND DISCUSSION

The formation of tin(II) complexes by the equimolar reactions of tin(II) methoxide and benzothiazoline and their further adduct formation with pyridine can be depicted by the following equations:

$$Sn(OMe)_2 + ONSH_2 \rightarrow Sn(ONS) + 2\,MeOH$$

$$Sn(ONS) + Py \rightarrow Sn(ONS) \cdot Py$$

(where $ONSH_2$ and Py represent the benzothiazoline and pyridine molecules respectively).

The resulting new derivatives are coloured solids and found to be soluble in DMF and DMSO. The molar conductance of 10^{-3} M solutions of the adducts in DMF lies in the range, 8–14 $ohm^{-1}\,cm^2\,mol^{-1}$, indicating their non-electrolytic behaviour and the molecular weight determinations indicate their monomeric nature.

Electronic spectra

The electronic spectra of the ligands show two bands around 250 nm and 315 nm. These bands are consistent with the typical spectrum of benzothiazoline[2] (cyclic form) and may be attributed to

the ϕ–ϕ^* and π–π^* benzenoid transitions.[9,10] In the corresponding tin(II) complexes, an additional band around 410 nm due to the n–π^* electronic transitions of the azomethine group is also observed.[11] This new band may be due to the isomerization of the ligands on complexation.

IR spectra

A comparison of the characteristic IR absorption bands of the benzothiazolines with those of the corresponding tin(II) complexes reveals the following important features:

(1) In the IR spectra of ligands, a strong broad band at 3400–3250 cm^{-1} is observed which can be assigned to the association of ν (NH) with the phenolic OH vibrations.[12] In the spectra of metal complexes, these bands disappear, indicating the chelation of oxygen as well as nitrogen to the metal atom.

(2) A strong band at 1670–1705 cm^{-1} may be assigned to the N–H deformation vibrations and the absence of ν (SH) at $\sim$ 2500–2600 cm^{-1} is indicative of the benzothiazoline rather than the Schiff-base structure of the ligands. In the spectra of complexes, a new band at $\sim$ 1605 cm^{-1} is observed and which can be assigned to ν (C=N) vibrations. The presence of this band clearly indicates that the resulting metal complexes are Schiff-base derivatives and these are formed by the rearrangement of the benzothiazoline structure.

(3) New bands at $\sim$ 405 and 360 cm^{-1} may be attributed to ν(N $\rightarrow$ Sn) and ν(S $\rightarrow$ Sn) bands, while ν (O $\rightarrow$ Sn)[14] is observed at 645 cm^{-1} in the complexes.

(4) The formation of the pyridine adduct is evidenced by the appearance of new bands in the region, 650–700 cm^{-1}.

Proton magnetic resonance spectra

The proton magnetic resonance spectra of salicylaldehyde-2-mercaptoanil (H_2SSP) and its 1:1 (SnSSP) derivatives have been recorded in DMSO-d_6. The signals at δ 9.25 ppm and δ 4.20 ppm in the case of the ligand are due to the phenolic and NH protons respectively. These, however, disappear from the spectra of tin(II) complexes indicating the deprotonation of the functional groups during complexation with the tin atom.

The ligand shows a complex multiplet in the region δ 7.40–6.40 ppm for the benzene protons, and it remains at almost the same position in the spectra of the tin(II) complexes. The proton signal for the azomethine proton at δ 8.30 ppm in the ligand shifts downfield in the spectra of complexes due to the donation of a lone pair of electrons by the nitrogen to the central tin atom on account of the formation of a coordinate linkage.

Thus on the basis of the above spectral evidence, the following structures can be proposed for the resulting tin(II) complexes and in which the tin atom is probably in tri- (i) and tetra-coordinated (ii) environments.

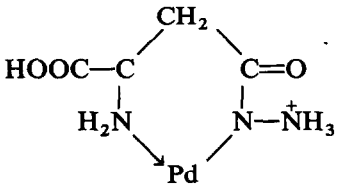
Abstract—Mononuclear platinum(II) complexes of the hydrazides of aspartic and glutamic acids have been synthesized and studied. The 1:1 complexes are of the type $[Pt(HL)Cl_2] \cdot 3H_2O$, while the 1:2 complexes are $[Pt(HL)_2]Cl_2 \cdot 3H_2O$. In DMF solutions the water molecules are substituted completely by DMF, while in 1:1 (v/v) water–DMF solutions complexes with one DMF and two water molecules are formed. The complexes are characterized using spectroscopic methods (IR, electronic spectra, ESCA), DTA, elemental analysis and titration curves, on the basis of which the ligands are thought to coordinate through the amino- and the hydrazide groups, the carboxylic one remaining deprotonated and non-coordinated.



Recently we have synthesized and studied complexes of mono- and dihydrazides of aspartic and glutamic acids firstly with copper(II),[1] nickel(II) and cobalt(II)[2] and then with palladium(II).[3,4] The complexes of the last metal ion were most interesting, because in this case two types of complexes were synthesized, that differ in the way of bonding between the metal and the ligand. In the first type, denoted conventionally as type B complexes, binuclear species were formed

where $X = Cl^-$ or OH^-, depending on the acidity. The ligands are bonded through the amino group and the hydrazide group via its carbonyl oxygen, the carboxylic groups being not engaged in coordination:

In the second group of complexes (type C) the ligands are bonded *via* the amino group and through the deprotonated hydrazide nitrogen

In this case, depending on the pH of the solution and the excess of the ligand either mononuclear complexes PdL_2 and $[Pd(HL)_2]Cl_2$ are formed, or the binuclear species $[Pd_2(HL)_2Cl_2]Cl_2$.

The present work is dedicated to the synthesis of the corresponding platinum complexes with the same ligands and to the investigation of the type of bonding in them.

EXPERIMENTAL

The hydrazides of aspartic and glutamic acids and the dihydrazide of aspartic acid (AH, GH and DH correspondingly) were synthesized and purified, according to the literature data.[5]

The formation of the complexes was studied in slightly acidic aqueous solutions, where the formation of type B complexes is favoured, and in

* Author to whom correspondence should be addressed.

acetone–water, DMF–water and pure DMF media as well. As in the case of Pd(II) complexes with DH and of Cu(II) with the three ligands, only complexes of type B were obtained with platinum(II). The complexes were synthesized according to the following procedure.

Aqueous 0.2 M solutions of K_2PtCl_4 (0.415 g in 5.00 cm^3) and of the ligands (AH—0.147 g and GH—0.161 g in 5.00 cm^3) were prepared, adjusted to *ca.* pH 4.5 and mixed. The reaction mixture with AH was stirred and heated on water bath for 10 min and after cooling a yellow precipitate was formed. The reaction system with GH was kept for 24 hr at room temperature, because heating of the system leads to slow reduction of Pt(II) to metal. The complexes thus obtained were filtered off, washed with ethanol and diethyl ether successively and vacuum-dried at room temperature. The complexes with M : L = 1 : 2 were synthesized in the same way using 0.4 M solutions of the ligands.

In the case of Pt(II) complexes with DH the IR data also indicate the formation of a type B complex, but the elemental analysis showed a variable non-reproducible content of the precipitates. After many experiments we were not able to obtain pure platinum complexes of this ligand with a well defined constant composition. For that reason the data for the platinum complexes of DH are not presented in the paper.

All the reagents and solvents used throughout the work were of A.R. grade and were used without any additional purification.

The elemental analysis was performed in a standard way. Palladium was determined gravimetrically with dimethylglyoxime after destruction of the complexes by heating with conc. HNO_3. Nitrogen was determined by the Dumas' method, the total chlorine assay—after destruction of the complexes with hot conc. HNO_3—gravimetrically as AgCl. The ionic chloride was titrated potentiometrically with $AgNO_3$ after dissolution of the complexes.

The IR spectra were recorded on a Perkin–Elmer, model 580 spectrophotometer in KBr pellets and the electronic reflectance spectra—on a VSU 2P spectrophotometer (Carl Zeiss). The DTA data were obtained with a microdifferential thermoanalyser MIKRO ATD M4 and the ESCA measurements were carried out on a VIEE-15 spectrometer using the carbon 1*s* photoelectron line (285.0 eV) for energy calibration.

RESULTS AND DISCUSSION

The complexes of Pt(II) with AH and GH were obtained from solutions with M : L = 1 : 1 and 1 : 2. In aqueous media the pH of the solution over the precipitate was 3.8–4.2, depending on the metal to ligand ratio. The complexes obtained in such conditions represent white to light yellow precipitates.

Table 1. Bonding energy (eV)

Complexes with	Pt $4f_{7/2}$	Cl 2*p*	N 1*s*
AH	73.3	198.7	400.9
GH	73.5	198.9	400.9
DH	73.4	198.9	401.0

Using the ESCA method it was found that in all complexes platinum is in oxidation state +2. The values for the energy of electron detachment determined for the complexes studied vary from 73.3 to 73.5 eV, while from literature data it is known that usually in Pt(II) complexes the value for Pt $4f_{7/2}$ is in the range 72.4–73.9 eV.[6] In contrast with palladium(II) complexes chlorine is present in all complex species obtained as follows from the appearance of the Cl 2*p* line. The data for the complexes synthesized with AH, GH and DH in aqueous solutions with M : L = 1 : 1 are summarized in Table 1. The N 1*s* line is broadened to a considerable extent indicating the different types of nitrogen atoms present in the complexes. In the same samples no indication was found for the presence of potassium.

With DTA it was found that all the complexes obtained in aqueous solutions contain crystallohydrate water, which in the 1 : 1 complexes was removed at *ca.* 130°C, while in the 1 : 2 species formed in

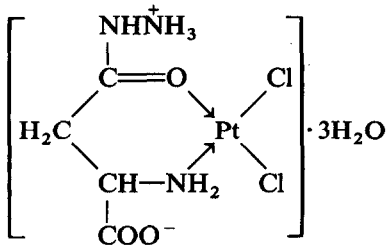
[a] Broad band.

[b] Only in 1 : 1 complexes.

aqueous medium it was determined at *ca.* 135°C. The amount of crystallohydrate water is three mols per mol of platinum(II). It was found, that when the synthesis is carried out in H_2O+DMF solutions (1:1 v/v), one mol of the crystallohydrate water is replaced by DMF, and if pure DMF is used as a reaction medium, water is completely substituted in the complex by an equivalent amount of DMF. The presence of DMF in the complexes was proved by IR spectra and by the elemental analysis data combined with determination of water in these samples.

The direct potentiometric titration of the complexes in solution showed that the 1:1 complexes do not contain ionic chloride, while in the 1:2 species the chlorine assay is due completely to ionic chloride. At the same time the electronic reflectance spectra of the 1:1 complexes do not show absorption bands at wavelengths $\lambda > 350$ nm. This fact excludes the presence of units such as $PtCl_4^{2-}$ or $Pt_2Cl_6^{2-}$ in the solid phase.

The IR data (Table 2) have indicated that the carboxylic groups are deprotonated and not engaged in coordination. This follows from the absence of ν(COOH) = 1720 cm^{-1} observed in complexes with protonated carboxylic groups, and from the appearance of $\nu(COO^-)_{sym}$ = 1400 cm^{-1} and $\nu(COO^-)_{asym}$ = 1670 cm^{-1}.[3] The position of the amide(I), amide (II) and amide(III) bands[3,7–9] shows that most probably the hydrazide group is bonded to platinum through oxygen as in type B complexes of palladium(II), and not through nitrogen, as is the case with type C complexes of Pd(II).[3] This is confirmed also by the absence of the typical bands indicating bonding through the hydrazide nitrogen—at 1375 cm^{-1} and 385+405 cm^{-1}.[3] The protonation of the hydrazide amino group is shown by the presence of the band at 1510 cm^{-1} and confirmed also by titration of the complexes with NaOH. It was shown, that while the 1:1 complexes with AH and GH consume one mol NaOH per mol complex, the 1:2 complexes consume two mols NaOH per mol complex, i.e. in both complexes the ligand contains one protonated group, namely $-CONH\overset{+}{N}H_3$.



The presence of two chlorine atoms in *cis*-positions in the 1:1 complexes was shown by the presence of the doublet band 330+340 cm^{-1},[10–12] that is observed only in the 1:1 and not in 1:2 complexes. The coordination of NH_2 from the aminocarboxylic group follows from the appearance of ν(Pt–NH_2) at 540 cm^{-1} [3,10] and from the shift of the band at 3280 cm^{-1} of the free ligands to 3170–3160 cm^{-1} in the complexes.[3]

The experimental data thus obtained are consistent with the following structure of the complexes. In the 1:1 complexes there is one ligand with deprotonated carboxylic and protonated hydrazide groups, coordinated to platinum(II) through the amino group and the carbonyl oxygen of the hydrazide group. Two chlorides are also present

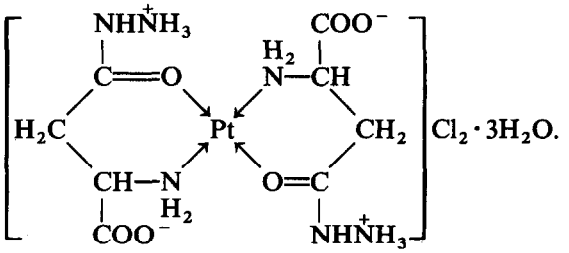


Table 3. Elemental analysis data

M:L ratio in the solution	Complex formed	Found (calc.)%				
		Pt	Cl	N	C	H_2O
1:1 in H_2O	$[Pt(AH)Cl_2]\cdot 3H_2O$	41.50 (41.76)	15.08 (15.20)	9.24 (8.99)	10.42 (10.28)	11.38 (11.56)

1:2 in H_2O	$[Pt(GH)_2]Cl_2\cdot 3H_2O$	30.56 (30.37)	10.92 (11.06)	13.12 (13.08)	18.60 (18.69)	8.30 (8.41)
1:2 in H_2O +DMF(1:1)	$[Pt(GH)_2]Cl_2\cdot 2H_2O\cdot DMF$	28.14 (27.98)	9.96 (10.19)	14.12 (14.06)	22.40 (22.38)	5.28 (5.16)
1:2 in DMF	$[Pt(GH)_2]Cl_2\cdot 3DMF$	24.36 (24.16)	8.62 (8.80)	15.40 (15.61)	28.17 (28.25)	— —

in the inner coordination sphere and three crystallohydrate water molecules are bonded to the complex:

The 1:2 complexes contain two molecules of the ligand, bound in the same way and as the complex thus formed is positively charged it contains also two chlorides as counter ions:

In a mixed DMF+H_2O (1:1 v/v) reaction medium the 1:2 complexes obtained have the formulae $[Pt(HL)_2]Cl_2 \cdot 2H_2O \cdot DMF$, and those synthesized in a pure DMF correspond to $[Pt(HL)_2]Cl_2 \cdot 3DMF$.

All the conclusions stated above were confirmed by the elemental analysis data presented in Table 3. The values given there are average from the analysis of three parallel samples.

Summarizing the results of the present work it must be mentioned first of all that in contrast with Pd(II) complexes, where we were also able to obtain complexes in which the ligand is bonded through $-NH_2$ from the aminocarboxylic group and through the deprotonated hydrazide nitrogen, the complexes of Pt(II) with the ligands studied are only of type B. Another significant difference between the complexes of Pt(II) and Pd(II) studied is that all the platinum complexes obtained with these ligands are mononuclear, while in most cases the corresponding palladium(II) complexes were binuclear with chloride bridges.

HIGH-RESOLUTION SOLID-STATE NMR MEASUREMENTS OF OLIGOMERIC POLYSILANES

R. K. HARRIS*† and K. METCALFE‡
School of Chemical Sciences, University of East Anglia, Norwich NR4 7TJ, U.K.

and

E. HENGGE
Institut für Anorganische Chemie der Technischen Hochschule, Graz, Austria

(*Received* 15 *November* 1984; *accepted* 6 *February* 1985)

Abstract—High-resolution solid-state ^{13}C and ^{29}Si NMR spectra have been obtained for $(Ph_3Si)_2$, $(Ph_2Si)_4$ and $(Ph_2Si)_5$ under conditions of high-power decoupling, cross-polarization and magic-angle rotation. The spectra reveal crystallographic inequivalences for $(Ph_2Si)_5$ but not for the other two compounds. There are significant ^{29}Si chemical shift variations.

Polysilanes are now well-known, and their spectroscopic properties have been reported. In particular, ^{29}Si-NMR chemical shifts have been measured for a range of oligomeric polysilanes in solution.[1–5] However, difficulties are sometimes encountered because of the low solubility of phenyl-substituted polysilanes, combined with the poor sensitivity of ^{29}Si-NMR. Recently, the high-power-decoupling/cross-polarisation/magic-angle-rotation suite of techniques has enabled NMR spectra of dilute spins (e.g. ^{13}C or ^{29}Si) to be obtained in high-resolution for solids, and this is clearly an attractive possibility for relatively insoluble organometallic compounds. Much use has been made of these methods for ^{29}Si spectra of zeolites and other silicate species (see, for example, ref. 6). This has been extended to polysiloxanes,[7] but has scarcely been used for polysilanes. There is, however, one report[8] of a high-resolution solid-state NMR spectrum for $Me_3SiSiPh_3$, which showed that the two types of silicon could be distinguished. This note presents results for both ^{13}C and ^{29}Si solid-state NMR for three perphenylpolysilanes, namely hexaphenyldisilane (HPDS), $Ph_3SiSiPh_3$; octaphenylcyclotetrasilane (OPTS), $(Ph_2Si)_4$; and decaphenylcyclopentasilane (DPPS) $(Ph_2Si)_5$.

EXPERIMENTAL

The ^{29}Si solid-state NMR spectra were obtained at 39.76 MHz using a Bruker *CXP 200* spectrometer. The ^{13}C spectra were recorded at 50.3 MHz using a specially-constructed spectrometer based on a 4.7 T Oxford Instruments superconducting magnet, a Nicolet 1180 computer, Bruker gating and phase-shifting units for both high- and low-frequency channels, and a Bruker CP/MAR probe. In all cases, the high-power-decoupling (HPD), cross-polarization (CP) and magic-angle-rotation (MAR) techniques were used. Proton relaxation characteristics were measured in order to assist choice of operating parameters for the ^{29}Si and ^{13}C spectra. They were found to be in the region of 3–4 s for T_1 and 2–6 ms for $T_{1\rho}$. Additional ^{13}C spectra were obtained using the non-quaternary suppression (dipolar dephasing) pulse sequence[9] in order to locate the signal(s) arising from the *ipso* carbon of the phenyl rings. Chemical shifts were measured by replacement and are reported with respect to the ^{29}Si and ^{13}C signals of tetramethylsilane using the high-frequency-positive convention. Ambient probe temperature (*ca.* 22°C) was used for all NMR experiments. The compounds used were prepared by known preparative routes. HPDS is formed in a

coupling reaction from triphenylchlorosilane.[10] Diphenyldichlorosilane reacts to form OPTS[11] and DPPS[12] in good yields.

RESULTS AND DISCUSSION

Signals were observed in all cases and the results are given in Tables 1 and 2. The ^{29}Si spectra are displayed in Fig. 1. Single resonances were seen for the proton-decoupled ^{29}Si spectra of HPDS and OPTS. The crystal structure of OPTS shows[12] that although there are four molecules per unit cell, the asymmetric unit consists of half a molecule. Evidently NMR cannot resolve the difference between the two silicon atoms in the asymmetric unit. Indeed, the environments of these atoms revealed by the X-ray diffraction studies are very similar.

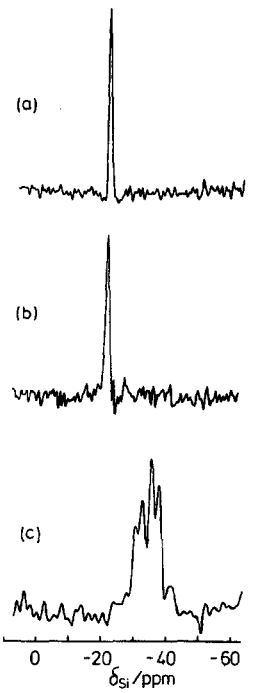

Fig. 1. 39.8 MHz ^{29}Si-{^1H} cross-polarization/magic-angle-rotation NMR spectra of solid (a) $Ph_3SiSiPh_3$, (b) $(Ph_2Si)_4$, and (c) $(Ph_2Si)_5$. Spectrometer conditions: contact time 5 ms; recycle time 10 s; number of transients (a) and (c) ~ 5000, (b) ~ 1000.

Table 2. Carbon-13 chemical shifts for solid polysilanes

	136.1	
	134.3	134.9[a]
	132.0	132.1
	127.3	
	126.0	125.6

[a] Of greater intensity than the other NQS peaks (see Fig. 2).

On the other hand, DPPS gives four ^{29}Si signals. It is not easy to determine the relative intensities of these resonances, in spite of using a long accumulation time. However, one signal appears to be more intense (possibly twice as intense) as the others, though this may be an artefact of the particular contact time used. The crystal structure of DPPS has been published,[16] and shows eight molecules per unit cell. The asymmetric unit appears to be a complete molecule, thus allowing all five silicon atoms to be different—consistent with the NMR result if this contains an accidental equivalence.

The spread of ^{29}Si chemical shifts for DPPS is substantial (7.3 ppm), indicating a considerable diversity of environment, though whether this arises from inter- and intra-molecular effects is difficult to establish. The molecule is known[16] to have a puckered ring, intermediate between C_s and C_2 symmetry. The solution-state ^{29}Si NMR shows a single resonance (see Table 1), which falls within the solid-state range. The solution-state ^{29}Si shifts for HPDS and OPTS are also known (Table 1), and represent only small (< 3 ppm) deviations from the solid-state values. There is a substantial effect of ring

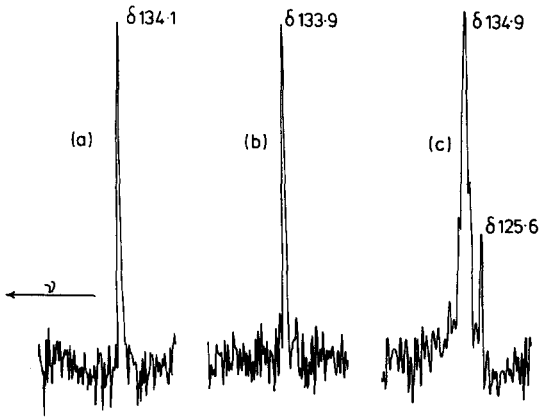

Fig. 2. 50.3 MHz ^{13}C–{^{1}H} cross-polarization/magic-angle-rotation NMR spectra of solid (a) $Ph_3SiSiPh_3$, (b) $(Ph_2Si)_4$, and (c) $(Ph_2Si)_5$, obtained using the non-quaternary suppression (dipolar dephasing) pulse sequence. Spectrometer conditions: contact time (a) 5 ms, (b) 4 ms, (c) 2 ms; recycle time 10 s; number of transients (a) and (b) 3000, (c) 4000; dephasing delay 40 μs.

size on the shifts, as already thoroughly reported from solution-state work.[17]

The solid-state ^{13}C spectra support the ^{29}Si results. The non-quaternary suppression (NQS) experiment is particularly helpful in this regard, since it gives very clearly only one signal for both HPDS and OPTS. As for the ^{29}Si spectra, the theoretical non-equivalences for OPTS are not revealed by ^{13}C NMR, indicating that the various environments are very similar. On the other hand, the solid-state ^{13}C spectra of DPPS are more complex (Fig. 2). Although the quality of these spectra in terms of resolution is not high, the NQS experiment clearly reveals more than one peak, and a possible interpretation is that there are four peaks, with one of double intensity.

CONCLUSIONS

The work reported here demonstrates that solid-state NMR is a valuable adjunct to both X-ray diffraction studies and solution-state NMR for organometallic systems. In the present cases, although the compounds are not very soluble, their solution-state ^{29}Si spectra were obtainable. Obviously, for even less soluble systems, solution-state NMR is not an option. Moreover for glassy (or otherwise amorphous) materials, or those which, though crystalline, do not give suitable crystals, X-ray studies may not be feasible or informative. On the other hand, solid-state NMR suffers few limitations.

Acknowledgements—We would like to thank K. J. Packer for allowing the use of his spectrometer for the ^{13}C spectra. We are grateful to the U.K. Science and Engineering Research Council for the award of a Research Assistantship to KM under research grant GR/C/04376 (Cooperative Award involving ICI PLC) and for financial support to purchase the CXP 200 spectrometer under research grant GR/B/81298.

THE ASSOCIATION CONSTANT OF THE FIRST CHLORO-COPPER(II) COMPLEX IN WATER TO 100°C

LESLEY A. ASHTON, JOSEPH I. BULLOCK* and PETER W. G. SIMPSON
Cecil Davies Laboratory, Department of Chemistry, University of Surrey, Guildford, Surrey GU2 5XH, U.K.

(*Received* 12 *November* 1984; *accepted* 6 *February* 1985)

Abstract—The equilibrium constant, K_1, for the reaction $Cu^{2+} + Cl^- \rightleftharpoons [CuCl]^+$ has been determined in the range 15–100°C from spectrophotometric data. The method of analysis, which is widely used, requires both slope and intercept from a reciprocal plot of absorbance against total metal ion concentration. The calculated values of K_1, particularly at low temperature, are very sensitive to the chosen method of data treatment such that the application of weighting factors to the absorbance data for a given photometric accuracy can halve the values. The large variations in K_1 found in the literature are likely to be caused by underestimation of the instability inherent in the method as much as by the neglect of chemical effects such as the formation of higher complexes. By appropriate weighting of the absorbance data an increase in K_1 is apparent above 30°C and the method may have limited usefulness at high temperatures.

Complexes of the 3*d*-transition elements with simple inorganic anions are often difficult to study in water at high temperatures. Hydrolysis sets in at a progressively lower pH as the temperature is raised, complexes with thermally stable anions of technological interest, e.g. Cl^- and SO_4^{2-}, are often weak although the formation constants should increase with temperature, reduction of a metal ion is more favourable at high temperature, and a non-complexing, thermally stable supporting electrolyte is difficult to find.

Spectrophotometry is a commonly used method for the study of weak metal–ion complexes[1–6] and we have previously shown it to be a convenient method for the acid dissociation complexes of organic acids,[7] the protonation constants of heterocyclic bases,[8] and the stability constants of some strong iron(II) complexes[9–10] in water at temperatures above 100°C. The present work is an evaluation of a spectrophotometric method for the determination of the first chloro-copper(II) complex to 100°C. The equilibrium has been studied extensively at low temperatures but with widely differing results.

RESULTS AND DISCUSSION

The chosen method[1,2,5,6] involves the use of a large excess of a metal ion M over a ligand L in order to prevent the formation of all but the first complex and to allow the simplification that the variable, total metal concentration M_T equals the free metal ion concentration M_F.

$$Cu^{2+} + Cl^- \rightleftharpoons [CuCl]^+ \qquad K_1.$$

This results in a high ionic strength, I, if the complexes are weak. The total ligand concentration L_T is held constant and for a 1 cm cell eqn (1) results

$$1/(A - A_0) = 1/L_T \varepsilon K_1 M_T + 1/\varepsilon L_T, \qquad (1)$$

where ε ($dm^3\ mol^{-1}\ cm^{-1}$) is the molar extinction coefficient of the first complex ML at a chosen analytical wavelength, K_1 ($dm^3\ mol^{-1}$) is the required formation constant and $(A - A_0)$ is the measured absorbance using a reference solution of absorbance A_0 containing all the components of the system except L. It is also assumed that the formation of complexes between L and cations from the supporting electrolyte can be ignored.

A plot of $1/(A - A_0)$ against $1/M_T$ should give a straight line of intercept $1/\varepsilon L_T$ and gradient $1/L_T \varepsilon K_1$. Since ε cannot be found from an independent experiment under the same conditions, ε and K_1 are highly correlated through the use of eqn (1). The analysis depends on the complex formed, e.g. $[CuCl]^+$, having an absorption maximum for which the absorptions of the free metal ion, ligand, and other components are slight. Such bands are usually associated with ligand to metal ion charge-transfer

so that the metal ion may be readily reduced at higher temperature. On the other hand, a non-absorbing, non-complexing mineral acid, e.g. $HClO_4$, can be conveniently added to prevent hydrolysis and perchlorate salts can be used to make up the necessary high ionic strengths.

In the present work, two series of experiments were performed, in series 1 the ionic strength was brought to 1.00 mol dm^{-3} with $NaClO_4$ while in series 2 with $HClO_4$. In common with most previous spectroscopic experiments[1,2,5,6] absorbances were measured to long wavelength of $\lambda_{max}[CuCl]^+$ which occurs[2] at 251 nm at 25°C. As the temperature was raised the absorption of a given solution increased and λ_{max} shifted to longer wavelength. The results in Table 1 were obtained by linear regression to find the straight line of best fit. Errors in intercept and slope of one standard deviation, obtained from the linear regression analysis, were combined to estimate the deviations in K_1 shown in Table 1 and are thus not dependent on any predefined photometric accuracy. The way in which deviations were calculated in previous work[1,2,5,6] is not clear but more likely tolerances might be obtained by at least doubling those quoted by us and others to allow for systematic spectrophotometric and other errors. In these terms there was little real variation with temperature (except perhaps at 90°C and above), wavelength, or nature of the ionic medium.

A selection of literature data with I close to 1 mol dm^{-3} are compared with ours in Table 2. A wide variation in K_1 and ε is apparent. It has been stated[3,5] that the variations arise at least in part by interference of higher complexes, $[CuCl_n]^{(2-n)+}$, for example in Nasanen's work[4] with $CuCl_2$ since ε, $CuCl_2$ is apparently[3] greater than ε, $[CuCl]^+$ near 270 nm and by neglect[6] of the polymeric form, $[Cu_2Cl]^{3+}$, see footnote *b*, Table 2. With the copper concentration at 5×10^{-3} mol dm^{-3} and chloride in the range 0–0.25 mol dm^{-3} it is possible[3] to find K_1 and K_2 simultaneously but the values obtained can be altered considerably by adjusting the minimisation procedure. Preliminary determination of K_1 through eqn (1) can be used[1] to find K_2 from a second set of experiments. In our work at 25°C M_F was 98.9–99.3% of M_T in Series 1 and 99.2–99.4% of M_T in Series 2 and in either case, if K_2 is[1,3] about 0.25 K_1, the amount of chloride contained in $CuCl_2$ was less than 0.1% of the total. An iterative loop could be added to take account of the small difference between M_T and M_F but little is to be gained by this in view of other likely errors. In addition, Libus[2] has suggested that the variation in K_1 is caused by ignored variation in the activity coefficients of the reacting species and recommends the use of $Mg(ClO_4)_2$ as the supporting electrolyte if one of the reacting species is divalent when better control should be obtained. The interaction of magnesium ions with chloride is not well understood at high temperature so it was not used in our study. At 25°C our K_1 values (Table 1) fall within the values reported previously (Table 2).

[a] High temperature cell (see Experimental).

At 40°C, values[6] of K_1 (2.00 mol dm^{-3}, $NaClO_4$) of 1.35 (265 nm), 1.38 (270 nm) and 1.29 (275 nm) are reported and at 46.9°C (1.00 mol dm^{-3}, $HClO_4$) a value[1] of 1.39 ± 0.05 (270 nm) was found.

A striking feature of Table 2 is the fair agreement in the value of the product εK, obtained from the slope of the plot which gave, however, wide variation in K_1. This has been mentioned before[3] when the importance of the chosen method of evaluation was noted. In view of the calculated value[1,2] of K_2 it is unlikely that neglect of higher complexes is alone the cause of the variation in K_1 since, as is shown above, a very small amount of the second complex is present

in our experiments and those of others[1,2,5,6] because of the relative concentrations of copper and chloride. However the method of evaluation should take note of the photometric accuracy. It is usual[11] in the determination of rate constants by spectrophotometric methods to weight the data used in linear regression analysis for a constant photometric accuracy in absorbance. Weighting factors are not usually applied to the time data.

Weighting factors are particularly appropriate here since in a given set of experiments $(A - A_0)$ might vary from, say 0.1 to 1 or above and reciprocals are used for the plot. Following the usual procedures,[12] weighting factors, w_i, proportional to $1/\sigma^2(A - A_0)$, where $\sigma(A - A_0)$ was set at 0.002 (0.004 at 90°C), were applied through a locally written program to the absorbance data from the Series 1 experiments (Table 1). The program calculated the slope, intercept, ε, and K_1 and their standard deviations. As can be seen from Table 3 the values of K_1 were much reduced as a result and there was on average a smaller standard deviation. This derived from a very much better defined intercept. The actual numerical values of the product εK_1 was little changed at any temperature and at 25°C remained well within the range reported previously (Table 2), e.g. at 25°C, εK_1 was 523 compared with 564 for the unweighted data at 270 nm. The standard deviation in slope was worsened by a few percent through the use of weighting factors. This alternative use of the absorbance data highlights the fragiligy of the method itself. As widely differing values of K_1 can be obtained from a single set of data, the variation in Table 2 becomes more understandable. The general instability is also indicated by the large increase in K_1 to what would seem to be an unacceptable value by the inclusion[5] of a few percent of the polymeric $[Cu_2Cl]^{3+}$ (Table 2).

The method relies on a non-linear relationship between $(A - A_0)$ and M_T. While, from visual

K_1^a	1.24 (0.08)	1.18 (0.08)	1.24 (0.05)	1.41 (0.03)	1.62 (0.04)	1.95 (0.04)	4.79 (0.20)

[a] K_1, dm^3 mol^{-1}, standard deviation in parentheses.

inspection, plots of $(A-A_0)$ against M_T were invariably non-linear the degree of curvature is in all cases slight. As an example, the unweighted Series 1 results at 25°C and 270 nm were plotted as $(A-A_0)$ against M_T for 12 data points to give through linear regression the best fit straight line which had a correlation coefficient of 0.9982. The corresponding unweighted reciprocal fit [eqn (1)] had a correlation coefficient of 0.9998. The degree of curvature must be governed by the values of ε and K_1 as well as the concentrations M_T and L_T required to obtain acceptable absorbance data. An attempt to use the program SQUAD,[13,14] successful in our other studies,[7-9] failed to calculate K_1 or K_1 and K_2 simultaneously through non-convergence which was caused by the near linear relationship between $(A-A_0)$ and M_T. It seems likely that the use of eqn (1) cannot lead to a definitive value of K_1 at 25°C.

Interestingly, the use of a weighting scheme produced a more noticeable trend in the variation of K_1 with temperature (Table 3). Bearing in mind the expected large increase in K_1 at high temperature, it would appear that the use of the method with weighted data is an appropriate route to the high temperature determination of weak metal ion complexes with simple inorganic ions. Unfortunately, above 100°C perchloric acid reacted with the cell materials used to construct our high temperature cell.

It is possible to calculate the thermodynamic parameters ΔH^0, ΔS^0, etc. from the temperature variation in K_1. There is little profit in doing so when the total inaccuracies of the method are considered particularly as a plot of $\log_{10} K_1$ against $1/T$ is clearly non-linear (Table 3).

EXPERIMENTAL

Series 1 experiments

Copper(II) perchlorate was prepared[15] from Analar copper(II) oxide and Analar perchloric acid and recrystallised from perchloric acid (0.25 mol dm^{-3}). Stock solutions of copper(II) perchlorate ($\sim$1 mol dm^{-3}) were prepared in Analar perchloric acid (0.25 mol dm^{-3}). The Cu(II) and hydrogen ion concentrations of the stock solutions were determined by standard methods. The test solutions (100 cm^3) were prepared by taking appropriate aliquots of the Cu(II) stock solution, standardised Analar hydrochloric acid, and Analar sodium perchlorate solution to bring all the solutions to an ionic strength (I) of 1.00 mol dm^{-3}. No chloride ion was detectable in either the Cu(II) or sodium perchlorate stock solutions. The reference solutions were identical except they contained no hydrochloric acid.

Except at 90°C (see later), absorbances were measured on a Pye–Unicam SP8-100 spectrophotometer calibrated for absorbance with solutions from Pye–Unicam traceable to National Physical Laboratory Standards with matched 1 cm silica cells to give $(A-A_0)$ directly. Both sample and reference cells were thermostatically controlled to $\pm$0.05°C.

Series 2 experiments

Copper(II) perchlorate stock solutions ($\sim$ 1 mol dm^{-3}) were prepared from Analar copper(II) oxide and Analar perchloric acid and analysed for copper and acid concentrations by standard methods. Test and reference solutions were prepared as for Series 1 except that perchloric acid was used to make up the ionic strength to 1.00 mol dm^{-3}. Analar reagents were used throughout.

Except at 100°C (see later), absorbances were measured on a Unicam SP3000 spectrophotometer with the same cells as for Series 1.

If a reference solution had an absorbance greater than 0.2, the photometric accuracy worsened so that all $(A-A_0)$ values were obtained by separate measurements on the test and reference solutions using a water blank to give an overall accuracy of $\pm$0.004 units in absorbance. The cell temperature was controlled to $\pm$0.05°C and the instrument calibrated in absorbance as before.

High temperature cell

This has been described previously.[16] The cell has a pathlength of 1 cm with a teflon body and sapphire windows. A modified SP1800 spectrometer is used to measure absorbance. Absorbance measurements became unreliable above 2.0 so that in Series 2, Table 1 at 100°C, 280 nm became the lowest acceptable wavelength for accurate data. Because the reference beam is air-filled and sealed off, separate measurements on the test and reference solutions are necessary. The instrument was calibrated with neutral density filters which were first measured on the calibrated SP3000 and SP8-100 spectrometers. Under these conditions the spectrophotometric accuracy is about $\pm$0.004 overall. This cell was used at 90°C and above. Above 110°C absorbance readings increased rapidly with time and subsequent experiments showed that an absorbing material (λ_{max} 236 nm) was produced by reaction between teflon and acidic perchlorate solutions at high temperature.

SOME COMMENTS ON THE MECHANISM OF THE PREPARATION OF $(Et_4N)_2B_{10}H_{10}$ BY THERMOLYSIS OF Et_4NBH_4

DEIRDRE POWER and TREVOR R. SPALDING*
Department of Chemistry, University College, Cork, Ireland

(*Received* 11 *December* 1984; *accepted* 6 *February* 1985)

Abstract—The volatile intermediate Et_3NBH_3 was isolated during the thermolysis of Et_4NBH_4 at 185°C for 16 hr under dynamic vacuum. The rate of decomposition of Et_4NBH_4 was studied. Separate thermolyses of Et_4NBH_4 (or Et_3NBH_3) with *closo* $B_9H_9^{2-}$, *nido* $B_9H_{12}^-$, or *arachno* $B_9H_{14}^-$ did not produce $B_{10}H_{10}^{2-}$ as the major product. These results are inconsistent with the "build-up" mechanism previously proposed for the thermolytic convertion of BH_4^- to $B_{10}H_{10}^{2-}$ and a new mechanism is required.

The remarkable formation of the $[B_{10}H_{10}]^{2-}$ cluster by thermolysis of Et_4NBH_4 in the solid state at 185°C under atmospheric pressure was first reported almost 20 years ago.[1] The stoichiometry of the reaction is given in eqn (1). The yield of $B_{10}H_{10}^{2-}$ was 94%. No mechanism for the reaction has been established and any proposed mechanism has to explain the following,

(i) the production of only one borane product in high yield, $[B_{10}H_{10}]^{2-}$;

(ii) the conversion of monoanionic to dianionic species;

(iii) a sequence of steps from $[BH_4]^-$ to $[B_{10}H_{10}]^{2-}$ and recognise the possible intermediates involved;

(iv) effects due to the cation (note, when Me_4NBH_4 was thermolysed under identical conditions, methane and Me_3NBH_3 were the major products with only residual amounts of $[B_{10}H_{10}]^{2-}$, $[B_{11}H_{14}]^-$, and $[B_{12}H_{12}]^{2-}$).[1]

$$10Et_4NBH_4 \xrightarrow[16\,hr]{185°C} (Et_4N)_2B_{10}H_{10} + 8Et_3N + 8C_2H_6 + 11H_2 \quad (1)$$

In their original work, Makhlouf *et al.* proposed eqn (2) as the first step of the reaction,

$$Et_4NBH_4 \rightarrow Et_3NBH_3 + EtH. \quad (2)$$

They did not report the isolation of the Et_3NBH_3 intermediate or obtain any evidence for it. However the same reaction was later assumed to occur in a proposed sequential mechanism which involved BH_3 additions to $[BH_4]^-$ to give $[B_nH_{n+7}]^-$ and $[B_nH_{n+5}]^-$ anions (n = 2–12).[2] These anions were suggested to convert to the dianions $[B_nH_n]^{2-}$ (n = 6–12), but the mechanism was not discussed. It was also suggested that BH_3 reacted with $[B_nH_n]^{2-}$ (n = 6–10) to produce finally $[B_{12}H_{12}]^{2-}$. The observed selectivity to $[B_{10}H_{10}]^{2-}$ in the thermolysis of Et_4NBH_4 was not expained.

We have attempted to isolate and identify neutral intermediates in the thermolysis of Et_4NBH_4 and to investigate the steps from B_9-species to $[B_{10}H_{10}]^{2-}$. We compare our results with the previously proposed mechanism.

RESULTS AND DISCUSSION

The original thermolysis of Et_4NBH_4 was carried out at atmospheric pressure.[1] We decided to modify the experiment to study the thermolysis under dynamic vacuum conditions. Accordingly the reaction vessel was connected to a vacuum line *via* a liquid N_2 cooled trap which would retain the volatile compounds other than H_2 which are produced during the reaction. Thermolysis under these conditions produced $(Et_4N)_2B_{10}H_{10}$ as the major ionic product (> 85%) and Et_3NBH_3 (confirmed by IR, NMR and mass spectrum) which was the only volatile boron containing compound to be trapped. Triethylamine was also trapped as expected from eqn (1). There was no evidence for any other neutral borane being produced during the reaction. This is consistent with the reported lack of observation of $(Et_3NH)_2B_{10}H_{10}$ which may have been anticipated

* Author to whom correspondence should be addressed.

0.0	100.0
1.0	85.0
2.3	73.6
4.0	63.5
8.0	44.2
16.0	5.8

by deprotonation by Et_3N of the neutral borane $B_{10}H_{14}$ (which would be an expected product of thermolysis of lower boranes at 185°C).[1] In confirmation of the previous results,[1] no Et_3NH^+ salts were observed in the present study. It would appear that Et_3NBH_3 is the only neutral intermediate species responsible for the transformation of $[BH_4]^-$ to $[B_{10}H_{10}]^{2-}$ and all other intermediates are presumably ionic species.

The rate of loss of Et_4NBH_4, i.e. rate of production of Et_3NBH_3, was studied. The results shown in Table 1 were obtained by stopping the thermolysis at various time intervals and analysing the solid mixture for Et_4NBH_4 by IR and acid hydrolysis (H_2 gas evolution). The only compounds identified by IR were unreacted Et_4NBH_4, $(Et_4N)_2B_{10}H_{10}$ and $(Et_4N)_2B_{12}H_{12}$ as a minor product. Possible anionic intermediates such as $[B_2H_7]^-$, $[B_3H_8]^-$, etc. were not observed at any stage. Clearly Et_4NBH_4 is present during the 16 hr reaction time, suggesting that the production of Et_3NBH_3 is continuous.

A previously suggested mechanism contained steps involving the addition of "BH_3" to both mono- and dianions from $[BH_4]^-$ to $[B_{12}H_{12}]^{2-}$.[2] In order to explore the feasibility of some of these steps we studied the thermolyses of $[B_9H_9]^{2-}$, $[B_9H_{12}]^-$, and $[B_9H_{14}]^-$ salts and their cothermolyses with Et_4NBH_4 or Et_3NBH_3.

The *closo* $[B_9H_9]^{2-}$ system can be prepared by thermolysis of CsB_3H_8 at 200–230°C,[4] and hence is stable to thermolysis at 185°C. The dicaesium salt $Cs_2B_9H_9$ was recovered unchanged after heating at 185°C for 16 h with a 10-molar excess of Et_3NBH_3. This indicates that the conversion of $[B_9H_9]^{2-}$ to $[B_{10}H_{10}]^{2-}$ is not feasible under the conditions of the thermolysis of Et_4NBH_4. This result was somewhat surprising since previous work showed that reaction of $(NH_4)_2B_{10}H_{10}$ with excess Et_3NBH_3 at 190°C for 2 h gave a 27% yield of $(NH_4)_2B_{12}H_{12}$.[5] Similarly in the present work reaction of $(Et_4N)_2B_{10}H_{10}$ with excess Et_3NBH_3 at 185°C for 16 h gave 66% of the $[B_{12}H_{12}]^{2-}$ salt. The reason for the difference in the reactivity of $[B_9H_9]^{2-}$ and $[B_{10}H_{10}]^{2-}$ is not immediately obvious.

Thermolysis of the *nido* borane $Et_4NB_9H_{12}$ at 185–190°C produced only $(Et_4N)_2B_{12}H_{12}$. Cothermolysis of an equimolar mixture of $Et_4NB_9H_{12}$ and Et_4NBH_4 gave mainly $[B_{12}H_{12}]^{2-}$ with a proportion of $[B_{10}H_{10}]^{2-}$ equivalent to that expected from the thermolysis of Et_4NBH_4 alone. It appears probable that the borane anions reacted separately.

An alternative B_9-system, the *arachno* $[B_9H_{14}]^-$ ion was also studied. Thermolysis of either CsB_9H_{14} or $Et_4NB_9H_{14}$ alone produced $[B_{12}H_{12}]^{2-}$ salts as the predominant species. This result agrees with previously published work.[6] Cothermolysis of CsB_9H_{14} with a ten molar excess of $NaBH_4$ gave $CsB_{12}H_{12}$ and the $NaBH_4$ did not react. Cothermolysis of an equimolar mixture of $Et_4NB_9H_{14}$ and Et_4NBH_4 produced $(Et_4N)_2B_{12}H_{12}$ and an amount of $(Et_4N)_2B_{10}H_{10}$ equivalent to that expected from the thermolysis of Et_4NBH_4 alone.

In conclusion, during this investigation we have isolated Et_3NBH_3 as the only volatile boron containing intermediate in the thermolysis of Et_4NBH_4. With regard to the suggested build-up mechanism for the conversion of $[BH_4]^-$ to $[B_{10}H_{10}]^{2-}$ (and on to $[B_{12}H_{12}]^{2-}$) there does not appear to be a step involving conversion of a *closo*, *nido* or *arachno* B_9-species to $[B_{10}H_{10}]^{2-}$. Moreover the suggested mechanism would not explain the selective production of $(Et_4N_2)B_{10}H_{10}$ from $(Et_4N)BH_4$.

EXPERIMENTAL

Physical measurement

Infrared spectra were recorded as KBr disks or thin films between KBr plates on Perkin–Elmer 457 and 1310 spectrometers. Proton NMR were recorded on a Perkin–Elmer R20A spectrometer and ^{13}C spectra on a Jeol FX-60 spectrometer using Me_4Si as internal standard. Mass spectra were recorded on an AEI-Kratos 30–74 double beam spectrometer. Elemental analyses were carried out by the Analytical Laboratory, University College, Cork. Hydrogen gas analysis was carried out with a gas burette after samples had been hydrolysed by addition of 1.5 M sulphuric acid.

Materials

Tetraethylammonium borohydride,[7] Et_3NBH_3,[8] $(Et_4N)_2B_{10}H_{10}$, $(Et_4N)_2B_{12}H_{12}$,[1] $Cs_2B_9H_9$,[5] $(Et_4N)B_9H_{12}$,[9] CsB_9H_{14}, and $(Et_4N)B_9H_{14}$[10] were prepared as described in the literature.

Thermolyses

Reaction involving solids were carried out in a vacuum oven at $187 \pm 2°C$. Volatile products were collected in a liquid N_2 trap. Reactions involving Et_3NBH_3 were carried out at atmospheric pressure at 185°C. Separation of $B_{10}H_{10}^{2-}$ salts from $B_{12}H_{12}^{2-}$ was achieved using the method described in the literature.[1]

THE ^{35}Cl NQR SPECTRA AND STRUCTURE OF PENTAFLUOROPHENYLTETRACHLOROPHOSPHORANE, $C_6F_5PCl_4$

KEITH B. DILLON* and JAMES LINCOLN
Chemistry Department, University of Durham, South Road, Durham DH1 3LE, U.K.

(*Received* 9 *October* 1984; *accepted* 6 *February* 1985)

Abstract—The low temperature structure of $C_6F_5PCl_4$ was confirmed by ^{35}Cl NQR measurements as ψ-trigonal bipyramidal, with the C_6F_5 group axial. Discrepancies were found with previously reported data, and possible causes of these are discussed.

Pentafluorophenyltetrachlorophosphorane, i.e. $C_6F_5PCl_4$, may be readily prepared by chlorination of $C_6F_5PCl_2$; its ^{31}P NMR shift of -70.9 ppm in CH_2Cl_2/CD_2Cl_2 (50:50) suggests a five-coordinate molecular structure.[1] Fild and co-workers reported ^{35}Cl NQR signals for the compound at 34.4 and 27.1 MHz (77 K), in an approximately 3:1 intensity ratio, which they ascribed to the equatorial and axial chlorines respectively in a ψ-trigonal bipyramidal structure, with the C_6F_5 group occupying the remaining axial position.[1] We have recently reprepared $C_6F_5PCl_4$ (Experimental section), and obtained a ^{31}P NMR signal from the liquid (307.2 K) at -69.5 ppm, in very good agreement with the previous value. The compound is a liquid at room temperature, so ^{35}Cl NQR spectra can only be recorded at lower temperatures from the frozen material. At 77 K three equally intense signals were observed near 34.4 MHz (Table 1), with an average frequency of 34.38 MHz, but we could find no resonance near 27.1 MHz. A careful search showed the presence of a fourth, equally intense signal at 25.300 MHz, ascribed to the axial chlorine. The results are thus compatible with the previously deduced structure but there are significant differences, particularly for the lower frequency line. The most probable explanation is that the signal seen by Fild *et al.* at 27.1 MHz[1] is the ^{37}Cl resonance from the equatorial chlorines. The ^{37}Cl frequency calculated[2] from a ^{35}Cl resonance at 34.4 MHz is 27.1 MHz, and the isotopic ratio for $^{35}Cl:^{37}Cl$ is 3.07:1, in excellent agreement with the reported signal intensities. The reasons for our observation of three signals instead of one for the equatorial chlorines are less apparent. Our instrument may have shown better resolution, but the possibility of two different structural modifications of this compound at 77 K cannot be discounted, one form having all three chlorines crystallographically equivalent, and one showing three types of equatorial chlorines with minor crystallographic differences between them.

Four weak equally intense signals were also detected at 195 K (Table 1); the average frequency for the equatorial chlorines is 33.92 MHz. All resonances showed a normal temperature dependence, and there was no evidence of a phase transition between these temperatures. The structure of $C_6F_5PCl_4$ at 77 and 195 K is thus confirmed as ψ-trigonal bipyramidal, with the electronegative C_6F_5 group occupying an axial position.

EXPERIMENTAL

All manipulations, including NMR sample preparation, were carried out either *in vacuo* or under an inert atmosphere of dry nitrogen. Pentafluorophenyldichlorophosphine, $C_6F_5PCl_2$, was prepared via reaction of the Grignard reagent C_6F_5MgCl (obtained from C_6F_5Cl and Mg in Et_2O, with a small quantity of 1,2-dibromoethane as an initiator[3]) with PCl_3. The Grignard reaction was very slow. The ^{31}P NMR of the product showed the presence of some C_6F_5PClBr as well as $C_6F_5PCl_2$,

Table 1. ^{35}Cl NQR frequencies for $C_6F_5PCl_4$

T (K)	77	195
ν ^{35}Cl (MHz)	34.480	34.100
	34.380	33.900
	34.290	33.749
	25.300	25.085

* Author to whom correspondence should be addressed.

presumably because of the initiator used, but the former was converted to $C_6F_5PCl_2$ by treatment with Et_4NCl, followed by removal of tetraethylammonium salts. $C_6F_5PCl_2$ was then chlorinated in CH_2Cl_2 solution, and the product $C_6F_5PCl_4$ was obtained as a colourless liquid after removal of the solvent.

^{31}P NMR spectra were recorded at 307.2 K as described previously; [4] chemical shifts are quoted relative to external 85% H_3PO_4, with the downfield direction taken as positive. ^{35}Cl NQR spectra were also recorded as described in previous papers.[5,6]

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry. Fe—Organoiron Compounds. Part B12, Mononuclear Compounds. Edited by U. Krüerke and W. Petz, Springer, Berlin, 1984, ISBN 0-387-93500-2, 340 pp. 34 illus., DM1188, approx. $443.20.

It is nearly 30 years since the synthesis of the first cyclopentadienyl iron carbonyl compounds. Within the space of a generation, a vast number of these compounds have been prepared. The present volume represents a continuation of series B on the mononuclear organoiron compounds; the preceding volume, B11, concluded with compounds of type $(C_5H_5)Fe(CO)_2X$, where X represents a ligand bound through a group V element. Volume B12 completes the treatment of this type of compound by examining the derivatives where iron is bound to elements within groups IV (Si, Ge, Sn, Pb), III (B, Al, Ga, In), II (Mg) and transition metals, in successive sections. The impressive volume of derivatives involving the group IV elements could well present a considerable and indigestible bulk; this book, however, adopts a lucid treatment (aided by both empirical formula and ligand formula indexes). It successively examines synthetic routes, spectroscopic data, and reactions of the derivatives themselves. The properties of individual compounds are listed in clearly-arranged tables (appearance, m.p., b.p., NMR, IR, Mössbauer and UV parameters). Intelligibility is further aided by good structure diagrams, with molecular dimensions and angles, where appropriate. Compared to 77 pp. of compounds with iron—group IV bonds, the next section takes a mere 11 pp., which are mainly taken up with derivatives where the cyclopentadienyl iron carbonyl group is bound to a borane or carborane fragment.

The field of metal—metal bonds is now vast, but of the relatively small number involving the $(C_5H_5)Fe(CO)_2$ fragment, most involve bonds to Hg and Co. The IR data, necessary to comprehend structural possibilities particularly for bridged and non-bridged isomers of the cobalt compounds, are easily found.

The subsequent section involves compounds of the $^5LFe(CO)_2X$ type which do not contain unsubstituted cyclopentadienyl rings (e.g. methylcyclopentadienyl, 1,3-dimethylcyclopentadienyl, pentamethylcyclopentadienyl etc.), which are treated in a similar way (30 pp.), followed by 5 pp. dealing with derivatives with other dienyl ligands.

The importance of compounds containing the $[(C_5H_5)Fe(CO)_2L]^+$ *ion (and related systems)* is indicated by the 60 pp. that deal with them, again further subdivided according to the donor atom in the ligand L (successively O, S, N, P, As and Sb). Again the compounds are tabulated clearly, yet with further discussion of particular facets of the preparation and properties of individual compounds given subsequently.

The closing section (92 pp.) contains the immense number of σ-bonded organometallic compounds of type $(C_5H_5)Fe(CO)_2{}^1L$. Subdivision is according to the type of substituent, successively R = alkyl, halogen-substituted alkyl, alkyl groups containing group VI elements, then group V and group IV elements (presumably the remaining derivatives and aryls are to be continued in Vol. B13). Treatment follows that previously outlined, this time including compendia of kinetic data.

In summary, this volume, as usual, presents the accumulated material in readily assimilated form with literature coverage complete to the end of 1981 and with many key references into 1983. Iron is fortunate in its Gmelin treatment of organometallics; only the elements Au, Cu, Sb, Sn, Ti, U, Sc, Y and the lanthanides are anything like so up-to-date. The continued expansion in published research makes it increasingly difficult for the Gmelin philosophy of literature coverage on a "global" scale to be fulfilled, but that is no reason for criticism of their attempts to succeed.

HISTORICAL SKETCH

THE EARLY HISTORY OF COORDINATION CHEMISTRY IN AUSTRALIA

ANTHONY T. BAKER and STANLEY E. LIVINGSTONE*
School of Chemistry, University of New South Wales, Kensington, N.S.W. 2033, Australia

Although Prussian blue was discovered by the Berlin artists' colour maker, Diesbach, during the first decade of the eighteenth century and Lewis in 1763[1] reported the sparingly soluble potassium chloroplatinate, coordination chemistry is considered to have begun with the discovery of the cobaltammine $CoCl_3 \cdot 6NH_3$ by Tassaert in 1798.[2] During the next 50 years many "complex" compounds were reported, including potassium ferricyanide in 1822, Magnus's green salt, $[Pt(NH_3)_4][PtCl_4]$, in 1828, and the nitroprussides in 1849. In the ensuing 40 years large numbers of these "complex" compounds were reported, particularly by Jørgensen in Copenhagen, but it was not until 1893 that Werner[3] put forward a satisfactory explanation of the type of bonding present in these compounds. He proposed that in addition to the "primary" valency, which satisfied the chemical equivalence, a metal atom displayed a "secondary" valence, directed in space around the metal atom. This secondary valence or coordination number, usually 4 or 6, was satisfied by the requisite number of neutral molecules, such as NH_3, or negative ions, such as Cl^-, which were accommodated in an inner sphere about the metal atom. For his work Werner was awarded the Nobel Prize in 1913 and, although his active career spanned only 25 years, he published 174 papers and supervised some 200 PhD students. His concepts have remained the basis of coordination chemistry since 1893.[4]

Perhaps it is germane to review briefly the beginnings of science and chemistry in Australia. It now seems likely that the Portuguese naval captain Cristovão de Mendonça charted the entire east coast of Australia in 1524,[5,6] but the Dutchman Dirk Hartog is usually considered to be the first European to set foot in Australia. Hartog landed in 1616 on what is still a remote and arid region of Western Australia. However, it is to the English navigator James Cook that credit is given for the discovery of the fertile east coast of Australia. His voyage had been financed by the Royal Society, of which he was made a Fellow in 1776, in order to observe the transit of Venus in Tahiti on 3 June 1769. Having accomplished this, he was directed by the Royal Navy to explore the east Coast of New Holland, the name by which Australia was then known. He was accompanied by two botanists, the Swede Dr Solander and Joseph Banks, later to become President of the Royal Society for nearly 40 years. A tablet on the shore of Botany Bay, just south of Sydney, bears the inscription: "A.D. MDCCLXX. Under the auspices of British science, these shores were discovered by James Cook and Joseph Banks, the Columbus and Maecenas of their time. This spot once saw them ardent in the pursuit of knowledge..."

European colonization of Australia began with the establishment of a British convict settlement at Sydney Cove in January 1788. The Philosophical Society of Australasia was formed in 1821 and a few months later the newly arrived sixth governor of New South Wales, Sir Thomas Brisbane, became President of the Society. He was a keen astronomer and set up the first observatory in the colony. The Philosophical Society in 1866 became the Royal Society of New South Wales and continues to this day as a viable scientific society.

The University of Sydney was established in 1850 and one of the four Foundation Professors was John Smith, the first Professor of Chemistry in Australia. In 1874 Archibald Liversidge was appointed Professor of Chemistry, although Smith retained his Chair until 1881. Liversidge, in an academic career which extended until 1907, was active in research, particularly in the area which we would now call geochemistry, and he did much for the development of chemistry in Australia.[7] The University of Melbourne was founded in 1853. Chemistry instruction was begun in 1855 by Frederick McCoy, Professor of Geology and Mineralogy, but it was not

* Author to whom correspondence should be addressed.

until 1882 that John D. Kirkland was appointed to the first Chair of Chemistry in Melbourne.[8] In 1878 William A. Dixon was requested by the Committee of the newly formed Sydney Technical College to set up a chemical laboratory. In 1879 he commenced courses in chemistry and thus began the Sydney Technical College Chemistry Department, which in 1950 became the School of Chemistry in the University of New South Wales. Dixon remained in charge until his retirement in 1896 and published a number of papers on the chemical constituents of minerals and natural waters. One of his students in 1889 was Henry G. Smith who was the father of Australian phytochemistry.[9]

The University of Adelaide was established in 1874 and in 1885 the University appointed Edward H. Rennie as its Foundation Professor of Chemistry, the first Australian-born occupant of a chair of chemistry. Rennie was an organic chemist and worked on essential oils of Australian flora.[7] Other Australian universities were established: Tasmania (1890), Queensland (1909), Western Australia (1911), Australian National University (ANU) (1946) and New South Wales (1949). Between 1954 and 1974 another 11 were founded, so that there are now 19 universities in Australia, all of which have Departments or Schools of Chemistry.

It seems that the earliest research in coordination chemistry performed in Australia was by Masson and Steele at the University of Melbourne in 1898. Professor Sir David Orme Masson (1858–1937) was born and educated in Britain; he occupied the Chair of Chemistry in the University of Melbourne from 1886 to 1924. In his inaugural lecture in March 1887 he stated: *A School of Chemistry*! That is what it should be. Not a mere adjunct to one particular technical training . . . a school . . . permeated by the atmosphere of Research."[8] He did much to raise the status of chemistry in Australia and was the founder of the Royal Australian Chemical Institute in 1917. In their paper "The blue salt of Fehling's solution and other cuprotartrates" published in 1899, Masson and Steele[10] proved by electrolytic experiments that the deep blue colour of Fehling's solution was due to an anionic copper species. They isolated the K, Ag, Ba and Pb salts of the complex anion $[Cu_4C_{12}H_9O_{19}]^{3-}$. Apparently this early work on coordination chemistry was not extended further until 1920 (see below). Bertrand Dillon Steele later worked with William Ramsay at University College, London, and became the Foundation Professor of Chemistry at the University of Queensland.

Coordination chemistry can be said to have begun in Sydney in 1919 when E. E. Turner was appointed Lecturer in Chemistry at the University of Sydney. Eustace Ebenezer Turner (1893–1966) (Fig. 1) during

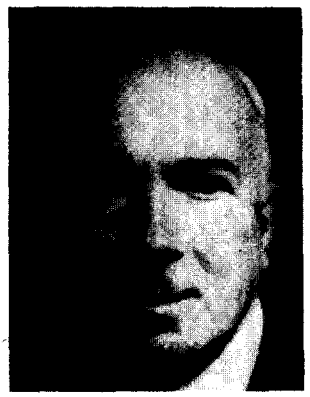

Fig. 1. Eustace Turner.

the First World War had been research assistant at Cambridge to Professor W. J. (later Sir William) Pope, who was a member of the Chemical Warfare Committee. The German Army had begun to use shells containing phenylarsonic acid, $PhAsO(OH)_2$, diphenylarsinous chloride, Ph_2AsCl, and phenylarsinous dichloride $PhAsCl_2$. Turner and Pope worked on the synthesis of arsines but the work was confidential and was not published until 1920 when it appeared in a paper entitled "Triphenylarsine and diphenylarsenous salts".[11] In Sydney Turner began a collaborative research effort with George Joseph Burrows (1888–1950) who had been appointed to the staff at the University of Sydney in 1919. Chemistry in Sydney at that time was under Charles Edward Fawsitt (1878–1960), a former pupil at Ostwald. Fawsitt succeeded Liversidge to the Chair of Chemistry in 1907 and retained it until 1946. Although no longer doing original work himself, he encouraged his staff to do research.

The first conjoint work by Burrows and Turner, "The constitution of the nitroprussides. Part I. Conductivity and cryoscopic measurements", was published in *J. Chem. Soc.* in 1919.[12] They showed conclusively that the nitroprussides contain the $[Fe(CN)_5NO]^{2-}$ ion and not a dimeric anion as had been previously proposed. Another paper, "A new type of compound containing arsenic", described addition compounds of the type $R_1R_2R_3As \cdot RAsI_2$.[13] In their next publication, "Compounds containing arsenic as a centre of optical activity",[14] they reported the optical resolution of phenyl-α-naphthylbenzylmethylarsonium ion, the first resolution of an arsenic compound to be achieved. A short paper entitled "Some additive compounds derived from arsines" reported the isolation of $PhMe_2As \cdot MI_3$ (M = P, As, Sb, Bi), $2PhMe_2As \cdot SnI_4$, $[PhMe_3As]_2[CdI_4]$ and $[PhMe_2EtAs][MI_3]$ (M = Hg, Pb).[15]

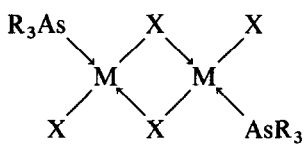
Although metal–arsine complexes had been reported in 1854,[16] this was the first work done in Australia in this area and Turner had aroused in Burrows a deep interest in metal–arsine complexes which was to be further developed in Sydney. Burrows and Turner published two more papers, one on the alkylation of nitroprussic acid[17] and the other on ferrioxalates.[18]

In 1921 Turner returned to England. In 1923 he became Senior Lecturer in Chemistry at East London (later Queen Mary) College, where he and his energetic research student Raymond J. W. Le Fèvre worked on the orientation of electrophilic substitution in biphenyl compounds, publishing 11 papers together in the period 1926–1928. Le Fèvre was later to become a Fellow of the Royal Society and Professor of Chemistry at Sydney from 1946 to 1970. Thus, although Turner spent only 2 years in Sydney, his influence was profound. In 1928 Turner went to Bedford College for Women, London, as Head of the Department of Organic Chemistry and his research interests thereafter were concentrated in organic chemistry. He was elected FRS in 1939 and became Professor and Head of Department at Bedford College in 1946 until his retirement in 1960; he was the author of 164 publications.[19]

Meanwhile at the University of Melbourne Masson in 1920 put his research students Packer and Wark to work on cupritartrates, the problem on which he and Steele had worked 22 years before. This resulted in a publication, "Cupritartrates",[20] which confirmed Masson and Steele's results and reported the isolation and identification of several complex cupritartrates. John Packer (1899–1971) entered the University of Melbourne in 1917 and became a Lecturer in Chemistry at Canterbury University College, Christchurch, New Zealand, in 1923 and its Professor in 1944.

Ian William (later Sir Ian) Wark was to become one of Australia's most distinguished scientists. He was born in 1899 and, like Packer, entered the University of Melbourne in 1917. In 1921 he was awarded an 1851 Exhibition Overseas Scholarship to University College, London, where, under the supervision of Professor F. G. Donnan, he gained his PhD in 1923, doing further research on copper complexes of hydroxy acids. This work was published in three papers: "Cuprilactates", "Cuprimalates", and "Constitution of cuprimalates and analogous compounds".[21] In the third paper of this series Wark made the somewhat remarkable statement: "Ordinary views of primary valance lead to a satisfactory explanation of the structure (of these complexes) without recourse to Werner's ideas on inner complexes". Wark spent a short time in Bragg's laboratory gaining some knowledge of X-ray crystallography. In 1924 he worked with Professor G. N. Lewis at the University of California, Berkeley, where he increased his understanding of thermodynamics and its application to solution chemistry. In 1925 he spent a year as Lecturer in Chemistry at the University of Sydney and collaborated with Burrows on salicylato complexes.[22]

In 1926 Wark returned to Melbourne as research chemist with the Electrolytic Zinc Company, where he completed his investigations on copper complexes of hydroxy acids.[23,24] In a paper in 1927 he applied the concept of free energy to galvanic cells.[25] He also investigated the distribution coefficients of inorganic compounds such as $Fe(NCS)_3$ and $HgCl_2$ in water and organic solvent mixtures.[26] However, in 1929 his interests changed to surface chemistry and his work on flotation processes for sulfide ores was widely recognized throughout the world. His book *Principles of Flotation*[27] became the standard work on the subject. In 1939 he was appointed Chief of the Australian Commonwealth Scientific and Industrial Research Organization (CSIRO) Division of Industrial Chemistry and was Director of CSIRO (1958–1960). He was H. G. Smith Medallist (1933) and Leighton Medallist (1966) of the Royal Australian Chemical Institute (see Fig. 2) of which he was President in 1958.



In Sydney Burrows continued research on metal complexes. Following on from his work with Turner on ferrioxalates,[18] Burrows established the exact constitution of $Na_3[M(C_2O_4)_3]\cdot 5H_2O$ (M = Fe, Cr, Al)—over which there had been some confusion in the literature—and investigated their dissociation.[28] Several iodobismuthites, $[BiI_6]^{3-}$, of organic bases[29] and further work on complex oxalates of aluminium were reported, including an unsuccessful attempt to resolve the ion $[Al(C_2O_4)_3]^{3-}$.[30]

In 1933 Burrows took up work again on metal–arsine complexes, a line of research he had begun with Turner some 13 years previously and which he was to follow for the remainder of his career. The silver complexes $[Ag(Ph_2MeAs)_2]X$ (X = Cl, Br, I)[31] and the copper complexes $[Cu(Ph_2MeAs)X]$ (X = Cl, Br, NO_3), $[Cu(PhMe_2As)X]$ (X = Br, I), $[Cu(PhMe_2As)_2]X$ (X = Cl, I) and $Cu_2X_3(Ph_2MeAs)_3$ (X = Cl, Br)[32] were isolated and the platinum complexes $[Pt(Ph_2MeAs)_2Cl_2]$ and $[Pt(PhMe_2As)_2X_2]$ (X = Cl, Br) were obtained in two isomeric forms, one soluble in toluene, the other in chloroform.[33] Complexes of zinc, cadmium and mercury were prepared: viz. $[Zn(R_3As)_2X_2]$ (R_3As = Ph_2MeAs, $PhMe_2As$; X = Br, I), $PhMe_2As\cdot ZnCl_2$,[34] $R_3As\cdot CdX_2$ (X = Cl, Br, I),[35] $[Hg(R_3As)_2X_2]$ and $R_3As\cdot HgX_2$ (X = Cl, Br, I).[36] The 1:1 complexes $R_3As\cdot MX_2$ (M = Zn, Cd, Hg)

Fig. 2. The Governor General of Australia, Lord Casey (left) presenting the Leighton Medal to Dr I. W. Wark, Canberra, 19 August 1966.

are probably dimeric with the tetrahedral halogen-bridged structure (**I**):

I

Complexes of 8-aminoquinoline with iron, cobalt, nickel and copper and the phthalic acid complexes $Na_2[M(C_6H_4C_2O_4)_2]\cdot 2H_2O$ (M = Co, Cu) were described.[37] Apart from this work and some papers dealing with arsines,[38] Burrows did not publish any more research papers. However, in 1940 he was the Royal Society of New South Wales Liversidge Lecturer and his published lecture, "Organic arsenicals in peace and war", is an excellent review of arsines and arsine–metal complexes.[39] In the 1930s Burrows lectured on coordination chemistry to third-year undergraduates at the University of Sydney and he so interested one of these students in 1936 that he worked with Burrows on an honours project on metal–arsine complexes in 1937. The student's name was Ronald Nyholm, who was to have a significant influence on coordination chemistry in Australia, Britain and elsewhere. Burrows' health was declining and he retired on medical grounds in 1941.

David Paver Mellor (1903–1980) (Fig. 3) was born in Launceston, Tasmania, and graduated from the University of Tasmania in 1924. He was appointed Lecturer in Chemistry in the University of Sydney in 1929 and promoted to Reader in Inorganic Chemistry in 1946. His lifelong interest was in the structure of inorganic compounds and metal complexes. In 1931 he undertook supervision of a brilliant graduate student, Francis Patrick Dwyer (1910–1962) (Fig. 4). Dwyer's initial interest was in organic chemistry in which he hoped to specialize. As an undergraduate he had investigated the reaction of potassium dichromate, aniline and sodium nitrite

Fig. 3. David Mellor.

Fig. 4. Frank Dwyer.

which led to an improved method for the preparation of pure diazoaminobenzene;[40] this work was published 2 years later.[41] Mellor and Dwyer were to do a great deal in the development of coordination chemistry in Australia.

Mellor's early interest lay in X-ray crystallography and his first three papers—all with Dwyer—viz. "The crystal structure of indium", "The occurrence of β-cristabolite in Australian opals", and "An X-ray study of opals",[42] were in this area. For his MSc degree Dwyer worked on glyoximato complexes of palladium and succeeded in isolating *cis* and *trans* isomers of bis(benzylmethylglyoximato)palladium(II).[43] This was an important contribution to coordination chemistry, since controversy still existed concerning the stereochemistry of four-coordinate palladium(II) and platinum(II). In 1934 Dwyer became Lecturer in Inorganic Chemistry at Sydney Technical College where he commenced active research in chemistry; little research had been done in chemistry at Sydney Technical College since William Clunies Ross's death in 1914.[9]

Mellor and his students continued work on metal complexes, using a variety of physical techniques including refractive index, X-ray diffraction, optical resolution and magnetic susceptibility measurements and stability determinations.[44–50] In 1938 Mellor went to California to work with Linus Pauling. Upon his return to Sydney in 1940 he introduced the ideas contained in Pauling's book *The Nature of the Chemical Bond* into the teaching of inorganic chemistry and into his own research and subsequently his writings show Pauling's influence. In two papers of a five-part series, "Magnetic studies of coordination compounds",[51–53] Mellor and Craig reported the magnetic moments of 37 nickel and 21 cobalt complexes with the chromophores: O_4, O_2N_2, N_4, N_2S_2, O_2S_2 and S_4. These were important data at the time, as the authors attempted to explain the preference for high- or low-spin behaviour on the basis of the chromophore (i.e. the donor atom grouping). David Parker Craig did his MSc under Mellor's supervision; later he occupied chairs of Physical Chemistry at the University of Sydney, University College, London, and the Research School of Chemistry, ANU, Canberra, and became a Fellow of the Royal Society and of the Australian Academy.

In three papers, "The significance of large angle distortions in relation to the stereochemistry and magnetic properties of quadricovalent metals", "The stereochemistry of some metallic complexes with special reference to their magnetic properties and the Cotton effect", and "A study of the magnetic behaviour of complexes containing the platinum metals", Mellor gave a lead in the clarification of the rather muddy area of the magnetic behaviour of transition metals.[54] His review, "The stereochemistry of square complexes",[55] based on his Presidential Address to the Royal Society of New South Wales in 1942,[56] became the standard reference work in this area for many years. For this and his other work on metal complexes Mellor was awarded the DSc degree by the University of Tasmania.

In two important publications[57] Mellor and Maley established that the stability sequence for bivalent metals in complexes with oxygen and nitrogen donors is: Pd > Cu > Ni > Co > Zn > Cd > Fe > Mn > Mg. These papers preceded the publication of the classic work of Irving and Williams,[58] who showed that the sequence for the first transition series is: Mn < Fe < Co < Ni < Cu > Zn. Additional papers followed reporting the paramagnetism of tungsten bronzes[59] and the crystal structures of $K_2[PtF_6]$,[60] $K_2[RuCl_6]$[61] and Zeise's salt, $K_2[PtCl_3(C_2H_4)] \cdot H_2O$, in which it was shown that the C—C axis of the ethylene ligand is perpendicular to the plane containing the $PtCl_3$ grouping.[62]

In 1955 Mellor accepted the Foundation Chair of Inorganic Chemistry in the University of New South Wales and the following year became Head of the School of Chemistry, a position he held until his retirement in 1968. During this period this was the largest School of Chemistry in Australia and this position took up much of his time so that he did no more active research. He was the author of several books, including *The Rôle of Science and Industry in Australia in the War of 1939–1945*;[63] the writing singlehanded of this large work of 738 pages occupied his efforts over several years in the early 1950s. Upon Dwyer's death he took over the editing of *Chelating Agents and Metal Chelates*,[64] a book

with contributions by Mellor, Dwyer, Nyholm, and a number of their former students and colleagues. His historical work, *The Evolution of the Atomic Theory*,[65] was published in 1971 and his "Chemistry of chelation and chelating agents"[66] was published just prior to his death in January 1980. Mellor made considerable contributions to education and held many honorary positions in this field, such as Chief Examiner for Science and Chairman, Syllabus Committee, N.S.W. Higher School Certificate. He was the recipient of many honours, including the H. G. Smith Medal (1949), the Liversidge Medal (1951), and the Leighton Medal (1969) of the Royal Australian Chemical Institute and the Dwyer Memorial Medal (1969) of the University of New South Wales Chemical Society. An earnest and quietly spoken man not without a sense of humour, he and his contributions to education are commemorated by the endowment in 1972 by the University of New South Wales of the Mellor Lecture and Medal for Chemical Education.

Shortly after his appointment as Head Teacher of Inorganic Chemistry at Sydney Technical College in 1934, Frank Dwyer began an investigation of the reactions of diazoamino compounds with metallic salts to produce highly coloured "lakes", which are loose coordination complexes chemisorbed at the surface of metal hydroxides.[67] Using these reactions, Dwyer devised a number of micro-analytical tests for metals such as magnesium, cobalt, copper, zinc and cadmium; the work was reported in 18 papers in *J. Soc. Chem. Ind.* and *J. Proc. Aust. Chem. Inst.* in the period 1936–1939. This was followed by four papers on furfuraldoxime as a ligand[68] and two papers on diazoaminobenzene complexes.[69]

In 1940 Ronald Sydney Nyholm (1917–1971) (Fig. 5) was appointed to the chemistry staff at Sydney Technical College. He was born in Broken Hill, an isolated mining town in a semi-desert area in New South Wales, some 1200 km west of Sydney. In Broken Hill streets have the names of minerals, metals and acid radicals: *inter alia*, Blende, Cobalt, Chloride, Bromide and Sulphide Streets are to be found there. Nyholm's grandfather, Erik Nyholm (1850–1887), was born in Nykaleby, Finland, and had migrated to Adelaide, South Australia, in 1873. Ronald Nyholm valued this Finnish connection and he took great pleasure in his election in 1959 as a Corresponding Member of the Finnish Chemical Society.[70]

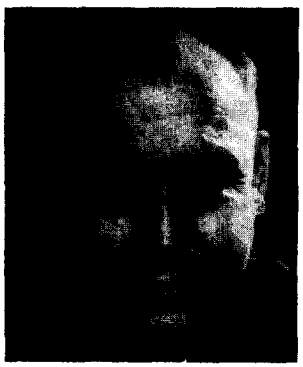


Fig. 5. Sir Ronald Nyholm.

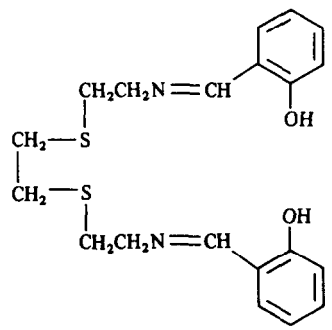
Dwyer with his enthusiasm and experimental skills and Nyholm with his keen interest in coordination chemistry and experience with arsines, gained from Burrows, developed not only a good working combination, but a close personal friendship. With a heavy teaching load, very limited resources, and a small quantity (5 g) of rhodium they set to work. In a 10-part series, "The chemistry of bivalent and trivalent rhodium",[71,72] they reported a number of Rh(III) and Rh(II) complexes with arsines, pyridine, dimethylglyoxime and dimethylsulfide. The Rh(II) complexes, prepared by reduction with hypophosphorous acid, included such compounds as the halogen-bridged dimeric compounds $[RhX_2(Ph_2MeAs)_3]_2$ (X = Cl, Br, I). The presence of Rh(II) in these diamagnetic complexes was later questioned, since Rh(II) would be expected to have one unpaired electron, and a reinvestigation in 1960 by Lewis, Nyholm and Reddy[73] showed that at least some of these compounds are hydrido complexes of Rh(III). This should not be taken as a criticism of the early work of Dwyer and Nyholm, since hydrides of transition metals were unknown at that time. It is noteworthy that hydride complexes of rhodium have been extensively used as catalysts in the organic chemical industry. The Rh(IV) complex $Cs_2[RhCl_6]$, which was found to be isomorphous with $(NH_4)_2[PtCl_6]$, was also reported.[72] In a four-part series, "The chemistry of bivalent and trivalent iridium",[74,75] Dwyer and Nyholm reported the Ir(III) complexes $[IrX_3(Ph_2MeAs)_2]_2$ and $H[IrX_4(Ph_2MeAs)_2]$ and the Ir(II) complexes $[IrX_2(Ph_2MeAs)_3]_2$ (X = Cl, Br, I); the latter are no doubt hydrido complexes of Ir(III). The standard redox potentials for $[IrCl_6]^{3-}/[IrCl_6]^{4-}$ and $[IrBr_6]^{3-}/[IrBr_6]^{4-}$ were reported as 1.017 and 0.99 V, respectively.

Some papers with Gibson followed, describing the use of quaternary arsonium salts and their coordination compounds with bismuth, cadmium and cobalt as analytical reagents.[76] Neville Gibson later joined the staff of Sydney University and became an Associate Professor of Inorganic Chemistry. Nyholm and Dwyer continued work on arsines, reporting complexes of Ru(III), Ru(II), Os(III) and Os(II) with Ph_2MeAs.[77,78] The stability constant of $[Fe(phen)_3]^{2+}$ and the redox potentials of the systems $[Ru(phen)_3]^{3+}/[Ru(phen)_3]^{2+}$,



$[OsBr_6]^{3-}/[OsBr_6]^{4-}$ and $[OsCl_6]^{3-}/[OsCl_6]^{4-}$ were determined.[79–81] This work brought to a close the collaboration of Dwyer and Nyholm at Sydney Technical College. It had been a most fruitful collaboration, not only because of the intrinsic value of the work but also because of the pattern it set within the Chemistry Department, which soon after became the School of Chemistry in the University of New South Wales. Ever since the early 1940s research in coordination chemistry has been vigorously pursued within this Department.

In 1945 the University of Sydney awarded the DSc degree to Dwyer for his thesis entitled "The diazoamino compounds and their metallic salts and metallic hydroxide lakes". It was the first DSc in chemistry awarded by the University in nearly 20 years. In January 1946 Dwyer accepted a position as Senior Lecturer in Inorganic Chemistry at Sydney University. And in 1947 Nyholm was awarded an Imperial Chemical Industries Fellowship to work with Professor C. K. Ingold, later Sir Christopher Ingold, in the William Ramsay and Ralph Forster Laboratories at University College, London.

Soon after his arrival at the University of Sydney Dwyer began a productive collaboration with Frank Lions. Francis Lions (1901–1972) was Dux of Sydney High School in 1918, coming first in Chemistry and second in Physics in the New South Wales Leaving Certificate examinations. He won an Exhibition bursary to the University of Sydney, where he represented the university at rugby football and graduated in 1923 with First Class Honours and the University Medal in Chemistry and also in Organic Chemistry. He was awarded an 1851 Science and Research Scholarship to the University of Manchester where he gained his PhD in organic chemistry. He then spent a year on post-doctoral research at Brasenose College, Oxford. He was appointed Lecturer in Chemistry at Sydney University in 1926 and promoted to Senior Lecturer in 1944 and to Reader in 1946, retiring in 1966.

Lions was a popular lecturer, emphasizing the essential points with clarity. He had breadth of vision not only in science but also in humanity. He was considerate of students needs, being an elected representative of the graduates on the University Senate (1949–1959) and a strong and early advocate of the establishment of a Student Health Service.

In 1946 Lions was President of the Royal Society of New South Wales and had published 56 papers in its journal. All but two of these were in the area of organic chemistry, the two exceptions being "1-Hydroxyacridine as a chelate compound"[82] and "Coordination compounds derived from nicotinylacetone".[83] Dwyer, Lions and others had discussed the possibility of synthesizing a sexadentate chelating agent. Owing to the Second World War many European journals of the war period were not available in Australia in 1946 and the work of Brinzinger on the sexadentate function of ethylenediaminetetraacetic acid was not known to the group at Sydney University. Accepting the challenge, Lions set out to synthesize a sexadentate and soon succeeded in producing 1,8-bis(salicylideneamino)-3,6-dithiaoctane (**II**) ($H_2ONSSNO$).[40] Dwyer reacted **II** with cobalt acetate and isolated the Co(III) complexes [Co(ONSSNO)]X (X = Cl, I, NO_3, ClO_4) and succeeded in resolving the cation by treating the chloride with silver *d*-α-bromocamphor-π-sulfonate and precipitating the *d*- and *l*-iodides, which, after several recrystallizations, gave molar rotations of $\pm 50{,}160°$.[84] This was the highest molar rotation recorded up to that time.

II

Dwyer became interested in complexes of group VIII metals with 1,10-phenanthroline and 2,2′-bipyridyl.[85–87] He then began in earnest to develop his skill in resolving metal complexes into their optical isomers. He was fortunate in acquiring Nora Gyarfas as a research student. Eleonora Clara Gyarfas was born in Hungary and was a graduate of the University of Budapest; she had migrated to Australia after the war. In 1948 she began work with Dwyer and in 1951 was one of the first two PhD graduates from the University of Sydney. (The first Australian PhD was awarded in 1948 by the University of Melbourne to R. H. Myers, later Sir Rupert Myers, Vice-Chancellor, University of New South Wales, 1969–1981.) After gaining her PhD degree, she worked as a Teaching Fellow in the School of Chemistry and between 1949 and 1957 no less than 32 papers appeared under the name of Dwyer and Gyarfas. She left Australia in 1955 to go to the University of Illinois, where she worked with Professor John C. Bailar, Jr. She married Dr C. Liu of the University of Michigan and they now live in Chicago.

In their first paper Dwyer and Gyarfas reported the resolution of $[Ru(phen)_3]^{2+}$ and showed that the

enantiomorphous forms were stable and could be oxidized to $[Ru(phen)_3]^{3+}$ with retention of optical activity.[88] The resolutions of $[Ru(bipy)_3]^{2+}$, $[Ni(phen)_3]^{2+}$, $[Fe(phen)_3]^{2+}$ and $[Os(bipy)_3]^{2+}$ were also achieved.[89,90] The optical resolution of $[Os(bipy)_3]^{2+}$ was the first recorded resolution of an osmium compound. In an ingenious experiment they showed the existence of electron transfer and dynamic equilibrium between oxidized and reduced forms of complex ions.[91] Previously this had been demonstrated with the ions $[Co(en)_3]^{2+}$ and $[Co(en)_3]^{3+}$ by the use of radioactive cobalt. Dwyer and Gyarfas mixed equimolar solutions of *d*-$[Os(bipy)_3]^{2+}$ and *l*-$[Os(bipy)_3]^{3+}$. In the absence of electron transfer the optical rotation of the mixture would be expected to be the algebraic sum of the rotations of the two solutions before mixing. It was found that the mixture rapidly lost all optical activity, indicating the existence of the following equilibria:

$$d\text{-}[Os(bipy)_3]^{2+} \rightleftarrows d\text{-}[Os(bipy)_3]^{3+} + e,$$

$$l\text{-}[Os(bipy)_3]^{3+} + e \rightleftarrows l\text{-}[Os(bipy)_3]^{2+}.$$

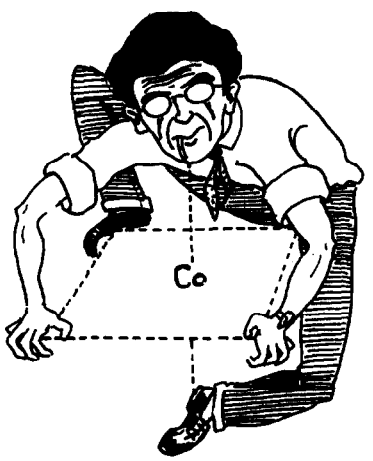
By lowering the temperature they were able to slow down the rate of exchange and show how such a technique could be used to determine reaction rates. They also prepared the optical isomers of $[Fe(bipy)_3]^{2+}$, $[Os(phen)_3]^{3+}$ and $[Os(bipy)_3]^{3+}$ by oxidation of the *d*- and *l*-forms of the bivalent metal complexes.[92]

Dwyer and Gyarfas discovered the phenomenon of configurational activity: briefly, the phenomenon is that, although both *d*- and *l*-forms of a complex ion normally have the same thermodynamic activity coefficient, in the presence of another optically active ion these activity coefficients are different. They predicted that configurational activity should be of biological importance, since the rates of many enzyme processes should be changed by the addition of inert optically active complex ions.[93] With these thoughts in mind, Dwyer became interested in what is now called bioinorganic chemistry and reported on a preliminary investigation of the biological activity (toxicity to mice) of some complex ions such as the *d*- and *l*-forms of $[Co(en)_3]^{3+}$ and $[Os(bipy)_3]^{2+}$.[94]

Dwyer and Lions did further work on sexadentates, preparing ligands similar to **II** but with three in place of two methylene groups in the N—S chains and resolving the metal complexes and measuring their magnetic moments.[95] One of the research students engaged in this work was Naida Gill who became a Senior Lecturer in Chemistry at the School of General Studies, Australian National University, Canberra. Another of Dwyer's students at this time was Alan McLeod Sargeson who is now Professor of Inorganic Chemistry, Research School of Chemistry, ANU and a Fellow of the Australian Academy and a Fellow of the Royal Society (London).

In 1954 Dwyer spent a year as Visiting Professor at Northwestern University, Evanston, Illinois, and was also George Fisher Baker Lecturer at Cornell University. Not long after his return to Sydney he was appointed to a new Chair at Pennsylvania State University. This was a major blow to inorganic chemistry in Australia. Many of his contemporaries thought that his work had not been fully recognized in Australia; nevertheless he had been awarded the Rennie Medal (1940) and the H. G. Smith Medal (1945) of the R.A.C.I. and the David Syme Medal of the University of Melbourne (1953) and he was Liversidge Lecturer in 1959. A group of people including Dr I. W. Wark of CSIRO sought means of retaining Dwyer in Australia and, with financial assistance from CSIRO, the Australian National University offered him the position of Reader in Biological Inorganic Chemistry within the John Curtin School of Medicine. Dwyer accepted this position without ever taking up the post in Pennsylvania. At a farewell function at Sydney University prior to his departure for Canberra Dwyer was presented with a caricature of himself as a sexadentate coordinated to a cobalt atom (see Fig. 6). It was drawn on the spot by Graham Hunt, a postgraduate student working with Dr Ian Ross.

As it is our intention in this historical review to deal with matters only up until 1954, Dwyer's subsequent career will be briefly summarized. In 1960 he was offered a Personal Chair at ANU and in 1961 he was elected Fellow of the Australian Academy. He continued his research on optical activity and stereospecificity while at the same time



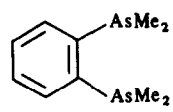


Fig. 6. Frank Dwyer as a sexadentate.

becoming involved in investigating the biological activity of complex ions. He died suddenly at his home in June 1962 at the age of 51. During his career he was the author of 160 papers and his book *Chelating Agents and Metal Chelates*[64] was published posthumously in 1964.

Frank Dwyer above all else was a highly skilled experimenter and spent long periods at the laboratory bench. His enthusiasm was infectious and, as Keith Sutherland once said, he gloated over each new compound establishing a record for optical rotation. He was admired and respected by colleagues and students for his depth of chemical knowledge and his sense of humour. His friends and former students in the University of New South Wales Chemical Society established the Dwyer Memorial Lecture Fund. Table 1 lists eminent chemists who have delivered the Dwyer Lectures. The first was given by his close friend and former colleague Ron Nyholm (see also Fig. 7).

Nyholm was awarded his PhD by the University of London in 1950 for research on metal complexes of tertiary arsines. In 1948 he met Joseph Chatt, a former student of F. G. Mann, who had prepared the diarsine *o*-phenylenebisdimethylarsine (**III**) in 1939.[96] Nyholm wanted to prepare dimeric halogen-bridged complexes of Fe(III) which would be soluble in organic solvents; he had attempted to make such complexes with arsines R_3As but without success. Chatt suggested that he use the diarsine **III**. Nyholm prepared the diarsine but he did not obtain the iron complexes he was seeking. However, he did obtain a range of transition metal complexes of the diarsine, including complexes of Ni(III) and Ni(IV), thus opening up a new area of coordination chemistry.[97]

III

In 1950 Ingold appointed Nyholm on his staff as a lecturer. On 21–22 September 1950 he attended a Discussion on Coordination Chemistry, organized by Joe Chatt at the Butterwick Research Laboratories of ICI Ltd at The Frythe, Welwyn, U.K. Papers were read by N. V. Sidgwick (Oxford), F. G. Mann (Cambridge), G. Schwarzenbach (Zürich), H. Irving (Oxford), R. S. Nyholm (University College, London), J. Chatt (ICI), R. G. Wilkins (ICI), K. A. Jensen (Copenhagen), L. E. Orgel (Oxford), A. F. Wells (ICI) and L. E. Sutton (Oxford); others in attendance included A. Albert (ANU), D. P. Craig (University College, London) and J. S. Anderson (AERE, Harwell, U.K.). This historic meeting came to be regarded as the Ist International Conference on Coordination Chemistry. These conferences have been held at approximately 2-year intervals ever since at venues all around the world, including XII Sydney, Australia (1969), XVIII São Paulo, Brazil (1977), and XX Calcutta, India (1979).

In February 1952 Nyholm returned to the University of New South Wales School of Chemistry, which until 1950 had been the Chemistry Department, Sydney Technical College. His effect on the inorganic chemistry staff was immediate and profound. He brought back the fresh ideas of what he called the "Renaissance of inorganic chemistry" taking place overseas. The teaching of inorganic chemistry was updated and a new enthusiasm for

research was engendered. The lecturers and research students affected were: G. A. Barclay, C. M. Harris, S. E. Livingstone, R. L. Martin, R. J. Irving, L. N. Short, G. J. Sutton, J. R. Backhouse, B. N. Figgis, B. M. Gatehouse, E. A. Magnusson and N. C. Stephenson. Gordon Barclay became Foundation Professor of Chemistry and later Pro-Vice-Chancellor, Macquarie University; Ray Martin became, in turn, Professor of Inorganic Chemistry at the University of Melbourne and the Research School of Chemistry, ANU, Canberra, and Vice-Chancellor, Monash University; Stanley Livingstone succeeded David Mellor as Professor of Inorganic Chemistry, University of New South Wales; Laurence Short became Professor of Education and later Pro-Vice-Chancellor, Newcastle University (N.S.W.); and Brian Figgis became Professor of Inorganic Chemistry, University of Western Australia. All owe a heavy debt to Nyholm. Martin's and Figgis's interest in magnetochemistry stemmed from Nyholm's influence in this period.

Nyholm was promoted to Associate Professor in 1953 and in the same year received the Corday Morgan Medal of The Chemical Society. In 1954 he was President of the Royal Society of New South Wales and received his DSc (London). In February 1955 he left Australia to accept a Chair of Chemistry at University College London. He had spent only 3 years in Sydney, yet in that time he had taken coordination chemistry out of one rut and put it in another. During that period he supervised several PhD students and published four important reviews, viz. "Stereochemistry and valence states of nickel",[98] "Magnetism and inorganic chemistry",[99] "The stereochemistry of complex compounds",[100] and "Magnetism and stereochemistry".[101]

At University College Nyholm soon built up a flourishing research group which attracted PhD and postdoctoral students not only from Britain but from the United States, Australia, New Zealand, India and elsewhere. After Ingold's retirement and the early death of his successor Edward Hughes in 1963, Nyholm became Head of the Chemistry Department. He received many honours: Tilden Lecturer (1961), Liversidge Lecturer of The Chemical Society (1967), and President of The Chemical Society (1968–1970); during his tenure of office he saw the amalgamation of the Society with the Faraday Society, the Royal Institute of Chemistry and the Society for Chemical Industry. He was knighted in 1967. He also became active in the area of chemical education and played a leading rôle in the launching of a new journal, *Education in Chemistry*, and in the organization of the large (6000 pp.) work, *Comprehensive Inorganic Chemistry*.[102] His publications numbered 278. He was killed in a motor car accident near Cambridge in December 1971 at the age of 54.

Many tributes were paid to Nyholm. Sir Jack Lewis once said to one of the authors (S.E.L.): "When you talk to him (Nyholm), he makes you feel that you are the most important guy around." Professor Jim Millen of University College, London, wrote: "He

was the master of the general survey and could condense and bring order to the large areas of chemical knowledge." Lord Annan, Provost of University College said at Nyholm's Memorial Service: "Ron Nyholm never entered a room, he bubbled into it and exploded into good fellowship, mirth and happiness." David Craig wrote: "He had warmth, sympathy, humour, great kindness and vitality. He had star quality... and reserves of energy seemingly without limit."[70] One of us stated: "He was probably the noblest person associated with this School (of Chemistry at the University of New South Wales) and he always maintained a close relationship with it."[9]

Let us return to Melbourne. After Wark's work on copper complexes of hydroxy acids in the 1920s, interest in coordination chemistry died. In 1939 John Stuart Anderson was appointed Senior Lecturer. He had a brilliant record as an undergraduate and research student at Imperial College, London, and had done research on nitrosyl–carbonyl complexes and isotopic exchange reactions of cobaltammines.[103] In 1941 he was awarded the Grimwade Prize in Industrial Chemistry for work on the recovery of indium from industrial by-products. In 1942 he and Keith Sutherland were engaged on research for the Defence Department's munitions laboratory at Maribyrnong, Victoria. He published two papers on the kinetics of interchange of hydrogen isotopes with cobaltammines and tetrammine complexes of Pd(II) and Pt(II), although some of this work was done at Imperial College.[104] However, during this period in Melbourne Anderson's main interests were in solid state chemistry, including crystal lattice defects, semi-conductors and non-stoichiometric compounds. Among his research students were Norman N. Greenwood and Thomas A. O'Donnell, now Professor of Inorganic Chemistry at Melbourne. In 1942 he delivered the Liversidge Lecture entitled, "Chemistry of the earth".[105] In 1947 Anderson left Melbourne to take up a senior position at the AERE (Harwell, U.K.).

The arrival of Gordon M. Harris from Saskatchewan as Senior Lecturer in 1947 introduced radiochemistry into the Department. Harris's research was concerned with radio-isotopic studies of exchange mechanisms, particularly in regard to cobaltammines.[106] He attracted among his students Donald Richard Stranks and they published several papers on the mechanism of exchange reactions of $^{14}CO_3^{2-}$ with $[Co(NH_3)_4CO_3]^+$.[107,108] In 1953 Harris left Melbourne to go to the University of Buffalo, New York. James F. Duncan was appointed Senior Lecturer in 1953 and continued research, in radiochemistry but not in the same area. Stranks became Professor of Inorganic Chemistry, first at the University of Adelaide (1964–1973), then at the University of Melbourne (1973–1977) and Vice-Chancellor, University of Adelaide (1977).

Anderson, now a Fellow of the Royal Society, returned to Melbourne in 1954 as Professor of Chemistry. His research interests were still mainly in the area of solid state chemistry rather than coordination chemistry. He resigned the Chair in 1959 and went to the National Chemical Laboratory (Teddington, U.K.). He became Professor of Inorganic Chemistry at Oxford and was awarded the Davy Medal of the Royal Society in 1973.

Stuart Walter Pennycuick (1887–1966) was born in Blackall, Queensland, and graduated MSc from the University of Queensland in 1920. He was appointed Lecturer in Physical Chemistry at the University of Adelaide in 1922 and was later promoted to Reader, retiring in 1952. He carried out research on colloidal sols of platinum and gold, confirming that $H_2[Pt(OH)_6]$ is the strong acid present in solutions of colloidal platinum prepared by the Bredig method.[109] In a later paper[110] he showed that $H_2[Pt(OH)_6]$ is present in the micelles of a sol prepared by the Bredig method, accounting for 27% of the total mass of the micelle. Although this work was essentially physical chemistry, it was the first research relating to coordination chemistry done at the University of Adelaide.

Inorganic chemistry at Adelaide was taught by William Ternent Cooke from around 1910 until 1948. Cooke was an analytical chemist and taught applied chemistry without any reference to coordination chemistry. It is therefore somewhat surprising that Bruce West, who graduated from Adelaide in 1948, should have become interested in coordination chemistry. West was appointed Lecturer in Inorganic Chemistry at the University of Adelaide in 1950. He did research under the formal supervision of Pennycuick, working on stabilities of cobalt complexes and exchange reactions with radioactive ^{60}Co and gained his PhD in 1953. He then took leave to go to Cambridge to work in Professor H. J. Emeléus's laboratory under the supervision of Robert N. Haszeldine.[111] He obtained his Cambridge PhD in 1955 and upon his return to Adelaide worked on Schiff-base complexes.[112,113] His subsequent work included pyrromethene complexes, solvent extraction and electron-transfer reactions.[114] He was promoted to Reader in 1962 and in 1964 accepted the Chair of Inorganic Chemistry at Monash University, Clayton, Victoria.

At the University of Queensland in 1950 coordination chemistry was taught by Ian Lauder to Chemistry III students but it appears that no research in coordination chemistry was done before

the arrival of Ronald Arthur Plowman as Senior Lecturer in June 1951. Plowman was a graduate of Sydney Technical College (1941) and was appointed to the staff of Sydney Technical College in 1945. He gained his BSc (London) by external study. With Dwyer's encouragement he began research in 1948 on complexes of platinum and palladium[115,116] and obtained his PhD (London) externally in 1951, after travelling to London to be given a *viva voce* by W. Wardlaw. After his arrival in Queensland, Plowman worked on polarography of platinum complexes[117] and synthesis of substituted 1,10-phenanthrolines.[118]

There seems to have been no research in genuine coordination chemistry at the University of Western Australia before 1962. However, with the arrival of Donald W. Watts (1962), Brian N. Figgis (1963), David L. Kepert (1965) and Allan H. White (1966) research in this area rapidly developed in Perth. Similarly, at the University of Tasmania it began after the return of Peter W. Smith in 1960 after working with Nyholm at University College.

No history of the development of coordination chemistry in Australia would be complete without the name of Adrien Albert, FAA. Albert was born in 1907 and was educated at Scots College, Sydney, and gained his BSc from the University of Sydney and PhD Med. from London University. He was on the staff of the School of Pharmacy at the University of Sydney (1938–1947) before going to London to join the research staff at the Wellcome Research Institute. In 1949 he was appointed Professor of Medical Research in the John Curtin School of Medical Research, ANU, Canberra, a post he held until his retirement in 1973. Subsequently he was Research Professor at the State University of New York at Stony Brook (1975–1977). Albert's research interests were primarily in pharmacology as indicated by his book *Selective Toxicity—The Physico-Chemical Basis of Therapy*,[119] yet he has made considerable contributions to coordination chemistry.

As early as 1944 Albert had suggested[120,121] that oxine (8-hydroxyquinoline) owes its bactericidal and fungicidal action to metal chelation, a hypothesis which struck an unfamiliar note at the time. It was shown that the antibacterial activity of 1-hydroxyacridine was also due to its ability to chelate to metabolically important metals.[122,123] He determined stability constants for complexes of a number of metals with the amino acids cysteine and histidine and the anti-tuberculosis drug isoniazid.[124,125] In the mid-1950s Douglas D. Perrin, a New Zealander, joined Albert's staff and determined stability constants of Fe(III) and Fe(II) complexes of amino acids.[126]

On 25–26 May 1953 a Conference on Coordination Compounds was held at the University of Sydney. After an introduction by I. W. Wark (CSIRO), review-type papers were presented by D. P. Craig (Sydney), R. S. Nyholm (N.S.W.), L. N. Short (N.S.W.), D. P. Mellor (Sydney), D. D. Brown (Colonial Sugar Co. Ltd), N. R. Davies (N.S.W.), E.C. Gyarfas (Sydney), G. A. Barclay (N.S.W.), B. J. Ralph (N.S.W.), W. A. Rawlinson (Melbourne) and N. A. Gibson (Sydney). The full text of these reviews was published.[127] The fact that over 100 people attended all the sessions showed that coordination chemistry was being actively pursued at least in the state of New South Wales. It is at this point that we have chosen to end our detailed historical narrative.

Within the next decade research in coordination chemistry was going on in all six states of Australia and in Canberra. Consequently, on 18–19 May 1964 an Australian Conference on Coordination and Metal–Organic Chemistry was held at the Royal Society of Victoria Building in Melbourne. It was

Table 2. Royal Australian Chemical Institute Coordination and Metal–Organic Chemistry Division Conferences

VII	1984	D. L. Kepert

decided at this conference to form within the Royal Australian Chemical Institute a Coordination and Metal–Organic Chemistry Division, which would organize regular conferences. The first conference was held the following year. Table 2 lists the venues and dates of these conferences.

In 1974 it was decided to make an award for scientific work in the field of inorganic chemistry, the major portion of which was done in Australia, published in the previous 10 years. The successful candidate is required to deliver a lecture at the Division Conference. The lecture was to be known as the G. J. Burrows Lecture. The Burrows Lecturers are listed in Table 3. It is fitting that Burrows should be remembered in this way. And in the School of Chemistry at the University of New South Wales in 1972 three lecture theatres were named: Dwyer, Nyholm and Mellor.

MOLECULAR COMPLEXES OF ARYLTELLURIUM(IV) CHLORIDES

M. V. GARAD
Department of Chemistry, University of Poona, Pune 411 007, India

(*Received* 30 *April* 1984; *accepted* 13 *September* 1984)

Abstract—The synthesis and spectroscopic study of molecular complexes of type $[RTeCl_3 \cdot L]$ and $[RTeCl_3 \cdot 2L]$, where R = phenyl, 4-phenoxyphenyl and L = pyridine, pyridine-*N*-oxide, tri-*n*-octylphosphine oxide, 1,10-phenanthroline and 2,2′-bipyridyl are reported. These compounds were characterised by their IR spectra, elemental analysis and conductivity data. The conductivities in acetonitrile shows the non-electrolytic behaviour of these hygroscopic compounds which are monomeric in boiling benzene.

Tellurium tetrachloride, like tin and titanium tetrachlorides, forms molecular addition complexes with various neutral molecules containing O, S, N and P donor atoms with sites available for coordination by base.[1,2] Tellurium tetrachloride forms 1:1 and 1:2 molecular complexes. Several workers in this field have inferred the structure of these compounds on the basis of their X-ray crystallographic, spectroscopic conductivity and elemental analysis data. The octahedral configuration with *trans*-tetramethylthiourea groups around tellurium has been found in hexacoordinated derivatives of tellurium tetrahalides with tetramethylthiourea, which was studied earlier.[3,4]

Though several reports are found for molecular addition complexes of tellurium tetrachloride very little literature is available for alkyl- and aryltelluriumtrichloride. Molecular complexes of tetramethylthiourea with methyltelluriumtrihalide have been reported.[5] These monomeric complexes have been suggested to have a square pyramidal structure and are examples of five-coordinated tellurium. We have undertaken the study of molecular complexes of phenyltelluriumtrichloride and 4-phenoxyphenyltelluriumtrichloride with various O, N, P donor molecules, in continuation of our earlier work on chelated derivatives of aryltellurium chlorides.[6]

The geometry around tellurium in 1:1 complexes, i.e. M:L, where M = phenyltelluriumtrichloride, L = bidentate ligand, and 1:2 complexes, i.e. M:L, where M = 4-phenoxyphenyltelluriumtrichloride, L = monodentate ligand, is found to be octahedral. The coordination of the ligand is confirmed by IR spectra and conductivity data. All these compounds are readily obtained by mixing and refluxing solutions of the reactants in benzene in suitable molar ratios.

EXPERIMENTAL

All experiments were carried out using dry and distilled solvents and N_2 atmosphere. IR spectra were recorded as Nujol mulls on a Perkin–Elmer 599 B grating spectrometer. The conductivity measurements in acetonitrile were carried out using a modified Toshniwal conductivity bridge. Molecular weight was determined using Gallenkamp semimicro ebulliometer in the concentration range 0.3–1% (w/v).

The phenyltelluriumtrichloride and 4-phenoxyphenyltelluriumtrichloride were prepared as reported earlier.[7,8] The molecular complexes were prepared as follows.

Preparation of phenyltelluriumtrichloride bis-pyridine complex (1:2 *complex*)

Phenyltelluriumtrichloride (0.622 g, 0.002 mol) and pyridine (0.316 g, 0.004 mol) were mixed in benzene (50 cm^3) and refluxed for 3 h. The solution was then concentrated under reduced pressure to obtain crystals of desired product, which were washed with hexane and dried in vacuum at 60°C. The compound is hygroscopic, soluble in benzene and chloroform, insoluble in hexane. Yield: 0.75 g (79.95%).

Found: C, 40.50; H, 3.05; Te, 27.15; Cl, 22.7%. Calc. for $C_6H_5TeCl_3 \cdot 2C_5H_5N$: C, 40.94; H, 3.19; Te, 27.21; Cl, 22.68%.

Other molecular complexes were prepared using 1 : 2 molar ratios in case of monodentate donors.

Preparation of 4-phenoxyphenyltelluriumtrichloride 1,10-phenanthroline complex (1 : 1 complex)

4-Phenoxyphenyltelluriumtrichloride (0.80 g, 0.002 mol) and anhydrous 1,10-phenanthroline (0.36 g, 0.002 mol) were mixed in benzene (60 cm^3) and refluxed for 2.5 h. The solution was then concentrated under reduced pressure to obtain crystals of product which were washed with 3 cm^3 of hot benzene 3–4 times in order to remove some unreacted ligand impurity. The compound is dried under reduced pressure at 60°C.

The compound is hygroscopic, insoluble in benzene, chloroform and in hexane, sparingly soluble in hot benzene. Yield: 0.90 g (77.6%).

Found: C, 49.23; H, 2.90; Te, 21.85; Cl, 18.21%. Calc. for $C_6H_5OC_6H_4TeCl_3 \cdot C_{12}H_8N_2$: C, 49.40; H, 2.91; Te, 21.88; Cl, 18.22%.

Other molecular complexes were prepared using 1 : 1 molar ratio in the case of a bidentate donor like 2,2′-bipyridyl.

Analytical data of all these compounds are as reported in Table 1.

RESULTS AND DISCUSSION

Vibrational spectra

Compounds of the type $RTeCl_3 \cdot 2L$, R = *phenyl*, L = *pyridine*. The C=C and C=N stretching vibrations of pyridine were seen at 1590 cm^{-1}, after the complex formation the C=N and C=C stretching vibrations are split to 1615 and 1590 cm^{-1} which indicates the coordination of the C=N group to the central tellurium atom and hexacoordinated structure resulted.

L = *pyridine-N-oxide*. In pyridine-*N*-oxide C=C vibrations are observed at 1580 cm^{-1}, C=N at 1500 cm^{-1} and N–O at 1260 cm^{-1}. There is no appreciable change in the C=C absorption after the complex formation, but the C=N and N–O bands are seen at 1490 and 1245 cm^{-1} respectively as a result of coordination of the ligand through its oxygen to the metal atom.

L = *tri-n-octylphosphine oxide*. The absorption due to P=O of the ligand is seen in the region 1350–1260 cm^{-1}. This band is shifted to 1220 cm^{-1} as a result of complex formation. The coordination of the ligand to the central tellurium atom takes place through phosphoryl oxygen.

Compounds of the type $RTeCl_3 \cdot L$, L = *2,2′-bipyridyl*. In the free 2,2′-bipyridyl molecule, the C=C and C=N are observed at 1570 and 1420 cm^{-1}. New bands are observed at 1575 and 1405 cm^{-1} as a result of complex formation. The out-of-plane C–H bonding vibrations of the ligand are seen at 750 cm^{-1}. This band is split and seen at 715 and 760 cm^{-1}. This observation indicates the bidentate nature of 2,2′-bipyridyl. Similar behaviour is also observed in the 1,10-phenanthroline complex.

The hybridization of the tellurium atom in aryltellurium trichloride changes from sp^3d to sp^3d^2 in these complexes. It was observed that pyridine, pyridine-*N*-oxide and tri-*n*-octylphosphrine oxide formed 1 : 2 complexes while 1,10-phenanthroline and 2,2′-bipyridyl formed 1 : 1 complexes. The lone pair of electrons on tellurium act in an inert way in

* Aryl group = phenyl or 4-phenoxyphenyl.

these complexes and geometry remains octahedral, which is also evidenced in bis-tetramethylthiourea-telluriumtetrachloride complex.[4] X-ray crystal structure of above complexes will be reported in a forthcoming communication of this series. All reactions gave well defined products, which are hygroscopic and sparingly soluble in organic solvents. The conductivity measurement on modified Toshniwal conductivity bridge in acetonitrile shows that these complexes are non-ionic in nature. Similar behaviour was also observed for 4-phenoxyphenyltelluriumtrichloride complexes.

Acknowledgements—I am indebted to Drs Sarada Gopinathan and C. Gopinathan Scientists, National Chemical Laboratory, Pune 8, for helpful discussion. I thank Council of Scientific and Industrial Research for award of Scientist Pool. My sincere thanks are due to Prof. A. J. Mukhedkar for his encouragement and to the Head, Department of Chemistry for giving necessary facilities.

REACTION OF *TRANS*-$[Co(en)_2(SO_3)(H_2O)]^+$ WITH IMIDAZOLE AND IMIDAZOLE CONTAINING LIGANDS

H. F. REXROAT and N. S. ROWAN*
Department of Chemistry, The American University, Washington, DC 20016, U.S.A.

(*Received* 13 *March* 1984; *accepted after revision* 24 *September* 1984)

Abstract—*trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ reacts with imidazole (ImH) and imidazole containing ligands (L) to form *trans*-$[Co(en)_2(SO_3)L]^+$ in the pH range 6.0–9.0. The complex seems to react both in the hydroxy and in the aquo form. The rate constant for the reaction of imidazole with the aquo form is 6.0 ± 0.7 and $4 \pm 1\ M^{-1}\ s^{-1}$ for the reaction with the hydroxy form at 25°C. The apparent equilibrium constant for formation of the imidazole complex at pH 7 is consistent with the value of 3×10^2 measured previously. Appreciable amounts of complex form only in the pH 6–9 range. Above pH 9 NMR spectra show that even the immediate products are different. In aged solutions at all pHs other products form.

Because of the interest in labelling proteins with substitution inert metal ions,[1–5] we have investigated the reaction of *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ with imidazole and other imidazole containing ligands. Although the *trans* effect is more common in square planar complexes, it is found for some octahedral cobalt(III) complexes,[6] and the sulfite group produces a strong *trans* effect in *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ and causes it to react rapidly with ligands. In fact, sulfite has been found to have the strongest *trans* effect of a number of sulfur containing ligands.[7] Yandell and Tomlins have already investigated the reaction of *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ with imidazole and other ligands at pH 7.00.[8] Based on the curvature of their rate plots at high ligand concentration, they suggested that the reaction occurs by an ion-pair dissociative interchange mechanism. Stranks and Yandell have investigated the reactivity of *trans*-$[Co(en)_2(SO_3)(OH)]$[9] and Harris *et al.* have investigated the reaction of $[Co(en)_2(H_2O)(OH)]^{2+}$ with SO_2 to form O bonded sulfite.[10] In order to be useful for labelling proteins, the complex must bind rapidly to the protein at a reasonable pH, and then become substitution inert. With this in mind, we looked at the products of the reaction of the *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ with imidazole and imidazole-containing compounds in the pH range 7–10 both immediately and after ageing, studied the kinetics of the reaction with imidazole in the pH range 6–9 and finally looked at the ease of oxidation of coordinated sulfite to sulfate.

EXPERIMENTAL

Synthesis

trans-$[Co(en)_2(SO_3)(H_2O)]ClO_4$, was prepared by the method of Baldwin.[11] The *trans*-$[Co(en)_2(SO_3)(ImH)]ClO_4$ was prepared by the action of 1.5 mole excess of imidazole on the aquo complex dissolved in a minimum volume of water. Crystals formed after adding solid $NaClO_4$ to the solution and letting it cool in ice for several minutes. The crystals were filtered and washed with ethanol and ether. Purity of the crystals was determined by Co(II) analyses by the method of Kitson,[12] and spectrophotometrically. The λ_{max} for the Co(III) imidazole complex was 452 nm ($\varepsilon = 162$).[8] Our values of ε were within 5% of this value. Reagent grade imidazole and sodium perchlorate were used.

Ion exchange

Ion exchange chromatography using Dowex 50-X4 100–200 mesh resin in the Na^+ form was chosen for product analysis of aged solutions. Known solutions of

$$[Co(en)_2(SO_3)(ImH)]^+, [Co(en)_2(SO_3)(H_2O)]^+$$

and $[Co(en)_2(ImH)(H_2O)]^{3+}$ were chromatographed using 0.1–1 M sodium perchlorate as eluant at pH = 7.5 and then UV–VIS spectra were run to determine the absorption maximum of each fraction. These results were compared to solutions of $[Co(en)_2(SO_3)(H_2O)]^+$ plus imidazole, at equal concentrations at pH 7.5 or pH 8.4, which were aged 20 days, chromatographed and the spec-

trum of the resulting fractions determined with a UV–VIS spectrophotometer. Solutions of $[Co(en)_2(SO_3)(H_2O)]^+$ plus *N*-methylimidazole, l-histidine or methyl l-histidine were aged at pH 7 and 9 and then treated as the imidazole-containing solutions.

Potentiometric determinations

pK_a determinations of imidazole and *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ were done by potentiometric titration with standard hydrochloric acid and sodium hydroxide. Generally, solutions were maintained at 1.0 M ionic strength with sodium perchlorate. A Fisher Accumet pH Meter with a NaCl combination electrode was used for all measurements. The electrode was standardized with buffers at the temperature of the titration. A constant temperature bath was used to maintain constant temperature through the titration.

Kinetics

Rate constants were measured by using a Durrum stopped flow apparatus. Experiments were done using 4.00×10^{-3} M *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ and varying the imidazole concentration between 0.050 and 0.40 M. Most solutions were 1.0 M in $NaClO_4$. Absorbance changes were measured at 430 nm and the rate constants were calculated by computer. Reported rate constants are the average of at least six determinations. All solutions were adjusted for pH prior to the reaction and checked afterwards.

Proton NMR spectra were obtained on a Bruker WP-80 spectrometer. Chemical shifts are reported in δ relative to trimethylsilylpropanesulfonic acid (DSS) as internal standard. All spectra were run in D_2O and pH adjustments were done with NaOD and DCl. (pH values are uncorrected for D_2O solution.)[13]

Equilibrium studies were done using Job's method where the total imidazole plus complex concentration was 5.0×10^{-3} M. The wavelength used for the determinations was 433 nm. All UV–VIS spectra were run on either a Cary 14 or a Varian DMS 90 Spectrophotometer.

RESULTS AND DISCUSSION

trans-$[Co(en)_2(SO_3)(H_2O)]^+$ reacts rapidly with imidazole, *N*-methylimidazole, l-histidine and methyl l-histidine, according to eqn (1):

$$[Co(en)_2(SO_3)(H_2O)]^+ + L \rightleftharpoons [Co(en)_2(SO_3)L]^+ + H_2O. \quad (1)$$

Only the reaction of the aquo complex with imidazole had been studied before[8] and a crystal structure of the product had been determined. The crystal structure showed the bond distance for the *trans* ligand was 0.04 Å greater than the *cis* ligand bond distance.[14] Because spectral changes were small, the products for the reaction of *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ with L were difficult to characterize by UV–VIS spectroscopy. For the bisethylenediamine sulfito complexes, the range for λ_{max} is between 475 and 430 nm for the lowest energy ligand field band. The λ_{max} for each of the above complexes was respectively 452, 451, 454 and 455 nm. It was easier to identify the coordinated ligands using ^1H NMR spectroscopy. The ^1H spectrum of each ligand with *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ was measured at pH 8. The chemical shifts of the coordinated imidazoles are given in Table 1. The chemical shifts found in Table 1 are at lower field positions than those found for *trans*-$[Co(en)_2(OH)(ImH)]^{2+}$ where for C_2–H δ equals 8.15, C_4–H, $\delta = 7.40$ and C_5–H, $\delta = 7.12$ ppm,[15] which may be due to electron donating effect of the sulfite ligand or the longer Co–N bond. At pH 8 the reaction with imidazole appears to be complete yielding only the imidazole complex. The same results are found for *N*-methylimidazole. With l-histidine the NMR spectrum showed very little coordination through the pyridine type nitrogen of the imidazole ring (about 16%) even though the reactions with imidazole and *N*-methylimidazole were favorable. However, at pH 8 the carboxyl group of the histidine is deprotonated and also probably binds to the Co(III) center, although this product cannot be detected spectrophotometrically or by NMR spectroscopy. To prevent coordination with the carboxyl group, methyl l-histidine was used. Once the carboxyl group was blocked, the product formed by coordination almost exclusively through the pyridine type nitrogen of the imidazole group. Little competition from the amine nitrogen was

Table 1. ^1H NMR chemical shifts for L in *trans*-$[Co(en)_2(SO_3)L]$ at pH 8

	Chemical shift*		
L	C_2–H	C_4–H	C_5–H
Imidazole	8.40	7.56	7.47
N-methylimidazole	8.29	7.48	7.41
l-Histidine	8.34		7.28
Methyl l-histidine	8.31		7.25

* Ppm relative to DSS.

found as it is mostly protonated at this pH. Consequently, the Co–sulfito complex might be expected to react with imidazole nitrogens in proteins as long as there are few deprotonated carboxyl groups to compete with.

A more thorough study of the reaction of *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ with imidazole was done and compared to the earlier work done by Yandell and Tomlins.[8] From their kinetic results they had found an equilibrium constant at 25°C and pH 7 of 3×10^2 for reaction (1). The equilibrium was studied three different ways in this work, kinetically, by ^1H NMR and spectroscopically by Job's method. The expression for K_{app} is given in eqn (2):

$$K_{app} = \frac{[trans\text{-}Co(en)_2(SO_3)(ImH)^+]}{[Co(III)_{free}][Im_t]} \quad (2)$$

$$Co(III)_{free} = trans\text{-}[Co(en)_2(SO_3(H_2O)]^+ + trans\text{-}[Co(en)_2(SO_3)OH];$$

$$Im_t = ImH + ImH_2^+$$

and the reaction in eqn (3):

$$Co(III)_{free} + ImH \underset{k_r}{\overset{k_f}{\rightleftharpoons}} trans\text{-}[Co(en)_2(SO_3)(ImH)]^+. \quad (3)$$

The kinetic results (below) show that $k_f \gg k_r$ in the pH 6–9 range and therefore K_{app} is large. Errors in the Job's method determinations are high because absorbance changes were small but K_{app} was found to be 3×10^2 at pH 6.15, 2×10^3 at pH 7.1, 3×10^2 at pH 7.70 and 3×10^2 at pH 8.8. Temperature seemed to have little effect on the equilibrium position.

Again, ^1H NMR studies gave the most detailed analysis of the products of the reaction although minor imidazole containing species were not detected. For the range pH 6–9.0, the only imidazole resonances apparent in the NMR spectrum in freshly prepared solutions of *trans*-$[Co(en)_2(SO_3)(ImH)]^+$ are those characteristic of free imidazole and those of the complexed imidazole (Table 2). At pHs 7 and 8 no free imidazole is apparent in the spectrum, indicating that K_{app} is >300, assuming the minimum amount of free imidazole that can be detected is 5% of the initial complex concentration. The chemical shifts of the complexed imidazole peaks do not change in the pH range 6–10 although new peaks start to appear in the spectrum at pHs above 9.0. (See Table 2.)

From the relative intensities of the peaks at pH 9.5, we suggest that the second set may be due to bridging imidazole. Above pH 10, the peaks of the original coordinated imidazole are absent. Between pH 10 and 11, a third set of peaks appears, all of which have approximately equal intensities and constant chemical shifts. This implies the formation of a third type of imidazole complex. Above pH 11, very little imidazole complex of any kind forms and the NMR spectrum shows mostly free imidazole. The imidazole sulfito complex does not show the usual NMR titration behavior for coordinated imidazole where there is a gradual change in chemical shift of the imidazole protons with change in pH.[15,16] Instead, it appears that the deprotonated imidazole, if it forms, is an excellent ligand and undergoes further coordination in the solution. Bridging imidazoles with Ru(II) and Co(III) have been synthesized in basic solutions.[17]

The NMR spectra of the freshly prepared solutions of *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ and imidazole showed that in the pH range 6–9 only free imidazole and $[Co(en)_2(SO_3)(ImH)]^+$ were present. Therefore, the kinetics of reaction (1) could be studied in this pH range.

The results of the kinetics runs showed the rate law is rate $= k_{obs}[Im_t][Co(III)_{free}]$ at all pHs in this range and all temperatures with no limiting rate at high ligand concentration or dependence of rate on

* Error on pH is ±0.1.

† Each rate constant is the average of at least six individual determinations; errors are standard deviations on the average values.

‡ These experiments were done to check the effect of ionic strength.

ionic strength in the 1.0–1.4 M range (Table 3). Rate constants at pH 7 and 25°C agree with those found previously by Yandell and Tomlins.[8] Plots of k_{obs} vs $[Im_t]$ appear to have a zero intercept which implies no contribution to k_{obs} from the aquation reaction (k_r). Slopes of the k_{obs} vs $[Im_t]$ plots gave values of the forward rate constant, k_f (Table 4). The immediate reaction seems to proceed according to eqn (3) which can be written as a two-path reaction:

$$trans\text{-}[Co(en)_2(SO_3)(H_2O)]^+ + ImH \underset{k_{r'}}{\overset{k_{f'}}{\rightleftharpoons}} trans\text{-}[Co(en)_2(SO_3)(ImH)]^+ + H_2O; \quad K' \quad (4)$$

$$trans\text{-}[Co(en)_2(SO_3)(OH)] + ImH \underset{k_{r''}}{\overset{k_{f''}}{\rightleftharpoons}} trans\text{-}[Co(en)_2(SO_3)(ImH)]^+ + OH^-; \quad K'' \quad (5)$$

$$trans\text{-}[Co(en)_2(SO_3)(H_2O)]^+ \rightleftharpoons trans\text{-}[Co(en)_2(SO_3)(OH)] + H^+; \quad K_c \quad (6)$$

but $k_{r'} \ll k_{f'}$ and $k_{r''} \ll k_{f''}$. The expression for k_{obs} for this mechanism shows that:

$$k_{obs} = \frac{k_f K_a}{K_a + [H^+]}[Im_t] \quad (7)$$

$$k_{obs} = \left[\frac{k_{f'}[H^+] + k_{f''}K_c}{K_c + [H^+]}\right]\left[\frac{K_a}{K_a + [H^+]}\right][Im_t] \quad (8)$$

$$K_a = \frac{[ImH][H^+]}{[ImH_2^+]}. \quad (9)$$

pK_a values for imidazole and *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ in 1.0 M sodium perchlorate were measured under the conditions of the kinetics experiments. At 20, 25 and 30°C, the values were 7.05, 7.02 and 6.98, respectively, for imidazole, and 9.04, 8.96 and 8.95, respectively, for *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$. They had previously been determined to be 7.12[18] and 9.27[19] at 25°C. ΔH^0 for both dissociations was small.

Using experimental values of K_c, K_a and k_f, values of $k_{f'}$ and $k_{f''}$ can be calculated, and are reported in

* Slope from graph of k_{obs} vs Im_t concentration and calculated from a linear least squares program. In this work:

$$\text{slope} = \frac{k_f K_a}{K_a + [H^+]} = \left(\frac{k_{f'}[H^+] + k_{f''}K_c}{K_c + [H^+]}\right)\frac{K_a}{K_a + [H^+]}.$$

From Yandell and Tomlin's assumption:

$$\text{slope} = \left(\frac{k_M[H^+]}{[H^+] + K_c}\right)\frac{K_a}{K_a + [H^+]}.$$

† Calculated from slope $\frac{K_a + [H^+]}{K_a}$ (see *).

‡ Average of k_f for pH 6 and 7.

§ Calculated from $\frac{k_f(K_c + [H^+]) - k_{f'}[H^+]}{K_c}$ at pH 8.9.

‖ Calculated from second equation in *.

Table 4. The results show that k_f reaches a maximum between pH 7 and 8 and then decreases at pH 9. Yandell and Tomlins' mechanism which does not account for the reaction of $[Co(en)_2(SO_3)(OH)]$ with the incoming ligand, consequently predicts that k_f will increase with increasing pH although at pH 7 their value of k_f is $5.5 \pm 0.3\ M^{-1}\,s^{-1}$ and ours is $6.2 \pm 0.1\ M^{-1}\,s^{-1}$ (see Table 4). Yandell and Tomlins studied the reaction between *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ and a number of ligands at pH 7 and neglecting the reaction with the hydroxy complex can be justified for several reasons. First, the value of the K_c shows that very little hydroxy complex exists at this pH and, secondly, comparisons between the aquo (positively charged) complex and hydroxy (neutral) complex show negatively charged ligands react with the aquo complex with a rate constant that is two orders of magnitude larger.[9] At pH 7, imidazole was the only neutral ligand in the previous study and the rate constant for the reaction with the neutral ligand was two orders of magnitude less than the reaction with negative ligands.[8] Because of this slower reaction with a neutral ligand and because at pHs 8 and 9 substantial amounts of the hydroxy complex were present, the reaction with the hydroxy form also had to be considered in our studies. For many complexes both the aquo and hydroxy forms react with incoming ligands.[6]

Ion-pairing constants for the neutral ligand, imidazole, with the positive aquo complex and neutral hydroxo complex have been estimated to be similar (about 0.1).[20] Therefore, the difference in reactivity between the aquo and hydroxy species would depend on the rates of dissociation of H_2O and OH^- from the complexes. The rate of dissociation of H_2O from the aquo complex has been estimated to be $13.0\ s^{-1}$ at 25°C and we find reasonable agreement with Stranks and Yandell with our $k_{f'} = 6\ M^{-1}\,s^{-1}$. The rate constants found in this work for the reaction of the hydroxy complex ($k_{f''} = 4\ M^{-1}\,s^{-1}$) are comparable also to the limiting rate constant of OH^- dissociation from

trans-$[Co(en)_2(SO_3)(OH)]$ of $> 3\ M^{-1}\ s^{-1}$ at 25°C found by Stranks and Yandell.[9]

Our activation energy for the substitution of ImH in the aquo complex of 22 ± 2 kcal mol^{-1} is consistent with other values for similar systems; for example, 16.5 kcal mol^{-1} for $[Co(en)_2(SO_3)(H_2O)]^+$[9] and 21.3 kcal mol^{-1} for $[Co(en)_2(SO_3(OH)]$,[9] and 11.5 kcal mol^{-1} reported for the forward reaction of $[Co(en)_2(SO_3)(H_2O)]^+$ with SCN^-.[8] The activation energy for the hydroxy species of roughly 7 ± 5 kcal seems lower than expected, but this is only an estimate because the error of $k_{f''}$ is so large.

Equation (1) shows the immediate reaction between *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ and L, but aging solutions of $[Co(en)_2(SO_3)L]^+$ yielded spontaneous production of SO_4^{2-} and formation of new Co(III) complexes. The λ_{max} of aged solutions shifts to longer wavelengths and the higher the pH (7–9) the more rapid is the color change. In the ion exchange chromatography of the aged solutions two or three fractions were found. The first behaved like $[Co(en)_2(SO_3)(H_2O)]^+$ with a similar λ_{max}. For the imidazole and *N*-methylimidazole solutions, the second fraction behaved like $[Co(en)_2(H_2O)(ImH)]^{3+}$ with a similar λ_{max} and the third fraction behaved like a dimer because it required concentrated sodium perchlorate to remove it from the column indicating that it was highly charged. For the imidazole product ^1H NMR showed, from intensities and chemical shifts, that the solution contained 60% *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$, 11% *cis*-$[Co(en)_2(H_2O)(ImH)]^{3+}$ and 21% *trans*-$[Co(en)_2(H_2O)(ImH)]^{3+}$ and 6% unidentified product. In the histidine and methylhistidine solutions the second fraction had a λ_{max} greater than 500 nm which does not correlate with any of our known solutions and the third fraction behaved like the $[Co(en)_2(H_2O)(ImH)]^{3+}$ complex. ^1H NMR spectra of some of the column fractions do not seem to contain ethylenediamine in the product complex. From these data, it seems that $[Co(en)_2(SO_3)L]^+$ aged in slightly basic solution loses sulfite or L and/or perhaps forms a dimer.

It was also found that thermal oxidation of sulfite in the complex could be accomplished with sodium bismuthate. Qualitative analysis for SO_4^{2-} and Co(II) showed substantial production of free sulfate without concurrent production of Co(II) indicating sodium bismuthate does not destroy the Co(III) complex. Milder oxidizing agents like MnO_4^-, $Cr_2O_7^{2-}$ and H_2O_2 had no effect on the sulfite or the complex.

Both the aging studies and oxidation study show that it is possible to convert the substitution labile complex $[Co(en)_2(SO_3)L]^+$ to a substitution inert one.

In summary we find that *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ reacts with imidazole and imidazole-containing ligands (L) rapidly to form *trans*-$[Co(en)_2(SO_3)L]^+$. The kinetics and the equilibrium constant for the reaction with imidazole were measured. The product forms via two paths with $k_{f'} = 6\ M^{-1}\ s^{-1}$ and $k_{f''} = 4\ M^{-1}\ s^{-1}$ at 25°C. The activation energy for $k_{f'}$ is 22 ± 2 kcal mol^{-1} and K_{app} at pH 7 is $> 3 \times 10^2$. Our equilibrium studies show that appreciable amounts of the complex form only in the pH 6–9 range. The initial product deteriorates on aging to a mixture of products and above pH 9 the immediate products are different possibly forming bridged complexes. Complexes of other imidazole containing ligands also form other products on aging. Oxidation of the coordinated sulfite with sodium bismuthate does not affect the Co(III) center. As a result, we have shown that it might be possible to react *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$ with a protein by having it react with the imidazole in histidine and then convert the resulting Co(III) complex to a substitution inert one, although the conditions for the oxidation of the sulfite are too harsh for use with proteins. We have also extended the studies on the mechanism of the reaction of imidazole with *trans*-$[Co(en)_2(SO_3)(H_2O)]^+$.

PHOTOCHEMISTRY OF PLANAR FOUR-CO-ORDINATE PALLADIUM(II) COMPLEXES—III.* PHOTOSYNTHESIS AND CRYSTAL STRUCTURE OF $[Pd_2(PPr^n_3)_2(NCS)(SCN)_2(\mu\text{-}CN)]$

G. BOMBIERI, G. BRUNO, M. CUSUMANO,† G. GUGLIELMO and V. RICEVUTO

Dipartimento di Chimica Inorganica e Struttura Molecolare, University of Messina, Via dei Verdi, 98100 Messina, Italy

(*Received* 13 *August* 1984; *accepted* 16 *October* 1984)

Abstract—U.V. irradiation of MeOH and CH_3CN solutions of *trans*-$[Pd(PPr^n_3)_2(NCS)_2]$ causes a stepwise photochemical reaction. When the solvent is CH_3CN the photoproduct can be conveniently isolated in a crystalline form. This compound has been shown, by X-ray analysis, to be a cyano bridged palladium(II) complex.

In the last few years we have been concerned with the study of the photochemical behaviour of several square planar palladium(II) complexes.[1,3] In particular, we have investigated the nitro–nitrito linkage isomerization in $[Pd(Et_4dien)NO_2]^+$ (Et_4dien = 1, 1, 7, 7-tetraethyldiethylenetriamine) and the *cis–trans* isomerization of the substrates *trans*-$[Pd(PPr^n_3)_2Cl_2]$ (X = Cl, Br, I). In the case of the latter complexes the derivatives formed in the early stage of irradiation, by further prolonged irradiation, can be transformed into the bridged complexes $[Pd_2(PPr^n_3)_2X_4]$. This photoreaction is an easy alternative to the thermal synthesis of these complexes. We have now extended our study to the complex *trans*-$[Pd(PPr^n_3)_2(NCS)_2]$ which could undergo both *cis–trans* and NCS–SCN linkage isomerization. In this paper we report the results of a spectrophotometric investigation of the photoreactivity of *trans*-$[Pd(PPr^n_3)_2(NCS)_2]$ in MeOH and CH_3CN. Furthermore the crystal structure of the photoproduct isolated from acetonitrile is described.

EXPERIMENTAL

The complex *trans*-$[Pd(PPr^n_3)_2(NCS)_2]$ was prepared by methatetic exchange from *trans*-$[Pd(PPr^n_3)_2Cl_2]$ obtained in turn by standard procedure.[4]

The photoproduct was obtained by irradiation of a saturated CH_3CN solution of *trans*-$[Pd(PPr^n_3)_2(NCS)_2]$ at 320 nm. The solvent was evaporated off and the resulting oily substance was washed with diethyl ether and subsequently crystallized from *n*-hexane.

Methanol and acetonitrile were of spectrophotometric grade.

The electronic spectra were recorded by means of a Cary 219 spectrophotometer.

Conductivity measurements were performed with a Radiometer CDM 3 conductivity bridge.

The solutions were irradiated by using a high intensity Bausch–Lomb monochromator or an Applied Photophysics MLU 18 photoreactor in the case of the preparative stage.

Determination of crystal structure

Crystal data. $C_{39}H_{65}N_3P_3S_3Pd_2$, orthorhombic, $a = 16.129(3)$, $b = 18.937(5)$, $c = 28.836(10)$ Å, $U = 8807.5$ Å, space group *Pbca*, $Z = 8$, $D_c = 1.47$ mg m^{-3}, $F(000) = 3696$, μ(Mo-K_α) = 9.9 cm^{-1}.

The data were collected on a Siemens–Stoe diffractometer, ω/θ scan 0.5 s count at each of 120 steps of 0.01° for each reflection and 10 s background count. Mo-K_α (λ radiation = 0.71069 Å) $1.5 \leqslant \theta \leqslant 25°$. Three standard reflections monitored every 100 to check crystal and electronic stability. No decay in intensity. 4428 reflections measured, 3063 observed [$I \geqslant 2.5\sigma(I)$]. The structure was solved by Patterson and Fourier methods and refined by full-matrix least squares procedure. Function $\sum W(|F_o|-|F_c|)^2$ was minimized; $W = 2.46/[\sigma^2(F_o)+1.1\times10^{-3}(F_o)^2]$. In the last refinement cycles all non-hydrogen atoms (except the

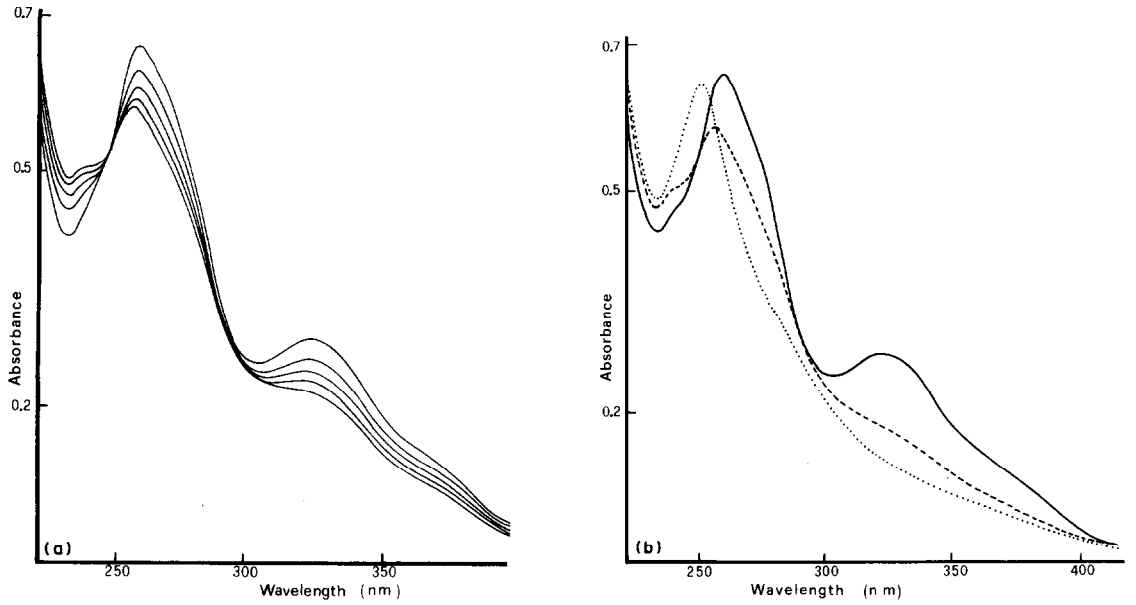

Fig. 1. Spectral variations on irradiation of a CH_3CN solution of *trans*-$[Pd(PPr^n_3)_2(NCS)_2]$ (4×10^{-5} M). Left: spectra of the complex at various irradiation times at 325 nm in the first photochemical step. Right: ——, complex; - - - -, intermediate photoproduct; ····, final photoproduct.

disordered propyl chains to which isotropic thermal parameters were assigned) were refined anisotropically. A general high thermal motion is present in the structure which is associated with a disordering in the propyl chains. For this reason some of the C–C bond distances were refined with fixed geometry [d(C–C = 1.53(2) Å] taking into account also the alternative positions for C(18), C(19), C(28), C(29), C(35) and C(36) atoms (labelled with additional Fig. 1 i.d. C(181), etc.). From relative peak heights in the electron density map and comparison of the isotropic thermal parameters an occupancy ratio 0.6/0.4 for C(18)/C(181), etc. was estimated. The final model reached convergence with $R = 0.059$ and $R_w = 0.065$. Relevant bond lengths and valence angles are reported in Table 1. Thermal parameters, F_o/F_c values, as well as final coordinates for non-hydrogen atoms have been deposited with the Editor as supplementary material. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre. The calculations were carried out on the IBM 4341 of the "Centro di Calcolo" at University of Messina with the SHELX-76 program.[5] Atomic scattering factors and anomalous dispersion terms (for Pd only) were from Reference 6.

RESULTS AND DISCUSSION

Irradiation of CH_3CN and MeOH solutions of *trans*-$[Pd(PPr^n_3)_2(NCS)_2]$ at the wavelengths relative to the absorption band of the complex (254, 325 and 370 nm) leads to a well defined spectral variation characterized by an isosbestic point respectively at 248 and 246 nm in the case of the former and the latter solvent. At this stage the process is thermally reversible; however, if the irradiation is prolonged, new thermally irreversible photoreactions occur. In the case of CH_3CN this new process is very clean and the spectral variation is characterized by only one absorption band, in the range 230 to 270, centred at 252 nm ($\varepsilon = 18{,}700\ M^{-1}\ cm^{-1}$). When the solvent is MeOH, however, the irradiation causes decomposition of the complex to give various unidentified products. Attempts to isolate the photoproduct in the early stage of irradiation failed and only the starting complex could be recovered from the reaction mixture. Nevertheless we have been able to isolate the final stable photoproduct of irradiation in CH_3CN. The availability of crystals of this substance suitable for X-ray analysis has allowed us to determine its structure.

Photoproduct crystal structure

The crystal of the photoproduct consists of the packing of discrete dimeric molecules $[Pd_2(PPr^n_3)_3(NCS)(SCN)_2(\mu\text{-}CN)]$. The molecular structure is shown in Fig. 2 together with the atom numbering scheme (only one of the alternate positions in the propyl chains is reported). The coordination geometry about the two palladium

atoms of each dimeric unit is approximately square planar. Palladium(1) is coordinated to two isothiocyanates *trans* related, to one phosphorus atom of the PPr^n_3 ligand and to the nitrogen of the bridging cyano group, whereas palladium(2) is coordinated to two phosphorus atoms of the PPr^n_3 ligands *trans* related, to one isothiocyanate ligand and to a carbon of the bridging cyano group. The

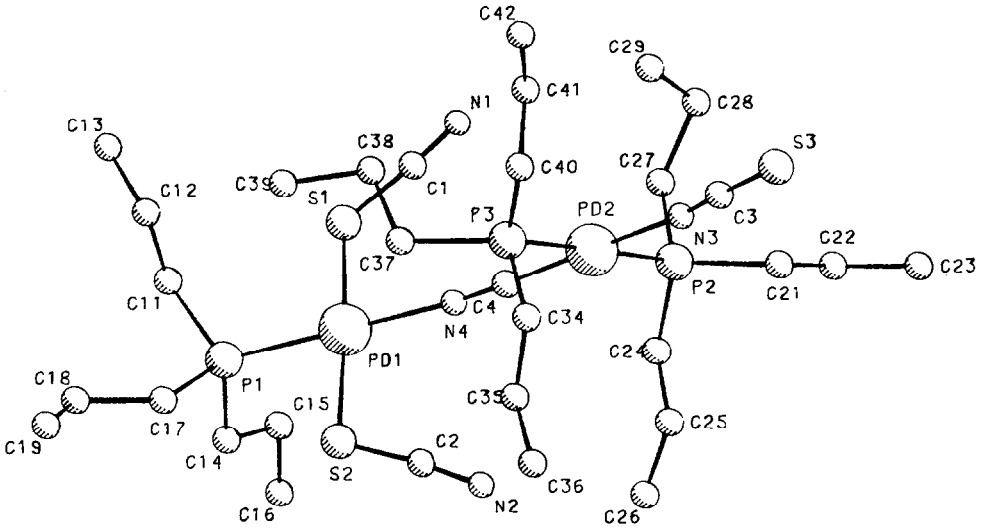

Fig. 2. Molecular configuration and atom naming scheme.

deviations from planarity for the atoms coordinated to Pd(1) are in a tetrahedral direction [S(1) 0.033(6), S(2) 0.048(7), P(1) 0.013(4) and N(4) 0.068(9) Å]; for those related to Pd(2) the deviations are lower [N(3) 0.014(12), P(2) 0.004(3), P(3) 0.08(5) and C(4) 0.010(11) Å] and in an approximately square pyramidal direction with the Pd(2) atom at the apex of the very flattened square pyramid. The two planes form a dihedral angle of 66°. Because of the very high thermal motion present in the structure (probably related to the way in which the crystal has been obtained) a clear distinction between nitrogen and carbon atom positions of the cyano group is impossible; however, the values of the bond distances to the respective palladium atoms suggests as highly probable the assignment made.

The major interest of this compound is related to the presence of thiocyanate ligands bound to the metal in both the bonding modes (S and N). The bonding mode of the thiocyanate ion to "soft" metals such as Pt(II) and Pd(II) is still a matter of controversy as electronic[7,8] effects and/or steric[9,10] effects have been suggested to play a determining role in the S or N coordination mode to the metal. The presence of phosphine ligands as possible π-acceptors in such complexes has also been thought to influence the thiocyanate coordination mode.[11,13] Recently it has been pointed out that Pd(II) is ambivalent[14] towards the thiocyanate ion and small changes in steric and electronic factors are sufficient in determining its coordinating mode as well as the geometry of the complex. This is in relation to a study on $[PdL_2(CNS)_2]$ complexes ($L = R_nP(C_6H_5)_{3-n}$; $n = 0$–3, $R = CH_3$ and $C_6H_5CH_2$) while in the phosphole complexes $[PdL_2(SCN)_2]$ the steric effects seem to be determinant. As a conclusion the authors said that the *cis*-$[PdL_2(SCN)_2]$ complexes S-bound are stable with small ligands, as was the case with L = 1,3,4-trimethylphosphole. On increasing the bulk of the phosphorus substituent the *trans*-N-bound thiocyanates are favoured: by substitution of a methyl group with a phenyl group in the previously quoted ligand a *cis* complex with both N and S bonded thiocyanate ligands present is obtained[15] and this suggests again the importance of the electronic effects as factors controlling the thiocyanate bonding mode in square planar complexes of the type $[Pd(PPr_3)_2(CNS)_2]$ because they favour *cis* coordination and the S-bonding mode. Here around Pd(1) we have a distortion in a pseudotetrahedral sense of the coordinated ligands (this is considered an unfavourable arrangement[16] for palladium). This means a relief from steric constraints and noticeable influence on the coordination geometry of the electronic factors. This is in agreement with the S-bonding mode of the thiocyanate ligand while for the *trans* disposition of the SCN ligands we have to consider the bulk of PPr^n_3 ligand which is in favour of the *trans* disposition. The Pd–P bond length of 2.252(4) Å is at the lower end of the range of Pd–P bond distances commonly found[17] showing that the *d*–*d* back bond is significant. Its value agrees well with those of 2.247(4) Å and 2.248(4) Å found in

$$[Pd_4(P(C_3H_7)_3)_4(NO_2)_4(ONO)_4]^{18}$$

and also with that of 2.243 Å found in

$$[Pd(C_6H_5\text{–}P\text{–}(CH_2)_2\text{–}C_6H_5)(SCN)(NCS)]^{19}$$

for a Pd–P bond distance *trans* to a Pd–N(NCS) bond of 2.062(10) Å which is again in agreement with the Pd–N(4) bond length of 2.07(1) Å for bridging the cyano groups (cf. also bond length of 2.078(7) Å in dithiocyanato bis-hydrogen bis-diphenylphosphinato dipalladium(II).)[20] The Pd–P bond distances (2.2334(6) and 2.316(5) Å) have the values expected for *trans* SCN group as in *trans*-dithiocyanato bis-(3,3-dimethylbuthynyl)diphenylphosphinepalladium(II).[21] The distance Pd–S of 2.323 Å is in agreement also with the averaged value of 2.323 Å found[22] in the anion $[Pt(SCN)_4]^{2-}$. The Pd(2) environment is more planar, the steric effects are important due also to the two *trans*-coordinated PPr^n_3 phosphines, and the N bonding mode of the thiocyanate ligand is fully justified. The Pd–P distances, 2.333(4) and 2.320(4) Å, are in very good agreement with those reported in *trans*-$[Pd(PPh_3)_2(CH_3CN)Cl]$. The Pd–N(NCS) and Pt–C(CN) lengths of 2.02(1) and 1.94(1) Å compare well with the corresponding values of 2.024(9) and 1.921(12) Å for Pt–N(NCS) and Pt–C(CN) in $[Pt(NCS)(PEt_3)_2]_2$-*p*-$C_6H_4(C{\equiv}C)_2$[24] as well as the Pd–P compared with the Pt–P bond lengths which average 3.30(1) Å.

From this structural analysis it can be seen that the old question concerning the factors influencing the (CNS) coordination mode cannot easily be rationalized because of the influence of both electronic and steric effects. Nevertheless it appears that while in a crowded geometry, as in the case of the Pd(2) environment, the N-bonding mode of (CNS) ligand is favoured; with less hindering about Pd(1) the S-mode is more likely.

Although at this stage we have no quantitative photochemical data, on the basis of the trend of the spectral variations upon irradiation and taking into account the structure of the product $[Pd_2(PPr^n_3)_2(NCS)(SCN)_2(\mu\text{-}CN)]$, we can tentatively propose a mechanism for the photoprocess. The presence of two (CNS) groups bound to palladium through sulphur suggests that in a first

step the complex *trans*-$[Pd(PPr^n_3)_2(NCS)_2]$ converts to its linkage isomer *trans*-$[Pd(PPr^n_3)_2(SCN)_2]$. Further reaction of two molecules of the S-bound isomer with direct participation of the solvent CH_3CN yields $[Pd_2(PPr^n_3)_2(NCS)(SCN)_2(\mu\text{-}CN)]$. It is significant in this respect that no stable photoproduct is obtained when the reaction is performed in MeOH. On the other hand we cannot exclude that the CN group bridging the two palladium atoms comes from fragmentation of (CNS) bound to metal, though, to our knowledge, such a fragmentation has never been reported.

REACTIONS OF MOLYBDENUM(III) WITH MACROCYCLIC POLYTHIAETHERS

D. SEVDIĆ* and L. FEKETE
Rudjer Bošković Institute, 41001 Zagreb, Yugoslavia

(*Received* 14 *May* 1984; *accepted* 20 *October* 1984)

Abstract—Reactions of $MoCl_3(THF)_3$ and $MoCl_3(PrCN)_3$ with the macrocyclic polythiaethers: 1,4,8,11-tetrathiacyclotetradecane (TTP) and 1,4,7,10,13,16-hexathiacyclooctadecane (HTO) were studied. The type of reaction and the complexes formed depend on reactant concentration and nature of the solvent. The complexes: $[MoCl_3(HTO)]$, $[(MoCl_3)_2(HTO)(THF)_3]$, $[MoCl_3(TTP)(THF)]$ and $[MoCl_3(TTP)]$ in which the macrocyclic polythiaethers are coordinated to the molybdenum through sulphur atoms were isolated. Some new mixed-valence complexes were formed in reactions where a partial change in the molybdenum oxidation state and a cleavage of the macrocyclic ring took place. The following complexes were isolated: $[Mo_3Cl_9(PHT)_2(PrCN)] \cdot CH_2Cl_2$, $[Mo_3Cl_9(PHT)_2(THF)] \cdot CH_2Cl_2$, $[Mo_2Cl_6(PHT)] \cdot CH_2Cl_2$, $[Mo_3Cl_9(TTT)_2(THF)] \cdot CH_2Cl_2$, where PHT = 3,6,9,12,15-pentathiaheptadec-16-ene-1-thiolato(1-) and TTT = 4,7,11-trithiatridec-12-ene-1-thiolato(1-). The complexes were characterized on the basis of elemental analyses, magnetic measurements, IR, ^1H NMR, ^{13}C NMR and mass spectra.

A variety of metalloproteins characterized by X-ray diffraction are known to contain sulphur atoms as a part of the coordination environments of metal ions. Molybdenum, together with iron and copper ions, is specially common in metalloenzymes containing sulphur ligands.[1] Among the other oxidation states, molybdenum(III) has also been suggested as a participant in biological and catalytic processes.[2]

The development of bioinorganic chemistry has also been an important factor in spurring the growth of interest in complexes of macrocyclic compounds since they may serve as models for biologically important species.[3]

In comparison to molybdenum(VI), (V) and (IV) complexes, the compounds of molybdenum(III) have been scantily investigated, especially those with sulphur-containing ligands.[4–11]

Previous studies have been concentrated on complex formation of molybdenum(VI), (V) and (IV) with potentially tetradentate and hexadentate polythiaethers TTP and HTO, respectively.[12] Now our studies are extended to the reactions of molybdenum(III) with the macrocyclic polythiaethers TTP and HTO.

EXPERIMENTAL

Starting materials

The ligands 1,4,8,11-tetrathiacyclotetradecane (TTP) and 1,4,7,10,13,16-hexathiacyclooctadecane (HTO) were prepared as described previously.[13,14] Reagent grade chemicals were used without further purification except in the cases noted. All solvents were purified by standard methods, dried and saturated with dry argon before use. Tetrachlorobis(propionitrile)molybdenum(IV) and tetrachlorobis(acetonitrile)molybdenum(IV) were obtained by the reaction of pentachloromolybdenum(V) with the corresponding alkylcyanide.[15] Trichlorotris(tetrahydrofuran)molybdenum(III) was prepared from $MoCl_4(RCN)_2$ following the method reported by Anker *et al.*[16] $Mo(CO)_4Cl_2$ was prepared by the reaction of hexacarbonylmolybdenum(0) with liquid chlorine at −78°C.[17] Trichlorotris(propionitrile)molyb-

* Author to whom correspondence should be addressed.

denum(III) was obtained by the reaction of $Mo(CO)_4Cl_2$ with the propionitrile.[6]

Preparation of complexes

All reactions and manipulations were performed under a dry argon atmosphere using a standard dry-box technique except in the case noted.

Trichloro(1,4,7,10,13,16 - *hexathiacycloocta* - *decane*)*molybdenum*(*III*) (**I**). $MoCl_3(THF)_3$ (0.418 g, 1 mmol) was dissolved in dichloromethane (15 cm^3) and the ligand HTO (2.164 g, 6 mmol) dissolved in the same solvent (15 cm^3) was added. After a few minutes the product started to precipitate. The next day the orange crystalline product formed was filtered off, washed with dichloromethane and dried.

IR cm^{-1}: 1199s, 1143w, 905s, 856s, 843s, 745(sh), 736m, 701s, 690w, 462vw, 441vw, 411vw, 322vs (sh), 312vs.

Bis(*trichloro*)(*μ*-1,4,7,10,13,16 - *hexathiacyclo* - *octadecane*)*tris*(*tetrahydrofuran*)*dimolybdenum*(*III*) (**II**). $MoCl_3(THF)_3$ (0.837 g, 2 mmol) was suspended in tetrahydrofuran (20 cm^3) and HTO (0.361 g, 1 mmol) dissolved in THF (25 cm^3) was added. The reaction mixture was stirred at room temperature in a stoppered reaction flask. After 2 h the reaction vessel was stored in a dry-box and the next day the orange crystalline product was filtered off, rinsed with THF and dried. The same product was obtained with the metal/ligand ratios 3:1 and 5:1.

IR cm^{-1}: 1209m, 1156vw, 1010s, 925vw, 917vw, 855vs, 745m, 688w, 452vw, 407vw, 320vs, br.

Trichloro(1,4,8,11 - *tetrathiacyclotetra* - *decane*)(*tetrahydrofuran*)*molybdenum*(*III*) (**III**). The TTP ligand (0.537 g, 2 mmol) and $MoCl_3(THF)_3$ (0.837 g, 2 mmol) were suspended in diethyl ether (50 cm^3). The reaction mixture was stirred 7 h in a stoppered flask and stored overnight in a dry-box. The pink–orange product formed was separated, washed with diethyl ether and dried.

IR cm^{-1}: 1204m, 1138w, 1009s, 922w, 849vs, 689w, 415vw, 403vw, 325vs, br.

Trichloro(1,4,8,11 - *tetrathiacyclotetra* - *decane*)*molybdenum*(*III*) (**IV**). A solution of TTP (1.611 g, 6 mmol) in dichloromethane (15 cm^3) was added to a solution of $MoCl_3(THF)_3$ (0.418 g, 1 mmol) in CH_2Cl_2 (15 cm^3). After two days orange crystals were formed on the walls of the reaction flask together with a fluffy brown precipitate. The brown product was separated by filtration. The filtrate was poured into the reaction flask and allowed to stand overnight in order to achieve further crystallisation of orange hemispherical crystals. The orange crystals were filtered off, washed with dichloromethane and dried.

IR cm^{-1}: 1124vw, 928m, 915w, 907m, 857s, 840m, 761s, 734m, 724m, 479m, 445(sh), 439vw, 407vw, 333(sh), 310vs, br.

A powder diffractogram showed that the orange agglomerates of the complex $[MoCl_3(TTP)]$ are crystalline. It was shown that the IR spectrum of the brown precipitate is identical to the spectrum of the complex **VIII**.

Nonachlorobis(*μ*-3,6,9,12,15-*pentathiaheptadec*-16-*ene*-1-(*thiolato*)(*propionitrile*)*molyb*-*denum*(*III*)*dimolybdenum*(*IV*) - *dichloro* - *methane*(1/1) (**V**). A solution of HTO (0.360 g, 1 mmol) in CH_2Cl_2 (25 cm^3) was added to a solution of $MoCl_3(CH_3CH_2CN)_3$ (0.735 g, 2 mmol) in CH_2Cl_2 (25 cm^3). Although a product started to form after 30 min, the stoppered reaction flask was allowed to stand two days in a dry-box to complete the reaction. The red–brown precipitate was filtered off, rinsed with dichloromethane and dried.

IR cm^{-1}: 2275vw, 1600vw, br, 1203w, 972m, 915w, 730m.

Nonachlorobis(*μ*-3,6,9,12,15-*pentathiaheptadec*-16-*ene*-1-(*thiolato*)(*tetrahydrofuran*)*molyb*-*denum*(*III*)*dimolybdenum*(*IV*) - *dichloro* - *methane*(1/1) (**VI**). $MoCl_3(THF)_3$ (1.256 g, 3 mmol) was dissolved in CH_2Cl_2 (20 cm^3). The solution was filtered and the HTO (0.721 g, 2 mmol) dissolved in CH_2Cl_2 (15 cm^3) was added. After two days the red–brown crystalline product formed was filtered off, washed with CH_2Cl_2 and dried.

IR cm^{-1}: 1610vw, br, 1207m, 1153vw, 1008vw, 986vw, 913w, 851m, 731vs, 698m, 455vw, 435vw, 415vw, 317vs, br.

Hexachloro(*μ*-3,6,9,12,15-*pentathiaheptadec*-16-*ene*-1-*thiolato*)*molybdenum*(*III*)*molybdenum*(*IV*)-*dichloromethane*(1/1) (**VII**). A solution of HTO (0.360 g, 1 mmol) in CH_2Cl_2 (20 cm^3) was added to a filtered solution of $MoCl_3(CH_3CH_2CN)_3$ (1.470 g, 4 mmol) in CH_2Cl_2 (25 cm^3). The reaction went on very slowly and after six days the main part of the brown crystalline product formed was separated and rinsed with dichloromethane.

IR cm^{-1}: 1600vw, br, 1208w, 983m, 929w, 730m, 698vw.

On the walls of the reaction vessel there remained dark-red (like rubies) hemispherical crystalline agglomerates. Their identification is in progress.

Nonachlorobis(*μ*-4,7,11-*trithiatridec*-12-*ene*-1-*thiolato*)(*tetrahydrofuran*)*molybdenum*(*III*)*dimolyb*-*denum*(*IV*) - *dichloromethane*(1/1) (**VIII**). $MoCl_3(THF)_3$ (0.837 g, 2 mmol) was dissolved in CH_2Cl_2 (25 cm^3) and TTP (0.268 g, 1 mmol) dissolved in CH_2Cl_2 (20 cm^3) was added. After four days the orange–brown crystalline product formed was filtered off, washed with CH_2Cl_2 and dried.

IR cm^{-1}: 1610vw, br, 1004vw, 984m, 918w,

908vw, 861m, 844vw, 743(sh), 732m, 697vw, 470vw, 455vw, 417w, 334vs, 312vs, br.

Trichloro(acetone)bis(tetrahydrofuran)molybdenum(III) (**IX**). Trichlorotris(tetrahydrofuran) molybdenum(III) (2 g) was dissolved in technical grade acetone (20 cm^3) without any precaution with regard to air. After a few minutes the product started to precipitate. The orange needle crystals formed were filtered off, washed with acetone and dried. The complex is stable for several days.

IR cm^{-1}: 1656vs, 1013vs, 924m, 917m, 854vs, br, 322vs.

Physical measurements

IR spectra of the complexes were recorded as Nujol mulls on a Perkin–Elmer 580 B (4000–180 cm^{-1}) spectrophotometer. Mass spectra were obtained on a Varian CH-7 mass spectrometer. ^1H NMR spectra for solutions in DMSO-d_6 were measured on a JEOL FX 90 Q spectrometer with tetramethylsilane as the internal standard.

^{13}C NMR were measured with a JEOL JNM-FX 100 spectrometer. Magnetic susceptibilities were determined by the standard Gouy method at 295 K using $CuSO_4 \cdot 5H_2O$ as calibrant.

RESULTS AND DISCUSSION

Investigations of the reactions of trichloromolybdenum(III) with macrocyclic polythiaethers TTP and HTO have shown that depending on the reactant concentration and the nature of the solvent used different types of complexes were formed.

The first type of complexes, in which macrocyclic polythiaethers are coordinated to the molybdenum(III) only through sulphur atoms, were formed when the reaction was carried out in tetrahydrofuran with the concentration of molybdenum higher than that of the ligand. The same reaction occurred in CH_2Cl_2 as solvent only when the concentration of the ligand was in excess of the molybdenum concentration.

When the reaction was carried out in CH_2Cl_2 with the metal–ligand ratio from 1 : 1 to 4 : 1, new mixed-valence complexes were formed. In this case a partial change in the molybdenum oxidation state and a cleavage of the macrocyclic ring took place leading to the formation of molybdenum thiolate complexes.

The complexes were formulated on the basis of elemental analysis and physical measurements. Most of the complexes were prepared several times. The analyses are presented as the mean of the results with different preparations. Conditions of preparation and analytical data for the complexes obtained are given in Tables 1 and 2. Some complexes were obtained as solvates, from which the solvate molecules were not removable by prolonged pumping at room temperature. The presence of dichloromethane was confirmed by examination of mass spectra. The complexes were not sufficiently soluble in suitable solvents, or their solutions were too unstable, for molecular-weight determinations. The air and moisture sensitivity of the complexes further limited their characterisation.

Complexes of trichloromolybdenum(III)

Although the complexes of $MoCl_3L_3$ have been widely investigated, only a few studies were performed on $MoCl_3$ complexes with sulphur-containing monodentate ligands.[4,6] Until now no complexes of $MoCl_3$ with multidentate sulphur-containing ligands have been prepared. However, we were able to obtain new complexes of trichloromolybdenum(III) with multidentate macrocyclic polythiaethers.

It has been found that HTO as ligand forms with $MoCl_3$ two different complexes depending on the experimental conditions.

One type of complex was formed in the reaction of $MoCl_3(THF)_3$ and HTO in CH_2Cl_2 as a solvent with the metal–ligand ratio 1 : 6. In this case the HTO ligand displaced all of the tetrahydrofuran and the new complex, according to the analyses, corresponds to the formula $[MoCl_3(HTO)]$ (complex **I**). This complex has a magnetic moment of 3.44 B.M., consistent with the results published for $MoCl_3L_3$ complexes, where L is an oxygen or sulphur donor.[6] These values are consistent with quasi-octahedral complexes containing a $4d^3$ ion. A comparison of the IR spectrum of the precursor molecule $MoCl_3(THF)_3$ with that of complex **I** shows that the IR band of the $MoCl_3$ unit at 325 cm^{-1}, assigned to the Mo–Cl stretching vibration, is affected by the complexation. In the spectrum of the complex $[MoCl_3(HTO)]$ two very strong bands at 322 and 312 cm^{-1} are present. Coordination of a sulphur from the ligand to the metal atom causes both a decrease in the frequencies and a lowering of the intensity of C–S–C stretching modes. The HTO ligand has four strong bands at 713, 699, 683 and 660 cm^{-1}, assigned to the C–S–C stretching vibrations, while in the spectrum of the complex only two bands at 701 and 690 cm^{-1} are present. Two weak bands at 462 and 441 cm^{-1} most probably correspond to Mo–S stretching vibrations. On the basis of these results we propose that the complex $[MoCl_3(HTO)]$ has an expected octahedral coordination in which chlorine and sulphur atoms have the meridional arrangement. The HTO ligand acts as a bridge between two molybdenum units. However, to

Table 1. Conditions of preparation of molybdenum complexes

	Compound	Starting compound	Ligand	Metal/ligand ratio	Solvent

achieve six coordination HTO probably behaves as a bidentate and monodentate ligand at the same time (Fig. 1, Structure **I**).

When the reaction between $MoCl_3(THF)_3$ and HTO was carried out in tetrahydrofuran as solvent with the metal–ligand ratios 2 : 1, 3 : 1 or 5 : 1 another complex $[(MoCl_3)_2(HTO)(THF)_3]$ was formed. The magnetic moment of this complex is 3.46 B.M. per molybdenum atom. The analytical data for this complex are listed in Table 2. As can be seen in the case where the molybdenum was in excess in comparison to the HTO, the ligand was not able to displace all molecules of tetrahydrofuran from the $MoCl_3(THF)_3$ compound. The presence of tetrahydrofuran is confirmed by the IR spectrum (complex **II**) which exhibits two very strong bands at 1010 and 855 cm^{-1}, assignable to ν(C–O–C) of coordinated tetrahydrofuran. The complex $[(MoCl_3)_2(HTO)(THF)_3]$, contrary to the $[MoCl_3(HTO)]$ complex, exhibits only one very strong band at 320 cm^{-1} corresponding to ν(Mo–Cl). The very weak band in its IR spectrum at 452 cm^{-1} can be assigned to the Mo–S stretching vibration. The complex also exhibits only one band at 688 cm^{-1}, which can be attributed to the ν(C–S). The results suggest that for the complex $[(MoCl_3)_2(HTO)(THF)_3]$ an alternative structure (**II**) (Fig. 1) involving coordination of tetrahydrofuran molecules is more acceptable. It can be expected that in this complex HTO, in order to retain six coordination, acts as a bridge between two molybdenum units in a bidentate and monodentate manner.

With TTP as a ligand we could not isolate any

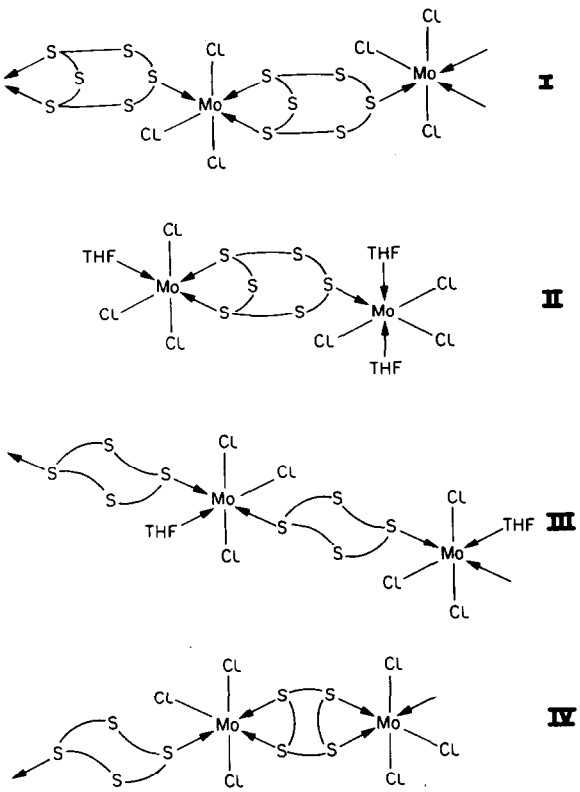

Fig. 1. Proposed structures of molybdenum(III) complexes with macrocyclic polythiaethers.

complex in tetrahydrofuran as solvent. However, we were able to prepare the complex of molybdenum(III) with TTP in the reaction of $MoCl_3(THF)_3$ and TTP in ether as solvent. With the metal–ligand ratio 1:1, a yellow–orange complex was formed whose analyses correspond to the formula $[MoCl_3(TTP)(THF)]$ (complex **III**). The presence of THF was also confirmed by the IR spectrum which shows two bands at 1009 and 849 cm^{-1} corresponding to the C–O–C stretching vibrations of coordinated THF. The C–S–C stretching vibrations which are present in the IR spectrum of the TTP ligand at 722, 715, 690 and 674 cm^{-1} disappeared completely by complexation, except one very weak band at 689 cm^{-1} which remained in the spectrum of the complex. The complex **III** has a very strong band at 325 cm^{-1} which corresponds to ν(Mo–Cl) and one very weak band at 415 cm^{-1} presumably arising from Mo–S stretching vibrations. $[MoCl_3(TTP)(THF)]$ has a magnetic moment of 3.47 B.M. and there is little doubt of an octahedral structure in the complex (**III**) (Fig. 1). In order to achieve this coordination around the molybdenum atom the TTP ligand should probably act as a bridge between two molybdenum units in a double monodentate manner.

When the reaction of $MoCl_3(THF)_3$ and TTP was carried out in CH_2Cl_2 with the metal–ligand ratio 1:6 the complex $[MoCl_3(TTP)]$ (complex **IV**) was formed, which does not contain THF. The IR spectrum of this complex has no bands which correspond to the coordinated or noncoordinated tetrahydrofuran. In contrast to the spectrum of $[MoCl_3(TTP)(THF)]$, in the IR spectrum of $[MoCl_3(TTP)]$ there are two strong bands at 333 and 310 cm^{-1} corresponding to ν(Mo–Cl), and three bands at 479, 445 and 439 cm^{-1} which can be assigned to Mo–S stretching vibrations. While free TTP ligand exhibits a very strong band at 1203 cm^{-1}, attributed to the *trans*-CH_2-wagging vibrations, in the spectrum of complex (**IV**) this band disappeared completely as well as the bands corresponding to the C–S stretching vibrations. On the other hand, two new bands at 857 and 849 cm^{-1}, corresponding to the *gauche*-CH_2-rocking vibrations, appeared in the spectrum. All these changes indicate that considerable conformation changes of the TTP ligand appeared upon complexation. The complex has a magnetic moment of 3.42 B.M. Therefore, it is reasonable to propose the structure (**IV**) (Fig. 1) in which one ligand molecule acts as a bridge between two molybdenum units as a double bidentate while the other molecule acts as a double monodentate in order to achieve 6 coordination around the molybdenum atom.

Mixed-valence complexes

During our investigation of the complex formation of molybdenum(III) with macrocyclic polythiaethers we have observed that under certain experimental conditions a new type of mixed-valence complexes was formed. These reactions were accompanied by a cleavage of the macrocyclic ring.

DeSimone *et al.*[18] have also observed that in the reaction of $[Mo_2(CF_3SO_3)_2(H_2O)_4](CF_3SO_3)_2$ with the cyclic polythiaether 1,5,9,13-hexathiacyclohexadecane some cleavage of the macrocycle ring occurred. Koray *et al.*[19–21] have also observed that in the reaction of 2,6,15,19-tetrathia(7,7)paracyclophane with metal carbonyls, the reaction products demonstrate the tendency of the 1,3-dithiapropane unit to be cleaved off under the influence of the metal carbonyl.

When the reactions between molybdenum(III) and macrocyclic polythiaethers were carried out in CH_2Cl_2 as solvent with a higher concentration of molybdenum in relation to the concentration of the ligand a new type of mixed-valence complexes was formed.

The reaction of HTO ligand with $MoCl_3(THF)_3$ or $MoCl_3(CH_3CH_2CN)_3$ at metal–ligand ratio 2:1

or 3:2 leads to the formation of red–brown complexes. The elemental analyses correspond to the formulae $[Mo_3Cl_9(PHT)_2(PrCN)]\cdot CH_2Cl_2$ (complex **V**) and $[Mo_3Cl_9(PHT)_2(THF)]\cdot CH_2Cl_2$ (complex **VI**), where PHT is 3,6,9,12,15 - penta - thiaheptadec - 16 - ene - 1 - thiolato(1-). These complexes have magnetic moments of 2.57 and 2.65 B.M. per molybdenum atom which are consistent with the proposed structures. The presence of CH_2Cl_2 was confirmed by examination of the mass spectra. In the complex **V** the presence of coordinated CH_3CH_2CN was confirmed by the IR spectrum in which a ν(C≡N) band at 2275 cm^{-1}, corresponding to the coordinated cyanide, is present. The complex **VI** contains THF as part of the composition. This can be seen from the IR spectrum which exhibits ν(C–O–C) bands at 1008 and 851 cm^{-1}, assignable to the coordinated THF. In the spectrum of the complex **VI** there is a very strong band at 317 cm^{-1} which corresponds to the ν(Mo–Cl) and two very weak bands at 455 and 435 cm^{-1}, presumably arising from M–S stretching vibrations.[22]

The IR spectra of both complexes differ significantly from the spectra of the previously mentioned complexes of molybdenum(III). The bands at 1152, 929, 843 and 743 cm^{-1}, corresponding to *trans*-CH_2-twisting, *gauche*-CH_2-rocking, and *trans*-CH_2-rocking of the ligand, disappeared completely in the spectra of these new complexes indicating that a drastic change in the ligand was taking place. At the same time new bands appeared in the spectra of these complexes. The complex **V** has three bands at 1600, 972 and 915 cm^{-1} and the complex **VI** at 1610, 986 and 913 cm^{-1}, respectively. These bands are normal characteristic vibrations of the vinyl group. The band at 1600 cm^{-1} corresponds to the stretching vibrations of the C=C group. The absorptions at 972 and 915 cm^{-1} for the complex **V** and at 986 and 913 cm^{-1} for the complex **VI** obviously represent the out-of-plane vinyl C–H deformation vibrations which are normally found near 990 and 910 cm^{-1} in hydrocarbons.[23–25] The appearance of the ν(C=C) band at 1600 cm^{-1} indicates that the ligand is not attached to the metal through this bond. The presence of the vinyl group is also confirmed by the ^1H and ^{13}C NMR spectra (peaks centred at 5.74 ppm and 117.39 ppm, respectively).

These results allow us to propose that during the reactions of macrocyclic polythiaethers with molybdenum, cleavage of the macrocyclic ring takes place with formation of $-S^-$ and $-CH{=}CH_2$ groups at the ends of the ligand chain. The thiol ligands have bands assigned to the S–H stretching vibrations at *ca* 2600 cm^{-1}. Since in the IR spectra of the investigated complexes there are no bands in this region, it could be considered that the bonding occurs through the ionised thiolato group accompanied by a partial change from the molybdenum(III) oxidation state to the molybdenum(IV) oxidation state. Since the complexes were prepared with careful exclusion of air we are confident that there was no change in the oxidation state of molybdenum owing to the formation of Mo=O or Mo–O–Mo bonds. The stability of the starting compound $MoCl_3(THF)_3$ towards air oxidation was confirmed by the preparation of the complex

$$[MoCl_3(THF)_2(CH_3COCH_3)]$$

(complex **IX**) which has a magnetic moment of 3.74 B.M. Namely, this preparation was carried out without any precaution with regard to air. On the basis of the fact mentioned it can be proposed that the complexes most probably have the structures **V** and **VI** (Fig. 2) in which all molybdenum atoms retain 6 coordination.

When the HTO reacted with

$$MoCl_3(CH_3CH_2CN)_3$$

in CH_2Cl_2 as solvent with the metal–ligand ratio 4:1 the brown complex $[Mo_2Cl_6(PHT)]\cdot CH_2Cl_2$ was formed (complex **VII**). This complex has a magnetic moment of 2.25 B.M. per molybdenum atom and does not contain CH_3CH_2CN molecules. In the IR spectrum of this complex there are also three bands at 1600, 983 and 920 cm^{-1} which arise from the vinyl group present. Two bands at 730 and 698 cm^{-1} which correspond to the C–S stretching vibrations are also present in the spectrum of this complex. For this complex structure (**VII**) (Fig. 2), in which all sulphur atoms from the ligand are engaged in bonding with two molybdenum atoms, is more likely to be acceptable.

Investigations have shown that the TTP ligand is less stable than HTO. It was possible to isolate only one well defined complex. This complex was obtained in the reaction of TTP and $MoCl_3(THF)_3$ in CH_2Cl_2 with metal–ligand ratio 2:1 or 1:1. The orange–brown complex formed has a magnetic moment of 2.58 B.M. per molybdenum atom. The elemental analyses correspond to the formula $[Mo_3Cl_9(TTT)_2(THF)]\cdot CH_2Cl_2$ (complex **VIII**), where TTT is 4,7,11 - trithiatridec - 12 - ene - 1 - thiolato(1-). The presence of THF was confirmed by the IR spectrum in which two bands at 1004 and 861 cm^{-1} corresponding to the coordinated THF are present. In comparison to the spectra of the complexes with HTO, in the spectrum of the complex with TTP there are some differences. Namely, bands at 908, 844 and 743 cm^{-1} arising from *gauche*-CH_2-

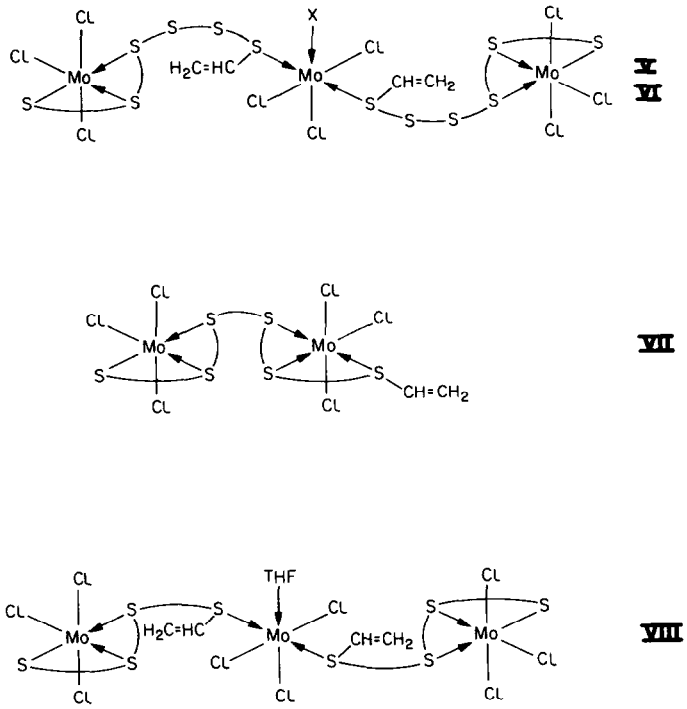

Fig. 2. Proposed structure of molybdenum mixed-valence complexes. X = THF or CH_3CH_2CN.

rocking and *trans*-CH_2-rocking remained in the spectrum of the complex **VIII**. This complex has three bands at 470, 455 and 417 cm^{-1} which probably arise from Mo–S stretching vibrations and two bands at 334 and 312 cm^{-1} corresponding to Mo–Cl stretching vibrations. In spectrum of the complex **VIII** there are also three bands at 1610, 984 and 918 cm^{-1}, arising from the vinyl group present, which confirm that during the complexation the cleavage of the TTP ring is also taking place. For this complex the structure **VIII** is proposed (Fig. 2) in which all sulphur atoms from two ligand units are engaged in complexation with three molybdenum units. The 6 coordination of the central molybdenum atom is maintained by one molecule of THF.

These different reactions between molybdenum(III) and macrocyclic polythiaethers, depending on the nature of the solvent used and the concentration of the molybdenum, can be explained by the great affinity of molybdenum(III) toward the sulphur from the investigated ligands. In the case where the reactions were carried out in a donor solvent such as THF, with a higher concentration of molybdenum, donor molecules of the solvent soften the reaction between molybdenum and ligands and formation of normal complexes of molybdenum(III) occurs. Similar reactions occur in the neutral solvent CH_2Cl_2 only when the ligand is in higher concentration. In this case there are enough sulphur atoms for molybdenum(III) to achieve the corresponding coordination. On the other hand, when the reactions were carried out in CH_2Cl_2 with a higher molybdenum concentration there was a lack of sulphur atoms to coordinate all the molybdenum atoms present in the reaction solution. Because of the strong affinity of molybdenum(III) toward the sulphur, cleavage of the macrocyclic ring occurs accompanied by a partial change from the oxidation state of molybdenum(III) to molybdenum(IV) and the formation of new types of mixed-valence complexes.

(*Received* 11 *July* 1984; *accepted* 1 *November* 1984)

Abstract—A solution of *trans*-bis(2-aminopyridine)dichloropalladium(II) in DMF and HCl 2 N was left for several weeks. The compound isolated from this solution was identified by X-ray structural analysis as the tetrachloropalladate of *meso*-3,7-diazonia tricyclo[4.2.2.2^{2,5}] dodeca-3,7,9,11-tetraen-4,8 diamine, which contains a dication not previously described in literature. The organic dication is formed by two aminopyridine rings linked by C–C bonds whose length is greater (1.61 Å) than a normal single C–C bond.

The title compound has been synthesized as a result of a series of experiments carried out in order to investigate the chemical behaviour of *trans*-dichlorobis(2-aminopyridine)palladium(II), as part of a research project on amino–halogen complexes of Pd(II).[1,2]

The crystalline form and the unexpected stoichiometric composition of the compound obtained have led us to determine its structure by X-ray diffraction.

The anion $PdCl_4^{2-}$ and an organic dication were identified. No references for this dication or similar forms have been found for what we suggest as a mechanism of formation under the working conditions.

EXPERIMENTAL

The compound of general formula $PdCl_4C_{10}N_4H_{14}$ whose structure has been proved to be that of the tetrachloropalladate of *meso*-3,7-diazonia tricyclo[4.2.2.2^{2,5}]dodeca-3,7,9,11-tetraen-4,8 diamine is obtained as a result of the slow evolving of a solution of *trans*-bis(2-aminopyridine) dichloropalladium(II) in DMF and HCl 2N (volume ratio 1:5). After several weeks light yellow needles are made visible.

X-ray data collection and refinements. Crystallographic data collection and processing parameters are given in Table 1. Intensities were measured on an Enraf–Nonius CAD-4 diffractometer with Mo-K_α radiation ($\lambda = 0.7107$ Å). Two standard reflexions were monitored at frequent intervals but showed no evidence of sample decomposition. Intensities were corrected for Lorentz and polarization, but not for absorptions.

The structure has been solved and developed by the heavy-atom method, and refined by least squares with anisotropic temperature factors assigned to all non-hydrogen atoms. The hydrogen atoms belonging to N(1) and N(2) were assumed geometrically. All other hydrogen atoms were found from difference Fourier syntheses. Each H atom was assigned the B ef. of the atom to which it was attached and included in all further calculations, but the parameters were not refined. Calculations were carried out with the X-ray system[3] and program PARST[4] on a Univac 1100/80 computer; scattering factors and anomalous dispersion corrections were from *International*

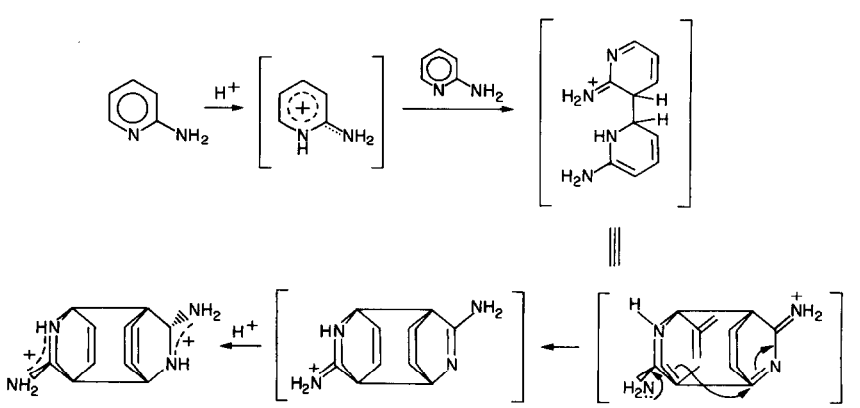
Atomic positional parameters, observed and calculated structure factors as well as final anisotropic thermal parameters and coordinates for the H atoms are listed in Supplementary Material, deposited with the Editor.



Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

An ORTEP drawing of the structure is shown in Fig. 1.

The complex consists of discrete $PdCl_4^{2-}$ anions and dimeric $[C_{10}N_4H_{14}]^{2+}$ cations. Relevant interatomic distances and bond angles are listed in Table 2. The structure clearly shows the presence of $PdCl_4^{2-}$ ions in the lattice without appreciable Pd... N, Pd... C interaction. The coordination around the Pd(II) ion is square planar, with almost equal Pd–Cl bonds (2.302(2)) and angles Cl $\hat{Pd}$ Cl of 90.04(6)°. These bond distances are similar to those observed in other Pd compounds.

During the process of formation of the dication cleavage of the Pd–N bond takes place so that the 2-aminoypridine molecule is released. This molecule evolves under the medium conditions according to the following scheme:

Scheme 1.

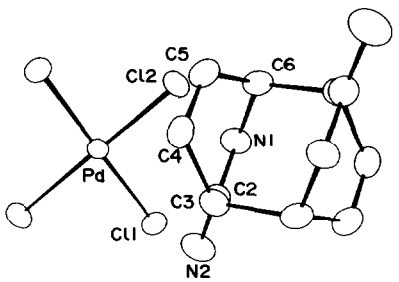


Fig. 1. An ORTEP view at the complex showing the numbering scheme used. The hydrogen atoms are omitted for clarity.

The protonated 2-aminopyridine behaves like an electrophilic agent in front of another molecule of non-protonated 2-aminopyridine forming an intermediate which evolves by a reaction of nucleophilic addition of an enamine to an imine type double bond. The dication observed in the crystal is finally generated by protonation of the resulting product of this addition. However the same dication could also be formed if the protonation took place previously to the nucleophilic addition.

Although the proposed mechanism seems chemically acceptable it demands further examination. The folding of the system which allows the spatial arrangement observed is entropically disfavoured. Probably, the palladium is involved in the process by complexing.

Table 2. Bond lengths (Å) and bond angles (°). E.s.d.s in parentheses

Pd–Cl1	2.303(2)	Cl1–Pd–Cl2	90.04(6)
Pd–Cl2	2.302(2)	C2–N1–C6	119.9(4)
N1–C2	1.310(4)	N1–C2–C3	116.7(3)
C2–C3	1.512(4)	C2–C3–C4	107.3(3)
C3–C4	1.517(5)	C3–C4–C5	117.5(3)
C4–C5	1.320(4)	C4–C5–C6	117.6(4)
C5–C6	1.509(5)	C5–C6–N1	107.5(3)
C6–N1	1.466(4)	N1–C2–N2	122.6(4)
C2–N2	1.311(4)	N2–C2–C3	120.7(3)
C6–C'3	1.610(5)	C5–C6–C3	111.8(3)
C3–C'6	1.610(5)	N1–C6–C'3	111.5(3)

The C3–C'6 and C'3–C6 bonds (1.610(5)) are long, indicating that cleavage of the dimer should occur easily. Similar long dimer C–C bond distances have been found in other compounds.[6–8]

The fact that C2–N2 and N1–C2 bond lengths are almost identical is an evidence for the existence of delocalization of positive charge between both nitrogen atoms.

The protonation of the pyridine nitrogen and not on the amino group is thus confirmed. Otherwise charge delocalization would not be possible and bond order for C2 with each nitrogen would be different.

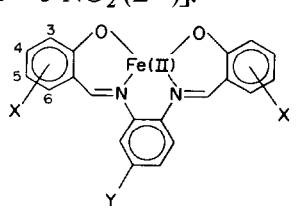
REDOX PROPERTIES OF NN′-X-PHENYLENEBIS(Y-SALICYLIDENEIMINATO)IRON(II) COMPLEXES AND REACTIVITY OF THE CORRESPONDING IRON(III) COMPLEXES TOWARDS CATECHOLATES

PIERO ZANELLO,* RENZO CINI and ARNALDO CINQUANTINI
Dipartimento di Chimica dell'Università di Siena, Pian dei Mantellini, 44, 53100 Siena, Italy



(*Received* 2 *October* 1984; *accepted* 29 *November* 1984).

Abstract—The electrochemical behaviour of a series of iron(II) complexes with the tetradentate ligand NN′-1,2-phenylenebis(salicylideneimine), [Fe(II)L], was studied in non-aqueous solvents. The redox properties of the complexes were related to the nature of the substituents in the aromatic rings. Attention was devoted to dioxygen reactivity of the complexes. The electrode activity of the catechol–[NN′-1,2-phenylenebis(salicylideneiminato) iron(III)] system, [Fe(III)L(catH)], was also studied; the results gave evidence that both the electrochemical oxidation and the chemical oxidation by dioxygen of [Fe(II)L] in the presence of catechol lead to the complex [Fe(III)L(catH)].

The electrochemistry of Schiff-base transition metal complexes is a field of research of wide interest, since redox potentials of central metal ions are often related to the functions of metal-containing molecules of biological interest[1–3] and for their importance in catalytic processes.[4]

In previous studies we investigated by electrochemical techniques the redox properties of complexes of trigonal bipyramide coordination geometry between quinquedentate ligands having N_3O_2 atom donor set and cobalt(II),[5,6] iron(II),[2,6] nickel(II),[2,6] copper(II)[2,6] and manganese(II)[6] ions.

We now report the results of the electrochemical investigation on planar complexes of iron(II) ion with the N_2O_2 tetradentate ligand NN′-1,2-phenylenebis(salicylideneimine) and its derivatives [see below: Y = H, X = H (L^1); Y = H, X = 3-OMe (L^2); Y = H, X = 4-OMe (L^3); Y = H, X = 5-OMe (L^4); Y = H, X = 5-Cl (L^5); Y = H, X = 5-NO_2 (L^6); Y = NO_2, X = H (L^7); Y = Cl, X = H (L^8); Y = OMe, X = H (L^9); Y = OMe, X = 5-OMe (L^{10}); Y = Cl, X = 5-OMe (L^{11}); Y = NO_2, X = 5-NO_2 (L^{12})].

* Author to whom correspondence should be addressed.

The first aim of the present study is to get information about electronic effects able to affect the redox potentials of the metal centre; in fact, except for manganese complexes,[7] previous electrochemical investigations on copper(II),[1,8–10,12] and cobalt(II) complexes[1,11,13] have been mainly devoted to unsubstituted NN′-1,2-phenylenebis(salicylideneiminato) derivatives.

This study is also devoted to test the ability of these complexes to act as oxygen carriers.

Finally we intend to study the interaction of these complexes with catecholates/semiquinones/benzoquinones redox systems in order to gain information on derivatives able to mimic important biological functions.[14–18]

RESULTS AND DISCUSSION

Voltammetric behaviour of [Fe(II)L] (L = L^1–L^{12}) *derivatives.* Figure 1 reports the responses in cyclic voltammetry, both at mercury and platinum microelectrodes, of [Fe(II)L^1], in dimethyl sulphoxide (DMSO) solution.

The anodic process gives rise to a well-formed anodic peak, *I*, with a cathodic one, *L*, directly associated in the reverse scan. Controlled potential coulometric tests performed at 0.0 V indicated the process to involve a one-electron charge-transfer, The analysis of the cyclic voltammetric responses with scan rates ranging from 0.02 to 50 V sec^{-1} revealed the following features:[19] the difference

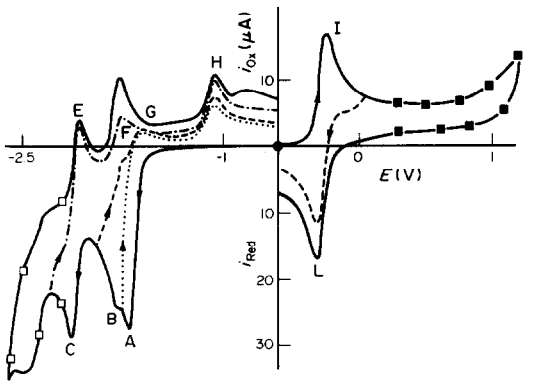


Fig. 1. Cyclic voltammetric responses recorded for a DMSO solution containing [Fe(II)L^1] (1.6×10^{-3} mol dm^{-3}) and [NEt_4][ClO_4] (0.1 mol dm^{-3}). between the peak potential value of the anodic and cathodic peaks, $E_p^a - E_p^c$, which is 61–63 mV at low scan rates (0.02–0.20 V sec^{-1}), progressively increases and reaches a value of 270 mV at 50 V sec^{-1}; the cathodic to anodic peak current ratio, $i_p^c : i_p^a$, is constantly equal to unity; the quotient of the anodic peak current and the square root of the scan rate, $i_p^a/v^{1/2}$, remains almost constant (a decrease of less than 10% was obtained in the cited scan rate range). All these findings are typical of an uncomplicated charge-transfer process characterized by a high degree of reversibility at low scan rates, which however decreases with increasing the scan rate. In the likely hypothesis that the transfer coefficient α ranges between 0.3 and 0.7, the reversible half-wave potential, $E_{1/2}^r$, which can be assumed as the formal electrode potential, $E^{o\prime}$, can be computed as the average of the potentials of the anodic peak and of its directly associated cathodic peak; in addition, the standard electron-transfer constant, k_s, can be evaluated by Nicholson's treatment,[20] if diffusion coefficients of both oxidized and reduced forms of the reactant are known. Under previous assumptions,[5] the electrochemical characteristics of the charge transfer formally attributable to the iron(II)–iron(III) couple have been computed, and they are reported in Table 1, together with the values relevant to all the studied complexes.

The cathodic behaviour of [Fe(II)L^1] is characterized in cyclic voltammetry by two successive cathodic peaks *A* and *B*. At mercury electrodes other peaks at more cathodic potentials (> -2 V), are also present, which, for comparison with the cathodic behaviour of [Na_2L^1], have to be attributed to the reduction of the deprotonated ligand. We attribute the two cathodic processes *A* and *B* to the successive one-electron reduction of the central iron(II) ion of the complex to formally iron(I) and iron(0) derivatives, respectively. In fact, controlled potential coulometric tests at -1.71 V, i.e. at the peak potential of peak *A*, indicate the consumption of one electron per molecule of [Fe(II)L^1]. The peak system *A–G* is attributable to the redox couple [Fe(II)L^1] | [Fe(II)L^1]$^-$. The $(i_p)_G : (i_p)_A$ ratio clearly

* The usual computation of formal electrode potentials as the average value between the peak potential of a response and that of the directly associated one can give in this case only approximate values, because the closeness of the two cathodic processes prevents a separate analysis with the scan rate in order to overcome the complications coupled to the charge transfers (see text), i.e. to reach the condition $i_p^a/i_p^c = 1$.

† Peak potential values at 0.2 V sec^{-1}.

shows that a chemical reaction follows the charge transfer; assuming an irreversible first-order reaction to be coupled to the charge transfer,[21] a half-life of about 1 sec was estimated for $[Fe(II)L^1]^-$. The further coulometric reduction at -1.95 V, in correspondence to peak *B*, consumes another mol of electrons per mol of starting compound. The peak system *B–F* is hence attributable to the redox couple $[Fe(I)L^1]^-|[Fe(0)L^1]^{2-}$. Also in this case the electrogenerated Fe(0)-complex is unstable in the macroelectrolysis time scale; its half-life is about 9 sec.

It must be pointed out that the electrogeneration of Fe(I)-complexes is not unusual.[22,23]

In acetonitrile solvent the electrochemistry of $[Fe(II)L^1]$ resulted less encouraging. In fact, the cathodic picture follows the same trend as in DMSO: two ligand-based processes at $E_p^c = -1.93$ V and -2.19 V, respectively, and two metal-based processes at $E_p^c = -0.96$ *V* and -1.68 V, respectively, were observed. On the contrary in the anodic range a response attributable to the charge transfer $[Fe(II)L^1] \overset{-e^-}{\rightarrow} [Fe(III)L^1]^+$ was detected at an $E^{\circ\prime} = -0.05$ V, but it resulted less well defined than in DMSO and followed by other electrode-poisoning anodic processes at potentials higher than $+1.3$ V.

The electrochemistry in DMSO of all other derivatives studied is qualitatively similar to that reported for $[Fe(II)L^1]$ except for nitro-compounds, because of the interference due to the cathodic reduction of the nitro-group. Table 1 summarizes the most significant features of the electrode behaviour of all studied compounds.

Electronic effects of the phenyl substituents. As expected, electron-donating groups favour the access to the Fe(III)-complex, where electron-withdrawing groups stabilize the Fe(II)-complex. As in the case of previously studied pentadentate ligands,[2,5,6] a linear correlation holds between oxidation potentials and the Hammett constants of X-type substituents only considering the 3-, 4-, 5-positions to be *ortho*, *meta*, *para* with respect to the phenolic oxygen atom, thus indicating that the electron density on the metal centre is enhanced or diminished by phenyl substituents chiefly *via* the Ph–O–Fe–O–Ph pathway. In this connection it must be noted that potential values are affected by electronic effects of Y-type substituents at an extent lower than that of X-type substituents.

The available set of data for the reduction potentials Fe(II)/Fe(I) is not sufficient for a reliable evaluation of relevant electronic effects.

The effect of dioxygen on the electrochemical behaviour of $[Fe(II)L](L = L^1–L^{12})$ *derivatives.* The oxygenation reaction of all [Fe(II)L] derivatives in

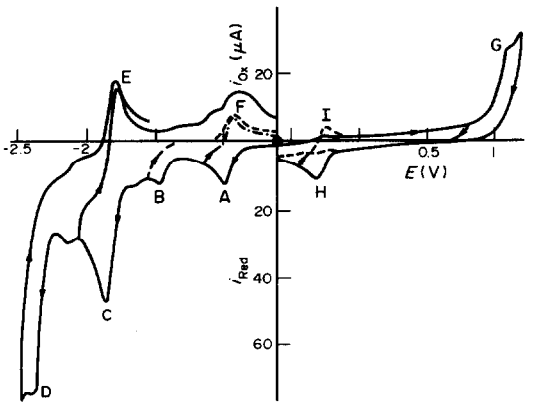

Fig. 2. Cyclic voltammograms recorded on a DMSO solution of $[Fe(II)L^1]$ (1.6×10^{-3} mol dm^{-3}) and $[NEt]_4[ClO_4]$ (0.1 mol dm^{-3}) upon oxygenation and subsequent deaeration. Cathodic scan at a mercury electrode. Anodic scan at a platinum electrode. Scan rate 0.2 V sec^{-1}.

DMSO solution was performed under the following experimental conditions: (a) bubbling of dioxygen ($p_{O_2} = 1$ atm) for 30 min in previously deaerated solution of the Fe(II)-complex; (b) subsequent bubbling of nitrogen for 30 min in order to purge from free dioxygen.

After the bubbling of dioxygen the voltammetric behaviour of $[Fe(II)L^1]$ reveals that the well-known catho–anodic system relevant to the $O_2 + e^- \rightleftarrows O_2^-$ process ($E_{1/2}^r \simeq -0.76$ V) gives an $i_p^a | i_p^c$ ratio equal to 0.86 at 0.2 V sec^{-1}, indicating that the electrogenerated superoxide ion is involved at a low extent in a reaction with species present in solution.

The voltammetric picture of the oxygenation product, after deaeration, is illustrated in Fig. 2.

Since it is ascertained that upon oxygenation $[Fe(II)L^1]$ is irreversibly oxidized to the μ-oxo dimer $[Fe(III)L^1]_2O$,[15,17,24] we try to explain the voltammogram in Fig. 2 on this basis. As it can be seen the response is complicated by the presence of a lot of peaks, however, a comparison with that of $[Fe(II)L^1]$ reported in Fig. 1, allows some interesting conclusions. The peak system *A–F* is likely attributable to the electrode process

$$[Fe(III)L^1\text{–O–}Fe(III)L^1] \underset{-e^-}{\overset{+e^-}{\rightleftarrows}} [Fe(II)L^1\text{–O–}Fe(III)L^1]^-.$$

Tests at different scan rates show that the charge transfer is complicated by following chemical reactions; however, the use of scan rates of the order of 10 V sec^{-1} allows to prevent the chemical complication ($i_p^a/i_p^c = 1$) and to compute a formal electrode potential of -0.97 V for the quasi-reversible charge transfer. The assignment of peak *B*

Table 2. Potential values for both the reduction of one Fe(III) center and the oxidation of the μ-oxo group in $[Fe(III)L]_2O$ ($L = L^1$–L^{12}), together with the lifetime of electrogenerated superoxide ion in the presence of oxygenation products

* Peak potential values at 0.2 V sec^{-1}.

† Lifetimes computed assuming a pseudo-first order chemical reaction with respect to superoxide ions to be involved in the consumption of the electrogenerated superoxide ions.

presents some difficulty because it can be attributed both to the subsequent Fe(II)/Fe(I) charge transfer and to the reduction of the second Fe(III) centre in the mixed-valence compound primarily electrogenerated. As regards the anodic scan, it is well evident the occurrence of an anodic process, irreversible in character, followed by a chemical reaction leading to the oxidized form of the precursor; we attribute peak *G* to the oxidation of the oxo group which causes the breakage of the μ-oxo dimer with formation of $[Fe(III)L^1]^+$, responsible for the peak system *H–I*.

It must also be pointed out that both the existence of some cathodic current at the starting potential (−0.6 V) and the cited presence of some species able to react with electrogenerated superoxide ions testify for the formation of an oxygenation by-product (very likely $[Fe(III)L^1]^+$ which can react with O_2^- to give the superoxo species $[Fe(III)L^1(O_2)^-]$).

A qualitatively similar voltammetric trend was also observed for the oxygenation of Fe(II)–Schiff base pentadentate complexes.[2,6]

The voltammetric picture illustrated for the oxygenation of $[Fe(II)L^1]$ is common to all other derivatives under investigation; Table 2 summarizes the relevant parameters, significant because rarely found.

As expected, the charge transfer $[Fe(II)L]_2O/[Fe(II)L–O–Fe(III)L]^-$ is favoured by the presence of electron-withdrawing groups and disfavoured by the presence of electron-donating groups in the aromatic portions of the ligand.

The electrochemical behaviour of the catechol/$[Fe(II)L^1]$ *system.* The first approach to the study of the catechol/$[Fe(II)L^1]$ system and its oxidation product was accomplished by a voltammetric investigation on the iron complex with monodentate catecholate coordination, $[Fe(III)L^1(catH)]$, which has been proposed as a model for the dioxygenases.[15,16]

Figure 3(a) illustrates the cyclic voltammetric response of $[Fe(II)L^1(catH)]$ in deaerated DMSO solution. For comparison, the responses relevant to both catechol and Na[catH] are also reported in Figs. 3(b) and 3(c), respectively. The peak system *A–D* is just coincident with the one of the redox couple $[Fe(III)L^1]^+/[Fe(II)L^1]$; the peak systems *E–G* and *F* are to be attributed to the oxidation of Hcat group to semiquinone and quinone, respectively, according to electrode mechanisms reported by Sawyer.[25] It must be remarked the anodic potential shift of peak *E* ($\Delta E_p = 0.38$ V) in respect to the one-electron oxidation of free $[Hcat]^-$, due to the complexation of Hcat with the iron substrate. The processes occurring at peaks *C* have been previously described in the reduction of $[Fe(II)L^1]$. About peak *B* it must be pointed out that the successive addition of increasing amount of $[Hcat]^-$ to the solution of $[Fe(III)L^1(catH)]$ causes the peak system *A–D* to decrease up to its disappearance and the peak *B* to increase up to a maximum ($E_p = -1.24$ V). On the contrary the addition of catechol to $[Fe(III)L^1(catH)]$ does not cause changes in the starting voltammetric response, except

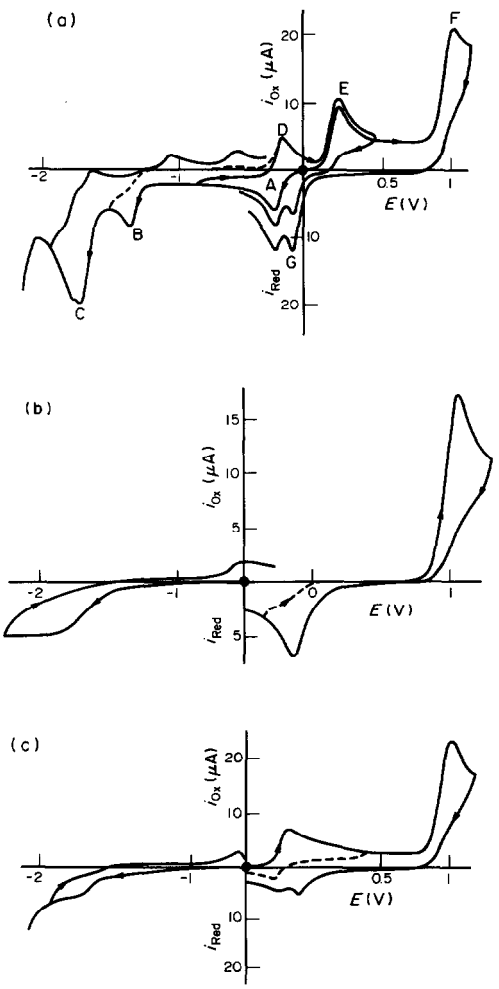

Fig. 3. Cyclic voltammetric responses of deaerated DMSO solutions containing $[NEt_4][ClO_4]$ (0.1 mol dm^{-3}) and: (a) $[Fe(III)L^1(catH)]$ (1.32×10^{-3} mol dm^{-3}); (b) catechol (1.11×10^{-3} mol dm^{-3}); (c) $[Hcat]^-$ (1.45×10^{-3} mol dm^{-3}). Platinum working microelectrode. Scan rate 0.2 V sec^{-1}.

for peak *F*. This behaviour suggests peak *B* must be attributed to the cathodic reduction $[Fe(III)L^1(catH)]/[Fe(II)L^1(catH)]^-$. The ligand exchange reaction in the presence of an excess of $[Hcat]^-$ to form $[Fe(III)(cat)_3]^{3-}$ has to be disregarded, as this anion reduces at a potential of -2.2 V (Hg electrode). In addition these data suggest that in DMSO solution the following equilibria hold:

$$[Fe(III)L^1(catH)] \rightleftarrows [Fe(III)L^1][catH]$$
$$\rightleftarrows [Fe(III)L^1]^+ + [catH]^-.$$

This equilibria could constitute a further reason, together with the hydrolytic formation of the μ-oxo dimer, for the differences noted between the properties of $[Fe(III)L^1(catH]$ in the solid state and in dichloromethane solution,[16] even if the relatively high polarity of DMSO can strengthen this dissociating process at an extent higher than in CH_2Cl_2.

Electrochemically induced reactivity of $[Fe(II)L^1]$ *towards catecholate.* A preliminary examination of the effect of addition of either catechol or $[Hcat]^-$ to a deaerated solution of $[Fe(II)L^1]$ indicated that complexation of the catecholate occurred upon electrode oxidation, the reactivity of electrogenerated $[Fe(III)L^1]^+$ towards $[Hcat]^-$ being much more effective than towards catechol. Figure 4 illustrates the most significant complexation steps of $[Fe(II)L^1]$ by $[Hcat]^-$.

As it can be seen the addition of $[Hcat]^-$ causes the appearance of both the peak system *D–E*, attributable to the one-electron oxidation of coordinated Hcat to the semiquinone form cited above, and peak *C* ($E_p = -0.59$ V), which more and more takes the place of the peak system *A–B* of the redox couple $[Fe(II)L^1]/[Fe(III)L^1]^+$. It must be further observed [see Fig. 4(d)] that in the reverse scan after traversing the anodic processes, peak *F* arises just at the potential of peak *B* of Fig. 3, which has been attributed to the couple $[Fe(III)L^1(catH)]/[Fe(II)L^1(catH)]^-$. The anodic peak *C* is hence attributable to the process:

$$[Fe(II)L^1] + [Hcat]^-(\text{excess}) \rightarrow$$
$$[Fe(III)L^1catH] + e^-.$$

In agreement with this hypothesis, controlled potential coulometric tests at -0.3 V (Pt macroelectrode) on DMSO solution containing the system $[Fe(II)L^1]$–$[Hcat]^-$ in a ratio of about 1:4.5 give a black–green solution displaying the already described voltammetric response of $[Fe(III)L^1(catH)]$ in the presence of excess of $[Hcat]^-$, and showing an IR spectrum superimposable to that of a DMSO solution of $[Fe(II)L^1(catH)]$ prepared according to Ref. 15.

Reactivity of the $[Fe(II)L^1]$*–catecholate system towards dioxygen.* The voltammetric investigation on DMSO solutions of catechol or catecholate monoanion as function of the addition of dioxygen showed that catechol does not undergo oxidation processes, while the catecholate monoanion is oxidized to quinone.

By bubbling dioxygen ($p_{O_2} = 1$ atm) in deaerated DMSO solutions containing $[Fe(II)L^1]$ and catechol (in a 1:2.5 ratio) a black–green solution forms, able to give cyclic voltammetric responses similar to those reported in Figure 3(a). This accounts for the formation of $[Fe(III)L^1(catH)]$, and demonstrates that the usual irreversible oxidation of the Fe(II)-complex by dioxygen to the μ-oxo dimer is prevented by the presence of catechol.

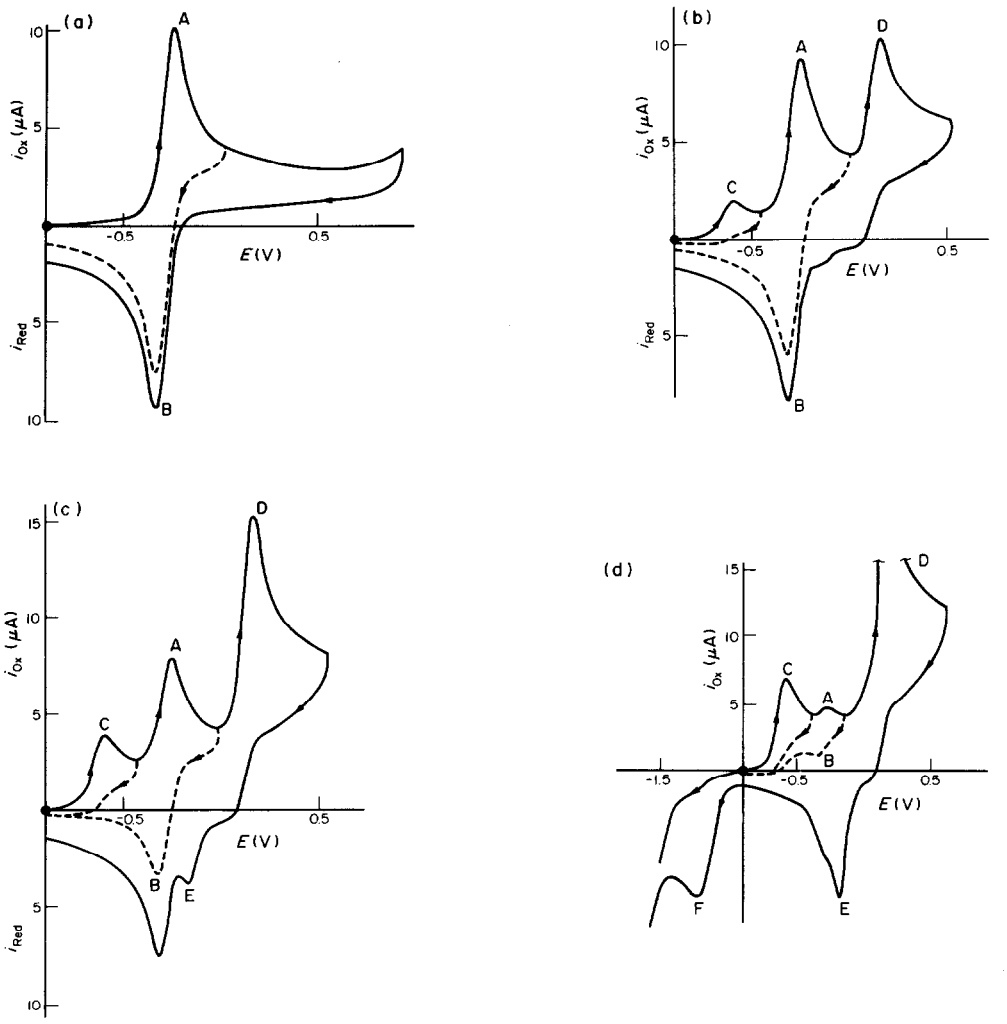

Fig. 4. Cyclic voltammetric responses of a deaerated DMSO solution containing $[NEt_4][ClO_4]$ (0.1 mol dm^{-3}) and $[Fe(II)L^1]$ (1.61×10^{-3} mol dm^{-3}) as a function of the addition of catecholate monoanion. (a) Before the addition of $[Hcat]^-$; (b) after the first addition ($[Hcat]^- = 1.74 \times 10^{-3}$ mol dm^{-3}); (c) after the second addition ($[Hcat]^- = 3.18 \times 10^{-3}$ mol dm^{-3}); (d) after the third addition ($[Hcat]^-$ 6.5×10^{-3} mol dm^{-3}). Platinum working microelectrode. Scan rate 0.2 V sec^{-1}.

In addition we thought this reaction could be an alternative route to the synthesis of $[Fe(III)L^1(catH)]$ if performed in acetonitrile solution. In this connection a deaerated acetonitrile solution of catechol and $[Fe(II)L^1]$ (in a ratio of about 3:1) leads to crystalline $[Fe(III)L^1(catH)]$ when dioxygen is bubbled through it.

These results suggest that, under the present experimental conditions, the oxidizing power of dioxygen stops at the level of iron(II) centre oxidation. A confirmation of this comes from the fact that the bubbling of air in a deaerated DMSO solution of $[Fe(III)L^1(catH)]$, followed by deaeration, does not cause changes with respect to the starting voltammetric picture, i.e. no chemical oxidation occurs. This is in marked contrast to the dioxygen reactivity of [NN′-ethylenebis (salicylideneiminato)] (3,5-di-*tert*-butylcatecholato) iron(III).[26]. Hence, at least for $[Fe(III)L^1(catH)]$ as dioxygenases model,[15,16,26] the enzyme mechanism, which attributes to iron the role of binding and activation of dioxygen after substrate reduction of the ferric centre to the ferrous oxidation state,[27] could be preferred over the one which assumes the coordination of the catechol to the ferric centre to activate the catechol to attack by oxygen, with the formation of semi-quinone and superoxide.[26,28]

EXPERIMENTAL

Materials. *o*-Phenylenediamine, *o*-hydroxobenzaldehyde (salicylaldehyde) and their derivatives, as

well as catechol, were reagent grade products and were used without further purifications.

Ferrous acetate was prepared as previously described.[2]

Dimethyl sulphoxide and acetonitrile solvents (Burdick and Jackson, distilled in glass, UV grade) were used as received.

Tetraethylammonium perchlorate ($[NEt_4][ClO_4]$) supporting electrolyte (Carlo Erba) was dried in a vacuum oven and used without further purification.

Deaeration or oxygenation of solutions, when necessary, were performed by using ultrapure dinitrogen or dioxygen.

Synthesis of the complexes. [Fe(II)L] (L = L^1–L^{12}) derivatives were prepared according to the method described in Ref. 17 for [Fe(II)L^1], and identified by IR spectroscopy and elemental analyses.

[Fe(III)L^1(catH)] was prepared either according to Ref. 15, or by the following method (see text): a deaerated acetonitrile solution containing [Fe(II)L^1] and catechol (in a molar ratio of about 1:3) was refluxed for 1 hour under a dioxygen atmosphere (p_{O_2} = 1 atm). The black solid was filtered and washed three times with acetonitrile. The product was characterized by IR spectroscopy and microanalysis. The yield was about 40%.

$[Fe(cat)_3]^{3-}$ was prepared according to Ref. 29.

$[H_2L^1]$ was synthesized by condensation of salicylaldehyde and *o*-phenylenediamine in dry methanol. $[Na_2L^1]$ was obtained by neutralizing a methanol solution of $[H_2L^1]$ with a methanol solution of sodium methoxide, and identified by its IR spectrum.[30]

$[Hcat]^-$ was prepared by mixing equimolar amounts of catechol and sodium methoxide in deaerated methanol solution.

Apparatus. The electrochemical apparatus used has been previously described.[5] All potential values refer to an aqueous saturated calomel electrode (SCE). The temperature was controlled at 20 ± 0.1°C.

The IR absorption spectra, both in solution and in the solid state, were recorded on a Model 782 Perkin–Elmer grating spectrophotometer.

Abstract—MCl_5 (M = Nb, Ta) reacts with 2 equivalents of $Me_3SiNHCMe_3$ to give $[M(NCMe_3)Cl_3(NH_2CMe_3)]$ from which $[M(NCMe_3)Cl_3(PMe_3)_2]$ is obtained on addition of PMe_3. One equivalent of $Me_3SiNHCMe_3$ reacts with MCl_5 in the presence of 3 equivalents of PMe_3 to give $[M(NCMe_3)Cl_3(PMe_3)_2]$ and PMe_3HCl. MCl_5 reacts with excess RNH_2 (R = CMe_3, $CHMe_2$, CH_2Me) to give $[M(NR)(NHR)Cl_2(NH_2R)]$ and 3 equivalents of RNH_3Cl. One equivalent of alcohol replaces the amido ligand in $[M(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$ to give $[M(NCMe_3)(OR)Cl_2(NH_2CMe_3)]_2$ (M = Nb, R = $OCMe_3$; M = Ta, R = OEt). The structure of $[Ta(NCMe_3)(\mu\text{-}OEt)Cl_2(NH_2CMe_3)]_2$ was determined by single-crystal X-ray diffraction methods. Crystals are triclinic, space group $P\bar{1}$ with $a = 9.900(5)$, $b = 10.161(17)$, $c = 9.017(6)$ Å and $\alpha = 103.91(8)$, $\beta = 97.77(4)$, $\gamma = 64.40(7)°$. The structure was solved by Patterson and Fourier methods and refined to an R value of 0.062 for 1319 observed data. The Ta–N_{imido} and Ta–N_{amino} bond lengths are 1.70(2) Å and 2.28(2) Å, respectively; the bridging Ta–O bond lengths are 2.01(2) Å and 2.32(2) Å, the longer one lying *trans* to the imido function.

Organo-imido complexes of the heavier group V transition metals (Nb, Ta) are generally less well known than those of group VI and VII.[1] Early methods of preparation included thermolysis of dialkylamido complexes[2] and reaction of the pentachlorides with lithium dialkylamides[3] or lithium dialkylamide–monoalkylamide mixtures.[4] More recently the imido function has been generated by reaction of low valent complexes with PhN=NPh[5] or Me_3SiN_3[6] and by elimination of methane from species containing both alkyl and monoalkylamido groups.[7] To date, the most convenient method has been the reaction of *neo*pentylidene complexes with imines.[6,8]

With the aim of obtaining both niobium and tantalum organo-imides by simpler and more direct methods, we believed that by analogy with high-valent metal–alkyl–alkylidene chemistry,[9] proton abstraction from one of two coordinated mono-alkylamido ligands [eqn (1)] or base promoted deprotonation of a single monoalkylamido ligand [eqn (2)] might lead to the required imido linkage. These reactions are likely in view of the greater acidity of an NH proton in comparison with a CH proton.

$$M(NHR)_2Cl_3 \rightarrow M(NR)Cl_3 + RNH_2 \quad (1)$$

$$M(NHR)Cl_4 + \text{base} \rightarrow M(NR)Cl_3 + \text{base, HCl.} \quad (2)$$

These ideas were further encouraged by a recent report that bridging imido complexes

$$(M{-}\overset{\overset{R}{|}}{N}{-}M)$$

could be prepared by thermolysis or addition of primary amine to $CpTiCl_2(NHR)$ complexes.[10] Monoalkylamido complexes are relatively rare but are known for titanium,[10,11] molybdenum,[12] tungsten[13] and rhenium (phenylamido complexes).[14] For group V, $[Ta(NHR)_2Cl_2(NH_2R)]$ (R = Me, Et, "propyl, "butyl)[15] and $Nb(NHR)_3Cl_2$

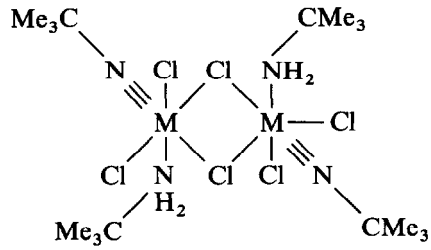
($R = Me$)[16] have been claimed on the basis of analytical data.

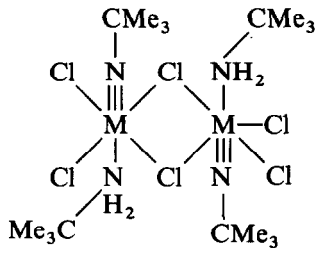
We report here some reactions of niobium and tantalum pentachlorides with $Me_3SiNHCMe_3$ and primary amines. A brief report of this work has appeared.[17]

RESULTS AND DISCUSSION



Addition of slightly more than two equivalents of $Me_3SiNHCMe_3$ to $NbCl_5$ in benzene solution leads to dissolution of the niobium halide and development of an orange red colouration after approximately 2 h. After a further 6 h the solution pales to a light yellow–brown and a yellow precipitate is deposited. This air-sensitive product analyses as $Nb(NHCMe_3)_2Cl_3$ but was shown to be the imido complex $[Nb(NCMe_3)Cl_3(NH_2CMe_3)]$ on the basis of spectroscopic data. Sharp NH absorbances in the IR spectrum at 3243 and 3175 cm^{-1} as well as NH resonances in the ^1H NMR spectrum at 3.90 and 7.01 ppm are similar to those found for $[W(NPh)(NCMe_3)Cl_2(NH_2CMe_3)]_2$ for which an X-ray structure determination has shown terminal *t*-butylimido and amine ligands.[18] By ^{13}C NMR spectral comparisons with other complexes we have prepared (see Table 2), the position of the *t*-butyl group quarternary carbon resonance is conveniently found to distinguish between imido, amido and amine ligands (see Table 2). For $[Nb(NCMe_3)Cl_3(NH_2CMe_3)]$ there are imido resonances at 71.6 and 70.4 ppm as well as two amine resonances at 54.8 and 53.7 ppm, suggesting two forms of the complex in solution. In addition there are three *t*-butyl group methyl resonances in both ^{13}C and ^1H NMR spectra, the NH protons in the latter being of unequal intensity.

The reaction of $TaCl_5$ and $Me_3SiNHCMe_3$ also gave a product which analysed as $[Ta(NCMe_3)Cl_3(NH_2CMe_3)]$ and had similar IR, ^1H and ^{13}C NMR spectra to the niobium analogue. Insolubility has precluded molecular weight determinations but the complexes are most likely chloro-bridged dimers with lone pair donation from a ligand lying *trans* to the imido function as found in the X-ray structure determination of $[Ta(NCMe_3)Cl_3(PEt_3)(THF)]$.[19] For the $[M(NCMe_3)Cl_3(NH_2CMe_3)]$ complexes, two forms [(a) and (b)] are then possible depending on the nature of the *trans* ligand. We have been unable to separate the two cleanly by recrystallization but the product obtained from reacting $NbCl_5$ with one equivalent of $Me_3SiNHCMe_3$ shows only the ^{13}C NMR spectral features of one isomer.



The $[M(NCMe_3)Cl_3(NH_2CMe_3)]$ complexes reacted with PMe_3 to give yellow gums which failed to crystallise but, after extensive washing and pumping down, flaky solids were obtained which gave analytical data that were close to the formulation $[M(NCMe_3)Cl_3(PMe_3)_2]$ (for example, see $[Nb(NCMe_3)Cl_3(PMe_3)_2]$ in Table 1). The ^1H NMR spectra contained PMe_3 and ^{t}butyl methyl resonances (2:1 ratio) as did the ^{13}C NMR spectrum which additionally showed the quaternary carbon of a *t*-butylimido group. For example $[Nb(NCMe_3)Cl_3(PMe_3)_2]$ shows a quaternary carbon at 70.3 ppm, a single resonance for the *t*-butyl methyl group at 30.0 ppm, and PMe_3 doublets at 15.5 and 14.3 ppm. The spectrum is essentially the same as that of $[Ta(NCMe_3)Cl_3(PMe_3)_2]$ prepared from $[Ta(NCMe_3)Cl_3(THF)_2]$ where one PMe_3 was assigned *trans* to the imido function.[6,8] The ^1H NMR of $[Nb(NCMe_3)Cl_3(PMe_3)_2]$ shows a doublet for the PMe_3 groups indicating a *cis* orientation.

We have found that a variety of $M(NCMe_3)Cl_3L_2$ complexes can be prepared from the $[M(NCMe_3)Cl_3(NH_2CMe_3)]$ species but they generally persist as gummy materials which fail to crystallise and are best characterised by NMR spectroscopy. For example the ^{13}C NMR spectrum of $Nb(NCMe_3)Cl_3 \cdot$ bipyridyl contains *t*-butylimido resonances at 76.3 and 30.0 ppm. The proton spectrum shows α,α-dipyridyl and a *t*-butyl group in the required ratio as well as a downfield shift of the bipyridyl α-protons, compared with the free ligand.

In attempting an alternative preparation of $[Nb(NCMe_3)Cl_3(PMe_3)_2]$ by deprotonation of a single coordinated monoalkylamido ligand, 3 equivalents of PMe_3 were added to $NbCl_5$

[a] Formulations with added benzene are supported by ^1H NMR spectra.
[b] Calculated figures in parentheses.

in benzene followed by one equivalent of $Me_3SiNHCMe_3$, whereupon the solution turned dark red, lightening to yellow after several hours and depositing PMe_3HCl. Unsatisfactory analytical data were again obtained for the yellow flaky material isolated but it was formulated as $[Nb(NCMe_3)Cl_3(PMe_3)_2]$ on the basis of the 2:1 ratio of PMe_3 and *t*-butyl methyl groups in the ^1H NMR spectrum; IR and ^{13}C NMR spectra were similar to those of $[Nb(NCMe_3)Cl_3(PMe_3)_2]$ formed from $[Nb(NCMe_3)Cl_3(NH_2CMe_3)]$. $TaCl_5$, PMe_3 and $Me_3SiNHCMe_3$ also reacted to give a yellow flaky solid which was somewhat contaminated but the ^1H NMR spectrum clearly showed a 2:1 ratio of PMe_3 and *t*-butyl methyl resonances while the IR and ^{13}C NMR spectra were similar to those of $[Ta(NCMe_3)Cl_3(PMe_3)_2]$ prepared from either

$$[Ta(NCMe_3)Cl_3(NH_2CMe_3)]$$

or

$$[Ta(NCMe_3)Cl_3(THF)_2].^{6,8}$$

The reactions described so far demonstrate that the *t*-butylimido function may be generated from the pentahalides and $Me_3SiNHCMe_3$. Monoalkylamido species are the most likely intermediates involved during the initial darkening of solution colour, so that the possibility arises during the formation of the $[M(NCMe_3)Cl_3(NH_2CMe_3)]$ complexes that a steric effect may be responsible for deprotonation of one of two *cis* coordinated monoalkylamido ligands.* However our ongoing investigations have shown that $[Ta(NEt)Cl_3(NH_2Et)]$ is the result of using $Me_3SiNHEt$. For base promoted deprotonation of a single monoalkylamido species it is apparent that a strong base such as PMe_3 is required to direct the reaction course since reacting $NbCl_5$ with NEt_3 and $Me_3SiNHCMe_3$ does not appear to produce NEt_3HCl while ^1H and ^{13}C NMR spectra suggest the presence of $[Nb(NCMe_3)Cl_3(NH_2CMe_3)(NEt_3)]$ and $NbCl_5(NEt)_x$.

Niobium and tantalum pentachlorides also react with excess *t*-butylamine in benzene to produce colourless to slightly yellow solutions and 3 equivalents of insoluble *t*-butylamine hydrochloride based on the amount of pentahalide used. Crystalline complexes analysing as $M(NHCMe_3)_3Cl_2$ were obtained from these solutions but the alternative formulation

$$[M(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$$

* *cis* oriented alkylamido ligands are not without precedent. Crystal structure determinations have shown that dialkylamido ligands are orientated *cis* in $Ta(NMe_2)_3Cl_3(NHMe_2)$, $[Ta(NMe_2)Cl_2(NHMe_2)]_2O$ and $[Ta(NMe_2)_3Cl_2]_2$.[20] Ligands with a high *trans* influence always prefer a mutual *cis* configuration irrespective of their π-acceptor or donor properties.[20,21]

Table 2. NMR data

Complex	^{13}C NMR: α-Carbon (N–C) Imido	Amido	Amino	^{13}C NMR: Others	^{1}H NMR

$[Ta(NCMe_3)(NHCMe_3)Cl_2(PMe_3)_2]$	64.7	56.6	—	34.9, 33.7 (CMe_3) 16.0t ($^1J_{P-C}$ = 11.5 Hz,[a] *trans* PMe_3)	1.35s (CMe_3) 1.50t ($^2J_{P-H}$ = 4 Hz, *trans* PMe_3) 10.91b (NH)
$[Nb(NCMe_3)(\mu\text{-}OCMe_3)Cl_2(NH_2CMe_3)]_2$	69.6	—	52.3	85.2 (OC) 31.0, 30.6 (CMe_3)	1.36, 1.39, 1.50 (CMe_3) 3.84, 4.67 (NH_2)

[a] Values taken from noise decoupled spectra.

is consistent with spectral data. Thus the niobium complex exhibited 3 *t*-butylmethyl resonances of equal intensity in the ^{1}H NMR spectra as well as NH proton resonances at 4.0 and 8.5 ppm in an approximate 2:1 ratio. The ^{13}C NMR spectrum contained quaternary carbons of *t*-butylimido and amino ligands as found for

$[Nb(NCMe_3)Cl_3(NH_2CMe_3)]$

but also an additional resonance (59.4 ppm) attributable to a *t*-butylamido ligand. The ^{13}C NMR spectrum of

$[Ta(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$

showed the presence of two species in solution which appear to persist in the same ratio after successive recrystallisations. So far variable temperature studies have been inconclusive but we believe that dissociation of a chloro-bridged dimer gives rise to these features.

The complexes react with two equivalents of PMe_3 to form $[M(NCMe_3)(NHCMe_3)Cl_2(PMe_3)_2]$ species again obtained as non-crystalline flaky solids which were characterised by NMR spectroscopy. Thus the ^{1}H NMR of the niobium analogue exhibited PMe_3 and *t*-butyl group methyl resonances in a ratio of 2:1 and a single broadened NH proton at 10.9 ppm. The ^{13}C NMR spectrum

contained *t*-butyl quaternary carbon resonances characteristic of imido and amido ligands whereas the *t*-butylamino quaternary carbon observed for the parent complex was absent.

The amido proton in these species apparently resists abstraction as we have been unable to obtain diimido species by reaction with excess PMe_3. The

$$[M(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$$

complexes may also be prepared by adding two equivalents of Me_3CNH_2 to the

$$[M(NCMe_3)Cl_3(NH_2CMe_3)]$$

complexes but no further reaction occurs when excess of the amine is present. The compound

$$[Nb(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$$

does, however, react with two equivalents of $LiNHCMe_3$ but convincing analytical data for the petroleum ether soluble material have not yet been obtained. Chlorine is absent from the product and the ^{13}C NMR spectrum shows two *t*-butylimido quaternary carbons so that a diimido species may be present.

We were also interested in determining the role of steric factors in the formation of the $[M(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$ complexes. Reactions of $TaCl_5$ with the less sterically demanding amines Me_2CHNH_2 and $EtNH_2$ again led to deposition of 3 amine hydrochloride equivalents and colourless complexes analysing as $[Ta(NR)(NHR)Cl_2(NH_2R)]$ were obtained from solution. The formulation is again supported by NMR spectra, particularly the appearance of α-carbon resonances attributable to an amino ligand in the ^{13}C NMR spectrum of each complex. The imido and amido α-carbons have approximately the same shift downfield and we are further investigating this facet of their chemistry at present.

An X-ray structure determination of $[Ta(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$ reported earlier,[17] showed the molecule to be a chloro-bridged dimer containing *t*-butylimido, amido and amino ligands orientated about each tantalum. Several points emerged from this structure and these are presented more fully here. The short Ta–N bond distance [1.86(3) Å] and large Ta–N–C bond angle [160(2)°] observed for the amido ligand are of particular interest. An 18 electron count for the complex requires $Ta–N_{amido}$ π-bonding and this is reflected by the comparatively short $Ta–N_{amido}$ bond distance and lengthening of the *trans* Ta–Cl(2) bond to 2.66(1) Å. This latter distance is similar to the Ta–Cl(1) bond length [2.69(1) Å] *trans* to the imido function where the essentially linear $Ta–N–C_{imido}$ bond angle indicates significant π-bonding. However, the $Ta–N_{amido}$ π-bonding situation may well be further complicated since a calculation of the amido proton position places it approximately 2.2 Å from the metal centre.*

In alkylidene complexes of tantalum, short Ta–C bond distances and large $Ta–C_\alpha–C_\beta$ bond angles are important in identifying metal . . . H–C interactions.[23] A neutron study of $[Ta(CHCMe_3)Cl_3(PMe_3)_2]_2$[24] has shown the above bond length and angle to be 1.898(2) Å and 161(1)°, respectively, values which are similar to the present tantalum–amido ligand data. With a Ta–C–H bond angle of 84.8° the alkylidene proton was located only 2.12 Å from the metal suggesting a 2-electron-3 centre bond or "protonated" triple bond.[24]

Distorted alkylidene ligands in tantalum complexes are simply identified from $^1J_{C-H\alpha}$ values[23] but the only easily obtainable NMR data for the amido ligand is the NH proton shift. Table 3 contains structural data for known monoalkylamido complexes as well as ^1H NMR NH proton shifts. A relationship between M–N–C bond angles or M–N bond lengths with the NH proton shift is not apparent but within the limits of structure refinement, the largest bond angle and shortest bond length are shown by the Ta–amido complex where the NH proton resonates upfield compared with the low valent molybdenum amido complex.[12] The proton is observed even further upfield in

$$[W(NCMe_3)_2(NHCMe_3)_2]$$

and

$$[WO(NEt)(NHEt)Cl]$$

for which structural data are not available. Clearly precise structural information is now needed to determine the extent of the Ta . . . H–N interaction as well as possible Cl . . . H–N interactions especially as both may be important in proton abstraction processes.

The reactivity of the metal–monoalkylamido bond in the

$$[M(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$$

complexes was also investigated. The complexes do not react with excess Me_3SiCl to produce the

$$[M(NCMe_3)(NH_2CMe_3)Cl_3]$$

species but the amido group may be replaced by an

* For $(adamantyl–NH)_2Mo(OSiMe_3)_4$ a modified extended Hückel calculation predicted a Mo–N–H bond angle of 77°.[22] If the Ta–N–H bond angle of the present complex is allowed to range from 77 to 91°, the calculated Ta . . . H approach has the limiting values of 1.96 and 2.20 Å.

Table 3. Structural and ^{1}H NMR data for amido complexes [M(NHR)]

	M–N–C (°)	M–N (Å)	Calc. M . . . H (Å)	δNH	Ref.
$[Ta(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$	161(2)	1.86	2.20	8.0	17
$Mo(NHadamantyl)_2(OSiMe_3)_4$	150.8	2.057	2.50 (2.097)[a]	—	22

[a] Value for Mo–N–H angle of 77°.

alkoxide. One equivalent of *t*-butanol reacted with the niobium complex to give a crystalline material analysing as

$$[Nb(NCMe_3)(OCMe_3)Cl_2(NH_2CMe_3)],$$

the imido and amine ligands being confirmed by *t*-butyl group quaternary carbons at 69.6 and 52.3 ppm in the ^{13}C NMR spectrum. The ^{1}H NMR spectrum shows two amino protons at 3.8 and 4.7 ppm but no amido NH proton.

Addition of one equivalent of EtOH to $[Ta(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$ initially gave a gummy material which NMR spectral analysis indicated to be a mixture. However, crystals were obtained from the sample, one of which was examined by X-ray crystallography. The molecule was found to be an ethoxy-bridged dimer with the two halves centrosymmetrically related (see Fig. 1). Each tantalum atom adopts a distorted octahedral coordination geometry with the bridging ethoxides lying *trans* to both *t*-butylimido and chloro ligands. The remaining chloro group lies *trans* to a *t*-butylamino ligand. Selected bond lengths and angles are given in Table 4.

The Ta–N bond distance of 1.70(2) Å and Ta–N–C(1) bond angle of 171(2)° indicate a linear *t*-butylimido ligand involving multiple bonding between tantalum and nitrogen. The bond length is

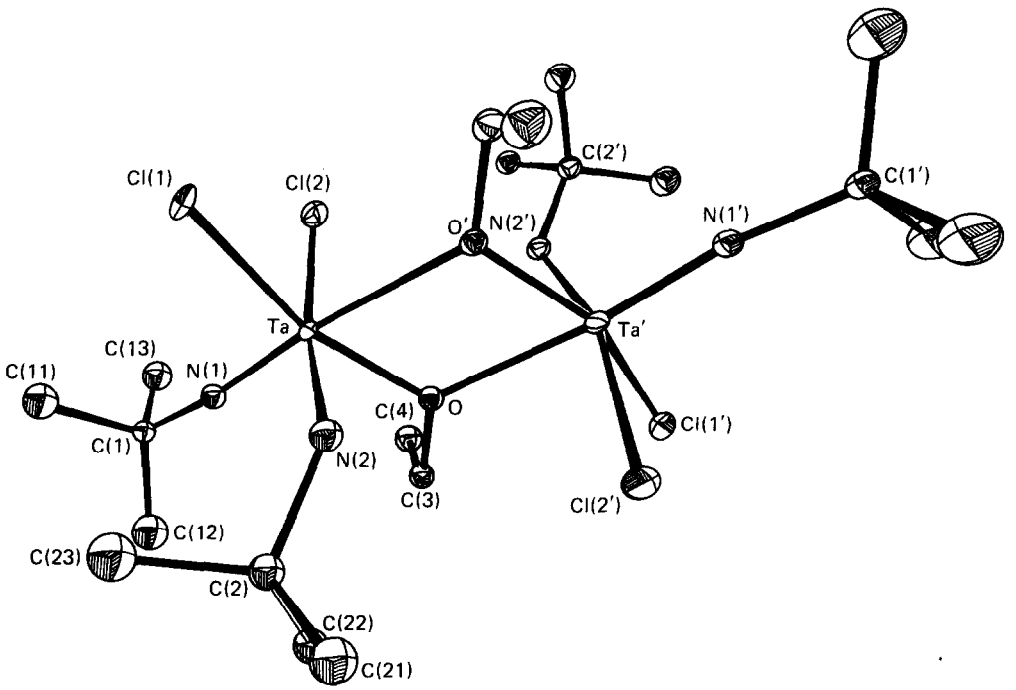

Fig. 1. The molecular structure of $[Ta(NCMe_3)(\mu\text{-}OEt)Cl_2(NH_2CMe_3)]_2$. Hydrogen atoms have been omitted for clarity. Thermal ellipsoids have been drawn at the 15% probability level.

Table 4. Selected bond lengths and angles for $[Ta(NCMe_3)(\mu\text{-}OEt)Cl_2(NH_2CMe_3)]_2$

(a) Bond lengths (Å)			
Ta–Cl(1)	2.421(6)	Ta–O′	2.32(2)
Ta–Cl(2)	2.407(7)	Ta–N(1)	1.70(2)
Ta–O	2.01(2)	Ta–N(2)	2.28(2)
Ta . . . Ta	3.58		
(b) Bond angles (°)			
Ta–N(1)–C(1)	167(2)	Cl(2)–Ta–N(1)	95.3(7)
Ta–N(2)–C(2)	130(2)	O′–Ta–N(1)	171.1(8)
N(2)–Ta–N(1)	101.7(8)	Cl(2)–Ta–N(2)	161.5(5)
O–Ta–N(1)	102.7(8)	O–Ta–O′	68.5(6)
Cl(1)–Ta–N(1)	98.6(7)	Ta–O–Ta′	111.5(7)
N(2)–Ta–Cl(1)	81.6(6)		
N(2)–Ta–O	88.4(7)		
N(2)–Ta–O′	80.4(7)		

in accord with that predicted for a Ta–N triple bond (4-electron donor)[1] and lies within the range of values found for other organo-imido complexes of tantalum.[1,17,19,20,25] The Ta–N(2) bond distance of 2.28(2) Å is indicative of σ lone pair donation to the metal whereas the two terminal Ta–Cl bond distances [2.421(6) and 2.407(7) Å] are not significantly different from others reported,[19,20,25] the shorter distance occurs *trans* to the amino N.

A significant *trans* lengthening (*ca* 0.31 Å) occurs for the Ta–O bond *trans* to the imido function and this results in the asymmetric bridge linking the two tantalum atoms, a feature which also prevails in other tungsten phenylimido alkoxide complexes.[26] The shorter Ta–O bond distance [2.01(2) Å] is not significantly different from the sum of the covalent radii (2.08 Å) so that a normal Ta–O single bond is present. This absence of Ta–O π-interactions is noted in other bridging alkoxide complexes.[27] The molecule $[Ta(NCMe_3)(\mu\text{-}OEt)Cl_2(NH_2CMe_3)]_2$ is thus a 16 electron species as are

$$[Ta(NPh)Cl_3(PEt_3)(THF)]^{19}$$

and

$$[TaCl_3(THF)_2]_2(=NC(Me)=C(Me)N=).^{28}$$

They are in contrast to

$$[Ta(NCMe_3)(NHCMe_3)Cl_2(NH_2CMe_3)]$$

where the possibility of π-bonding from the amido nitrogen allows an 18-electron count.

The distorted octahedral geometry about each metal centre is shown by the relatively large distance (0.37 Å) the tantalum atoms lie above the plane perpendicular to the Ta–N(1) vector. Similar deviations are observed in other organo-imido and the related nitrido complexes as a result of the short M–N bond distance.[29] It may be contrasted with the distance (0.05 Å) of the Ta from the plane containing N(1), Cl(1), O and O′. Calculation of the proton positions of the amino group indicates a weak interaction [H . . . Cl(2), 2.27 Å] across the dimer to an adjacent chloride. (This hydrogen bond is as strong as that observed in

$$[W(NPh)(NCMe_3)Cl_2(NH_2CMe_3)]_2.^{18}$$

There is also an even weaker interaction (2.6 Å) between a *cis* chloro group (H . . . Cl(1)) and the second amino proton. The combined effect apparently causes the *t*-butyl group to face the *t*-butylimido ligand which would otherwise not be a favoured orientation.

In conclusion we summarise the similarities of some of the chemistry presented here to features found in metal–carbon multiple and single bonded d^0 transition metal complexes. In particular, the deprotonation of NH groups has analogies to that of α-CH groups of bulky alkyl ligands.[9] Three types of metal–nitrogen bonding occur about the same metal centre in the

$$[M(NCMe_3)(NHCMe)Cl_2(NH_2CMe_3)]$$

complexes which may be compared with the three types of metal–carbon bonding in

$$[W(CCMe_3)(CHCMe_3)(CH_2CMe_3)(dppm)].^{30}$$

The close approach of an amido NH proton to the metal centre in the amido complex is similar to that observed in alkyl[31] and alkylidene[23] chemistry where metal–proton interactions are now a well established feature.

EXPERIMENTAL

Microanalyses were performed by Dr. A. C. Campbell and associates, University of Otago, New Zealand.

Spectrometers—IR: Perkin–Elmer 597; spectra in Nujol mulls between CsI plates. NMR: Varian T60 (^{1}H, 60 MHz), JEOL FX60 (^{13}C, 15.04 MHz).

All operations were performed under oxygen-free nitrogen and solvents were dried over sodium and distilled from sodium wire or sodium/benzophenone except for chlorinated hydrocarbons which were dried and distilled over CaH_2. Amines were dried and distilled over CaH_2. Silylamines and PMe_3 were prepared by literature methods.[33,34] Niobium and tantalum pentachlorides (Riedel de-Haën) were sublimed prior to use. Melting points were determined in sealed tubes under nitrogen and are uncorrected. Analytical data are collected in Table 1.

t-*Butylamine*-t-*butylimidotrichloroniobium*

Trimethylsilyl-*t*-butylamine (1.9 cm^3, 9.8 mmol) in benzene (40 cm^3) was added to a suspension of $NbCl_5$ (1.3 g, 4.8 mmol) in benzene (50 cm^3). After 2 h the solution was an orange–red colour and after a further 12 h the colour was yellow–brown and a yellow precipitate was deposited. The volume was reduced to *ca* 20 cm^3 and the solid filtered followed by washing with cold benzene (2 × 5 cm^3) to give the complex as yellow microcrystals. Yield: 1.2 g (67%). M.p. 237–240°C.

IR 3243m; 3175m; 2560w; 1560m; 1395m; 1355m; 1280m; 1210s; 1160s; 1140m; 1104m; 1022w; 923w; 890m; 842w; 801w; 740w; 720w; 678m; 646m; 584w; 542m; 530m; 444w; 418m; 370s; 350s; 322s; 302s; 280s cm^{-1}.

Further complex is obtained by removal of solvent from the filtrate but the product is less pure.

Addition of trimethylsilyl-*t*-butylamine (1.2 cm^3, 6.3 mmol) in benzene (30 cm^3) to $NbCl_5$ (1.6 g, 5.9 mmol) suspended in benzene (40 cm^3) gave a yellow precipitate, containing only one species by ^{13}C NMR [δ, CD_3CN, 71.8, 55.5 (CMe); 29.5, 27.5 (CMe_3) ppm].

t-*Butylamine*-t-*butylimidotrichlorotantalum*

Trimethylsilyl-*t*-butylamine (1.6 cm^3, 8.3 mmol) in benzene (30 cm^3) and $TaCl_5$ (1.4 g, 3.9 mmol) suspended benzene (50 cm^3) were reacted as before to give at first a yellow orange solution which paled to light yellow brown. The solution was filtered, the solvent reduced to *ca* 20 cm^3 and the white solid filtered off and washed with cold benzene as before. Yield: 1.45 g (83%). M.p. 258–262°C.

IR 3240m; 3180m; 2700m; 2580w; 2480w; 2050w; 1600m; 1560m; 1400m; 1360s; 1290s; 1258s; 1210s; 1170s; 1140w; 1020w; 880s; 805s; 735s; 670s; 655s; 558m; 535m; 522m; 522w; 422m; 417w; 345s; 340s; 314s; 260s cm^{-1}.

t - *Butylimidotrichlorobis(trimethylphosphine)niobium*

(a) Trimethylphosphine (0.92 cm^3, 8.4 mmol) in benzene (30 cm^3) was added to a suspension of $NbCl_5$ (0.75 g, 2.7 mmol) in benzene (50 cm^3). To the red solution obtained was added trimethylsilyl-*t*-butylamine (0.57 cm^3, 2.9 mmol) in benzene (20 cm^3) and the mixture was stirred for 12 h. The solution was filtered from the precipitate of PMe_3HCl and the solvent removed to give a yellow–orange gum which was washed several times with petroleum ether (20 cm^3 aliquots) and finally with diethyl ether (20 cm^3). After holding the product *in vacuo* for several hours the complex was obtained as a yellow, flaky solid. Yield: 1.0 g (85%). Found: Cl, 25.8. $C_{10}H_{27}NP_2Cl_3Nb$ requires Cl, 25.3%.

(b) Trimethylphosphine (0.7 cm^3, 6.4 mmol) in petroleum ether (30 cm^3) was added slowly to a rapidly stirring suspension of *t*-butylamine-*t*-butylimidotrichloroniobium (1.0 g, 2.9 mmol) in petroleum ether (30 cm^3) and the solution stirred for 18 h. The resulting yellow solution was filtered from a small amount of white solid material and the solvent removed to give a gum which after extensive washing with cold petroleum ether and pumping on the residue gave the impure complex as a yellow, flaky solid (see analytical data in Table 1). Yield: 0.9 g (73%).

IR (KEL-F) 2950s; 2890s; 1410m; 1400m; 1375w; 1358m. (Nujol) 1410m; 1400m; 1355m; 1300w; 1280m; 1245s; 1215m; 1145m; 1124m; 960s; 844w; 800w; 730s; 720s; 645w; 320s; 300s cm^{-1}.

t - *Butylimidotrichlorobis(trimethylphosphine)tantalum*

(a) Trimethylsilyl-*t*-butylamine (0.7 cm^3, 3.6 mmol) in benzene (25 cm^3) was added to $TaCl_5$ (1.3 g, 3.6 mmol) and trimethylphosphine (1.3 cm^3, 11.8 mmol) in benzene (50 cm^3) and the mixture stirred for 18 h. The solution was filtered and the solvent removed to give a gum which was washed extensively with petroleum ether (20 cm^3) and finally diethylether. After a prolonged pumping a flaky, off-white solid was obtained. Yield: 1.4 g (78%). Borderline analytical data were obtained. Found: C, 24.7; H, 5.6; N, 2.1. $C_{10}H_{27}Cl_3NP_2Ta$ requires C, 23.5; H, 5.3; N, 2.7%.

(b) Trimethylphosphine (0.7 cm^3, 6.4 mmol) in petroleum ether (30 cm^3) was added slowly to a rapidly stirring suspension of *t*-butylamine-*t*-butylimidotrichlorotantalum (1.0 g, 2.9 mmol) in petroleum ether (30 cm^3) and the solution stirred for 16 h. The reaction was worked up as the niobium reaction to give the complex as a white solid. Yield: 0.9 g (73%).

IR 1410m; 1400m; 1355m; 1300w; 1280m; 1245s; 1215m; 1145m; 1124m; 960s; 844w; 800w; 730s; 720s; 645w; 320s; 310s; 300s cm^{-1}.

Bis(t - *butylamido*)*bis*(t - *butylamine*)*bis*(t - *butylimido*)*tetrachlorodiniobium*

t-Butylamine (3.7 cm^3, 35.3 mmol) in benzene (25 cm^3) was added to a rapidly stirring suspension of $NbCl_5$ (1.2 g, 4.4 mmol) in benzene (50 cm^3) and the mixture stirred for 6 h. The solution was filtered from the precipitated *t*-butylamine hydrochloride (1.5 g, 3 equivalents based on $NbCl_5$) and the solvent removed to *ca* 10 cm^3 to give the complex as light yellow crystalline solid. Yield: 1.3 g (76%). M.p.: decomposes above 220°C.

IR 3295w; 3230w; 3178m; 3108w; 2705w; 2595w; 2500w; 2070w; 1610w; 1568m; 1510w; 1403m; 1360s; 1340w; 1300w; 1280m; 1240s; 1210s; 1165m; 1132m; 1027m; 977m; 925m; 895m; 805w; 785m; 730m; 674m; 645m; 610w; 553m; 535w; 450w; 424w; 370w; 348w; 308s; 285m cm^{-1}.

The complex was also prepared by adding *t*-butylamine (0.85 cm^3, 8.1 mmol) in benzene (25 cm^3) to a suspension of *t*-butylamine-*t*-butylimidotrichloroniobium (0.7 g, 2.0 mmol) in benzene (30 cm^3) and working up as above.

Bis(t-*butylamido*)*bis*(t-*butylamine*)*bis*(t-*butylimido*)-*tetrachloroditantalum*

t-Butylamine (6 cm^3, 57 mmol) in benzene (30 cm^3) was reacted with $TaCl_5$ (2.0 g, 5.6 mmol) in benzene (60 cm^3) for 12 h to give *t*-butylamine hydrochloride (1.8 g, 3 equivalents based on $TaCl_5$) and a colourless solution which gave the complex as colourless crystals. Yield: 2.1 g (78%). M.p. decomposes above 270°C.

IR 3300w; 3250w; 3200m; 2710m; 2600m; 2500m; 2225w; 2075w; 1610m; 1580m; 1555m; 1512m; 1400m; 1360m; 1302m; 1280m; 1255s; 1215s; 1164m; 1140m; 1025w; 984w; 930m; 910m; 900m; 740s; 650w; 600w; 558w; 540w; 455m; 426w; 350m; 295w; 260w cm^{-1}.

The complex was also prepared by adding *t*-butylamine (1.2 cm^3, 11.4 mmol) in benzene (25 cm^3) to a suspension of *t*-butylamine-*t*-butylimidotrichlorotantalum (1.1 g, 2.6 mmol) in benzene (30 cm^3) and working up as above.

Crystallinity of both tantalum and niobium complexes is lost when the solid is not in contact with solution.

Bis(i - *propylamido*)*bis*(i - *propylamine*)*bis*(i - *propylimido*)*tetrachloroditantalum*

i-Propylamine (2.0 cm^3, 23 mmol) in benzene (30 cm^3) was reacted with $TaCl_5$ (1.1 g, 3.1 mmol) in benzene (50 cm^3) to give *i*-propylamine hydrochloride (0.9 g, 3 equivalents based on $TaCl_5$) and the complex. Yield: 0.9 g, (64%) after crystallisation. M.p.: decomposition above 220°C.

IR 3300w; 2340m; 3150w; 3125w; 2725w; 1560m; 1550m; 1355m; 1320w; 1280s; 1238s; 1170m; 1122m; 1090s; 1068w; 995w; 948w; 850w; 818w; 725w; 680m; 650w; 620w; 540w; 470w; 415w; 390w; 260w cm^{-1}.

Bis (*ethylamido*) *bis* (*ethylamine*) *bis* (*ethylimido*) *tetrachloroditantalum*

Ethylamine (2.5 cm^3, 38.3 mmol) in benzene (30 cm^3) was reacted with $TaCl_5$ (1.75 g, 4.9 mmol) in benzene (60 cm^3) to give ethylamine hydrochloride and the complex as a white solid. Yield: 1.2 g (63%) after crystallisation. M.p.: decomposes above 180°C.

IR 3200m; 2740m; 2500w; 2340; 2050w; 1578m; 1360m; 1324w; 1292m; 1215m; 1196m; 1110m; 1050s; 960w; 910w; 880w; 790m; 720m; 660m; 615m; 415w; 390w; 260m cm^{-1}.

t - *Butylamido* - t - *butylimidodichlorobis*(*trimethylphosphine*)*niobium*

Trimethylphosphine (0.7 cm^3, 6.4 mmol) in benzene (30 cm^3) was added to bis(*t*-butylamido)bis(*t* - butylamine)bis(*t* - butylimido)tetrachloroditantalum (1.0 g, 2.6 mmol) in benzene (50 cm^3) and the mixture stirred for 4 h. After filtering the solution, the solvent was removed *in vacuo* to give a flaky solid. Yield: 1.1 g, (92%). Borderline analytical data were obtained (e.g. Found: N, 5.3; Cl, 16.4. $C_{14}H_{37}N_2P_2Cl_2Nb$ requires N, 6.1; Cl, 15.5%) but the complex was characterised by ^1H and ^{13}C NMR spectroscopy (see Table 2). Product melts at 96–100°C.

IR (KEL-F) 3200m; 3150m; 2925s; 2880s; 2850s; 1560w; 1442m; 1400s; 1345s. (Nujol) 3250m; 3200m; 2900w; 2700w; 1560w; 1560w; 1405s; 1442s; 1300m; 1285s; 1240s; 1210s; 1180s; 1130s; 1030w; 960s; 858m; 805s; 790s; 740s; 680s; 610m; 580m; 570m; 550m; 445w; 380w; 300s; 260s cm^{-1}.

t - *Butylamido* - t - *butylimidodichlorobis(trimethylphosphine)tantalum*

Trimethylphospine (0.4 cm^3, 3.6 mmol) in benzene (30 cm^3) was added to bis(*t*-butylamido)bis(*t*-butylamine)*bis(t-butylimido)tetrachloroditantalum* (0.5 g, 0.5 mmol) in benzene (30 cm^3) and the mixture stirred for 5 h. The solution was worked up as for the niobium analogue to give the complex as colourless crystals. *Yield: 0.5 g (86%). M.p. 142–145°C.* Boron-free analytical data were obtained. Found: C, 27.8; H, 6.5; N, 5.2. $C_{14}H_{36}Cl_2N_2P_2Ta$ requires C, 30.8; H, 6.6; N, 5.1%.

IR 3250w; 2700w; 2600w; 2500w; 2075w; 1610w; 1515w; 1418m; 1358m; 1305m; 1284m; 1260s; 1218m; 1208m; 1180w; 960s; 850w; 808w; 786w; 742m; 720w; 660w; 610w; 576w; 558w; 540w; 550w; 350w; 265m cm^{-1}.

t-Butylamine - t - butylimido - t - butoxydichloroniobium

t-Butanol (0.3 g, 4.1 mmol) in benzene (30 cm^3) was added to bis(*t*-butylamido)bis(*t*-butylamine)bis(*t*-butylimido)tetrachlorodiniobium (*1.35 g, 3.6 mmol*) in benzene (40 cm^3) and the mixture stirred for 12 h. The resulting solution was filtered from a small amount of precipitate and the solvent removed giving a white crystalline solid. Recrystallisation from toluene at −5°C gave the complex as large, light yellow crystals. 0.4 g (30%). M.p.: decomposes above 235°C.

IR 3300w; 3190m; 3100w; 2700w; 2600w; 2500w; 2050w; 1610m; 1570s; 1510m; 1502s; 1360s; 1340w; 1300w; 1280m; 1240s; 1220s; 1180vs; 1125m; 1020s; 980vs; 930w; 900m; 804w; 790m; 740m; 674m; 650m; 560m; 485w; 450w; 420w; 370m; 348m; 310s cm^{-1}.

Bis(t - *butylamine*)*bis*(t - *butylimido*)*bis*(*μ-ethoxy*)*tetrachloroditantalum*

Ethanol (0.068 cm^3, 11.8 mmol) in benzene (25 cm^3) was added slowly to bis(*t*-butylamido) bis(*t*-butylamine) bis (*t*-butylimido)tetrachloroditantalum (0.55 g, 11.8 mmol) and the mixture was stirred for 5 h. The solution was filtered from a small amount of solid and the solvent removed to give a gum which partly solidified on pumping. The crude product had the following physical data.

IR 3250w; 3160w; 2700w; 2590w; 2500w; 2050w; 1610m; 1560w; 1510m; 1400m; 1358m; 1300m; 1264s; 1215m; 1290m; 1250m; 1210m; 1075m; 1020m; 925m; 875s; 840m; 802m; 740m; 720s; 670m; 550m; 520m; 445m; 420w; 345m; 320w; 280m cm^{-1}.

^{1}H NMR (δ, $CDCl_3$) 1.19s, CMe_3; 1.30s CMe_3; 1.0–1.5 several poorly defined methyl resonances of OCH_3CH_3; 4.2–4.8 broad multiplet OCH_2 and NH_2.

^{13}C NMR (δ, $CDCl_3$) 72.6, 71.4, OCH_2; 66.6, imido CMe_3; 53.5, 51.8, amino CMe_3; 32.1, 31.9, 31.0, 30.9, imido and amino Me_3; 19.4, 18.2 alkoxide Me.

Recrystallisation of the complex from toluene at −20°C gave a small quantity of colourless crystals, one of which was used for an *X*-ray crystallographic study.

Crystallographic study

Crystal data.

$[Ta(NCMe_3)(\mu\text{-}OEt)Cl_2(NH_2CMe_3)]_2$,

$C_{20}H_{50}Cl_4N_4O_2Ta_2$,

M = 888.36, triclinic, *a* = 9.900(5), *b* = 10.161(17), *c* = 9.017(6) Å, α = 103.91(8), β = 97.77(4), γ = 64.40(7)°, *U* = 794 $Å^3$, space group $P\bar{1}$, *Z* = 1, D_c = 1.859 g cm^{-3}, *F*(000) = 428, μ(Mo-K_α) = 76.3 cm^{-1}.

Data collection. CAD4 diffractometer, Mo-K_α radiation (λ = 0.71073 Å), $\omega/2\theta$ scan mode. Crystal (approx. dimensions 0.28 × 0.22 × 0.10 mm), sealed under N_2 in a glass capillary tube, 2357 data measured (θ_{max} = 23°). The intensities of three standard reflections were monitored during the data collection (1 h intervals) but any variation was less than 3%. Empirical absorption corrections were applied,[35] minimum and maximum transmission factors being 0.891 and 0.998, respectively.

Structural solution and refinement. The structure was solved by Patterson and Fourier methods and refined by a full matrix least-squares technique.[36] The final refinement cycle converged to a value of 0.062 for both *R* and R_w, for the 101 variables and 1319 data for which $F^2 > 3\sigma(F^2)$. The function minimized was $\sum w(|F_o|-|F_c|)^2$ with the weight, *w*, being defined as $0.1756/[\sigma^2(F)+0.005600F^2]$. In the final refinement cycle all hydrogen atoms were included in calculated positions (C–H, N–H; 1.08 Å) and only the tantalum and chlorine atoms were refined assuming anisotropic thermal motion; all hydrogen atom temperature factors were fixed at $U = 0.10\ e\ Å^{-2}$. The atomic scattering factors were taken from the tabulations of Cromer and Mann,[37] anomalous dispersion corrections were by Cromer and Liberman.[38]

Final atomic coordinates, anisotropic thermal parameters and thermal parameters for the complex as well as listings of calculated hydrogen atom coordinates, complete lists of bond distances and

angles and F_o/F_c values have been deposited with the Editor as supplementary material.*

(*Received* 18 *July* 1984; *accepted after revision* 27 *November* 1984)

Abstract—By oxidation of nitridotechnetate(V) complexes of the type $[TcN(\hat{S}\hat{S})_2]^{0,2-}$ ($\hat{S}\hat{S}$ = diethyldithiocarbamate, diphenyldithiophosphinate and maleonitrile-dithiolate) with chlorine the Tc^{6+} complex anion $[TcNCl_5]^{2-}$ was created and studied by EPR in liquid and frozen solutions. The EPR spectra are in agreement with a d^1 ($S = 1/2$) system. The hyperfine interactions are used to characterize the bonding properties in the molecular orbital of the unpaired electron.

The availability of the long lived isotope of technetium (^{99}Tc), half-life $t_{1/2} = 2.13 \times 10^5$ years, from fission products lead to a more intensive exploration of the chemistry of this element.[1,2] Nevertheless, the coordination chemistry in which the metal possesses the formal oxidation state "+6" is almost unknown. Up to now only two EPR studies on Tc(VI) compounds have been reported, made on the trigonal prismatic complexes tris(toluene dithiolato)technetium(VI), $Tc(tdt)_3$,[3] and tris(*o*-aminobenzene thiolato)technetium(VI), $Tc(abt)_3$.[4] In the former case only the liquid solution EPR spectrum was reported; for $Tc(abt)_3$ studies in frozen solution have been made. In the EPR spectra of $Tc(tdt)_3$ and $Tc(abt)_3$ only very small ^{99}Tc hyperfine splittings (hfs) are observable due to their trigonal-prismatic structure.[4,5] For Tc(VI) complexes in which the ligand arrangement comes close to C_{4v} symmetry well resolved ^{99}Tc hfs should be observed in the spectra as found for some d^5 low-spin nitrosyl complexes of Tc recently reported.[6–9] The EPR behaviour of Tc(VI) compounds ($4d^1$, $S = 1/2$) having symmetries which differ from the trigonal-prismatic one is unknown up to now.

In this paper we report an EPR investigation of the reaction between $[TcN(\hat{S}\hat{S})_2]^{0,2-}$ complexes (**I**), containing Tc in the oxidation state "+5" and molecular chlorine dissolved in $CHCl_3$.

(**I**)

The $\hat{S}\hat{S}$-ligands used are diethyldithiocarbamate, et_2dtc^-, diphenyldithiophosphinate, ph_2dtpi^-, and 1,2-dicyanoethylene-1,2-dithiolate, mnt^{2-} [see (**I**)].

The preparation of the Tc(V)N(dialkyldithiocarbamate)$_2$ complexes has been reported previously.[10] Since $TcN(ph_2dtpi)_2$ and $(Et_4N)_2[TcN(mnt)_2]$ have not yet been reported in the literature, the synthesis of these complexes will be briefly described.

EXPERIMENTAL

All solvents were reagent grade and used without further purification. The ligands Hph_2dtpi[11] and Na_2mnt[12] have been prepared by literature methods.

Preparation of the complexes

$TcN(ph_2dtpi)_2$. (a) 100 μl of a 0.3 M NH_4TcO_4 solution (30 μmole) was added to 1 cm^3 6 M HCl.

* Author to whom correspondence should be addressed.

Reduction with 100 μl hydrazine hydrate (25%) yields a clear yellow solution. After neutralization with concentrated NaOH solution 0.5 g Hph_2dtpi in 5 cm^3 acetone was added. The mixture was stirred for 1 hr and after cooling yellow crystals deposited.

(b) 100 mg $TcNCl_2(PPh_3)_2$[13] was stirred in 10 cm^3 acetone containing 1 g Hph_2dtpi for 1 hr. The resulting mixture was filtered and cooled to 0°C. The deposited crude product was recrystallized from $CHCl_3$/iso-propanol solutions.

M.pt. 268°C; elemental analysis, $C_{24}H_{20}NSP_2Tc$ (calc./found): C: 47.14/47.03, H: 3.27/3.03, N: 2.29/2.10, S: 20.95/21.11, P: 10.15/9.85, Tc: 16.20/15.41%.

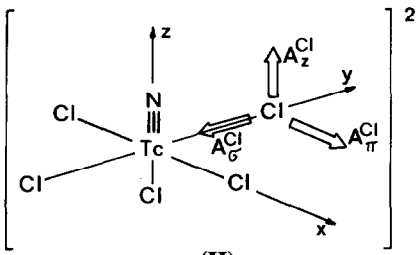
$(Et_4N)_2[TcN(mnt)_2]$. According to procedure (b) 100 mg of $TcNCl_2(PPh_3)_2$ was stirred with 1 g Na_2mnt in 10 cm^3 boiling acetone for 1 hr. After addition of an excess Et_4NBr in 5 cm^3 EtOH and cooling $(Et_4N)_2[TcN(mnt)_2]$ could be obtained. After recrystallization from acetone/iso-propanol the product has a melting point of 167–168°C.

Elemental analysis, $C_{24}H_{40}N_7S_4Tc$ (calc./found): C: 44.10/43.97, H: 6.13/6.12, N: 15.01/14.84, S: 19.60/19.98, Tc: 15.16/15.16%.

$TcN(et_2dtc)_2$ was prepared according to Ref. 10.

EPR measurements

EPR spectra were recorded in the X-band ($\nu \approx 9.3$ GHz) on an E-112 spectrometer (VARIAN, U.S.A.) at $T = 295$ and 140 K. The solutions used for the EPR experiments have been prepared as follows: 0.5–1 mg of the corresponding $Tc(V)N(\hat{S}\hat{S})_2$ complex was dissolved in about 1 cm^3 $CHCl_3$. To the solution obtained a small amount (1–3 drops) of a saturated solution of Cl_2 in $CHCl_3$ is added. The reaction mixtures were measured immediately after mixing.



Health precautions

Due to the radioactivity of ^{99}Tc some health precautions have been made. All operations have been carried out in a fume cupboard with gloves. EPR spectra have been measured in sealed glass tubes to avoid contamination.

^{99}Tc is a only weak β^--emitter ($E_{max} = 0.29$ MeV; specific activity of 17 μCi/mg) and so no further precautions are necessary provided some elementary ones are taken and no volatile compounds are being produced during the reaction. Normal glassware gives adequate protection against the weak β^--emission. Secondary X-rays (bremsstrahlung) become important if handling ^{99}Tc in a larger scale (> 20 mg) only.

RESULTS AND DISCUSSION

In all cases the solutions of the $[Tc(V)N(\hat{S}\hat{S})_2]^{0,2-}$ complexes oxidized by Cl_2 give intense EPR spectra which are typical for d^1 complexes ($S = 1/2$) having a well separated orbital state occupied by the unpaired electron. The spectra are found to be strongly dependent on the experimental conditions applied for the oxidation. The oxidation of the systems in cooled solutions (253–273 K) with small amounts of Cl_2 results in very complex EPR spectra showing the presence of 2–4 different mixed-ligand Tc(VI) complexes. However, if the Tc(V) complexes are oxidized with a large excess of Cl_2 at room-temperature, in all cases the same spectrum was observed consisting of the EPR signals of one Tc(VI) compound only. Since very different Tc(V) complexes have been used, the common oxidation product is expected to be $[TcNCl_5]^{2-}$ **(II)**.

(II)

The X-band EPR spectrum of a $CHCl_3$ solution of **(II)** recorded at $T = 295$ K is shown in Fig. 1. It consists of 10 hyperfine lines resulting from the hyperfine interaction of the unpaired electron with the ^{99}Tc nucleus (^{99}Tc, nuclear spin $I = 9/2$). In Fig. 2 the EPR spectrum of a frozen solution of **(II)** at $T = 140$ K is reproduced. The general feature of the spectrum is characteristic for an axially symmetric, randomly oriented $S = 1/2$ system with parallel and perpendicular sets of ^{99}Tc-hyperfine lines, as described by the spin Hamiltonian

$$\hat{H}_{sp} = \beta_e[g_\parallel H_z\hat{S}_z + g_\perp(H_x\hat{S}_x + H_y\hat{S}_y)] + A_\parallel^{Tc}\hat{S}_z\hat{I}_z + A_\perp^{Tc}(\hat{S}_x\hat{I}_x + \hat{S}_y\hat{I}_y), \quad (1)$$

where $g_\parallel$, $g_\perp$, $A_\parallel^{Tc}$ and $A_\perp^{Tc}$ are the principal values of the $\tilde{g}$ and the ^{99}Tc hfs tensor $\tilde{A}^{Tc}$. Quadrupolar interactions are expected to be small and will be neglected. The principal values of $\tilde{g}$ and $\tilde{A}^{Tc}$ obtained by second-order expressions outlined in Ref. 14 are given in Table 1.

Ligand hyperfine interactions due to the coupling of the unpaired electron with the $^{35,37}Cl$ nuclei and, possibly, the ^{14}N nucleus of the nitrido-nitrogen could not be observed. The noticeably different line widths found in the parallel and perpendicular parts of the spectrum suggest, however, the presence of unresolved ligand hyperfine interactions. In Table 1

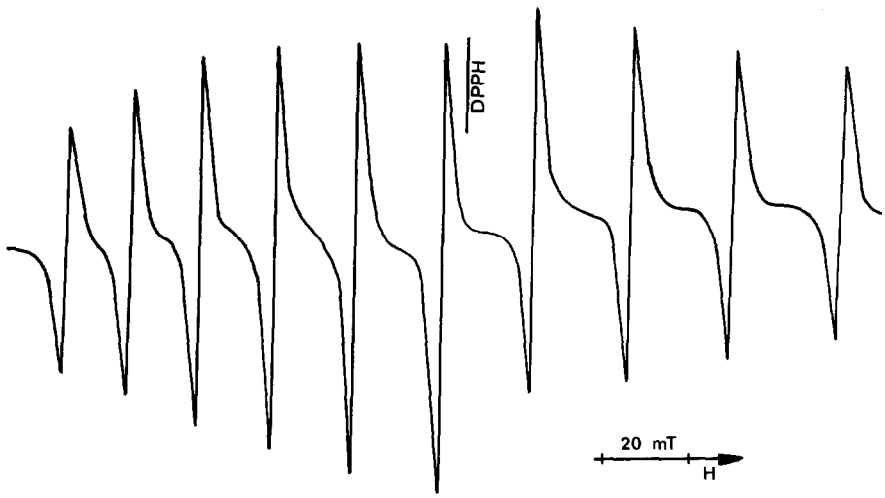


Fig. 1. Room-temperature EPR spectrum of $[TcNCl_5]^{2-}$, solvent: $CHCl_3$.

the upper limits of the ^{35}Cl hfs tensor components estimated from linewidth considerations for the equatorial (x, y) ligands are given using the notation illustrated in (II).

The EPR spectra are in agreement with an "in-plane-π-type" ground state for the molecular orbital (MO) of the unpaired electron (C_{4v} symmetry assumed):

$$\psi_{MO}(B_2) = \beta_2|d_{xy}\rangle - \beta_2'|\phi_L\rangle. \quad (2)$$

$|\phi_L\rangle$ represents a linear combination of $3p$ orbitals of the equatorial Cl ligands; contributions of the Cl $3s$ orbitals are expected to be very small because of symmetry considerations.

The ^{99}Tc hfs can be used to estimate the degree of covalency of the equatorial Tc–Cl bonds. Using the familiar eqns (3a–c):[15]

$$A_{\parallel}^{Tc} = -K - 4/7\beta_2^2 P + (g_{\parallel} - g_e)P + 3/7(g_{\perp} - g_e)P, \quad (3a)$$

$$A_{\perp}^{Tc} = -K + 2/7\beta_2^2 P + 11/14(g_{\perp} - g_e)P, \quad (3b)$$

and

$$a_0^{Tc} = -K + (g_{av} - g_e)P, \quad (3c)$$

where K is a measure of the Fermi contact interaction and $P = g_e g_N \beta_e \beta_N \langle r^{-3}\rangle_{4d} = 230 \times 10^{-4}$ cm^{-1},[16] a value of $\beta_2^2 = 0.81$ will be obtained. β_2^2 is a measure of covalency of the equatorial Tc–Cl bonds in the MO of the unpaired electron.

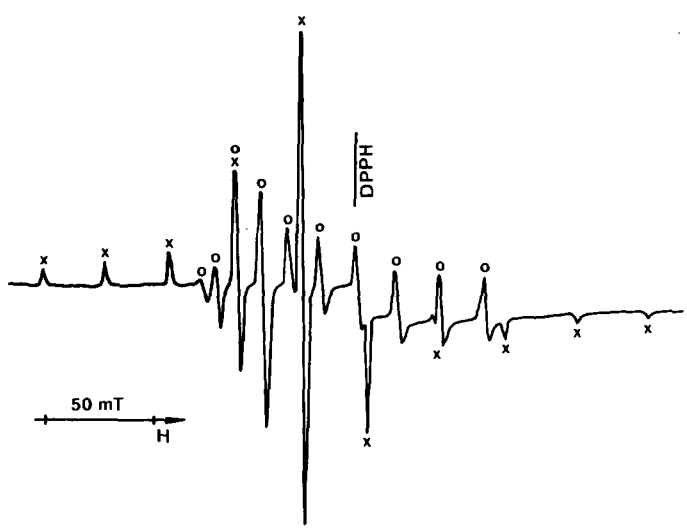

Fig. 2. X-band EPR spectrum of $[TcNCl_5]^{2-}$ in $CHCl_3$ at $T = 140$ K [parallel part of the spectrum is indicated with (×), perpendicular part with (○)].

Table 1. EPR parameters[a] for $[TcNCl_5]^{2-}$ (hyperfine coupling constants are given in 10^{-4} cm^{-1})

$\tilde{g}$	$\tilde{A}^{Tc}$	$\tilde{A}^{Cl}$
$g_{\parallel} = 2.016 \pm 0.003$	$A_{\parallel} = 295.0 \pm 2.0$	$A_{\pi}^{Cl} \leqslant 5.4$
$g_{\perp} = 2.003 \pm 0.005$	$A_{\perp} = 136.8 \pm 5.0$	$A_{z}^{Cl} \leqslant 0.9$
g_{av}[b] $= 2.007$	A_{av}[b] $= 189.5$	
g_0[c] $= 2.006 \pm 0.003$	a_0[c] $= 188.0 \pm 3.0$	$a_0^{Cl} \leqslant 1.5$

[a] Principal values of the Cl-hfs tensor are obtained from linewidth considerations.

[b] $\langle g_{av} \rangle = (g_{\parallel} + 2g_{\perp})/3$; $\langle A_{av} \rangle = (A_{\parallel} + 2A_{\perp})/3$.

[c] Obtained from the liquid solution spectrum.

Additional information about delocalization of unpaired spin density can be obtained from the $^{35,37}Cl$ hyperfine interactions. Neglecting the very small contributions of the Cl 3*s* orbitals $(\beta')^2$ can be estimated by eqn (4):

$$A_{\parallel}^{Cl} - a_0^{Cl} = (4/5) g_e g_N \beta_e \beta_N \langle r^{-3} \rangle_{3p} \times (\beta'^2/4). \quad (4)$$

Using $(4/5) g_e g_N \beta_e \beta_N \langle r^{-3} \rangle_{3p} = 78 \times 10^{-4}$ cm^{-1},[17] $(\beta')^2$ is found to be ≈ 0.2 which corresponds to an overall spin density of about 20% in the four equatorial Cl 3*p* orbitals. It should be noted that the parameters derived are close to those found for $Mo(V)OCl_5^{2-}$.[18]

In addition, the experimentally obtained hyperfine parameters have been analyzed using the following atomic parameters recently calculated by Morton and Preston:[19] ^{35}Cl; $a_{0,calc.}^{Cl} = 1909 \times 10^{-4}$ cm^{-1}; $b_{calc.}^{Cl} = (A_{\parallel}^{Cl} - a_0^{Cl})/2 = 58.6 \times 10^{-4}$ cm^{-1}; $a_{0,calc.}^{Tc} = 3149.8 \times 10^{-4}$ cm^{-1} and $b_{calc.}^{Tc} = (A_{\parallel}^{Tc} - a_0^{Tc})/2 = 65.4 \times 10^{-4}$ cm^{-1}. By means of eqns (5a–d) the following bonding parameters were obtained: $\beta'^2 = 0.14$, $n_{Cl}^2 = 0.98$, $\beta^2 = 0.88$ and $n_{Tc}^2 = 0.93$ (n_{Cl}^2 and n_{Tc}^2 are the Cl 3*s*/3*p* and Tc 5*s*/4*d* hybridization degrees, respectively).

$$a_{0,exp.}^{Cl}/a_{0,calc.}^{Cl} = 1/4(\beta')^2(1 - n_{Cl}^2), \quad (5a)$$

$$b_{exp.}^{Cl}/b_{calc.}^{Cl} = 1/4(\beta')^2 n_{Cl}^2, \quad (5b)$$

$$a_{0,exp.}^{Tc}/a_{0,calc.}^{Tc} = \beta^2(1 - n_{Tc}^2) \quad (5c)$$

and

$$b_{exp.}^{Tc}/b_{calc.}^{Tc} = \beta^2 n_{Tc}^2. \quad (5d)$$

As expected the contributions of the Cl 3*s* orbitals to the MO of the unpaired electron are very small ($n_{Cl}^2 \approx 1$); the covalency degree of the Tc–Cl bonds is smaller than that estimated using the atomic parameters given by Wertz and Bolton.[17] It is, however, difficult to use these values for comparison purposes because up to now in the literature the values given in the outlined procedure were used for interpretation of hyperfine data in nearly all cases.

Finally, it should be noted that all attempts made to isolate the $[TcNCl_5]^{2-}$ anion were without success because of its instability. The EPR spectra recorded from the reaction mixtures after standing for two hours are much less intense than those obtained for the freshly prepared solutions.

STRUCTURAL STABILITY INDEX OF HETEROPOLY- AND ISOPOLYANIONS—IV. APPLICATION TO SITE-VACANT KEGGIN POLYANIONS, MIXED-TYPE KEGGIN POLYANIONS, SOME MOLYBDO- AND TUNGSTO-VANADATES AND JEANNIN-TYPE POLYANION

(*Received* 4 *October* 1984; *accepted* 29 *November* 1984)

Abstract—The theory of structural stability, being based on the number of closed loops per MO_6 octahedral unit in the polyanion-cage, has been applied to a variety of heteropoly- and isopoly-compounds with previously unreported structures. The discussion includes the prediction of the structure of lacunary Keggin heteropoly-compound, $Cs_7Na_2[PW_{10}O_{37}]\cdot 8H_2O$, recently obtained by Knoth and Harlow, the reinvestigation of mixed-type Keggin polyanions, $[SiW_9Co_3(H_2O)_3O_{37}]^{10-}$ and $[SiW_{11}CoO_{39}]^{6-}$, recently prepared by Pope's group, the interpretation of chemical behaviours of some molybdo- and tungsto-vanadates, the structural stabilities of Jeannin-type $[As_2W_{21}O_{69}(H_2O)]^{6-}$ polyanion and its related compounds, and some remarks on Weakley-type $[X(W_5O_{18})_2]^{n-}$ polyanions and Flynn–Stucky-type $[X(Nb_6O_{19})_2]^{n-}$ complexes belonging to the hybrid-complex of polyanion.

As an attempt at rationalizing the structures of heteropolyanions (HPA) and isopolyanions (IPA), we have proposed the idea of structural stability on the basis of the number of closed loops in the polyanion-cage.[1–3] The closed loop can be counted as a geometrical circuit of the interpenetrating linkage –O–M–O–M–O–, which is formed by a junction of M ion and mutually-*trans* bridged oxygens (edge-sharing and/or corner-sharing) around the polyanion-cage. The structural stability index (η) has been defined as the number of closed loops per MO_6 octahedral unit and estimated from $\eta = (\Sigma B \cdot C)/A$, where A is the number of MO_6 octahedral units constituting the polyanion-cage, B the number of MO_6 units constituting the closed loop and C the number of closed loops. The index represents not only a topological feature of the polyanions, but also the degree of condensation and the relative stability of them. Furthermore, it clarifies the phenomenological classification of the structural types according to the number of terminal oxygens attached to each M atom, which has been proposed by Pope in 1972.[4,5] There is no precedent for the idea and its application is available for a variety of polyanions. The properties of the structural stability indexes determined in some fundamental structures of HPA (Keggin-, Dawson-, Anderson-, Waugh-, Silverton- and Evans–Showell-type) and IPA ($[M_6O_{19}]^{n-}$, $[W_{10}O_{32}]^{4-}$, $[Mo_7O_{24}]^{6-}$, α- and β-$[Mo_8O_{26}]^{4-}$, $[H_2W_{12}O_{40}]^{6-}$ and $[H_2W_{12}O_{42}]^{10-}$) have been summarized as general rules; (1) the polyanions with the larger index are more stabilized, (2) the polyanions with an identical index within the same series of M ion and heteroatom can be interconverted, or converted from one polyanion to another, (3) the index reveals the degree of condensation, (4) when an HPA decomposes, or degradates, into some IPA under an appropriate condition, the IPA possessing the largest index is predominantly produced, and (5) the real heteropoly- and isopoly-compounds with the small index are stabilized by some supporting factors other than the structural one. Incidentally, it should be noted that the comparison of the structural stability is limited within the polyanion-series comprising identical heteroatom and identical M atom. Only if this is observed can these rules be conveniently

* Author to whom correspondence should be addressed.

applied to some interesting polyanions. For example, it has been previously elucidated that a molybdo-HPA with the reverse Keggin structure, a vanado-HPA with "*trans*"-bicapped Keggin structure, and a Finke-type HPA formed by an interpenetration of two trisubstituted Keggin subunits are more stabilized than the respective parent Keggin HPA.[1,2] In Pope's recently published book,[6] which reviews all important or representative papers published by the beginning of 1982 in the chemistry of HPA and IPA, we found a number of polyanions with previously unreported structures. Here we intend to discuss, according to our stability index, the structural stabilities of some important polyanions, which include (1) some site-vacant Keggin HPA, (2) mixed-type Keggin HPA, (3) Jeannin-type HPA and related compounds, (4) some molybdo- and tungsto-vanadates, and (5) Weakley-type HPA as hybrid-complex of polyanion.

RESULTS AND DISCUSSIONS

1. *Divacant Keggin polyanions.* Of many site-vacant polyanions derived from Keggin structure including α-, β-, γ-, δ- and ε-isomers, the lacunary structures from α- and β-$[XM_{12}O_{40}]^{n-}$ by removal of one MO_6 octahedron or a trigonal group of three adjacent MO_6 octahedra have been well-known (Fig. 1).[6] They have been usually called α-XM_{11} and β-XM_{11} (containing three isomers of β_1-, β_2- and β_3-) for monovacant species and α-*A*-XM_9, α-*B*-XM_9, β-*A*-XM_9 and β-*B*-XM_9 for trivacant species. Our theory has indicated that their structural parameters are $A = 11$, $(B, C) = (6, 2)$; $\eta = 1.09$ for the monovacant species, and $A = 9$, $(B, C) = (6, 1)$; $\eta = 0.67$ for the trivacant species, independent of α- and β-isomers.[1,3]

Knoth and Harlow have recently determined the crystal structure of $Cs_7[PW_{10}O_{36}]\cdot 7H_2O$, which is the divacant species of hypothetical γ-Keggin structure formed by each 60° rotation of two W_3O_{13} units (Fig. 1C).[7] Two octahedra of "new" edge-shared contact between WO_6 octahedra are lost. There is no isomer with such lacunary sites. Using the molecular model of γ-Keggin structure, we can find two closed loops and estimated the index η of 1.2 from $A = 10$ and $(B, C) = (6, 2)$. Since this is only one species with the largest index of all γ-divacant Keggin polyanions, it is reasonable that such a compound has been actually isolated. Knoth and Harlow have also obtained the crystals of

$$Cs_7Na_2[PW_{10}O_{37}]\cdot 8H_2O,$$

the composition of which has been only determined from elemental analyses, but its structure has been unreported.[7] As far as all divacant Keggin HPA are concerned, the largest structural stability can be observed in the HPA with the parameters of $A = 10$ and $(B, C) = (6, 2)$. Our theory predicts the latter crystals will be 1,11-vacant species, α-$[PW_{10}O_{38}]^{11-}$, if the species is a derivative of α-Keggin HPA (Fig. 1A), otherwise it will be a "1,8"-vacant species, β-$[PW_{10}O_{38}]^{11-}$, if it is a derivative of β-Keggin HPA (Fig. 1B). The numbering of vacant site is performed according to the Pope's manner.[8] In these cases, the vacant sites are nonadjacent. If this is the case, the isolated species will be a protonated form of such α- or β-divacant species, $[PW_{10}O_{38}H_2]^{9-}$,

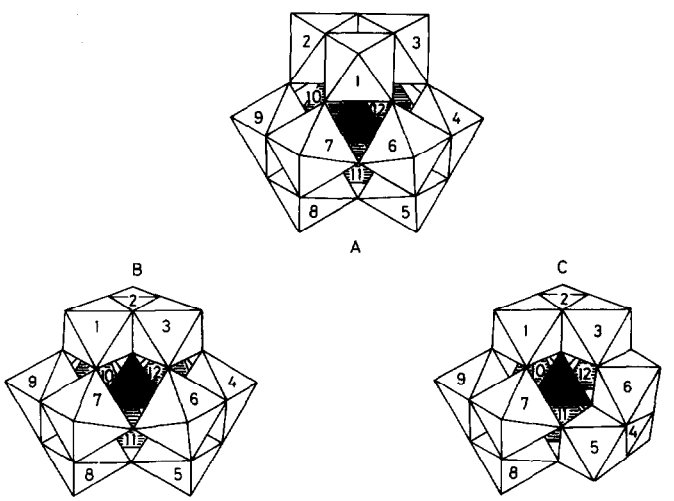

Fig. 1. Polyhedral models of three of five isomers of idealized α-Keggin structure (A) and the numbering according to Pope.[8] In B (β-isomer) and C (γ-isomer), one and two M_3O_{13} groups have been rotated by 60°.

and the formula will be rewritten as

$$Cs_7Na_2[PW_{10}O_{38}H_2]\cdot 7H_2O,$$

where the analytical data are unchanged. Of course, the forms derived from hypothetical δ- and ε-Keggin structures could be considered as divacant species with $\eta = 1.2$. However, in these cases, the formula should become $[PW_{10}O_{36}]^{7-}$ or its protonated form, but not $[PW_{10}O_{37}]^{9-}$, because two vacant sites are adjacent as observed in the γ-divacant polyanion.

2. *Mixed-type Keggin polyanions.* In the mixed-Keggin structures, e.g. $[XM_{12-x}M'_xO_{40}]^{n-}$ and $[XM_{11}Z(H_2O)O_{39}]^{n-}$ (X: heteroatom, Z: metal ion other than Mo and W, M and M′: Mo or W), there exist two kinds of closed loop, which are "homo"-type loop such as –O–M–O–M–O– and "hetero"-type loop such as –O–M–O–Z–O– and –O–M–O–M′–O–.[2] For the estimation of stability index, they have been treated as equivalent loops. Therefore, the stability index of mixed-Keggin HPA is identical with that of normal Keggin HPA [$A = 12$, $(B, C) = (6, 4)$ and $\eta = 2$]. This accounts for the fact that the closed loop itself is derived from the topological or geometrical consideration, even though the actual chemical bonds along the closed loops are different. The trisubstituted Keggin HPA $[SiW_9Co_3(H_2O)_3O_{37}]^{10-}$, recently prepared by Pope's group,[9] has also the same index as that of parent Keggin HPA. If the compound is the 1,2,3- or 1,6,7-trisubstituted derivative of $[SiW_{12}O_{40}]^{4-}$ by Co(II) ion, it will be probably what Finke *et al.* have initially desired to prepare.[10] The Finke-type HPA,

$$[P_2W_{18}Co_4(H_2O)_2O_{68}]^{10-},$$

which Finke *et al.* have unexpectedly obtained, is a dimeric and interpenetrating form of two trisubstituted Keggin HPA.[10,11] By such a condensation, two new closed loops of "hetero"-type passing through two Keggin subunits are generated besides some local closed loops belonging to each subunit. This leads to the larger stability index than that of the trisubstituted Keggin HPA at which they have initially aimed. The structural parameters are $A = 22$ and $(B, C) = [(6, 2)_{homo} + (6, 4)_{hetero} + (10, 2)_{hetero}]$ and the index is $\eta = 2.55$.[2] Pope's group have also obtained a new HPA containing unsaturated coordination of surface atoms represented as $[SiW_{11}CoO_{39}]^{6-}$.[9] This is derived from a mixed-Keggin HPA $[SiW_{11}Co(H_2O)O_{39}]^{6-}$ in anhydrous nonpolar solvents and contains the square-pyramidal Co(II) moiety, which is provided by elimination of a coordinated water molecule and can be saturated by a variety of donors such as alcohols, acetone, acetonitrile, pyridine etc. In this case, the "hetero"-loops passing through the five-coordinate Co(II) moiety may well be counted and they can be treated as that of parent HPA $[SiW_{11}Co(H_2O)O_{39}]^{6-}$.

3. *Molybdo- and tungsto-vanadates.* Some molybdovanadates as mixed-metal polyanions show interesting behaviours in the standpoint of the structural stability. The skeletal cage of $[V_5Mo_8O_{40}]^{7-}$, in yellow acicular crystals obtained as $K_7[V_5Mo_8O_{40}] \sim 8H_2O$, consists of a puckered ring of eight edge-sharing MoO_6 octahedra to which are attached four VO_5 trigonal bipyramids (Fig. 2A).[6,12] Since a centrally buried VO_4 tetrahedron and the four external VO_5 polyhedra, the latter of which are described as bridging tetrahedra in Pope's book, can be treated as "heteroatoms", we can find no closed loop passing through Mo atoms and the equatorial oxygens. Thus, the stability index η is zero and this compound is predicted to be unstable. As a matter of fact, the structure is stabilized in the crystals by two potassium ions which are coordinated to surface cavities of the polyanion. This is compatible with the rule (5) described earlier. By slow recrystallization of the V_5Mo_8 compound from water, the salt of $K_8[V_8Mo_4O_{36}]\cdot 12H_2O$ has been obtained.[13] The structure of $[V_8Mo_4O_{36}]^{8-}$ has been described as an arrangement of four MoO_6 octahedra, six VO_5 square pyramids and two VO_4 tetrahedra (Fig. 2B).[6] In this skeletal cage, although one closed loop passing through two MoO_6 octahedra and VO_5 polyhedra seems to be present, it is unrealized because of attaching two external VO_4 tetrahedra.

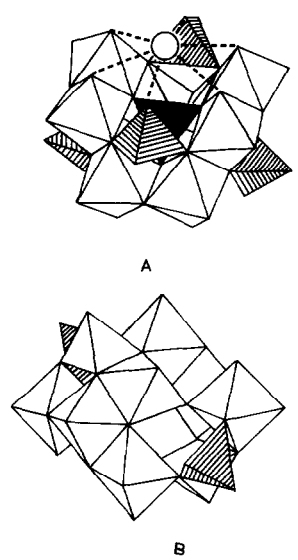

Fig. 2. Polyhedral models of the $[V_5Mo_8O_{40}]^{7-}$ (A) and the $[V_8Mo_4O_{36}]^{8-}$ (B) polyanions illustrated according to Pope.[6] In A, the open circle shows the position of one of two potassium ions.

Since each of two external VO_4 tetrahedra is binding only by two oxygens to the cage, the stabilization of crystal structure by potassium ions is also expected as observed above. This polyanion will be also unstable in solution. In fact, when the mother liquor from the crystallization of the V_8Mo_4 polyanion is allowed to stand for some months, the brown cubic crystals of the partially-reduced salt

$$K_6[V_3Mo_{10}O_{40}]\cdot 13H_2O$$

are formed. It has been confirmed by X-ray investigation that it contains a Keggin HPA $[V(V)V(IV, V)_2Mo_{10}O_{40}]^{6-}$ with a central tetrahedral vanadium(V) atom.[14] The Keggin structure is in the state with the degree of polymerization more progressed, as expected from the stability index ($\eta = 2$). Thus, these observations reveal the validity of rule (1).

On the other hand, one of the tungsto-vanadates, $[V_2W_4O_{19}]^{4-}$, is a vanadium-substituted species of the $[W_6O_{19}]^{2-}$ IPA and its stability index η becomes 2, since $(B, C) = (4, 3)_{hetero}$ or $[(4, 1)_{homo} + (4, 2)_{hetero}]$ and $A = 6$ (Fig. 3) Interesting reactions have been reported; acidification and heating of solutions of orange V_2W_4 leads to the darker coloured polyanions of the Keggin-series $[VV_xW_{12-x}O_{40}]^{(3+x)}$ $(x = 2, 3)$.[15] These polyanions are vanadium-substituted species of the hypothetical Keggin $[VW_{12}O_{40}]^{3-}$ HPA and also belonging to the mixed-type Keggin HPA. Although each of these polyanions exists as mixtures of several isomers with different distributions of V and W atoms in the $[M_{12}O_{40}]$-cage, all of them have the stability index identical with that of the parent structure ($\eta = 2$) as described in the preceding section. Thus, the reaction of $[V_2W_4O_{19}]^{4-}$ to $[VV_xW_{12-x}O_{40}]^{(3+x)-}$ will become an example compatible with the rule (2), since both of them are belonging to the same series of the polyanions comprising V, W and O.

Apart from the oxidation state of vanadium, the $[V(IV)_{18}O_{42}]^{12-}$ polyanion has been obtained as deep red–brown crystals of $Na_{12}[V_{18}O_{42}]\cdot 24H_2O$ by Johnson and Schlemper from combining solutions of $VOSO_4$ with appropriate hydroxide at 60–70°C under nitrogen or argon.[16] The structure consists of almost spherical shell of edge- and corner-sharing VO_5 square pyramids with the axial V–O bonds directed outwards. This polyanion results from the considerably high degree of polymerization. In fact, a number of closed loops can be counted and its structural stability is expected to be extremely large. It will be reasonable, as mentioned by Johnson and Schlemper, that this polyanion occupies a position in the aqueous chemistry of vanadium(IV) analogous to that of $[V(V)_{10}O_{28}]^{6-}$ in the chemistry of vanadium(V).

4. *Jeannin-type polyanion and related compounds.* In 1981, Jeannin and Martin-Frère reported the synthesis and the structural study by X-ray and ^{183}W NMR techniques of

$$H_2Rb_4[As_2W_{21}O_{69}(H_2O)]\cdot 34H_2O.^{17}$$

The

$$[As_2W_{21}O_{69}(H_2O)]^{6-} \text{ HPA } (As_2W_{21})$$

is made of two α-*B*-As(III)W_9O_{33} subunits, joined together in an asymmetrical way by three W atoms among which one is octahedrally surrounded and two are in a square-pyramidal environment. The former W atom accompanies with the coordination of one water molecule (Fig. 4). This HPA is one of the new type HPA with As(III) as a heteroatom and some of them have been already known as

$$[H_2AsW_{18}O_{60}]^{7-}$$

and inorganic cryptate-like

$$[As_4W_{40}O_{140}]^{28-} \text{ HPA.}^{18,19}$$

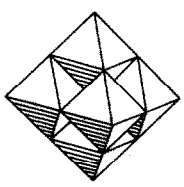

Fig. 3. Polyhedral model of the $[W_6O_{19}]^{2-}$-structure.

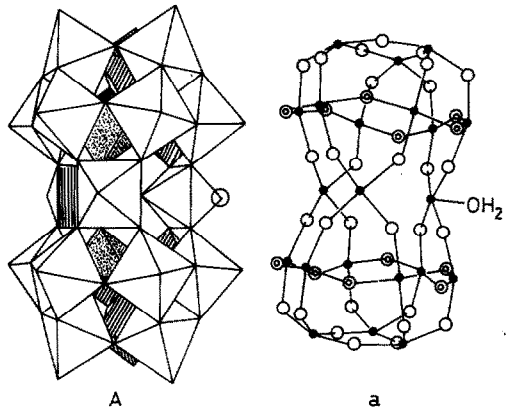

Fig. 4. Polyhedral model of the Jeannin-type HPA $[As_2W_{21}O_{69}(H_2O)]^{6-}$ (A) and its framework bond model (a). In A, the circle shows the position of coordinating water molecule and two tetrahedra of As(III) are stippled. In a, open circles are bridged-oxygens and filled ones are tungsten atoms. The oxygens illustrated by double circles represent local closed loops. Heteroatoms, terminal oxygens and triply bridged oxygens to which are attached the heteroatoms are omitted.

The consideration of structural stability for the As_2W_{21} HPA can be performed as usual (Fig. 4a). We can find two local closed loops belonging to each subunit, or $(B, C) = (6, 2)$, and one overall closed loop passing through two subunits, $(B, C) = (30, 1)$; the latter is a very large and continuous loop passing two times through each central bridging W atom. Thus, the stability index is $\eta = (6 \times 2 + 30 \times 1)/(18 + 3) = 2$. It is beyond imagination and very interesting that the index is identical with that of Keggin- and Dawson-structures.[1]

As related compounds, the mixed-type polyanions $As_2W_{20}M$, $As_2W_{19}M_2$ and $As_2W_{18}M_3$ have been reported, where three W atoms bridging between two subunits in the As_2W_{21} are replaced, one by one, with metal ion M.[20,21] One of them,

$$[Cu_3As_2W_{18}O_{66}(H_2O)_2]^{12-}$$

polyanion, is also introduced in Pope's book.[6] Since the "hetero"-loop through the bridging M atoms can be treated equivalently as the "homo"-one through the bridging W atoms in the parent HPA as described above, the structural stability of these mixed-type HPA is unchanged by the metal-substitution. As other related compounds, the lacunary species of As_2W_{21}, such as As_2W_{19} and As_2W_{20} polyanions, have also been known. They have been used as reactants producing the mixed-type $As_2W_{19}M_2$ and $As_2W_{20}M$ HPA.[22] However, their structures have been unreported yet. If the bridging W atoms in the As_2W_{21} are removed, the large closed loop of $B = 30$ is broken and only the local loops of $(B, C) = (6, 2)$ remain. This leads to the remarkable decrease of structural stability; $\eta = 0.63$ for the As_2W_{19} and 0.60 for the As_2W_{20}.

5. *Weakley-type HPA as hybrid-complex of polyanion.* The variety of tri- and tetravalent metals of rare-earth group has constituted two interesting groups of HPA, because of the large ionic radii and the high oxidation state. One is eight-coordination compounds represented as $[X(W_5O_{18})_2]^{n-}$ and $[XL_2]^{n-}$ (L: monovacant HPA of Keggin- and Dawson-structures such as $[PW_{11}O_{39}]^{7-}$, $[SiW_{11}O_{39}]^{8-}$, $[P_2W_{17}O_{61}]^{10-}$, etc.), which have been first characterized by Peacock and Weakley,[23,24] and the other is twelve-coordination compounds known as the Silverton-type $[XMo_{12}O_{42}]^{n-}$ HPA,[25] the structural stability of which has been previously described.[1,2] The $[X(W_5O_{18})_2]^{n-}$ polyanion is a predominantly "ionic" coordination complex incorporating two quadridentate $[W_5O_{18}]^{6-}$ ligands, which may be regarded as lacunary derivatives of the $[W_6O_{19}]^{2-}$ structure (Fig. 3), and the central XO_8 moiety is confirmed to be approximately square antiprismatic (Fig. 5A).[26–29] Analogous coordination of X has been also provided in the $[XL_2]^{n-}$ polyanion, where the lacunary Keggin and Dawson polyanions act as quadridentate ligand L.[30,31] These are attributed exclusively to the largeness of ionic radius of X and contrast to the examples of the mixed-IPA $[MW_5O_{19}]^{n-}$ (M = Mo, V, Nb) and the mixed-type Keggin and Dawson HPA $[ML]^{n-}$ such as $[PW_{11}M(H_2O)O_{39}]^{n-}$, $[SiW_{11}M(H_2O)O_{39}]^{n-}$ and $[P_2W_{17}M(H_2O)O_{61}]^{n-}$. Thus, these rare-earth compounds are, rather than the normal HPA, close to the metal complex with polyanions as ligand and may be classified to the category of the hybrid-complex of polyanion, to which the complex $[X(Nb_6O_{19})_2]^{n-}$ [X = Mn(IV) and Ni(IV)], first characterized by Flynn and Stucky,[32,33] belongs as a typical example (Fig. 5B). Since the Weakley-type HPA and the Flynn–Stucky-type complex have no polyanion-cage as an overall skeleton, the application of the structural stability theory is not suitable to such compounds. Only the structural stability of the "ligand" moiety can be discussed. From this point of view, the Weakley-type HPA is distinct from the Silverton-type HPA with the heteroatom of rare-earth metal. The latter has no closed loop, although it has the polyanion-cage.[1,2] Here, it should be noted that the $[XL]^{n-}$ as mixed-type Keggin and Dawson HPA and the $[XL_2]^{n-}$ as hybrid-complex of polyanion are quite distinguished in the discussion of the structural stability. Generally, whether the compound is belonging to a mixed-type HPA or to a hybrid-complex will be readily judged from the possibility of replacing X with Mo(VI), W(VI) and V(V) ions. Recently, the curious copper complex $[Cu_2(SiMo_9O_{33})_2]^{12-}$, which contains two $SiMo_9$ units formally derived from hypothetical β-*B*-$SiMo_9$, has been established by X-ray investigation.[34] This compound may be considered to be a hybrid-complex.

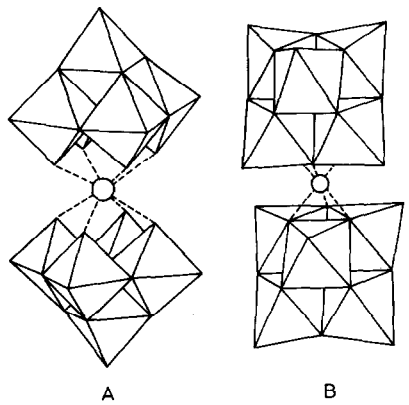

Fig. 5. Polyhedral models of the Weakley-type HPA $[X(W_5O_{18})_2]^{n-}$ (A) and the Flynn–Stucky-type complex $[X(Nb_6O_{19})_2]^{n-}$ (B).

THE CRYSTAL AND MOLECULAR STRUCTURE OF $Rh_2(CH_3CO_2)_4[HCON(CH_3)]_2$—EFFECT OF LIGANDS ON METAL–METAL BONDING

MONIKA MOSZNER, TADEUSZ GŁOWIAK and JÓZEF J. ZIÓŁKOWSKI*
Institute of Chemistry, University of Wrocław, 50-383 Wrocław, Poland

(*Received* 22 *October* 1984; *accepted* 18 *December* 1984)

Abstract—The structure of $Rh_2(CH_3CO_2)_4(DMF)_2$ {DMF = $HCON(CH_3)_2$} has been determined by single crystal X-ray methods. The compound crystallizes with eight formula units in a cell of dimensions: $a = 29.438(7)$ Å, $b = 7.978(2)$ Å, $c = 20.279(5)$ Å, $\beta = 113.20(4)°$, $V = 4377.5$ Å^3, space group $C2/c$. The structure has been refined by full-matrix least-squares method to a final $R = 0.030$ for the 4156 observed data. Two Rh(II) atoms are linked by four acetate groups forming a dimeric unit, where the Rh–Rh distance is 2.383(1) Å. The coordination sphere about each Rh atom is completed by a DMF molecule; the average Rh–O(DMF) distance is 2.296(3) Å.

$Rh_2(CH_3CO_2)_4(DMF)_2$ is one of the rhodium(II) dimer carboxylates of a general formula $Rh_2(CH_3CO_2)_4L_n$ ($n = 1, 2$)[1,2] where the problem of correlation between the Rh–Rh distance, its bond order and electronic structure of Rh–Rh core is still unresolved.[3–9]

It is known that the Rh–Rh bonding distance in $Rh_2(CH_3CO_2)_4L_n$ complexes is determined by the donor–acceptor properties of the terminal ligands L and of the bridging ligands RCO_2^-. Some authors who have reported the electronic structure of this type rhodium dimers believed that the influence of the L ligands on Rh–Rh bond distance was limited by their σ donor ability only.[4,5] The X-ray data[1,2] revealed that the Rh–Rh distance in the presence of ligands L of σ-donor and π-acceptor properties was longer ($d_{Rh-Rh} = 2.449$ Å in $Rh_2(CH_3CO_2)_4(PPh_3)_2$; $pK_bPPh_3 = 11.3$) than that found in the presence of ligands regarded as typical σ donors ($d_{Rh-Rh} = 2.402$ Å in $Rh_2(CH_3CO_2)_4(NHEt_2)_2$, $pK_bNHEt_2 = 3.51$).[3]

From the crystallographic data it follows that the Rh–Rh distance in $Rh_2(CH_3CO_2)_4L_n$ increases with decrease of donor properties of bridging ligands RCO_2^- ($d_{Rh-Rh} = 2.371$ Å in $Rh_2(Me_3CCO_2)_4(H_2O)_2$, $d_{Rh-Rh} = 2.409$ Å in $Rh_2(CF_3CO_2)_4(H_2O)_2 \cdot 2DTMN$).[1] The effect of structural elements of $Rh_2(RCO_2)_4L_n$ complexes on the Rh–Rh distance may suggest that, in interactions between the Rh–Rh core and the surrounding ligands, both σ and π interactions should be taken into account.

EXPERIMENTAL

Dark blue–green single crystals of $Rh_2(CH_3CO_2)_4(DMF)_2$ were obtained by slow evaporation at room temperature of the solvent after dissolving a small amount of $Rh_2(CH_3CO_2)_4$ (prepared according to Ref. 10) in neat DMF.

Found: C, 28.3; H, 4.3; N, 4.5. Calc. for $Rh_2(CH_3CO_2)_4(DMF)_2$; C, 28.57; H, 4.42; N, 4.76%.

X-RAY STUDY

All measurements for a crystal $0.3 \times 0.3 \times 0.35$ mm were made on a Syntex $P2_1$ computer-controlled four-circle diffractometer equipped with a scintillation counter and graphite monochromator. Indexing of 15 intense reflections in the range $22.0° \ll 2\theta \ll 29.5°$ produced a unit cell in the monoclinic system with dimensions: $a = 29.438(7)$ Å, $b = 7.978(2)$ Å, $c = 20.279(5)$ Å, $\beta = 113.20(4)°$, $V = 4377.5$ Å^3, $M = 588.2$, $D_m = 1.78(1)$ g cm^{-3} (by flotation), $D_c = 1.78$ g cm^{-3}, $Z = 8$, μ(Mo-K_α) = 15.2 cm^{-1}.

Systematic absences (khl; $h + k = 2n + 1$ and $h0l$, $l = 2n + 1$) established the space group as $C2/c$.

Intensities of 4865 independent reflections were

* Author to whom correspondence should be addressed.

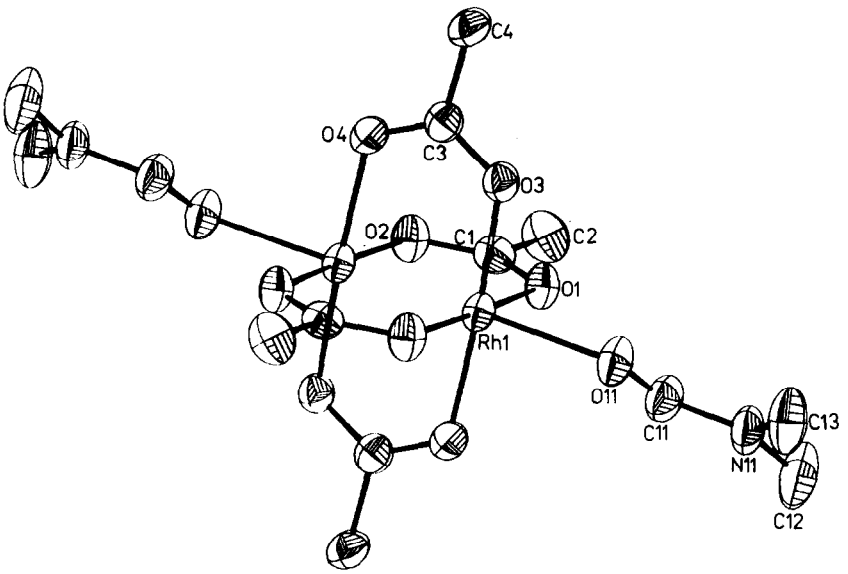

Fig. 1. Structure of the $Rh_2(CH_3CO_2)_4(DMF)_2$ molecule.

measured up to $2\theta = 55.0°$ with the variable θ–2θ scan technique. The scan rate varied from 2.0 to 29.0° min^{-1}. The intensities of two standard reflections were monitored during the data collection but the maximum variation was less than 2%.

The structure was solved by Patterson and Fourier methods and refined by a full-matrix least squares technique. The final refinement cycle converged to values of 0.030, 0.036 and 2.457 for R, R_ω and S respectively for 4256 data for which $I \geqslant 1.96\sigma(I)$. The H atoms and their isotropic thermal factor ($B = 4.5$ Å^2) were not refined.

The function minimised was $\Sigma\,\omega(|F_o| - |F_c|)^2$ with $\omega = 1/\sigma^2(F)$. The atomic scattering factors were taken from the tabulations of Cromer and Waber.[11] All calculations were performed with the Syntex XLT system.[12]

RESULTS AND DISCUSSION

Interatomic distances and bond angles for $Rh_2(CH_3CO_2)_4(DMF)_2$ are reported in Tables 1 and 2.*

A stereoscopic diagram of the unit cell contents of $Rh_2(CH_3CO_2)_4(DMF)_2$ is depicted in Fig. 1.

The structure of $Rh_2(CH_3CO_2)_4(DMF)_2$ is centrosymmetric with an Rh–Rh of 2.383(1) Å and axially bound *N,N*-dimethylformamide ligands at a distance of 2.296(3) Å (average). The Rh–Rh–O(DMF) linkage is not quite linear, being 177.46°. The Rh–O bond is approximately 0.256 Å longer than expected on the basis of covalent radii of oxygen and Rh(II) or in comparison with the literature data.

Average Rh–O and C–O ($CH_3CO_2^-$) bond distances are 2.038(3) Å and 1.261(5) Å, respectively; average Rh–Rh–O($CH_3CO_2^-$), Rh–O–C and O–C–O angles are 88.33(9)°, 118.92(30)° and 126.1(44)°, respectively.

Correlations between Rh–Rh, Rh–L distances, Rh–Rh–O, Rh–O–C and O–C–O ($CH_3CO_2^-$) angles and the basicity of L ligands measured by the pK_b values and donor number DN are listed in Table 3.

Comparison of the Rh–Rh bond distances in $Rh_2(CH_3CO_2)_4L_n$ type complexes, where L = CH_3OH, DMF, H_2O, shows the slight increase of the Rh–Rh distance as the ligand L acidity increases: CH_3OH (2.377 Å) < DMF (2.383 Å) < H_2O (2.386 Å).

The data in Table 3 indicate that the Rh–Rh bond distances in fact could be correlated with acidity of the ligand L (expressed by pK_b or DN) only within the determined group of donors, i.e. ligands coordinating via the same atom (O, N, S, C, P). It is striking, that the Rh–Rh bond distance increases with increase of the π acceptor ability of ligands L. This trend is in agreement with a position of the donor atom of the ligand L in the nephelauxetic series.[13]

From the crystallographic data it is known that the Rh–Rh bond distances in $Rh_2(RCO_2)_4L_2$ complexes depends on the R and increases in the order: $(CH_3)_3C$ (2.37 Å) < CH_3 (2.386 Å) < CF_3 (2.409 Å), i.e. according to the ability of the RCO_2^-

* Atomic positional and thermal parameters and lists of F_o/F_c have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

ligand to decrease the electron density in the Rh–Rh core.[14]

Comparison of the Rh–Rh distances in complexes:

$Rh_2(CH_3CO_2)_4(H_2O)_2$ (2.386 Å),[15]

$Rh_2(CH_3CO_2)_4(DMSO)_2$ (2.406 Å),[16]

$Rh_2(CH_3CO_2)_4(THT)_2$ (2.413 Å)[16]

and

$Rh_2(CH_3CSO)_4(CH_3COSH)_2$ (2.550 Å)[17]

revealed that substitution of oxygen by sulphur in the carboxylate ligands resulted in elongation of the Rh–Rh bond distance like the replacement of oxygen by sulphur in the terminal ligands. The differences in the Rh–Rh distances in the case of thioacetate and

acetate could be explained by the steric effects (longer S ... O distance in CH_3CSO, compared with O ... O distance in CH_3COO);[18] increase of the Rh–Rh bond distance in complexes

$$Rh_2(CH_3CO_2)_4(DMSO)_2$$

and

$$Rh_2(CH_3CO_2)_4(THT)_2$$

compared with the $Rh_2(CH_3CO_2)_4(H_2O)_2$ dimer requires the consideration of π-acceptor properties of coordinated sulphur.

This observation suggests that not only the steric effect but also the replacement of one oxygen atom in acetate ion by the sulphur capable of greater delocalization of the electron density could be responsible for elongation of the Rh–Rh distance in the $Rh_2(CH_3CO_2)_4(CH_3COSH)_2$ complex. The data presented here point out that while the influence of donor properties of bridging carboxylate ligands on the Rh–Rh bond distance was reversible compared to the influence of the donor properties of the terminal ligands L, the influence of acceptor power of both ligands on the Rh–Rh distance was the same.

Elongation of the Rh–Rh bond distance in the presence of ligands able to decrease the electron density in the Rh–Rh core (e.g., $CF_3CO_2^-$, CO, PR_3, DMSO, coordinating via S atom) could be caused by the increase of the positive charge on metal ions, and, simultaneously by contraction of the *d* orbitals, and in consequence, by their weaker mutual overlapping.[19]

Analysis of the crystallographic data seems to point out that in discussion of interactions between the Rh–Rh core and the bridging and terminal ligands, the σ and π interactions should be considered equally.

RUTHENIUM(II) COMPLEXES WITH TRIPHENYLPHOSPHINE OR TRIPHENYLARSINE AND OTHER MONODENTATE LIGANDS

RAJ K. PODDAR,* K. P. SARMA and U. C. SARMA
Department of Chemistry, North-Eastern Hill University, Bijni Complex, Shillong—793 003, India

(*Received* 24 *October* 1984; *accepted* 18 *December* 1984)

Abstract—Synthesis and studies on some five-coordinate ruthenium(II) complexes, viz. $[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$ and $[Ru(MPh_3)_2(CO)Cl_2]$ (where M = P or As) have been described. Reactions of $[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$ with *N*,*N*-dimethylformamide, dimethylsulphoxide and pyridine and of $[Ru(MPh_3)_2(CO)Cl_2]$ with pyridine are described.

The chemistry of the complexes of ruthenium(II) and ruthenium(III) containing strong donor ligands such as mono-tertiary-phosphine, arsine or stibine has been studied extensively.[1–23] The chemistry of the complexes of ruthenium(II) and ruthenium(III) with relatively weak donor ligands, such as dimethylsulphoxide, pyridine and acetonitrile has been relatively less studied.[24–28] Complexes of ruthenium(II) and ruthenium(III) containing both strong and weak donor ligands where the coordination around metal ion is generally six have also been studied in detail.[2,9,13,19,21,22,29–37] Complexes of ruthenium(II) containing weak donor ligands or having both strong and weak donor ligands have a strong potential to act as catalysts in various homogeneous reactions.[24]

Most of the complexes of ruthenium(II) and ruthenium(III) of the type discussed above involve six coordinated metal ions. Complexes having pentacoordination have a strong potential to act as catalysts in various homogeneous reactions. Here, some pentacoordinated complexes of ruthenium(II) containing triphenylphosphine or triphenylarsine and benzaldehyde are reported. Some of their reactions to substitute the coordinated benzaldehyde by weak donor ligands are also described.

EXPERIMENTAL

All the chemicals used were reagent grade. Ruthenium trichloride hydrate was supplied by Aurora-Matthey Limited, Calcutta.

$[RuCl_2(PPh_3)_2]_n$,[20]

$[RuCl_2(PPh_3)_3]$[2]

and

$[RuCl_2(AsPh_3)_2]_2$[20]

were prepared according to reported methods.

Preparations

$[RuCl_2(MPh_3)(C_6H_5CHO)_2]$ (M = P *or* As). To a solution of ruthenium trichloride hydrate ($RuCl_3 \cdot xH_2O$) (0.1 g) in *n*-butanol (10 cm^3), benzaldehyde (2 cm^3) was added. A solution of triphenylphosphine (0.5 g) or triphenylarsine (0.6 g) in *n*-butanol (5 cm^3) was added to the hot solution of ruthenium trichloride mentioned above. The resulting solution was then refluxed for about 30 min or 2 h, in the case of triphenylphosphine or triphenylarsine respectively. The reaction mixture was cooled overnight when a brownish-yellow crystalline compound in the case of triphenylarsine and a light green compound in the case of triphenylphosphine was obtained. The compound was separated by centrifugation and washed first with methanol and then with diethylether and dried under vacuum. The compounds were analysed for $[RuCl_2(MPh_3)(C_6H_5CHO)_2]$.

$[RuCl_2(CO)(AsPh_3)_2]$. (i) To a clear solution of ruthenium trichloride hydrate (0.1 g) in *n*-butanol (10 cm^3) and benzaldehyde (2 cm^3) mixture, a solution of triphenylarsine (1 g) in *n*-butanol (5 cm^3) was added

* Author to whom correspondence should be addressed.

and the mixture was refluxed for about 20 h. Initially, benzaldehyde complex was formed which went into solution and finally an orange solution was obtained which on cooling yielded a yellow compound. The mother liquor upon concentration under reduced pressure and cooling yielded more of the yellow compound, which was centrifuged, washed first with acetone and then with ether and dried under vacuum. It was analysed for $[Ru(CO)(AsPh_3)_2Cl_2]$.

(ii) $[RuCl_2(CO)(AsPh_3)_2]$ could be obtained also by boiling under reflux $[RuCl_2(AsPh_3)_2]_2$ (0.2 g) in benzaldehyde (2 cm^3) and *n*-butanol (10 cm^3) mixture for about 8 h or by boiling under reflux $[RuCl_2(C_6H_5CHO)_2(AsPh_3)]$ (0.2 g) and triphenylarsine (0.2 g) in *n*-butanol (10 cm^3) for about 10 h and cooling the orange–red solution obtained.

$[RuCl_2(CO)(PPh_3)_2]$ *(reddish-brown).* To a solution of ruthenium trichloride hydrated (0.2 g) in *n*-butanol (20 cm^3) and benzaldehyde (4 cm^3) mixture, a solution of triphenylphosphine (1.5 g) in *n*-butanol (10 cm^3) was added and the mixture was boiled under reflux for 6–8 h, when a reddish-brown crystalline compound (m.p. 195–200°C) separated out which was separated by centrifugation and washed first with methanol and then with diethylether and dried under vacuum. It was analysed for $[RuCl_2(CO)(PPh_3)_2]$.

$[RuCl_2(CO)(PPh_3)_2]$ *(yellow).* (i) The reaction was carried out in a way similar to that for the reddish-brown compound mentioned above, except that the reaction mixture was refluxed for 15–20 h, when the red crystalline compound obtained as an intermediate went into solution and finally a reddish-yellow solution was obtained, which on cooling resulted in the separation of a yellow compound. The compound was separated and washed first with acetone and then with ether. Concentration of the mother liquor resulted in the separation of more yellow compound. The compound was analysed for $[RuCl_2(CO)(PPh_3)_2]$.

(ii) The yellow compound could also be obtained by boiling under reflux $[RuCl_2(PPh_3)_2]_n$ or $[RuCl_2(PPh_3)_3]$ (0.2 g) in benzaldehyde (2 cm^3) and *n*-butanol (10 cm^3) mixture for about 8 h or by boiling under reflux $[RuCl_2(C_6H_5CHO)_2(PPh_3)]$ (0.2 g) and triphenylphosphine (0.2 g) in *n*-butanol (10 cm^3) for about 10 h and cooling the reddish-yellow solution obtained.

Reactions of $[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$ (M = P, *or* As) *with* L = *pyridine,* N,N-*dimethylformamide (DMF) and dimethylsulphoxide (DMSO).* $[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$ (0.2 g) was taken with L (0.5 cm^3) and heated on a water-bath for about 1 h, when a clear solution was obtained. To the cold solution, methanol was added in the case of DMF or DMSO and the diethylether in the case of pyridine reaction and the mixture was kept overnight when crystalline compound separated out. It

was centrifuged, washed with ether and dried under vacuum. The compounds obtained had the composition $[RuCl_2(MPh_3)L_3]$ (where M = P or As and L = pyridine or DMF) and $[RuCl_2(DMSO)_4]$.

Reaction of $[Ru(MPh_3)_2(CO)Cl_2]$ *with pyridine.* $[Ru(MPh_3)_2(CO)Cl_2]$ (M = P or As) (0.2 g) was taken with pyridine (1 cm^3) and heated on a water bath when a clear yellow solution was obtained. After cooling the solution, ether was added when yellow compound precipitated out, which was centrifuged, washed with ether and dried under vacuum. The compounds had the composition $[RuCl_2(CO)(MPh_3)(py)_2]$.

Carbon, hydrogen and nitrogen analyses were obtained from the Microanalytical Laboratory, I.I.T., Kanpur. Chloride estimations were carried out according to standard methods[38] gravimetrically after decomposing the complexes using KNO_3, KOH mixture. IR spectra were recorded in KBr as pellets in the region 4000–600 cm^{-1} on a Perkin–Elmer 297 IR spectrophotometer, and on Perkin–Elmer 580 spectrophotometer in the region 600–250 cm^{-1} for some complexes. Visible electronic spectra were recorded in chloroform in the region 800–350 nm on a Beckmann-26 spectrophorometer. Proton magnetic resonance spectra were recorded on a Varian EM-390, 90 MHz spectrometer in $CDCl_3$, with TMS as reference. Magnetic susceptibility measurements were carried out using a Gouy balance at room temperature. Mercury tetrathiocyanatocobaltate(II) was used as calibrant. All the melting points are uncorrected. The conductivity measurements were made using an Elico type CM 82 conductivity bridge in nitrobenzene.

RESULTS AND DISCUSSION

(a) $[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$ (M = P *or* As)

Ruthenium compounds containing triphenylphosphine or triphenylarsine and benzaldehyde have the composition $[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$ (M = P or As). Benzaldehyde is easily oxidised to benzoic acid. As the reactions were carried out in the presence of air, the possibility of benzaldehyde getting oxidised to benzoic acid and coordinating to the ruthenium can not be eliminated. However, a similar reaction under nitrogen atmosphere also gave the same products. The PMR of $[Ru(AsPh_3)(C_6H_5CHO)_2Cl_2]$ in dueterated chloroform showed signals at 10, 7.31 and 7.23δ. The signals at 10 and at 7.31 and 7.32δ were in the ratio 2:25. The aryl aldehyde proton is normally observed in the 10.1–9.5δ range.[39] In the benzaldehyde complex containing triphenylarsine, a proton signal at 10δ can unambiguously be assigned as due to the proton of the aldehyde functional group of benzaldehyde. The signals at 7.31 and 7.23δ are due to the phenyl groups of triphenylarsine and benzaldehyde respectively. The ratio of the proton signals for aldehydic proton and the phenyl protons is as expected (2:25). Similarly, the triphenylphosphine analogue, viz. $[Ru(PPh_3)(C_6H_5CHO)_2Cl_2]$, gave proton signals at 10, 7.5 and 7.23δ. The ratio of 10δ to 7.5 and 7.23δ signals is again 2:25 as expected for two aldehyde protons and 25 phenyl protons. The signals at 7.5 and 7.23δ are due to the phenyl groups of triphenylphosphine and benzaldehyde respectively. Thus, the PMR spectra of $[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$ (M = P or As) confirmed the presence of three phenyl groups due to triphenylphosphine or arsine, two phenyl groups and two aldehydic protons due to two benzaldehyde molecules.

The IR spectra of the two complexes discussed above showed all the bands due to triphenylphosphine or triphenylarsine and benzaldehyde. Among the important IR bands due to benzaldehyde are three bands of medium intensity at 1615, 1595 and 1575 cm^{-1} and bands at 1450, 1220 and 670 cm^{-1}. ν_{CO} for free benzaldehyde occurs at 1698 cm^{-1}. Due to coordination of benzaldehyde to the metal, the stretching frequency of ν_{CO} goes down and one of the bands around 1600 cm^{-1} could be due to ν_{CO} of benzaldehyde coordinated to ruthenium. Other IR bands are present in free benzaldehyde too but with a slight shift in the position. A strong band at 330 cm^{-1} was observed for $[Ru(AsPh_3)(C_6H_5CHO)_2Cl_2]$. Triphenylarsine also shows absorption around 330 cm^{-1}. Hence this band cannot be assigned unambiguously; however, it may be due to the coupled vibrations of ν_{Ru-Cl} and the characteristic vibrations of triphenylarsine.[20] The complexes discussed above are diamagnetic, thereby confirming the presence of bivalent ruthenium. These complexes are probably pentacoordinated as suggested by the electronic absorption spectra in chloroform. These spectra (Fig. 1) show one absorption band in the region 760–810 nm and another around 410 nm. The band around 800 nm is observed in ruthenium(II) pentacoordinated square-pyramidal complexes, viz. $[RuCl_2(PPh_3)_3]$ and $[RuCl_2(AsPh_3)_2]_2$.[20] Electronic absorption in this region is generally not observed for octahedrally coordinated complexes of ruthenium(II). Hence, the benzaldehyde complexes seem to have a distorted square-pyramidal structure. The diamagnetic behaviour thus suggests that the six electrons in ruthenium(II) are probably distributed as $(d_{xz}, d_{yz})^4$, d_{xy}.[2] The band around 800 nm could be assigned to $d_{xy} \rightarrow d_{z^2}$ and around 400 nm to $(d_{xz}, d_{yz}) \rightarrow d_{z^2}$ transitions. The complexes are non-conducting in nitrobenzene, thereby confirming non-ionic type of structure for the complexes.

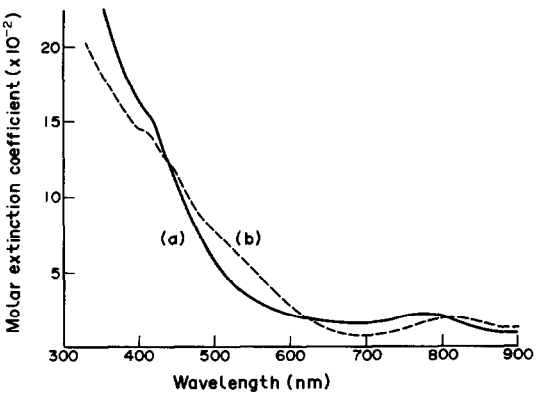

Fig. 1. Electronic spectra of (a) $[RuCl_2(PPh_3)(C_6H_5CHO)_2]$ and (b) $[RuCl_2(AsPh_3)(C_6H_5CHO)_2]$ in chloroform.

(b) $[Ru(MPh_3)(CO)Cl_2]$

The reaction of ruthenium trichloride, benzaldehyde and triphenylphosphine in *n*-butanol for a period of about 6–8 h yielded a reddish-brown crystalline compound of the composition $[Ru(PPh_3)_2(CO)Cl_2]$. It is diamagnetic in nature and shows a strong and sharp IR absorption at 1980 cm^{-1} assignable to ν_{CO} (terminal). A compound with the same molecular formula and yellow in colour was reported by James *et al.*[19] which showed IR absorptions at 1931 and 1921 cm^{-1} in Nujol and at 1940 cm^{-1} in methylene chloride solution for

ν_{CO} (terminal). It was characterised as a pentacoordinated complex, which apparently isomerized in methylene chloride solution showing a broad band at 1970 cm^{-1}. The reddish-brown compound may be an isomer of the yellow compound reported by James *et al.*[19]

Prolonged reaction ($\sim$ 20 h) of ruthenium trichloride, benzaldehyde and triphenylphosphine or triphenylarsine resulted in the formation of yellow compounds of the composition $[Ru(CO)(MPh_3)_2Cl_2]$ (M = P or As). These compounds could also be obtained by the reaction of $[RuCl_2(PPh_3)_3]$, $[RuCl_2(PPh_3)_2]_n$ or $[RuCl_2(AsPh_3)_2]_2$ with benzaldehyde in *n*-butanol or by the reaction of $[RuCl_2(MPh_3)(C_6H_5CHO)_2]$ with the corresponding triphenylphosphine or arsine in *n*-butanol. Formation of these carbonyl containing complexes is due to the extraction of a carbonyl group from a benzaldehyde molecule, either coordinated to the metal or free (present in the reaction medium). The infrared spectra of these yellow carbonyl complexes show a strong and sharp band at 1940 cm^{-1} assignable to ν_{CO} (terminal), and all other bands due to triphenylphosphine or triphenylarsine. Yellow $[Ru(CO)(PPh_3)_2Cl_2]$ obtained by us may be same as reported by James *et al.*[19]

(c) *Reactions of* $[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$ (M = P *or* As) *with donor solvents*

Reactions of $[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$ (M = P or As) with donor solvents were carried out to find out the ease of substitution of the coordinated benzaldehyde. The donor solvents used were pyridine, *N,N*-dimethylformamide (DMF), and dimethylsulphoxide (DMSO).

Reactions with pyridine or DMF results in the formation of the six coordinate species $[Ru(MPh_3)L_3Cl_2]$ (L = py or DMF) because two molecules of benzaldehyde in the original complexes are replaced by three molecules of pyridine or DMF. The inability to form hexacoordinate complexes with benzaldehyde may be due to partial blocking of the sixth coordination site by the phenyl groups of the two benzaldehyde molecules or the triphenylarsine or phosphine molecule. The IR spectra of the complexes containing DMF showed a very strong band at 1640 cm^{-1} which is due to ν_{CO} of DMF coordinate through the oxygen atom.[22] In the case of pyridine complexes, all bands due to coordinated pyridine were observed besides bands due to triphenylphosphine or triphenylarsine in the IR region. A medium-sharp band at 1445 cm^{-1} characteristic of pyridine was also observed.

Pyridine or DMF containing complexes are diamagnetic, thereby confirming that ruthenium(II) is present in the low-spin state. The electronic absorption spectra of these complexes showed two bands one in the region 450–550 nm and other one in the region 415–390 nm, with a molar extinction coefficient of the order of 10^2–10^3. These bands may be assigned to $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ transitions respectively. The values of the molar extinction coefficient ($\sim 10^3$) are relatively high but this may be due to the mixing of the energy levels with the charge-transfer band(s) in that region.[22] These complexes are non-electrolytes in nitrobenzene, thereby confirming their non-ionic character.

Reaction of DMSO with

$$[Ru(MPh_3)(C_6H_5CHO)_2Cl_2]$$

resulted in the substitution of all the benzaldehyde and triphenylphosphine or triphenylarsine molecules by DMSO and gave $[Ru(Cl_2(DMSO)_4]$. The DMSO complex showed strong IR absorptions at 1120, 1090 and 915 cm^{-1}. The former two absorptions could be due to $\nu_{S=O}$ of the S-bonded DMSO and the later one due to $\nu_{S=O}$ of the O-bonded DMSO. The complex was same as reported by Evans *et al.*[27]

(d) *Reactions of* $[Ru(CO)(MPh_3)_2Cl_2]$ (M = P *or* As) *with pyridine*

Reddish-brown or yellow compounds of the composition $[Ru(CO)(MPh_3)_2Cl_2]$ (M = P or As), on treatment with pyridine resulted in the formation of $[Ru(CO)(MPh_3)(py)_2Cl_2]$, which showed all IR absorptions due to triphenylphosphine or triphenylarsine and pyridine. A band at 1444 cm^{-1} characteristic of pyridine was observed. Besides, two or three bands in the region 1965–1920 cm^{-1} due to ν_{CO} were also observed.

The potential of some of the above mentioned pentacoordinated complexes to act as homogenous catalysts is being examined.

ESR STUDIES ON THE REACTIONS OF SULPHITE RADICAL ANION, $SO_3^{\dot{-}}$, WITH NITROALKANE COMPOUNDS IN AQUEOUS SOLUTIONS

TOSHIHIKO OZAWA* and TAKAO KWAN†
Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bukyo-ku, Tokyo 113, Japan

(*Received* 9 *October* 1984; *accepted* 4 *January* 1985)

Abstract—The reactions of the sulphite radical anion, $SO_3^{\dot{-}}$ (generated from the Ti^{3+}–H_2O_2–Na_2SO_3 system at pH 9), in aqueous solutions with some nitroalkane compounds were investigated by using a rapid-mixing flow technique coupled with electron spin resonance (ESR) which can detect the radicals having a lifetime of 5–100 ms. The $SO_3^{\dot{-}}$ radical added to the double bond of C=N in the nitroalkane *aci*-anions which are the main form of nitroalkanes in aqueous alkaline solutions. From the observed hyperfine splitting constants of the $SO_3^{\dot{-}}$ adducts of nitroalkane *aci*-anions, the preferred conformation of the adducts was deduced.

It is well known that the rapid-mixing flow technique coupled with electron spin resonance (ESR) is very useful to detect the short-lived radicals having a lifetime longer than a few msec. In previous papers, by the use of this technique we have reported that the sulphite radical anion, $SO_3^{\dot{-}}$, which is generated from Ce^{4+}–$NaHSO_3$ system in acidic solutions, can add to the compounds having C=C,[1] C≡C[2] and C=S[3] bonds to give the corresponding secondary radicals, respectively. Also, in the alkaline aqueous solutions at pH 9, the same radical species, $SO_3^{\dot{-}}$, which is obtained from a Ti^{3+}(ethylenediaminetetraacetic acid)–H_2O_2–Na_2SO_3 system, can add to uracil derivatives having the C=S bond.[4] Further, we have found that the reactive characteristics of the oxy anion radicals of sulphur, $SO_2^{\dot{-}}$, $SO_3^{\dot{-}}$ and $SO_4^{\dot{-}}$, are different from each other and reported that these differences of reactivity towards the organic substrates may be caused by the difference in the distribution of the unpaired electron density in each radical anion.[5] It was also found that the $SO_3^{\dot{-}}$ radical could not react with aromatic nitro compounds.[3] However, Norman *et al.* briefly reported that in aqueous alkaline solutions, the $SO_3^{\dot{-}}$ radical could add to the nitroalkane compounds.[6] Therefore, we have further examined in detail the reactions of the $SO_3^{\dot{-}}$ radical with the nitroalkane compounds in alkaline aqueous solutions by use of the rapid-mixing flow technique.

EXPERIMENTAL

Materials. $TiCl_3$ (20% v/v), ethylenediaminetetraacetic acid (EDTA) and Na_2SO_3 were purchased from Wako Pure Chemical Ind. Ltd. and used without further purification. H_2O_2 (30%) was obtained from Mitsubishi Gas Chemical. Nitroalkane compounds were purchased from Tokyo Kasei Kogyo Co. Ltd. and used without further purification. Other chemical reagents were of commercial GR grade.

ESR measurements. ESR measurements were carried out on a JEOL-PE-1X ESR spectrometer (X-band) with 100 kHz field modulation in conjunction with a JEOL mixing chamber and T-shaped cell which enabled three reagents to mix almost simultaneously.[4] This apparatus enabled us to detect radicals having lifetimes of 5–100 ms. The hyperfine coupling constants and g-values were calibrated by comparison with an aqueous solution of Fremy's salt ($g = 2.0055$, $a^N = 13.0$ G)[7] in a capillary tube attached to the sample.

Procedure. All solutions were prepared from triply distilled water, and their pH was adjusted by aqueous ammonia solution.

† Present address: Faculty of Pharmaceutical Sciences, Teikyo University, Sagamiko-cho, Tsukui-gun, Kanagawa 199-01, Japan.

For the generation of the $SO_3^{\dot{-}}$ radical in alkaline aqueous solutions,[6] $TiCl_3$ (20%), H_2O_2 (30%) and Na_2SO_3 were used. The conditions for oxidation with and without an added organic substrate were the same except that, in the latter case, only two of the three entry of ports into the mixing chamber were employed and the third solution referred to below was omitted. Three solutions were prepared: the first solution contained 0.01 M Ti^{3+}, 0.01 M EDTA, and 0.1 M Na_2SO_3; the second contained 0.05 M H_2O_2; and the third contained the organic compound (0.1 M). Aqueous ammonia was added to the first and the third solution to give a pH of 9.

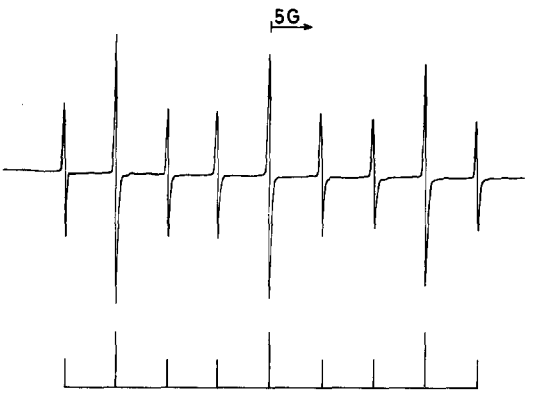

Fig. 1. ESR spectrum and its stick diagram observed by the reaction of nitromethane *aci*-anion with the $SO_3^{\dot{-}}$ radical at pH 9.

RESULTS

It is well known that nitroalkane compounds exist as *aci*-anion forms ($R_1R_2C{=}NO_2^-$) in alkaline aqueous solutions, and that these *aci*-anions from several nitroalkanes react rapidly enough with various radicals such as hydroxyl,[8] amino,[8] methyl[9] and α-aminoalkyl[10] to give the corresponding secondary radical anion adducts

$$[R_1R_2C(X)\text{–}NO_2^{\dot{-}}]$$

in sufficient concentration for ESR detection. The formation of the same radical anion adduct was expected during the reaction of the $SO_3^{\dot{-}}$ radical with nitroalkane *aci*-anions.

When solutions of Ti^{3+} and EDTA, H_2O_2, and Na_2SO_3 were mixed in the cavity of the ESR spectrometer, the pH after mixing being 9, a singlet absorption line at $g = 2.0028$, which has been assigned to the $SO_3^{\dot{-}}$ radical,[4] was observed. Since when either Ti^{3+} or H_2O_2 was omitted no ESR spectrum could be observed, the $SO_3^{\dot{-}}$ radical may be formed by one-electron oxidation of the sulphite ion by the hydroxy radical which is generated by the reaction of Ti^{3+} ion with H_2O_2[11] [eqns. (1)–(3)], taking into consideration the pK of HSO_3^- of 7.2.[12]

$$Ti^{3+} + H_2O_2 \rightarrow Ti^{4+} + HO^- + HO\cdot \quad (1)$$

$$HSO_3^- \rightleftarrows SO_3^{2-} + H^+ \quad (2)$$

$$HO\cdot + SO_3^{2-} \rightarrow HO^- + SO_3^{\dot{-}}. \quad (3)$$

Nitromethane aci-*anion.* When nitromethane was added as the third solution and allowed to react with the solution mentioned above, the absorption line due to the $SO_3^{\dot{-}}$ radical was completely consumed, and a new ESR signal appeared at $g = 2.0050$ (Fig. 1). This spectrum can be analyzed in terms of parameters: $a^N(1) = 22.22$ G and $a^H(2) = 7.53$ G. Since these parameters are different from those of nitromethane radical anion[9] or those of OH adduct of nitromethane *aci*-anion,[8] the radical species observed is assignable to the $SO_3^{\dot{-}}$ adduct, $H_2C(SO_3^-)NO_2^{\dot{-}}$.

Nitroethane aci-*anion.* When nitroethane was mixed with the $SO_3^{\dot{-}}$ radical, the ESR signal due to the latter disappeared and a new ESR signal was observed at $g = 2.0050$ (Fig. 2), This spectrum can be analyzed in terms of the parameters: $a^N(1) = 22.80$ G, $a^H(1) = 3.33$ G and $a^H(3) = 0.42$ G. Since the spectral pattern is similar to that of OH adduct of nitroethane *aci*-anion, but the parameters are different from each other, the radical species observed can be assigned to the $SO_3^{\dot{-}}$ adduct, $MeCH(SO_3^-)NO_2^{\dot{-}}$.

1-*Nitropropane* aci-*anion.* When 1-nitropropane was reacted with the $SO_3^{\dot{-}}$ radical at pH 9, only the ESR spectrum as shown in Fig. 3 was observed. This newly observed spectrum can be analyzed in terms of the parameters: $a^N(1) = 22.08$ G, $a^H(1) = 2.18$ G and $a^H(1) = 0.70$ G. Since these parameters are different from those of OH adduct of 1-nitropropane *aci*-anion, the observed radical species is assignable to the $SO_3^{\dot{-}}$ adduct, $EtCH(SO_3^-)NO_2^{\dot{-}}$. In this case, only

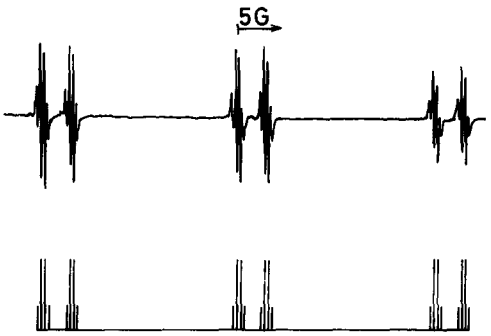

Fig. 2. ESR spectrum and its stick diagram observed during the reaction of the $SO_3^{\dot{-}}$ radical with nitroethane *aci*-anion at pH 9.

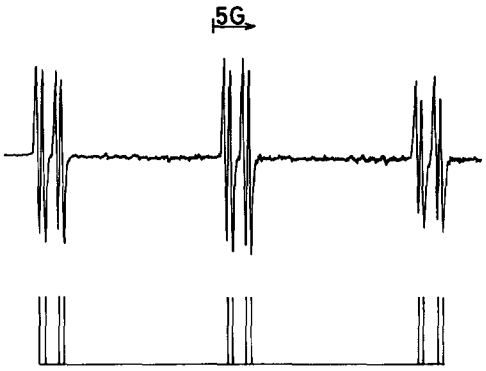

Fig. 3. ESR spectrum and its stick diagram observed during the reaction of the $SO_3^{\dot{-}}$ radical with 1-nitropropane *aci*-anion at pH 9.

one hyperfine splitting attributable to a γ-proton was observed. Possibly the other splitting was small enough to be marked by the line-widths (*ca* 0.3 G). This type of the magnetic non-equivalency is ascribed to the chirality of the adjacent carbon atom.[13]

2-*Nitropropane* aci-*anion*. The similar $SO_3^{\dot{-}}$ adduct of 2-nitropropane *aci*-anion, $(Me)_2C(SO_3^-)NO_2^{\dot{-}}$, was observed when 2-nitropropane was reacted with the $SO_3^{\dot{-}}$ radical at pH 9. The spectrum can be analyzed as follows: $a^N(1) = 22.83$ G and $a^H(6) = 0.42$ G.

The ESR parameters observed during the reaction of the $SO_3^{\dot{-}}$ radical with some nitroalkanes are summarized in Table 1.

DISCUSSION

From Table 1, it is apparent that the $SO_3^{\dot{-}}$ radical can easily add to the C=N bond of nitroaklane *aci*-anions to yield the $SO_3^{\dot{-}}$ adducts.

The β-proton splitting constants of the radical anions as shown in Table 1 are less than that of nitromethane radical anion, $CH_3NO_2^{\dot{-}}$ (12.0 G).[9] The sensitivity of the hyperfine splitting from a β-proton

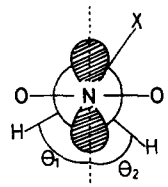

Fig. 4. Possible model of the nitroxide radical. θ represents the dihedral angle.

to the dihedral angle between the orbital of the unpaired electron and the β C–H bond has continued to provide a useful probe for the study of the radical conformation.

Generally, the hyperfine splitting constant due to the β-protons could be represented by the following eqn (4).

$$a(\beta\text{-H}) = \beta_0 + B\cos^2\theta \qquad (4)$$

where θ is dihedral angle made between the orbital of the unpaired electron and the β C–H bond, and B_0 and B are constants. In this equation, since B_0 is approximately zero, $a(\beta$-H) is mainly dependent on $\cos^2\theta$.

Now, consider the conformation of the model as shown in Fig. 4.[14] Since methyl group in the nitromethane radical anion (X = H) is thought to be freely rotating around the C–N bond, $\cos^2\theta$ in the eqn (4) is averaged to be 1/2. That is, θ is 45°. On the other hand, $a(\beta$-H) in the $SO_3^{\dot{-}}$ adduct (X = SO_3^-) is less than that of nitromethane radical anion. Then, from the eqn (4),

$$1/2(\cos^2\theta_1 + \cos^2\theta_2) = \text{average of } \cos^2\theta < 1/2.$$

Consequently, $\theta > 45°$. This result shows that the preferred conformation of the $SO_3^{\dot{-}}$ adduct is the conformation in which the dihedral angle between the β C–H bond and the p_z orbital of nitrogen atom is larger than 45°.

Also, the larger reduction in the hyperfine splitting of the β-proton in the other $SO_3^{\dot{-}}$ adducts when substituent (R_2) is replaced by a methyl and ethyl group is observed (Table 1). These results are

Table 1. Hyperfine splitting constants (Gauss) and *g*-factors for radicals, $R_1R_2C(SO_3^-)NO_2^{\dot{-}}$

R_1	R_2	a^N	$a(\beta$-H)	$a(\gamma$-H)	*g*
H	H	22.22	7.53(2H)	—	2.0050
H	Me	22.80	3.33(1H)	0.42(3H)	2.0050
H	Et	22.08	2.18(1H)	0.70(1H)	2.0050
Me	Me	22.83	—	0.42(6H)	2.0051

explained by the idea that the bulky substituents such as methyl and ethyl further affect the conformation of the $SO_3^{\pm}$ adduct. That is, in these adducts, the dihedral angle (θ) gradually approaches 90° as shown in Fig. 5, dependent on the substituents.

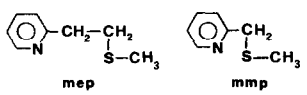
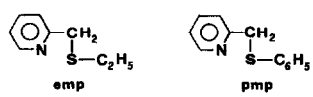
THE REACTIONS BETWEEN TETRACHLOROPLATINATE(II) ANION AND BIDENTATE SULPHUR–NITROGEN CHELATING AGENTS: A DIRECT ROUTE FOR THE SYNTHESIS OF THE NEUTRAL DICHLORO SPECIES



A. BALDO, G. CHESSA, G. MARANGONI* and B. PITTERI
University of Venice, Department of Chemistry, 30123 Venice, Italy

(*Received* 9 *October* 1984; *accepted* 6 *February* 1985)



Abstract—A direct route for the synthesis of the neutral dichloro complexes $[Pt(N–S)Cl_2]$, (N–S = 2-[(ethylthio)methyl]pyridine and 2-[(phenylthio)methyl]pyridine) in dimethylformamide, which avoids the formation of bis-chelate cations, is reported.

In the general context of a program dealing with kinetic studies on planar tetracoordinate complexes, we faced the problem of synthesizing neutral dichloro complexes containing sulphur–nitrogen chelating ligands, of general formula $[Pt(N–S)Cl_2]$.

It is reported that the reaction between tetrachloroplatinate(II) anion and 2-[(methylthio)-ethyl]pyridine (mep) in aqueous-methanol solution, gives the neutral tetracoordinate $[Pt(mep)Cl_2]$,[1] in which the organic ligand forms a six-membered chelate ring containing the metal. Attempts to obtain the analogous $[Pt(mmp)Cl_2]$ (mmp = 2-[(methylthio)methyl]pyridine) in which the ligand is expected to form a five-membered chelate ring, under the same experimental conditions, yielded only the insoluble Magnus type salt $[Pt(mmp)_2][PtCl_4]$[2].

We have now confirmed this observation on reacting $[PtCl_4]^{2-}$ with the parent ligands 2-[(ethylthio)methyl]pyridine (emp) and 2-[(phenylthio)methyl]pyridine (pmp). The Magnus type salts $[Pt(emp)_2][PtCl_4]$ and $[Pt(pmp)_2][PtCl_4]$ are the products when the reactions are carried out in water or methanol–water.

* Author to whom correspondence should be addressed.

In this report we describe a new synthetic route which allows the direct preparation of the neutral dichloro species by carrying out the reactions in dimethylformamide (dmf).

EXPERIMENTAL

Physical measurements

IR spectra as KBr discs and Nujol mulls were recorded on a Perkin–Elmer 683 spectrophotometer. Electronic spectra were measured in the 250–370 nm range on a Varian-Cary 219 spectrophotometer. ^1H NMR spectra in CD_3NO_2 were obtained with an FT-80 Varian spectrometer. Conductivity measurements were performed on a Radiometer Copenhagen CDM 83 conductivity meter.

Preparation of 2-[*(phenylthio)methyl*]*pyridine hydrochloride* (*pmp*)

This compound was obtained according to the method of Bauer *et al.*[3] by condensation of sodium thiophenolate with 2-chloromethylpyridine in refluxing 95% ethanol. The product was converted to the hydrochloride salt which was crystallized from ethanol–diethylether. Yield 85%; m.p. 136–137°C (Lit. 137°C). Found: C, 60.3; H, 5.1; N, 5.9; Cl, 14.9; S, 13.5. $C_{12}H_{12}NClS$ requires: C, 60.3; H, 5.0; N, 5.8; Cl, 15.0; S, 13.5%.

Preparation of 2-[*(ethylthio)methyl*]*pyridine hydrochloride* (*emp*)

This was prepared in a similar way to pmp and crystallized from hot acetone. Yield 70%; m.p. 101–

102°C. Found: C, 50.8; H, 6.3; N, 7.2; Cl, 18.7; S, 16.7. $C_8H_{12}NClS$ requires: C, 50.7; H, 6.4; N, 7.4; Cl, 18.7; S, 16.9%.

Preparation of bis(2-[(ethylthio)methyl]pyridine)-platinum(II) tetrachloroplatinate(II), $[Pt(emp)_2][PtCl_4]$

K_2PtCl_4 (0.415 g, 1 mmol) in water (10 cm^3) was added to a warm solution of 2-[(ethylthio)methyl]-pyridine hydrochloride (0.189 g, 1 mmol), previously neutralized with 1 M KOH, in water (20 cm^3). The pink precipitate of the complex salt which was obtained, was filtered off, washed with water, ethanol and diethyl ether and dried under vacuum. Yield 95%. Found: C, 22.9; H, 2.5; N, 3.3; Cl, 17.1; S, 7.4. $C_{16}H_{22}N_2Cl_4S_2Pt_2$ requires: C, 22.9; H, 2.6; N, 3.3; Cl, 16.9; S, 7.6%.

Preparation of bis(2-[(phenylthio)methyl]pyridine)-platinum(II) tetrachloroplatinate(II), $[Pt(pmp)_2][PtCl_4]$

This was prepared following the same procedure as in the previous case. Yield 95%. Found: C, 30.7; H, 2.2; N, 3.3; Cl, 15.4; S, 6.7. $C_{24}H_{22}N_2Cl_4S_2Pt_2$ requires: C, 30.8 ; H, 2.35; N, 3.0; Cl, 15.2; S, 6.85%.

Preparation of cis*-dichloro-2-[(phenylthio)methyl]-pyridine platinum(II)*, $[Pt(pmp)Cl_2]$

A solution of 2-[(phenylthio)methyl]pyridine hydrochloride (0.238 g, 1 mmol) in dmf (10 cm^3) was neutralized with an aqueous solution of 1 M KOH (1 cm^3) and then dried with anhydrous Na_2SO_4. The filtered solution was slowly dropped under vigorous stirring into a solution of K_2PtCl_4 (0.415 g, 1 mmol) in dmf (50 cm^3) at room temperature. The temperature was then raised to 60°C and the mixture left to react for 6 hr. During that time the initially deep red solution became orange yellow and KCl precipitated. It was then cooled to room temperature, acetone was added (10 cm^3) and any solid filtered. The clear solution was concentrated to 5 cm^3 and a microcrystalline yellow product recovered by adding diethyl ether. It was filtered off, washed with diethyl ether and dried under vacuum. Yield 0.33 g (70%), m.p. (decomp) 175°C. Found: C, 30.2; H, 2.3; N, 3.1; Cl, 15.2; S, 6.9. $C_{12}H_{11}NCl_2SPt$ requires: C, 30.85. H, 2.4; N, 3.0; Cl, 15.2; S, 6.85%. A 1×10^{-3} molar solution of the complex in nitromethane is non-conducting. ^1H NMR (CD_3NO_2, δ from TMS as internal standard: 7.14–9.65 (complex multiplets, 9H, pyridyl and phenyl residues), 3.09–5.28 (m, 2H, $-C\underline{H}_2-$). The IR spectrum shows significant bands at: 1610s, ν(C=N); 328, 340m, ν(Pt–Cl).

Preparation of cis*-dichloro-2-[(ethylthio)methyl]-pyridine platinum(II)*, $[Pt(emp)Cl_2]$.

This complex was prepared following the same procedure as in the previous case. Yield 70%, m.p. (decomp) 175°C. Found: C, 22.9; H, 2.6; N, 3.4; Cl, 16.7; S, 7.7. $C_8H_{11}NCl_2SPt$ requires: C, 22.9; H, 2.6; N, 3.3; Cl, 16.9; S, 7.6%. A 1×10^{-3} molar solution of the complex in nitromethane is non-conducting. ^1H NMR (CD_3NO_2, δ from TMS as internal standard): 7.04–9.77 (complex multiplets, 4H, pyridyl residue), 2.37–3.49 (m, 2H, $-C\underline{H}_2-$), 4.38 (q, 2H, $-C\underline{H}_2-CH_3$), 1.38 (t, 3H, $-CH_2-C\underline{H}_3$). The IR spectrum shows significant bands at: 1612s, ν(C=N); 318, 333m, ν(Pt–Cl).

RESULTS AND DISCUSSION

When potassium tetrachloroplatinate(II) is reacted with an equimolar amount of emp or pmp in aqueous solution at room temperature, the pink, very insoluble Magnus type salts $[Pt(emp)_2][PtCl_4]$ and $[Pt(pmp)_2][PtCl_4]$, which can be easily recognized by IR spectra, are obtained quantitatively. IR spectra of both the salts show a medium to strong single band at 312 cm^{-1}, typical of the Pt–Cl stretching vibration of the symmetric $[PtCl_4]^{2-}$ anion.[4] All attempts to obtain the neutral dichloro monochelated species under the same experimental conditions were unsuccessful.

It is known[5] that, when equimolar amounts of K_2PtCl_4 and ethylenediamine are allowed to react in water, a mixture of $[Pt(en)Cl_2]$ and $[Pt(en)_2][PtCl_4]$ precipitates. Furthermore, treatment of K_2PtCl_4 with two equivalents of trialkylphosphine gives a precipitate of $[Pt(PR_3)_4][PtCl_4]$.[6] However in that case, the product can be transformed into a mixture of the neutral dichloro species *cis-* and *trans-* $[Pt(PR_3)_2Cl_2]$ by boiling in water for several hours. The polydentate molecules, pyridine-2,6-dicarboxylic acid and 2-pyridine-carboxylic acid behave similarly, giving the neutral compounds containing two chelating ligands per molecule.[7] In the case of the ligands emp and pmp, the transformation of the Magnus type salts by prolonged boiling in water does occur, but only partially, and the final product is a mixture which is difficult to handle and decomposes, probably as a consequence of the very low solubility of the first product in water. Very pure neutral dichloro species, $[Pt(emp)Cl_2]$ and $[Pt(pmp)Cl_2]$ can be directly obtained by reacting K_2PtCl_4 with an equimolar amount of the appropriate ligand in dmf at 60°C. The K_2PtCl_4 is soluble in dmf at this temperature and, on addition of the ligand, the colour of the solution gradually changes from cherry-red to orange–yellow

with simultaneous precipitation of KCl and the formation of the neutral dichloro species, which is also soluble in dmf. The neutral dichloro species can be easily recovered from the dmf solution as microcrystalline yellow products by adding diethyl ether after a preliminary concentration. They are, as expected, non-conducting and their IR spectra show two well separated absorption bands in the 340–315 cm^{-1} range, which are the typical stretching vibrations of *cis*-dichloro platinum species. ^1H NMR resonances are in full agreement with the proposed formulation. In particular the complex multiplet in the range 3.49–2.27 for the emp complex and 5.28–3.09 for the pmp complex indicate, as expected, the magnetic non-equivalence of the methylene protons. Methanolic solutions of the two neutral complexes closely follow Beer's law.

The fact that the dichloro neutral species can be directly obtained in dmf is probably related to the different solubility of the Magnus type salt intermediate in the two solvents. This is in agreement with the observation that these intermediates, prepared in water and isolated as pure solids, are soluble in dmf where, on heating, they are transformed into the dichloro species.

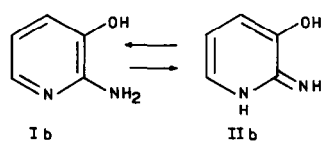
(*Received* 26 *November* 1984; *accepted* 6 *Febraury* 1985)



Abstract—Complexation of copper(II) with two different pyridinols in three solvents has been studied by visible spectrophotometry and flow-microcalorimetry. The influence of the solvent on tautomeric equilibrium of the ligand, on distribution, on stability and on formation enthalpies of the main complex species is discussed.

The thermodynamic properties of complexes in solution are remarkably influenced by the interactions of the solvent with both metal and the ligand.[1–3] These interactions are generally interpreted on the basis of donor power (DN), acceptor power (AN), dielectric constant values (DEC) and hydrogen bonding ability which all influence the solvation and/or ionization of the species present.

In the present work the solvent effect on the complexation equilibria of copper(II) with 2,3-dihydroxypyridine (HHP) and 2-amino-3-hydroxypyridine (AHP) is evaluated having chosen the following media: ethanol (EtOH), dimethylacetamide (DMA) and dimethylsulphoxide (DMSO). These solvents can influence also the tautomeric equilibria of the considered ligands:

Ia IIa

Ib IIb

Moreover the results may be discussed considering also those obtained in the copper(II)–aminopyridine systems[4] to formulate some hypothesis concerning the influence of the substituents of the heterocyclic ring on complexation equilibria.

EXPERIMENTAL

All products used were of analytical grade. Solvents were dehydrated and purified in the usual way.[5] The water content of the products was determined using Karl–Fischer reagent and found to be less than 0.05% in all cases.

The ligands were recrystallized from EtOH : ligroin (1 : 1) until their proper melting points.

The metal solutions, prepared from $Cu(ClO_4)_2 \cdot 6H_2O$, were analyzed by complexometric titration.

The spectrophotometer was a Perkin–Elmer 559. Quartz cells of different lengths (5 cm, 3 cm, 1 cm) were used.

The flow microcalorimeter was a LKB 10700 apparatus with two glass syringes on an injection pump. All measurements were carried out at 25 ± 0.1°C.

NMR measurements were carried out with a Bruker WP 80 at 25°C in DMSO-d_6 solutions, using TMS as reference.

RESULTS

2,3-*Dihydroxypyridine* (HHP)

The addition of HHP to a solution of constant metal concentration (1×10^{-3} M) led to the appearance of a new absorption band at $\lambda = 440$ nm

* Author to whom correspondence should be addressed.

Table 1. Absorbance values at certain wavelengths (A_λ) of copper(II)-2,3-dihydroxypyridine system in ethanol, dimethylacetamide, dimethylsulphoxide at constant metal concentration $C_M = 1 \times 10^{-3}$ M and various initial molar concentration ratios $C_L/C_M = 0.5$–40. Blank: solvent; $b = 1$ cm; $T = 25°C$

EtOH		DMA		DMSO

2.0	0.311	2.0	0.428	30.0	0.243
3.0	0.325	3.0	0.434	35.0	0.250
4.0	0.340	4.0	0.440	40.0	0.255

in EtOH and DMSO and at $\lambda = 460$ nm in DMA, in the range $C_L/C_M = 0$–40.

Optical densities measured at these wavelengths were constant for at least one day, and the ionic strength was maintained at 0.05 M with tetrabutylammonium perchlorate.

Mathematical elaboration[6] of the absorbance variation vs C_L/C_M (Table 1) has evidenced the formation of only one species, in all the solvents characterized by a complexation ratio L/M = 1 : 1.

Equilibrium constants and the molar absorptivities have been calculated using Rose and Drago's method.[7] A graphical procedure, based on plotting several curves obtained from equation (1), was used. The eqn (1) which is applicable only when one complex is formed and when the donor molecule does not absorb in the region studied, is that of a straight line with two unknowns, K^{-1} and ε_c:

$$K^{-1} = A/b\varepsilon_c - C_M - C_L + C_M C_L \varepsilon_c b/A, \quad (1)$$

where b = path length; C_M = initial concentration of the metal; C_L = initial concentration of ligand; ε_c = molar absorptivity of the constant; A = total absorbance.

The stability constant and molar absorptivities, determined intersection of the curves, are reported in Table 2.

Calorimetric investigations, carried out in the same experimental conditions, have given suitable data in all the solvents considered. In particular

Table 2. Concentration quotients at equilibrium, β_i ($mol^{-i}\ l^{-i}$), molar absorptivities, ε_i ($mol^{-1}\ l\ cm^{-1}$), and formation enthalpies ΔH_{β_i} (kcal mol^{-1}) for the copper(II)-2,3-dihydroxypyridine and copper(II)-2-amino-3-hydroxypyridine systems in ethanol, dimethylacetamide and dimethylsulphoxide at 25°C

Solvents	EtOH	DMA	DMSO
Parameters of the solvent	DN = 24.0 AN = 37.9 DEC = 25.3	DN = 27.8 AN = 13.6 DEC = 37.9	DN = 29.8 AN = 19.3 DEC = 45.0
Copper(II)-2,3-dihydroxypyridine	$\log \beta_1 = 4.41$ $\varepsilon_1 = 71$ ($\lambda = 440$ nm) $\Delta H_1 = -4.6$	$\log \beta_1 = 4.56$ $\varepsilon_1 = 86$ ($\lambda = 460$ nm) $\Delta H_1 = -2.7$	$\log \beta_1 = 2.54$ $\varepsilon_1 = 52$ ($\lambda = 440$ nm) $\Delta H_1 = -2.2$
Copper(II)-2-amino-3-hydroxypyridine	$\log \beta_2 = 6.13$ $\log \beta_3 = 12.12$	$\log \beta_3 = 12.18$	$\log \beta_2 = 7.08$

the calculated values were: $\Delta H_1 = -4.6$ in EtOH; $\Delta H_1 = -2.7$ in DMA; $\Delta H_1 = -2.2$ in DMSO.

Although NMR measurements did not provide any useful results it is reasonable to suppose the formation of a chelating ring, through the oxygen atoms of hydroxylic groups.

2-*Amino*-3-*hydroxypyridine* (AHP)

For all the solvents considered the complexation reactions are not instantaneous. In fact it required 4 hr in EtOH, 5 hr in DMA and 7 hr in DMSO to reach constant values of the absorbances. Therefore it was impossible to carry out calorimetric investigations.

Spectrophotometric measurements have been performed on solutions of different metal concentrations ($1–10 \times 10^{-5}$ M).

In EtOH the spectra behaviour shows the change in the absorption curve of a copper perchlorate solution on the addition of AHP. With increasing AHP concentrations the absorption maximum is displaced to shorter wavelengths, indicating that more than one complex is formed in solution.

Mathematical elaboration[6] of the absorbance values allowed the identification of two complex species with complexation ratios L/M = 2:1 and 3:1 and the determination of concentration quotients at equilibrium β_2 and β_3. The trend of the curves C_L/C_M vs A (Fig. 1) suggests the presence of a 1:1 complex species.

In DMA only one species, characterized by complexation ratio L/M = 3:1 exists in significant amounts in the range $C_L/C_M = 0–10$.

In DMSO only the species with complexation ratio L/M = 2:1 has been found in the range $C_L/C_M = 0–40$ at $\lambda = 510$ nm.

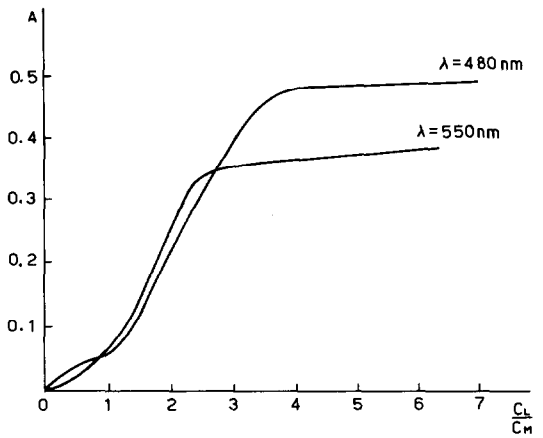

Fig. 1. Absorbance values of the copper(II)-2-amino-3-hydroxypyridine system in ethanol, at constant metal concentration $C_M = 5 \times 10^{-5}$ M and various initial molar concentration ratios $C_L/C_M = 0–7$ at two different wavelengths $\lambda_1 = 480$ nm, $\lambda_2 = 550$ nm. Blank: solvent, $b = 3$ cm, $T = 25°C$.

In Table 3 the absorbance values at different C_L/C_M are reported for all the solvents.

In this case, NMR measurements have confirmed that the coordinating centre on the ligand is the heterocyclic nitrogen atom. NMR spectra of AHP and its copper complex (Fig. 2) indicate that the signal of proton 6 and in less amount the proton 5 are perturbed by the presence of copper ion.

DISCUSSION

The data obtained allow us to formulate some hypotheses concerning the influence of the solvent

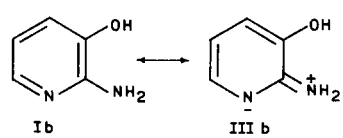
on formation equilibria of complex species in the systems examined.

Regarding the 2,3-dihydroxypyridine, the values of concentration quotients at equilibrium are very similar in EtOH and DMA while in DMSO the value is considerably lower (Table 2). This order does not agree with that of the ΔH_1 values; in fact the ΔH_{EtOH} is twice as great as ΔH_{DMA}. This discrepancy suggests that the "model system" changes, in particular that in EtOH the ligand is in the oxo-hydroxy-form (**IIa**) whereas in DMSO and in DMA it is in the diol-form (**Ia**).

This hypothesis is in agreement with the assumption that the hydrogen bonding ability of the solvent plays an obvious role as hydrogen bond donors stabilize the oxo-hydroxy-form and hydrogen bond acceptors stabilize the diol-form.[8]

The stability sequence EtOH $\simeq$ DMA > DMSO can be explained if we consider that besides the metal solvation (DN) an important role is played by the ligand solvation. In fact we must consider that the ability of the ligand to give intermolecular (HHP-solvent) or intramolecular hydrogen bonding depends on the solvent. In particular in DMSO and DMA, that are good acceptors of hydrogen bonding the intermolecular bonds are favoured, while in EtOH the favoured intramolecular bond determines a decrease in the basicity of the two oxygen atoms involved in the chelating ring.



The values of concentration quotients at equilibrium, that are remarkably higher than those of corresponding complexes concurs with the assumption that the ligand is chelating.

In the system copper(II)–AHP the influence of solvent is evident both from thermodynamic and kinetic results.

It is reported in the literature[9] that the formation of complex species with this ligand is not instantaneous. Our results obtained in various media have evidenced that the rate of complex formation is strongly influenced by the nature of solvent. In particular the time needed for the reaction to be complete increases with increasing donor number of the solvent. In fact, increasing DN of the solvent causes a decrease in acceptor strength of the coordination centre (metal) and hence in formation rate of the intermediate. Moreover the donor power of the ligand decreases as solvation of AHP increases (EtOH > DMA > DMSO). This sequence agrees with the observed solubility order of the ligand.

With regard to the stability of the evidenced complex species the results obtained (Table 2) can be explained if we consider that the solvent influences the concentration quotients at equilibrium because of various factors: (i) the solvation of the metal and the ligand; (ii) the dielectric constant; (iii) the possibility of π-interactions between solvent and ligand.

In fact while the solvation order of ligand and metal (DMSO > DMA > EtOH) favours the stabilization of complex species in EtOH, the effect of dielectric constant and π-interactions (DMSO > DMA > EtOH) favours the stabilization of complex species in DMSO and DMA respectively. In fact if we consider the resonance forms of the ligand it is evident that the form **IIIb**, in which the basicity of the nitrogen atom is higher, is the prevailing one in the solvents characterized by high DEC and stronger π-interactions. The two effects act in opposition causing a levelling of complex stability.

Ib III b

The data obtained compared with those reported in a previous paper[4] allow us to formulate some considerations on the influence of substituents in the pyridine ring:

(i) In HHP the presence of hydroxy groups in the 2- and 3-positions allows the formation of a very stable five-membered chelate with the copper ion.

(ii) In AHP the presence of a hydroxy group in α-position to the amino group increases the resonance and hence the basic strength of the heterocyclic nitrogen atom increases. In such a way the complex species are more stable than those ones of the aminopyridine.

(iii) The presence of chlorine and bromine atoms in *para*-positions to the amino group decreases the basic strength of nitrogen atom because of the inductive effect ($-I$). The stability order agrees with the Lewis basicity of the ligands: CuApy > CuBrApy > CuClApy.

Acknowledgments—This work was carried out with financial support by the Consiglio Nazionale delle Ricerche (C.N.R., Rome), which also gave a grant for one of us (A.M.G.). The authors thank Mr. G. Frachey for NMR measurements.

(*Received* 12 *November* 1984; *accepted* 6 *February* 1985)

Abstract—Copper powder reacts photochemically with tetraalkylthiuram disulphides [$(R_2NCS_2)_2$, TRTD] in chloroform. The effect of different alkyl substituents (R) on the reaction was studied systematically by means of both high-performance liquid chromatography (HPLC) and spectrophotometry. The results obtained show that the reactivity of $(R_2NCS_2)_2$ increases with increase of R in the order butyl > propyl > ethyl > methyl. In addition, this reaction is applicable to the analysis of the copper content in copper powder, copper oxides, copper(II) hydroxides, and basic copper carbonates.

The direct reaction of β-diketones with metals has been known for a long time.[1] Kamimori *et al.*[2,3] examined the reaction of β-diketones, mainly of acetylacetone, with several metals and compared their reactivity. Sievers *et al.*[4–6] applied the direct reaction of fluoro derivatives of β-diketones with many metals and the resultant formation of complexes to the analysis of metallic elements by gas chromatography. We previously confirmed the formation of metal(II) dialkyldithiocarbamate complexes [$M(R_2NCS_2)_2$] when TRTD was injected into gas chromatographic columns containing metal powder.[7] This fact suggested that metal powders and TRTD might react with each other, even in solution. Contrary to this expectation, no complex-forming reactions occurred at all. However, it is found that copper powder reacts with TRTD under irradiation by light. Hence the complex-forming reactions were run under irradiation with a mercury-arc lamp set at a constant distance. Then, the decreasing quantity of TRTD and the quantity of copper complexes formed were measured by means of liquid chromatography and ultraviolet spectroscopy, and the effect of alkyl substituents (R) of TRTD on their reactivity was examined. The reaction of copper powder with tetrabutylthiuram disulphide [$(Bu_2NCS_2)_2$, TBTD], was satisfactorily applied to the quantitative analysis of copper in copper powder, copper oxides, copper hydroxides and basic copper carbonates.

EXPERIMENTS AND RESULTS

(a) *Materials.* TRTD and $Cu(R_2NCS_2)_2$ were purified as previously reported.[7] The other materials were of analytical-reagent grade available in the market.

(b) *Apparatus.* A Shimadzu UV-240 spectrophotometer equipped with a thermoelectric cuvette temperature controller was used to record absorption spectra at 25 ± 0.5°C. HPLC was performed using a Shimadzu LC-4a HPLC system fitted with a variable-wavelength detector. The column was a stainless-steel tube (25 cm × 4.6 mm I.D.) packed with Zorbax ODS and was held at 20°C. A Toshiba mercury-arc lamp H-400-PL with a stabilizer was utilized to irradiate with light at a constant distance from the cuvette. A Yanagimoto CHN recorder (MT-Model 2) was used for elemental analyses, and a Nippon Jarrel–Ash A-8100 atomic absorption spectrophotometer for copper analysis. Each sample weight was measured with a Shiebel–Mettler ME-Model 22 balance.

[a] Titrating with 0.01-M EDTA solution.

(c) *Reaction between metallic powder and* TRTD. We found that the yield of copper complex formed by reaction of copper powder with a TRTD in chloroform varied considerably from day to day and was dependent upon positions where the reaction flask was set. These facts strongly suggest the participation of the light in the reaction. Moreover, no copper complex was formed at all when the flask was covered with aluminium foil to shield it from the light. The products formed were isolated by filtering the reacted solutions, and recrystallized from chloroform for elemental analyses. As shown in Table 1, the values found are in good agreement with the calculated ones as $Cu(R_2NCS_2)_2$; therefore, copper powder is considered to react with TRTD in chloroform to form $Cu(R_2NCS_2)_2$. On the other hand, iron, cobalt, and lead powders did not react with TRTD at all; neither did nickel nor zinc powders.

(d) *Calibration curves of* TRTD *and* $Cu(R_2NCS_2)_2$. The calibration curves were constructed by plotting the peak areas of TRTD or $Cu(R_2NCS_2)_2$ vs their concentrations in chloroform. In this chromatography, the column of ODS and both eluents of methanol– and acetonitrile–water mixtures were used. In the case of the methanol–water system, the satisfactory, good separation of TMTD and $Cu(Me_2NCS_2)_2$, or $Cu(Pr_2NCS_2)_2$ and $Cu(Bu_2NCS_2)_2$ could not be attained with isocratic elution. In the case of the acetonitrile–water (99:1) system, the calibration curves are straight lines passing through the origin. The correlation coefficients of TRTD and $Cu(R_2NCS_2)_2$ were more than 0.997. The flow rate of the eluents was 1.0 cm^3/min, and the wavelength utilized for detection was 290 nm. The spectrophotometric calibration curve for each $Cu(R_2NCS_2)_2$ was also a straight line passing through the origin.

(e) *Effect of alkyl substituents on reactivity.* The determination of the copper complexes produced was performed as follows. After the addition of each of 15, 30, 45 or 100 mg of copper powder to 3 cm^3 of 1.5×10^{-4} mol dm^{-3} TRTD which had been put in a 1.0 cm wide quartz cell for spectrophotometry, the changes of absorbance at 437 nm were measured with irradiation of light with a constant intensity to the cell in the thermostat. The amount of the copper complexes produced was also determined together with that of unreacted TRTD by withdrawing 1 μl of the reaction mixture with a microsyringe and by injecting it into the liquid chromatograph under the conditions as in (d). Figure 1 shows a typical example of the reaction behaviours of copper powder and

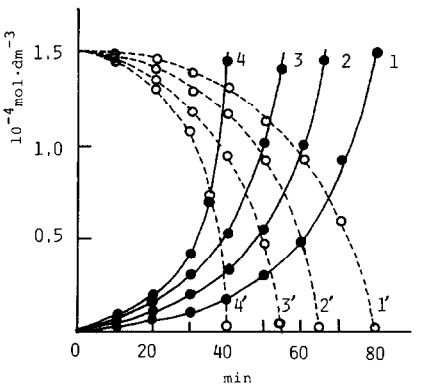

Fig. 1. Reaction behaviour between Cu and TETD. $Cu(Et_2NCS_2)_2$: —●——●—, TETD: --○---○--. 1, 15 mg; 2, 30 mg; 3, 40 mg; 4, 100 mg.

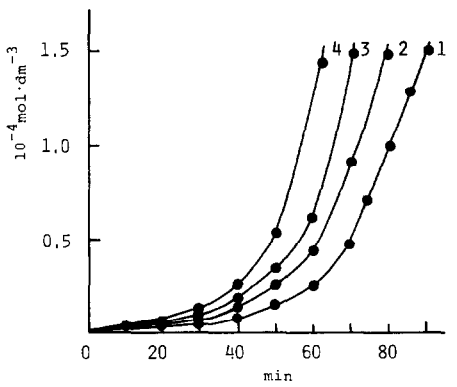

Fig. 2. Reaction behaviour between Cu (15 mg) and TRTD [$(R_2NCS_2)_2$]. 1, TMTD; 2, TETD; 3, TPTD; 4, TBTD.

TETD. The reaction rate is relatively slow at the beginning of the reaction, but rapidly increases as the time proceeds. As can be seen in Fig. 2, the relative reactivity of TRTD increases in the order of TBTD > TPTD > TETD > TMTD, and the amount of complex formed, of course, increases with increase of the quantity of copper powder added.

(f) *Application to the determination of copper.* By taking advantage of the selective photochemical reaction of TRTD with copper, an attempt was made to determine the copper content in the samples such as copper powder, copper oxides, copper hydroxides and basic copper carbonates. In a 30 cm^3 weighing bottle, 0.5–10 mg of each sample was weighed out accurately, and then TBTD two or three times by weight as much as each sample was added together with chloroform to the sample in the bottle. The mixture in the bottle was allowed to react for 1 hr under irradiation.

At the end of the reaction period, the reaction mixture was transferred into a 100 cm^3 measuring flask, and the flask was made up to the mark with chloroform. Further dilution with chloroform was performed, if necessary. The copper content of the reacted solution put in the 1.0 cm wide quartz cell was calculated from the following regression equation, the calibration curve of $Cu(Bu_2NCS_2)_2$:

$$C\,(10^{-4}\ \text{mol dm}^{-3}) = 0.9198 \times abs + 0.0018,$$

where C and abs are the concentration of $Cu(Bu_2NCS_2)_2$ and the absorbance, respectively. The results are given in Table 2. As can be seen in the table, the values obtained by the above-mentioned method agree well with those from atomic absorption spectrophotometry.

DISCUSSION

The elemental analyses (Table 1) for the reaction products of copper powder with TRTD are in good agreement with the ones calculated for $Cu(R_2NCS_2)_2$. It is, therefore, evident that copper powder reacts with TRTD under irradiation of light to form $Cu(R_2NCS_2)_2$. By the irradiation of the light, TRTD is presumed to become $R_2NCS_2\cdot$ which subsequently reacts selectively with copper. The relative reactivity of TRTD is in the order of TBTD > TPTD > TETD > TMTD. This is reasonably interpreted as follows. With an increase in R (butyl > propyl > ethyl > methyl) of TRTD, the electron-

Table 2. Analytical results of copper in practical samples

donating power of R increases. This results in the increase of electron density around the S atoms. The same tendency of relative reactivity is also observed in the reaction of copper powder with TRTD in the gas phase or in the reaction of metal powder with R_2NCS_2Na.

Table 2 shows that the coefficients of variation are less than 5.0%. It is apparent that good agreement is found between the spectrophotometric and atomic absorption spectrophotometric methods.

(*Received* 26 *October* 1984; *accepted* 6 *February* 1985)

Abstract—The crystal structures of diaquabis[(phenylsulfinyl)acetato]bis(pyridine)-copper(II), (**1**), and bis[(benzylthio)acetato]bis(pyridine)copper(II) (**2**) have been determined using X-ray diffraction. In (**1**), the copper atom is at the centre of a distorted octahedron with the equatorial sites occupied in a *trans* configuration by two unidentate (phenylsulfinyl)acetate oxygens [Cu–O, 1.97(2), 2.01(2) Å] and two pyridine nitrogens [Cu–N, 1.99(2), 2.05(2) Å] with water molecules completing the polyhedron [Cu–O, 2.51(2), 2.58(2) Å]. The copper atom in (**2**) is at the inversion centre of a distorted octahedron having in the equatorial sites, *trans*-related pyridine nitrogens [Cu–N, 1.993(3) Å] and four oxygens from two asymmetric bidentate (benzylthio)acetate ligands [Cu–O, 2.012(3), 2.510(5) Å].

In a survey of the crystal structures of metal–(phenylthio)alkanoic acid complexes determined so far, all the copper(II) complexes have been tetracarboxylate bridged dimers of the copper acetate type.[1–3] This paper reports two examples of other stereochemistries for copper(II). The compounds studied are diaquabis[(phenylsulfinyl)-acetato]bis(pyridine)copper(II),

$$[Cu(PSA)_2(py)_2(H_2O)_2], \text{ (1)}$$

and bis[(benzylthio)acetato]bis(pyridine)copper(II), $[Cu(BTA)_2(py)_2]$, (**2**).

EXPERIMENTAL

a. *Preparation of complexes*

(**1**) and (**2**) were prepared by reacting an ethanolic solution of (phenylsulfinyl)acetic acid, PSAH, or (benzylthio)acetic acid, BTAH, respectively and pyridine with excess copper(II) carbonate as previously described.[4] (**1**) crystallised as light blue prisms, elongated along the *b* axis, m.p. 125.7°C. Crystals of (**2**) were deep purple in colour and formed diamond shaped plates which decomposed on melting at 125.1°C.

(1) and (2) are given in Table 1. For (1), systematic absences (*h*0*l* absent for $l = 2n+1$) suggested either *C*2/*c* or *Cc*, while a statistical analysis of intensities indicated a noncentrosymmetric space group $[(E^2-1) = 0.64]$. The copper atom was located from the Patterson synthesis but the subsequent model obtained using the heavy atom method failed to reduce *R* below 0.22 (*C*2/*c*, with all non-hydrogen atoms anisotropic) or 0.23 (*Cc*, isotropic atoms). Using the *C*2/*c* model in the space group *C*2, the remaining atoms related by a pseudo centre of symmetry at 0, 0, $\frac{1}{4}$ were located by difference methods. The atomic positions were refined by blocked-matrix least-squares with anisotropic thermal parameters for only the copper, sulphurs, the thiophinyl oxygens and the atoms of the coordination sphere. The pseudo symmetry means that positions *x*, *y*, *z* and $-x$, $-y$, $\frac{1}{2}-z$ are related. The two-fold axis generates $-x$, *y*, $-z$ and *x*, $-y$, $\frac{1}{2}+z$. Thus there is a pseudo *c* glide operation (*h*0*l*, $l = 2n+1$ weak or absent). Structure factor calculations for these odd reflections gave amplitudes which could be considered close to background.

For (2), with $Z = 1$ in a triclinic space group, the copper atom was placed at the origin and initially gave $R = 0.53$. The weighted difference-Fourier gave the remainder of the non-hydrogen atoms. Blocked-matrix least-squares refinement was used with anisotropic thermal parameters for all non-hydrogen atoms. For both complexes, hydrogen atoms were located in difference-Fourier syntheses and included in the refinements at fixed positions with the isotropic *U* values also fixed (0.05 Å^2). Program systems used were SHELX 76,[5] PLUTO[6] and APPLECRYST 83.[7]

Neutral atom scattering factors were used and Cu and S were corrected for anomalous dispersion. Atomic coordinates, thermal parameters, observed and calculated structure factors and intra-ligand

bond distances and angles have been deposited with the Editor as supplementary material; copies are available on request from the Editor or the Authors. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre. Bond distances and angles about the coordination polyhedrons for both compounds are given in Table 2.

DISCUSSION

$[Cu(PSA)_2(py)_2(H_2O)_2]$, (1) (Fig. 1), is an example of a copper(II) complex in which the metal is at the centre of a distorted octahedron, with the equatorial sites occupied in a *trans* configuration by two unidentate PSA ligands bonding through carboxyl oxygens [Cu–O, 1.97(2), 2.01(2) Å] and two pyridines [Cu–N, 1.99(2), 2.05(2) Å]. Water molecules complete the octahedron [Cu–Ow, 2.51(2), 2.58(3) Å]. One half of the molecule is related to the other half by a pseudo centre of inversion at 0, 0, $\frac{1}{4}$. The difference between comparable atoms ranges up to 0.35 Å in x for C(4), and 0.23 Å in y for the acetate and pyridine atoms. The structure of the deep green coloured complex, diaquabis[ethylthio)-acetato]-copper(II) has ligands similar to (1), bonded through unidentate carboxylate oxygens [Cu–O, 1.916(2) Å]. However, the complex is centrosymmetric with each ligand forming a five-membered chelate ring through the sulphur atom [Cu–S, 2.381(1) Å], with the distorted octahedron completed by two water molecules [Cu–O, 2.457(1) Å].

Leiserowitz *et al.* have determined the structures for acids similar to PSAH, (1-naphthylsulfinyl)acetic acid,[10] and (4-chlorophenylsulfinyl)acetic acid.[11] Unlike most carboxylic acids which form cyclic

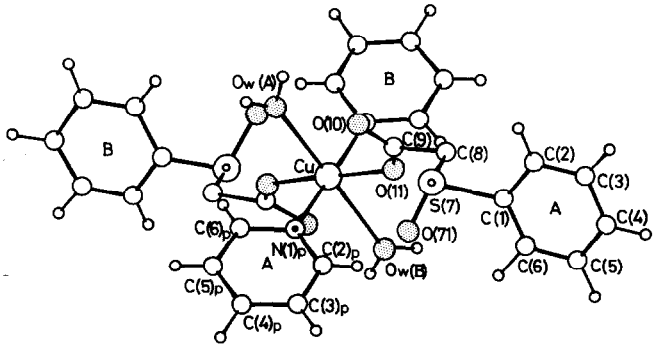

Fig. 1. Molecular configuration and atom naming scheme for $[Cu(PSA)_2(py)_2(H_2O)_2]$ (1). Ligands A and B and related by pseudo inversion symmetry.

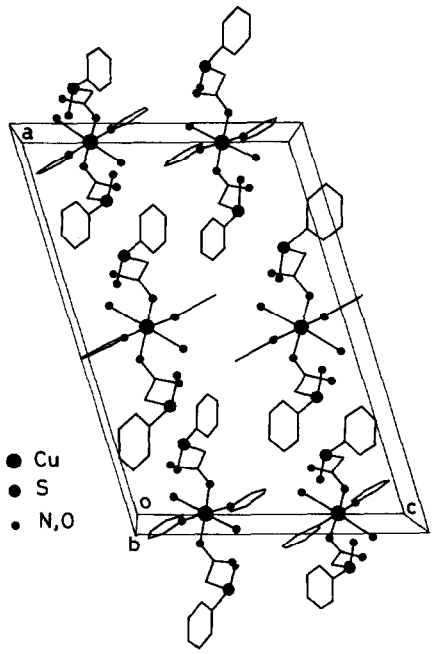

Fig. 2. The packing of (**1**) in the unit cell viewed down the *b* axis.

hydrogen-bonded dimers,[12] these compounds have extended hydrogen bonded arrays formed through single OH···O=S bonds [2.58 Å,[10] 2.64 Å[11]]. In (**1**), the sulfinyl oxygen is hydrogen bonded to waters from a neighbouring complex molecule [O(71)···Ow, 2.59(1), 2.88(1) Å for ligands A and B respectively]. In (**1**), the sulfinyl oxygen is hydrogen bonded to waters from neighbouring molecules [O(71)···Ow, 2.59(1), 2.88(1) Å for ligands A and B respectively]. These are the only significant intermolecular interactions involved in the packing of the complex in the unit cell (Fig. 2). Within the complex, stability is enhanced by the presence of hydrogen bonding contacts between the waters and the uncoordinated carboxyl oxygens [2.72(1), 2.67(1) Å for A and B respectively]. In addition, the presence of the tetrahedral sulfinyl oxygen significantly changes the stereochemistry of the side chain compared to (phenylthio)acetic acid (PTAH),[13] [C(2)–C(1)–S(7)–C(8): (**1**), −99, +93°; PTAH, −170°, C(1)–S(7)–C(8)–C(9): (**1**), −174, +165°; PTAH, +177°. S(7)−C(8)−C(9)−O(10): (**1**), −41, +56°; PTAH, −4°].

The copper atom in (**2**) is at a centre of symmetry, and has a distorted octahedral ($CuN_2O_2+O_2$) coordination (Fig. 3). This is made up of two nitrogen atoms from *trans* pyridines [Cu–N, 1.993(3) Å] and two oxygens from BTAH ligands [Cu–O(10), 2.012(3) Å] in the equatorial plane. The six-coordination is completed by the BTAH carboxyl group behaving as an asymmetric bidentate ligand [Cu–O(11), 2.510(5) Å]. There are a number of other examples in which bidentate carboxylate groups form four-membered chelate rings with the same copper atom. These may be categorized according to the coordination number of the copper atom.

a. *Five-coordinate*

$CuN_2O_2+O^*$. In green-blue (*o*-phthalato)bis (pyridine)copper(II), Cingi *et al.*[14] describe the metal coordination as square pyramidal for both of the two independent molecules. The square base comprises a pyridine nitrogen, [Cu–N, 2.028(5), 2.015(5) Å], two oxygens from the bidentate carboxylate group, [Cu–O, 1.954(5), 2.285(4) and 1.967(5), 2.316(4) Å], and an oxygen from a

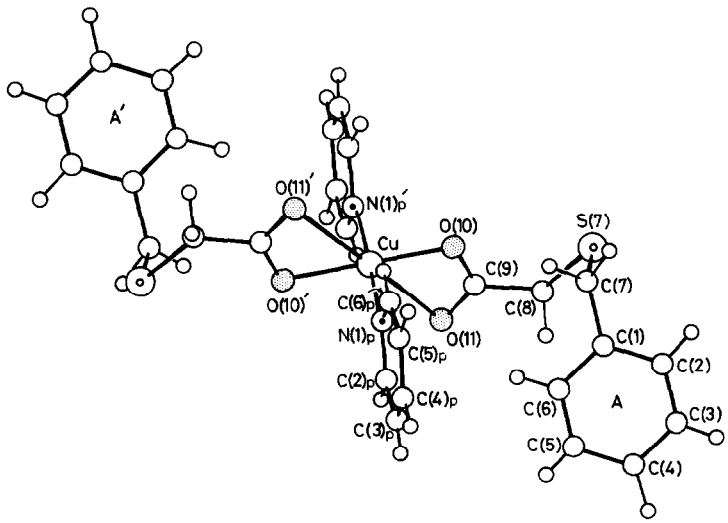

Fig. 3. Molecular configuration and atom naming scheme for $[Cu(BTA)_2(py)_2]$, (**2**). Primed atoms are related by inversion symmetry.

unidentate carboxylate group [Cu–O, 1.921(4), 1.922(4) Å]. The other nitrogens, in the apical positions, and coppers, are at 2.428, 0.265 and 2.442, 0.343 Å respectively above the square plane.

b. *Six-coordinate*

(i) CuN_4O+O^*. These are essentially five-coordinate with the second oxygen at a considerable distance from the metal. Typical examples belong to the [CuX_2(acetate)] Y series, where X = bipyridine, Y = ClO_4^-;[15] X = phenanthroline, Y = ClO_4^-;[16] and X = phenanthroline, Y = BF_4^-.[16,17]

(ii) $CuN_2O_2+O^*N^*$. Violet bis[(isopropylthio)-acetato]tris(isoquinoline)copper(II)[22] has tetragonally distorted octahedral coordination for the metal atom with *trans*-related oxygens from the two acetate groups and two isoquinoline nitrogens forming the square plane. The other two carboxylate oxygens are 2.642(10) Å and 3.282(10) Å from the metal while the third isoquinoline nitrogen is at 2.359(11) Å. Although this was considered "potentially hepta-coordinated", it is being classified in this discussion as six-coordinate.

(iii) $CuN_2O_2+O^*O^*$. Complex (**2**), which is deep purple in colour, represents one of the few examples in this category. Ogawa *et al.*[9] claim that colour in such complexes is possibly due to a charge transfer band caused by the presence of the strong Cu–S bond, while Bonomo[21] attributes the coordination between copper and sulphur to both electronic and steric effects. Cu–S bonding [2.697(1) Å] occurs in blue [aqua(2,2′-bipyridine)(thiodiacetato)-copper(II)] tetrahydrate and deep green diaquabis-[(ethylthio)acetato]copper(II) [2.381(1) Å][22] but no bonds are found in bright green [(2,2′,6′,2″-terpyridine)(thiodiacetato)copper(II)]. Similarly, compound (**2**) (purple) has no bonds involving the sulphur atom, nor do any other examples of the copper(II) (phenylthio)acetate complexes investigated to date.[1–3] Only with the cadmium complex, *catena*-aquabis[(phenylthio)acetato)]cadmium(II)[13] is a M–S bond found but this involves only one ligand [Cd–S, 2.738(5) Å]. In comparable copper(II) phenoxyalkanoate complexes, there are a number of examples involving copper-O(ether) links, e.g. [Cu(*p*-X-phenoxyacetate)$_2$(H_2O)$_n$], where $n = 0$, X = H;[18] $n = 2$, X = H;[19] $n = 2$, X = Cl;[4] $n = 2$, X = F;[23] $n = 2$, X = CH_3O;[20] $n = 2$, X = NO_2.[20] With the exception of the anhydrous complex,[18] which is a hexamer, these compounds are tetragonally distorted octahedral monomers with the axial positions invariably occupied by ether oxygens.

There are no significant intermolecular distances for (**2**), the molecules packing as unassociated monomers in the unit cell (Fig. 4). The additional carbon atom in the side chain compared to (phenylthio)acetic acid prevents the benzene ring from influencing significantly the metal stereochemistry.

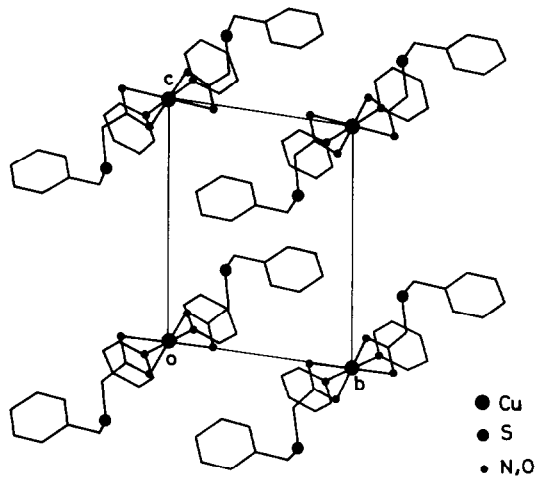

Fig. 4. The packing of (**2**) in the unit cell viewed down the *a* axis.

POTASSIUM TRIFLUOROPEROXOTITANATE(IV) TRIHYDRATE, $K[Ti(O_2)F_3]\cdot 3H_2O$

M. K. CHAUDHURI* and B. DAS
Department of Chemistry, North-Eastern Hill University, Shillong 793003, India

(*Received* 24 *September* 1984; *accepted after revision* 6 *February* 1985)

Abstract—Potassium trifluoroperoxotitanate(IV) trihydrate, $K[Ti(O_2)F_3]\cdot 3H_2O$, with the peroxide (O_2^{2-}) being bonded to the Ti(IV) centre in a triangular bidentate manner (C_{2v}) as evidenced from the IR and laser Raman spectroscopic studies, has been synthesised from the reaction of a solution of TiO_2 in 40% HF with an excess of 30% H_2O_2 and KOH, followed by the addition of aqueous HF to adjust the pH of the reaction solution between 8 and 9.

It has been known that Ti(IV) produces a characteristic colour reaction, with H_2O_2, which is used for the detection of either reagent.[1] Some solid peroxotitanate complexes have been reported, however, there is little agreement over their composition let alone their structure.[1,2] Pentafluoroperoxotitanate(IV) complex, $[Ti(O_2)F_5]^{3-}$, is rather well studied, and constitutes the only example of fluoroperoxotitanate(IV) known to date. Reported herein are the synthesis and assessment of molecular structure by IR and laser Raman spectroscopic studies of a new fluoroperoxotitanate(IV), potassium trifluoroperoxotitanate(IV) trihydrate, $K[Ti(O_2)F_3]\cdot 3H_2O$.

EXPERIMENTAL

The chemicals used were all reagent grade products. IR spectra were recorded on a Perkin–Elmer Model 983 spectrophotometer. The laser Raman (LR) spectra were recorded on a SPEX Ramalog Model 1403 spectrometer. The 4880 Å laser line from the Spectra-Physics Model 165 Argon laser was used as the excitation source. The scattered light at 90° was detected with the help of a cooled RCA 31034 photomultiplier tube followed by photon counting processsing system. The spectra were recorded at ambient temperatures by making a freshly prepared solution of the sample, or a pressed pellet of the compound. Molar conductance was measured using a Philips PR9500 conductivity bridge. The pH of the reaction solution was measured with a Systronic Type 335 digital pH meter, and also with pH indicator (BDH) paper. Magnetic susceptibility was measured by the Gouy method, using $Hg[Co(NCS)_4]$ as the calibrant.

Synthesis of potassium trifluoroperoxotitanate(IV) trihydrate, $K[Ti(O_2)F_3]\cdot 3H_2O$. An amount of 1.0 g (12.5 mmol) of TiO_2 was dissolved in 10 cm^3 (200 mmol) of 40% HF by heating for *ca* 10 min over a steam-bath. The clear solution was cooled to 20°C, and 20 cm^3 (176.4 mmol) of 30% H_2O_2 was added under stirring, followed by the addition of 17.5 g (311.9 mmol) of powdered potassium hydroxide. The colourless solution thus obtained was maintained at *ca* 20°C for 15 min. Dropwise addition of 40% HF to the solution, until the pH of the medium was reduced to 8–9, changed colour of the reaction solution to yellow and afforded yellow microcrystalline potassium trifluoroperoxotitanate(IV) trihydrate, $K[Ti(O_2)F_3]\cdot 3H_2O$. Addition of hydrofluoric acid was stopped at this stage and the product was isolated by centrifugation, washed 3–4 times with ethanol, and finally dried *in vacuo* over concentrated sulphuric acid. Yield of $K[Ti(O_2)F_3]\cdot 3H_2O$ was 2 g (69%).

Elemental analysis. Peroxide, fluoride and potassium were estimated by the methods described in earlier papers.[3] Titanium content in the compound was determined gravimetrically by estimating as TiO_2, after precipitation with cupferron.[4] Found: K, 17.3; Ti, 20.45; O_2^{2-} (active oxygen), 14.2; F, 24.3%. Calc. for $K[Ti(O_2)F_3]\cdot 3H_2O$: K, 17.0; Ti, 20.82; O_2^{2-} (active oxygen), 13.91; F, 24.78%.

RESULTS AND DISCUSSION

The pentafluoroperoxotitanate(IV), $[Ti(O_2)F_5]^{3-}$, was synthesised from the reaction of TiF_6^{2-} with

* Author to whom correspondence should be addressed.

H_2O_2. It was expected, however, that a viable synthesis of fluoroperoxotitanates(IV) may be possible from TiO_2 under suitable conditions. In view of this and also considering the importance of pH in the syntheses of peroxometalates,[3,5] the reaction of a solution of TiO_2 in 40% HF with hydrogen peroxide and KOH was conducted followed by adjusting the pH of the reaction medium between 8 and 9 by the addition of 40% HF. This has led to the successful synthesis of potassium trifluoroperoxotitanate(IV) trihydrate,

$$K[Ti(O_2)F_3]\cdot 3H_2O,$$

in a high yield. It is believed that TiO_2 dissolves in 40% HF producing fluorotitanate(IV) in solution which subsequently undergoes peroxygenation in the presence of H_2O_2 and KOH ultimately leading to the synthesis of the complex $[Ti(O_2)F_3]^-$ ion at a pH 8–9. Further lowering of pH to 6 by the addition of 40% HF produced the already known complex $K_3[Ti(O_2)F_5]$.[6,7]

Potassium trifluoroperoxotitanate(IV) trihydrate, $K[Ti(O_2)F_3]\cdot 3H_2O$, is stable in the absence of moisture, and in water it decomposes slowly as evident from the comparatively higher molar conductance at room temperature. The results of a magnetic susceptibility measurement show that the compound is diamagnetic suggesting the occurrence of titanium(IV). Estimation of peroxide, accomplished by red-ox titrations separately involving standard potassium permanganate and Ce^{4+} solutions, conspicuously suggested the presence of one O_2^{2-} per titanium atom in the compound.

The IR spectrum of the compound showed bands at 900vs and 860s cm^{-1}, at 610s cm^{-1}, at 535s cm^{-1}, at 440 m and 310 cm^{-1}, while the laser Raman spectra, recorded in the solid state as well in a solution, were similar exhibiting peaks at 900 and 860 cm^{-1}, at 610 cm^{-1}, at 530 cm^{-1} and at 285 cm^{-1}. The peaks, at 900 and 860 cm^{-1} assigned to ν_{-O-O-} (ν_1), at *ca* 530 cm^{-1} to ν_{Ti-O_2} (ν_2), at 610 cm^{-1} to ν_{Ti-O_2} (ν_3), and at *ca* 300 cm^{-1} to δ_{Ti-F}, are in order and well precedented in the literature.[3,5–7] The additional bands in the IR spectrum are assigned to ν_{Ti-F} (440 cm^{-1}), ν_{O-H} (3450 cm^{-1}), and δ_{H-O-H} (1640 cm^{-1}) modes respectively of un-coordinated water.[8–10] The fact that the ν_{-O-O-} (ν_1) and the complementary ν_{Ti-O_2} (ν_2 and ν_3) modes in the IR and LR spectra were observed in the positions stipulated for a triangularly bonded peroxide, renders it certain that the peroxide (O_2^{2-}) is bonded to the Ti(IV) centre in a triangular bidentate (C_{2v}) manner.

Thus, it may be inferred that potassium trifluoroperoxotitanate(IV) trihydrate,

$$K[Ti(O_2)F_3]\cdot 3H_2O,$$

with the peroxide ligand being bonded to the metal in a triangular bidentate fashion, can be synthesised directly from TiO_2. The complex $[Ti(O_2)F_3]^-$ may be a penta-coordinated monomer; however, it is more likely that it has an octahedral or a distorted octahedral structure through –Ti–F–Ti– interactions.

THE EFFECT OF LIGAND DONOR ATOMS ON TERNARY COMPLEX STABILITY

C. R. KRISHNAMOORTHY,* S. SUNIL and K. RAMALINGAM
Department of Chemistry, Indian Institute of Technology, Madras 600036, India

(*Received* 26 *October* 1984; *accepted after revision* 6 *February* 1985)

Abstract—Formation constants of mixed ligand complexes of Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, and Mn^{2+}, with cytidine-5′-monophosphoric acid (CMP) and various primary ligands such as 1,10-phenanthroline (phen), glycylglycine (glygly) and salicylic acid (sal) have been determined in aqueous solution at 35°C and 0.1 M (KNO_3) by potentiometric measurements. The acid dissociation constants of all the above mentioned ligands together with their 1 : 1 binary metal complex formation constants were also measured at 35°C. In general all the 1 : 1 binary complexes follow the Irving–Williams order of stability. Further the binary metal complexes of primary ligands are more stable than their ternary complexes with CMP. For ternary complexes, $\Delta(\log K)$ values seem to change from positive to highly negative as the coordinating atoms of the primary ligands were varied from *N,N* to *N,O*$^-$ to *O*$^-$,*O*$^-$. The higher stability of ternary complexes involving phen is due to its Π-bonding interaction with the above metal ions and the relative decrease in the stability of other ternary systems is due to the coulombic repulsion of donor oxygen atoms of primary and secondary ligands. Thus for ternary complexes the stabilities follow a decreasing order of M–phen–CMP > M–glygly–CMP > M–sal–CMP.

Ternary complexes play a predominant role in many biological systems because of their involvement in enzyme–metal–substrate complexes and also due to their participation in the storage and transport of active substrates through membranes. Nucleotides and nucleosides are commonly used as ligands because many enzyme reactions need the presence of nucleotides like ATP, ADP, AMP, CMP, etc. In addition, metal ions seem to affect the structure of nucleic acids[1] *in vivo* and also the structure of nucleic acid–protein complexes.[1,2] Besides, specific interaction between nucleotides and amino acids must have been significant during the first steps of biochemical evolution.[3] Several reviews[2,4,5] have appeared on these lines. But most of them are confined to adenine nucleosides and nucleotides.[6–11] In the present study CMP is chosen as the secondary ligand because of the relatively fewer studies done on cytosine nucleosides in comparison to adenine nucleosides. Choice of phen, glygly and sal as primary ligands is because of their tendency to form stable metal complexes even in high acid medium and also to assess the influence of factors such as: (1) nature of coordinating atom; (2) steric factors; and (3) Π-bonding effects on the stabilities of these metal complexes. Moreover stabilities of the 1 : 1 binary complexes of the above mentioned primary ligands and metal ions are also determined for the sake of completion.

Thus the present investigation is the first attempt to study the formation of binary and ternary complexes of transition metal ions such as Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, and Mn^{2+} and the above mentioned primary and secondary ligands in aqueous solution.

EXPERIMENTAL

Reagents. Chromatographically pure samples of cytidine monophosphoric acid (CMP), 1,10-phenanthroline (S. Merck), glycylglycine (BDH) and salicylic acid (BDH) were employed in this study. For each measurement fresh solid ligand was weighed out to avoid possible photochemical decomposition or hydrolysis. The metal nitrates were analar grade samples (BDH), and stock solutions of these metal nitrates were estimated volumetrically by EDTA

titrations.[12] Carbonate free sodium hydroxide was prepared by known procedure and standardized by titration with pure potassium acid phthalate.

Procedure. Potentiometric titrations of various ligands (1.5×10^{-3} M) in the presence and absence of metal ions (1 : 1 ratio) were carried out with standard sodium hydroxide solution to calculate the disssociation constants of various ligands and the stability of their 1 : 1 binary metal complexes. The ionic strength of the solution was maintained at 0.1 M (KNO_3). A stream of nitrogen was passed throughout the course of the experiment to exclude the adverse effect of atmospheric carbon dioxide and the temperature was maintained at 35 ± 0.1°C. The reactants were equilibrated before commencing the titration and between each further addition of sodium hydroxide. The conditions used for the titration of ternary systems were the same as for binary ones (and for the determination of dissociation constants) but the solution contained both primary and secondary ligands and respective metal ions all in 1 : 1 ratio.

An Elico model LI-120 digital pH meter with a combined electrode was used to measure the hydrogen ion concentration. The electrode system was calibrated as previously described.[13]

Calculations. Acid dissociation constants of the ligands are calculated by a direct algebraic method.[14,15]

The stability of 1 : 1 binary complexes pertaining to equilibrium $M + A \rightleftharpoons MA$ was calculated by the method developed by Martell.[14] Stepwise formation of the ternary complex was assumed to take place as shown below and the respective formation constants were calculated by the method described earlier.[16]

$$MA + B \overset{K^{MA}_{MAB}}{\rightleftharpoons} MAB. \qquad (1)$$

The formation constants of 1 : 1 binary metal complexes of the secondary ligand (CMP) were calculated by the usual algebraic method corresponding to the following reaction, $M + B \rightleftharpoons MB$. The stability of the ternary complex characterized by its $\Delta(\log K)$ value can be defined by eqn (2).

$$\Delta(\log K) = \log K^{MA}_{MAB} - \log K^{M}_{MB}, \qquad (2)$$

where M = Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+} or Mn^{2+}; A = primary ligands such as phen, glygly or sal; B = secondary ligand, CMP. Charges on the complexes are omitted for simplicity. In the case of phen, sal and CMP the predominant equilibria involved in the binary complexation is $M + L \rightleftharpoons ML$, at the pH employed in our calculation. For glygly, the species M(H-1L) is excluded in our calculation for the sake of simplicity, and all other species such as M(H-1L)OH, $M(H\text{-}1L)(OH)_2$, ML_2, etc., are negligible in concentration at the pH employed in our calculations.

RESULTS AND DISCUSSION

Acid dissociation constants of both primary and secondary ligands calculated by a direct algebraic method are presented in Table 1. From the potentiometric titration curves shown (for Cu^{2+} alone) in Figs. 1–3, the stability of binary complexes were calculated assuming the equilibria indicated above and presented in Table 2. In all the cases the metal–ligand interaction was confirmed by checking the possibility of metal hydrolysis using titration procedure described earlier.[17,18] Stabilities of the ternary complexes were calculated in the region of titration curve, a = 3–4 based on the reaction shown above and the values are given in Table 3. So also $\Delta(\log K)$ values calculated from eqn (2) are presented in Table 4.

Proton ionization sites of primary ligands are assigned to the two ring nitrogen atoms in phen, COOH and NH_3^+ groups in glygly and carboxylate and phenolic oxygens in sal respectively. The corresponding dissociation constants presented in Table 1 are consistent with earlier published results.[19–21]

In the case of CMP the deprotonation takes place from N_3 and phosphatic oxygen respectively and

the corresponding dissociation constants reported agree well with the previous studies.[20] Stability of all binary metal complexes follow the Irving–Williams order and also agree well with earlier studies.[19–23] The enhanced stabilities of all the primary ligand–metal complexes are due to the chelate forming

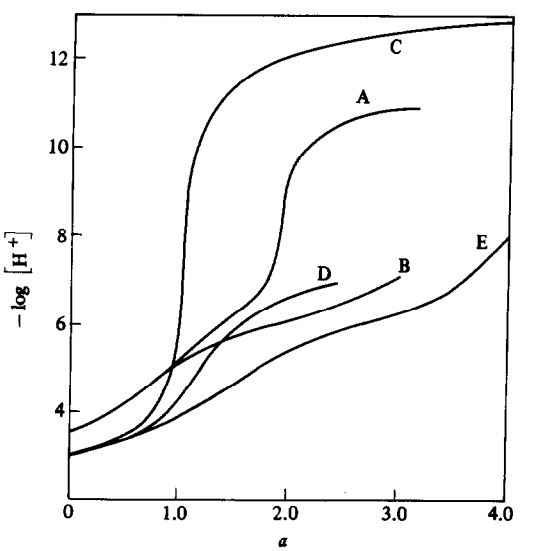

Fig. 3. Potentiometric titration curves of 1 : 1 binary and 1 : 1 : 1 ternary complexes involving Cu^{2+}, salicylic acid and cytidine-5-monophosphoric acid (CMP). A = CMP; B = 1 : 1 Cu^{2+}–CMP; C = salicylic acid; D = 1 : 1 Cu^{2+}–salicylic acid; E = 1 : 1 : 1 Cu^{2+}–salicylic acid–CMP; a = moles of base added per mole of ligand; t = 35°C; μ = 0.1 M (KNO_3).

tendency of these primary ligands using their donor atoms. For glycylglycine the presence of metal ion induces the deprotonation of the amide group proton. This makes the ionised amide nitrogen more basic than the amide oxygen and thereby metal chelation in glycylglycine occurs via aminonitrogen, deprotonated amide nitrogen and carboxylate oxygen.[24]

There are conflicting statements in literature about the metal ion binding sites in CMP especially in regard to the base nitrogen. Studies with Ni^{2+}, Mn^{2+}, and Mg^{2+} using magnetic resonance techniques have shown that there is a very weak interaction with the cytosine ring.[25] So also in other nucleotide–metal systems, the evidence for metal binding through the pyrimidine ring, apart from the phosphatic oxygen is indicated.[26] The relatively higher stabilities of Cu^{2+} and Co^{2+} complexes of CMP may be due to the simultaneous binding of cytosine ring nitrogen and phosphate oxygen to the metal ions.

In the case of ternary complexes the stabilities decrease in the order M–phen–CMP > M–glygly–CMP > M–sal–CMP. The $\Delta(\log K)$ values given in Table 4 show that in general the change is from positive to weakly negative to highly negative when the primary ligand is varied from phen, glygly to sal. This effect in turn is due to the change in the coordinating atoms from N,N to N,O^- and O^-,O^- respectively in these ligands.

Thus M–phen–CMP systems uniformly show positive $\Delta(\log K)$ in all the cases and this is expected when the primary ligand is an aromatic amine like phen or bipyridyl and the secondary ligand is a potential oxygen donor.[27] This is due to the back-donation from the metal d orbital into vacant Π-orbital of the aromatic amine and when the secondary ligand has oxygen donor that will neutralize the charge on the central atom resulting in the enhancement of the stability of the ternary complexes. This increased stability of the ternary complexes can also be explained in another way, namely, that the aromatic amine and transition metal ions are borderline cases according to Pearson HSAB principle and the drain of electron from metal to aromatic amine ligands increases the effective nuclear charge on the central metal ion thereby making it harder. This enables the metal ions to have a selective interaction with harder oxygen ligands.[28]

Except in the case of Cu^{2+}, the ternary systems of M–glygly–CMP have weakly negative $\Delta(\log K)$ values, which is due to the change of ligand donors to N,O^- in glygly. Similar observations were noticed for other ternary systems of glygly.[29] The positive $\Delta(\log K)$ value for Cu–glygly–CMP may be due to the fact that Cu^{2+} can also bind to N_3 of cystosine

ring and thus form stable square planar ternary chelate with glygly. This might also account for the weakly negative values for Ni^{2+} and Zn^{2+} which can form similar stable square planar and tetrahedral complexes respectively.

The literature information available is scanty regarding the ternary metal complexes involving phenolic acids as primary ligands and biologically significant ligands such as nucleotides as secondary ligands. Hence, it is of interest to examine the effect of these primary ligands on the interaction of nucleotides with metal ions, as some of these phenolic compounds are known to occur in biological systems.

In the present study it is noticed that there is very little interaction for CMP with metal ions already bound to salicylic acid as compared to its interaction with free (hydrated) metal ions. In fact the ternary systems of M–sal–CMP show large negative $\Delta(\log K)$ values in all the cases. This is because of the very high stability of the binary metal–sal complexes due to chelation and conjugation effects which detract from its tendency to interact further. Another reason could be due to the increased coulombic repulsion between the donor oxygen atoms of sal and CMP resulting in the destabilization of their ternary complexes. The situation in which sal acts as primary ligand the electronic repulsion is maximum from its two donor oxygen atoms with that of the oxygen atoms of CMP. Thereby the stability of their ternary complex will be much less with $\Delta(\log K)$ being most negative. However, glygly has only one such donor oxygen carrying a lone pair of electrons and their ternary complexes will be more stable [$\Delta(\log K)$ small and negative]. Whereas phen has no such coulombic repulsion and the greater stability of its ternary systems are shown by its large positive value for $\Delta(\log K)$. These marked differences in the stability of the ternary metal complexes could be directly related to the nature of primary ligands with varying donor atoms such as N,N, N,O^- and O^-,O^- in phen, glygly and sal respectively. This discriminating behavior of M–CMP complexes towards other ligands will have a significant role in many biological systems.

CONCLUSION

Thus as the donor atoms in the primary ligands are changed from N,N to N,O^- to O^-,O^- the stability of their corresponding ternary complexes show a drastic decrease. The added stability in the case of ternary complexes involving aromatic N,N donor ligands is due to Π-interaction with the central metal ion. The least stability seen in the ternary systems with O^-,O^- donor ligands is due to the coulombic repulsion of highly charged oxygen ions coming together to coordinate with the central metal ion thus leading to repulsion. Hence apart from Π-backbonding and chelation the nature of coordinating atoms of the primary ligands also influence the stabilities of the ternary systems. Since the stability of ternary complex is one of the major factors deciding its concentration in biological systems, the above discrimination of metal–CMP and similar systems towards primary ligands with varying donor atoms such as N,N, N,O^- and O^-,O^- will be helpful to have selectivity of carrier bases in biological systems. Besides this will help in designing suitable model systems for various reactions involving metalloenzymes. Further study on similar systems is in progress in our laboratory.

MIXED-VALENCE ELECTRON DELOCALIZED THIOCYANATO BRIDGED RUTHENIUM DINUCLEAR COMPLEX $[\{Ru(NH_3)_5\}_2SCN]^{4+}$

V. PALANIAPPAN, S. K. S. YADAV* and U. C. AGARWALA†
Department of Chemistry, Indian Institute of Technology, Kanpur 208 016, India

(*Received* 16 *October* 1984; *accepted after revision* 6 *February* 1985)

Abstract—The thiocyanato bridged mixed-valence ruthenium dinuclear species $[\{Ru(NH_3)_5\}_2SCN]^{4+}$ has been prepared and characterized. A solvent independent, low intensity intervalence transfer band was observed in the near IR absorption spectrum suggesting a delocalized limit in the [Ru(II)–SCN–Ru(III)] unit.

The syntheses of ligand bridged mixed-valence dinuclear complexes of transition metals have stimulated a great deal of interest[1–7] in the process of electron exchange in binuclear redox reactions and in getting information about the character of electron transmission through chemical systems. There also exists a possibility of thiocyanate ion acting as a bridging ligand in such systems. In this paper we would like to communicate the synthesis and characterization of a thiocyanato bridged mixed-valence ruthenium ammine complex and the behaviour of the intervalence transfer (IT) absorption band in the near IR region in different solvents.

EXPERIMENTAL

[A] *Chemicals*

All the chemicals used were of chemically pure or of Analar grade. $[Ru(NH_3)_5N_2]Br_2$ and $[Ru(NH_3)_5SCN]X_2$ (X = Br, ClO_4) were prepared by known procedures.[8,9] The purities of $[Ru(NH_3)_5SCN]X_2$ were confirmed by passing them through a Sephadex G-10 column (25 × 1 cm) and eluting with 10^{-4} M HBr or $HClO_4$.[10]

[B] *Preparation of complexes*

[B.1] *Preparation of* $[\{Ru(NH_3)_5\}_2SCN]Br_4$. Aqueous solutions of stoichiometric amounts of $[Ru(NH_3)_5N_2]Br_2$ and $[Ru(NH_3)_5SCN]Br_2$ (2×10^{-4} mole in 10 cm^3 each) were mixed. The resulting solution was stirred for about 14–15 hr at room temperature (~ 37°C), whereby the colour of the solution turned from red to reddish-yellow. It was centrifuged and a few cm^3 of conc. HBr was added to the centrifugate to precipitate a reddish-brown compound. It was filtered, washed with ethanol and ether and dried under vacuum; It was analysed for $[Ru_2(NH_3)_{10}SCN]Br_4$ (yield 60–70%).

Found: C, 1.8; H, 4.4; N, 20.2; S_{tot}, 4.7; S_{cat}, 4.3; Br_{tot}, 42.8; Br_{ion}, 42.5.

Calc.: C, 1.6; H, 4.0; N, 20.5; S_{tot}, 4.2; S_{cat}, 4.2; $Br_{tot} = Br_{ion}$, 42.6%.

[B.2] *Preparation of* $[\{Ru(NH_3)_5\}_2SCN](ClO_4)_4$. The procedure for the synthesis of the complex was the same as that described in B.1 except that (i) $[Ru(NH_3)_5SCN](ClO_4)_2$ was used in place of $[Ru(NH_3)_5SCN]Br_2$ and (ii) conc. $HClO_4$ was used to precipitate the reddish-violet perchlorate salt. The reddish-violet compound was analysed for $[Ru_2(NH_3)_{10}SCN](ClO_4)_4$ (yield 60–70%).

Found: C, 1.6; H, 3.4; N, 18.8; S_{tot}, 4.2; S_{cat}, 4.0; Cl_{tot}, 17.6; $ClO_{4\,ion}$, 49.0.

Calc.: C, 1.4; H, 3.6; N, 18.5; S_{tot}, 3.8; S_{cat}, 3.8; Cl_{tot}, 17.1; $ClO_{4\,ion}$, 48.1%.

[C] *Physico-chemical measurements*

Carbon, hydrogen and nitrogen present in the samples were analysed by the Microanalytical Laboratory, I.I.T., Kanpur (India). Analytical methods of sulphur (total and cationic) and bromide/chloride (total and ionic) were given

* Present address: Chemist, Thapar Research Group, Karwar, India.

elsewhere.[10] Spectra were obtained using the following intruments: IR; Perkin–Elmer model-521 IR Diffraction Grating Spectrophotometer; UV and Visible, Beckmann DB, UV and Visible Recording Spectrophotometer; near IR, Cary 17 model spectrophotometer using 1 cm matched quartz cells. The apparatus used for cyclic voltammetric studies was assembled in our laboratory using a triangular wavefunction generator potentiostat having three electrode operational amplifier assembly. All the measurements were made on platinum electrodes in the range of 0–0.9 V using KCl as supporting electrolyte. The values are with respect to saturated calomel electrode and are uncorrected for junction potentials.

RESULTS AND DISCUSSION

The analyses of both the complexes indicate that only one SCN group per two ruthenium atoms is present in the cation. Since NH_3 cannot form a bridge between two $[Ru(NH_3)_5]$ units, the only possibility is that the thiocyanate group must be the bridging ligand and is proved by the following studies.

Conductance measurements

Extensive conductance measurements at different concentrations were carried out to establish the charge type on the water soluble complex $[\{Ru(NH_3)_5\}_2SCN]Br_4$. Equivalent conductance vs $\sqrt{C_{eq}}$ graphs were plotted. Equivalent concentration (C_{eq}) of the species was calculated by the method suggested by Feltham *et al.*[11] Conductance at infinite dilution, λ_0, was determined from the plots by extrapolation from which the molar conductance value was found to be 423 Ω^{-1} cm^2 M^{-1} and that of λ_0, 232 Ω^{-1} cm^2 eq.$^{-1}$ Plots of $(\lambda_0 - \lambda_e)$ vs $\sqrt{C}_{eq}$ (cf. Onsager equation) were made and the slope of the straight line was found to be 1200, a value which was quite comparable to those reported for +4 charged species[11] (Fig. 1).

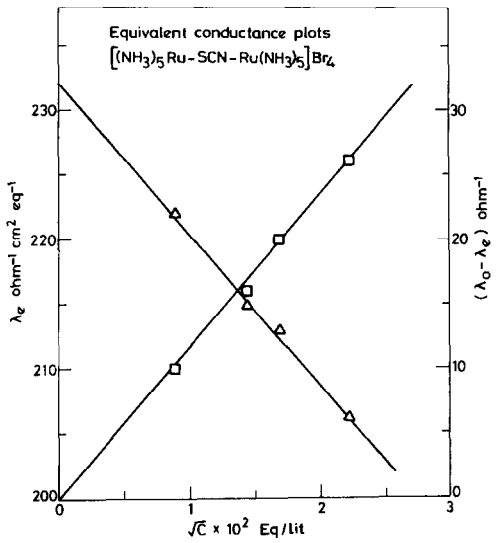

Fig. 1. Equivalent conductance plots.

Magnetic measurements

At room temperature, the dimer exhibited a μ_{eff} of 1.1 BM per ruthenium atom, which suggests the presence of one unpaired electron in the system. The fact that the two ruthenium sites are in different oxidation states, viz. +2 and +3, is also obvious.

IR spectroscopy

The IR spectra of the dimer $[\{Ru(NH_3)_5\}_2SCN]^{4+}$ is similar to the one of $[Ru(NH_3)_5SCN]^{2+}$ reported earlier,[10,12] except for a small shift in the position of the band due to ν(CN). A broad, intense band due to ν(CN) of the dimer was observed at 2060 cm^{-1} with a shoulder at 2090 cm^{-1}; the monomer exhibited the ν(CN) band at 2073 cm^{-1}.[12] The broadness of the band ($\Delta\nu_{1/2}$ = 120 cm^{-1}) suggests the presence of a bridging thiocyanato group.[13,14] Besides, all the characteristic bands of the coordinated NH_3 were observed around 3400(w), 3200, 1600, 1300, 800 and 450 cm^{-1}. The masking of the relatively weak band due to ν(CS) of SCN in the region 820–750 cm^{-1} by the broad and moderately intense band due to the rocking mode of the NH_3 around 800 cm^{-1} left some uncertainty in assigning the ν(CS) band. Although, due to the asymmetry of the bridging thiocyanato group, the IR studies are not strongly evidential as in the case of μ-pyrazine ion,[4] the slight shift in the positions of ν(CN) bands of the monomer and dimer does help. The shift may be attributed to the nitrogen end coordination of [Ru(III)–SCN] unit on Ru(II) and is understandable as the π-acceptor ability of the S-bonded thiocyanato group is only slightly higher than that of an N-bonded one.[15]

Electronic spectra

Analogous to most of the other mixed-valence species, the electronic spectra of the dinuclear species $[\{Ru(NH_3)_5\}_2SCN]^{4+}$ exhibited a near IR transition. The position of the absorption maximum of the band was found to be independent of solvent, similar to μ-pyrazine,[16] μ-cyanogen[17] and μ-dinitrogen[18] complex ions (Table 1).

Ignoring the asymmetry of the bridging

Table 1. Solvent independent near IR spectral data

Solvent	$\left(\frac{1}{n^2}-\frac{1}{D}\right)$	λ_{max} (nm)

(n and D are refective index and dielectric constant of the solvent.)

thiocyanato group, the bandwidth was calculated within the limits of the conceptual model proposed by Hush,[19,20] which is applicable to systems having trapped integral valences with a moderately small delocalization. For a symmetrical one-electron transfer, the absorption maximum and the bandwidth can be calculated from each other. In the high temperature limit at 300 K:

$$\nu_{max} = (\Delta\nu_{1/2})^2/2310 \qquad (\nu_{max} \text{ and } \Delta\nu_{1/2} \text{ in } cm^{-1}). \tag{1}$$

The weak band (ε_{max} = 331 M^{-1} cm^{-1} in C_6H_5Cl) is narrower than expected from eqn (1) ($\Delta\nu_{1/2}$ = 929 cm^{-1} compared to the calculated value of 3800 cm^{-1}; Fig. 2). The weak intensity, narrowness compared to the bands of other systems having largely trapped integral valences and the solvent independence of the absorption maximum of the band can be attributed to a comparatively higher delocalized limit rather than to trapped integral valences; i.e., in the classification of Robin and Day[21] the dimer can be designated as a class III system.

The d-levels of the dimer can be best described by molecular orbitals delocalized over both the metal centres as has been assumed for the $[\{Ru(NH_3)_5\}_2N_2]^{4+}$ dimer.[22] Assuming the linearity of the SCN bridge, the tentative ordering of the molecular orbitals of the dimer in C_{4v} symmetry can be given as $E(xz_1+xz_2,\ yz_1+yz_2) < B_2(xy_1+xy_2) \sim B_2(xy_1-xy_2) < E(xz_2-xz_2-yz_1-yz_2) < \pi^*(SCN)$ with an unpaired electron in the $E(xz_1-xz_2, yz_1-yz_2)$ level. From the above ordering, the two transitions $(xz_1-xz_2,\ yz_1-yz_2)E \leftarrow B_2$ and $(SCN)\pi^* \leftarrow B_2$ may be attributed to the near IR and the 490 nm charge transfer bands, respectively (Fig. 3).

Cyclic voltammetric studies

The cyclic voltammogram showed two one-electron reduction waves (Fig. 4), one having a maximum around 0.325 V and the other around 0.575 V with practically no anodic peaks in the first scan (scan rate 120 mV s^{-1}). The cathodic maximum around 0.575 V exhibited the anodic counterpart around 0.5 V after the second scan, suggesting quasi-irreversibility of the process (E_{pc} = 0.575 V; E_{pa} = 0.500 V; $E_{1/2}$ = 0.538; ΔE_p = 0.075 V). After the third scan, the cathodic peak around 0.325 V started disappearing with the appearance of a new peak around 0.2 V. It suggested the formation of an intermediate which was possibly disproportionating, with one of the disproportionation products, having ruthenium in the +3 oxidation state. The aquation of the electrogenerated intermediate may lead to the formation of $[Ru(NH_3)_5SCN]^{2+}$. This inference is understandable by the fact that after the third scan the system was showing the same redox behaviour as that of $[Ru(NH_3)_5SCN]^{2+}$.[10,12]

The equilibrium between the mixed-valence, completely oxidized and completely reduced

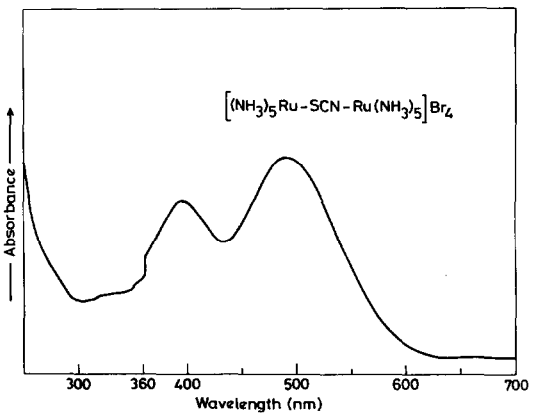

Fig. 3. Electronic spectrum.

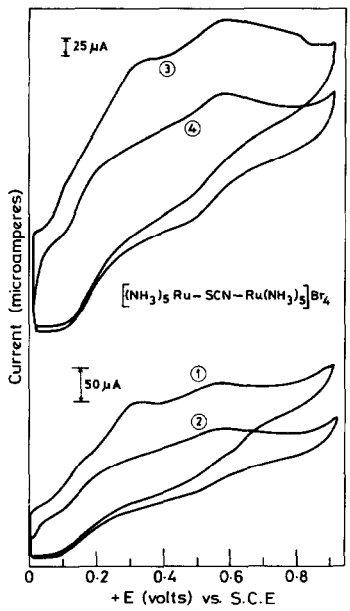

Fig. 4. Cyclic voltammograms.

moieties is also a possibility if the half-wave potentials of the two one-electron redox processes are close enough.[23] Such an equilibrium between mixed-valence and completely oxidized moieties can explain the following tentative scheme:

$$\text{Ru(III)–SCN–Ru(III)} \xrightarrow{0.325\,V} \text{Ru(II)–SCN–Ru(III)}$$

$$\text{Ru(II)–SCN–Ru(III)} \underset{}{\overset{0.575\,V}{\rightleftharpoons}} \text{Ru(II)–SCN–Ru(II)}$$

$$\text{Ru(II)–SCN–Ru(II)} \xrightarrow[\text{Disproportionation}]{} \text{Ru(III)–SCN}$$

$$\text{Ru(III)–SCN} \xrightarrow{0.2\,V} \text{Ru(II)–SCN}.$$

The confirmation of such a scheme was not possible because of the lack of coulometric data. Besides, the efforts to synthesize the completely reduced moiety failed and the product invariably decomposed to $[Ru(NH_3)_5SCN]^{2+}$. The instability of the Ru(II)–SCN–Ru(II) species can tentatively be attributed to the comparatively weaker π-acidities of the nitrogen and sulphur ends of the thiocyanate group.[15]

(*Received* 16 *November* 1984; *accepted* 6 *February* 1985)

Abstract—The ^{11}B and ^{1}H NMR spectra of the carbaborane CB_8H_{14}, and its anion $CB_8H_{13}^-$, have been recorded and assigned unambiguously by decoupling and COSY techniques. The results indicate the presence of unsymmetrical bridging hydrogen atoms in both the neutral and anionic species. More significantly the *endo*-hydrogen attached to the carbon atom is involved in exchange with all the three bridging hydrogen atoms in the $CB_8H_{13}^-$ anion, whereas no such exchange is observed in the neutral CB_8H_{14}.

The use of NMR spectroscopy in the study of boranes and their derivatives has been well documented.[1] More recently two-dimensional (2D), and homonuclear chemical shift correlation spectroscopy (COSY)[2] data have also been shown to be useful in providing additional information.[3] For example, the application of homonuclear 2D NMR techniques have been utilised to elucidate boron hydride cluster connectivity.[4–7]

The spectra produced exhibit diagonal symmetry with cross peaks due to scalar spin–spin coupling, indicating adjacent nuclei. Boron atoms connected by a bridging hydrogen have been found, in general, not to give rise to such coupling.[5,6] This is explained in terms of the negligible electron density along the B–B vector predicted in the theoretical description of three-centre bridging hydrogen bonds. However, some exceptions have been noted, as in

nido-2-$(C_5H_5)CoB_4H_8$

and

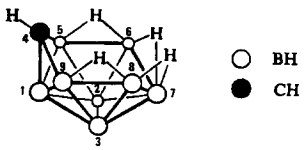
nido-$[C_6(CH_3)_6]Fe(C_2H_5)_2C_2B_3H_5$.[5]

We have applied these techniques to the monocarbaborane systems *arachno*-CB_8H_{14}, and the $CB_8H_{13}^-$ anion, to obtain more information about their properties, and to extend the current knowledge of the type of results to be expected using these techniques.

EXPERIMENTAL

The neutral carbaborane CB_8H_{14} was prepared as described elsewhere,[12] with spectra being obtained from a benzene-d_6 solution. The anion $CB_8H_{13}^-$ was prepared by a different route to that reported,[11] as follows. In a dry-box with a nitrogen atmosphere, a 10 mm diameter NMR tube, containing 0.82 cm^3 of a 0.16 mol dm^{-3} lithium butyl solution (0.13 mmol), was pumped under vacuum to remove the hexane solvent. The residue was dissolved in 1.0 cm^3 of tetrahydrofuran-d_8. To this solution was added 0.15 g of CB_8H_{14} (0.13 mmol), dissolved in the same solvent, and the mixture agitated for 15 min, whereupon reaction to form the anionic derivative, $CB_8H_{13}^-$, was complete.

The ^{11}B COSY and ^{1}H spectra were recorded on a Bruker WH-400 NMR spectrometer, at 128.0 and 400.1 MHz respectively. COSY 2D spectra typically required a 128 × 128 point spectrum matrix, with 64 transients per 64 time-domain points taking *ca.* 1 hr in total. ^{1}H–^{11}B shift-correlated 2D spectra required a similar matrix, but overnight accumulation of typically 256 transients with inter-transient delays of 1–2 s. A double sine-bell window function was used for COSY, and a double Lorentz-to-Gaussian function for shift correlation, in which the interpulse spacings were a compromise between the optima for terminal H–B couplings and bridging H–B couplings.



The ^{1}H–(^{11}B) spectra were recorded at 360 MHz on a similar spectrometer. The ^{1}H and ^{11}B spectra

* Author to whom correspondence should be addressed.

are referenced to $Si(CH_3)_4$ and $BF_3 \cdot OEt_2$ respectively, shifts to high frequency being positive.

RESULTS AND DISCUSSION

Neutral CB_8H_{14}. The application of Wade's rules to the neutral monocarborane, CB_8H_{14}, leads to a predicted *arachno* structure based on an octadecahedron.[9] The absence of the most highly connected vertex and one adjacent vertex, as indicated by Williams' rules,[10] with the four bridging hydrogens positioned symmetrically in the open face of the cluster, yields the predicted structure, as shown below.

Proposed structure of CB_8H_{14}.

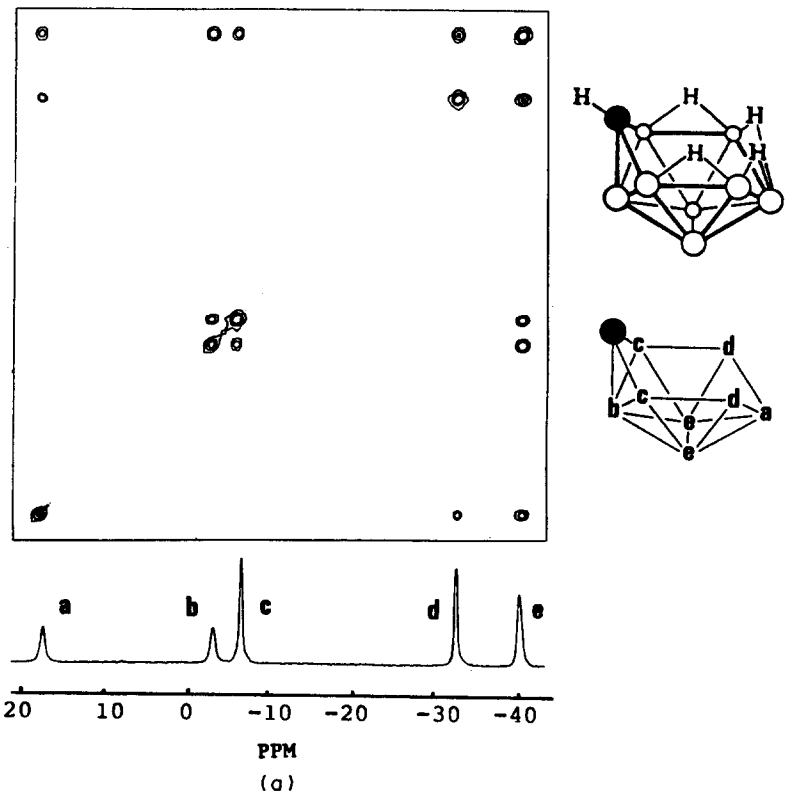
The ^{11}B NMR spectrum shows five resonances [relative intensities 1:1:2:2:2, denoted *a*, *b*, *c*, *d*, *e*, Fig. 1(a)] compatible with this structure. A complete assignment of the ^{11}B resonances has been proposed by Baše *et al.* based upon both $J(B–H_{bridge})$ couplings and experience of chemical shifts in related systems,[11] as follows: B(7), 17.0 ppm; B(1), −3.7 ppm; B(5, 9), −6.3 ppm; B(6, 8), −34.9 ppm; B(2, 3), −41.1 ppm.

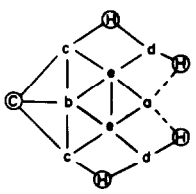
We have recorded the ^{11}B COSY spectrum of CB_8H_{14} [Fig. 1(a)] and the two possible alternative assignments of skeletal connectivity are as indicated [Figs. 1(b,c)].

The two possible assignments arise because of the high symmetry of the carborane; similar difficulties in assignment have been noted in the ^{11}B COSY of the 1,2- and 1,7-$C_2B_{10}H_{12}$ isomers.[5] The correct structure of CB_8H_{14} may be deduced by examining the ^1H NMR spectra obtained with selective ^{11}B decoupling as shown in Fig. 2.

The fully coupled ^1H NMR spectrum consists of a series of quartets at lower field arising from the $B–H_{(terminal)}$ bonds, while at higher field there are two resonances (−0.13 and −2.06 ppm) from the CH_2 group, and two broad resonances (centred at −0.64 and −3.76 ppm) from the two sets of bridging hydrogen atoms. These four higher field resonances have been previously reported, but not the complete ^1H spectrum, and no assignment of individual sets of bridging hydrogens exists.[11,12]

We have found that the broad band decoupled





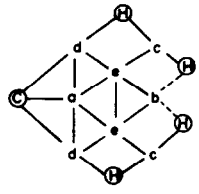


Fig. 1(a). ^{11}B COSY spectrum of CB_8H_{14}.

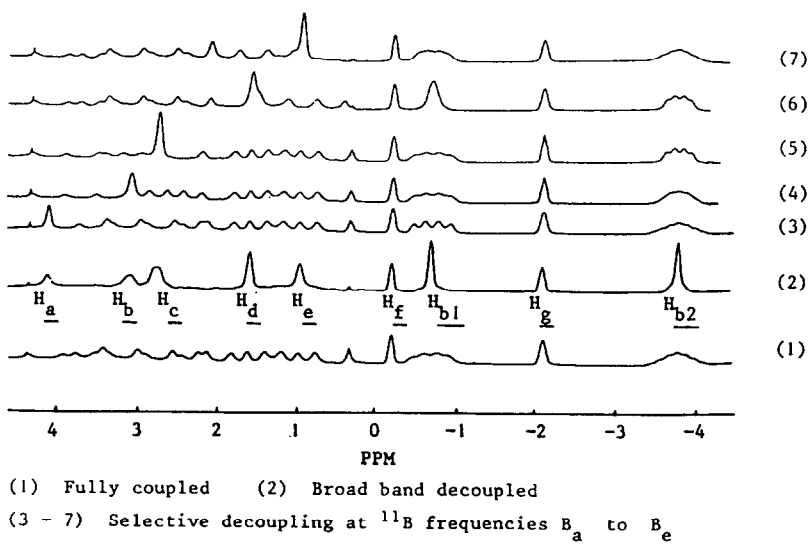
(b)

(c)

Fig. 1(b). Correct skeletal connectivity (see text).

Fig. 1(c). Alternative COSY connectivity.

spectrum gives little information, but selective decoupling at resonance *a* [assigned as in Fig. 1(a)] partially decouples the set of bridging hydrogens at −0.64 ppm, while the same treatment at resonance *b* only decouples the terminal proton at 3.17 ppm. On further decoupling at resonance *c* one of the CH resonances becomes sharpened, indicating that the resonance *c* is assignable to the boron atoms B(5, 9) adjacent to the carbon atom. The same effect does not result from decoupling at the ^{11}B frequency of resonance *d*. The unambiguous skeletal connectivity is therefore deduced as shown in Fig. 1(b), with the boron atoms being assigned as *a* = B(7), *b* = B(1), *c* = B(5, 9), *d* = B(6, 8) and *e* = B(2, 3).



Using the above information, the complete assignment of the resonances in the ^1H NMR spectrum of CB_8H_{14} is as follows: *terminal*: $H_a = H_{B(7)}$, 4.20 ppm; $H_b = H_{B(1)}$, 3.17 ppm; $H_c = H_{B(5,9)}$, 2.83 ppm; $H_d = H_{B(6,8)}$, 1.66 ppm; $H_e = H_{B(2,3)}$, 1.0 ppm; *bridging*: $H_{b1} = H_{B(6,8)-B(7)}$, −0.6 ppm; $H_{b2} = H_{B(5,9)-B(6,8)}$, −3.7 ppm. C—H: $H_f = H_{exo}$, −0.1 ppm; $H_g = H_{endo}$, −2.0 ppm. The $^1H_{(terminal)}$ resonances follow the same pattern as in the ^{11}B NMR spectrum.

Closer inspection of the ^{11}B COSY spectrum reveals that a coupling between B(6, 8) and B(7) is observed, though they are connected by a bridging hydrogen. This is in contrast to the absence of coupling between B(5, 9) and B(6, 8), which are also connected by bridging hydrogens.

The theoretical justification for the absence of such coupling is based on an ideal symmetrical bridging hydrogen bond where there is negligible electron density along the B–B vector. In an unsymmetrical bridge there may be significant electron density along the B–B vector, enabling scalar spin–spin coupling. The present results indicate therefore that CB_8H_{14} contains two distinctly different types of bridging hydrogen atoms, and further evidence in support of this proposal is seen in the ^1H–^{11}B shift correlation map (Fig. 3). The correlations between the ^{11}B resonances and the resonances due to the attached hydrogen atoms are as shown.

All of the hydrogen resonances are readily assignable and are in agreement with that deduced above. The high field symmetrical bridging hydrogens exhibit coupling to *c*[B(5, 9)] and *d*[B(6, 8)] as expected. The lowfield resonance due to the proposed unsymmetrical bridging hydrogens give an observable coupling to *d*[B(6, 8)] only and not to *a*[B(7)]. From this information the bridging group is deduced to be displaced towards the *d*[B(6, 8)] boron atoms; similar conclusions have been reached following theoretical CNDO/2 calculations.[11]

Corroborating evidence for the unsymmetrical bridge is provided by the ^1H–($^{11}B_{selective}$) NMR spectra (Fig. 2). Decoupling at both *c*[B(5, 9)] and

(1) Fully coupled (2) Broad band decoupled

(3 - 7) Selective decoupling at ^{11}B frequencies B_a to B_e

Fig. 2. ^1H–($^{11}B_{selective}$) NMR of CB_8H_{14}.

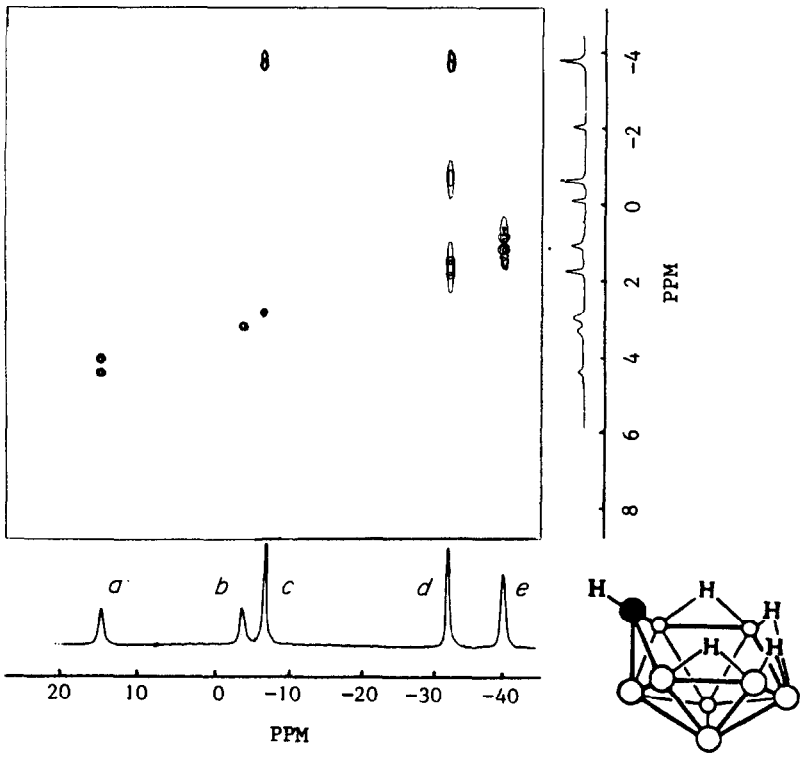


Fig. 3. ^{1}H–^{11}B correlation map of CB_8H_{14}.

d[B(6, 8)] resonance frequencies has an identical effect upon the highfield bridging hydrogen resonance, compatible with that expected for a symmetrical bridge. In comparison, decoupling at the *d*[B(6, 8)] frequency, results in a near-singlet resonance for the lowfield bridging hydrogen resonance, whereas decoupling at the *a*[B(7)] frequency has considerably less effect. The differential effect of selective decoupling reflects a larger association of the *d*[B(6, 8)] boron atoms with the bridging hydrogen atom compared to that of the *a*[B(7)] boron atom, as expected for an unsymmetrical bridging hydrogen displaced closer to the *d*[B(6, 8)] boron atoms. The refined structure is therefore as shown in Fig. 1(a).

Anion $CB_8H_{13}^-$. The ^{11}B–(^{1}H) NMR spectrum of the anion $CB_8H_{13}^-$ is similar to that of the neutral CB_9H_{14} showing five resonances (relative intensities 2:1:1:2:2, denoted *a**, *b**, *c**, *d**, *e**, Fig. 4), indicating that symmetry of the framework is preserved, in agreement with the model proposed by Base *et al.*[12]

The highest field resonance, *e**, shows the largest $J(B–H_{bridge})$ coupling, and can be assigned to the B(6, 8) pair of boron atoms. Further assignments cannot be made with confidence from this spectrum alone, since the relative chemical shifts of the resonances have changed substantially compared with those from CB_8H_{14}. Thus to date no complete assignment of the ^{1}H and ^{11}B resonances for the anion have been made. The connectivity in the skeleton of the anion is derived in a similar manner to that used for the neutral precursor, namely, from the ^{11}B COSY spectrum (Fig. 4) and the ^{1}H–($^{11}B_{selective}$) spectra to give the following ^{11}B NMR resonance assignments: *a** = B(5, 9), 4.0 ppm; *b** = B(7), −3.9 ppm; *c** = B(1), −21.5 ppm; *d** = B(2, 3), −30.4 ppm; *e** = B(6, 8), −35.2 ppm.

Notable features of the ^{11}B COSY spectra of the neutral CB_8H_{14} and the anionic $CB_8H_{13}^-$ are now evident, as follows. Firstly, in the anion, a strong coupling is observed between B(5, 9) and B(6, 8), which is absent in the neutral precursor, suggesting the symmetrical bridges in CB_8H_{14} are now unsymmetrical in $CB_8H_{13}^-$. Secondly, for the three boron atoms B(6, 8) and B(7) in the anion, now connected by a single unique bridging hydrogen, a weak coupling is still observed, and is a clear indication of significant electron density along the B–B vector in this four-centre bond. Thirdly, an unexpected reduction in the observed coupling between B(1) and B(5, 9) of the anion is also found, which is presumably produced by the shift of electron density on the open face of the cluster towards the B(6, 8) positions, resulting in a reduced electron density between those boron atoms adjacent to the carbon atom.

From the assignment shown in Fig. 4, the order of

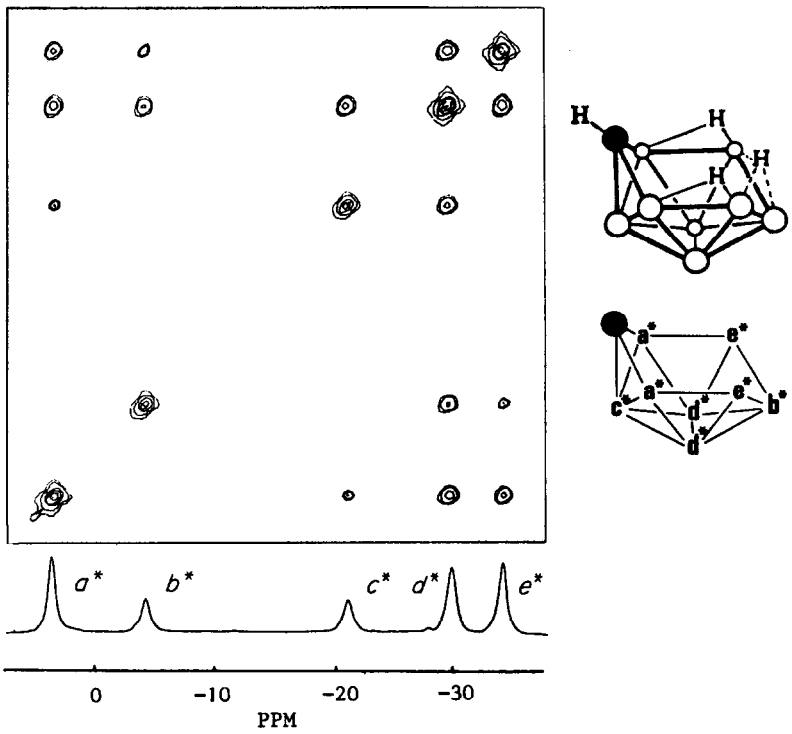

Fig. 4. ^{11}B COSY of $CB_8H_{13}^-$.

the resonances has changed in a way that confirms the electron density shift, such that the lowest-field resonance is now attributable to the relatively less electronegative boron atoms B(5, 9) adjacent to the carbon atom, though the major factor may be the relative up-field shift of the B(7) boron atom due to the reduction in co-ordination.

The practical difficulties involved in the preparation of the anion, namely the elimination of hexane residues from the lithium butyl solution, lead to impurity peaks in the ^1H spectrum. However, assignment of the lowfield resonances from the terminal hydrogen atoms was made possible by a series of difference spectra produced by subtracting the spectra obtained by selective ^{11}B decoupling from the fully decoupled spectrum.

The impurities do not interfere with the more important upfield CH_2 and bridging hydrogen resonances, which appear as two singlets (C–H), a distorted quartet and a broad multiplet, of ratio 1:1:2:1 respectively. The unique bridging hydrogen resonance, at highfield, is complex because of the coupling to three boron atoms. The distorted quartet resonance is due to greater coupling to the B(6, 8) boron atoms than to the B(5, 9) boron atoms in the unsymmetrical bridge. The complete assignment of the resonances in the ^1H NMR spectrum of $CB_8H_{13}^-$ is as follows: *terminal*: $H_a^* = H_{B(5,9)}$, 3.93 ppm; $H_b^* = H_{B(7)}$, 3.05 ppm; $H_c^* = H_{B(1)}$, 2.52 ppm; $H_d^* = H_{B(2,3)}$, 1.44 ppm; $H_e^* = H_{B(6,8)}$, 1.29 ppm; *bridging*: $H_{b1}^* = H_{B(5,9)-B(6,8)}$, −1.04 ppm; $H_{b2}^* = H_{B(6,8)-B(7)}$, −2.0 ppm. C—H: $H_f^* = H_{exo}$, 0.34 ppm; $H_g^* = H_{endo}$, −0.36 ppm. The $^1H_{(terminal)}$ resonances again follow the same pattern as in the ^{11}B NMR spectrum.

Confirmation of the unsymmetrical nature of both types of hydrogen bridge is provided by subtraction spectra. A significant effect on both bridging resonances is observed by decoupling at the *e**[B(6, 8)] frequency, whilst decoupling at *a**[B(5, 9)] and *b**[B(7)] frequencies has only a marginal effect on both bridging hydrogen resonances. The refined structure of the anion, $CB_8H_{13}^-$, to show the unsymmetrical bridging groups is shown in Fig. 4.

The highfield *endo*-CH resonance has a broader linewidth (50 Hz) than either the *exo*-CH resonance (24 Hz) of the anion, or the *endo*-CH resonance (33 Hz) in the neutral precursor. Saturation transfer experiments show that the *endo*-CH hydrogen, and all three bridging hydrogens, are in exchange at room temperature. The *exo*-CH hydrogen is not involved in the exchange process. Similar saturation transfer experiments also show that the neutral precursor does not exhibit such exchange. Linewidth broadening observed during variable temperature NMR studies yields a very approximate activation energy for this process of 50 kJ mol^{-1}. The removal of a proton has therefore significantly activated the open face of the cluster, including the *endo*-hydrogen on the carbon atom. While fluxional behaviour of

bridging hydrogen atoms in boranes and carboranes is well established, to our knowledge this is the first observation of such a process incorporating a C–H hydrogen atom.

Attempts to produce and identify the di-anion by further removal of a proton have been unsuccessful. This may be due to the insolubility of the product in a range of solvents, or more likely the probable cage degradation expected on further activation of the open cluster face.

CONCLUSIONS

The structure of the neutral monocarborane CB_8H_{14} is confirmed to be that proposed previously,[12] with the further refinement that the presence of both symmetrical and unsymmetrical bridging hydrogens on the open face of the cluster is indicated. Boron atoms connected by unsymmetrical bridges have been shown to give rise to observable coupling in the ^{11}B COSY spectrum, a feature so far found only in two metallo-borane derivatives, one of which results from tautomeric exchange between bridged and directly bound boron atoms.[5]

The removal of a proton from the open face of the *arachno* monocarborane, CB_8H_{14}, to yield the anion $CB_8H_{13}^-$, results in a significant activation of the open face of the cluster, involving exchange of all three $B–H_{(bridging)}$ hydrogen atoms and the *endo*-C–H hydrogen atom.

(*Received* 6 *December* 1984; *accepted* 6 *February* 1985)

Abstract—The overall stability constants of zinc bromide and iodide complexes in DMSO–water and those of zinc chloride, bromide and iodide in DMF–water mixtures have been determined potentiometrically at mole ratios about 0.2–1 for the organic solvents at 25°C and in a 0.5 M ammonium perchlorate ionic medium. The complex formation is much stronger in DMF and its mixtures than in DMSO and the log βs are generally higher in solvent mixtures than those expected from the values measured in the pure components.

In our previous study[1] the change of the stability constants of the zinc chloride complexes has been observed in DMSO–water mixtures. It was pointed out that the values of the constants change in response to the change of the composition of the solvent mixtures, but the constants are greater than could be expected from the values measured in pure DMSO and water. The above studies were extended to zinc bromide and zinc iodide systems in DMSO and to all the three zinc halides in DMF–water mixtures.

EXPERIMENTAL

Chemicals. Zinc perchlorate was examined according to our previous descriptions.[1] The ammonium halides were of analytical grade. DMSO was purified by vacuum distillation and DMF was purified by fractional distillation after the addition of 10% benzol and 5% water.

Titrations and *computer evaluation* of the results were carried out by the MAXIPOT program[2] corresponding to the previous paper.[1]

RESULTS

The titrations were performed at constant zinc ion concentration. Since only small differences were observed between the shapes of potentiometric curves obtained in either system, for the sake of conciseness, potentiometric results of the study of the zinc chloride and zinc iodide systems in DMF–water mixtures are presented as two extreme cases (Fig. 1).

The log β values showing the best agreement between the measured and calculated potentials are summarized in Tables 1 and 2. The standard deviations of the constants calculated from the residuals of the individual titration curves are given in brackets. However, it must be noted that these are the standard deviations of the fit of only one experimental curve and, considering reproducibility, the errors of the log β_2 and β_3 values amount to approximately 0.05–0.1. As can be seen from the data, the uncertainty of the constants of complexes (1, 1) is considerably greater than for the other complexes. Therefore, in Figure 2 illustrating the data of Table 2, the log β_1 values are displayed with their errors calculated from individual titration curves. It is worth mentioning that, because of the

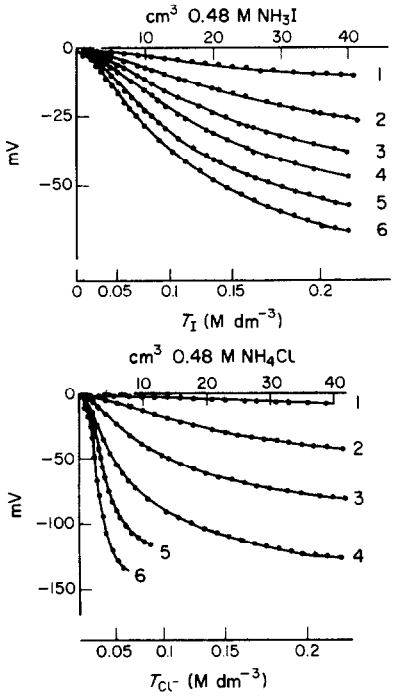

Fig. 1. Potentiometric titration curves of 50.0 cm³ 0.01 M zinc perchlorate in DMF–water mixtures, A: with 0.48 M ammonium chloride and B: with 0.48 M ammonium iodide. One half of the experimental points chosen randomly are plotted. The solid curves are the calculated ones using the formation constants summarized in Table 2.

minor solubility of ammonium chloride, measurements could be made in DMF only in mixtures containing more than 5% water.

From the experimental data it could be stated that the values of all the equilibrium constants are greater by several orders of magnitude in DMF than in DMSO. It is also obvious that the zinc iodide system can well be measured in DMF, but in DMSO a rather slight interaction can be experienced: the value of ΔE is only about 2 mV in response to the 0.2 mol iodide. Systems containing chloride or bromide can definitely be described by the supposition of the formation of complexes (1, 1), (1, 2) and (1, 3). Among systems containing iodide the formation of these three species could definitely be detected only in DMF and values with relatively great experimental errors were only obtained in the case of log β_1 values. However, in DMSO the formation of the diiodo complex was found to be minor and that of the triiodo complex cannot be substantiated on the basis of measurements.

DISCUSSION

The stability constants of zinc halide complexes obtained in the course of measurements made in solutions of 0.5 molar ionic strength with NH_4ClO_4 at 25°C are summarized in Table 3.

The values obtained in DMSO approximately correspond to the literature results,[3] the deviations are probably due to the difference in ionic strengths. Accessible data[4] are not available for the constants measured in DMF.

The difference between the measured values of equilibrium constants and those expected from the composition of the solvent mixtures is never negative in any system, i.e. the solvent mixtures usually have a stabilizing effect on the complex formation. In mixtures in which there are detectable deviations between the measured values and those expected from constants obtained in pure solvents, generally the maximum of the deviations is approximately at $\alpha = 0.5$ and the shapes of difference-curves are symmetrical. Deviations from this were detected

only in zinc bromide and zinc iodide systems in DMF, but only in the case of log β_2.

In order to aid in the interpretation of the constants, we have measured the relative permittivity of the solvent mixtures. They differ from additivity only to such a small extent, that the equilibrium constants variations could not be interpreted in terms of relative permittivity.

By means of the equilibrium constants the number of halide ions coordinated to the zinc ion ($\bar{n}$) was calculated and plotted against the composition of the solvent mixtures. In the case of all the systems studied

a curve similar to that of the zinc chloride system was obtained,[1] the limiting value of which cannot exceed $\bar{n} = 3$ even in the case of the most stable systems. On this basis, in accordance with our earlier supposition, for the geometry of the complexes a tetrahedral configuration is predicted in which three of the coordination sites are occupied by one halide ion each and the fourth coordination site is occupied by a solvent molecule. This result is consistent with the ultrasonic absorption measurements in $ZnCl_2$ systems in aqueous methanol, DMSO and DMF.[5,6] This supposition is also supported by electron-diffraction measurements recently made on the $LiZnBr_3$ solution.[7]

The experimental technique used in the course of experiments provided reliable values only for the stability constants of the (1,2) and (1,3) complexes. Generally, the stability constants of the (1,1) complex were determined only with relatively great experimental errors, moreover, in solutions in which the complex formation is rather strong they could not be treated as parameters of fits and the determination of their values was not possible by graphical treatment either. In spite of this, it would be difficult to exclude the possibility of the formation of this species.

(*Received* 11 *December* 1984; *accepted* 6 *February* 1985)

Abstract—The nature and stability of some transition and heavy metal cation complexes of an *N,N'*-methylated diaza-crown-ether have been determined in 0.1 M Et_4NClO_4 aqueous solution by means of pH metric measurements. The results are compared to previous ones concerning the homologous unmethylated ligand.

As part of our general study on the complexing properties of cryptands in different solvents,[1,2] we present here the results concerning the stability of some metallic complexes ($M^{n+} = Co^{2+}$, Ni^{2+}, Cu^{2+}, Zn^{2+}, Ag^{+}, Cd^{2+}, Pb^{2+} and Hg^{2+}) of the ligand 1,10-diaza-4,7,13,16 tetraoxacyclooctadecane, abbreviated Me_2-(2.2) according to the usual cryptand nomenclature. The nature of the species formed in 0.1 M Et_4NClO_4 aqueous solution and their stability constant β_{xyz} referring to the general equilibrium of complexation:

$$xM^{n+} + yL + zH^{+} \rightleftharpoons M_xL_yH_z^{(nx+z)+}$$

have been determined by following the pH changes resulting from successive additions of Me_4NOH to acidic solutions of ligand diperchlorate and of metallic perchlorate, of various stoichiometries. Details of the experimental procedure, the glass electrode conditioning and the calculation methods using the numerical program SCOGS[3] have been previously reported.[1] The results are summarized in Table 1: values of log β_{xyz} are given with their confidence interval $\pm 2\sigma$ (σ being the standard deviation calculated by the program). Previously determined values for the homologous (2.2) cryptates are also mentioned for comparison.

The two protonation constants β_{011} and β_{012} have been first determined from solutions without metallic cation ($x = 0$). The results corresponding to three experiments, summing up 138 experimental points, are in good agreement with the previous determinations of Gramain *et al.*[4] and Vitali.[5] They show that methylation of (2.2) slightly increases the basicity of the first protonation site but decreases the second one. The electrostatic interactions are greater in Me_2-(2.2) than in (2.2) as shown by the differences log K_1 − log K_2,† respectively 1.97 and 1.18.

Only 1:1 complexes have been found in the pH range explored, except for Cu^{2+} where an additional protonated species had to be taken into account to improve the calculation fit. In most cases results given in Table 1 correspond to a minimum of two experiments for which the ratio of the metal to ligand concentrations, $R = C_M/C_L$, was generally about 1 and 0.5. Some of our values have already been determined by Vitali[5] in 0.1 M Me_4NBr aqueous solution. Our values are generally slightly lower than theirs, except for Co^{2+} and Pb^{2+} which are higher. Most of the constants are rather low and hydrolysis of the metallic cations strongly competes with the complexation. In these cases hydrolysis equilibria were considered in the calculations.[6]

From the differences $\Delta \log \beta = \log \beta_{110}$ [Me_2-(2.2) − log β_{110} (2.2)], given in Table 1, it can be seen that Ag^{+}, Cd^{2+} and Hg^{2+} complexes with Me_2-(2.2)

are less stable than their homologs with (2.2). On the contrary, the presence of the methyl groups on the ring leads to a stabilization of the complexes of transition metal cations and particularly of Pb^{2+} for which $\Delta \log \beta = 1.49$. The same behaviour was already observed for the complexes of these ligands with alkaline-earth cations in water as well as in methanol.[7]

Methylation of the ligand (2.2) can affect the complexation mainly by inducing (i) a less important hydration of the ligand, (ii) a greater availability of the electrons in N–CH_3 than in N–H,[7] (iii) a steric hindrance caused by the two substituents.

The first two effects which would lead to a stabilization of the complexes, certainly prevail for the transition metal cations, overcoming the third one which would lead to a destabilization. This last effect must be therefore predominant for Ag^+, Hg^{2+} and Cd^{2+} complexes. These results could be expected from size considerations, the latter cations, which are much larger than the first ones, being more strongly affected by steric effects. Nevertheless the opposite behaviour displayed by the large Pb^{2+} and alkaline-earth cations suggests that another factor should be considered besides the sizes of the cations.

Acknowledgement—The authors thank Prof. J. M. Lehn who provided a sample of the ligand.

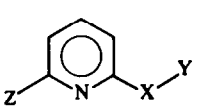
ELECTROCHEMICAL STUDIES ON THREE POLAR DIRUTHENIUM(II,III) COMPLEXES

AKHIL R. CHAKRAVARTY, F. ALBERT COTTON,* DEREK A. TOCHER and JOANNE H. TOCHER

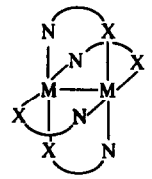
Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A & M University, College Station, TX 77843, U.S.A.



(*Received* 5 *October* 1984; *accepted* 7 *February* 1985)

Abstract—Electrochemical studies on a new class of diruthenium(II,III) compounds were done. The complexes having a polar arrangement of ligands across the diruthenium unit in $Ru_2Cl(hp)_4(Hhp)$, $Ru_2Cl(chp)_4$ and $Ru_2Cl(PhNpy)_4$ where Hhp, Hchp and PhNHpy are 2-hydroxypyridine, 6-chloro-2-hydroxypyridine, and 2-anilinopyridine, respectively, undergo two or more oxidations and reductions. The metal centered reductions in the range of +0.1 to −0.75 V and oxidations in the range +0.5 to +1.2 V are discussed and compared with diruthenium carboxylato and amidato complexes.

Unsymmetrical ligands of the type **1** bridging across a pair of metal atoms are known[1] to form complexes $M_2(NX)_4$ with short metal–metal bond distances. The arrangement of bridging ligands is usually[1–3] of the type **2**. In some dirhodium compounds, a type **3** arrangement was observed.[4,5] The type **4** arrangement was first found[6,7] in Hfhp complexes of Cr_2, Mo_2, W_2 and Rh_2. With these metals all other ligands are known[1] to form either type **2** or type **3** complexes. Recently we have reported[8,9] the syntheses and X-ray structures of three diruthenium(II,III) complexes having bridging ligands hp, chp and PhNpy in a totally polar arrangement as shown in **4**.



* Author to whom correspondence should be addressed.

In $Ru_2Cl(O_2CR)_4$[10–16] and $Ru_2Cl(RCONH)_4$[17–20] complexes, the formal oxidation state of the ruthenium is +2.5 and the coordination environments of the two metal centers are the same. In our compounds, **5**–**7**, the coordination environments of two ruthenium atoms are different.[8,9] We have previously[9] discussed the probable reasons for the occurrence of this polar type of arrangement, citing a combination of steric and electronic factors. The electronic character of the two metals is expected to be somewhat different, but the question is whether their different environments will lead to any gross differences in properties. With that question in mind we have been motivated to carry out electrochemical studies on these complexes and the results of this investigation will be reported here.

EXPERIMENTAL

The preparations of these complexes have been already reported.[8,9] Tetra-*n*-butylammonium tetrafluoroborate ($TBABF_4$) was used as a supporting electrolyte in electrochemical measurements. All solvents were freshly distilled under a dinitrogen atmosphere and measurements were carried out under an argon atmosphere. Redox studies were done with a Bioanalytical Systems, Inc. Model BAS 100 Electrochemical Analyser instrument in connection with a Bausch and Lomb, Houston Instruments Model DMP 40 digital plotter. In a three-electrode cell system, a platinum disk, Model BAS MF 2032, and a platinum wire were used as working and auxiliary electrodes, and a BAS MAF 2020 Ag–AgCl cell was used as reference electrode. All potentials were referenced to the Ag–AgCl electrode at $22 \pm 2°C$ and are uncorrected for junction potentials.

RESULTS AND DISCUSSION

Electrochemical data in different solvents are presented in Table 1. Cyclic voltammograms of $Ru_2Cl(PhNpy)_4$ in tetrahydrofuran are shown in Fig. 1. The complexes undergo one nearly reversible one-electron reduction in the potential range +0.1 to −0.8 V. On the positive side of the reference electrode one reversible one-electron oxidation in the range +0.5 to +1.2 V is observed in all complexes. The one-electron stoichiometry of the electron-transfer processes was verified by controlled-potential coulometry done on

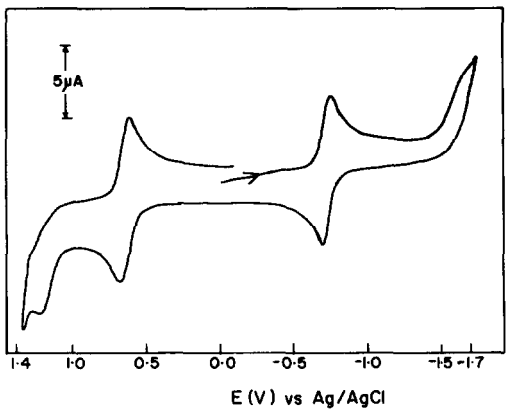

Fig. 1. Cyclic voltammograms of $Ru_2Cl(PhNpy)_4$ in tetrahydrofuran–0.1 M $TBABF_4$ at scan rate 200 mV s^{-1}.

$Ru_2Cl(chp)_4$ and $Ru_2Cl(PhNpy)_4$. For both the processes the $i_{p,c}/i_{p,a}$ ratio is $\simeq 1$ for sweep rates between 50 and 500 mV s^{-1}. The peak-to-peak separation, $E_{p,a} - E_{p,c} = \Delta E_p$, of 60–80 mV indicates a reversible electron-transfer process. In all complexes one further reduction is observed at higher negative potential. The process is irreversible since there is no anodic counterpart of the cathodic wave. Similarly all complexes display one or more oxidation waves at higher positive potentials and these processes are irreversible or quasireversible in nature.

In our earlier reports[8,9] we have mentioned that these complexes resemble $Ru_2Cl(O_2CR)_4$[10–16] and $Ru_2Cl(RCONH)_4$[17–20] in having magnetic moments corresponding to three unpaired electrons. For the carboxylates this has been attributed to a ground electronic configuration of

$$(\sigma)^2(\pi)^4(\delta)^2(\pi^*)^2(\delta^*)^1,$$

in which the π^* and δ^* orbitals are essentially degenerate.[12] One-electron oxidation of such compounds is expected to give either

$$(\sigma)^2(\pi)^4(\delta)^2(\pi^*)^2(\delta^*)^0$$

or

$$(\sigma)^2(\pi)^4(\delta)^2(\pi^*)^1(\delta^*)^1$$

as electronic configuration. Similarly one-electron reduction will add one electron either to the π^* or to the δ^* orbital. Comparing the electrochemical results of **5–7** we see a cathodic shift of the first reduction and oxidation potentials in the order PhNpy > hp > chp. This indicates that the energy of the antibonding π^* and δ^* levels follows the same order.

$Ru_2Cl(chp)_4$ in CH_3CN displays two reduction peaks at +0.09 and +0.34 V. The one at higher potential is less prominent and could be due to the couple $Ru_2(chp)_4^+ + e \rightleftharpoons Ru_2(chp)_4$. X-ray structural studies[8,9] on these compounds show that the Ru–Cl bond lengths in **6** and **7** are short (*ca.* 2.45 Å) compared to the ones in $Ru_2Cl(O_2CR)_4$[11,15,16] and $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4$[20] (*ca.* 2.56 Å). The amidato and carboxylato species thus have weak Ru–Cl bonds which can be easily cleaved by strong polar solvents. Electrochemical studies on these compounds do show[13,17,18] the presence of an equilibrium between dissociated and undissociated species. A similar phenomenon is also noticed in **5**. The compound is slightly soluble in CH_3CN. In DMF, it exhibits two reductions at −0.31 and −0.47 V and two oxidations at +1.12 and +1.25 V. The waves at −0.31 and +1.25 V are more prominent and they could be due to reduction and oxidation of the $[Ru_2(hp)_4(Hhp)]^+$ cation which is in equilibrium with $Ru_2Cl(hp)_4(Hhp)$.

The potential difference, $\Delta E_{1/2}$, between the first oxidation and the first reduction processes is *ca.* 1.3 V. In $Ru_2Cl(HNOCCH_3)_4$ the oxidation and two reductions takes place in Me_2SO at +0.47, −0.96 and −1.22 V, respectively.[18] The $\Delta E_{1/2}$ value is *ca.* 1.5 V. In $Ru_2Cl(O_2CC_3H_7)_4$, the reduction process is known[13] to occur in the range of 0.0 to −0.34 V vs SCE depending on the solvent. From our electrochemical studies, it is apparent that the redox behavior of the polar compounds is similar to that of other carboxylato and amidato species. We conclude that the completely polar arrangement of the ligands in **5–7** does not lead to any pronounced electronic difference from the carboxylato or amidato species, such as might be expected if there was a tendency to localize the +2 and +3 oxidation states.

A BINUCLEAR TANTALUM(III) COMPLEX WITH A BRIDGING CARBOXYLATO LIGAND

F. ALBERT COTTON,* MICHAEL P. DIEBOLD, STAN A. DURAJ and WIESLAW J. ROTH

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A & M University, College Station, TX 77843, U.S.A.

(*Received* 26 *November* 1984; *accepted* 7 *February* 1985)

Abstract—$Ta_2Cl_6(SMe_2)_3$ reacts with one equivalent of $C_4H_9CO_2Li$ to give a complex with a bridging carboxylate ligand, $Ta_2Cl_5(O_2CC_4H_9)(SMe_2)(THF)_2$. The product was isolated in two crystalline forms, **1** and **2**, from a THF/hexane and benzene/hexane solvent mixture, respectively. The following are the unit cell parameters, for **1**: monoclinic ($P2_1/n$), $a = 10.537(5)$ Å, $b = 22.015(4)$ Å, $c = 11.663(4)$ Å, $\beta = 107.80(3)°$, $V = 2576(3)$ Å^3, and $Z = 4$; for **2**: monoclinic ($P2_1/c$), $a = 15.584(4)$ Å, $b = 15.647(4)$ Å, $c = 11.275(3)$ Å, $\beta = 106.04(5)°$, $V = 2642(3)$ Å^3 and $Z = 4$. The complex is a dimer with a distorted octahedra-sharing-an-edge geometry. The Ta–Ta distances in **1** and **2** were 2.766(1) Å and 2.779(1) Å, respectively, which is somewhat longer than in previously reported Nb(III) and Ta(III) dinuclear compounds. Diamagnetism of the complex is shown by NMR. Fenske–Hall calculations, which correctly predict an electronic transition at about 16,000 cm^{-1}, indicate a double Ta–Ta bond. The observed elongation of the metal–metal bond is attributed mainly to steric crowding. The complex is the first proven low-valent Ta species with a coordinated carboxylate ion.

The chemistry of metal–metal bonded complexes of group V transition elements is not particularly well developed, especially when compared to that of their neighbors to the right in the periodic table.[1] One of the major lacunae in this area is the lack of unequivocally established carboxylato complexes of Nb and Ta.[2] The majority of other metals have extensive chemistry with RCO_2^- ligands, which play a very important role in the area of metal–metal multiple-bonded complexes of groups VI and VII. The reported non-monomeric carboxylates of Nb and Ta include $[CpNbO_2CH]_3(OH)_2(O)$,[3] $Nb_3O_2(O_2CR)_6(THF)_3^+$,[4] and $Ta_2Cl_4(O_2CBu)_4 \cdot 2BuCO_2H$.[5] The exact nature of the last compound is uncertain as no structural verification, which in this particular case would be desirable, has been carried out.

The chemistry of Nb and Ta in oxidation states lower than +5 with oxygen donors is in general not very rich.[6] A major reason seems to be the affinity of these elements for oxygen and consequently their tendency to abstract oxygen atoms from otherwise stable ligands, such as alkoxide, carboxylate, ketonate, etc. It appears that frequently mixtures of products are obtained in such systems, and this adversely affects the isolation of tractable products.

Following the characterization of bi-oxo-capped trimers[4] of niobium we began a similar study in tantalum chemistry, one result of which has been the isolation and characterization of a green intermediate which is seen with both metals when $M_2Cl_6L_3$, where $L = (CH_3)_2S$ or C_4H_8S, are reacted with an alkali metal carboxylate. The compound is a dimer, approximating to an edge-sharing bi-octahedron with a bridging pivalate anion. It is the first proven low-valent carboxylate of tantalum.[2] Its structural features are unique and in many respects different from those observed in previously reported Nb(III) and Ta(III) dimers.[7]

EXPERIMENTAL

All manipulations were carried out under an atmosphere of argon. Standard vacuum line techniques were used. $TaCl_5$ was purchased from Pressure Chemicals, Inc. and used as received. $Ta_2Cl_6(SMe_2)_3$ was prepared according to the literature method.[8] $C_4H_9CO_2Li$ was prepared by reacting pivalic acid with *n*-BuLi. The salt was

* Author to whom correspondence should be addressed.

recrystallized from THF and stored in the dry box. The spectra were recorded using the following instruments: UV–visible—Cary 17D spectrophotometer; ^{1}H NMR—Varian EM390 NMR spectrometer.

Preparation. $C_4H_9CO_2Li$ (0.07 g, 0.165 mmol) was added to a suspension of $Ta_2Cl_6(SMe_2)_3$ (0.5 g, 0.165 mmol) in 10 mL of THF (the observed precipitate was probably $Ta_2Cl_6(SMe_2)(THF)_2$).[7b] Within a few minutes the solution became dark green and stirring was maintained for *ca.* 0.5 hr. The solvent was removed under vacuum and the residue redissolved in 2–3 cm^3 of benzene. Excess hexane, about 20 cm^3, precipitated a green product which was contaminated with a reddish material. Purification involved extraction with 5–10 cm^3 aliquots of 2:1 hexane–THF mixture, which dissolved the complex leaving behind a brown, oily material. 30–40 cm^3 of hexane was added to each extract. On storing at −20°C a crystalline complex was obtained, with a combined yield varying between 30 and 50%.

The compound was obtained in two crystalline forms, **1** and **2**, by using THF/hexane and benzene/hexane solvent mixtures, respectively, for recrystallization. ^{1}H NMR ($CDCl_3/Me_4Si$), δ in ppm: 1.18—$C(CH_3)_3$, 3.03—$S(CH_3)_2$ and 3.37—$S(CH_3)_2$ with intensity ratio 3:1:1; 2.17 and 4.57—C_4H_8O. Visible spectrum (400–900 nm, benzene/hexane)—λ_{max} = 610 nm; a strong charge transfer band beginning at 500–600 nm.

X-ray crystallography. Single crystal X-ray analyses have been carried out by application of general procedures that are fully described elsewhere.[9] The relevant data pertaining to the

structure determination are summarized in Table 1. Polarization, Lorentz and absorption corrections were applied to the intensity data.

The position of one Ta atom in each structure was determined from a three-dimensional Patterson function. The remaining atoms were located by a series of alternating difference Fourier syntheses and least squares refinements. The final difference Fourier maps contained, in both cases, some residual electron density above 1 $e/Å^3$ but it was located in the vicinity of the Ta atoms. No peaks of chemical significance were left in the maps. The following are additional comments pertaining to the individual crystal structure determinations.

(1) Several carbon atoms were found to be disordered. They were assigned the following fractional occupancy factors by trial and error: C(3) to C(5), 0.7; C(3A) to C(5A), 0.3, C(14) and C(14A), 0.65 and 0.35, respectively. The disordered atoms were refined isotropically, while anisotropic thermal vibration parameters were assigned to the remaining atoms. The listing of reflections with the worst match between F_o and F_c showed a strong extinction for the top 20 of them. Since these reflections constituted a small fraction of the data set they were rejected altogether and no correction for extinction was made.

(2) Several carbon atoms had relatively high thermal parameters indicating the possibility of a disorder. However, either there was no residual electron density around them [C(3) to C(5)] or no peaks in the difference Fourier map generated an adequate disorder model (THF ring). Thus, taking into account that these atoms were not crucial for an accurate description of the structure, we did not attempt to find a refinable disordered model.

Tables of structure factors, anisotropic thermal parameters, complete lists of bond distances and bond angles and selected non-bonding intramolecular contacts (37 pages) have been deposited with the Editor at Queen Mary College. Positional parameters and isotropic thermal parameters have been forwarded to the Director, Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Molecular structure. $[TaCl_2(THF)]_2(\mu\text{-}Cl)(\mu\text{-}SMe_2)(\mu\text{-}O_2CC_4H_9)$ was isolated in two crystalline forms, **1** and **2** (see Table 1), by crystallization from THF/hexane and benzene/hexane mixtures, respectively. Both are monoclinic and have identical composition; they represent a case of polymorphism. The unit cell volumes differ by about 2.5% (66 $Å^3$), apparently as a result of different packing.

Important bond distances and angles are presented in Tables 2 and 3. Full listings of bonding interatomic dimensions are included in the supplementary material. The same atom labeling scheme, defined in Fig. 1, has been adopted for both compounds.

The molecule is an edge-sharing bioctahedron with a meridional disposition of chloride ions in each $TaCl_3SO(THF)$ half. There is a virtual mirror plane perpendicular to the Ta–Ta vector. Table 4 lists values of interatomic dimensions within the coordination sphere averaged for both molecules according to C_s symmetry. The pseudooctahedral environment around each metal atom is distorted to a considerable extent. A view along the Ta–Ta axis shown in Fig. 2 and the torsional angles listed in Table 5 show that SMe_2 is the ligand affected most by the deformation. It bends away from the Cl(2)–Ta(1)–Ta(2)–Cl(4) plane by *ca.* 45° due to spatial crowding, as indicated by short non-bonding S–Cl and Cl–C(7) contacts, which are about 3.25 and 3.45 Å, respectively. Such repulsion between a bridging SMe_2 and terminal Cl atoms in a dimeric Ta complex is seen in $Ta_2Cl_4(dmpe)_2(O)(SMe_2)$.[10] Since the distance from S and C(6) to Cl atoms *trans* to pivalate are also rather short, namely about 3.3 and 3.4 Å, the position of SMe_2 seems to be the optimal one allowed by the proximity of four Cl atoms. The other deformations are smaller, and while caused mainly by the positioning of SMe_2, may be also associated, to a smaller extent, with the terminal THF molecules.

Metal–metal bonding. While the tantalum to ligand bond distances are all very similar to corresponding ones in other Nb and Ta complexes, it is noteworthy that the Ta–Ta distance, 2.766(1) and

2.779(1) Å, in **1** and **2**, respectively, is somewhat longer (by 0.03–0.05 Å) than those previously reported[7] in dinuclear complexes of Nb(III) and Ta(III) with edge-sharing bioctahedral structures. We believe that this can be attributed principally to the steric crowding in the molecule and that a metal–metal double bond can be postulated here just as in other binuclear complexes of the trivalent metals. It is notable that the compound is shown by its display of a normal NMR spectrum to be diamagnetic.

The existence of a Ta=Ta bond is supported by the results of a Fenske–Hall[11] calculation, carried out on a simplified model,

$$Nb_2Cl_5(O_2CH)(SH_2)(H_2O)_2,$$

in which the experimental bond lengths and angles were retained. The results are summarized in the MO digram shown in Fig. 3. The σ and π orbitals each have predominant metal *d*-orbital parentage. The δ and δ^* orbitals, which are empty, are mainly localized on individual metal atoms. The calculation yields a π to δ orbital energy difference of about 16,000 cm^{-1}, which is in fortuitous agreement with the observed band in the visible spectrum at 16,400 cm^{-1} (610 nm).

Synthesis and properties. $C_4H_9CO_2Li$ readily

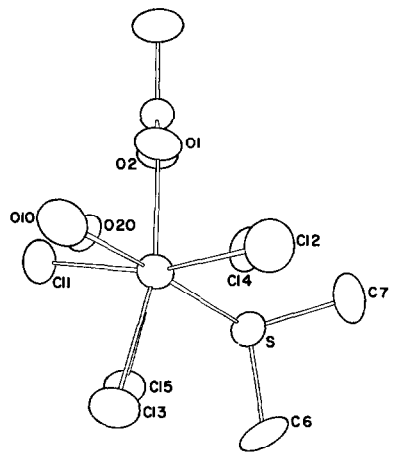

Fig. 2. A view of the $Ta_2Cl_5(O_2CC)(SMe_2)(O_{THF})_2$ skeleton along the Ta–Ta vector.

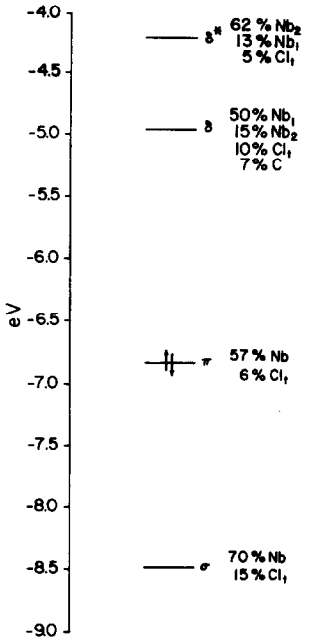

Fig. 3. An MO diagram for the model $Nb_2Cl_5(O_2CH)(SH_2)(H_2O)_2$ compound.

replaces one Cl ion in $Ta_2Cl_6L_3$ forming a green complex containing the bridging carboxylate. The product has to be isolated promptly as it undergoes further changes. If the reaction is carried out in a benzene/THF mixture the green color changes to brown after several hours. A small amount of the green species may still be obtained from this solution by solvent removal and extraction with THF/hexane but a brown, waxy material is the major product. When the latter is crystallized from a benzene/hexane mixture crystals with unit cell parameters matching those of $Ta_2Cl_6(SMe_2)(THF)_2$[7(b)] are obtained. This would indicate reversibility of the reaction but at this point it would not be appropriate to venture any specific explanation. With neat THF as the reaction medium the green color persists much longer but the brown material is also observed in the early stages of the workup. However, after purification the complex is quite stable in solution. The use of sodium pivalate instead of the lithium salt gives similar results but the reaction takes 1–2 weeks. The proton NMR spectrum was taken in $CDCl_3$ and is normal with respect to chemical shifts and line widths, in accord with the diamagnetism of the molecule. The *t*-Bu signal is at 1.18 ppm, which is only slightly different from the position for the free acid (1.21 ppm). The SMe_2 gives two signals at 3.03 and 3.37 ppm, consistent with the non-equivalence of the methyl groups. Their relatively large shift with respect to the free ligand (2.06 ppm) may be due to their proximity to the chlorine atoms. THF resonances are observed at 2.17 and 4.57 ppm. Based on intensity it is concluded that there is free THF in solution, as a result of crystallization from that solvent, and it undergoes exchange with the coordinated THF molecules. The spectrum in benzene is similar except that the chemical shifts for THF protons are somewhat different.

Although the reported complex is simply a product of ligand substitution in the starting material it is of importance in the area of multiple bonded complexes of Nb and Ta. As the first carboxylato complex of Ta(III) it shows that such species are stable and oxidation of low valent complexes of the heavier group V elements by oxo ligands can be avoided. It is also the first Nb(III) and Ta(III) dimer containing a bridging bidentate ligand. Such a species was not obtained with bis(diphenylphosphino)methane which instead bonded to Nb(III) in a chelating mode.7[a] The persistence of the Ta=Ta bond despite steric stress is notable. This compound may have potential as a reactant for synthesis of other binuclear compounds of low-valent tantalum.

(*Received* 10 *December* 1984; *accepted* 20 *February* 1985)

Abstract—The compound *trans*-$NbCl_2(dpm)_2$, Hdpm = 2,2,6,6-tetramethylheptane-3,5-dione, has been prepared and the molecular structure determined in each of two crystalline polymorphs by X-ray diffraction. The visible spectrum and the EPR spectrum have been measured and a Fenske–Hall calculation performed. The combined results give a reasonable and internally consistent picture of the electronic structure of the molecule. The HOMO is a b_{3g}-orbital (predominantly d_{yz}), while the two lowest-lying unoccupied orbitals (*ca* 16,000 cm^{-1} higher) are $b_{2g}(\sim d_{xz})$ and $a_g(\sim d_{x^2-y^2})$ orbitals, all in the D_{2h}-symmetry. The $b_{3g} \rightarrow b_{2g}$ and $b_{3g} \rightarrow a_g$ transitions are observed at 588.4 and 626.7 nm. The EPR spectrum in solution is a decet; the measured value of $\langle g \rangle$ is 1.930 and $\langle A_{iso} \rangle$ is 149 G. For the crystalline polymorph **1** the crystal data are: orthorhombic ($P2_12_12_1$), $a = 13.649(3)$ Å, $b = 18.166(4)$ Å, $c = 11.425(4)$ Å, $V = 2833(2)$ Å^3 and $Z = 4$. Polymorph **2** is monoclinic ($P2_1/n$) with $a = 12.288(5)$ Å, $b = 9.226(4)$ Å, $c = 12.545(4)$ Å, $\beta = 94.24(3)°$, $V = 1418(2)$ Å^3 and $Z = 2$. The molecule in **2** is centrosymmetric with virtual D_{2h}-symmetry. In **1** there are distortions in the chelate plane postulated to be due to packing forces. The two forms have comparable averaged values of interatomic dimensions.

Although the number of chemically and structurally well-defined complexes of niobium(IV) and tantalum(IV) has been growing rapidly in recent years,[1–3] their electronic structure and spectroscopic properties are still poorly defined,[4] even for the six-coordinate species with "octahedral" structures. These complexes have the simplicity of being d^1-systems, but they have the disadvantage that the metal atoms are in a high formal oxidation state, which means that charge-transfer transitions may occur at as low, or lower, energies than some *d–d* transitions, thus obscuring them. They also have rather large spin–orbit coupling constants [J = 750 cm^{-1} for Nb(IV) and a much higher, though imprecisely known, value for Ta(IV)].

We have isolated and structurally characterized the complex *trans*-$NbCl_2(dpm)_2$, where dpm represents the anion of dipivaloylmethane (Hdpm), $(CH_3)_3CC(O)CHC(O)C(CH_3)_3^-$, which has rhombic ($D_{2h}$) molecular symmetry. By combining the results of EPR and visible spectral measurements with a molecular orbital calculation (by the Fenske–Hall procedure[5]) we have been able to establish clearly at least some features of its electronic structure.

EXPERIMENTAL

All manipulations were performed under an atmosphere of argon using standard inert atmosphere techniques. $NbCl_5$ and 2,2,6,6-tetramethylheptane-3,5-dione (Hdpm) were purchased from Aldrich. $Nb_2Cl_6(SMe_2)_3$ was prepared as described previously.[6] Hdpm was stored over molecular sieves and degassed by a freeze–thaw method before use. The lithium salt, Lidpm, was obtained by reaction of *n*-BuLi with Hdpm.

Synthesis of $NbCl_2(dpm)_2$

A solution of Hdpm (0.7 cm^3, 3.4 mmol) in the 5 cm^3 of CH_2Cl_2 was added to a solution of $Nb_2Cl_6(SMe_2)_3$ (0.56 g, 1 mmol) in 20 cm^3 of CH_2Cl_2. The purple solution turned to deep blue after several minutes of stirring. After filtration the solvent was removed under vacuum, leaving a blue,

* Author to whom correspondence should be addressed.

waxy residue. Approximately 200 mg portions of the product were placed in glass tubes, which were then evacuated to about 10^{-3} torr and sealed. The sample end of an ampoule was placed in a furnace and the temperature was raised gradually in the course of 1 week to about 100°C. The sublimation afforded large blue crystals in *ca* 50% yield. A small amount of white non-volatile material was also observed in the tube.

Examination of the crystals on a diffractometer showed that two different forms were present, namely orthorhombic and monoclinic, **1** and **2**, respectively. The unit cell volume of **1** was almost exactly twice that of **2**, and the abundance of the former type of crystals was roughly twice the latter. Full crystallographic analysis showed that both types of crystals contain the same complex, $NbCl_2(dpm)_2$.

EPR spectra were recorded on an X-band Varian E-6S spectrometer. DPPH was used as a standard for the calculation of g values. To obtain the spectrum of pure $NbCl_2(dpm)_2$ the compound was prepared as described, sublimed and dissolved in toluene.

X-ray crystallography

Single-crystal X-ray analyses were carried out by application of general procedures that have been described elsewhere.[7] Relevant crystallographic data are summarized in Table 1. Polarization and Lorentz corrections were applied to the intensity data. No correction for absorption was made.

A Delaunay reduction (program TRACER) performed on both cells with the largest permissible

difference between any two reduced cell scalar products equal to 4.0 ruled out the possibility of transforming one cell into the other. In both cases the position of the Nb atom was derived from a three-dimensional Patterson function. The rest of the structure was developed by a sequence of alternating least-squares refinements and difference Fourier syntheses. After anisotropic refinement of all non-hydrogen atoms the hydrogen atoms bonded to the ring carbon atoms were located in the difference Fourier maps and included in the full matrix least-squares refinement. The two H atoms in the orthorhombic crystal were refined with an isotropic thermal parameter fixed at 4.0.

Tables of observed and calculated structure factors, anisotropic thermal parameters, complete lists of bond distances and bond angles, selected least-squares planes and short intermolecular contacts (26 pp.) have been deposited with the Editor at Queen Mary College. Positional parameters and isotropic thermal parameters have been forwarded to the Director, Cambridge Crystallographic Data Centre.

RESULTS

Molecular structure

Important bond distances and angles are presented in Tables 2 and 3, respectively. The atom-labelling scheme is defined in Fig. 1.

As can be seen in Table 2 the molecules of $NbCl_2(dpm)_2$ in both crystallographic forms are quite similar in terms of average values of bond distances and angles. In detail, however, there are some real differences between them. The monoclinic $NbCl_2(dpm)_2$, **2**, has a crystallographically imposed inversion center and its actual symmetry is very close

to D_{2h}. In the orthorhombic cell the molecule resides on a general position and owing to distortion in the NbO_4 plane, shown in Fig. 2, its symmetry is, at best, C_{2v}, even if the methyl groups are disregarded. The most prominent distortion is a 27° difference between the two O—Nb—O′ angles where O and O′ are in different chelate rings. The Nb—O bond lengths also differ by 0.1 Å. However, average values of the two quantities are comparable to those in the undistorted molecule in **2**, as is clear in Table 2.

Examination of unit cell packing (Fig. 3) and intermolecular contacts leads us to the conclusion that the deformations found in **1** are caused by packing forces, but we find that magnitude of the effects somewhat surprising. The orientation of methyl carbon atoms is quite revealing in this respect. In **2** the set of four *t*-butyl (*t*-Bu) groups has an approximate *mmm* symmetry. Such an arrangement seems to be the preferred one since, as discussed[8] for $Ni(dpm)_2$, where it also occurs, it minimizes the intramolecular contacts. The closing of the O(1)–Nb–O(2) angle in **1** results in a small separation between two of the C_4H_9 groups, which apparently prevents them from orienting so as to be related by a mirror plane. The shortest contact is between C(11) and C(5)′ and it is equal to 4.48 Å. On the other side, the two *t*-Bu groups are oriented as in **2** and there is a cavity between two pairs of methyl groups. That space is occupied by C(10) and C(11) atoms from another molecule. The intermolecular contacts between carbon atoms in this region are around 4 Å, which compares well with the accepted van der Waals' radius for a methyl group, viz. 2 Å. Naturally, in **2** there are also intermolecular contacts of the order of 4 Å, but they are directed away from the chelate ring.

Apart from the distortion in **1** the $NbCl_2(dpm)_2$ molecules are normal in terms of features expected for octahedral β-diketonate complexes. The $Nb(chelate)_2$ unit is essentially planar with somewhat more pronounced deviations in the orthorhombic form. The average Nb–O distance of

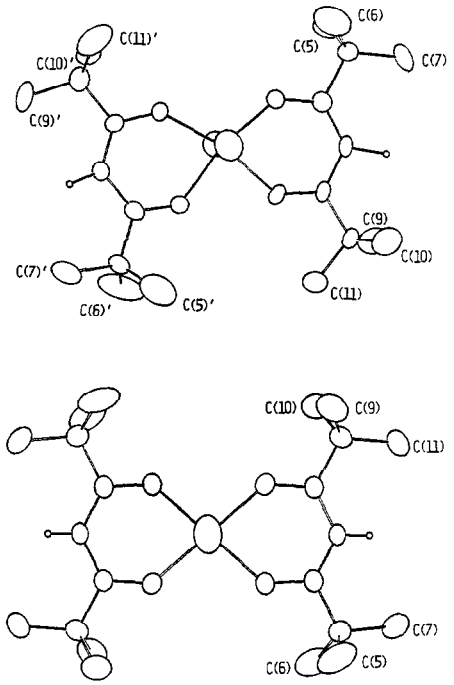

Fig. 2. A view of the $NbCl_2(dpm)_2$ molecules from above the chelate plane: upper—orthorhombic, **1**; lower—monoclinic, **2**.

ca 1.98 Å is 0.15 Å shorter than in the eight-coordinate $Nb(dpm)_4$ complex.[9] Steric crowding is clearly the major factor contributing to the lengthening of the bond in the latter case. We believe it is reasonable to assume, for purposes of analyzing the spectra and bonding, that the molecule in solution has true D_{2h}-symmetry.

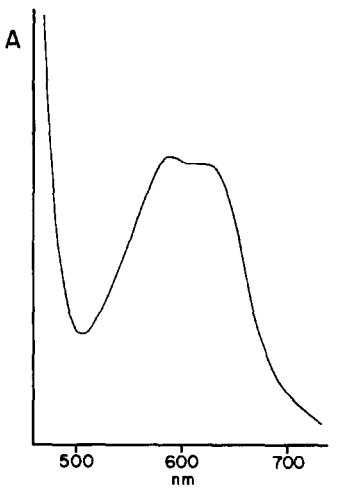

Fig. 4. The UV–visible spectrum of $NbCl_2(dpm)_2$ in toluene.

Spectroscopic data and Fenske–Hall calculations

The UV–visible spectrum of $NbCl_2(dpm)_2$ is shown in Fig. 4. The doublet band with maxima at 588.4 and 626.7 nm is very similar to that in $NbCl_2(acac)_2$.[10] In the latter an additional doublet is observed at higher energy but an intense charge-transfer band beginning around 500 nm covers this region in the dpm derivative.

The blue solutions obtained by reacting $Nb_2Cl_6(SMe_2)_3$ with Hdpm and Lidpm contained several paramagnetic species as evidenced by the complexity of low-temperature EPR spectra shown in Fig. 5. $NbCl_2(dpm)_2$, purified by sublimation, gives at room temperature the expected 10-line signal with $\langle g \rangle = 1.930$ and $\langle A_{iso} \rangle = 149$ G. At −196°C a well-resolved EPR spectrum consistent with the rhombic symmetry of the complex is obtained. It is noteworthy that spectrum C in Fig. 5 appears to be due to superposition of the signal from $NbCl_2(dpm)_2$ (predominant) and some other paramagnetic complex.

A Fenske–Hall calculation[5] has been performed on the model compound $NbCl_2(acac)_2$. Atomic parameters from the centrosymmetric $NbCl_2(dpm)_2$, **2**, crystal structure, idealized to D_{2h}-symmetry, were used, and a right-handed coordinate system was chosen with the Z-axis along a Nb–Cl bond vector and the X-axis directed from the niobium atom to the central carbon atom of a dpm ligand. As seen in Fig. 6, these calculations place the d_{yz}-orbital lowest in energy and singly occupied. The d_{xz} and $d_{x^2-y^2}$ orbitals are 2.223 and 2.470 eV higher in energy, respectively, and the a_u and b_{3g} combinations of the C=O π^*-orbitals are above these. The other two combinations of C=O π^*-

orbitals, as well as the remaining *d*-orbitals, are much higher in energy (> 15 eV above the d_{yz}-orbital).

DISCUSSION

Synthesis

The work reported here was begun in response to a recent report[11] describing the synthesis and properties of several β-diketonato complexes of niobium(III), which were assigned structures rather different from those previously recognized[12] for compounds with the metal atoms in oxidation state III. We were particularly interested in the reported compound $Nb_2Cl_3(dpm)_3$ and attempted to prepare it in crystalline form by the recommended method. Our attempts to obtain crystals from solution failed and we therefore tried to obtain them by sublimation. It was in this way that we obtained the two crystal forms of the title compound. There have been a few β-diketonato complexes of niobium and tantalum reported previously.[3,9,10,13,14] The +4 oxidation state is represented by a postulated nine-coordinate $Nb(LL)_4 \cdot$dioxane,[13] eight-coordinate $Nb(LL)_4$[9,13] and octahedral $NbCl_2(LL)_2$[10,13] species. Apparently no Ta(IV) β-diketonato complex has been characterized. So far a complete structural analysis has been carried out only for the dodecahedral $Nb(dpm)_4$.

Both the eight-coordinate $M(LL)_4$ and *trans*-$MX_2(LL)_2$ complexes, where X may be a mono-anionic or neutral ligand, are common types of β-diketonato compounds.[14]

Electronic structure and interpretation of the spectra

There are now three reported complexes of the stoichiometry $NbCl_2$(β-diketonate)$_2$, with acetylo-acetonate,[10] dibenzoylmethane (dbm)[13] and dpm. It is reasonable to expect that they would have analogous structures, and the similarity of the UV–visible spectra for the acac and dpm compounds supports this. For the dbm complex the diffuse reflectance spectrum was reported. Although it shows a band at 17.4 kK, which correlates well with what is seen for the other two compounds, the rest of the spectrum is somewhat more complicated. Since no information concerning the solution spectrum is available and only the band positions were reported we shall not try to explain this apparent discrepancy.

The results of the Fenske–Hall calculation provide an excellent basis for interpreting both the visible and EPR spectra. The doublet observed in the visible spectrum with maxima at *ca* 16,000 cm^{-1} and *ca* 17,000 cm^{-1} can be assigned to the following calculated $d \rightarrow d$ transitions: $yz \rightarrow xz$ (calc. 17,700

cm^{-1}) and $yz \rightarrow x^2-y^2$ (calc. 20,200 cm^{-1}). In view of the well-known tendency of the Fenske–Hall method to place virtual orbitals at energies that are too high, the agreement here is very satisfactory. No higher $d \rightarrow d$ transitions are expected until energies well above the onset of ligand-to-metal charge-transfer transitions. Because of the difficulties in handling solutions of this extremely air-sensitive compound, we have not attempted to record the spectrum in the charge-transfer region.

The EPR spectrum is also nicely accounted for by the results of the calculation. Using the standard method of calculating g values for a d^1-ion with spin–orbit coupling[15] the expressions for the three components of the diagonalized g tensor are:

$$g_x = 2 - \frac{6\lambda}{\Delta E(z^2)} - \frac{2\lambda}{\Delta E(x^2-y^2)},$$

$$g_y = 2 - \frac{2\lambda}{\Delta E(xy)},$$

$$g_z = 2 - \frac{2\lambda}{\Delta E(xz)},$$

where an expression like $\Delta E(xz)$ means the orbital energy difference between the lowest d-orbital (d_{yz}) and an upper one such as the d_{xz}-orbital. For Nb(IV) the free-ion value of λ is 750 cm^{-1} but the effective value in the complex is surely no more than 80% of this. We may also use the experimental values of $\Delta E(xz)$ and $\Delta E(x^2-y^2)$ and take the true values of $\Delta E(z^2)$ and $\Delta E(xy)$ to be about 50% of those calculated. On this basis we obtain the following calculated g values:

$$g_x = 1.877, \quad g_y = 1.988 \text{ and } g_z = 1.925,$$

from which a $\langle g \rangle$ value $[(g_x^2+g_y^2+g_z^2)/3]^{1/2}$ of 1.931 is obtained, in good agreement with the measured value of 1.930. The measured $\langle A_{iso} \rangle$ value of 149 G is quite reasonable when compared to such parameters in some other Nb(IV) complexes.[3,16]

Abstract—The complex [Pbc[15]crown-5]$(SCN)_2$ was synthesized and characterized spectroscopically (IR and FIR range) and the crystal structure was determined by X-ray diffraction on a single crystal (orthorhombic space group $Pmc2_1$). The structure was solved by Patterson synthesis with least-square refinement. The final R-value is 0.0328. Two Pb-atoms and two unidentical halves of the ligand were found in the asymmetric unit. For each complexed lead cation and each half of the crown ether there exists a plane of reflexion, whereby C18 and C28 are disordered. There is, however, no centre of inversion between these unidentical halves. The elementary cell comprises four units and two different types of two centrally coordinated Pb cations. Both lead cations are eight-coordinated. In the case of Pb1 the eight donor centres are the five O-atoms of the ligand and three N-atoms of the thiocyanates. For Pb2 these are five oxygens of the ligand, one nitrogen and two sulphurs of the three thiocyanates. In this complex the thiocyanate ligands occur in both ionic and covalent states. The complexation of the crown ether and the two different species of thiocyanate anions are indicated too by typical shifted absorption bands in the IR spectra. The vibrations in the FIR region can be assigned to the interactions between lead and the donor groups.

The complexation of main-group elements of the periodic system, especially the alkali and earth-alkali metals, by substituted and unsubstituted crown ethers has been widely studied.[1,2] However there is very little analogous work on other elements (metals); in particular the few investigations on the complexation with the ligands [18]crown-6, [15]crown-5 and [12]crown-4 have seldom ended in X-ray structural analysis.[5,6] The lanthanides[3,4,7] and uranium[11] are exceptions. In spite of that there are sufficient data indicating the capability of all metal ions to form complexes with polyethers of different sizes.

In the course of the systematic investigation of the complexation behaviour of the main group elements in the presence of [15]crown-5 we obtained the 1:1 or more correctly the 2:2 complex of $Pb(SCN)_2$.

To elucidate the structural and conformational features of the complex one has to resort to other complexes involving the same ligand for comparison since the necessary information from X-ray diffraction are lacking. Important complexes in this connection are those with direct metal–oxygen interactions such as $[Co(II)L(NO_3)_2]$,[5] $[Eu(III)L(NO_3)_3]$,[7] [NaL SCN][9] and $[Ba(L_2)Br_2]$[8] (L = [15]crown-5).

EXPERIMENTAL

The complex was prepared by reacting freshly distilled [15]crown-5 (Fluka) with $Pb(SCN)_2$ in

purified methanol. The $Pb(SCN)_2$ was obtained by dissolving freshly precipitated $Pb(OH)_2$ in 5% aqueous HSCN, which in turn was prepared from $Mg(SCN)_2 \cdot 4H_2O$ over an ion exchanger (in the H_3O^+ form). Crystallization took place in methanol/ether (80/20) by gradually lowering the temperature of a thermostat. The compound was characterized by elemental analysis: Calc. (found) Pb: 38.11 (38.2); C: 26.51 (26.42); H: 3.72 (3.80); N: 5.15 (5.18)%; by m.p. (480 K) as well as IR, FIR, ^1H and ^{13}C NMR spectroscopy. The typical IR and FIR bands are listed in Table 1. For IR spectrometry we used a Perkin–Elmer 683 grating spectrometer (Nujol mulls) and a Bruker FT-IR spectrometer (polystyrene matrix).

The NMR spectra were recorded on a Bruker WH 80 spectrometer in about 0.01 M solution in CD_3CN (^1H) and saturated solution in CH_3OH/CH_3OD (^{13}C) at room temperature with TMS as internal standard.

The colourless compound crystallizes in the orthorhombic system with $a = 1236.6 \pm 0.2$ pm, $b = 865.1 \pm 0.1$ pm, $c = 1679.9 \pm 0.2$ pm and belongs to a space group $Pmc2_1$. $V = 1797.13$ nm^3, $Z = 4$ ($8 \times 1/2$), crystal size = $0.11 \times 0.2 \times 0.5$ mm; density (calc.) = 2.009 g cm^{-3}.

The crystal was measured at room temperature on a STOE four-circle automatic diffractometer using Ni-filtered Cu-K_α radiation. From the 1667 reflexes collected ($2.5 < 2\theta < 64.5$) 1649 were found to be independent of symmetry.

The structure was solved by the Patterson synthesis. Programs used and structural factors are cited in the appendix.[10] The refinement was accomplished with the help of the least squares method employing an isotropic extinction function which is based on the absorption-corrected data ($\mu = 204$ cm^{-1}). All hydrogen atoms were placed at calculated positions, with a temperature factor of $u = 5.7$ pm^2 and at a distance of 105 pm from the

DISCUSSION

When $Pb(SCN)_2$ complexes the polyether [15]crown-5 eight-coordination around Pb is retained. The occupation and therefore the geometry of the coordination polyhedron are however altered.

The IR-absorption bands of the thiocyanate indicate a change of coordination of the SCN^- in $Pb(SCN)_2$ upon complexation with crown ether, i.e. from S to N. A shoulder at higher wave number represents SCN^- coordinated through sulphur. In the crystal structure this can be correlated well with the position of the SCN found generally (No. 3) (Fig. 1).

Furthermore, the intensities of these bands reveal that there has been a change in the ratio of coordination of the anions between N and S.

The C–O–C valence vibrations of the crown ether are shifted to lower wave numbers upon complexation. Noteworthy in this connection. is the appearance of three bands which can be correlated with the three different cation–oxygen donor distances shown by the X-ray diffraction analysis.

* Final atomic coordinates, thermal parameters and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

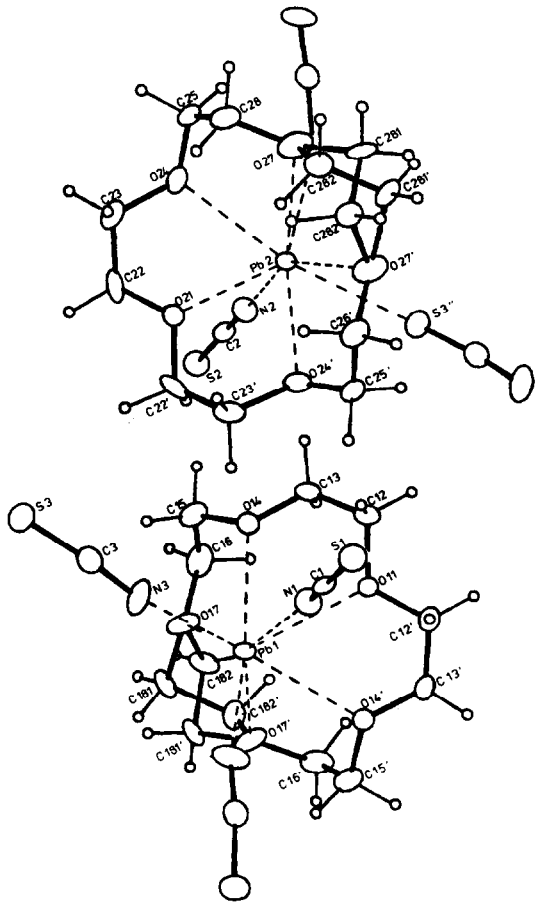

Fig. 1. ORTEP drawing of the asymmetric unit.

Complexes with approximately equal cation–donor distances do not exhibit such large splittings.

In the FIR region, between 700 and 100 cm^{-1} (Fig. 3) several absorptions appear, which cannot be assigned unambiguously. Absorptions between 568 and 509 cm^{-1} represent deformational vibrations of the macrocyclic ligand. The split strong band at 470/460 cm^{-1} again shows the deformation of the two types of thiocyanate. Bands below 400 cm^{-1} represent the different vibrations between the lead cation and sulphur (389, 360 cm^{-1}) and nitrogen (323, 296, 281, 266 cm^{-1}). This attribution of thiocyanate-cation vibrations is analogous to attributions in the cited literature.[13]

The bands below 250 cm^{-1} can be assigned to the stretching vibrations between Pb^{2+} and the ether oxygens and the deformation vibrations of the coordination sphere of the cation.

In the uncomplexed $Pb(SCN)_2$, lead is coordinated in a distorted tetragonal antiprism, in which each plane is formed by two nitrogen and two sulphur atoms.[12] Upon complexation to the crown ether the coordination polyhedron of the metal is changed to a pseudo-antiprism the base of which is formed by the five O-atoms of the polyether and the upper surface by the donors of the thiocyanates. In the case of Pb1 only N-donors form the upper surface of the pseudo-antiprism whereas two S and one N

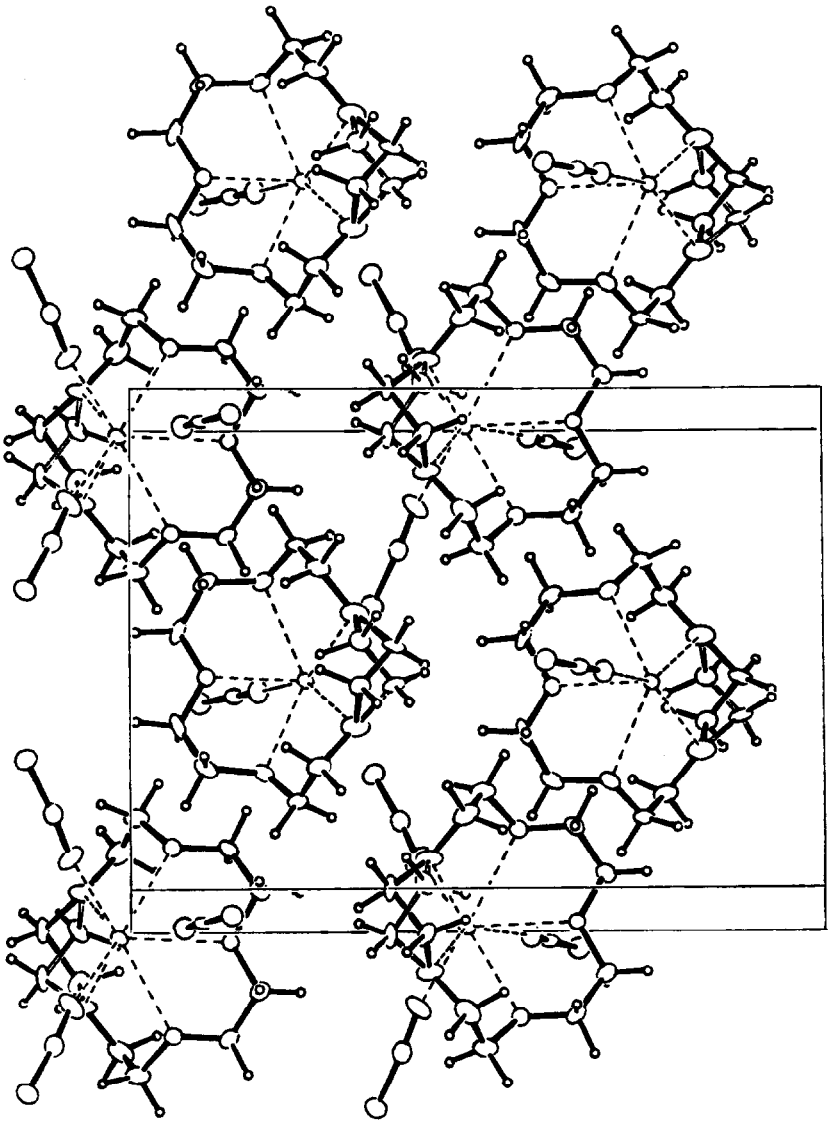

Fig. 2. ORTEP drawing of the unit cell contents.

atom are involved in the case of Pb2. This situation explains the splitting and the ratio of the intensities of the ν_{CN} bands encountered in the IR spectrum.

The ^{1}H NMR spectrum of the complex shows two signals at 3.74 and 3.81 ppm which were slightly shifted to lower field compared to the uncomplexed ligand (3.58 ppm). These two signals represent the two different species of macrocyclic ligand in the complex.

In contrast to the ^{1}H NMR, the ^{13}C NMR signal of the complex shows no significant change in chemical shift compared with that of the free polyether.

A conspicuous feature of this structure is that the asymmetric unit contains two halves of the crown ether and two lead cations and so, despite the formal 1 : 1-stoichiometry, both central cations have different environments. It is not uncommon that in sandwich complexes like $[Ba(L_2)Br_2]$[8] two different conformations of the ligand about a central atom are possible. The occurrence in the crystal lattice of two alternative conformations, each bearing a central atom is, on the contrary, unprecedented (Fig. 2: elementary unit cell). The two ligands in the Ba^{2+} complex have different energies as can be deduced from the deviation of the dihedral angle of the O–C–C–O unit from the theoretical 60°.

A comparison of the dihedral angles of the $Pb(SCN)_2$ complex with those of the complexes in Table 4 reveals that the conformation of the ligand in the lead complex assumes an intermediate position, although the C18 and C18′ as well as the C28 and

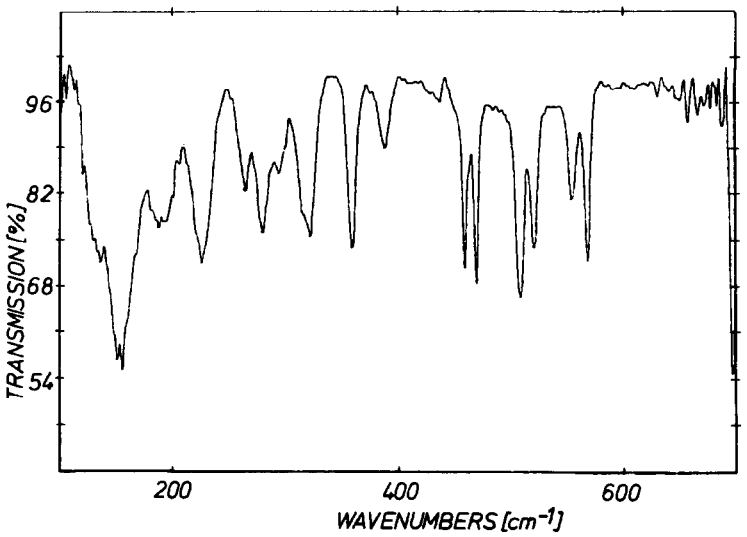

Fig. 3. FT-IR-spectrum of [Pbc[15]crown-5](SCN)$_2$.

C28′ are disordered. A special characteristic of the complex is the alternating position of the disorder in the crystal lattice (Fig. 2). A look at the planes described by the polyether shows a displaced sandwich structure in which the enclosed lead atoms are facing themselves. In spite of that there are no direct Pb–Pb interactions; the Pb–Pb distance is 775 pm. The deviations of the atoms and the distance of the lead atoms from the best planes are summarized in Table 5.

Table 5. Deviations of the oxygens from the plane and some other distances in the coordination sphere of lead

Ring 1 (O11, O14, O17, O14′ and O17′)

(*Received* 2 *January* 1985; *accepted* 12 *February* 1985)

Abstract—The adsorption of a long hydrocarbon chain oxine derivative, 7-(4-ethyl-1-methyloctyl)-8-quinolinol, on the macromolecular Amberlite XAD-7 support is shown by FT-IR spectroscopy to be the result of only weak extractant–support interactions. It is also shown that the chelation ability of the extractant towards gallium(III) does not suffer from the presence of the solid support. Finally the stereochemistry (*fac* or *mer* configuration) of the tris-7-(4-ethyl-1-methyloctyl)-8-quinolinato gallium(III) complex formed either in solution in an organic diluent or on the support is discussed on the basis of ^{1}H and ^{13}C NMR and FIR data.

Solvent-impregnated resins have attracted considerable attention since selective liquid ion-exchangers such as LIX 63 (an aliphatic alpha-hydroxyoxime), Kelex 100 (an 8-quinolinol derivative), etc., and high specific area macroreticular adsorbents have become commercially available. Indeed, the combination of appropriate extractants, adsorbents and eventually additives allows the formulation of efficient reactive resins for both analytical and industrial purposes.

In the present work we consider the chelation of gallium(III) in alkaline media (0.5 to 4 M NaOH) by a long hydrocarbon chain oxine derivative, 7-(4-ethyl-1-methyloctyl)-8-quinolinol, adsorbed on a macromolecular resin, the Amberlite XAD-7 support. The 7-alkyl-8-quinolinols are important in the hydrometallurgy of gallium[1] and germanium,[2–4] and their impregnated forms could be particularly well adapted for the recovery of traces of these two metals from zinc sulphate (Ge), zincate (Ga) or aluminate (Ga) solutions. Up to date, little has been done to elucidate the behaviours of impregnated extractants. Two papers published recently have proposed the use of ESR spectroscopy for elucidating the properties of grafted[5] or impregnated[6] chelating agents. However, the technique is limited to the study of the paramagnetic complexes such as those of copper(II). EXAFS spectroscopy has also been proposed,[7] but has not yet been widely used. Our investigation of the 7-(4-ethyl-1-methyloctyl)-8-quinolinol impregnated support is mainly based on FT-IR spectroscopy.

7-(4-Ethyl-1-methyloctyl)-8-quinolinol, a pale yellow viscous liquid at room temperature easily soluble in the organic solvents but insoluble in water,[8] is the main active component of a commercially available product (post-1976) Kelex 100 from Shering. The first spectroscopic investigation of Kelex 100 was reported by Ashbrook in 1975.[9] At that time, the active substance of Kelex 100 was 7-(1-ethenyl-3,3,5,5-tetramethylhexyl)-8-quinolinol. The IR evidence then given concerned only the presence of a C=C double bond in the substituent group and the involvement of the phenolic OH function in intramolecular hydrogen bonding. More recently, Demopoulos and Distin[10]

* To whom the correspondence should be addressed.

have identified the major constituents of post-1976 Kelex 100 by GLC, mass spectrometry and IR spectroscopy. The IR absorption spectra of vacuum distilled Kelex 100 (a two component-product) and of its copper chelate have been reported (4000–500 cm^{-1}), but some of the assignments given are speculative. Kelex 100 has not yet received much attention from the NMR spectroscopists. Indeed, only its ^1H NMR spectrum (for pre-1976 Kelex 100) has been partially reported.[9] On the other hand, an interesting literature has been published on ^1H and ^{13}C NMR spectroscopy of various oxine derivatives.[11–17]

In liquid–liquid systems (e.g. water/dodecane), 7-(4-ethyl-1-methyloctyl)-8-quinolinol forms with gallium(III) a three-liganded complex, GaL_3, the structure of which is assumed, as the one of the tris-chelated metal oxinates to be octahedral.[18] Nevertheless, no spectroscopic evidence of this has been given.

Due to the absence of comprehensive bibliographical data, the IR spectra of non-adsorbed 7-(4-ethyl-1-methyloctyl)-8-quinolinol and of its gallium(III) complex have been carefully examined in this work, preliminary to the study of the adsorbed species. This IR investigation has been complemented by Raman spectroscopy.

EXPERIMENTAL

(1) *Reagents*

7-(4-Ethyl-1-methyloctyl)-8-quinolinol (HL) was isolated from Kelex 100 (Shering) by: (i) vacuum distillation, (ii) precipitation and recrystallization of its lead complex, (iii) regeneration with 2 M H_2SO_4, and finally (iv) vacuum distillation.[18] Found (calc.): C, 80.27 (80.27); H, 9.82 (9.70); N, 4.51 (4.68); O, 5.16 (5.35)%.

Gas chromatography revealed that the product so obtained contained only one component, whereas Kelex 100 purified by a mere vacuum distillation was a three-component product (approx. percentage: 87, 10 and 3%). The molecular mass deduced from the mass spectrum of completely purified Kelex 100 (one component) was 299 as expected.

Tris-7-(4-ethyl-1-methyloctyl)-8-quinolinato gallium(III) complex (GaL_3) was obtained by mixing a 0.12 M solution of HL in hexane with a 0.4 M aqueous alkaline (1 M NaOH) solution of gallium(III). At the equilibrium, the two phases were separated. The hexane solution was then filtered on Whatman ^{1}PS phase separator and pumped dry to give a bright yellow compound. All attempts at recrystallization have failed to produce a crystalline solid. Found (calc.): C, 74.96 (74.71); H, 8.63 (8.72); N, 4.19 (4.36); Ga, 6.74 (7.23)%; Na < 50 ppm (0).

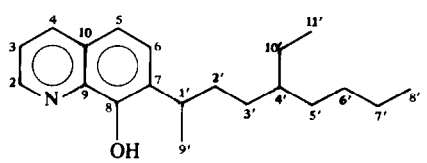
Tris-8-quinolinato aluminium(III) complex [$Al(Ox)_3$] was prepared by precipitation from homogeneous solution.[19] Found (calc.): C, 70.10 (70.53); H, 4.02 (3.92); N, 9.07 (9.14); Al, 5.75 (5.88)%.

The Amberlite XAD-7 resin (Serva) of practical grade quality was carefully washed with ethanol and water, and impregnated with HL in a classical way.[20,21] For gallium(III) fixation, the impregnated support was equilibrated with an aqueous alkaline (0.5 to 4 M NaOH) solution of gallium(III) prepared from gallium oxide (Rhône-Poulenc Co). After separation of the two phases, the gallium loaded resin was rinsed with water and dried before spectroscopic investigation.

The other reagents from Prolabo were all analytical grade.

(2) *Apparatus*

The spectroscopic instruments used were a Nicolet 7199 Fourier transform infrared spectrometer (4000–400 cm^{-1}) [32 co-added interferograms were scanned at 2 cm^{-1} resolution] and an IFS 113 V Bruker Fourier transform infrared spectrometer (400–60 cm^{-1}) [100 co-added interferograms were scanned at 4 cm^{-1} resolution] for FT-IR and far FT-IR spectroscopy, respectively; a T 800 Coderg model for Raman spectroscopy; a Varian EM 390 model (^1H) and a Varian FT 80 A model (^{13}C) for NMR measurements. The chemical shifts (δ) are referenced to Me_4Si (^1H and ^{13}C). Gas chromatography analyses were performed with an IGC 16 Intersmat chromatograph equipped with a 1.50 m 10% SE 30/PAW 60/100 column ($\phi = 1/8$). Mass spectra were recorded by the Laboratoire de Spectrométrie de Masse (E.N.S.C.P., Paris) with a Ribermag 10-10 mass spectrometer.



(3) *Analytical*

Microanalyses were performed by the Service Central d'Analyse (CNRS, Vernaison). Gallium(III) titrations in aqueous phases were carried out by atomic absorption spectrophotometry (at 294.4 nm) in an air–acetylene flame with a Varian AA6 spectrophotometer.

RESULTS AND DISCUSSION

(1) 7-(4-*Ethyl*-1-*methyloctyl*)-8-*quinolinol* (HL)

The formula of 7-(4-ethyl-1-methyloctyl)-8-quinolinol is given below:

The structure of the alkyl chain has been confirmed by selective irradiation NMR measurements.[22]

(a) *The non-adsorbed molecule.* The IR spectra of HL (spectrum 1 in Fig. 1 and 1 in Fig. 2) differ significantly from the one reported by Demopoulos and Distin[10] for vacuum distilled Kelex 100 (a two component product), especially in the range of the C–H stretching frequencies. Our spectrum exhibits four strong bands (*c*, *d*, *e* and *f* in Fig. 1) at 2957, 2927, 2871 and 2858 cm^{-1}, ascribed to the stretching modes of the methyl and methylene groups, and a weak band (*b*) at 3055 cm^{-1} corresponding to an aromatic C–H stretching vibration.

The band (*a*) at 3386 cm^{-1} is due to the stretching frequency of the intramolecularly hydrogen-bonded O–H group. Upon dilution of HL in carbon tetrachloride to 5×10^{-3} mole l^{-1} (2 mm cell path) this band still located at 3395 cm^{-1} confirms the presence of the chelate species.

By comparison with other heteroatomic cycles like pyridine, naphthalene, quinolines and phenols,[23] the bands observed at 1576 (*g*), 1505 (*h*), 1463 (*i*), 1435 (*j*), 1408 (*k*), 1376 (*l*) and 1331 (*m*) cm^{-1} are assigned to ring vibrations. These modes give rise to strong Raman lines. The 1463 and 1376 cm^{-1} bands also contain contributions due to the bending modes of the methyl and methylene groups.

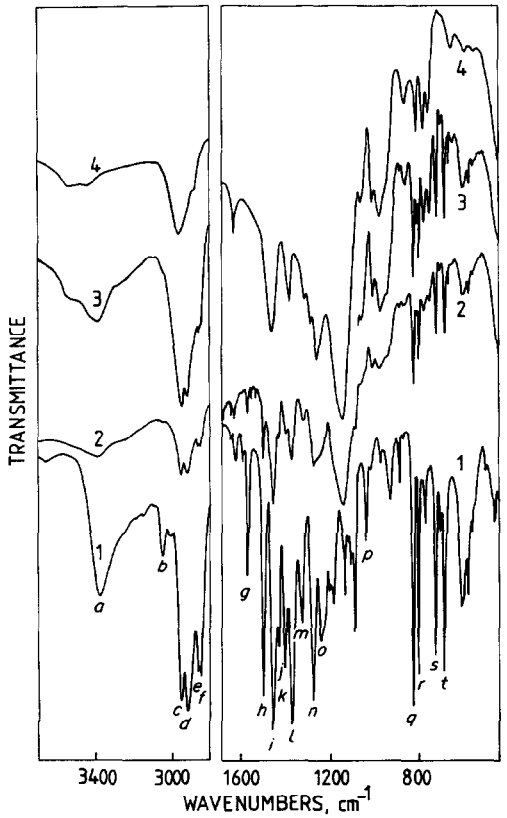


Fig. 1. IR spectra of (1) HL as a film on a CsBr disc; (2) HL 0.73 g/g on Amberlite XAD-7 [KBr pellet]; (3) HL 0.31 g/g on Amberlite XAD-7 [KBr pellet]; (4) Amberlite XAD-7 [KBr pellet].

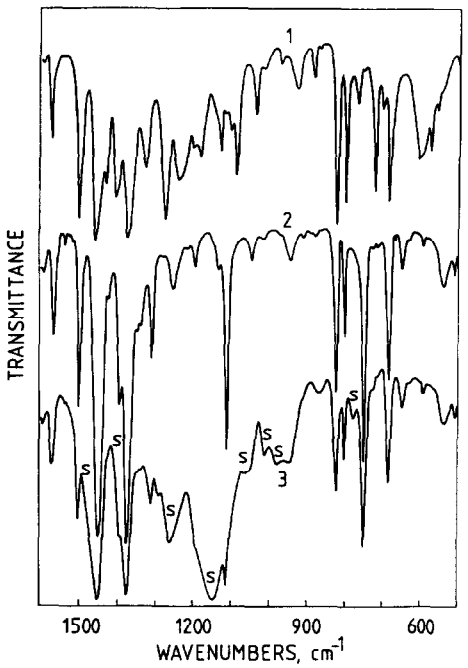

Fig. 2. IR spectra of (1) HL as a film on a CsBr disc; (2) GaL_3 as a film on a CsBr disc; (3) HL 0.73 g/g on Amberlite XAD-7 after complete reaction with gallium(III) [KBr pellet]. (S = support.)

The two bands occurring in substituted phenols between 1200 and 1300 cm^{-1} represent O–H deformation and C–O stretch which interact somewhat. Following Sharma *et al.*[23] and Mecke and Rossmy,[24] but in disagreement with Demopoulos and Distin,[10] the highest of the two frequencies located at 1279 cm^{-1} (*n*) is assigned to the C–O stretching mode whereas the band at 1244 cm^{-1} (*o*) is attributed to the O–H in-plane bending mode.

The ring breathing vibration is well known to give rise to a very strong and polarized band in the Raman spectrum. It is the reason why we assign this mode to the strongest Raman band at 724 cm^{-1} and, at the same frequency, to the strong band (*s*) observable on the IR spectrum. In the same spectral range, the IR bands at 826 (*q*), 803 (*r*) and 687 (*t*) cm^{-1} correspond to the out-of-plane C–H bending vibrations of the aromatic ring.

The Raman spectrum presents a strong band at 1040 cm^{-1} corresponding probably to a ring vibration and four bands at 429, 460, 501 and 560 cm^{-1}. The first two bands are assigned, by analogy with pyridine, to out-of-plane ring deformations, and the two others to in-plane ring deformations.

(b) *The adsorbed molecule.* Two impregnated supports containing respectively 0.31 and 0.73 g/g of HL (gram of HL per gram of dry Amberlite XAD-7 resin) have been prepared and investigated. It must be pointed out that, in the two cases, the content of HL is significantly lower than the loading capacity of the support (about 1.7 g/g),[3] so that all HL is presumably adsorbed on the inner surface (specific area: 450 m^2/g)[25] of the support, and not merely retained by capillarity in its pores.

The IR spectra of the two impregnated supports have been recorded (spectra 2 and 3 in Fig. 1). Examination of these spectra shows that the retention of the 7-(4-ethyl-1-methyloctyl)-8-quinolinol molecules by the Amberlite XAD-7 support does not involve any significant shift in the frequency of the normal modes of the alkyl chain or of the cycles of these extractant molecules: e.g. band *c* 2957.4[(i)], 2959.8[(ii)], 2959.9[(iii)] and 2958.7[(iv)], band *s* 724.5[(i)], 724.0[(iii)] and 724.1[(iv)] with: (i) HL as a film on a CsBr disc, (ii) HL in solution (5×10^{-3} M) in CCl_4, (iii) HL on XAD-7 (0.31 g/g) and (iv) HL on XAD-7 (0.73 g/g). Such an observation suggests that there is no strong interaction between HL and the support.

(2) *Tris-[7-(4-ethyl-1-methyloctyl)-8-quinolinato] gallium*(III), GaL_3

(a) *The non-adsorbed complex.* In liquid–liquid systems (e.g. water/dodecane), HL has been shown by the slope analysis technique to form a three-liganded complex of gallium(III): GaL_3.[18] Microanalysis obtained for the compound isolated from an hexane solution of HL treated with a large excess of gallium(III) (in solution in aqueous 1 M NaOH) confirm this result (experimental section). The tris-[7-(4-ethyl-1-methyloctyl)-8-quinolinato] gallium(III) complex has been investigated in the present work both by IR spectroscopy and NMR spectrometry.

IR (4000–400 cm^{-1}). The IR spectrum of gallium(III) loaded 7-(4-ethyl-1-methyloctyl)-8-quinolinol shows several modifications compared with the spectrum of the free reagent (spectra 1 and 2 in Fig. 2). The main change is the shift of the C–O stretching frequency from 1279 to 1114 cm^{-1}. The band at 1114 cm^{-1} has already been observed by Rane and Ravi[26] in the IR spectra of cobalt(II) and nickel(II)-8-quinolinates, and is taken by the authors as a characteristic band for the identification of the bond between the metal ion and the 8-quinolinate anion through oxygen.

Apart from the expected effects related to hydrogen replacement in the O–H group, some fundamental frequencies suffer significant shifts on coordination to the metal. As an example, the breathing mode shifts from 724 to 751 cm^{-1}. A similar effect was also observed when pyridine is coordinated and was explained by Filimonov and Bystrov[27] by an increase in the sigma nature of the carbon–nitrogen bonds of the ring, increase which strengthens these bonds.

FIR (500–80 cm^{-1}). In the FIR region, the metal–ligand vibrations ν(Ga–O) and ν(Ga–N) are expected. The vibrational analysis can give information about the structure of the complex and the strength of the metal–ligand bonds. As the normal tris metal oxinates $M(Ox)_3$, GaL_3 is expected to be octahedral. However, the complex can exist in *fac* (1,2,3 isomer) and *mer* (1,2,6 isomer) forms. In the *fac* isomer all three chelate rings are geometrically and magnetically equivalent; conversely, in the *mer* isomer they are not. On the basis of their ^1H NMR spectra, the aluminium(III), cobalt(III) and rhodium(III) oxinates have been shown to contain three unequivalent ligands, and logically to exist in solution in their *mer* configuration.[11] Nevertheless in a previous work[28] based on FIR data, the conclusion was reached that $Co(Ox)_3$ might exist in solution only as the *fac* isomer, whereas the solutions of $Al(Ox)_3$ and $Fe(Ox)_3$ might contain a mixture of the *fac* and *mer* isomers. More recently, Ohkaku and Nakamoto[29] concluded from the presence of only four metal–ligand bands (identified by the metal isotope technique) in the FIR region that $Fe(Ox)_3$ is *fac* in the solid state.

The *fac* configuration of octahedral GaL_3 would be of C_3 symmetry, whereas the *mer* configuration would be of C_1 symmetry. In C_3 symmetry, one expects four IR-active metal–ligand stretching bands ($2A + 2E$), whereas six bands are expected for C_1 symmetry. The IR spectrum of GaL_3 (spectra 1 and 2 in Fig. 3) presents a simple pattern in the FIR region: a strong and large band (a') at 299 cm^{-1} (304 cm^{-1} in solution), a weaker band (b') at 240 cm^{-1} (241 cm^{-1} in solution) and a very weak band (c') at 213 cm^{-1}. The two strongest bands (a' and b') must be assigned to the metal–ligand stretching frequencies since the free ligand exhibits only weak absorptions in that spectral range (spectrum 6 in Fig. 3). The assignment of these two modes were drawn according to the work of Ohkaku and Nakamoto[29] on metal complexes of 8-hydroxyquinoline. Their analysis using the metal isotope technique points out that in the IR absorption spectrum the metal–oxygen stretching band is generally more intense and located at a higher frequency than the metal–nitrogen stretching band. Therefore the strong band (a') at 299 cm^{-1} is assigned to the Ga–O stretching mode, whereas the weaker one (b') at 240 cm^{-1} is assigned to the Ga–N stretching mode. The few

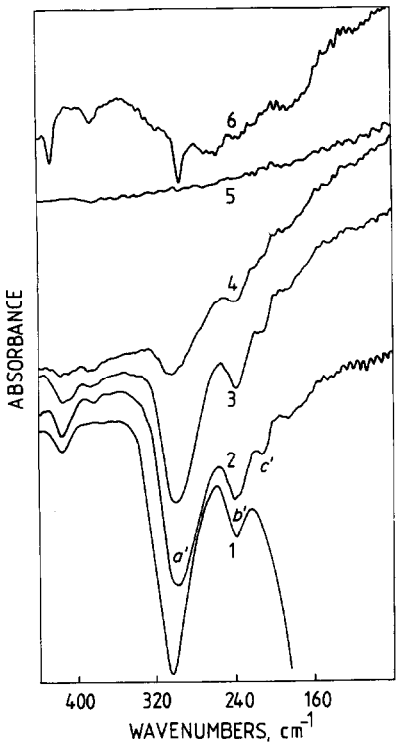

Fig. 3. FIR spectra of (1) GaL_3 in solution (0.3 M) in cyclohexane [recorded in a 5×10^{-5} m width CsI cell with a Perkin–Elmer 983 IR spectrometer]; (2) GaL_3 as a film on a polyethylene disc; (3) HL 0.73 g/g on Amberlite XAD-7 after complete reaction with gallium(III) [polyethylene pellet]; (4) = (3) but with HL 0.31 g/g; (5) = (2) but before reaction with gallium(III); (6) pure HL between two discs of polyethylene.

bands obtained in the spectrum of GaL_3 may support the hypothesis of a *fac* configuration. In this hypothesis, the bands *a'* and *b'* would correspond to the Ga–O (*E*) and Ga–N (*E*) stretching modes, respectively, and the weak band *c'* at 213 cm^{-1} might be attributed to the Ga–N (*A*) vibration. Indeed, the *A* vibration is usually less intense than the *E* vibration.[29] As for the Ga–O (*A*) stretching mode, it could give rise to a band overlapped with the Ga–O (*E*) vibration and appearing in the large and strong band *a'*. The comparison with the spectrum of $Fe(Ox)_3$ which is believed to be *fac* octahedral[29] reveals an interesting similarity: ν(Fe–O) (*E*) 314.9 cm^{-1} (very strong), ν(Fe–O) (*A*) 280.5 cm^{-1} (weak), ν(Fe–N) (*E*) 259.5 (medium), ν(Fe–N) (*A*) 201.5 cm^{-1} (weak and overlapped with a ligand band). In contrast, the spectrum of $Al(Ox)_3$ which is believed to be at least partially *mer* octahedral is more complex.[28]

NMR. The ^1H NMR spectrum of 7-(4-ethyl-1-methyloctyl)-8-quinolinol presents six signals between 7 and 9 ppm (spectrum 1 in Fig. 4), one multiplet at 3.40 ppm corresponding to H'_1 and three groups of multiplets at about 1.68, 1.23 and 0.80 ppm associated with the other aliphatic protons. On coordination with gallium(III), the hydroxyl proton signal disappears and the chemical shift values for some of the aromatic ligand protons are shifted substantially. In fact, the shape of the aromatic part of the ^1H NMR spectrum of GaL_3 greatly depends on the temperature. At low temperature (−14°C), this spectrum presents at least two, possibly three, separate sets of ligand resonances whereas at high temperature (+55°C) there is a collapse to a single set of ligand resonances (spectra 2–4 in Fig. 4). The signals associated with the protons H_2 are the most illustrative. Indeed, at 55°C the three protons H_2 of GaL_3 give rise to a single peak at about 8.2 ppm ($CDCl_3$) but on cooling this signal separates into two different signals, the first at about 8.7 ppm (CD_2Cl_2) corresponding to two protons H_2 and the second appearing between 6.8 and 7.6 ppm and associated with the third proton H_2. Such a phenomenon has already been reported by Baker and Sawyer[11] for the aluminium oxinate $Al(Ox)_3$, but in this latter case the separate sets of ligand resonances were observable at room temperature (spectrum 5 in Fig. 4) and the collapse required a temperature of 115°C.

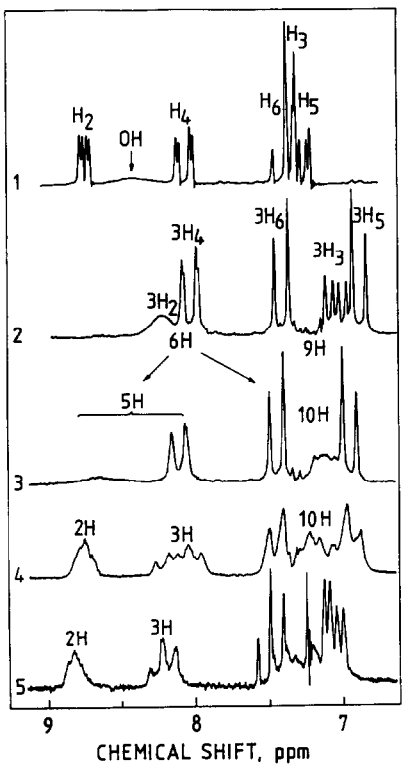

Fig. 4. ^1H NMR spectra of (1) HL in $CDCl_3$ at 33°C; (2) GaL_3 in $CDCl_3$ at 55°C; (3) GaL_3 in CD_2Cl_2 at 33°C; (4) GaL_3 in CD_2Cl_2 at −14°C; (5) $Al(Ox)_3$ in $CDCl_3$ at 33°C.

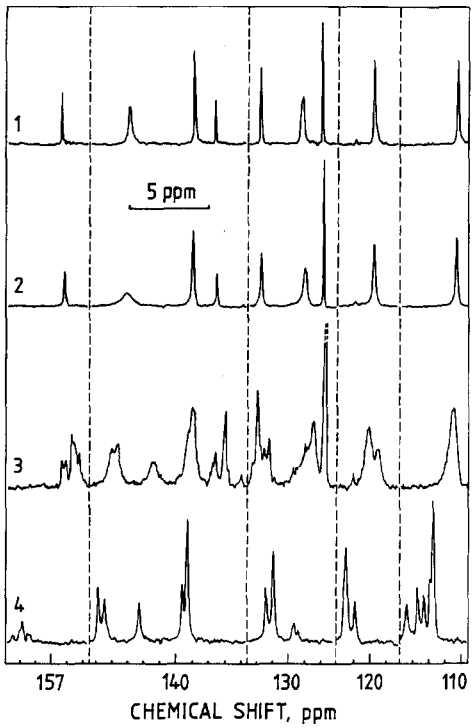

Fig. 5. Proton-decoupled ^{13}C NMR spectra of (1) GaL_3 in $CDCl_3$ at 50°C°;* (2) GaL_3 in $CDCl_3$ at 27°C;* (3) GaL_3 in $CDCl_3$ at −14°C;* (4) $Al(Ox)_3$ in $CDCl_3$ at 27°C. [(*) aromatic part only.]

Examination of the ^{13}C NMR spectra of GaL_3 and $Al(Ox)_3$ exhibits the same type of phenomena (Fig. 5). In particular, the spectrum of $Al(Ox)_3$ contains at least 18 signals which is many more than the 9 peaks expected for a *fac* molecule (spectrum 4 in Fig. 5). In the same way, the aromatic part of the spectrum of GaL_3 is complicated at low temperature but is collapsed to a simple pattern at 50°C (spectra 1–3 in Fig. 5).

Following Baker and Sawyer[11] one can conclude from the NMR data that GaL_3 has a *mer* configuration in solution at low temperature. Moreover, pointing out that the chemical shift for protons H_2 in the collapsed spectrum is about the average of the three corresponding chemical shifts measured at room temperature, the two authors reached the conclusion that the collapse observed when the aluminium chelate solution is heated is due to rapid exchange in the *mer* isomer rather than to conversion to the *fac* configuration. The same argument applies for GaL_3.

For $Al(Ox)_3$, the conclusions drawn from the NMR data are consistent with the ones reached from the FIR study, i.e. the complex $Al(Ox)_3$ can be regarded as actually *mer* octahedral. On the other hand, for GaL_3 the two methods lead to divergent conclusions. Indeed, the FIR spectrum of GaL_3 exhibits a simple pattern (suggesting a *fac* configuration), even when recorded on a film of pure product at the liquid nitrogen temperature. Therefore we cannot conclude as far as the actual stereochemistry of GaL_3. However, since the conclusions of the FIR study are based on the absence of absorption bands whereas the conclusions of the NMR investigation are derived from the presence of NMR signals, one might consider the latter as more likely.

(b) *The adsorbed complex.* The 7-(4-ethyl-1-methyloctyl)-8-quinolinol impregnated Amberlite XAD-7 supports can be used as the traditional chelating resins for the recovery of metal ions, especially gallium(III) and germanium(IV), from aqueous solutions. At saturation in gallium(III), the mol ratio of N/mol of Ga has been found to be close to 3, suggesting that the adsorbed molecules of HL react with gallium(III) to form the three-liganded complex, GaL_3, as they do in solution. IR and FIR spectra (spectra 3 in Fig. 2 and 2 and 3 in Fig. 3) give confirmation of this. In particular, the similarity in the FIR spectral pattern between GaL_3 in solution and the complex formed directly on the support leads us to conclude that the two complexes exhibit the same stereochemistry.

In conclusion, we can say that the adsorption of lipophilic extractants on a macroreticular support such as the Amberlite XAD-7 resin is a convenient technique for obtaining an efficient reactive resin. Indeed, the extractant–support interactions are weak enough to avoid any hindrance in the chelation ability of the extractant, but strong enough to reduce the losses of reagent by solubility in aqueous phases by a factor up to ten compared with what is observed in liquid–liquid systems.[3]

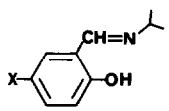
EFFECT OF THE SUBSTITUENTS ON THE ENANTIOMERIZATION BARRIER ENERGY OF *N*-ISOPROPYLSALICYLALDIMINATE BERYLLIUM AND ZINC COMPLEXES

F. A. BOTTINO* and P. FINOCCHIARO
Institute of Chemistry, Faculty of Engineering of the University, viale A. Doria 6, 95125 Catania, Italy



(*Received* 5 *June* 1984; *accepted after revision* 12 *February* 1985)

Abstract—Substituted bis-(*N*-isopropylsalicylaldiminate) complexes of Be(II) and Zn(II) have been prepared and their variable-temperature ^{1}H NMR spectra have been investigated. The variation of the $\Delta G^{\neq}$ values for the enantiomerization process in these complexes was studied as a function of the substituents present in the aromatic ring.

In our preceding works we have investigated the static and dynamic stereochemistry of bis-chelate complexes as a function of the variation of the complexed metal and (or) of the ligand structure.[1–4]

In this work our attention was devoted to the study of the dynamic stereochemistry of Be and Zn bis-chelate *N*-isopropylsalicylaldiminate complexes as a function of the substituents on the aromatic ring of the ligand, with the purpose of investigating the effect of the nature of the substituents on the energy of the enantiomerization process.

For this reason we prepared a series of ligands of general formula **I**:

I

X = H, OCH_3, CH_3, Br, Cl, NO_2

1 2 3 4 5 6

EXPERIMENTAL

The ligands **1**, **2** (b.p. 120°C; 0.2 mmHg) and **4** (m.p. 69–71°C) were prepared treating the commercial grade salicylaldehyde with *N*-isopropylamine in benzene solution. The ligands **3** (b.p. 58°C; 0.015 mmHg) and **5** (m.p. 64–5°C) were obtained by condensation with isopropylamine of the 5-methyl and 5-chloro-salicylaldehyde which were prepared starting from *p*-cresol and *p*-chlorophenol according to the procedure described by Duff.[5] The ligand **6** was obtained by nitration of salicylaldehyde[6] and successive condensation with *N*-isopropylamine of the 5-nitro-salicylaldehyde obtained. The ^{1}H NMR spectra in $CDCl_3$ were in agreement with the proposed structure **I**.

The corresponding Zn-complexes were prepared treating the respective Schiff bases in methanol with zinc acetate dihydrate dissolved in methanol.[7] After 30 min at reflux temperature, a pale yellow crystalline precipitate was obtained from the cooled solution.

The Be-complexes of the substituted ligands were obtained by a method at variance with that described by Green *et al.*[8] The ligand was mixed with an excess of dried $Be(OH)_2$ and maintained at 120°C for 15 min. The slurry was extracted with hot methanol. After concentration of the methanolic solution a crystalline product was obtained. Also the Be-complex of the non-substituted ligand was obtained according to this procedure.

The melting points and the elemental analyses of the complexes obtained are reported in Table 1. NMR spectra were recorded by means of a Bruker WP 80 FT spectrometer equipped with variable temperature accessories. $CDCl_3$ was used as solvent for room and low temperature experiments, while $C_6D_5NO_2$ was used for the high temperature spectra and, when possible, for measurements below room temperature only in some Zn-complexes.

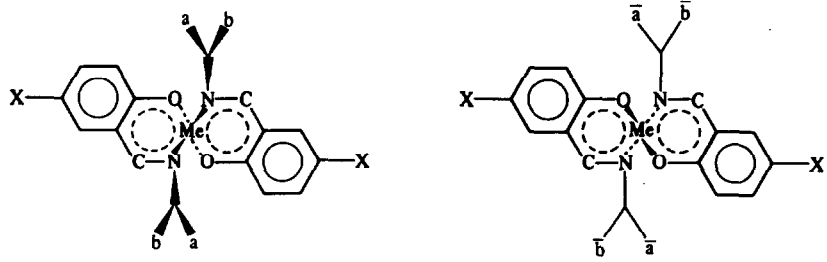
RESULTS AND DISCUSSION



In our previous studies[1,2] compelling evidence has been reported that β-diketonate or bis-chelate salicylaldiminate complexes of beryllium and zinc adopt a tetrahedral idealized D_{2h} structure in solution and in the solid state. Such a conformation, provided that the two ligands are unsymmetrically substituted, is chiral and can exist as only *dl* pair. Therefore the isopropyl groups present in these compounds (structures **IIa** and **IIb**) act as a diastereotopic probe in the sense that under conditions in which the chirality of the structure is preserved the two methyl groups within each isopropyl moiety (labelled a and b in Fig. 1) are magnetically non-equivalent, giving rise to two doublets in the methyl region of the ^1H NMR spectrum. Any process which corresponds to a loss of chirality in the transition state will render the two methyl groups equivalent on the NMR time-scale, and the two doublets will collapse to a single doublet permitting the calculation of the inversion barrier energy at the tetrahedral metal centre.

The ^1H NMR spectra of the Be-complexes at probe temperature show two doublets in the methyl region; the spectra of the Zn complexes have only one doublet at the same temperature.

Lowering the temperature below 250 K caused the Zn-derivatives to show the same pattern (two doublets) as the Be-derivative, due to the two diastereotopic methyl groups of each isopropyl moiety.

This observation is consistent with a tetrahedral configuration of such complexes on the NMR time-scale, with low interconversion of the two enantiomers at probe temperature for the Be-derivatives and at low temperature for the Zn-complexes.

A NMR study at variable temperature shows that when the temperature of the samples is increased the two diastereotopic methyl groups coalesce to a single doublet at temperatures of 306, 300, 292, 285 and 252

1b 2b 3b 4b 5b 6b

Fig. 1.

K for the compounds **2b**, **3b**, **4b**, **5b** and **6b** respectively ($CDCl_3$ as solvent) and at higher temperatures for the Be-derivatives, 404, 412, 420, 417 and 440 K for the compounds **2a**, **3a**, **4a**, **5a** and **6a** respectively ($C_6D_5NO_2$ as solvent).

The use of $C_6D_5NO_5$ as solvent for the Be-derivatives was necessary owing to the high coalescence temperatures (404–440 K) but only a few Zn-derivatives can be studied in this solvent due to its melting point of 279 K. However, the compounds **1b**, **2b** and **3b**, for which it is possible to obtain the coalescence temperature (Table 1), show practically the same trend as that in $CDCl_3$ solvent. Furthermore, the values of the free-energy of coalescence remain almost unchanged on varying the solvent, and this could be taken as strong evidence that the role of the solvent is trivial in such process.

The Gutowsky–Holm equation[9] was used to derive the rate constant at the coalescence temperature, and this was used to calculate an Eyring free energy of activation for the enantiomerization process. The results are reported in Table 1.

A plot of $\Delta G^{\neq}$ as a function of the σ of Hammett is shown in Fig. 2. Satisfactory linear relationships are observed for both Be (1) and Zn (2) complexes:

$$\Delta G^{\neq} = 1.81\sigma + 21.96 \quad (1)$$

and

$$\Delta G^{\neq} = -2.48\sigma + 15.44 \quad (2)$$

with a correlation coefficient of 0.970 for eqn (1) and 0.978 for eqn (2).

Interestingly, the trend is just opposite for the two series of metal complexes independently of the solvent used for the experiments. Thus, in the Zn-complexes, $\Delta G^{\neq}$ values increase with increasing the electron donor capability of the substituents on the aromatic nucleus, whereas in the Be-complexes a greater free energy of activation for racemization process is associated with electron-withdrawing groups in the aromatic ring.

However, although the trend is opposite, the slopes of the two linear relationships are similar to each other, indicating that the effect of the substituents on the values of such inversion barrier is equally sensed in both series of complexes.

Many effects can be invoked in order to explain such concomitant and opposite trends. A first tentative explanation could be the following.

Literature data[10] indicate that in such complexes the Be–O bond has relatively more covalent character in contrast with the Zn–O bond in the corresponding Zn-complexes.

These differences can account for the greater energy barrier to the racemization encountered in the Be-complexes.

Under these conditions, electron-donating groups should increase the strength of the partially ionic Zn–O bond in agreement with the experimental

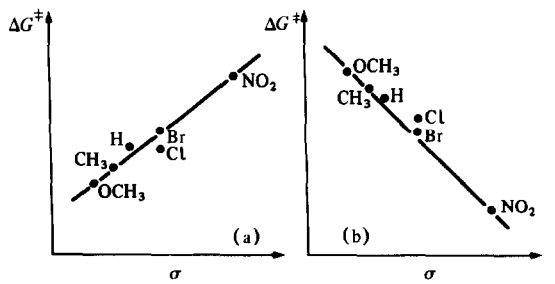

Fig. 2. Plot of $\Delta G^{\neq}$ for the Be(II)-complexes (diagram a) and the Zn(II)-complexes (diagram b) vs σ.

data (see Fig. 2); conversely, considering the differences in the bonds of the two Be- and Zn-complexes, electron-donating groups should reduce the energy necessary for the racemization process (inversion at tetrahedral central atom) in the Be-complexes.

Further experiments by other techniques are in progress in order to verify such a tentative explanation.

SYNTHESIS AND SPECTRAL STUDIES OF COPPER(II) COMPLEXES WITH AMIDE GROUP LIGANDS

V. RAVINDAR, S. J. SWAMY, S. SRIHARI and P. LINGAIAH*
Department of Chemistry, Kakatiya University, Warangal 506 009, Andhra Pradesh, India

(*Received* 13 *March* 1984; *accepted after revision* 12 *February* 1985)

Abstract—Complexes of copper(II) with 2-(acetylamino)benzoic acid, 2-(benzoylamino) benzoic acid, 2-(aminocarbonyl)benzoic acid, 2-[(phenylamino)carbonyl]benzoic acid, 2-[(1-naphthalenylamino)carbonyl]benzoic acid, 2-[(2-aminophenylamino)carbonyl]benzoic acid, 2-aminobenzanilide, 2(aminobenzoyl)benzoic acid, maleanilic acid and malea-1-naphthalanilic acid have been prepared and characterized by chemical analyses, molar conductivity, magnetic susceptibility measurements, thermal data, IR, electronic and ESR spectra. The visible and ESR spectral studies of these complexes (except those of maleanilic acid and malea-1-naphthalanilic acid) indicate that they are monomeric having either square planar or distorted octahedral geometry around Cu(II). The Cu(II) complexes of maleanilic acid and malea-1-naphthalanilic acid have been tentatively assigned dimeric structures. From the ESR spectra of Cu(II) complexes various parameters have been calculated.

An amide group offers two potential binding atoms, the oxygen and nitrogen, for complexation of metal ions. A number of complexes have been reported with amide group ligands which exhibit diverse coordinating behaviour with different metal ions.[1–4] However, studies on the metal complexes of the derivatives of amide groups are limited. Wiersema and Windle,[5] on the basis of ESR spectra of Cu(II)–salicylamide complexes, have reported that the salicylamide coordinates through nitrogen of the amide group. On the other hand, Pannu *et al.*,[6] have proposed the structure for this complex with oxygen, but not nitrogen, of the amide group coordinating. The majority of amide ligands form monomeric complexes with Cu(II) showing a doublet state. But the ESR spectra of Cu(II)–cyclic acid amide complexes are of a dimeric species, in which the two metal ions are exchange-coupled, leading to a paramagnetic triplet state. In view of these differences, investigation of the coordinating behaviour of the amide group containing ligands is worthwhile. In this paper, complexes of copper(II) with 2-(acetylamino)benzoic acid (AABA), 2-(benzoylamino)benzoic acid (BABA), 2-(aminocarbonyl)benzoic acid (ACBA), 2-[(phenylamino)carbonyl]benzoic acid (PACBA), 2-[(2-naphthalenylamino)carbonyl]benzoic acid (NACBA), 2-[(2-aminophenylamino)carbonyl]-benzoic acid (APACBA), 2-aminobenzanilide (ABn), 2-(aminobenzoyl)benzoic acid (ABBA), maleanilic acid (MA) and malea-1-naphthalanilic acid (MNA) are discussed.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

All the chemicals used were of AR grade. The ligands AABA,[7] BABA,[8] ACBA,[9] PACBA,[10] NACBA,[10] APACBA,[11] ABn,[12] MA[13] and MNA[13] were prepared by the literature methods. The purity of these compounds was checked by TLC and melting point determination. ABBA was obtained from Aldrich Chemical Company (U.S.A.) and was used as such.

Preparation of complexes

The complexes were prepared by mixing an aqueous solution of cupric acetate or cupric sulphate and methanolic solution of the ligands in 1 : 2 molar ratio and heating the mixture on a hot water bath for about 30 min. The crystalline complexes formed were suction filtered, washed with hot water and methanol and dried *in vacuo* over anhydrous calcium chloride.

Analyses

Copper in the complexes was estimated by iodometry using sodium thiosulphate. C, H and N analyses were obtained from the Microanalytical Laboratory, Calcutta University, Calcutta, India.

Physical measurements

The magnetic susceptibility measurements were made at room temperature (25°C) on a Gouy balance and corrected for diamagnetism using Pascal's constants. Molar conductivities of the complexes in DMF were measured using a Digisun Digital Conductivity Meter, model D 1-909. The thermal data of the complexes were obtained using a Stanton Thermobalance available at R.R.L., Hyderabad. IR spectra of the ligands and the complexes (4000–200 cm^{-1}) in Nujol mulls or in KBr (using cesium iodide plates in FIR region) were recorded on Perkin–Elmer-283 spectrophotometer. The electronic spectra of the complexes in DMF or in Nujol mulls were obtained using a Shimadzu MPS 5000 spectrophotometer. ESR spectra of the complexes in the solid state and in solution were recorded at 25°C and liquid nitrogen temperature employing JEOL PE-3X- and Varian X-band spectrometers.

RESULTS AND DISCUSSION

All the copper(II) complexes are crystalline powders, their colour being light blue or light green. They (except MA and MNA complexes) are slightly soluble in ethanol and freely soluble in DMF and DMSO. On the basis of analytical data (Table 1) the metal chelates are found to have 1 : 2 (metal : ligand) stoichiometry. The molar conductance values of the complexes in DMF at 10^{-3} molar concentration are low (7–18 Ω^{-1} cm^2 mol^{-1}) suggesting that they are non-electrolytes, but the complex of ABn has a value of 67 Ω^{-1} cm^2 mol^{-1} indicating that it is a 1 : 1 electrolyte.

Table 1. Analytical and physical data of Cu(II) complexes

Thermal analysis

The decomposition temperatures of the complexes obtained from their thermograms are recorded in Table 1. The thermograms of Cu(II) complexes of AABA, and ABn show initial weight loss in the temperature range 140–220°C corresponding to two water molecules. The expulsion of water molecules in the above temperature range indicates that they are coordinated.[14] The presence of water molecules in these complexes is further evidenced by their DTA curves which give endothermic peaks in the range 140–200°C. On the other hand, the Cu(II) complexes of PACBA and NACBA show initial weight loss curves in the temperature range 70–130°C, again amounting to two water molecules. The loss of water molecules in this low temperature range indicates that they are present as lattice-held water.[14] Also, each of the DTA curves of these complexes shows an endothermic peak in the range 90–120°C giving additional evidence for the presence of water molecules. The other Cu(II) complexes are thermally stable up to 240°C and are not hydrated. This is confirmed by the absence of an endothermic peak in the range 150–220°C in their DTA curves. The final products of decomposition above 560°C, in all the complexes, correspond to metallic oxide. The decomposition temperatures of the complexes are taken as a measure of their thermal stability. The ligands under study form complexes of varying stability in the order: ACBA < AABA < ABn < PACBA < BABA < NACBA < ABBA < APACBA < MNA < MA.

Despite the good amount of work on thermogravimetry, considerable difficulty still exists in assigning definite reasons for the increase or decrease in thermal stability of complexes with different ligands. One of the reasons advanced in the literature to explain the relative order of thermal stability of complexes formed with different ligands is that the thermal stability of the complexes increases with increase in π-electron delocalization, size of the molecule and also the nature and number of the rings formed.[15–17] The relative order of stability observed for the present complexes (except those of MA and MNA) might well be explained in terms of these reasons. The high decomposition temperatures of the Cu(II) complexes of MA and MNA may be ascribed to their polymeric nature.

IR spectra

The C=O and C–O stretching frequencies at 1700 and 1330 cm^{-1} in uncomplexed ligands containing carboxylic groups[11,18] are shifted to 1550 and 1380 cm^{-1} in complexes and are assigned to ν_{as}(COO) and ν_s(COO) modes respectively.[19] The ν(O–H) of the carboxylic group appearing at 2600 cm^{-1} in free ligands disappears in the IR spectra of their complexes.

The ν(N–H) frequency in AABA and BABA shifts to lower frequency by 100–140 cm^{-1} in complexes indicating that the nitrogen of the amide group is coordinating. A band at 1650 cm^{-1} in these ligands assignable to ν(C=O) of the amide group shows no considerable shift in the complexes, thus ruling out coordination through amide oxygen. In the ACBA, PACBA, NACBA, APACBA, ABn, ABBA, MA and MNA complexes ν(N–H) shifts towards higher frequencies compared with the ligand spectra, indicating non-participation of the nitrogen atom in coordination.[20] On the other hand, ν(C=O) (or the amide-I frequency) in the above set of ligands undergoes a negative shift (40 cm^{-1}) in the complexes, indicating coordination of this group through oxygen.[20] The N–H bands in AABA, BABA, ABn, PACBA, and NACBA complexes are somewhat obscured by ν(O–H) mode of water of crystallization and broadening due to hydrogen bonding. But the spectra of Cu(II) complexes of AABA and BABA recorded after heating them to 200°C for one hour clearly show bands around 3300 cm^{-1}, quite characteristic of N–H group. IR data also indicate that the anion SO_4^{-2} retains its ionic character in the Cu(II)–ABn complex.[21]

The amine ν(N–H) frequency in APACBA, ABn and ABBA undergoes a lower shift in the complexes showing that nitrogen of this group is coordinating. Further, the FIR spectra of the complexes show bands corresponding to ν(M–O) and ν(M–N) vibrations.[19] Some of the stretching frequencies relevant to the characterization of the complexes are listed in Table 2.

Electronic spectra

The electronic spectra of the complexes of ACBA, PACBA and NACBA show absorption bands in the ranges 14,500–15,100 cm^{-1} and 18,200–20,200 cm^{-1} assignable respectively to the transitions $^2B_{2g} \leftarrow {}^2B_{1g}$ and $^2E_g \leftarrow {}^2B_{1g}$ of square-planar structure.[22] Complexes of MA and MNA show a broad band centred at 20,600 cm^{-1} which is characteristic of square-planar geometry. Further, a strong charge-transfer band (CuO) has been observed around 27,000 cm^{-1} in these complexes.[23]

The complexes of AABA and BABA give rise to two bands, one of broad nature at 13,300 and 13,200 and the other as a shoulder of low intensity at 16,400 and 17,200 cm^{-1} respectively. These positions suggest distorted octahedral geometry for the

complexes.[24] The complexes of APACBA, ABn and ABBA, on the other hand, exhibit a single broad band in the region 14,500–14,800 cm^{-1} due to $^2T_{2g} \leftarrow {}^2E_g$ of octahedral structure. This band is considerably blue shifted compared to the first band maximum of the corresponding Ni(II) complexes, the ν(Cu)/ν(Ni) being 1.40. This suggests appreciable distortion from octahedral geometry in these Cu(II) complexes.[4]

Magnetic moments

complexes with all the ligands are paramagnetic, μ_{eff} value corresponding to the presence of one unpaired electron. But in the case of Cu(II) complexes of MA and MNA, the magnetic moments are found to be 1.13 and 1.06 B.M. respectively. These subnormal moments indicate some metal–metal interaction in solid state, possibly due to the formation of dimeric or polymeric structure.[25]

ESR spectra

The ESR spectral and bonding parameters of the Cu(II) complexes are presented in Table 3. The ESR spectra of Cu(II) complexes of PACBA, ABBA, MA and MNA are given in Figs 1–4.

The spectra of Cu(II) complexes of AABA, BABA, ACBA, PACBA, NACBA and ABn show at room

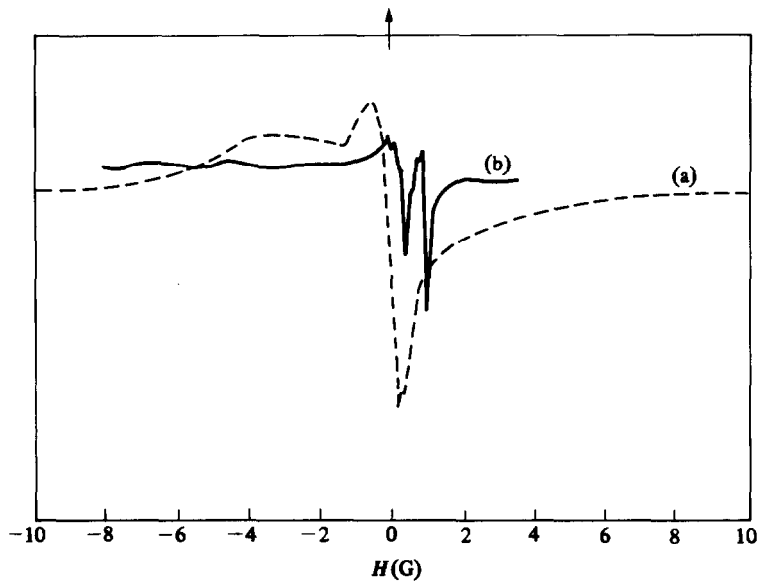

Fig. 2. ESR spectra of Cu(II)–PACBA complex at room temperature (a) and at liquid-nitrogen temperature (b).

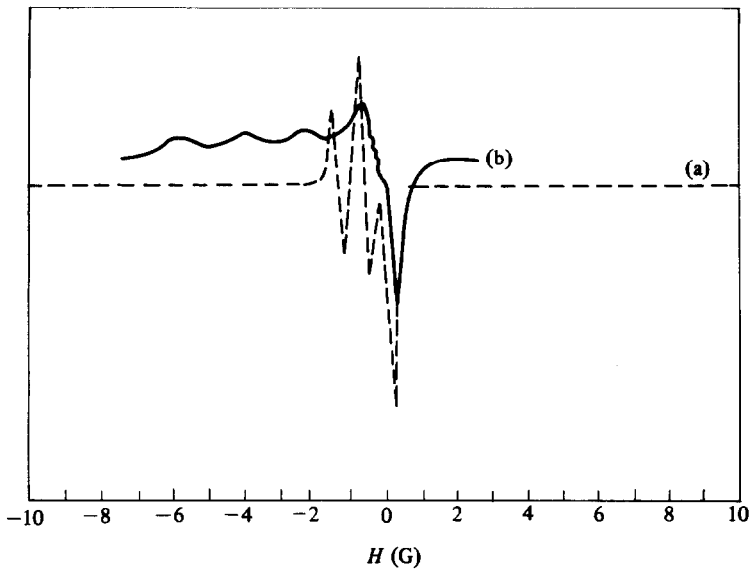

Fig. 3. ESR spectra of Cu(II)–ABBA complex at room temperature (a) and at liquid-nitrogen temperature (b).

temperature two peaks, one of intense absorption at high field and the other of less intensity at low field both in solid and solution states. From these peaks $g_{\|}$ and $g_{\perp}$ have been calculated. Inspection of the ESR data in the solid and in solution shows no significant difference in the room temperature values of $g_{\|}$ and $g_{\perp}$. Therefore, it is quite probable that the arrangement of Cu(II) ion in polycrystalline state and in solution is the same.

The spectrum of Cu(II)–ABBA complex at room temperature is isotropic due to tumbling motion of the molecules. The isotropic value, g_0, is calculated at the centre of the four-line spectrum. The isotropic nuclear hyperfine constant, A_0, expressed in cm^{-1} is calculated from the separation between two adjacent lines of the spectrum. However, this complex in the frozen state at 77 K shows three well resolved peaks of low intensity in the low-field region and one intense

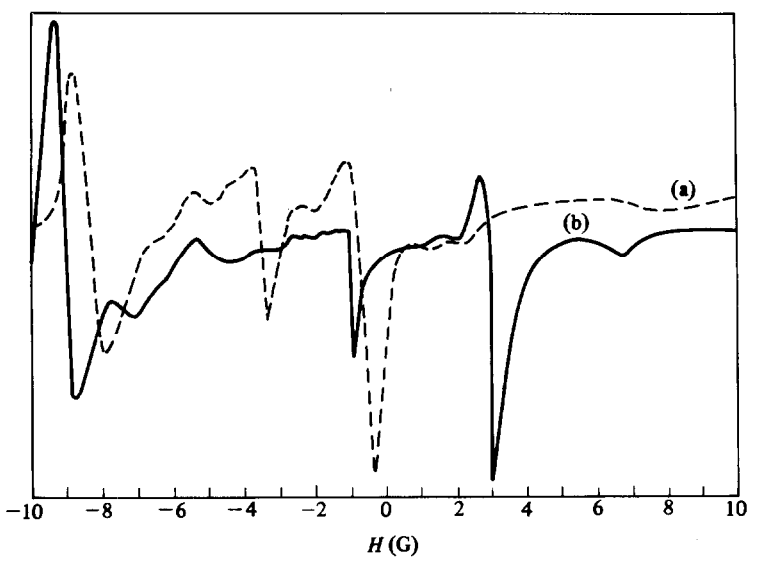

Fig. 4. ESR spectra of Cu(II)–MA complex at room temperature (a) and at liquid-nitrogen temperature (b).

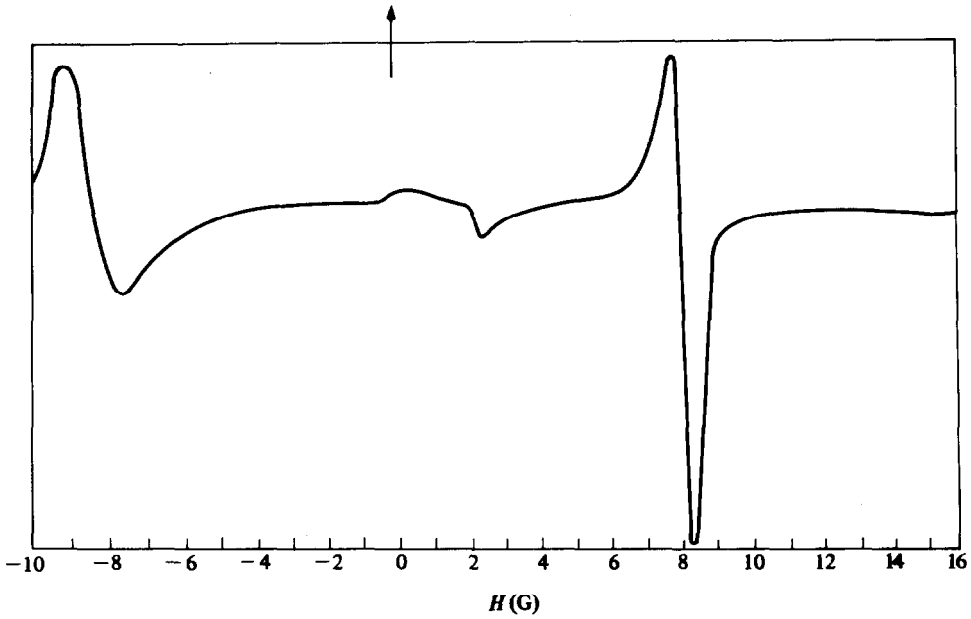

Fig. 5. ESR spectrum of Cu(II)–MNA complex at room temperature.

unresolved peak in the high-field region. The $g_{\|}$ and $A_{\|}$ values were calculated from the spectrum while $g_{\perp}$ and $A_{\perp}$ were evaluated using the following equations.[26]

$$g_{\perp} = \frac{3g_0 - g_{\|}}{2} \quad \text{and} \quad A_{\perp} = \frac{3A_0 - A_{\|}}{2}.$$

The $g_{\|}$ values of these Cu(II) complexes are greater than the corresponding $g_{\perp}$ values (Table 3) and, therefore, they have the unpaired electron in $d_{x^2-y^2}$ molecular orbital.[4]

Kivelson and Neiman[27] have shown that $g_{\|}$ is a moderately sensitive function for indicating covalency; for an ionic environment $g_{\|}$ is normally > 2.3 and for covalent environment it is < 2.3. The $g_{\|}$ for all the complexes (except those of MA and MNA) is found to be < 2.3 and taking these values into consideration the covalency of the M–L bond in the complexes may be formulated in the order AABA > BABA > NACBA > ABBA > ABn > APACBA > PACBA > ACBA.

Further, the bonding parameters, α^2, β^2 and γ^2 have been evaluated and based on the values obtained, the following bonding scheme is proposed for the present complexes: strongly covalent bonding with α^2 values in the range 0.62–0.78; strongly covalent in-plane π-bonding with β^2 values of the order 0.62–0.69 except in the case of Cu(II) complexes of ACBA and PACBA where it is moderate (β^2 = 0.82 and 0.90) and strongly covalent out-of-plane π-bonding with γ^2 values of the order 0.62–0.79 while in Cu(II) complexes of AABA and ACBA it is only moderate with γ^2 = 0.83 and 0.90.

The ESR spectra of Cu(II) complexes of MA and MNA were recorded in the solid state at 25°C and at liquid nitrogen temperature. The spectra consist of a moderately strong absorption at *ca* 250 G, strong absorption at *ca* 4500 G, a weak absorption at *ca* 6450 G and an absorption of varying intensity at *g ca* 2. The intensities of the first three absorptions decrease with a decrease in temperature, while that of the last at *g ca* 2 remains virtually unchanged. The *g ca* 2 absorption has, therefore, been assigned to a small percentage of monomeric impurity present to a different extent in each of the samples. It is noticeable that the linewidth of the three triplet absorptions differ (Figs 4 and 5). The linewidth of the high- and low-field absorptions is *ca* three times that of the absorption at *ca* 4500 G. All these features of the present MA and MNA complexes are similar to those observed in the case of the Cu(II) complexes of unsaturated carboxylic acids[28] and dicarboxylic acids and acid amides[29] for which a dimeric structure was proposed. Based on this, the present two complexes are tentatively assigned a dimeric structure.

ANNOUNCEMENT

INTERNATIONAL CONFERENCE ON COMPOSITE INTERFACES

The first international conference on composite interfaces (ICCI) is scheduled to be held from 27 to 30 May 1986 at Case Western Reserve University in Cleveland, Ohio. This international conference will provide a forum for discussion on recent advances in the fundamental, scientific understanding of the microstructure of composite interfaces and their influences on macroscopic properties of composite materials.

The first circular including a preregistration form is available from Prof. H. Ishida, General Chairman of ICCI, Department of Macromolecular Science, Case Western Reserve University, Cleveland, OH 44106, tel.: (216) 368-4285. Extended abstracts of two single-spaced pages are due on 1 December 1985 for review purposes. Final papers are due on 31 January 1986.

SPECTROPHOTOMETRIC STUDY OF THE COMPLEXATION EQUILIBRIA OF URANIUM(VI) WITH 1,4-BIS(4′-METHYLANILINO)ANTHRAQUINONE AND DETERMINATION OF URANIUM(VI)

K. A. IDRISS,* M. M. SELEIM, M. S. ABU-BAKR and H. SEDAIRA
Department of Chemistry, Faculty of Science, Assiut University, Assiut, Egypt

(*Received* 15 *November* 1983; *accepted* 10 *January* 1984)

Abstract—The reaction of U(VI) with 1,4-bis(4′-methylanilino)anthraquinone (quinizarin green) in water-dimethylformamide medium was investigated spectrophotometrically. The complexation equilibria in solution were demonstrated. The study of the reaction in presence of equimolar concentrations or in solutions containing metal or ligand excess gave evidence for the formation of complexes with stoichiometric ratios of UO_2:L = 1:1 and 1:2 in dependence on the pH of the medium. Their thermodynamic stabilities and the values of their molar absorption coefficients were determined. The optimum conditions for spectrophotometric determination of U(VI) with this reagent were found.

The ligand 1,4-bis(4′-methylanilino)anthraquinone, quinizarin green (QG), has very interesting properties as an analytical reagent. Solid complexes of this ligand with some metal ions have been isolated and characterised,[1,2] but solution studies have not yet been discussed in detail. Recent work from this laboratory involving the acid-base properties of arylaminoanthraquinone dyes in aqueous medium[3] and in water-solvent mixtures[4,5] has led us to obtain information in this area.

The preliminary results of our study showed that QG yields five variously coloured acid-base forms: LH_4^{2+}, LH_3^+, LH_2, LH^- and L^{2-}. In 40% (v/v) DMF at pH 3.2–5 there is a pronounced ionisation from LH_4^{2+} form to the monoprotonated species LH_3^+, and the latter is converted to LH_2 at pH 6–8. It has been spectrophotometrically determined, at the working pH region of solutions and 40% (v/v) DMF, that pK_{a_1} (LH_3^+/LH_2) = 5.15 and pK_{a_2} (LH_2/LH^-) = 9.46. The determination of the first dissociation constant (LH_4^{2+}/LH_3^+) was rather difficult because of the poor solubility of QG in strongly acidic solutions (see Fig. 1). The different acid-base equilibria liable to occur in solutions of QG can be represented as:

$$\underset{(pH \leqslant 2.5)}{LH_2^{2+}} \overset{-H^+}{\rightleftharpoons} \underset{(pH\ 3\text{–}5)}{LH_3^+} \overset{-H^+}{\rightleftharpoons} \underset{(pH\ 6\text{–}8)}{LH_2} \rightleftharpoons \underset{(pH\ 9\text{–}10.5)}{LH^-} \rightleftharpoons \underset{(pH \geqslant 11)}{L^{2-}}.$$

The dissociation constants corresponding to the last three ionisation steps have been calculated by treating the non-linear dependences $A = f(pH^*)$ as described elsewhere.[4] The mean pK_a values are given in Table 1. The experimental data can be obtained from the authors of this work.

The present paper deals with the study of the complexation equilibria of the analytically useful reagent QG and U(VI) in water-DMF medium and the conditions for the spectrophotometric determination of U(VI).

EXPERIMENTAL

Quinizarin green (QG) was purified by recrystallization of commercial reagent. 10^{-3} M solution of QG was prepared by dissolving the accurately weighed amount of the compound in dimethylformamide. 10^{-3} M solution of U(VI) was prepared from the analytically pure uranyl nitrate and standardized by conventional method.[6]

Thiel buffers (boric acid, borax, succinic acid and sodium sulphate) of pH 3–9, sodium acetate-acetic acid buffers of pH 3–6 or tris-(hydroxymethyl)aminomethane–HCl buffer (pH 7–9) were used for pH adjustment and were prepared as recommended.[7,8] The ionic strength, I, of solutions was kept constant at 0.1 ($NaClO_4$). Dimethylformamide was purified by a recommended procedure.[9] The pH-measurement was carried out using on Orion pH-meter (M 601 A). The pH-values in water-solvent mixtures were corrected according to the method of Douheret.[10]

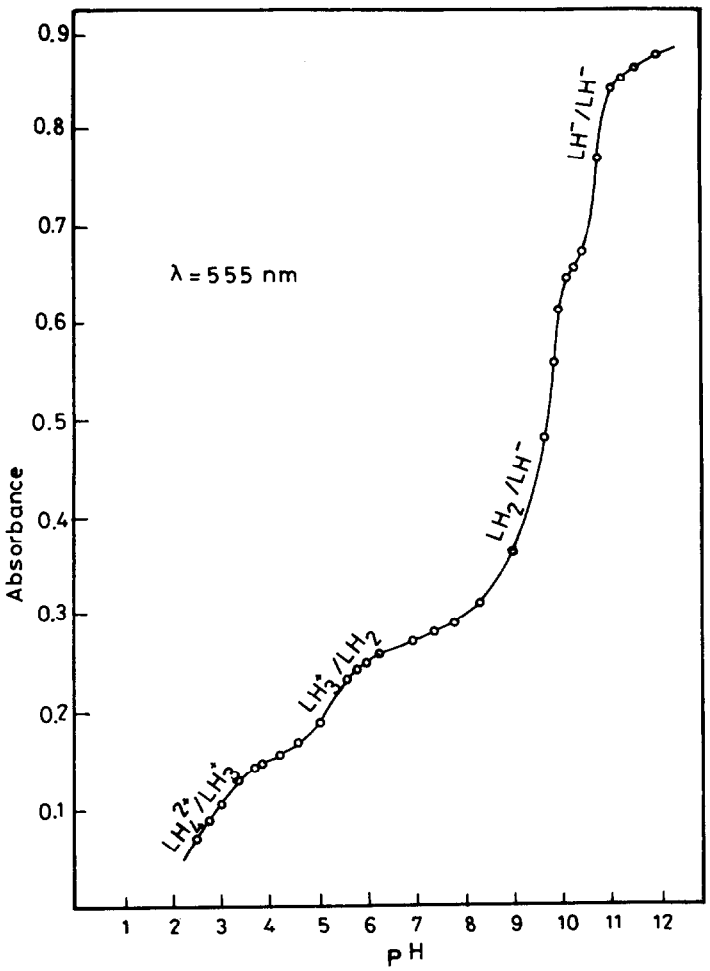

Fig. 1. Variation of absorbance with pH for the QG solution (1.12×10^{-4} M), λ = 555 nm, 40% DMF.

The absorption spectra of solutions were recorded on a Unicam SP 8000 spectrophotometer within the 350–750 nm range using 1 cm matched quartz cells. Measurements were performed at 25 ± 0.1°C.

RESULTS AND DISCUSSION

The absorption spectra of solutions with equimolar amounts of the metal ion and QG or with an excess of one component were investigated at different pH values. The spectra reflect the formation of a complex with a double-headed band (λ_{max} at 600 and 650 nm). The conversion of the orange–yellow protonated form of the ligand LH_3^+ (λ_{max} = 465 nm), which is the predominant species at pH 3–5, to the pink–violet complex of UO_2^{2+} with QG is characterised by a substantial red-shift ($\sim$ 185 nm). Above pH 8, the spectrum of the complex exhibits a more or less symmetrical band with λ_{max} at $\sim$ 650 nm and the colour changes to deep blue. The intensity of the latter band decreases with rise of pH.

() LH_3^+/LH_2

To explain the complexation equilibria and to establish the stability constant spectrophotometrically, the methods based on the relationship $A = f(pH^*)$ were employed.[11] The absorbance-pH curves in equimolar solutions and with excess metal or with excess ligand (Figs. 2 and 3) exhibit two inflections within the pH range 3–9.5. The two straight line portions of the three curves in the absorbance-pH plots, used for calcu-

a) λ = 605 nm,

b) λ = 650 nm.

lations, fall in the pH regions 3.5–5 and 6–8. As indicated in Fig. 4 the absorbance-pH curves indicate the existence of two chelate equilibria. At higher pH values (pH > 8) the absorbance for the U(VI)–QG complex decreases rapidly owing to hydrolysis effect.

The number of protons released during complexation and the equilibrium constants were deduced graphically from the plots obtained with the three metal to ligand mole ratios as follows:

(a) For equimolar solutions, the eqn (1) was applied:

$$K_{eq} = \frac{AA_0^2[H^+]^n}{4C_M^2(A_0 - A)^3} \quad (1)$$

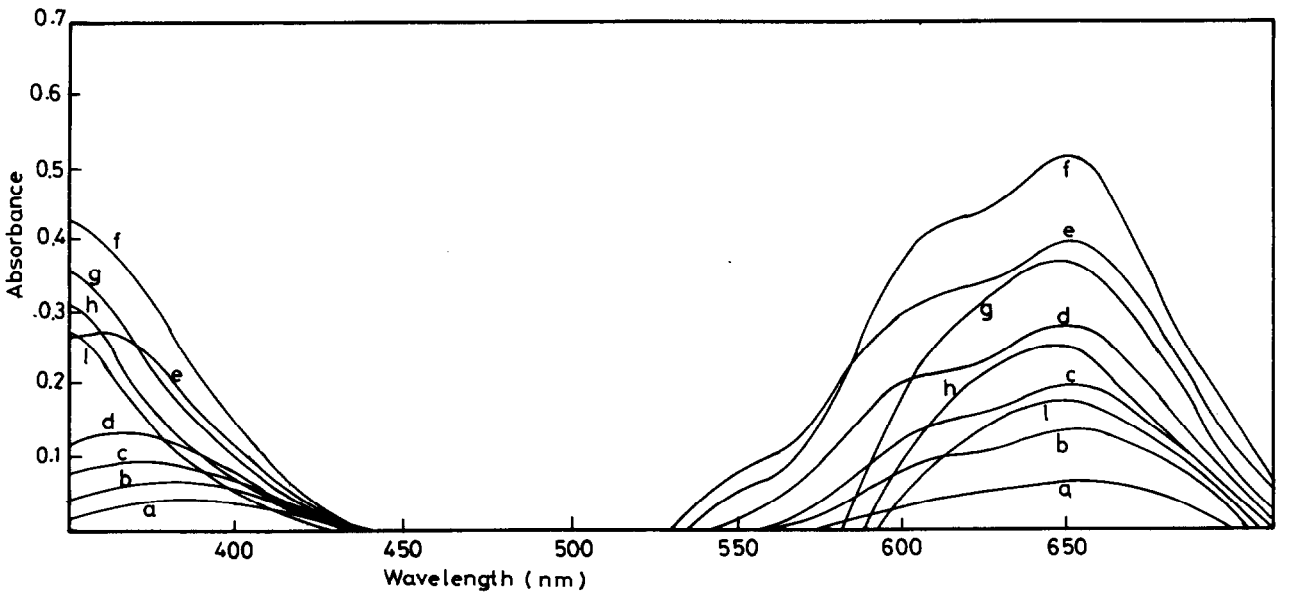

Fig. 2. Absorption spectra of UO_2(II)–QG complexes, $C_L = 2 \times 10^{-4}$ M, $C_M = 2 \times 10^{-4}$ M, I 0.1, 40% DMF; pH: (a) 3.12, (b) 4.36, (c) 5.5, (d) 6.89, (e) 7.22, (f) 7.92, (g) 8.72, (h) 9.39, (i) 9.88.

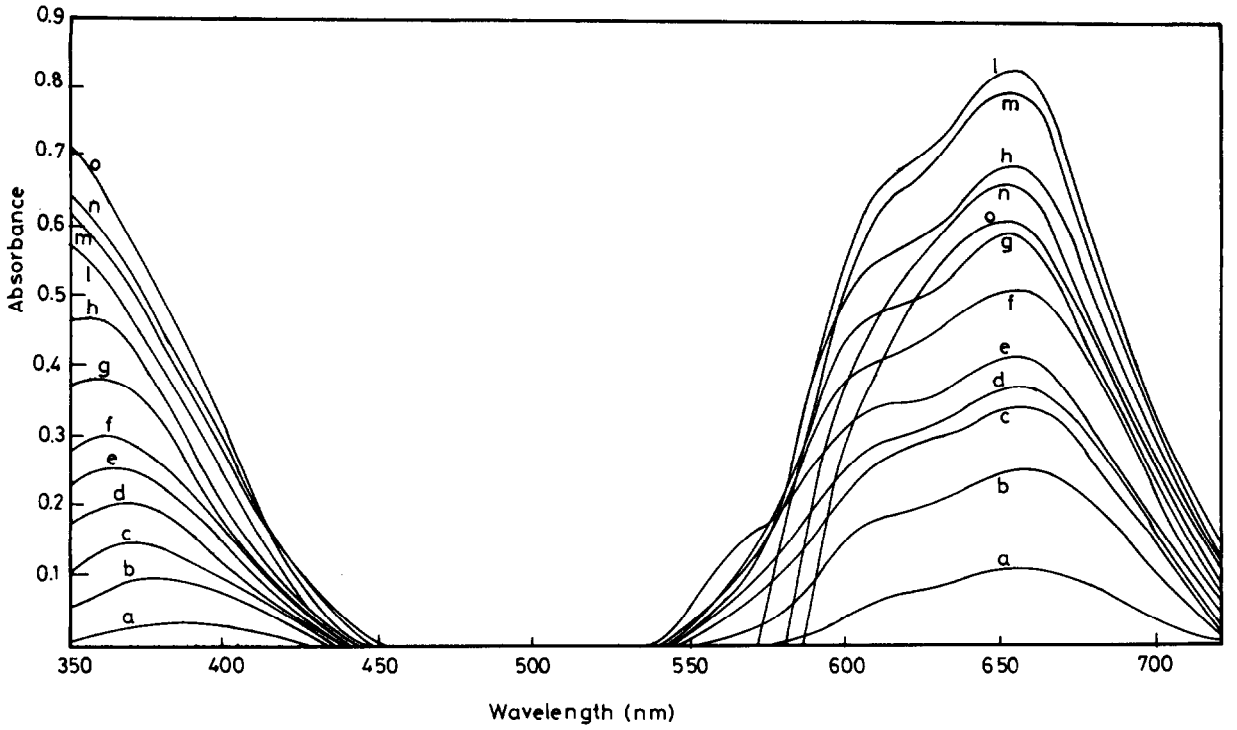

Fig. 3. Absorption spectra of UO_2(II)–QG complexes, $C_L = 4.5 \times 10^{-4}$ M, $C_M = 1.5 \times 10^{-4}$ M, I 0.1, 40% DMF; pH = (a) 3.18, (b) 4.46, (c) 5.4, (d) 6.09, (e) 6.45, (f) 6.95, (g) 7.31, (h) 7.67, (i) 8.19, (m) 8.88, (n) 9.35 (o) 9.65.

where A is the absorbance at given pH value, A_0 is the absorbance maxima and C_M is the total metal concentration. The logarithmic dependence of this equation is a straight line with a slope n and an intercept including K_{eq}:

$$\log \frac{A}{(A_0 - A)^3} = \log K_{eq} - \log \frac{A_0^2}{4C_M^2} + n\text{pH}$$

(b) In the presence of excess metal ion, the following equation is valid

$$K_{eq} = \frac{AA_0^2[H^+]^n}{mC_M^2(2A_0 - mA)(A_0 - A)^2} \qquad (2)$$

where $m = C_L C_m < 1$, C_L being the total ligand concentration. The logarithmic transformation of this equation gives also a straight line.

(c) For solutions with excess of ligand, the logarithmic transformation of the equation:

$$K_{eq} = \frac{\Delta A[H^+]^n}{(\Delta A_0 - \Delta A)C_L^2} \qquad (3)$$

was used.

The stability constants of the complexes β, and values of the molar absorption coefficients ϵ, were found for selected wavelengths from the shape of the non-linear dependences. The number of hydrogen ions released in the reaction

$$M + mLH_n \rightleftharpoons ML_mH_z + qH^+; {}^*B_m$$

were found graphically (the ionic charges were omitted except for protons). In the reaction scheme $n = 3$ or 2 (depending on the pH of the reaction mixtures) and $z + q = nm$.

According to the results of this study, the reaction of U(VI) with QG can be represented by the schemes:

(A) $UO_2^{2+} + LH_3^+ \rightleftharpoons [UO_2(LH_2)]^{2+} + H^+$, $K^*_{1(H^+)}$

(B) $[UO_2(LH_2)]^{2+} + LH_2 \rightleftharpoons UO_2(LH)_2 + 2H^+$, $K^*_{2(2H^+)}$.

In solutions with $C_M = C_L$ or with excess of one component, the logarithmic absorbance-pH curves indicated unambiguously the presence of equilibrium (A) over the entire formation interval pH 4–6. Assuming that LH_3^+ species of QG predominates at this pH range, reaction (A) takes place independently of the metal to ligand ratio and a diprotonated complex is formed.

The complexation equilibrium (B) is attained at pH 6–8.5 in solutions with excess ligand and at pH

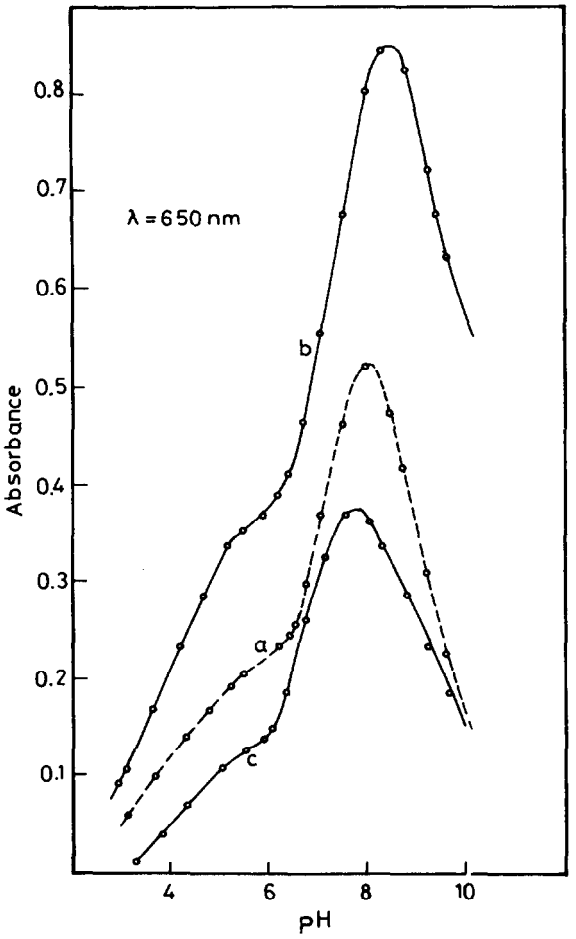

Fig. 4. Absorbance-pH curves in the QG–UO_2(II) system, λ = 650 nm, I 0.1, 40% DMF. (a) $C_L = 2 \times 10^{-4}$ M, $C_M = 2 \times 10^{-4}$ M; (b) $C_L = 4.5 \times 10^{-4}$ M; $C_M = 1.5 \times 10^{-4}$ M; $C_L = 1.67 \times 10^{-4}$ M, $C_M = 5 \times 10^{-4}$ M.

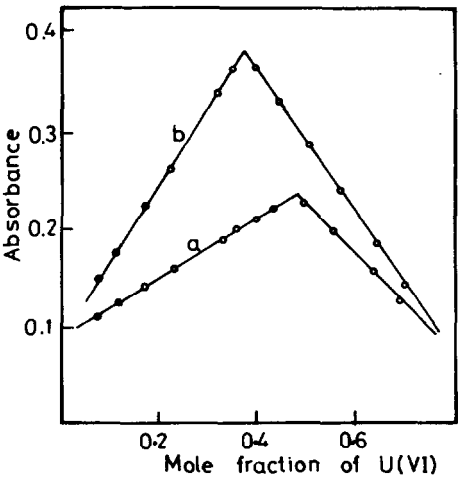

Fig. 5. Continuous variation plots for the QG–UO_2(II) system, λ = 650 nm, 40% DMF, $C_0 = 3.6 \times 10^{-4}$ M. (a) pH = 4.5, (b) pH = 7.8.

6.5–8 in equimolar solution or in presence of excess metal. The component ratios of the complexes was confirmed by the method of continuous variations in equimolar solutions[12] and by the molar ratio method[13] at selected pH values. It follows from the shape of the dependences obtained that U(VI) do not form higher complexes at pH 4.5. It has also been confirmed that the stoichiometry of the complexed ligand at pH 7.8 is 1:2 (M/L) (see Fig. 5).

Equilibrium constants $K_n^*(qH)$ are related to stability constants β_n by the expressions[14]

$$\beta_1 = K^*_{1(H)} \cdot K_{a_1}^{-1}$$

$$\beta_2 = B_1 K^*_{2(2H)} \cdot K_{a_2}^{-1}$$

a) equilibrium constant for reaction(A), mean value.

b) equilibrium constant for reaction (B), mean value.

$\Delta\lambda$: the difference in the wavelengths of the maximum of the uranium complex and that of the given acid-base form of the reagent.

The constants K_n^* and β_n as concluded from the average values determined at various metal to ligand ratios are given in Table 3.

The effect of buffers

At pH 3–6 sodium acetate-acetic acid, tris-(hydroxymethyl)aminomethane–HCl buffer (pH 7–9) or thiel buffer (boric acid-borax-succinic acid and sodium sulphate) can be employed, as they do not interfere. Buffers based on phosphate, tetraborate, citrate, triethanolamine strongly interfere. Thiel buffer gave the best results.

The effect of DMF

Dimethylformamide affects neither the absorbance of the complexed ligand nor the complex stability at concentrations from 25 to 40% (v/v). At lower concentrations of DMF < 20% the absorbance measurements could not be carried out in acidic solutions owing to the precipitation of the reagent.

The effect of ionic strength

The solution absorbance increases with increasing salt concentration. However, this effect is negligible within I = 0–0.2 ($NaClO_4$).

Determination of uranium (VI) with quinizarin green

The spectrophotometric determination of U(VI) with QG employs the complex with molar ratio M:L = 1:2, which is formed in solutions with equimolar components or with a concentration excess of the ligand, at a pH of 7.5 in a medium of 40% (v/v) DMF. Calibration curves $A = f(C_M)$ are linear up to 49.5 μg U/cm^3 at 605–650 nm, $C_L = 2 \times 10^{-4}$ M ($\epsilon = 3.55 \times 10^3$ for 650 nm).

Procedure. To a 20 cm^3 volumetric flask was gradually added 5 cm^3 of 1×10^{-3} M reagent solution in 40% DMF, 5 cm^3 0.4 M $NaClO_4$, 5 cm^3 thiel buffer (pH = 7.5) and a weakly acidic uranium sample solution containing less than 1 mg U. The solution was diluted to the mark with the required amounts of DMF and doubly-distilled water. After thoroughly mixing the reaction mixture, the absorbance was measured at 650 nm against a reagent blank similarly prepared but containing no uranium.

KINETIC STUDY OF THE REACTION OF *meso*-TETRAKIS (*p*-TRIMETHYLAMMONIUMPHENYL)PORPHINATO-DIAQUORHODATE(III) WITH CHLORIDE, BROMIDE, IODIDE, HEXACYANOCOBALTATE(III) AND THIOCYANATE IONS IN AQUEOUS SOLUTION

J. G. LEIPOLDT* and H. MEYER

Department of Chemistry, University of the Orange Free State, Bloemfontein, Republic of South Africa

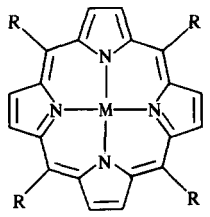
(*Received* 4 *September* 1984; *accepted* 18 *December* 1984)

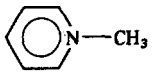
Abstract—The reaction of Cl^-, Br^-, I^-, $Co(CN)_6^{3-}$ and NCS^- with *meso*-tetrakis (*p*-trimethylammoniumphenyl)porphinatodiaquorhodate(III), $[RhTAPP(H_2O)_2]^{5+}$, has been studied at 15, 25 and 35°C in 0.1 M $[H^+]$ with $\mu = 1.00$ M ($NaNO_3$). The value of the acidity constant, K_{al}, at 25°C is 4.39×10^{-9} M. The reactions are first order in anion concentration up to 0.9 M. The values of the stability constants, K_1, and the second order rate constants, k_1, for the reaction with Cl^-, Br^-, I^-, $Co(CN)_6^{3-}$ and NCS^- are respectively 0.23 M^{-1} and 2.5×10^{-3} $M^{-1}\,s^{-1}$, 1.1 M^{-1} and 6.92×10^{-3} $M^{-1}\,s^{-1}$, 40.0 M^{-1} and 17.0×10^{-3} $M^{-1}\,s^{-1}$, 550 M^{-1} and 20.0×10^{-3} $M^{-1}\,s^{-1}$, 3400 M^{-1} and 20.9×10^{-3} $M^{-1}\,s^{-1}$. The porphine greatly labilizes the Rh(III). There has been about a 500-fold increase in the rate constant for substitution compared to that of $[Rh(NH_3)_5H_2O]^{3+}$. The substitution rates are however about the same as for $[Rh(TPPS)(H_2O)_2]^{3-}$, indicating that the overall charge on the complex plays only a minor role. The kinetic results indicate that dissociative activation is occurring in these reactions.

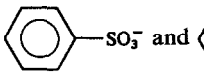
The axial ligand substitution reactions of cobalt(III), rhodium(III) and chromium(III) porphyrins are known to be much faster than for the normal complexes like the metal pentaammineaquo complexes indicating that the porphyrin ligand labilizes the axial positions.[1–7] In the case of the porphine TPPS (TPPS = *meso*-tetra(*p*-sulphonatophenyl)-porphine) the labilization of the axial water molecules was about 10^9 for the cobalt(III) complex,[3,8] about 10^3 and 10^2 for the rhodium(III)[4,8] and chromium(III)[5,8] complexes respectively. The extent of labilization also depends on the porphine. For example the anation reaction of $[Co(TPPS)(H_2O)_2]^{3-}$ are more than 100 times faster than those of $[Co(TMPP)(H_2O)_2]^{5+}$, TMPP = *meso*-tetra(4-N-methylpyridyl)porphine.[1,3] The effect of the different porphines is, as may be expected, not so pronounced in the case of the chromium(III) complexes. The anation reaction of $[Cr(TPPS)(H_2O)_2]^{3-}$ is only 6 times faster than the anation reactions of $[Cr(TMPP)(H_2O)_2]^{5+}$.[5,6] The labilization effect of the porphine ligand is probably due to its ability to donate electron density to the central metal ions, making the metal(III) ions more like the labile metal(II) ions. The fact that the TPPS complexes are more reactive than the TMPP complexes, is in agreement with this view since TPPS is more electron rich and thus a better electron donor than TMPP. The structures of the different porphines are shown in Fig. 1.

The kinetic data that are available, indicate that the labilization of the metal(III) ion is accompanied by promoting a dissociative mechanism. This is probably due to the electron donating capability of the electron rich porphine, not only making the central metal(III) ion more like a metal(II) ion, but also stabilizing the five coordinate intermediate in a dissociative reaction mode. This is also seen in the complete different pressure dependencies found for the anation reactions of $[Co(TPPS)(H_2O)_2]^{3-}$ compared to the results of the substitution reactions of the corresponding metal pentaamineaquo complexes.[8,9] The high-pressure data for the TPPS

* Author to whom correspondence should be addressed.







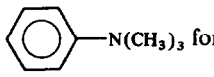


Fig. 1. The structures of the different porphine complexes. M = Co, Rh or Cr. R =   and  for TMPyP, TPPS and TAPP respectively.

complexes suggested a *D* mechanism for the anation reaction of the cobalt(III) complex and an I_d mechanism for the rhodium(III) and chromium(III) complexes.[9]

The formation constants for the $[Rh(TPPS)(H_2O)(X)]^{4-}$ complexes (X = NCS^-, I^-, Br^- and Cl^-) varied by a factor of about 1.6×10^4 whereas the anation reaction rate constants varied only by a factor of about ten.[4] These results also imply a dissociative reaction mode.

This work on the reaction mechanisms of different porphine complexes is extended to the metal complexes of another water soluble porphine TAPP, TAPP = tetrakis(*p*-trimethylammoniumphenyl)-porphine.

EXPERIMENTAL AND RESULTS

The iodide salt of TAPP was synthesized as described by Krishnamurthy.[10] The rhodium complex of this porphine was prepared in the same way as $[Rh(TPPS)(H_2O)_2]^{3-}$:[4] 200 mg of the iodide salt of TAPP was dissolved in 100 cm^3 N,N-dimethylformamide (DMF). The solution was filtered to remove any undissolved impurities. A solution of $[RhCl(CO)_2]_2$ in DMF (prepared by refluxing 100 mg of $RhCl_3 \cdot 3H_2O$ in 20 cm^3 DMF until a yellow solution was obtained;[11] approximately 30 min) was added to the porphine solution. This solution was refluxed for about 60 min until all the free porphine were converted into the rhodium(III) complex as indicated by the visible spectrum. The solution was cooled and about five drops of concentrated $HClO_4$ were added, followed by about 500 cm^3 diethylether to precipitate the rhodium(III) complex. The $[Rh(TAPP)(H_2O)_2](ClO_4)_5$ was washed with ether and allowed to dry in the atmosphere at room temperature. The wavelength of the Soret band for this complex is at 418 nm with molar absorptivity $1.75 \times 10^5\ M^{-1}\ cm^{-1}$.

The determination of the acid dissociation constant, K_{al}, was difficult, as a result of the small change in the absorption spectrum from the acidic form to the basic form. K_{al} was determined at an ionic strength of 1.0 M. In changing the pH between 1 and 13, there was a change in absorbance between about pH 7 and 9 over a pH range of 2. We believe that the absorbance change for the second deprotonation is too small to detect and that the observed absorbance change is the result of the first deprotonation.

Taking into account the mass balance, Beer's law and the definition of K_{al} (Scheme 1), we can write

$$A = \frac{A_b K_{al} + A_a[H^+]}{K_{al} + [H^+]}. \qquad (1)$$

A is the absorbance at a particular $[H^+]$, A_b is the absorbance of the deprotonated form and A_a is the absorbance of the protonated form. The absorbance vs pH data were fitted to eqn (1) by using a nonlinear least squares program.[12] The change in the absorbance at 435 nm as a function of pH is shown in Fig. 2. The solid line is the computer fit of the data. The value of K_{al} at 25°C and μ = 1.0 M is 4.39×10^{-9} M.

The values of the stability constant K_1 (Scheme 1)

$$\begin{array}{ccc} [RhTAPP(H_2O)_2]^{5+} + L^{n-} & \underset{k_{-1}}{\overset{k_1; K_1}{\rightleftharpoons}} & [RhTAPP(H_2O)L]^{(5-n)+} + H_2O \\ K_{al},\ -H^+ \Big\downarrow\Big\uparrow +H^+ & & \\ [RhTAPP(H_2O)(OH)]^{4+} & & \end{array}$$

Scheme 1. Reaction scheme under the experimental conditions

for the different ligands were determined spectrophotometrically in 0.1 M HNO_3 and an ionic strength of 1.0 M at 25°C. The following equation is derived from the definition of K_1 and Beer's law

$$A = \frac{A_r + A_p K_1[L]}{1 + K_1[L]}. \quad (2)$$

A_r is the absorbance of the reactant, A_p the absorbance of the product and A the absorbance at the particular concentration of the incoming ligand L. The absorbance vs $[L]$ data were fitted to eqn (2) by using a nonlinear least squares program with A_r held constant at the experimental value. Figure 3 is a typical curve, with the solid line the computer calculated line. The results for the various ligands are represented in Table 1.

The anation reaction of $[Rh(TAPP)(H_2O)_2]^{5+}$ by $[Co(CN)_6]^{3-}$, NCS^-, I^-, Br^- and Cl^- were studied at 15, 25 and 35°C in 0.1 M HNO_3 and $\mu = 1.0$ M ($NaNO_3$). It was established that the reaction rates were $[H^+]$ independent at $[H^+] > 10^{-4}$ M.

The rate law under these experimental conditions is

$$-\frac{d[RhTAPP(H_2O)_2^{5+}]}{dt} = (k_1[L] + k_{-1})[Rh(TAPP)(H_2O)_2^{5+}]. \quad (3)$$

All the kinetic studies were performed under pseudo-first order conditions with

$$k_{obs} = k_1[L] + k_{-1}. \quad (4)$$

Figure 4 is a typical plot of k_{obs} vs $[L]$ for L = NCS^-. The kinetic results obtained in this way, are summarized in Table 1. The values of k_{-1} were calculated from the values of K_1 and k_1. The activation parameters were calculated by means of a nonlinear least square program fit of the data to the Eyring–Polanyi equation and are also reported in Table 1.

The accuracy of the rate constants, as well as the equilibrium constants, was not as good as one would like. This was due to the formation of a precipitate near the completion of the reaction. The value of the absorbance at the completion of the reaction was thus accordingly calculated by means of a computer fit of the absorbance vs reaction time data. The rate constants obtained by this method were verified by the Guggenheim method.

The small, but significant change in the absorbance with pH, as well as the determination of the stability constants and the kinetic data, point to a

similar reaction scheme as proposed for the anation reactions of $[Rh(TPPS)(H_2O)_2]^{3-}$ [4]— see Scheme 1. The fact that the rate constants were pH independent for $[H^+] > 10^{-4}$ M clearly indicate that $[Rh(TAPP)(H_2O)_2]^{5+}$ is the only reactive species under our experimental conditions.

DISCUSSION

The trend in the values of the stability constants, see Table 1, indicates that the rhodium(III) behaves as a soft acid towards the different ligands. This is the case for all the porphine complexes of rhodium(III), cobalt(III) and chromium(III) studied so far and may be explained in view of the delocalized electron density in the porphine ligand that is apparently available to the central metal ion. The formation constants for the reaction of $[Rh(TAPP)(H_2O)_2]^{5+}$ with the different ligands are about the same as found for the $[Rh(TPPS)(H_2O)_2]^{3-}$ complex—see Table 1. These results indicate that the overall change on the complex plays a minor role and that π-bonding is important in the metal–ligand bonding.

The reaction of $[Rh(TAPP)(H_2O)_2]^{5+}$ with NCS^-, $[Co(CN)_6]^{3-}$, I^-, Br^- and Cl^- shows no deviation from second order kinetics up to 0.9 M in the concentration of the incoming ligand. There is thus no kinetic evidence for an intermediate. As there is also no other evidence for an intermediate, the possibility of a *D* or *A* mechanism for these reactions may be rejected. The comparison of the stability constants and the rate constants, however, gives an indication of the mode of activation. The stability constants vary by a factor of about 1.5×10^4, while the rate constants (k_1) vary by a factor of only about 8. These results indicate that the rate is not sensitive to the nature of the incoming ligand, but very sensitive to the nature of the leaving group. This is indicative of a dissociative reaction mode.

If an I_d mechanism is assumed, see eqns (5) and (6), the observed rate constants are a measure of $K_{os}k_i$.

$$[Rh(TAPP)(H_2O)_2]^{5+} + X^- \overset{K_{os}}{\rightleftharpoons} [Rh(TAPP)(H_2O)_2 \cdot X]^{4+}, \quad (5)$$

$$[Rh(TAPP)(H_2O)_2 \cdot X]^{4+} \overset{k_i}{\rightarrow} [Rh(TAPP)(H_2O)(X)]^{4+} + H_2O. \quad (6)$$

The relative small difference in the values of the observed anation rate constants is thus indicative of a dissociative activation since the values $K_{os}k_i$ are expected to remain fairly constant for similarly charged incoming ligands.[13]

Figure 5 is a plot of log k_{-1} vs log K_1 for the various incoming ligands. The line is drawn with a unit slope. This linear relationship is indicative of a dissociative activation.

The reaction rate constants for the reaction of $[Rh(TPPS)(H_2O)_2]^{3-}$ with the different incoming ligands, are also given in Table 1. It is clear that the anation rate constants and the equilibrium constants for the reaction of $[Rh(TPPS)(H_2O)_2]^{3-}$ and $[Rh(TAPP)(H_2O)_2]^{5+}$ with the different incoming ligands are very similar. The overall charge on the complex thus plays a minor role in the reaction process. In this respect, it is important to note that the overall charge on the complex is spread over a large planar surface area since the negatively charged sulphonato groups and the positively charged trimethylammonium groups are removed far from

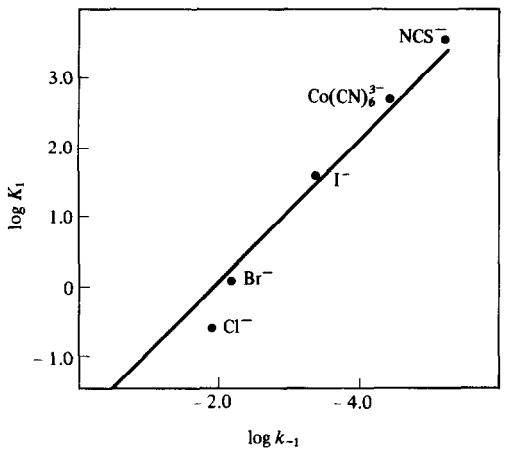

Fig. 5. Plot of log K_1 vs log k_{-1} for the various ligands. The line is drawn with unit slope.

the metal centre. Further evidence for an I_d mechanism for the anation reaction of $[Rh(TAPP)(H_2O)_2]^{5+}$ is this similarity in the anation rate constants for these two complexes and the fact that it was established by means of high-pressure kinetic data that the anation reaction between $[Rh(TPPS)(H_2O)_2]^{3-}$ and NCS^- proceeds via an I_d mechanism.[9] The similarity of the activation parameters for substitution reactions of these two complexes support this hypothesis.

The kinetic data clearly indicate that the porphine ligand labilizes the rhodium(III) ion, although not as much as in the case of the cobalt(III) complexes. The anation rate constants are about 500 times faster than the anation rate constants for $[Rh(NH_3)_5H_2O]^{3+}$. The central metal ion seems thus to control not only the extent to which the porphine ligand modifies the mode of the substitution process, but also the extent of labilization.

Abstract—There appears to be a correlation between the ^{31}P chemical shift differences between A^+ and AX (Δ_1), and between A^+ and AX_2^- (Δ_2), where A^+ is a phosphonium ion and X is an anionic ligand. This relationship holds for a wide range of substituents on phosphorus, despite the expected changes in hybridisation along the series, and is very useful for predicting the shifts of new or unknown species.

During investigations into the coordination chemistry of phosphorus(V) compounds[1–6] we observed a correlation between Δ_1, the ^{31}P chemical shift difference between a phosphonium ion A^+ and the corresponding phosphorane AX, and Δ_2, the corresponding shift difference between A^+ and AX_2^-, where X is an anionic ligand;[7] further data, both from this research group[8–11] and the literature,[12–20] has shown its wide applicability to a large variety of substituents on phosphorus.

The ^{31}P chemical shifts of some phosphorus(V) compounds A^+, AX and AX_2^- are shown in Table 1, together with Δ_1 and Δ_2. All shifts have been rounded off to the nearest ppm, and are expressed relative to 85% H_3PO_4, with the downfield direction taken as positive. Δ_1 is plotted against Δ_2 in Fig. 1. It is clear that Δ_1 and Δ_2 increase systematically in the same direction; the relationship is not perfectly linear—indeed there is no reason to expect a linear correlation—but appears to tail off for higher values of Δ_1 and Δ_2. The best straight line from a least squares fit of the data, neglecting the last point, is shown.

The occurrence of this relationship is rather unexpected since the change in coordination number is expected to cause a change from sp^3 (ψ-tetrahedral) through sp^3d (trigonal bipyramidal or square pyramidal[21]) to sp^3d^2 (ψ-octahedral) hybridisation. There are also greater possibilities of Π-bonding in the four-coordinate species with suitable substituents present, although Π-bonding may still be possible in special cases even in six-coordinate compounds.[22]

One other system for which the shifts of the four- and six-coordinate species as well as the molecular form have been reported is for addition of Cl to $EtPCl_3^+$.[9] There is a problem, however, in that the chemical shift for $EtPCl_4$ is difficult to establish in $PhNO_2$, the solvent used for recording the shifts of $EtPCl_3^+$ and $EtPCl_5^-$, since it appears to be partially dissociated in this solvent.[9] If δ ^{31}P for $EtPCl_4$ is taken as −24.2 ppm from the results in CH_2Cl_2 and

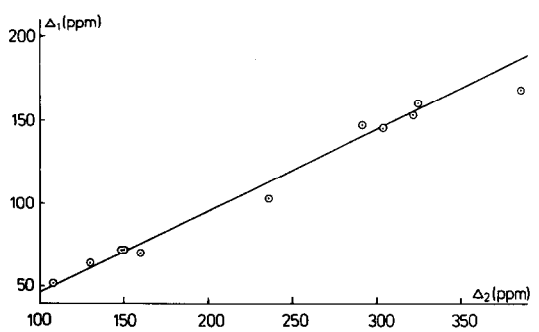

Fig. 1. Relationship between Δ_1 and Δ_2 for some phosphorus(V) species.

Table 1. Shift data for A^+, AX and AX_2^-

A	X	δ ^{31}P (ppm) for A^+	AX	AX_2^-	Δ_1	Δ_2	References
$(C_6H_4O_2)_2P$	Cl	42	−10	−66	52	108	6
$(PhO)_4P$	PhO	−22	−86	−152	64	130	8, 12
$(C_6H_4O_2)_2P$	PhO	42	−30	−107	72	149	6, 13, 14
$(MeO)_4P$	MeO	5	−67	−145	72	150	15, 16
$(C_6H_4O_2)_2P$	N_3	42	−28	−113	70	155	6, 17
$(C_6H_4O_2)PCl_2$	Cl	77	−26	−159	103	236	6
Me_2PF_2	F	155	8	−137	147	292	18, 19
$PhPCl_3$	Cl	101	−44	−203	145	304	2, 5
$C_6F_5PCl_3$	Cl	82	−71	−240	153	322	10
$MePCl_3$	Cl	120	−40	−205	160	325	9
PCl_4	Cl	88	−80	−298	168	386	1, 11, 20

C_6H_6,[9] Δ_2 is lower than expected from Fig. 1. It is possible that $EtPCl_5^-$ is always partially dissociated, even at high chloride ion concentrations, and that the shift value of −138.0 ppm, although the highest obtainable in $PhNO_2$,[9] does not represent the limiting shift for this ion. This hypothesis is in accordance with UV results, which suggested that partial formation only of $EtPCl_5^-$ took place when $EtPCl_4$ was treated with either Me_4NCl or Et_3PCl_2.[23] The alternative possibility of a lower field value than −24.2 ppm for molecular $EtPCl_4$ in $PhNO_2$, thus lowering Δ_1, cannot be entirely discounted, however.

Geometrical isomerism is possible in the six-coordinate complexes with two different substituents present and at least two of each type of ligand. For the compounds in Table 1 this applies to the addition of either two Cl, two PhO or two N_3 groups to $(C_6H_4O_2)_2P^+$, but only one shift was reported for the six-coordinate species in each case.[6,14,17] These results imply either preferential formation of one structural isomer or rapid exchange on the NMR time-scale between the possible isomers. $Me_2PF_4^-$ may also exist in isomeric forms, but again only one ^{31}P shift was reported.[19] ^{1}H and ^{19}F NMR data for this anion suggested either a *trans* configuration of the methyl groups or a fluxional species at room temperature, but the limited solubility of the salts at lower temperatures prevented *T*-dependence studies of the ^{19}F NMR,[24] which would have clarified this ambiguity. In any event the shift differences between isomeric six-coordinate phosphorus(V) species are usually small[5,9,22,25–28] compared with the values of Δ_1 and Δ_2 in Table 1, and seem unlikely to affect the graph significantly.

The plot is very useful for predictive purposes. For example, the shift of the ion PF_4^+, which is known in the compound $PF_4^+Sb_3F_{16}^-$[29] but for which no ^{31}P NMR has been recorded, may be predicted as *ca* −15 ppm from the shifts of PF_5[30] and PF_6^-.[25] Similarly the shift of the unknown ion $Ph_2PCl_4^-$ may be derived as *ca* −150 ppm from the data for $Ph_2PCl_2^+$ and Ph_2PCl_3.[11,31]

OPTICAL ACTIVITY OF COMPOUNDS FORMED BY AMINO-COMPLEXES OF Co(III) AND CARBOHYDRATES—I

S. BUNEL* and C. IBARRA

Departamento de Análisis Químico, Facultad de Ciencias Básicas y Farmacéuticas, Universidad de Chile, Casilla 233, Santiago, Chile

(*Received* 2 *January* 1985; *accepted* 20 *February* 1985)

Abstract—The preparation of aminocomplexes of Co(III) containing D-ribose, L-sorbose or D-glucosamine as second ligand is described. Their spectral features and optical activity are reported. Formation in solution of complex species with other chosen carbohydrates gives ground for discussion as to the origin and sign of the observed Cotton effects.

While the formation of complexes by interaction of carbohydrates with metallic ions has been a subject of ever increasing interest,[1] the generation of optically active species has received little attention as compared with other chiral ligands.

We herein report the results of a study which was originally aimed at finding out whether the asymmetric medium provided by a carbohydrate in solution was able to orient the chelate rings of the complex *cis*-$[Co(phen)_2(H_2O)_2]^{3+}$,[2] (phen = 1,10-phenanthroline), according to a preferred chirality. The presence of a Cotton effect under the Co(III) ion first visible absorption band and the existence of carbohydrate in the compound chromatographically isolated from the reacting mixture revealed that coordination of the carbohydrate to the metallic ion takes place.

Preliminary studies showed that other amino-complexes of Co(III) such as *cis*-$[Co(en)_2(H_2O)_2]^{3+}$, (en = ethylenediamine),[3] and *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ react in the same way with several monosaccharides, incorporating them into the coordination sphere.

We will here show results of measurements performed on compounds formed by reaction between the complex ion *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ and the monosaccharides D-ribose, L-sorbose and D-glucosamine. These last were chosen considering the number of asymmetric carbon atoms per molecule, the series they belong to, and the presence of an amino group which has a good donor atom in the case of D-glucosamine (Fig. 1).

At the same time, studies in solution were carried out with the same Co(III) aminocomplex and other carbohydrates in an attempt to find a correlation between the characteristics of the observed Cotton effects and their structure.

EXPERIMENTAL

Materials

The carbohydrates came from Merck and were used without further purification, but their $[\alpha]_D^t$ values were checked.

The complex *cis*-$[Co(NH_3)_4(H_2O)_2]_2(SO_4)_3 \cdot 3H_2O$ was synthesized in the laboratory following reported methods.[4]

Preparation of $[Co(NH_3)_4(D\text{-}ribose)]_2(SO_4)_3 \cdot 4H_2O$

A mixture of 0.835 g (1.25 mmole) of

cis-$[Co(NH_3)_4(H_2O)_2]_2(SO_4)_3 \cdot 3H_2O$

and 3.750 g (25 mmole) of D-ribose is dissolved in 25 cm^3 of water and the solution pH is adjusted to 6.2 with drops of ammonia solution. The temperature of

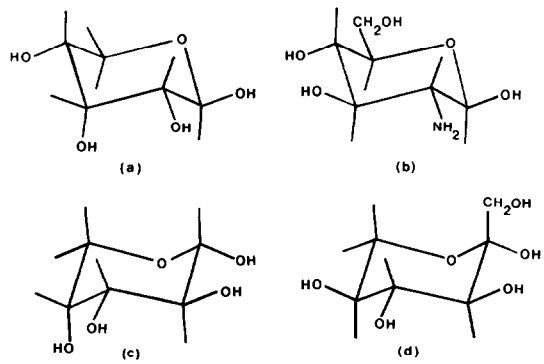

Fig. 1. (a) β-D-ribose; (b) β-D-glucosamine (2-amino-2-deoxy-D-glucose); (c) α-D-arabinose; (d) α-L-sorbose.

* Author to whom correspondence should be addressed.

the reacting mixture is kept at 30°C for 60 min in a thermoregulated water bath. A sample of the solution is placed in a thermostatted polarimetric cell of 0.5 cm pathlength and the course of the reaction is followed through the change of rotation of polarized light at 475 nm. Once the reaction stops the solution is removed from the bath and poured into a beaker, and 25 cm^3 of methanol is added dropwise with constant stirring. The liquid is then centrifuged to eliminate traces of the polynuclear complex

$[Co\{(OH)_2Co(NH_3)_4\}_3](SO_4)_3nH_2O$ (n = 2–9),[5]

which is also formed in the course of the reaction and it was identified by analysis and IR spectrum. Methanol is then added to the clear solution with constant stirring up to a total addition of 100 cm^3. During this process, the formation is observed of a microcrystalline precipitate which adheres to the walls of the beaker. The precipitate is separated by filtration in glass plates, washed with 5 cm^3 methanol and then 5 cm^3 ethanol; it is then quickly removed from the plate and dried under vacuum. The yield is about 350 mg.

The microcrystalline solid is deep pink, very soluble in water, giving a solution of the same colour. The solid compound is stable if kept in a dry atmosphere.

Found: C, 13.18; H, 5.48; N, 12.47; Co, 13.86; SO_4, 31.32. Calc: C, 13.13; H, 5.68; N, 12.25; Co, 12.91; SO_4, 31.51%.

Preparation of $[Co(NH_3)_4$(L-*sorbose*)$]_2(SO_4)_3$

0.835 g (1.25 mmole) of *cis*-$[Co(NH_3)_4(H_2O)_2](SO_4)_3 \cdot 3H_2O$ and 4.5 g (25 mmole) of L-sorbose are dissolved in 25 cm^3 of water; the solution pH is raised to nearly 6.5 with drops of ammonia solution. The procedure previously described is followed, but in this case the maximum value of rotation is reached after 45 min of heating at 30°C. The yield is 400 mg.

The compound is a deep pink microcrystalline solid, stable in a dry atmosphere. It is soluble in water and the solutions decompose slowly. Dissociation of the complex species was checked by measuring the rotation of solutions prepared by successive dilutions.

Found: C, 15.49; H, 5.43; N, 12.67; Co, 14.3; SO_4, 32.63. Calc: C, 15.96; H, 5.32; N, 12.42; Co. 13.8; SO_4, 31.93%.

Preparation of $[Co(NH_3)_3$(D-*glucosamine*)$]_2(SO_4)_3 \cdot 4H_2O$

A mixture of 0.835 g (1.25 mmole), of

cis-$[Co(NH_3)_4(H_2O)_2]_2(SO_4)_3 \cdot 3H_2O$

and 2.69 g (12.5 mmole) of D-glucosamine hydrochloride is dissolved in 55 cm^3 of water; the solution pH is raised to 7 with drops of ammonia solution. The procedure described for the preparation of the complexes previously mentioned is applied with the following modifications: (a) the time needed to reach the maximum value of rotation at 475 nm is 40 min; (b) after addition of the first 25 cm^3 of methanol to the solution and centrifugation, another 50 cm^3 of the same solvent is added. Formation is observed of a viscous dark red product adhering to the walls of the beaker. The supernatant is then separated and residues of methanol and water are evaporated with an air current. The viscous material is redissolved in 3 cm^3 of water and then poured, drop by drop, into 70 cm^3 of 95% methanol containing about 100 mg $NaClO_4$. The liquid is constantly stirred during the process. The yield is 400 mg.

The compound is a violet microcrystalline solid, water soluble, giving deep red solutions. It is a stable compound in the absence of humidity.

Found: C, 15.47; H, 5.52; N, 12.01; Co, 12.45; SO_4, 31.36. Calc: C, 15.38; H, 5.55; N, 11.96; Co, 12.60; SO_4, 30.76%.

Analyses of C, H and N were performed with a Perkin–Elmer 240 microanalyzer. Carbon was also determined from the sugar content and analyzed by oxidation with ceric sulphate,[6] and nitrogen was checked as NH_3 with a specific electrode, after digestion with sulphuric acid.

Cobalt content was iodometrically determined as Co_2O_3.[7]

Sulphate analyses were carried out both gravimetrically and by means of a chloride-exchange resin in a column, the exchanged chloride being measured with an appropriate electrode.

Water of hydration was estimated by variation in whole number multiples to give best agreement with analytical data. Compounds with different number of hydration water molecules are obtained. Results herein reported correspond to one batch in each case. These variations in composition are reflected through bigger or smaller values of the measured optical activity.

Absorption spectra were measured with a Zeiss PMQ-2 spectrophotometer over 10^{-2} to 10^{-3} M solutions of the complexes.

Optical rotatory dispersion measurements were carried out with a modified Perkin–Elmer 141 polarimeter and Bausch and Lomb monochromator over 10^{-2} M water solutions using 2 cm pathlength cells. Variation of the angle of rotation against time was followed employing a 0.5 cm pathlength cell.

Circular dichroism measurements were carried out with a Schimadzu QV-50 spectrophotometer

fitted with circular dichroism attachment, on 10^{-2} M solutions with 1 cm pathlength cells.

RESULTS AND DISCUSSION

Figure 2 is shown as an example of the optical activity of the reaction product in solution between the Co(III) aminocomplex and D- and L-arabinose respectively, once the maximum value of rotation at one wavelength is reached in each case. These carbohydrates were chosen because they are enantiomorphs. They give optical rotatory dispersion curves of opposite sign. It can also be seen that, considering the dispersion curve of the carbohydrate as a base line, two Cotton effects are apparent in the region of Co(III) visible first absorption band. Maximum rotation is attained after 100 min.

The reagent *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ has two visible absorption bands: the first one is located at 505 nm and the second one at 355 nm. Introduction of carbohydrate into the coordination sphere causes a shift of the first absorption band maximum to 525 nm and of the second one to 375 nm. Besides, the second band is overlapped by an intense charge-transfer transition located at 220 nm with an extinction coefficient of 11,600 cm^2 $mole^{-1}$.

From the spectroscopic point of view, complexes of the type $[Co(NH_3)_4(carbohydrate)]^{3+}$ behave like the complex $[Co(NH_3)_4CO_3]^+$,[8] whose first and second absorption bands are located at 522 and 360 nm respectively. The spectra correspond, in both cases, to the coordination of 4 nitrogen and two *cis*-oxygen atoms around the Co(III) ion. Therefore the carbohydrate contribution would turn out to be similar to that of the carbonate ion.

In the complexes formed by D-ribose and L-sorbose the second absorption band keeps its identity (Table 1); but in the complex with D-glucosamine overlapping is broader and the second *d–d* band appears as only a shoulder at 375 nm.

The two Cotton effects with $-+$ sign sequence observed in Fig. 3 are located under the first absorption band of the complexes formed by D-ribose, L-sorbose and D-glucosamine, in agreement with the two signals of opposite sign revealed by the circular dichroism spectra of the same compounds (Table 1).

This pattern of separation is characteristic of complexes of the type *cis*-$[Co(NH_3)_4L_2]$ where L is a bidentate or a non-charged monodentate ligand. The $^1T_{1g}$ transition in C_{2v} symmetry is split in one component with A_2 symmetry and two others with B_1 and B_2 symmetries. The last two components generally intermix, whereas the A_2 state remains invariant.[9] Similar result is obtained under the holohedrized D_{4h} symmetry, where the $^1T_{1g}$ transition is split into the $^1A_{2g}$ and E_g transitions, which have an energy difference $\frac{1}{4}[\Delta_O - \Delta_{NH_3}]$. Considering that Δ_O (O = carbohydrate oxygen atom) is smaller than Δ_{NH_3}, it is possible to deduce that the negative circular dichroism component would correspond to the A_2 state, whereas the positive component would correspond to the E state.[10]

In all three cases the molar amplitudes of the Cotton effects centred at 510 nm are remarkably high: values range from 5900 to 13,350°. They are thus much higher than values given by a complex such as $[Co(NH_3)_4(sarcosinate)]^{2+}$, where the molar amplitude of the positive Cotton effect in the visible region is 1800°.[11]

The complexes formed by D-ribose and L-sorbose show only one positive circular dichroism signal in the charge-transfer spectral zone and they are placed at 300 and 320 nm respectively. The complex formed by D-glucosamine has two circular dichroism signals instead: a positive one at 315 nm and a negative signal at 270 nm.*

Taking account of the fact that the isolated compounds showed the same type of optical rotatory dispersion curve as that of the reaction products in solution, further experiments were performed with other carbohydrates and derivatives. They were selected so that they would permit the correlation of the sign of optical rotation of the complexes formed with the structure of the carbohydrate. In this way, the sign of the Cotton effect centred at 500 nm is positive for the product of the reaction between the tetramino Co(III) complex and 2-deoxy-D-glucose, whereas in the reaction product with α-methyl-D-glucoside the same is negative (Fig. 4).

The signs of the Cotton effects in the visible absorption region are the same for the compounds formed by D-ribose, L-sorbose, D-glucosamine and L-arabinose. This result is striking at first sight in view of the different configurations of these carbohydrates, the number of asymmetric carbon atoms and the possibilities of anomeric mixtures and pyranoidal or furanoidal structures. The constant pattern of optical rotatory dispersion in spite of the diversity of structural possibilities can be accounted for if one admits the requirement of a surrounding of identical chirality around the Co(III) ion in all these compounds.

It is well known that the anomeric equilibrium is

* Circular dichroism spectra in the UV region were measured in Santa Barbara, California with a Cary 60 spectropolarimeter. The complexes could have partially lost their optical activity on travelling; therefore we have omitted the $\Delta\varepsilon$ values obtained.

shifted towards the β-form in the carbohydrates D-glucosamine and D-ribose; whereas D-arabinose is mainly an α-anomer.[12] Accepting that the carbohydrates bond to Co(III) preferably through the OH groups of C1 and C2, the chelate rings formed display an arrangement of one carbon atom over and another one under the *xy* plane of the $\{Co(NH_3)_4\}$ species looked at from the metallic centre and moving from left to right, as can be appreciated in Fig. 5. This arrangement of atoms is somehow equivalent to the conformation adopted by the N–C–C–N chain of the ethylenediamine molecule when bonding to the Co(III) ion to form a complex.[13]

Besides the bonding sites already mentioned, other existing possibilities would lead to identical chiral ring, for example the OH groups of C3 and C4 of D-glucosamine; or else, the OH groups of C2 and C3 of D-ribose or of L-sorbose.

The preference for coordination through the donor groups bonded to C1 and C2 is perhaps reflected in the signs of the Cotton effects observed in the reaction product in solution of α-methyl-D-glucoside with the Co(III) aminocomplex, which are

Table 1. Visible-absorption and circular dichroism data

	Absorption		Circular dichroism

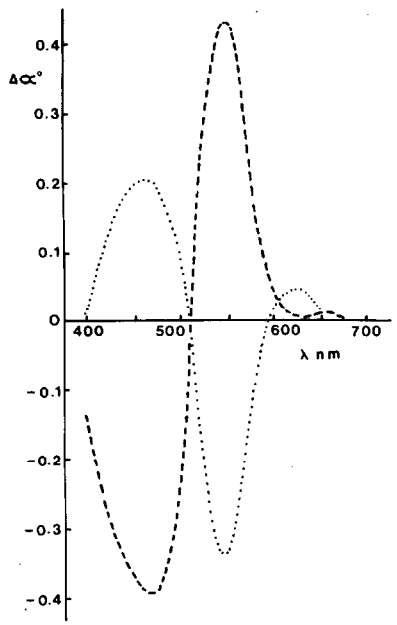

Fig. 4. Optical rotatory dispersion of complex species formed in solution after 30 min at 30°C, pH 6, 0.5 cm pathlength cell. (····) *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ 0.1 M/α-methyl-glucose 0.5 M; (— —) *cis*-$[Co(NH_3)_4(H_2O)_2]^{3+}$ 0.1 M/2-deoxy-glucose 0.5 M. $\Delta\alpha = \alpha_{\text{complex species}} - \alpha_{\text{carbohydrate}}$

opposite to those of the complexes containing D-ribose, L-sorbose and D-glucosamine. Structurally, coordination through sites 1 and 2 of the glucoside gives rise to a ring of the corresponding opposite chirality, although bonding to the metallic ion can also be achieved through the OH groups of C3 and C4.

When 2-deoxy-D-glucose is used for the reaction, the sign of the Cotton effect centred at 510 nm, is the same as that obtained for the complexes formed by D-ribose, L-sorbose and D-glucosamine. According to our proposal this is achieved by coordination through the OH groups of C3 and C4, which are the only sites properly arranged for chelation in this carbohydrate.

The difficulties we have found to isolate a solid compound from the reaction product with 2-deoxy-D-glucose can indicate that bonding through OH groups of carbon atoms other than C1 and C2 leads to unstable species.

In the case of L-sorbose, which is formed in solution by 98% of the α-anomer,[14] coordination is probably established through the OH groups of C2 and C3, since bonding through sites 1 and 2 is sterically hindered, as revealed by a molecular model to scale. Again, decomposition of the complex in solution by dissociation may be reflecting the lability of the bond between the Co(III) aminocomplex and this sugar.

Finally when 2-deoxy-ribose was used for the reaction there was no evidence of coordination. For the pyranoidal structure, the OH groups of C3 and C4 are the only ones that can be used for chelation.

THEORETICAL STUDY OF THE STATIC JAHN–TELLER EFFECT—I. TWO-MODE VIBRONIC COUPLING IN OCTAHEDRAL HALOCOMPLEXES WITH DOUBLY DEGENERATE ELECTRONIC STATES

PETER PELIKÁN, MARTIN BREZA and ROMAN BOČA*
Departments of Physical and Inorganic Chemistry, Slovak Technical University, CS-812 37 Bratislava, Czechoslovakia

(*Received* 11 *December* 1984; *accepted* 20 *February* 1985)

Abstract—A two-mode E_g–$(a_{1g}+e_g)$ vibronic coupling is analyzed for octahedral systems. Analytic formula for the adiabatic potential surface (APS) is obtained considering quadratic vibronic terms and anharmonicities of normal vibrations as well. Potential constants, viz. five elastic force constants and three vibronic constants, are evaluated from the numerical map of the APS applying the non-linear regression analysis. Numerical values are obtained for hexahalocomplexes on the CNDO/INDO level of total energy calculations.

The adiabatic potential surface (APS) represents a principal concept useful in various different areas of chemical physics, connecting together molecular structure, spectroscopy, statistical thermodynamics, chemical thermodynamics and kinetics in a unified manner. The usual procedure is to consider the APS in a parametric form where some constants, specifying its shape, occur. They may be obtained from experimental data. Another approach lies in the direct quantum-chemical calculations of the total molecular energy for fixed positions of nuclei thus yielding a continuous parameteric function of nuclear configurations.

However, the existence of electron degeneracy for certain configurations of nuclei makes the problem of specifying the analytic form of the APS more complex. The electron-vibration (vibronic) interaction manifests itself in new phenomena among which the Jahn–Teller effect plays the dominant role. The generally accepted formulation of the Jahn–Teller theorem[1] consists of the assertion that a non-linear nuclear configuration in the degenerate electronic state is energetically unstable. This theorem implies the existence of at least one stable nuclear configuration in which the electron degeneracy is removed so that the system relaxes to an energetically more advantageous non-degenerate state.[2–9]

Considerations resulting in an analytic form of the APS for doubly degenerate electronic states (mostly in octahedral or tetrahedral reference configurations) have a long history. Among them let us mention the approaches by van Vleck,[10] Öpik and Pryce,[11] Moffitt and Liehr,[12] Liehr and Ballhausen,[13] Coffman,[14] O'Brien[15] and Goodenough.[16] Nevertheless, those considerations seem to be incomplete as they are based on the *E*–*e* single-mode coupling scheme only. In two papers[17,18] we have indicated that the two-mode *E*–(a_1+e) coupling scheme appears to be a more realistic model. In trying to develop our two-mode approach, the conditions yielding the analytic form of the APS were here re-derived. They resulted in a more complex (and hence the more flexible) form of the APS for the case of two-fold degenerate electronic state. Connections with other approaches and possibilities of further extensions are clearly demonstrated.

Several authors have applied the MO–LCAO–SCF method in predicting the Jahn–Teller distortions in metal complexes and organic cation radicals.[19–23] The EHT, CNDO, INDO, MINDO/3 and *ab initio* calculations proved the existence of a stable nuclear configuration with lowered symmetry, the results being in qualitative agreement with the Jahn–Teller theorem. The Jahn–Teller distortions and stabilization energies, however, represent only one aspect of the vibronic coupling. More complete information may be obtained if the elastic force constants and the vibronic coupling constants are evaluated. For this purpose we outlined a non-

* Author to whom correspondence should be addressed.

linear regression method by which the numerical values of the APS were used to fit its analytic form. The semiempirical CNDO–UHF and INDO–UHF methods were applied in order to calculate the total molecular energy of hexahalo complexes $^m[MX_6]^q$.

TWO-STATE STRONG VIBRONIC COUPLING

The non-relativistic electronic Hamiltonian $\hat{H}(r, Q)$ of a molecule may be partitioned into the electronic kinetic energy operator $\hat{T}_e(r)$, the electronic repulsion $\hat{V}_{ee}(r)$, the electron-nuclear potential energy $\hat{V}_{eN}(r, Q)$ and the mutual repulsion of nuclei $\hat{F}_{NN}(Q)$:

$$\hat{H}(r, Q) = \hat{T}_e(r) + \hat{V}_{ee}(r) + \hat{V}_{eN}(r, Q) + \hat{F}_{NN}(Q), \quad (1)$$

r and Q being the electron and nuclear coordinates, respectively. For a fixed set of nuclear coordinates $[Q]$, this Hamiltonian has a set of eigenfunctions $v_n(r; [Q])$:

$$\{\hat{H}(r, Q) - E_n[Q]\} v_n(r; [Q]) = 0, \quad (2)$$

with corresponding eigenvalues $E_n[Q]$. The total Hamiltonian, including the nuclear kinetic energy operator $\hat{T}_N(Q)$, obeys the Schrödinger equation

$$\{\hat{T}_N(Q) + \hat{H}(r, Q) - W\} \Psi(r, Q) = 0, \quad (3)$$

where the electron-nuclear (vibronic) wave function Ψ may be expanded to the form:

$$\Psi(r, Q) = \sum_i v_i(r; [Q^0]) \chi_i(Q). \quad (4)$$

Usually, Q^0 is a configuration of nuclei where the energy $E_n[Q]$ displays a minimum value.

Following Özkan and Goodman,[24] an approximate solution of vibronic equations for W and $\chi_i(Q)$, as they appear by combination of eqns (3) and (4), may be obtained by the partitioning technique. For the two-state strong coupling case the unperturbed (zero-order) wave function stands:

$$\begin{aligned} \Psi^0 &= v_n(r; [Q^0]) \chi_n(Q) + v_m(r; [Q^0]) \chi_m(Q) \\ &= v_n^0 \chi_n + v_m^0 \chi_m \end{aligned} \quad (5)$$

and the perturbation covers the remaining terms, namely:

$$\Psi^1 = \sum_{i \neq m,n} v_i^0 \chi_i. \quad (6)$$

An ordered set of eigenvalues, $E_n^0 \leqslant E_m^0 < E_i^0$, is assumed where a simplified notation of $E_n^0 = E_n[Q^0]$ is used. In a first approximation, the vibrational functions χ_n^0 and χ_m^0 are calculated by means of equation:

$$\begin{bmatrix} \hat{T}_N + U_{nn} - W; & U_{nm} \\ U_{mn}; & \hat{T}_N + U_{mm} - W \end{bmatrix} \begin{bmatrix} \chi_n^0 \\ \chi_m^0 \end{bmatrix} = 0, \quad (7)$$

where the total energy W is measured relative to E_n^0 by

$$W = E_n^0 + \varepsilon_n, \quad (8)$$

thus defining a purely vibrational energy ε_n. The matrix elements U_{nm} contain a Taylor expansion of $H_{nm} = \langle v_n^0 | \hat{H}(r, Q) | v_m^0 \rangle$ (usually up to the quadratic terms) and the second-order energy correction $E^{(2)}$ as it follows from the first-order wave function by the perturbation treatment:

$$\begin{aligned} U_{nm} = E_n^0 \delta_{nm} + H_{nm}^{(1)} + H_{nm}^{(2)} \\ + \ldots + \sum_{i \neq n,m} H_{ni}^{(1)} H_{im}^{(1)} / (E_n^0 - E_i^0) \end{aligned} \quad (9)$$

or

$$\mathbf{U} = E^0 \mathbf{1} + \mathbf{H}^{(1)} + \mathbf{H}^{(2)} + \cdots + \mathbf{E}^{(2)}. \quad (10)$$

Therefore, the U_{nm} elements may be considered as a projection of the electronic Hamiltonian into the subspace spanned by the electronic functions v_n^0 and v_m^0.

The lowest powers of the Taylor series are:

$$\begin{aligned} H_{nm}^{(1)} &= \sum_k \left\langle v_n^0 \middle| \left(\frac{\partial \hat{H}}{\partial Q_k} \right)_0 \middle| v_m^0 \right\rangle \Delta Q_k \\ &= \sum_k \left\{ \left(\frac{\partial \hat{F}_{NN}}{\partial Q_k} \right)_0 \delta_{nm} \right. \\ &\quad \left. + \left\langle v_n^0 \middle| \left(\frac{\partial \hat{V}_{eN}}{\partial Q_k} \right)_0 \middle| v_m^0 \right\rangle \right\} \Delta Q_k \\ &= \sum_k \{ F^k \delta_{nm} + V_{nm}^k \} \Delta Q_k \\ &= F^{(1)} \delta_{nm} + V_{nm}^{(1)}, \end{aligned} \quad (11)$$

$$\begin{aligned} H_{nm}^{(2)} &= \tfrac{1}{2} \sum_{k,l} \left\langle v_n^0 \middle| \left(\frac{\partial^2 \hat{H}}{\partial Q_k \partial Q_l} \right)_0 \middle| v_m^0 \right\rangle \Delta Q_k \Delta Q_l \\ &= \tfrac{1}{2} \sum_{k,l} \left\{ \left(\frac{\partial^2 \hat{F}_{NN}}{\partial Q_k \partial Q_l} \right)_0 \delta_{nm} \right. \\ &\quad \left. + \left\langle v_n^0 \middle| \left(\frac{\partial^2 \hat{V}_{eN}}{\partial Q_k \partial Q_l} \right)_0 \middle| v_m^0 \right\rangle \right\} \Delta Q_k \Delta Q_l \\ &= \tfrac{1}{2} \sum_{k,l} \{ F^{kl} \delta_{nm} + V_{nm}^{kl} \} \Delta Q_k \Delta Q_l \\ &= F^{(2)} \delta_{nm} + V_{nm}^{(2)} \end{aligned} \quad (12)$$

and analogically

$$\begin{aligned} H_{nm}^{(3)} &= \tfrac{1}{6} \sum_{k,l,j} \{ F^{klj} \delta_{nm} + V_{nm}^{klj} \} \Delta Q_k \Delta Q_l \Delta Q_j \\ &= F^{(3)} \delta_{nm} + V_{nm}^{(3)}, \end{aligned} \quad (13)$$

where the derivatives are to be evaluated at the nuclear configuration of Q^0. The quantities $\Delta Q = Q - Q^0$ are the internal displacement coordinates measured relative to Q^0. They may be chosen, within a symmetry point group G_0, each of them belonging

to a γ line of the Γ representation. Thus, the electron-nuclear interaction terms are:

$$V^{(1)}_{nm} = \sum_{\Gamma_1\gamma_1} V_{nm}[\Gamma_1\gamma_1]\Delta Q[\Gamma_1\gamma_1], \tag{14}$$

$$V^{(2)}_{nm} = \tfrac{1}{2}\sum_{\Gamma_1\gamma_1}\sum_{\Gamma_2\gamma_2} V_{nm}[\Gamma_1\gamma_1, \Gamma_2\gamma_2] \times \Delta Q[\Gamma_1\gamma_1]\Delta Q[\Gamma_2\gamma_2]. \tag{15}$$

The last expression is a scalar convolution of two second-rank tensors, their components forming a basis of the $\Gamma_1 \otimes \Gamma_2$ direct product. These considerations are useful in reducing the number of indepedent parameters and in specifying the analytic form of the potential **U**. The matrix elements can be expressed through reduced matrix elements and the respective Clebsh–Gordan coefficients via the Wigner–Eckart theorem or the group theory treatment.[25]

Considering the fixed (frozen) nuclei, the nuclear kinetic energy disappears ($T_N \to 0$) and thus the vibrational energy vanishes ($\varepsilon_n \to 0$). Consequently, the eigenvalues of the secular equation

$$\det\begin{bmatrix} U_{nn}-W; & U_{nm} \\ U_{mn}; & U_{mm}-W \end{bmatrix} = 0 \tag{16}$$

adopt a meaning of the adiabatic potential surface (APS) in the two-state strong coupling case. This is the basic equation which connects various treatments in a unified manner, namely:

(i) the strict degeneracy at the nuclear configuration of Q^0 ($U_{nn} = U_{mm}$) considered in the static Jahn–Teller effect;

(ii) the quasi-degeneracy ($U_{nn} \approx U_{mm}$) considered in the pseudo-Jahn–Teller effect.

Moreover, the method may be simply extended to the three-state strong coupling case and the limiting case for a single state weakly coupled with excited ones is obvious. Having calculated the matrix elements **U**, the solution of vibronic eqn (7) is processed. Notice, **U** looses a meaning of the potential energy in dynamical equations for nuclear motion (7).

ANALYTIC FORM OF APS FOR E_g–($a_{1g}+e_g$) COUPLING

Let us consider an octahedral system ML_6 with the doubly degenerate electronic state E_g. The set of internal displacement coordinates may be represented by 15 normal modes, $Q_1, \ldots, Q_{15}$. Among them, $Q_1(a_{1g})$ is the symmetric stretching, $Q_2(e_g)$ corresponds to the orthorhombic and $Q_3(e_g)$ to the tetragonal distortion. The remaining coordinates span to t_{2g}, t_{2u}, t'_{1u} and t''_{1u} irreducible representations. This assignment allows one to select the non-zero linear integrals in eqn (11), because the Wigner–Eckart theorem states:

$$V^k_{nm} = \left\langle n\left|\left(\frac{\partial \hat{V}(r,Q)}{\partial Q_k}\right)_0\right|m\right\rangle = X(\Gamma_k;\Gamma_n,\Gamma_m)C^{\Gamma_n\Gamma_k\Gamma_m}_{\gamma_n\gamma_k\gamma_m}. \tag{17}$$

The reduced matrix element $X(\Gamma_k;\Gamma_n,\Gamma_m)$ depends only on the irreducible representations Γ_k, Γ_n and Γ_m, and the Clebsh–Gordan (Wigner) coefficients C (or the $3j$-symbols) have been tabulated.[25] For the electronic doublet ($\Gamma_n = \Gamma_m = E_g$) the integral V^k_{nm} is non-zero only if Γ_k will be contained in the symmetrized direct product

$$[\Gamma_n \otimes \Gamma_m] = [E_g \otimes E_g] = A_{1g} + E_g. \tag{18}$$

Thus the integrals V^k_{nm} for $k = 4, 5, \ldots, 15$ (the t-type representation of Q_k) are vanished and for the linear part $\mathbf{V}^{(1)}$ it holds:

$$\mathbf{V}^{(1)} = X_A\Delta Q_1\mathbf{C}_1 + X_E\Delta Q_2\mathbf{C}_2 + X_E\Delta Q_3\mathbf{C}_3, \tag{19}$$

where

$$\mathbf{C}_1 = \begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix},\quad \mathbf{C}_2 = \frac{1}{\sqrt{2}}\begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix},\quad \mathbf{C}_3 = \frac{1}{\sqrt{2}}\begin{pmatrix}-1 & 0\\ 0 & 1\end{pmatrix} \tag{20}$$

are the matrices of Wigner coefficients in the doubly degenerate function space. Totally, $2\times 15\times 2 = 60$ linear integrals V^k_{mn} are reduced to the number of six non-zero elements where only two distinct reduced matrix elements, $X_A = X(a_{1g}; E_g, E_g)$ and $X_E = X(e_g; E_g, E_g)$, occur.

The quadratic terms V^{kl}_{nm} in eqn (12) require a successive reduction of the operator part according to the Wigner formula:

$$|\Gamma_k\Gamma_l\gamma_k\gamma_l\rangle = \sum_{\Gamma,\gamma}\begin{pmatrix}\Gamma_k & \Gamma_l & \Gamma\\ \gamma_k & \gamma_l & -\gamma\end{pmatrix}|\Gamma_k\Gamma_l\Gamma_\gamma\rangle \tag{21}$$

where the $3j$-symbols in parentheses again have been tabulated. The summations run over all Γ and γ contained in the reducible representation of the direct product $\Gamma_k \otimes \Gamma_l$.[26]

Applying the above procedure, the quadratic part $\mathbf{V}^{(2)}$ can be partitioned into three terms:

$$\begin{aligned}\mathbf{V}^{(2)} &= \mathbf{V}^{(2)}[a+e,a+e] + \mathbf{V}^{(2)}[t,t] + \mathbf{V}^{(2)}[a+e,t]\\ &= \tfrac{1}{2}\sum_{k=1}^{3}\sum_{l=1}^{3}\mathbf{V}^{kl}[a+e,a+e]\,\Delta Q_k\Delta Q_l\\ &\quad + \tfrac{1}{2}\sum_{k=4}^{15}\sum_{l=4}^{15}\mathbf{V}^{kl}[t,t]\,\Delta Q_k\Delta Q_l\\ &\quad + \tfrac{1}{2}\sum_{k=1}^{3}\sum_{l=4}^{15}\mathbf{V}^{kl}[a+e,t]\,\Delta Q_k\Delta Q_l.\end{aligned} \tag{22}$$

For the first term it may be written:

$$\mathbf{V}^{(2)}[a+e,a+e]$$
$$= \left\{\frac{1}{2}X_{AA}\Delta Q_1^2 + \frac{1}{2\sqrt{2}}X_{EE}(\Delta Q_2^2+\Delta Q_3^2)\right\}\mathbf{C}_1$$
$$+\left\{X_{AE}\Delta Q_1\Delta Q_2 + \frac{1}{\sqrt{2}}X_{EE}\Delta Q_2\Delta Q_3\right\}\mathbf{C}_2$$
$$+\left\{X_{AE}\Delta Q_1\Delta Q_3 + \frac{1}{2\sqrt{2}}X_{EE}(\Delta Q_2^2-\Delta Q_3^2)\right\}\mathbf{C}_3, \quad (23)$$

where three reduced matrix elements occur (X_{AA}, X_{AE} and X_{EE}). The second term of eqn (22) can be evaluated in an analogous manner but it is not considered within the E_g–$(a_{1g}+e_g)$ coupling model. The last term vanishes exactly by the symmetry. In this way, the number of $2\times15\times15\times2 = 900$ quadratic integrals V_{nm}^{kl} becomes reduced to 16 non-zero elements.

The nuclear–nuclear interaction part of **H** for three relevant vibrational modes is:

$$F^{(1)} = \sum_{k=1}^{3} F^k \Delta Q_k = F_A \Delta Q_1, \quad (24)$$

$$F^{(2)} = \tfrac{1}{2}\sum_{k=1}^{3}\sum_{l=1}^{3} F^{kl}\Delta Q_k\Delta Q_l$$
$$= \tfrac{1}{2}F_{AA}\Delta Q_1^2 + \tfrac{1}{2}F_{EE}(\Delta Q_2^2+\Delta Q_3^2), \quad (25)$$

$$F^{(3)} = \tfrac{1}{6}\sum_{k=1}^{3}\sum_{l=1}^{3}\sum_{j=1}^{3} F^{klj}\Delta Q_k\Delta Q_l\Delta Q_j$$
$$= F_{AAA}\Delta Q_1^3 + F_{AEE}\Delta Q_1(\Delta Q_2^2+\Delta Q_3^2)$$
$$+F_{EEE}(3\Delta Q_2^2\Delta Q_3 - \Delta Q_3^3). \quad (26)$$

Notice, that the contribution from the nuclear vibrations has to be of a_1 symmetry. The procedure outlined by Goodenough[16] may be used in order to derive eqns (25) and (26).

Omitting the weak vibronic coupling of the ground-state electronic doublet E_g with excited states (the second-order perturbation correction $\mathbf{E}^{(2)}$), the potential U adopts the general form of

$$\mathbf{U} = E^0\mathbf{1} + \mathbf{H}^{(1)} + \mathbf{H}^{(2)} = c_1\mathbf{C}_1 + c_2\mathbf{C}_2 + c_3\mathbf{C}_3 \quad (27)$$

and its eigenvalues, according to eqn (16), are:

$$W = c_1 \pm \sqrt{(c_2^2+c_3^2)/2}. \quad (28)$$

The explicit form of the Wigner matrices (20) has to be considered in order to prove eqn (28). After simple algebraic manipulations, inspection of eqns (19) and (22)–(28) proves, that it is legitimate to consider the adiabatic potential surface in the analytic form of:

$$W = E^0 + (F_A+X_A)\Delta Q_1 + \frac{1}{2}(F_{AA}+X_{AA})\Delta Q_1^2$$
$$+\frac{1}{2}\left(F_{EE}+\frac{1}{\sqrt{2}}X_{EE}\right)(\Delta Q_2^2+\Delta Q_3^2)$$
$$\pm\left\{\frac{1}{2}(X_E+X_{AE}\Delta Q_1)^2(\Delta Q_2^2+\Delta Q_3^2)\right.$$
$$+\frac{1}{16}X_{EE}^2(\Delta Q_2^2+\Delta Q_3^2)^2$$
$$+\frac{1}{2\sqrt{2}}X_{EE}(X_E+X_{AE}\Delta Q_1)$$
$$\left.\times\Delta Q_3(3\Delta Q_2^2-\Delta Q_3^2)\right\}^{1/2}. \quad (29)$$

PHYSICAL MEANING OF POTENTIAL CONSTANTS

The reduced matrix elements X_A, X_{AA}, X_E, X_{EE} and X_{AE}, as well as F_A, F_{AA} and F_{EE} are constants (evaluated at the configuration of Q^0); they determine the shape of the adiabatic potential surface. Their physical meaning will be here briefly discussed.

First of all, $\Delta Q_2 = Q_2$ and $\Delta Q_3 = Q_3$ are valid since the reference configuration Q^0 is a regular octahedron where $Q_2^0 = Q_3^0 = 0$ holds. The matrix element

$$H_{mm}^1 = H_{nn}^1 = \left\{\frac{\partial}{\partial Q_1}\langle n|\hat{H}(r,Q)|n\rangle\right\}_0$$
$$= \left\{\frac{\partial E_n}{\partial Q_1}\right\}_0 = F_A + X_A = 0 \quad (30)$$

vanishes because of the condition of minimum energy in the optimum octahedral configuration. Thus, F_A and X_A are cancelled at the configuration Q_1^0. The matrix element

$$H_{mm}^{11} = H_{nn}^{11} = \left\{\frac{\partial^2 E_n}{\partial Q_1^2}\right\}_0 = F_{AA} + X_{AA} = K_{AA} \quad (31)$$

is positive and represents a harmonic force constant. In reality, the observable quantity is lowered by an additional term following from the $E_{nn}^{(2)}$ correction—the interaction (weak coupling) with excited electronic states. The reduced matrix element X_E usually is named as a linear vibronic coupling constant. It provides the existence of lower sheet of W referring to E^0 in directions of Q_2 and Q_3, which leads to a well-known "Mexican hat"-type behaviour of W. The reduced matrix element X_{EE} appears in two parts of the APS. In combination with F_{AA} it defines a

harmonic force constant K_{EE}:

$$K_{EE} = F_{EE} + \frac{1}{\sqrt{2}} X_{EE} > 0. \quad (32)$$

Standing under the square root of W, the quadratic vibronic coupling constant X_{EE} is responsible for a warping of the "Mexican hat"-type of potential. Finally, the reduced matrix element X_{AE} couples the a_{1g} and e_g modes and it means the two-mode vibronic coupling constant.

CONNECTIONS WITH OTHER APPROACHES

Works dealing with the static Jahn–Teller effect mostly are based on the potential W, where only the single mode E_g–e_g coupling is considered. Within this more approximative approach the coupling constant X_{AE} is omitted and the APS is simplified as:

$$W = E^0 + \tfrac{1}{2}K_{AA}\Delta Q_1^2 + \tfrac{1}{2}K_{EE}\rho^2 \pm \rho\{A^2 + B^2\rho^2 + 2AB\rho\cos(3\phi)\}^{1/2}, \quad (33)$$

where the following substitutions were used:

$$A = -X_E/\sqrt{2}, \quad B = X_{EE}/4, \quad \rho = (Q_2^2 + Q_3^2)^{1/2}, \quad Q_2 = \rho\sin\phi, \quad Q_3 = \rho\cos\phi. \quad (34)$$

Taking into account the term

$$Z = X_{AE}/\sqrt{2} \quad (35)$$

our formula (29) relaxed to:

$$W = E^0 + \tfrac{1}{2}K_{AA}\Delta Q_1^2 + \tfrac{1}{2}K_{EE}\rho^2 \pm \rho\{(A - Z\Delta Q_1)^2 + B^2\rho^2 + 2(A - Z\Delta Q_1)B\rho\cos(3\phi)\}^{1/2}. \quad (36)$$

It is seen that eqn (36) has the same form as eqn (33) usually used in interpreting the experimental data. Only the term $A \to A - Z\Delta Q_1$ needs a slight re-interpretation.

Several authors[7,11,15] tried to include a third-order term $F^{(3)} = F_{EEE}(3Q_2^2Q_3 - Q_3^3) = -F_{EEE}\rho^3\cos(3\phi)$ where the parameter F_{EEE} has a dimension of energy per volume. This term is responsible for warping the "Mexican hat"-type potential too. The corresponding function

$$W = E^0 + \tfrac{1}{2}K_{EE}\rho^2 \pm A\rho - F_{EEE}\rho^3\cos(3\phi) \quad (37)$$

has the extreme points (three absolute minima and three saddle points) for angular coordinates $\phi = n\pi/3$, being the same as for eqn (33).

The most complex potential within the E_g–e_g coupling model was considered by Goodenough[16] in the form:

$$W = E^0 + \tfrac{1}{2}K_{EE}\rho^2 \pm \rho\{A^2 + B^2\rho^2 + 2AB\rho\cos(3\phi)\}^{1/2} - F_{EEE}\rho^3\cos(3\phi). \quad (38)$$

Its counterpart within the E_g–$(a_{1g} + e_g)$ coupling scheme, proposed here, is

$$W = E^0 + \tfrac{1}{2}K_{AA}\Delta Q_1^2 + \tfrac{1}{2}K_{EE}\rho^2 + F_{AAA}\Delta Q_1^3 + F_{AEE}\Delta Q_1\rho^2 - F_{EEE}\rho^3\cos(3\phi) \pm \rho\{(A - Z\Delta Q_1)^2 + B^2\rho^2 + 2(A - Z\Delta Q_1)B\rho\cos(3\phi)\}^{1/2}. \quad (39)$$

This is the most complex analytic form of the APS derived up to now where five force constants (K_{AA}, K_{EE}, F_{AAA}, F_{AEE} and F_{EEE}) as well as three vibronic constants (A, B and Z) occur. The necessity to include a cubic term $F^{(3)}$ was discussed elsewhere.[27]

The potential (39) may be still a subject of extensions, e.g.:

(i) to include some $V^{kl}[t,t]$ terms in eqn (22), as well as the corresponding $F^{kl}[t,t]$ terms;

(ii) to consider relevant third-order terms V^{klj};

(iii) to take into account the second-order energy correction $E^{(2)}$ as it follows from the first-order wave function by the perturbation theory treatment.

Finally, it must be mentioned that the formula (39) is valid not only for octahedral systems; it is also fulfilled for the E–$(a_1 + e)$ coupling scheme of tetrahedral systems. This is a consequence of the relation $O_h = C_i \otimes O$. Since the groups O and T_d are izomorphous, they exhibit the same form of the vibronic coupling.

CALCULATION OF POTENTIAL CONSTANTS

For practical applications it is useful to evaluate the potential constants occuring in eqn (39). A direct integration approach requires knowledge of the corresponding derivatives of the $\hat{V}_{eN}$ operator. Such calculations were presented only for simple qualitative methods, like the angular overlap model.[28]

Our treatment is based on a qualitatively new idea. The numerical map of the APS values is to be calculated using certain quantum-chemical method. Then, the least-squares method is applied in order to fit the numerical map $W^c(Q_i)$ to the analytic form. Actually, the set of approximate values $W^a(Q_i)$ is produced so that the functional

$$\mathcal{F} = \sum_i w_i^2\{W^c(Q_i) - W^a(Q_i)\}^2 \quad (40)$$

adopts a minimum value. The values of $W^q(Q_i)$ are calculated by eqn (39) for a trial set of potential constants. The statistical weights w_i were chosen in accordance with the metric weighing concept:

$$w_i = 1 \Big/ \left\{ \sum_k Q_k^2 \right\}^{1/2}, \qquad (41)$$

where Q_k is a set of displacement coordinates for the given APS point. The established minimization procedure is not a numerically trivial problem. The gradient minimization was used by the Newton–Raphson method and, alternatively, the Fletcher–Powell algorithm.[29] In order to accelerate a convergence the process may be split into two, linear and non-linear optimizations. Good starting values of potential constants may be obtained considering $Q_2 = 0$. This leads to a simpler, polynomial form of the APS[27] which can be fit by the linear optimization only, as outlined elsewhere.[18]

The quality of the regression was measured by statistical characteristics. The standard deviations of individual potential constants, the correlation coefficient and the discrepancy R-factor belong to them.

NUMERICAL APPLICATION

For numerical application a series of hexahalo complexes was chosen. Eighteen complexes of the $^m[MX_6]^q$ type covered systems having a doubly degenerate electronic state E_g in octahedral configuration. The semiempirical CNDO–UHF method was used[30–32] for the total energy calculations of above complexes. The numerical map of the APS was obtained in this way, considering *ca* 50 points for each system. The energy cut-off was 10^{-4}–10^{-5} eV.

Table 1 shows the calculated potential constants (three vibronic and five elastic force constants) which are presented in significant number of digits (the order of the last number being higher than the standard deviation). Calculated statistical characteristics ($\rho > 0.9999$ and $R < 0.01$) show that the regression is fairly good. The cubic terms of eqn (39), however, partly include vibronic coupling terms, i.e. those which are reduced by the Wigner matrix $\mathbf{C}_1$. Therefore, we leave both, the F_{ijl} and K_{ijl} notation and T_{ijl} is used in this sense.

From Table 1 it can be seen that the two-mode vibronic constant Z is higher than the quadratic vibronic constant B. This demonstrates a considerable role of the a_{1g} vibration in the two-mode E_g–$(a_{1g}+e_g)$ coupling model. It is obvious that the single-mode E_g–e_g coupling model is obtained for vanishing value of Z. Since K_{AA} is much higher relative to K_{EE}, the e_g-mode may be considered as a "soft" mode. In other words, the tetragonal or orthorhombic distortions are much easier than the symmetric stretching.

The characteristics of the extremal points of individual APS are collected in Table 2. It is registered that the calculated Jahn–Teller distortions are too small (*ca* 10^{-12} m) and they do not approach the experimental values (of order of 10^{-11} m) found in solid-state compounds. Also the corresponding Jahn–Teller stabilization energies are underestimated. This indicates that solid-state influences may be responsible for amplification of the static Jahn–Teller effect. Preliminary calculations show that a certain arrangement of cations around the primary coordination sphere raises the degree of distortion.[33] On the other hand, a more sophisticated method (*ab initio* in good basis set) is to be used in order to clear up this particular problem.

A more detailed analysis of Table 2 shows that the fluoro-complexes exhibit the greatest degree of distortion. Consequently, the Jahn–Teller stabilization energies are much higher so that the strength of the static Jahn–Teller effect increases with increasing polarity of the metal–ligand bond. The interesting fact is that free fluoro-complexes have the energy minimum for compressed tetragonal bipyramid (the tetragonality parameter $T > 1$) unlike the chloro- and bromo-complexes.

Application of the INDO–UHF method[34] shows that the characteristics of the APS do not change significantly when compared with CNDO results. The Jahn–Teller stabilization energy, however, increases for the complex $^1[NiF_6]^{4-}$.

The central atom effect—the influence of $^mM^q$ characteristics—manifests itself in a great variability of the strength of the static Jahn–Teller effect. Comparing two central atoms with the same number of d-electrons (e.g. d^4 in Cr(II) and Mn(III) or d^7 in Co(II) and Ni(III)) it is registered that the Jahn–Teller distortions and stabilization energies increase with increasing oxidation state of the central atom. Evidently, it is a consequence of a higher polarity of the M–X bond. Also another effect takes place as follows from comparison of ^{2}Co(II), ^{1}Ni(II) and ^{2}Cu(II) systems. Although the ^{2}Cu(II) complexes exhibit a usual behaviour when compared with ^{2}Co(II) systems (a weakening of the Jahn–Teller effect is registered), the ^{1}Ni(II) complex displays the greatest distortion and stabilization, respectively. Its unique feature lies in the high assymetry of the corresponding electronic configuration $(e_g)_n^2(e_g)_m^0$ compared with configuration $(e_g)_n^2(e_g)_m^1$ for ^{2}Cu(II) or configuration $(e_g)_n^1(e_g)_m^0$ for ^{2}Co(II) complexes. This effect clearly predominates over the oxidation state influence as follows from comparison of ^{1}Ni(II) and ^{2}Ni(III) systems.

CONCLUSIONS

Some theoretical aspects of the static Jahn–Teller effect were studied in the present communication. Using the group theory treatment the analytic formula for the adiabatic potential surface of octahedral and/or tetrahedral systems was derived. Actually, the non-linear, two-mode E–(a_1+e) vibronic coupling was considered. The potential constants may be evaluated if a numerical map of APS values is known where for the total energy calculations an arbitrary quantum-chemical method is applicable. Consequently, the potential constants (three vibronic constants and five elastic force constants) are to be enumerated by the least-squares method. Their physical meaning is discussed in detail.

The above procedure was applied for the hexahalo complexes over the first transition metal series having a doubly degenerate electronic state E_g in octahedral configuration. Actually, the CNDO method was used for the total energy calculations. The most important results may be summarized as follows:

(i) The inclusion of the total symmetric vibrational mode manifests itself in significant values of corresponding vibronic constants.

(ii) In the light of CNDO calculations the Jahn–Teller distortions are small when compared with distortions found for solid-state complexes. It indicates that solid-state influences may prevail over the net Jahn–Teller effect. However, this result stimulates subsequent studies where some solid-state influences are to be included into the model calculations.

(iii) The e_g-vibrational modes are much more softer than the non-degenerate a_{1g} ones as follows from the calculated force constants. This fact may play an important rôle in deformations of the solid-state systems.

(iv) The central atom effect of the metal centre has significant consequences on the static Jahn–Teller effect.

26. Notice the identities of $e_g \otimes e_g = a_{1g}+a_{2g}+e_g$, $e \otimes t_1 = e \otimes t_2 = t_1+t_2$ and $t_1 \otimes t_1 = t_2 \otimes t_2 = a_1+e+t_1+t_2$.
27. If only the tetragonal distortion is considered, $Q_2 = 0$ and $\cos(3\phi) = \pm 1$ are valid. Consequently the square root in eqn (36) has an explicit solution and the APS relaxes to $W = c_1 \pm c_3/\sqrt{2} = E^0 + \frac{1}{2}K_{AA}\Delta Q_1^2 + \frac{1}{2}K_{EE}Q_3^2 \pm \{(A - Z\Delta Q_1)Q_3 + BQ_3^2\}$. A behaviour of such a paraboloid potential is better visualized in the basis set of internal coordinates, say two axial (R_a) and four equatorial (R_e) metal–ligand distances. The corresponding harmonic potential has the form of $W = E^0 + bR_a + cR_a^2 + dR_e + eR_aR_e + fR_e^2$ and it leads to the following condition for the local energy minima: $(\partial E/\partial R_a)_{R_e} = b + eR_e + 2cR_a = 0$ so that an R_a vs R_e dependence[18] adopts a form of a descending straight line. This yields an unacceptable prediction of $R_e \leqslant 0$ for larger displacements of R_a. Therefore, at least the cubic or higher degree terms must be considered in order to obtain a correct form of the R_a vs R_e dependence.

COORDINATING ABILITY OF METHYLPIPERIDINE DITHIOCARBAMATES TOWARDS PLATINUM GROUP METALS

GIAN CARLO FRANCHINI, ALEARDO GIUSTI, CARLO PRETI, LORENZO TASSI and PAOLO ZANNINI*
Istituto di Chimica Generale ed Inorganica, University of Modena, 41100 Modena, Italy

(*Received* 18 *December* 1984; *accepted* 20 *February* 1985)

Abstract—New rhodium(III), iridium(III), palladium(II) and platinum(II) dithiocarbamate complexes of the types $M(Rdtc)_3$ and $M(Rdtc)_2$ (Rdtc = 2-, 3- and 4-methylpiperidine dithiocarbamate) have been prepared and characterized by chemical analyses, conductance measurements, electronic and IR spectral studies, magnetic measurements and thermal analyses (TG and DTG techniques). From the electronic absorption spectra the values of the ligand field parameters were determined; the nephelauxetic parameters are indicative of a strong covalency in the metal–ligand bond. All the complexes here reported are diamagnetic and nonconducting both in the solid state and in DMF solution.

As a part of our study on the coordinating behaviour of the heterocyclic containing dithiocarbamate ligands toward transition and *p*-block metals we report in this study the synthesis and characterization of new complexes of rhodium(III), iridium(III), palladium(II) and platinum(II) with three derivatives of the piperidine dithiocarbamate

i.e. 2-, 3-, 4-methylpiperidine dithiocarbamate sodium salts, hereafter abbreviated as 2-MePipdtc, 3-MePipdtc, and 4-MePipdtc.

We have previously described the complexes of other cyclic dithiocarbamates with many *d*- and *p*-block metals, the reactivity of the obtained complexes towards nitrogen donor ligands, the mass spectral investigations and the structural characterization by XPS techniques.[1–6]

This paper extends our previous studies on the dithiocarbamates in which dialkyl groups are replaced by heterocycles and, as a further extension, the heterocycle bears aryl or alkyl groups in different positions on the ring. It is of interest to study the influence of the substituent in the ring on the C···N and C···S bonds and on the electronic structure of the complexes. The nature and the position of the substituent can also influence the behaviour of the dithiocarbamate ligands through variation in the electronic releasing ability of the different amines.

RESULTS AND DISCUSSION

The analytical data of the compounds are listed in Table 1 and show that the complexes possess 1 : 3 and 1 : 2 metal to ligand stoichiometry in the case of rhodium and iridium, and of palladium and platinum derivatives respectively. They are soluble in common organic solvents, particularly in *N*,*N*′-dimethylformamide (DMF), chloroform, acetone, benzene and nitrobenzene. The molar conductances of 10^{-3} M solutions of all these compounds in DMF lie below 40 ohm^{-1} cm^2 $mole^{-1}$, indicating their non-electrolytic nature; all the complexes are non-conducting even in the solid state. The solid state electronic spectra are given in Table 2, while the most important IR bands are summarized in Table 3.

Electronic spectra

The trisdithiocarbamate derivatives of rhodium(III) and iridium(III) are low-spin type (t_{2g}^6) and their solid state electronic spectra suggest an octahedral configuration of the central atom, Table 2. The band positions are similar to those reported for other sulphur containing ligands; the dia-

magnetic behaviour of these metal complexes indicates octahedral surroundings of the donor atoms around the metal ions producing a strong field.

Rhodium and iridium derivatives (Table 2) show a band at 19,120–22,200 cm^{-1} ($^1A_{1g} \rightarrow {}^1T_{1g}$) and a second band in the 23,800–28,200 cm^{-1} range, ($^1A_{1g} \rightarrow {}^1T_{2g}$). These two peaks at lower energy are the two expected spin allowed transitions to the $t_{2g}^5 e_g^1$ configuration and they are not obscured by charge-transfer absorptions. The values of $10Dq$ and B' as calculated from the positions of these bands by means of the available methods are reported in Table 2 and are well within those found for other trivalent rhodium and iridium complexes,[8] indicating the presence of RhS_6 and IrS_6 chromophores and suggesting a considerable orbital overlap with a strong covalency in the metal ligand σ bond.

The effective ionic charges for the rhodium complexes studied here, calculated using the available methods,[7] are in the 0.27–0.30 range, considerably below the formal +3 oxidation state.

The bands at somewhat higher energies, Table 2, can be attributed to charge-transfer transitions,[10,11] see below.

The electronic spectra of the diamagnetic palladium(II) and platinum(II) derivatives, recorded in the solid state as Nujol mulls, are indicative of square planar geometry,[12,13] Table 2. The bands at 16,700 cm^{-1} in the palladium derivatives may be assigned to a *d–d* transition.[14]

The solid state electronic spectra of all the complexes reported in this study show absorption bands at high energy values due to the chromophore group NCS_2;[15] these absorptions are indicated as bands I, II and III.

Band I is assigned to an intramolecular charge-transfer in the ligand of the type $\pi^* \leftarrow \pi$ located on the N···C···S group.[16,17] The band II is attributed to a second transition of the type $\pi^* \leftarrow \pi$ in the S···C···S group.[18] The position of these bands is affected by the nature of the central atom and it is not sensitive to the position of the methyl group in the piperidine ring.

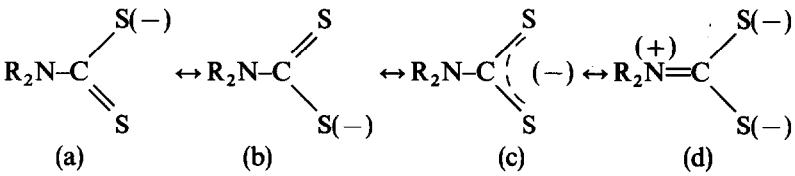
Band III may be due to an electronic transition $\pi^* \leftarrow n$ located on the sulphur atom.[19–21]

In the palladium(II) and platinum(II) complexes band IV at some 22,500 and 25,300 cm^{-1} respectively is present, which can be assigned either to a charge-transfer transition of the type M → L or to a *d–d* transition.

IR spectra

The most important IR peaks of the free ligand sodium salts and of the complexes are reported in Table 3.

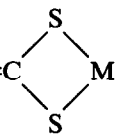
The thioureide band near 1450 cm^{-1} indicates considerable double-bond character in the C···N bond; this behaviour, already observed for many other dithiocarbamates, may be attributed to the electron releasing ability of the amines, which forces high electron density towards the sulphur atoms, via the π system, thus producing greater double-bond character in the carbon–nitrogen bond, and shifting ν(C···N) to higher energy.



As regards the influence of the position of the methyl group on the piperidine ring, the ν(C···N) value increases in the order 2-MePipdtc < 3-MePipdtc < 4-MePipdtc. Furthermore, the position of this band is affected by the nature of the central atom in the complexes and is shifted to lower

frequencies as follows: Ir > Rh and Pt > Pd; this is a reflection of the higher electron acceptor ability of Ir than Rh and of Pt than Pd.

The band in the region 965–940 cm^{-1} is attributed to the stretching vibration of the C⋯S bonds.



The ν(C⋯S) mode indicates whether the diothiocarbamato moiety is mono- or bidentate; the presence in our complexes of only one strong band in this region strongly supports bidentate coordination of the dithioligand, a doublet being expected in the 1000 ± 70 cm^{-1} region for monodentate behaviour.[22–24] Further confirmation comes from the analysis of the position of the ν(C⋯N) mode; this band undergoes a blue shift in all the complexes while for unidentate coordination this stretching would be shifted towards lower wavenumbers or remain unchanged at the value of the free dithiocarbamate sodium salt.[25]

The structure of the dithioligands can be represented by the following formalism

and we can suggest, according to our previous studies, that the contribution of the structure (d), greatest for the dialkylderivatives, is lower for more complex aliphatic chains and relatively small for the heterocyclic derivatives. Perhaps because of the rigid heterocyclic ring system which shows less tendency to release electrons to the carbon–nitrogen bond, this bond has a less double-bond character. This tendency to release electrons is less in the compounds reported here than in the piperidine dithiocarbamate complexes; this fact is quite surprising taking into account the inductive effect of the methyl group which should cause an increase in the carbon–nitrogen bond order.

As for the 600–500 cm^{-1} region, where the bands arise with mainly ν(CS) and δ(SCS) character, it is interesting to point out that the bands in this range

must entail some  M ring deformation and

stretching modes involving ν(CS) and δ(SCS), as demonstrated by a detailed IR isotopic study.[2]

In the far IR region the bands of the ligands appear unchanged in spectra of the complexes. New bands appear in the rhodium derivatives at 327–331 cm^{-1} and at some 320 cm^{-1} in the iridium complexes, Table 3. These absorption bands, absent in the spectra of the free ligands and in those of the palladium and platinum derivatives, are probably due to a metal–ligand interaction; we can assign these bands to ν(Rh–S) and ν(Ir–S) stretching vibrations respectively.[9]

Passing to the palladium and platinum derivatives, the vibration modes in the 373–359 cm^{-1} range can be assigned to Pt–S stretching vibrations (λ_8), whereas the second band at some 340 cm^{-1} could be attributed to complex normal modes involving both metal–sulphur bond and ring vibration modes. The band in the 315–296 cm^{-1} range is assigned to the NCS bending mode (λ_9).[26]

The methyl group absorptions both in the free ligands and in the complexes can be assigned without ambiguity; the medium strong bands in the 2970–2960 cm^{-1} range can be attributed to the asymmetric CH_3 stretching vibration, while the two series of bands at 1380–1373 cm^{-1} and at 1189–1175 cm^{-1} are evidently due to the degenerate symmetric and rocking vibrations of the methyl group.

Thermal analyses

The rhodium(III) derivatives were stable up to 375°C; beyond this temperature a rapid mass loss up to 500°C occurs, corresponding to the decomposition of the dithiocarbamato complexes to the metal. The next step over 500°C corresponds to the oxidation of metallic rhodium to the black Rh_2O_3 oxide.

The iridium(III) complexes, stable up to 360°C, undergo decomposition in the 360–500°C range, giving metallic iridium as a product. From this last temperature, up to 800°C, the Ir_2O_3 is obtained.

The palladium(II) derivatives were thermally stable up to 400°C. Above this temperature decomposition sets in and continues transforming the dithiocarbamates into polysulphides of the type Pd_xS_y, which slowly give PdO.

The platinum(II) complexes were also stable up to 400°C, but, beyond this point, a single step decomposition starts and proceeds with the loss of the ligands giving metallic platinum sponge as the end-product.

B is taken to be 720 and 660 cm^{-1} for the free gaseous Rh^{3+} and Ir^{3+} ions respectively.

EXPERIMENTAL

Preparation of the ligands

The sodium salts of the ligands were prepared by treating 2-methyl-, 3-methyl- or 4-methylpiperidine (reagent grade) in dry diethylether with CS_2 and adding NaOH with vigorous stirring over a 5 h period. Molar ratio amine: CS_2 : NaOH = 1 : 1 : 1. The crude products were recrystallized from isopropyl alcohol.

Analyses. For 2-MePipdtcNa · $2.5H_2O$. Found: C, 34.4; H, 7.0; N, 5.8; S, 26.2%. For 3-MePipdtcNa · $2.5H_2O$. Found: C, 34.1; H, 7.1; N, 5.7; S, 26.0%. For 4-MePipdtcNa · $2.5H_2O$. Found: C, 34.9; H, 7.0; N, 5.9; S, 26.3%. Calc. for $C_7H_{12}NS_2Na \cdot 2.5H_2O$: C, 34.7; H, 7.1; N, 5.8; S, 26.5%.

Preparation of the complexes

The complexes were obtained by reaction of an aqueous solution of rhodium trichloride, ammonium hexachloroiridate(III), palladium nitrate, potassium tetrachloroplatinate(II) with the dithiocarbamate sodium salt dissolved in methanol or water at room temperature, in 1 : 3 or 1 : 2 molar ratios. The products were filtered off, washed several times with cold water and dried over P_4O_{10} *in vacuo*. Repeated syntheses and elemental analyses gave reproducible results.

Electronic spectra

The electronic spectra were recorded with a Shimadzu MPS-50L spectrophotometer in the solid state in the 5000–45,000 cm^{-1} region. Samples were prepared by grinding the complexes on a filter paper as support.

IR spectra

The IR spectra have been recorded in the 4000–50 cm^{-1} range with a Perkin–Elmer 180 spectrophotometer of the Instruments Centre of Modena University. The spectra in the 4000–400 cm^{-1} range were measured for KBr discs or Nujol mulls. Far IR spectra were measured for Nujol mulls supported between polyethylene sheets. Atmospheric water was removed from the spectrophotometer housing by flushing with dry nitrogen.

Magnetic susceptibility measurements

These measurements were carried out by Gouy's method at room temperature. The molecular

susceptibilities were corrected for the diamagnetism of the component atoms by use of Pascal's constants. All the complexes were diamagnetic.

Conductivity measurements

These measurements were carried out with a WTW LBR type conductivity bridge for freshly prepared 10^{-3} M solutions in DMF at 25 ± 0.1°C. The solid state measurements were performed using the four probes method.

Thermal analyses

Thermogravimetric analyses (TG and DTG) were performed in air on a Mettler TG50 thermobalance equipped with a Mettler TC10TA processor. A scan rate of 10°C min^{-1} was used.

Analyses

Carbon, nitrogen, hydrogen and sulphur were determined with a Carlo Erba 1106 elemental analyzer.

Acknowledgements—We thank Mr. G. Goldoni for elemental analyses, the Instruments Centre of Modena University for recording the IR spectra and the Consiglio Nazionale delle Ricerche (C.N.R.) of Italy for the financial support.

(*Received* 17 *January* 1985; *accepted* 20 *February* 1985)

Abstract—^{17}O (40.7 MHz) and ^{183}W (12.5 MHz) NMR spectra of aqueous

$Na_{10}[H_2W_{12}O_{42}]\cdot 27H_2O$ (**1**), $Na_6[W_7O_{24}]\cdot 14H_2O$ (**2**)

and $(NH_4)_6[Mo_7O_{24}]\cdot nH_2O$ solutions, as well as of 2, 1 and 0.1 M Na_2WO_4 and 2 M Li_2WO_4 solutions acidified up to $P = 0.5$, 1 and 1.14 have been measured. The composition of the $W_7O_{24}^{6-}$ anion remains unchanged (**2**), its structure being similar to that of $Mo_7O_{24}^{6-}$. The W_7O_{24} ^{183}W NMR spectrum shows three resonances with the chemical shifts +269.2, −98.8 and −178.9 ppm relative to WO_4^{2-} and intensity ratio 1:4:2. "Paratungstate A" produced during polycondensation of WO_4^{2-} at $P \leqslant 1.17$ is identical with heptatungstate $W_7O_{24}^{6-}$. The $[H_2W_{12}O_{42}]^{10-}$ ^{183}W NMR spectrum in the acidified 2 M Li_2WO_4 solution has four resonances with the chemical shifts in the range −105–145 ppm and intensity ratio 1:2:1:2. As suggested by NMR data, the $H_2W_{12}O_{42}^{10-} \rightleftarrows W_7O_{24}^{6-}$ transformations occur, which depend upon concentration and temperature.

The formation of two types of paratungstate anions in aqueous Na_2WO_4 solutions acidified up to $P = 1.17$ is well known.[1] Crystalline paratungstate $Na_{10}[H_2W_{12}O_{42}]\cdot 27H_2O$, containing a discrete anion, is deposited from such solutions. The structure of $Na_{10}[H_2W_{12}O_{42}]\cdot 27H_2O$ has been determined by X-ray method crystallography.[2] The existence of this anion (paratungstate B) in solutions has been proved by various methods.[1,3] The other polyanion, the so-called paratungstate A, is regarded as a hexameric particle $HW_6O_{21}^{5-}$ on the basis of potentiometric and spectrophotometric acidity measurements.[1] However, no direct experimental evidence for such composition of these anions has been obtained. From solutions with $P \sim 1.14$ the crystalline paratungstate, $Na_6[W_7O_{24}]\cdot nH_2O$ ($n =$ 14 or 21), has been obtained recently and has been shown to contain the discrete polyanion too.[4–6] The question arises whether the polyanion retains its integrity upon dissolution in water and whether it is the first product of WO_4^{2-} polycondensation, i.e. paratungstate A, as follows from the thermodynamic analysis of the polycondensation reactions.[7] To answer these questions, we have used ^{17}O and ^{183}W NMR methods, which can give structural information about polycomplexes in solutions.[8–10]

EXPERIMENTAL

Solutions of crystalline sodium paratungstates and ammonium paramolybdate, as well as acidified aqueous solutions of Na_2WO_4 and Li_2WO_4 were studied. Paratungstates,

$$Na_{10}[H_2W_{12}O_{42}]\cdot 27H_2O \text{ (1)}$$

and

$$Na_6[W_7O_{24}]\cdot 14H_2O \text{ (2)},$$

were prepared as described.[4–6] The concentrated solutions of **1** were prepared by rapid dissolution in hot water; paratungstate (**2**) and paramolybdate were dissolved in cool water. The spectra were taken immediately after the preparation of the solutions. Aqueous solutions of Na_2WO_4 (2, 1 and 0.1 M) and a 2 M solution of Li_2WO_4 were acidified with 5 N HCl up to $P = 0.5$, 1 and 1.14. 0.1 M Na_2WO_4 solutions were prepared using water enriched with ^{17}O ($\sim 1\%$). ^{17}O and ^{183}W NMR spectra were taken on a Bruker CXP-300 spectrometer at 40.7 and 12.5 MHz, respectively, over the temperature range 280–345 K. The chemical shifts (δ) were given relative to

* Author to whom correspondence should be addressed.

H_2O (^{17}O) and WO_4^{2-} in the solution of Na_2WO_4 (^{183}W). The downfield shift was taken as positive.

RESULTS AND DISCUSSION

Crystalline paratungstate (2) has the $W_7O_{24}^{6-}$ polyanions with the structure of heptamolybdate anions, $Mo_7O_{24}^{6-}$.[5,11] The seven MO_6 polyhedra fall into three structural types 4 M_I, 2 M_{II} and 1 M_{III} (Fig. 1). The anion contains oxygens of the following types: 12 *cis*-dioxo terminal (two types), 8 doubly bridging (four types), 2 threefold bridging and 2 fourfold bridging oxygens. A single M_{III} atom is not bound with the terminal oxygens; however, the lengths of its bonds with two oxygens O_E in the bridge M_{III}–O_E–M_{II} ($\sim$ 1.75 Å) are close to the lengths of the bonds of M_I and M_{II} atoms with the terminal oxygens $O_{F,G}$ (1.71–1.74 Å).

A comparison of ^{17}O NMR spectra of paratungstate (2) and paramolybdate (Fig. 1) in solutions indicates that they correspond to polyanions of the same structural type. The spectrum of the solution of paratungstate (2) completely corresponds to the structure described. The peaks A, B, C, D and G (Fig. 1, Table 1) were assigned using the ^{17}O chemical shift scale for polyoxotungstates and the "δ ^{17}O NMR–O–W bond length correlation",[9,10] and taking into account the line intensities. This correlation is insufficient for attribution of three lines of the same intensity at 590, 595 and 624 ppm (from four O_F oxygens and two O_E oxygens) because the corresponding bonds have nearly the same lengths. As usual,[8] the resonances of oxygen atoms bound with tungsten atoms are shifted to the high field, as compared with the resonances of the corresponding oxygen atoms bound with molybdenum atoms. The difference in the chemical shifts of the two spectra becomes less pronounced as the coordination number of oxygen atoms increases, and, correspondingly, the paramagnetic contribution to the screening decreases. However, in the case of $Mo_7O_{24}^{6-}$, the resonances of the oxygens O_D and O_F bound with the Mo_{II} atoms appear in the

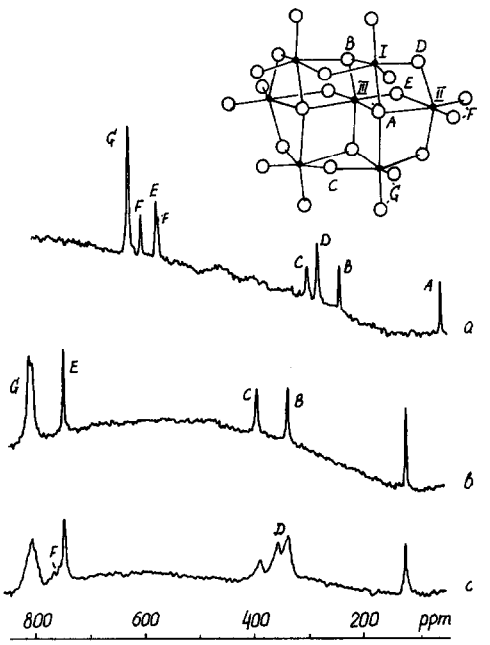

Fig. 1. ^{17}O NMR spectra of aqueous solutions of $Na_6[W_7O_{24}]\cdot 14H_2O$, 330 K (a), $(NH_4)_6Mo_7O_{24}\cdot nH_2O$, 293 K (b) and 283 K (c); and idealized bond structure of the polyanion.

* The lines enhanced during oxygen exchange with water enriched with ^{17}O.

spectra at temperatures below 286 K [Fig. 1(c)]. At higher temperatures, the lines from O_D and O_F are broadened rapidly and then disappear. This indicates chemical exchange between these atoms, which leads to the broadening of their resonances separated by a 400 ppm interval. The exchange appears to be the result of the rotation of the $Mo_{II}(O_FO_D)_2$ fragments weakly bound with the Mo_{III} atom (the lengths of the Mo_{II}–O_A and Mo_{II}–O_E bonds are 2.16 and 2.42 Å, respectively).[11] With increase in temperature (310–320 K), the other lines of the $Mo_7O_{24}^{6-}$ spectrum are broadened too and become unobservable.

For $W_7O_{24}^{6-}$, a small linewidth indicates a very slow rotation, if any, even at 330 K. However, if the temperature of the solution is raised to 345–350 K, the broadening of the line from O_D and of the lines at 590 and 624 ppm can be observed. Therefore, by analogy with $Mo_7O_{24}^{6-}$, these lines can be attributed to four O_F atoms and, the line at 595 ppm to the O_E atoms. A 34 ppm difference in δ of the two pairs of the O_F atoms corresponds to *ca* 0.015 Å difference in the lengths of two O_F–W_{II} bonds in *cis*-positions.

Thus, the ^{17}O NMR spectra suggest retention of the composition and structure of the $W_7O_{24}^{6-}$ anion in aqueous solutions. This conclusion is supported by the ^{183}W NMR spectrum of the solution containing, according to ^{17}O NMR, the $W_7O_{24}^{6-}$ anions solely: three peaks with the ratio of intensities 1:4:2 from W atoms of three types are observed. The line positions of the spectrum are similar to those of the ^{51}V NMR spectrum of the $V_{10}O_{28}^{6-}$ polyanion, which has the V atoms of the same three types but with the ratio 2:4:4.[11]

During aging of the concentrated $Na_6[W_7O_{24}]$ solutions, crystalline $Na_{10}[H_2W_{12}O_{42}]\cdot 27H_2O$ is deposited. The crystals of this compound appear on the ampoule walls even an hour after the preparation of the solution. The concentration of the $W_7O_{24}^{6-}$ anions in the solution gradually decreases, and the line intensities also decrease. However, new lines do not appear, which points to a very low concentration of the $H_2W_{12}O_{42}^{10-}$ anions in the solution.

^{17}O NMR spectra of the paratungstate (1) solution were taken at 315–330 K immediately after its dissolution in hot water. The spectrum has no lines from polytungstates observed previously by ^{17}O NMR.[8–10] All lines seem to belong to the $H_2W_{12}O_{42}^{10-}$ anions, which remain in freshly prepared solutions of paratungstate (1), as evidenced by Raman spectra.[1,3] $H_2W_{12}O_{42}^{10-}$ has a complex structure.[2,11] The WO_6 polyhedra of four structural types (Fig. 3) have several different groups of oxygens: 18 terminal (4 types); 18 doubly bridging (3 or 4 types), and 6 threefold bridging (two types) atoms. The chemical shifts, corresponding to the lengths of the W–O bonds of approx. 1.75–1.77 Å, and the ratio of line intensities (~ 2:4:4:8) of the terminal oxygens, as well as the number, and the integrated intensity of the resonances of the bridging oxygens, are in good conformity with the $H_2W_{12}O_{42}^{10-}$ structure.

The lines corresponding to $W_7O_{24}^{6-}$ gradually appear in the spectrum of the solution of paratungstate (1). Their part comprises *ca* 25% at 330 K in 30 min after dissolution and tends to increase. Upon cooling the solutions down to 293 K, the reverse transformation occurs, and the major part of tungsten(VI) progressively crystallizes in the form of paratungstate (1), the remainder being in the form of $W_7O_{24}^{6-}$ in the solution. At higher temperatures, the solubility of paratungstate (1) and the concentration of $H_2W_{12}O_{42}^{10-}$ in the solution increases, but simultaneously the rate of $W_7O_{24}^{6-}$ formation also increases.

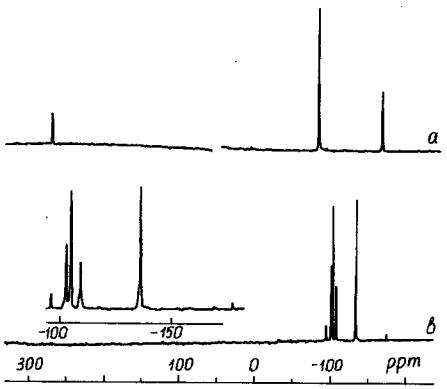

Fig. 2. ^{183}W NMR spectra of $W_7O_{24}^{6-}$ in the acidified Na_2WO_4 solution, pH ~ 7 (293 K) (a), and of $H_2W_{12}O_{42}^{10-}$ in the acidified Li_2WO_4 solution, pH ~ 6 (293 K) (b).

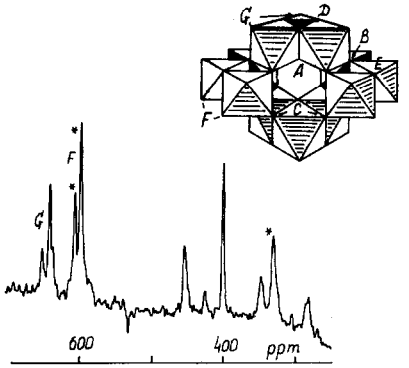

Fig. 3. ^{17}O NMR spectrum of the freshly prepared aqueous solution of $Na_{10}[H_2W_{12}O_{42}]\cdot 27H_2O$ (330 K) and polyhedral model of the polyanion structure.

At the natural abundance of ^{17}O ($\sim 0.04\%$), ^{17}O NMR measurements can be made at tungsten concentrations approx. equal to or higher than 1 M. It is essential that at such concentrations the system is a two-phase one due to the very low solubility of $Na_{10}[H_2W_{12}O_{42}]$. We have succeeded in registering ^{17}O NMR spectra of $H_2W_{12}O_{42}^{10-}$ anions in such solutions because freshly prepared supersaturated solutions of paratungstate (1) were studied, and also because its transformation to $W_7O_{24}^{6-}$ occurs rather slowly. The enhanced sensitivity of modern high-field NMR spectrometers provides the possibility to quite rapidly accumulate ^{17}O NMR spectra at the natural abundance of ^{17}O and to register the state of the solution even in 10–15 min after dissolution. When operating on the previously used spectrometers, the preliminary enrichment with ^{17}O in the heated solution and a prolonged accumulation of spectra were necessary. As a result, the equilibrium state of the solutions, in which $W_7O_{24}^{6-}$ prevailed, was registered.[9] Moreover, in the case of enrichment of anions via dissolution of preliminary prepared samples of paratungstate (1) in the enriched water, we observed only three lines—from the oxygens in the side fragments of $H_2W_{12}O_{42}^{10-}$, because of the non-uniform enrichment of oxygens of the polyanion (Fig. 3, Table 1).

Thus, the heating of the solutions of sodium paratungstate (1) accelerates the formation of the $W_7O_{24}^{6-}$ anions in the solution. Using the concentrated solutions prepared by prolonged heating of $Na_{10}[H_2W_{12}O_{42}]\cdot 27H_2O$ with water accompanied by their rapid cooling and acetone addition, it is possible to obtain almost pure, crystalline heptatungstate.[4]

From ^{17}O NMR spectra of freshly acidified 1 and 2 M Na_2WO_4 solutions one may judge about the presence of $W_7O_{24}^{6-}$ anions solely. At $P = 0.5$ and 1 excess WO_4^{2-} anions are also observed. During aging, paratungstate (1) was crystallized from the solutions, however no $H_2W_{12}O_{24}^{10-}$ anions were detected in their spectra. By using water enriched with ^{17}O, it was possible to measure ^{17}O NMR spectra of 0.1 M Na_2WO_4 solutions. In freshly acidified solutions ($P = 1$), only $W_7O_{24}^{6-}$ and excess WO_4^{2-} anions were observed. The composition of the solution remained unchanged during a 3-months storage at 293 K. On the contrary, in the solution with the same concentration of W(VI) prepared from $Na_{10}[H_2W_{12}O_{42}]\cdot 27H_2O$ and stored for 3 months at 293 K, nearly complete conversion to heptatungstate occurred.

In freshly acidified 2 M Li_2WO_4 solutions, $W_7O_{24}^{6-}$ was also registered. At room temperature $W_7O_{24}^{6-}$ transforms to $H_2W_{12}O_{42}^{10-}$ rather quickly (for several hours). At elevated temperatures this transformation is incomplete and occurs more slowly. In the presence of Li^+ the $H_2W_{12}O_{42}^{10-}$ anions remain in the solution. Their ^{183}W NMR spectra (Fig. 2, Table 1) show four resonances with the intensity ratio 1:2:1:2, which corresponds to the anion structure in the crystalline state. The chemical shifts of the ^{183}W NMR depend upon pH of the solution and differ from those in the presence of sodium by 10–15 ppm toward the high field. This seems to indicate a stronger association of Li^+ with polyanions, as compared with Na^+. Upon heating the solution, the $H_2W_{12}O_{42}^{10-}$ anions partly transform to $W_7O_{24}^{6-}$. The lower the concentration of tungsten the larger the extent of such transformation.

Thus, using ^{17}O and ^{183}W NMR, we have shown that, when formed in aqueous WO_4^{2-} solutions acidified up to $P \leqslant 1.17$, the complex of paratungstate A (whose composition has long been in question[1]) is actually heptatungstate $W_7O_{24}^{6-}$ rather than hexatungstate. Other isopolyanions of tungsten(VI), except for $W_7O_{24}^{6-}$ and $H_2W_{12}O_{42}^{10-}$, have not been observed in such solutions.

MOLYBDENUM(V) DIMERIC COMPLEXES WITH DIALKYL CARBAMATES

R. LOZANO,* J. ROMAN, M. D. ARMADA and A. DOADRIO
Departamento de Química Inorgánica, Facultad de Farmacia, Universidad Complutense de Madrid, Madrid 28040, Spain

(*Received* 4 *April* 1984; *accepted after revision* 28 *February* 1985)

Abstract—Syntheses are reported for a number of novel oxo and sulphido bridged molybdenum(V) complexes with *N*-methyl-*N*-cyclohexyl carbamate and *N*,*N*-dicyclohexyl carbamate as ligands, and we have compared these complexes with the molybdenum(V) complexes with dialkyldithiocarbamates as ligands. These complexes were identified by IR and electronic spectra, magnetic susceptibility and analytical data, and were assigned the formulae $[Mo_2O_3(LL)_4]$, $[Mo_2O_4(LL)_2]$, $[Mo_2O_2S_2(LL)_2]$ and $[Mo_2O_3S(LL)_2]$. IR and electronic spectra of these compounds are sensitive to substitution of sulphur atoms into the bridge system. It is suggested that the low magnetic moments observed are due, at least in part, to intramolecular metal–metal interactions.

In previous communications, we have reported the isolation and study of dimeric molybdenum(V) complexes with xanthates, oxinates and dithiocarbamates as ligands.[1–7]

The object of the present study, has been to obtain binuclear complexes of molybdenum(V) with *N*-methyl-*N*-cyclohexyl carbamate and *N*,*N*-dicyclohexyl carbamate as ligands (O-donor), and to compare these complexes with the molybdenum(V) complexes with dithiocarbamates as ligands (S-donor) and similar structures, obtained previously[6–11] and studied by X-ray diffraction.[12–14]

In this paper, we describe the isolation and characterization of four different dimeric complexes of molybdenum(V):

(a) Molybdenum(V) oxo-complexes with a monoxo bridge $[Mo_2O_3(LL)_4]$;

(b) Molybdenum(V) oxo-complexes with a dioxo bridge $[Mo_2O_4(LL)_2]$;

(c) Molybdenum(V) oxo-complexes with a disulphido bridge $[Mo_2O_2S_2(LL)_2]$;

(d) Molybdenum(V) oxo-complexes with oxo-sulphido bridge $[Mo_2O_3S(LL)_2]$.

EXPERIMENTAL

Materials. $Na_2MoO_4 \cdot 2H_2O$ was Merck commercial product used as supplied. Potassium *N*-methyl-*N*-cyclohexyl carbamate and potassium *N*,*N*-dicyclohexyl carbamate were prepared by the reaction of potassium hydroxide with carbon dioxide and *N*-methyl-*N*-cyclohexyl amine or *N*,*N*-dicyclohexyl amine in water, and were recrystallized from water : methanol. The solvents used to prepare the complexes were Carlo Erba or Merck; the solutions for absorption spectra were prepared with dimethylsulphoxide (DMSO) spectral grade Merck-Uvasol and water.

Analytical procedures. Elemental analyses were performed on a Perkin–Elmer Analyzer model 240 B. Molybdenum was determined by atomic absorption spectrophotometry, with a Perkin–Elmer model 430 atomic absorption spectrophotometer after the complexes had been decomposed with a 1:1 mixture of concentrated nitric and sulphuric acids. Analytical data are collected in Table 1.

Magnetic susceptibilities. Measurements were made using the Gouy method at room temperature on a Mettler H-51 A.R. balance and an Oxford electromagnet. Molar susceptibilities given are corrected for the diamagnetism of the constituent molecules. The magnetic moments were calculated according to the formula $\mu = 2.84\ (\chi'_M \cdot T)^{0.5}$ BM, where χ'_M is the corrected molar susceptibility.[15] Table 1 shows the results obtained for the molybdenum(V) oxo-complexes with dialkylcarbamates as ligands.

The IR spectra were obtained using a Perkin–Elmer spectrophotometer model 283. The samples

were run as KBr pellets. Important IR absorption peaks for the complexes prepared in this study are listed in Table 2.

The visible–near UV spectra of the compounds, were measured in the range 200–900 nm on a Beckman recording spectrophotometer model 5240, over dissolutions of the complexes in DMSO and water. The results obtained in this study and the ones obtained for the complexes with dialkyl dithiocarbamates as ligands (only *d–d* transitions), are given in Table 3.

Preparation of the complexes. $Mo_2O_3\{O_2CN(CH_3)(C_6H_{11})\}_4$. $Na_2MoO_4 \cdot 2H_2O$ (2.42 g) was dissolved in water (40 cm^3) and it was depolymerized with NaOH. The solution was added to a solution of potassium *N*-methyl-*N*-cyclohexyl carbamate (3.90 g) in water (50 cm^3), with vigorous stirring, and a solution (freshly prepared) of sodium dithionite (0.5 g) in water (20 cm^3) was added. Lastly, drop-by-drop, glacial acetic acid was added to give pH = 5. There was an immediate brown precipitate. The suspension was set aside for 1 hr and then filtered *in vacuo* and dried over P_4O_{10}. Yield: 53%.

$Mo_2O_4\{O_2CN(CH_3)(C_6H_{11})\}_2$. A solution of $Na_2MoO_4 \cdot 2H_2O$ (2.42 g) in water (40 cm^3) was treated with concentrated sodium hydroxide. The resulting solution was added to a solution of potassium *N*-methyl-*N*-cyclohexyl carbamate (1.95 g) in water (30 cm^3). A solution of sodium dithionite (0.5 g) in water (20 cm^3) was prepared and this solution was added to the previous one. Diluted hydrochloric acid was added dropwise until precipitation of the complex was complete. The precipitate was filtered by suction and the green residue was dried *in vacuo* over P_4O_{10}. Yield: 60%.

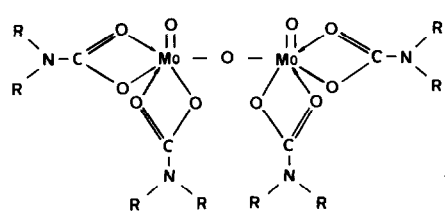
$Mo_2O_2S_2\{O_2CN(CH_3)(C_6H_{11})\}_2$. 2.42 g of $Na_2MoO_4 \cdot 2H_2O$ was dissolved in water (40 cm^3) and to this solution was added concentrated sodium hydroxide to give pH = 8–9. The resulting solution was treated with potassium *N*-methyl-*N*-cyclohexyl carbamate (1.95 g) in water (40 cm^3). Hydrogen sulphide was passed through the resulting solution with simultaneous cooling in freezing mixture for 30 min. The solution gradually takes a brown colour. Drop-by-drop, glacial acetic acid was added to give pH = 6, and a brown solid precipitates. The residue was filtered *in vacuo* and dried over P_4O_{10}. Yield: 64%.

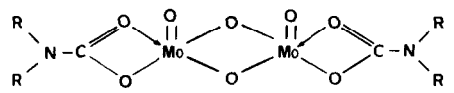
$Mo_2O_3S\{O_2CN(CH_3)(C_6H_{11})\}_2$. A solution of $Na_2MoO_4 \cdot 2H_2O$ (2.42 g) in 2 M sodium hydroxide (40 cm^3) was treated with dilute hydrochloric acid to give pH = 6. Hydrogen sulphide was bubbled slowly through the resulting solution for 1 hr. The solution gradually takes a brown colour, and it was added to a solution of potassium *N*-methyl-*N*-cyclohexyl carbamate (1.95 g) in water (40 cm^3). Lastly, glacial acetic acid was added dropwise until the precipitation of the complex was complete. The precipitate was filtered *in vacuo* and the brown residue was dried over P_4O_{10}. Yield: 80%.

A similar preparation was carried out for the complexes with *N*,*N*-dicylohexyl carbamate as ligand.

DISCUSSION

According to the analytical results and spectroscopic data, the four synthesized complexes have dimeric structures. If we carry out the precipitation at pH = 5, with acetic acid, the complexes present a monoxo bridge, the stoichiometry is 2:1, and the molybdenum is six-coordinated. The formula which most closely fits the analyses is $Mo_2O_3(LL)_4$:





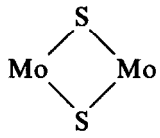


Table 2. IR absorption maxima, in cm^{-1}, of molybdenum(V) oxo-complexes

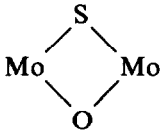
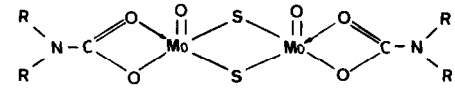
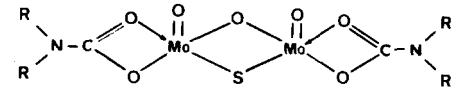
Compound	ν(C–N)	ν(C–O)	ν_s(Mo=O)	ν_a(Mo–O_b)	ν_s(Mo–O_b)	ν_a(Mo–S_b)	ν_s(Mo–S_b)	ν(Mo–O_t)
$Mo_2O_3\{O_2CN(CH_3)(C_6H_{11})\}_4$	1415	1580	940	640	480	—	—	317
$Mo_2O_4\{O_2CN(CH_3)(C_6H_{11})\}_2$	1405	1625	950	630	475	—	—	310
$Mo_2O_2S_2\{O_2CN(CH_3)(C_6H_{11})\}_2$	1410	1570	932	—	—	605	405	330
$Mo_2O_3S\{O_2CN(CH_3)(C_6H_{11})\}_2$	1412	1580	924	640	—	610	405	332
$Mo_2O_3\{O_2CN(C_6H_{11})_2\}_4$	1390	1635	930	650	480	—	—	310
$Mo_2O_4\{O_2CN(C_6H_{11})_2\}_2$	1385	1620	950	640	560	—	—	300
$Mo_2O_2S_2\{O_2CN(C_6H_{11})_2\}_2$	1380	1580	925	—	—	600	450	320
$Mo_2O_3S\{O_2CN(C_6H_{11})_2\}_2$	1380	1585	920	640	—	600	450	305



However, if we carry out the precipitation at pH = 2, the stoichiometry of the compounds is 1 : 1, the molybdenum is five-coordinated and these complexes present a dioxo bridge. The formula that we assign to these complexes is $Mo_2O_4(LL)_4$:



The complexes obtained by bubbling H_2S through $Na_2MoO_4 \cdot 2H_2O$ solution and the corresponding dialkyl carbamate, and the ones synthesized by bubbling H_2S through $Na_2MoO_4 \cdot 2H_2O$ solution in diluted hydrochloric acid, with posterior addition of the dialkyl carbamate, present a 1:1 stoichiometry, the molybdenum being five-coordinated. The union between the molybdenum atoms is realized by means of a disulphido



bridge, in the first case, with formula $Mo_2O_2S_2(LL)_2$; and through an oxo-sulphido bridge

in the second case.

The complexes obtained in this paper, gave low values of magnetic moments (see Table 1) that suggest the presence of polymeric species and involve

interaction through the oxygen or sulphur bridges or by direct metal–metal bonding. Similar behaviour has been observed in other dimeric molybdenum(V) complexes.[12–16]

The IR spectra of the four various kinds of complexes studied exhibit a very strong band in the range 920–952 cm^{-1}, which we attribute to the vibration of the symmetric stretching mode of the terminal Mo=O bond. The antisymmetric stretch-

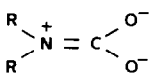
[a] This work.

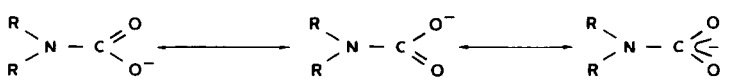
[b] Reference 7.

[c] Reference 6.



ing mode has not been observed. However, the appearance of the symmetric stretching mode is sufficient to designate, in the dimeric complexes, a *cis* disposition of the two terminal Mo=O.[12]

The complexes with monoxo bridge, dioxo bridge and oxo-sulphido bridge exhibit two bands in the IR spectra between 640 and 480 cm^{-1}, which we attribute to the vibration of the antisymmetric and symmetric stretching mode, respectively, of the Mo–O bridge bond.



The IR spectra of the complexes with disulphido and oxo-sulphido bridges show two bands between 605 and 450 cm^{-1}, which we attribute to the vibration of the antisymmetric and symmetric stretching mode, respectively, of the Mo–S–M bridge bond.

The IR spectra of the analogous molybdenum(V) complexes with *N*-methyl-*N*-cyclohexyl dithiocarbamate and *N*,*N*-dicyclohexyl dithiocarbamate as ligands show the vibration of the symmetric stretching mode of the terminal Mo=O bond displaced to lower frequencies and the vibration of the antisymmetric stretching mode of the Mo–O bridge bond displaced to greater frequencies[6,7] than the molybdenum(V) carbamates studied here. These differences can be attributed to the more covalent character of the Mo(V)–S bond in the dithiocarbamates than the Mo(V)–O in the carbamates.

If we compare the IR spectra of the molybdenum(V) carbamate complexes with the IR spectra of potassium carbamates, we observe that the molybdenum(V) complexes exhibit the band of the stretching mode of the C–N bond displaced to higher frequencies than potassium carbamates. The IR spectra of molybdenum(V) complexes exhibit this band in the range 1415–1380 cm^{-1} (see Table 2) while the IR spectra of potassium *N*-methyl-*N*-cyclohexyl carbamate and potassium *N*,*N*-dicyclohexyl carbamate exhibit this band at 1365 and 1360 cm^{-1}, respectively. This difference may be attributed to a substantial contribution of resonance form:

in the molybdenum(V) carbamate complexes, while in potassium carbamates, the following resonance forms take place:

Consequently, the frequencies of the stretching mode of the C–O bond must be lower in molybdenum(V) carbamate complexes than in potassium salts, because the C–O bond is not so strong in the complexes due to the stronger C–N bond. The IR spectra of molybdenum(V) complexes exhibit the band of the C–O stretching mode in the range 1635–1570 cm^{-1}, while in the IR spectra of potassium carbamates this band appears at 1650 cm^{-1}. A similar behaviour has been observed in the frequencies of the stretching mode of the C–S bond and C–N bond to the molybdenum(V) complexes with dithiocarbamates as ligands and the potassium dithiocarbamates.[6,7]

The IR spectra of all carbamate complexes show also other bands between 332–300 cm^{-1}, attributed to molybdenum–oxygen ligand frequencies.

All the complexes studied here show, in the electronic spectra, two bands in the 645–600 nm region which we attribute to *d–d* transitions. We cannot observe appreciable differences between the six-coordinated dimeric complexes with monoxo bridge and the five-coordinated dimeric complexes with dioxo, disulphido and oxo-sulphido bridge, which can be attributed to a distortion of octahedral structure for a d^1 ion in the complexes with monoxo bridge, due to a Jahn–Teller effect (Ballhausen–Gray scheme).[17]

We assign the two bands to $^2B_2 \rightarrow {}^2E(I)$ and $^2B_2 \rightarrow {}^2B_1$ transitions, respectively, for a distorted octahedral structure[17] for the monoxo bridge complexes and for a square pyramidal structure[18] for the complexes with dioxo, disulphido and oxo-sulphido bridges.

If we compare the electronic spectra in the visible region of the Mo(V) carbamate complexes obtained in this study with the electronic spectra of the Mo(V) dithiocarbamate complexes previously studied,[6,7] we observe that the $^2B_2 \rightarrow {}^2E(I)$ transition is displaced to greater frequencies (750 cm^{-1}) in the carbamate complexes, while the $^2B_2 \rightarrow {}^2B_1$ transition is displaced to greater frequencies (3000 cm^{-1}) in the dithiocarbamate complexes. These differences may be attributed to the greater distortion of the octahedral structure in the Mo(V) carbamate complexes and to the more covalent character of the Mo(V)–S bond (see Table 3).

In the visible region we detect two bands over 470 and 420 nm that we attribute to charge transfer transitions. We observe no significant differences between these transitions and the charge transfer transitions observed in Mo(V) complexes with dithiocarbamates as ligands.[6,7]

In the UV region, three transitions are detected at 330, 300 and 250 nm, that we attribute to intraligand transitions.

Inorganic Chemistry Division, National Chemical Laboratory, Poona 411 008, India

(*Received* 1 *February* 1985; *accepted* 28 *February* 1985)

Abstract—The reaction between acrylonitrile and the Ru–H bond in $HRu(CO)Cl(PPh_3)_3$ results in the formation of a binuclear ruthenium(II) complex having chlorine bridges which are easily broken by sodio-derivatives of bidentate chelating ligands giving mononuclear hexacoordinated ruthenium(II) compounds. The Ru–C bond in these new complexes has been found to be stable towards nucleophilic reagents. The stereochemistry for these complexes has been suggested on the basis of IR, ^1H and ^{31}P NMR spectra.

Binuclear ruthenium(II) complexes of the type $[Ru(CO)Cl(CH_3CHCN)(L)_2]_2$, where L = triphenyl phosphine or picoline, have been synthesised and studied by Hiraki *et al.*[1] Our interest in the synthesis of stable ruthenium–alkyl σ-bonded compounds[2] prompted us to isolate several 1-cyanoethyl derivatives of ruthenium(II) containing monobasic bidentate chelating ligands.

EXPERIMENTAL

Experiments were carried out in an atmosphere of dry, oxygen-free nitrogen. Solvents were carefully purified, dried, distilled and degassed before use. Other reagents used were of the highest purity available.

(a) *Preparation of* $HRu(CO)Cl(PPh_3)_3$

This compound was prepared from ruthenium trichloride trihydrate, triphenyl phosphine and formaldehyde in 2-methoxyethanol medium as previously reported.[3] The yield of the brown crystalline powder was 95%.

(b) *Preparation of the* 1-*cyanoethyl complex*, $[Ru(CO)Cl(CH_3CHCN)(PPh_3)_2]_2$

$HRu(CO)Cl(PPh_3)_3$ (1.95 g; 2 mmol) in THF (30 cm^3) was reacted with freshly distilled acrylonitrile (0.85 g; 15.5 mmol) in a Schlenk tube by stirring the contents for 24 h at room temperature. The solvent was then removed under reduced pressure, the residue washed with cold hexane and the product dried *in vacuo*. Nearly white crystals, m.p. 154°C. Yield 1.45 g (95%).

(c) *Preparation of chelated complexes of* (b), $[Ru(CO)(CH_3CHCN)(PPh_3)_2(chelate)]$

(i) 8-*Hydroxyquinoline complex.* The sodio-derivative of 8-hydroxyquinoline was prepared by reacting the ligand (0.08 g; 0.55 mmol) and oil-free sodium hydride (0.013 g; 0.55 mmol) in refluxing ether (8 h). Ether was then removed, THF (30 cm^3) added to it and, to this stirred suspension, $[Ru(CO)Cl(CH_3CHCN)(PPh_3)_2]_2$ (0.37 g; 0.5 mmol) was introduced. The reaction was completed at room temperature within 12 h. THF was then replaced with benzene, the contents centrifuged and the benzene solution concentrated to crystallisation. The yellow crystals obtained were washed with hexane and dried *in vacuo* at room temperature. Yield 0.36 g (80%).

(ii) *Acetylacetone complex.* This was obtained similarly to the above complex from 0.55 mmol of the sodio-derivative of acetylacetone and 0.5 mmol of the chlororuthenium complex prepared in (b). Yield of the cream coloured crystalline product was 0.32 g (80%).

Other chelated complexes (Table 1) were similarly prepared.

RESULTS AND DISCUSSION

Treatment of a THF solution of $HRu(CO)Cl(PPh_3)_3$ with an eight-fold excess of acrylonitrile

at room temperature resulted in the complete conversion into a binuclear (1-cyanoethyl)ruthenium(II) derivative with chlorine bridges.[1] This complex, $[Ru(CO)Cl(CH_3CHCN)(PPh_3)_2]_2$, is sparingly soluble in common organic solvents. Stable octahedral mononuclear derivatives have been prepared by chlorine bridge cleavage reaction using sodio-derivatives of potential bidentate chelating ligands in THF at ambient temperatures. The chelating ligands used were β-diketones, 8-hydroxyquinoline, 2-hydroxy-4-methoxybenzophenone and *N*-benzoyl-*N*-phenyl hydroxylamine. These complexes were coloured solids soluble in common organic solvents. Unlike other Ru–C (alkyl/aryl) bonded compounds, the metal–carbon bond in these complexes is found to be remarkably stable. The products isolated contain both 1-cyanoethyl and bidentate chelating ligand. The unusual stability of the Ru–C bond could be attributed to the proximity of the cyanoethyl group which controls the electronic effect. The Ru–C bond in these derivatives, $[Ru(CO)(CH_3CHCN)(PPh_3)_2(chelate)]$, did not undergo insertion reactions; there was no reaction with liquid SO_2. Likewise treatment of a chloroform solution of the compound with carbon monoxide at room temperature as well as at refluxing temperature did not produce the corresponding acyl derivative.

IR spectra

The IR spectrum of the binuclear complex $[Ru(CO)Cl(CH_3CHCN)(PPh_3)_2]_2$ shows $\nu(C{\equiv}N)$ at 2220 cm^{-1} and $\nu(C{\equiv}O)$ at 1930 cm^{-1}. In the chelated ruthenium(II) complexes,

$$[Ru(CO)(CH_3CHCN)(PPh_3)_2(chelate)],$$

the $\nu(C{\equiv}N)$ is observed at 2200 cm^{-1}. The observed reduction of carbon–nitrogen bond order could be attributed to the increased electronic charge on the nitrile carbon as a result of chlorine bridge cleavage by the electron-rich bidentate chelating ligand. A similar reduction ($\Delta \sim 15$ cm^{-1}) is observed for the carbonyl stretching frequency of most of the complexes. All these new products show bands due to chelated bidentate moiety (Table 2).

NMR spectra

^1H NMR spectra (Table 2) of mononuclear chelated derivatives,

$$[Ru(CO)(CH_3CHCN)(PPh_3)_2(chelate)],$$

exhibit resonances associated with methyl and > CH protons of the 1-cyanoethyl group. The acetylacetonato complex

$$[Ru(CO)(CH_3CHCN)(PPh_3)_2(acac)]$$

exhibits a doublet centred at δ 0.75 [$^3J(HH) = 8$ Hz] due to the methyl protons of the 1-cyanoethyl group and a multiplet at δ 2.30 assignable to > CH protons. Similar doublets for methyl protons are observed in the case of other β-diketone derivatives. The resonances due to CH_3–CO groups are seen at δ 1.25 and 1.50 with equal intensity, indicative of chelated acetylacetone bonded to an asymmetric ligand pair. A high field shift is seen for the γ-CH

COMPLEXES OF SILVER(III) WITH OXOANIONS

JAMES D. RUSH* and LOUIS J. KIRSCHENBAUM†
Department of Chemistry, University of Rhode Island, Kingston, RI 02881, U.S.A.

(*Received* 17 *January* 1985; *accepted* 28 *March* 1985)

Abstract—Silver(III) has a half-life at pH 11 of several hundred seconds in aqueous solutions in the presence of 0.1–1.0 M concentrations of certain basic oxoanions (Oxo) (phosphate, carbonate, borate, pyrophosphate, and arsenate). This compares with a lifetime of a few seconds at pH 11 in the absence of these oxoanions. UV–visible spectra and kinetic data for these solutions are interpreted as evidence for the following equilibria in the pH range 9–13.

$$Ag(OH)_4^{-1} + H_2O \rightleftharpoons Ag(OH)_3H_2O + OH^- \quad (1)$$

$$Ag(OH)_4^{-1} + Oxo \rightleftharpoons Ag(OH)_3Oxo + OH^- \quad (2)$$

$$Ag(OH)_3Oxo + H_2O \rightleftharpoons Ag(OH)_2(Oxo)H_2O + OH^- \quad (3)$$

Values of K_3 lie in the range $10^{-3} < K_3 < 10^4$ M for the systems studied. K_2 is estimated to be $\sim 10^2$ for phosphate and slightly smaller for the other systems. $Ag(OH)_4^-$ undergoes an unusual reaction with pyrophosphate at pH $\sim$ 8 to form a novel silver(II) complex, $[Ag(P_2O_7)_2]^{6-}$, for which EPR and electronic absorption spectral parameters are reported.

The tetrahydroxo-argentate(III) ion, $Ag(OH)_4^-$, is a square-planar complex of tervalent silver that is highly oxidizing and metastable in aqueous solution at pH > 13 ($t_{1/2} \sim 1.5$ h in 1.2 M NaOH at room temperature). Its solutions decompose to AgO with resulting oxidation of water. $Ag(OH)_4^-$ solutions are prepared electrochemically by oxidizing a silver metal anode in 1.2 M NaOH.[1,2]

We have previously investigated the kinetics of $Ag(OH)_4^-$ reactions with a number of reductants and complexing agents.[3–8] When coordinated by strong ligands, such as periodate or tellurate,[2] silver(III) is quite stable even near pH neutrality. The redox stability of $Ag(OH)_4^-$ solutions decreases as the pH is lowered[2,7] suggesting that substitution of OH^- by solvent water [eqn (1)] is the principal mechanism for decay of $Ag(OH)_4^-$.

$$Ag(OH)_4^- + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ag(OH)_3(H_2O) + OH^- . \quad (1)$$

The aquo species, $Ag(OH)_3(H_2O)$ rapidly oxidizes the solvent ($k = 142\ s^{-1}$).[7] Its instability arises from the poor electron-donating properties of solvent water.

At pH $\sim$ 11 decomposition of Ag(III) is controlled by the rate of aquation ($k_1 = 2 \pm 1\ s^{-1}$)[5] of $Ag(OH)_4^-$. The reverse reaction in eqn (1), abstraction by OH^- of a proton from the aquo complex, is relatively slow, presumably because of internal hydrogen bonding. This accounts for the importance of the solvent path for ligand substitution on Ag(III) even at pH > 13.[8]

In this report we describe some labile complexes of silver(III) with oxoanions (phosphate, borate, carbonate, arsenate, and pyrophosphate—general designation "Oxo"), which show enhanced kinetic stability at pH < 13. The preparation of these species provides new approaches to the study of silver(III) reactivity under conditions where the hydroxyl ion concentration is significantly reduced.

We also report here the first trapping of an intermediate silver(II) complex, resulting from the decomposition of the Ag(III) pyrophosphate complex. This suggests that the oxidation of water to oxygen by Ag(III) may proceed by one-electron processes.

EXPERIMENTAL

The electrochemical preparation of $Ag(OH)_4^-$ has been described previously.[1] Stock solutions for the present study generally contained $3–5 \times 10^{-4}$ M $Ag(OH)_4^-$ as determined at its absorbance maximum at 267 nm ($\varepsilon_{267} = 1.17 \times 10_4\ M^{-1}\ cm^{-1}$). Dilution of $[OH^-]$ at a constant ionic strength was made using 1.2 M $NaClO_4$.

The chemicals used in all preparations were of reagent grade. The sodium hydroxide used was Mallinckrodt 50% solution (low carbonate), and the water was doubly-distilled. Oxoanion solutions were made from the sodium salts, and pH adjustments were made with perchloric acid or NaOH. The pH was measured with a Markson Electromark pH meter calibrated at pH 10 with standard buffers.

Solutions of Ag(III) with oxoanions at pH 9–13 were prepared in two ways: (1) slow addition of perchloric acid to an $Ag(OH)_4^-$ solution containing the oxoanion ([Oxo] > 0.1 M) while the solution was stirred rapidly, and (2) addition of a neutral or slightly acidic oxoanion solution to $Ag(OH)_4^-$ in NaOH. The final pH was adjusted by varying [NaOH] in the Ag(III) component prior to mixing. This method was used exclusively in the kinetic and spectral studies because the loss of Ag(III) during mixing due to local regions of low pH is minimal.

Concentrations of Oxo in excess of 0.1 M were necessary to neutralize the excess OH^-. Because ionic strength could not be uniform for all experiments (the speciation and charges of the oxoanion vary over the pH range of the study), the Ag(III) Oxo preparations were made to a final μ (1 M < μ < 2 M) over which ionic strengths effects are expected to be small.

Electronic spectra were obtained on a Cary 15 or a Varian DMS-90 UV-Vis spectrometer with a thermostated reaction cell. The decomposition kinetics of Ag(III) solutions were measured at 20°C. Observed decay rate constants, k_d, were calculated from plots of $\ln(A - A_\infty)$ vs time which were linear for most runs. In cases where catalytic effects from solid reaction products were evident, k_d was obtained from the initial slope of the absorbance vs time data. Absorbance changes were generally monitored at 270 nm.

Fast reactions were monitored in an Aminco–Morrow stopped-flow apparatus.[1] A solution of the oxoanion was mixed with $Ag(OH)_4^-$, and absorbance changes were recorded on a storage oscilloscope.

Analysis for the +2 oxidation state of silver was done by EPR of frozen solution samples on a Bruker ER200 spectrometer. The interaction of the unpaired spin in the d^9 electronic configuration with the $Ag^{107,109}$ ($I = 1/2$) gives a characteristic spectrum.[9(a),(b)] The diamagnetic trivalent oxidation state in solution was detected by addition of sodium periodate. The bis periodatoargentate(III) complex is bright yellow and indefinitely stable.[2]

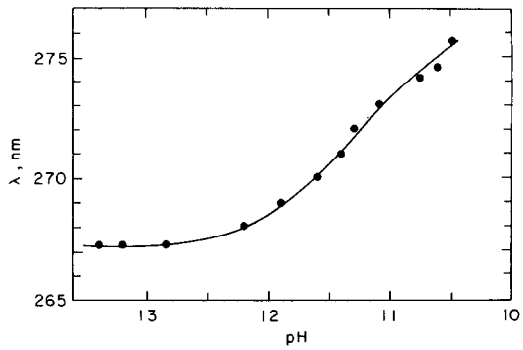

Fig. 1. pH dependence of the absorbance maximum of Ag(III) phosphate solutions: [phosphate] = 0.35 M; 20°C. The solid curve is calculated using eqn (4) (see Discussion).

RESULTS

Spectra of oxoanion solutions. The addition of an oxoanion causes a pH-dependent shift in the absorption maximum of Ag(III). For Oxo = borate, phosphate, arsenate, and pyrophosphate, λ_{max} changes from 267 to ~ 276 nm as the pH is lowered from 13 to 10. The spectral data for phosphate shown in Fig. 1 are typical of the other systems as well. At pH > 12.5, the spectrum is indistinguishable from that of $Ag(OH)_4^-$. In the pH range 11–12 the spectrum broadens and exhibits a small shoulder near 280 nm which merges into a single peak at ~ 276 nm as the pH is further reduced (Fig. 2). These pH-dependent shifts are reversible upon addition of NaOH. The presence of labile complexes of tervalent silver was confirmed by the addition of sodium periodate.

Over the same pH range, solutions, containing 0.2 M carbonate become orange coloured owing to the formation of a Ag(III) carbonate complex with the spectrum shown in Fig. 2. The colour change seems to be associated with the pK_a of the complex. Ag(III) borate solutions have spectra similar to that of phosphate when pH > 10. At lower pH, further reactions result in a new spectrum which is also shown in Fig. 2. As with carbonate, the change in spectrum appears to be associated with the pK_a of the oxoanion complex. The extinction coefficients of the spectra in Fig. 2 are approximate (± 15%).

The addition of 0.2 M pyrophosphate to $Ag(OH)_4^-$ with $HClO_4$ sufficient to reduce the pH to ~ 8 (a

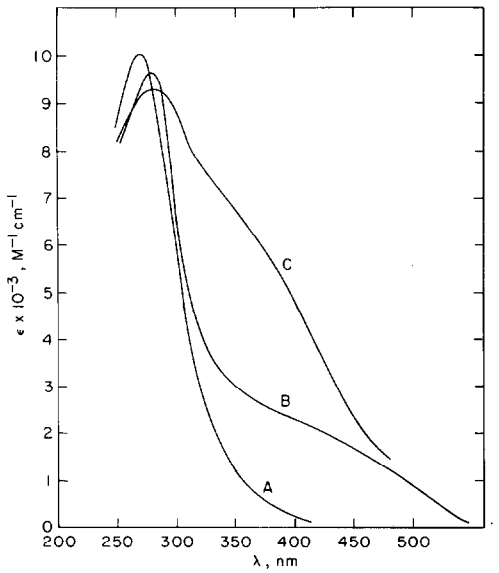

Fig. 2. Solution spectra of Ag(III) oxoanion complexes at selected pHs. (A): 0.35 M phosphate at pH 10.5. Borate, arsenate, and pyrophosphate solutions are similar at this pH; (B): 0.4 M carbonate at pH 10.5; (C): 0.6 M borate at pH ~ 9.5.

buffer region for $P_2O_7^{4-}/HP_2O_7^{3-}$) causes the immediate formation of a pale yellow-brown solution containing a silver(II) species with the absorption spectra shown in Fig. 3. Spectrum A is indefinitely stable in 0.1 M pyrophosphate at pH 6–8. Its stability decreases at lower pH. At pH 2–2.5 a species with the spectral peak shown in B predominates which has a half-life of ~3 s. A spectrum identical to A is obtained when an Ag(I) solution is oxidized with sodium persulphate under the same conditions. The silver in solutions prepared

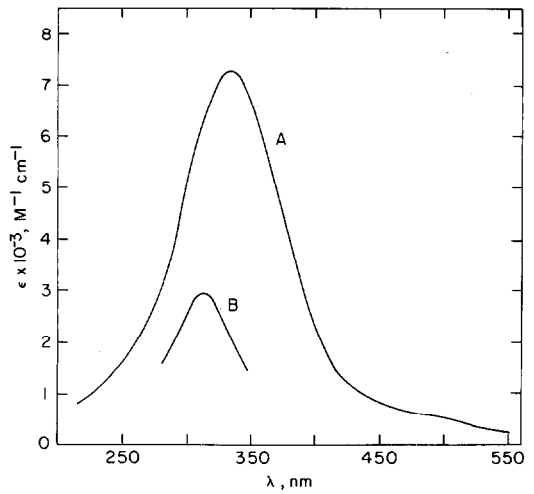

Fig. 3. Spectra of Ag(II) complexes in 0.1 M pyrophosphate at (A): pH 7.8, and (B): pH 2.2.

from $Ag(OH)_4^-$ (frozen at −100°C, pH = 8.2) had the following EPR parameters: $g_\perp = 2.051$, $g_\parallel = 2.269$, and $A_\perp = 32.3$ G, $A_\parallel = 39.3$ G. These parameters are typical of many tetragonal Ag(II) complexes.[9] At pH 8, the complex is predominately $[Ag(II)(P_2O_7)_2]^{6-}$ by analogy with the Cu(II) pyrophosphate system.[10]

Products of Ag(III) oxoanion decomposition. With the exception of pyrophosphate, Ag(III) oxoanion solutions of pH < 12 decay almost entirely to silver(I) products. Black precipitates which result from slow decomposition of $Ag(OH)_4^-$ contain mostly AgO, a mixed Ag(I)/Ag(III) oxide which, in base, may form from the fast disproportionation of Ag(II)[11] or the very slow reaction between $Ag(OH)_2^-$ and $Ag(OH)_4^-$.[12] However, the rapid decomposition of $Ag(OH)_4^-$ at reduced pH gives Ag(I),[7] suggesting that AgO is formed via the latter pathway in strongly alkaline solution. By contrast, the addition of pyrophosphate causes Ag(III) to be reduced entirely to Ag(II) over the pH range 8–14, and eventually results in precipitates of AgO at pHs where the decompositions of other Ag(III) Oxo systems yield Ag(I) as a product. AgO is detected by its reaction with bipyridine in acid to give the red bis-bipyridyl Ag(II) complex.[9(b)]

Formation of Ag(III) Oxo complexes. Qualitative observations of the reactions between $Ag(OH)_4^-$ and some oxoanions were made in the stopped-flow apparatus in the pH range 10–13. Concentrated Oxo solutions (0.4 M phosphate, 0.6 M borate and carbonate) which produced a final pH > 12.5 caused no discernable spectral changes when mixed with $Ag(OH)_4^-$. At lower pH a fast decrease in the absorbance ($t_{1/2}$ ~ 8–15 ms) was monitored at 270 nm in all three systems. The amplitude of the absorbance changes, though not the rates, depended upon the pH. In the cases of borate (pH < 10) and carbonate (pH 10–11.5), the spectra of Fig. 2 were attained by slower processes ($t_{1/2}$ ~ 3 s and 75 ms, respectively) following the initial, much faster, reaction. Only the faster reaction was observed for the phosphate system.

These kinetic observations and the solution spectra (Figs. 1 and 2) show that $Ag(OH)_4^-$ is in a pH-dependent equilibrium with silver(III) oxoanion complexes where one or more hydroxyl ligands have been substituted by the oxoanion as in eqn (2).

$$Ag(OH)_4^- + n\text{Oxo} \overset{K_2^n}{\rightleftharpoons} Ag(OH)_{4-n}(\text{Oxo})_n + nOH^- . \quad (2)$$

The relatively small spectral shifts and the single step formation reaction suggest that $n = 1$ when Oxo = phosphate. At pH > 10 this condition also seems to hold for all except the carbonate system where

further substitution may occur. These substitution reactions are reversible upon changing the pH.

In the case of oxoanions which have protolytic equilibria in this pH range, a proton ambiguity exists as to the source of the spectral changes upon which eqn (2) is, so far, based. In eqn (2) we have treated "Oxo" without regard to its degree of deprotonation. Some justification for this exists. In the range $12 \lesssim \text{pH} \lesssim 10$ the spectral shifts which occur on the phosphate system (Fig. 1) are qualitatively similar to spectral changes in the borate and pyrophosphate systems, in which the ligands have pK_as below this range. Thus, we have attributed the speciation to a single equilibrium, eqn (2), with the realization that ligand protonations might also contribute to the complexity of the systems. It should be noted that the rather pronounced spectral changes due to protonations in the borate and carbonate systems may arise from further substitutions or chelation, rather than protonation at a remote site which would not result in a structural change in the complex.

Kinetics of the decomposition of Ag(III) Oxo solutions. The first-order rate constants for decomposition of Ag(III) in oxoanion solutions, k_d, were measured over the range $9 < \text{pH} < 13$ at 20°C. At $\text{pH} > 12.5$ half-lives generally exceeded $\frac{1}{2}$ h (except for pyrophosphate preparations) and are very susceptible to the catalytic effects of solids (e.g. AgO) which often complicate the slower reactions of $Ag(OH)_4^-$.[4] At lower pH the decay remains first-order in [Ag(III)], although values of k_d varied by as much as 50% over repeat runs due to impurities or the effect of solid products. Rate constants were selected to minimize these effects.

The Ag(III) phosphate system shows typical characteristics and was the most extensively studied. Values of k_d obtained at different phosphate concentrations are shown in Table 1. At pH 11 k_d is virtually independent of [phosphate] in the range 0.065–0.5 M. Lower concentrations could not be achieved because of limitations imposed by the preparative procedure. However, in the absence of stabilizing ligands, Ag(III) decomposes within a few seconds[7] at this pH.

Table 1. Phosphate dependence of k_d (pH 11, 20°C, 1 M $< \mu <$ 2 M)

[Phosphate], M	$10^3\ k_d$, s^{-1}
0.5	2.6
0.46	2.5
0.35	1.3
0.21	2.3
0.175	1.6
0.1	2.0
0.065	1.9

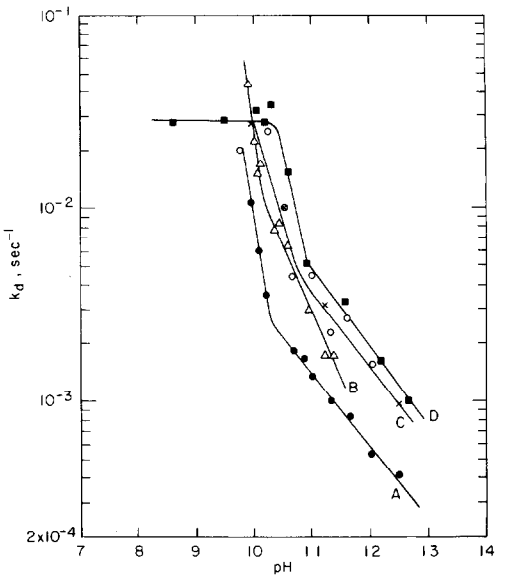

Fig. 4. pH dependence of the rate constant for decay of Ag(III) Oxoanion systems at 20°C: A, ●, 0.35 M phosphate; B, △, 0.40 M carbonate; C, ×, 0.10 M pyrophosphate; D, ■, 0.33 M borate; ○, 0.2 M arsenate. Ionic strengths vary between 1 and 2 M.

The pH dependence of k_d at constant [Oxo] is shown in Fig. 4 for several systems. For Ag(III) phosphate, log k_d varies linearly with pH with a slope of -0.4 in the range $10.3 < \text{pH} < 12.5$. The slopes increase sharply at a "break point" which occurs between pH 10 and 11 for all of the systems studied. Values of k_d for the different systems (except for arsenate) are correlated with solid lines in Fig. 4. In the pH range of greater stability the values of k_d vary by less than an order of magnitude between the least stable (borate) and the most stable (phosphate) systems. This presumably reflects differences in the stability constants (K_2) of the Ag(III) Oxo complexes. The pH dependence of k_d in the Ag(III) carbonate system reflects the combined effect of two complex pK_as on Ag(III) speciation. This produces a more pronounced dependence above pH 10.5 than is seen in the other systems. The Ag(III) arsenate system appears to have intermediate stability. However, the scatter in the data obtained for this system causes us to present several observations of k_d in Fig. 4 without attempting to correlate them.

The acid/base properties of the ligand have no specific effect upon the pH dependence of k_d except in those systems where pronounced spectral changes appear to be associated with a pK_a of the ligand. The rapid increase in k_d between pH 10 and 11 in these

Table 2. Equilibrium constants for aquation of Ag(III) oxoanion complexes (K_3) (20°C, 1 M < μ < 2M)

Oxo	Log K_3
Phosphate	-3.75 ± 0.2
Borate	-3.2 ± 0.2
Pyrophosphate	-3.25 ± 0.2
Carbonate	-3.7 ± 0.2

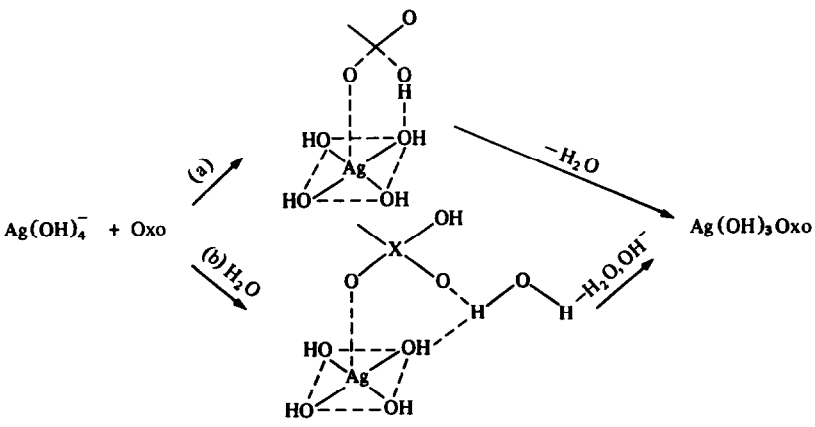
systems indicates a protonic equilibrium in this range which we suggest is due to reaction (3).

$$Ag(OH)_3Oxo + H_2O \overset{K_3}{\rightleftharpoons} Ag(OH)_2(Oxo)(H_2O) + OH^- \quad (3)$$

The qualitatively similar variations in k_d (at pH > 10) observed in the phosphate, borate, and pyrophosphate systems support the contention that the acid/base properties of the $Ag(OH)_3$ moiety in $Ag(OH)_3Oxo$, rather than those of the ligands, are the primary cause of the decreasing stability of the systems as pH is lowered. Values of $\log K_3$ for the various systems were evaluated at the inflection points of the data in Fig. 4 and are listed in Table 2.

In the borate system, k_d reaches a constant value of $\sim 3\ s^{-1}$ to pH $\sim$ 10. A complex (spectrum C in Fig. 2) which decays at a rate almost independent of pH is formed in competition with the pH-dependent decay of its precursor.

DISCUSSION



Formation reactions. The fast reactions observed in the stopped-flow experiments between $Ag(OH)_4^-$ and the Oxo ligands are too rapid to be mediated by the aquation of $Ag(OH)_4^-$ [eqn (1)]; $k_1 \sim 2\ s^{-1}$,[5] indicating that a direct reaction occurs. Although the oxoanions differ in structure as well as other properties, their common ability to form hydrogen bonds at several sites suggests a possible mechanism for complex formation. If, as in other reactions of $Ag(OH)_4^-$,[3,5] the axial attack on Ag(III) by the entering nucleophile occurs, the oxoanion might assist in transferring a proton to a hydroxyl ligand via a sequence such as those shown in Scheme 1.

Path (a) would result in deprotonation of protonated ligands (e.g. $B(OH)_4^-$, $H_2PO_4^{2-}$, $HAsO_4^{2-}$) while path (b) would be possible for most species throughout our pH range. Path (b) would be required for pyrophosphate (which is $P_2O_7^{4-}$ down to about pH 8) and would be inaccessible to borate both as $B(OH)_4^-$ and $B(OH)_3$.

The five-coordinate Ag(III) transient may be stabilized by the formation of a chelate ring which effectively protonates a hydroxyl ligand. Tetrahedral oxoanions might indeed form two such rings within the five-coordinate intermediate. The formation of the four-coordinate entity $Ag(OH)_3Oxo$ is then assisted by elimination of an aquo rather than a hydroxyl ligand. Similar hydrogen bond assisted pathways are important, e.g. in the complexation of molybdate and tungstate with catecholate dianion.[13]

Transient silver(III) species in which one OH^- ligand is replaced by a monodentate ligand have spectra very similar to that of the parent $Ag(OH)_4^-$,[4,5] whereas multidentate ligands typically produce charge-transfer bands at longer wavelengths.[6,14] The formation of a monosubstituted complex, as in Scheme 1, appears to be common to all the oxoanions studied. However, as the pH is reduced, slower processes are observed in the borate and carbonate systems which appear to be further substitutions.

Decomposition reactions. Our analysis of the pH stability data will be qualitative and is based on assumptions which seem to be in accord with the

Scheme 1.

experimental observations. These are (1) decay of Ag(III) proceeds mainly through steady-state amounts of aquated Ag(III) species, (2) Ag(III) speciation is basically described by eqns (1)–(3), and (3) coordination by either OH^- or Oxo should affect the hydrolysis properties of the silver(III) moiety similarly.

At pH > 11, where decomposition is slow, the speciation of an Ag(III) Oxo solution is described approximately by eqn (4).

$$\frac{[Ag(OH)_3Oxo]}{[Ag(III)]_{Tot.}} = \frac{K_2^1[Oxo]}{[OH^-]+K_2^1[Oxo]}. \quad (4)$$

If it is allowed that the spectral shifts shown in Fig. 1 arise from two species, $Ag(OH)_4^-$ and the silver(III) phosphate complex, which contribute to the shift in peak maximum proportionately to their concentrations, eqn (4) can be applied to obtain a rough estimate for K_2. Using values of $\lambda_{max} = 267$ nm for $Ag(OH)_4^-$ and $\lambda_{max} \sim 276$ nm for $Ag(OH)_3(PO_4)$ the data in Fig. 1 yields $K_2^1 = 10^{-2}$ and the calculated curve.

The reaction of excess Oxo with aquo Ag(III) species in equilibrium with $Ag(OH)_4^-$ and $Ag(OH)_3Oxo$ [eqns (1) and (3)] prevents the rapid decomposition of the solutions even at pH < pK_1 or pK_3. Still, when the pK_as of the complexes are approached the concentration of reactive aquo complex, and hence k_d, increases. The values of K_3 obtained for these systems (see Table 2) suggest that 10^{-3} M > K_1 > 10^{-5} M, in agreement with earlier estimates.[7]

The above interpretations of the formation, speciation, and decay of the Ag(III) oxoanion complexes is qualitative and accounts only for general features. The differences among the oxoanion systems have not been emphasized. However, it is clear from Fig. 4 that K_2 and K_3, and hence k_d, depend on the nature of the oxoanion ligand.

The reaction of $Ag(OH)_4^-$ with pyrophosphate. This reaction, which at pH < 8 results in the one-electron Ag(II) reduction product rather than Ag(I) warrants further discussion. This system differs from the others in the sequence of reactions which follow eqn (3), aquation of the monosubstituted complex, since the pH dependence of k_d is quite similar to that of the other oxoanion systems. Evidently, closure of the pyrophosphate ring must follow aquation at a *cis*-position resulting in a chelated Ag(III) transient which is reduced (by solvent) to form an Ag(II) species. In base (pH > 9) this complex hydrolyzes to produce AgO precipitates, but at pH 6–8 (following probable addition of a second pyrophosphate ligand) the complex is quite stable. In contrast to this system, the addition of bipyridyl (which also forms strong Ag(II) complexes) to $Ag(OH)_4^-$ solutions does not result in spontaneous one-electron reduction.[15] This is probably because the weakly basic bipyridyl nitrogens are unable to mediate a proton transfer to OH^- and thus cannot complex Ag(III) in strong base.

(*Received* 3 *October* 1984; *accepted after revision* 5 *March* 1985)

Abstract—Three new palladium(II) complexes of formula [Pd(bipy)(XX)] [where bipy is 2,2′-bipyridine and XX are dianions of catechol (CAT), 4-*tert*-butylcatechol (BCAT) and 3,4-dimercaptotoluene (DMT)] have been prepared and characterized by physical methods. A ligand–ligand charge-transfer band in each complex was observed between 16–21 kK (ε_{max} = 1500–2200 l mol^{-1} cm^{-1}) which is negatively solvochromic. These palladium(II) complexes in dimethylformamide photosensitize the formation of singlet oxygen and their ability to photosensitize triplet oxygen ($^3O_2$) to singlet oxygen ($^1O_2$) are compared with analogous platinum(II) complexes. In addition, 2,2′-bipyridine-platinum(II) complex of 3,4-dimercaptotoluene also undergoes self-sensitized photooxidation.

Several mixed-ligand complexes of beryllium(II),[1] zinc(II),[2] nickel(II)[3] and platinum(II)[4,5] having 2,2′-bipyridine, 1,10-phenanthroline and other related ligands show absorption bands corresponding to ligand-to-ligand charge-transfer (LLCT) transitions to low energies if one ligand is reducing and the other is oxidizing. This intense LLCT transition in [Pt(bipy)(DMT)] is involved in its photooxidation in $CHCl_3$ solution.[4] This and other related complexes show the formation of $^1O_2$ by energy transfer from their triplet LLCT excited states to $^3O_2$.[5] In view of the importance of mixed-ligand metal complexes in inorganic photochemistry, we report here the synthesis and characterization of some new [Pd(bipy)XX] complexes. These complexes show intense LLCT transitions in the visible region. They also photosensitize $^3O_2$ to $^1O_2$ and their propensity to form $^1O_2$ are compared with analogous platinum(II) complexes.

EXPERIMENTAL

Chemicals

Potassium tetrachloroplatinate, palladium dichloride, 2,2,6,6-tetramethyl-4-piperidinol and 2,2′-bipyridine were purchased from Strem Chemical Co. (U.S.A.), Johnson Matthey (U.K.), Aldrich Chemical Co. (U.S.A.), SISCO (India) respectively. Catechol, 4-*tert*-butylcatechol, thiosalicylic acid and 3,4-dimercaptotoluene were bought from B.D.H. (England). The solvents were of reagent grade and were purified before use by the standard methods.[6] Other chemicals used were of analytical reagent grade and used as such.

Synthetic procedures

[Pd(bipy)Cl$_2$] and [Pt(bipy)Cl$_2$]. These complexes were prepared by the following methods as given elsewhere.[7,8]

[Pt(bipy)(CAT)], [Pt(bipy)(BCAT)] and [Pt(bipy)(DMT)]. They were synthesized by following the procedures published earlier.[5]

[Pd(bipy)(DMT)]. [Pd(bipy)Cl$_2$] (333 mg, 1 mmol) was dissolved in 20 cm^3 of dimethyl sulphoxide. 3,4-Dimercaptotoluene (155 mg, 1 mmol) was dissolved in 2 cm^3 of 1 N NaOH, which was added to the above solution with stirring. The reaction mixture was stirred at room temperature for 30 min and diluted with 100 cm^3 of chloroform. The chloroform layer containing the desired complex was repeatedly washed with fresh water. The chloroform layer, was finally separated and dried over anhydrous sodium sulphate. Sodium sulphate was later removed by filtration. The chloroform from dry chloroform layer was removed under vacuum at room temperature. The complex was recrystallized

* Author to whom correspondence should be addressed.

from chloroform. The crystals were filtered, washed with small quantity of cold chloroform and finally with petroleum ether. The violet red crystals were dried in vacuum at room temperature. The whole process was carried out in the absence of light. Visible max. (CH_3OH) 20.79, (DMF) 20.08, ($CHCl_3$) 18.18 and (C_6H_6) 16.72 kK; ^{1}H NMR (DMSO-d_6) δ 8.72 (m, 2, H-6,6'), 7.84 (m, 2, H-5,5'), 6.96 (d, 1, H_A), 6.64 (d, 1, H_B), 2.20 (s, 3, H_C) and 6.86 ppm (s, 1, H_D).

[*Pd(bipy)(BCAT)*]. This compound was prepared by following the procedure as given for [Pd(bipy)(DMT)] except 4-*tert*-butylcatechol was used in place of 3,4-dimercaptotoluene. The complex was recrystallized from acetone and petroleum ether mixture. The violet crystals obtained were filtered, washed with acetone and finally with petroleum ether. They were dried in vacuum at room temperature. Visible max. (CH_3OH) 20.74; (DMF) 17.84, ($CHCl_3$) 16.62 and (C_6H_6) 16.08 kK; ^{1}H NMR (DMSO-d_6) 8.66 (m, 2, H-6,6'), 7.84 (m, 2, H-5,5'), 6.39 (d, 1, H_A), 6.26 (d, 1, H_B), 1.20 (s, 9, H_C) and 6.24 ppm (s, 1, H_D).

[*Pd(bipy)(CAT)*]. This violet crystalline compound was prepared by following the procedure as given for [Pd(bipy)(BCAT)] except the catechol was used in place of 4-*tert*-butylcatechol. Visible max. (CH_3OH) 21.36, (DMF) 18.59 and ($CHCl_3$) 17.48 kK; ^{1}H NMR (DMSO-d_6) δ 8.68 (m, 2, H-6,6'), 7.80 (m, 2, H-5,5') and 6.30 ppm (m, 4, H_A, H_B, H_C and H_D).

Photochemical measurements

(a) *Photosensitized oxidation of 2,2,6,6-tetramethyl-4-piperidinol using 2,2'-bipyridine-palladium(II) and -platinum(II) complexes as sensitizers.* These experiments were carried out on a merry-go-round apparatus. The stabilized light source of 150 W × 24 V tungsten halogen lamp operating at 18 V was housed at the centre of merry-go-round apparatus in a double jacketted pyrex vessel thermostatted at 28° ± 1°C by circulating water through the jacket. The solutions to be irradiated were taken in pyrex glass tubes (20 cm × 1 cm) and kept on the merry-go-round apparatus.

The photoproduction of singlet oxygen ($^1O_2$) was measured by electron paramagnetic resonance (EPR) method using 2,2,6,6-tetramethyl-4-piperidinol as singlet oxygen acceptor.[9,10] Typically a 200 μmol l^{-1} solution of the above complex in dimethylformamide (DMF) was bubbled for 15 min with solvent saturated molecular oxygen. Then 2,2,6,6-tetramethyl-4-piperidinol was added to a final concentration of 10 mM. The mixture was irradiated on the merry-go-round apparatus at different irradiation times.

The nitroxide free radicals thus formed by reaction of 2,2,6,6-tetramethyl-4-piperidinol with singlet oxygen were recorded at room temperature in aqueous EPR cell on a Varian E-112 ESR spectrometer (X-band) using TCNE as g marker (g = 2.00277). The quantitative EPR measurements were made by comparison with the EPR spectrum of a solution of nitroxide free radicals of known concentration.

(b) *Self-sensitized photooxidation of some 2,2'-bipyridine-palladium and -platinum complexes.* A stabilized beam of light from 200 W × 24 V tungsten halogen lamp operating at 22 V was directed through a dichroic heat filter having range of transmission between 400 and 710 nm. This filter was placed 14 cm from the light source. The filtered light coming out from this filter was directed through a solid clear cast acrylic cylinder (16 × 4 cm) placed 45 cm from the light source. A stoppered 1 cm path length quartz cuvette having solution of the complex in DMF was placed on the other side of the cylinder. The course of the photolysis was followed by difference absorption spectroscopy in the visible region.

Other physical measurements were carried out as described earlier.[11,12]

RESULTS AND DISCUSSION

Three new neutral mixed-ligand palladium(II) complexes of general formula [Pd(bipy)(XX)] (where bipy is 2,2'-bipyridine and XX are dianions of catechol, 4-*tert*-butylcatechol and 3,4-dimercaptotoluene were prepared. The colour, yield, molar conductance and chemical analysis of these complexes are given in Table 1. The molar conductance values of these complexes in dimethylformamide (10^{-3} M) lie between 4.2 to 8.6 $cm^2\ \Omega^{-1}\ mol^{-1}$. These small values of molar conductance suggest that these complexes are non-electrolytes.[13]

UV–visible spectra

The UV–visible absorption spectra of palladium(II) complexes recorded in dimethylformamide solution show several band maxima in the UV–visible region, the positions of which along with their extinction coefficients (ε_{max}) are given in Table 1. These bands are assigned following the band assignments of [Pd(bipy)Cl_2].[14] The band 2 between 25 and 30 kK is due to a charge-transfer band from palladium d-orbital to π-antibonding orbital of 2,2'-bipyridine. The band 4 is due to charge-transfer transition from same palladium orbital to a higher π-antibonding orbital of 2,2'-bipyridine. The bands 1, 3 and 5 are assigned to the first, second and higher internal π–π^* type transitions of 2,2'-bipyridine respectively. Each of these complexes has shown an

additional strong band in the visible region between 17 and 21 kK (ε_{max} = 1600–2200 $l\ mol^{-1}\ cm^{-1}$). This band has comparable intensity to the charge-transfer band 2 and is strongly solvent dependent. The maximum of this band for these complexes in different solvents is given in the experimental section. This peak experiences a bathochromic shift with decrease in polarity of the solvent. Similar shift was earlier observed in [Pt(bipy)(DMT)] and other related complexes[4,5] and thus this band is assigned to ligand-to-ligand charge-transfer (LLCT) band.

IR spectra

In order to characterize the palladium(II) complexes and throw light on the mode of binding of ligands to palladium, the IR of these complexes were recorded between 4000 and 300 cm^{-1}. There were, in general, spectral changes in ligands of these complexes as compared to the free ligands. This suggests the coordination of these ligands to palladium ion. The IR spectrum of [Pd(bipy)Cl_2] shows two vibrational bands at 342 and 354 cm^{-1} (shoulder).[15] These bands due to ν(Pd–Cl) vibrations are absent in the [Pd(bipy)(XX)] complexes as expected.

The IR spectrum of [Pd(bipy)(CAT)] complex shows two strong bands at 1490 and 1270 cm^{-1}. This suggests the bonding of ionized hydroxyl groups of catechol to palladium(II).[16] In the [Pd(bipy)(BCAT)] complex, the bands at 1480 and 1265 cm^{-1} have also been observed and assigned to the bonding of ionized hydroxyl groups to palladium(II). The IR spectrum of 3,4-dimercaptotoluene shows ν(S–H) vibration at 2540 cm^{-1} which is absent in the spectrum of [Pd(bipy)(DMT)] complex. This suggests that the –SH groups are present in the ionized form in the palladium(II) complex.[17]

^1H NMR spectra

The ^1H NMR spectra of [Pd(bipy)(XX)] complexes in deuterated dimethyl sulphoxide (DMSO-d_6) were measured using tetramethyl silane (TMS) as internal reference. The chemical shifts of H-6,6′ and H-5,5′ protons of 2,2′-bipyridine and various protons of XX ligands in the above palladium(II) complexes have been given in the experimental section. The numbering scheme of the ligand protons is followed as published elsewhere.[5] The information regarding the bonding of ligand (XX) to palladium is based on the downfield chemical shifts of the protons of ligand in the [Pd(bipy)(XX)] complex as compared to proton chemical shifts of the free ligand.[18] The protons H-6,6′ and H-5,5′ resonate at 9.18 and 7.86 ppm respectively in [Pd(bipy)Cl_2]. In [Pd(bipy)(XX)] complexes these protons show upfield shifts as compared to [Pd(bipy)Cl_2]. The upfield shifts can be interpreted in terms of stronger bonding of ligands (XX) to palladium(II) as compared to bonding of chloride ions.[11] This effect is more dominant on the H-6,6′ protons, indicating that they are better shielded.

The ^1H NMR spectra of [Pd(bipy)(CAT)], [Pd(bipy)(BCAT)] and [Pd(bipy)(DMT)] show down-field shifts of H_A, H_B and H_C and in the former compound also of H_D in coordinated ligands as compared to corresponding protons in the free ligands. Similar observations have been made earlier for analogous platinum(II) complexes.[5] The above observations suggest that the ligands are coordinating to palladium(II) by $-O^-$, $-O^-$ or $-S^-$, S^- groups.

Photooxidation of 2,2,6,6-tetramethyl-4-piperidinol

The aerated DMF solutions of [Pd(bipy)(XX)] (where XX are CAT, BCAT and DMT) and [Pt(bipy)(XX)] (where XX are CAT, BCAT and

DMT) were irradiated in presence of 2,2,6,6-tetramethyl-4-piperidinol by light at different irradiation times. The singlet oxygen thus formed combines with 2,2,6,6-tetramethyl-4-piperidinol forming nitroxide free radical. Nitroxide radicals are detected by EPR spectroscopic method.[9,10] The 2,2,6,6-tetramethyl-4-piperidinol does not react with O_2^-, H_2O_2 and .OH radicals.[19] Figure 1 shows the amount of nitroxide free radical measured by EPR spectroscopy for various complexes such as [Pd(bipy)(CAT)], [Pd(bipy)(BCAT)], [Pd(bipy)(DMT)], [Pt(bipy)(CAT)] and [Pt(bipy)(BCAT)], as a function of irradiation time. Since the amount of nitroxide free radical measured by the EPR method bears a direct relationship to the singlet oxygen produced possibly via energy transfer from triplet excited LLCT state of the above complexes, the slopes calculated from experimental plots in Fig. 1, are 0.047 for [Pt(bipy)(BCAT)], 0.015 for [Pt(bipy)(CAT)], 0.036 for [Pd(bipy)(BCAT)], 0.012 for [Pd(bipy)(CAT)] and 0.01 for [Pd(bipy)(DMT)]. These data suggest that [Pt(bipy)(BCAT)] is the best photosensitizer of singlet oxygen because of its largest slope. Thus the efficiency of these complexes to photosensitize the formation of singlet oxygen is [Pt(bipy)(BCAT)] > [Pt(bipy)(BCAT)] > [Pt(bipy)(CAT)] > [Pd(bipy)(CAT)] > [Pd(bipy)(DMT)]. If comparison is made with Rose-Bengal as photosensitizer, the [Pt(bipy)(BCAT)] is about 10 times less efficient than Rose-Bengal to photosensitize the formation of singlet oxygen.

Self-sensitized photooxidation

The oxygenated solutions of [Pt(bipy)(BCAT)], [Pd(bipy)(BCAT)], [Pt(bipy)(CAT)] and [Pd(bipy)(CAT)] complexes were stable to light after five hours of irradiation. However, the oxygenated solution of [Pd(bipy)(DMT)] was slightly decolorized after irradiation with light for five hours. On the other hand the oxygenated solution of [Pt(bipy)(DMT)] was very much affected by light irradiation. This self-sensitized photooxidation of [Pt(bipy)(DMT)] and [Pd(bipy)(DMT)] is now discussed below:

(a)*Pt(bipy)(DMT)*]. An oxygen saturated solution of [Pt(bipy)(DMT)] (200 μM) in DMF was irradiated with light of wavelength greater than 400 nm. The course of photolysis was followed by

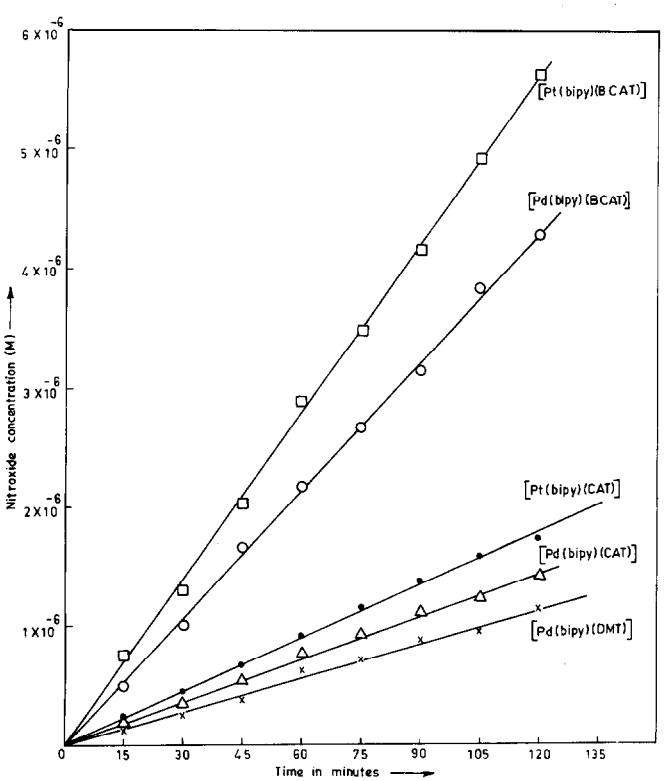

Fig. 1. Nitroxide concentrations as measured by EPR measurements against different times of light irradiation of DMF solutions of [M(bipy)(XX)] (200 μM) in presence of 2,2,6,6-tetramethyl-4-piperidinol at 27 ± 1°C.

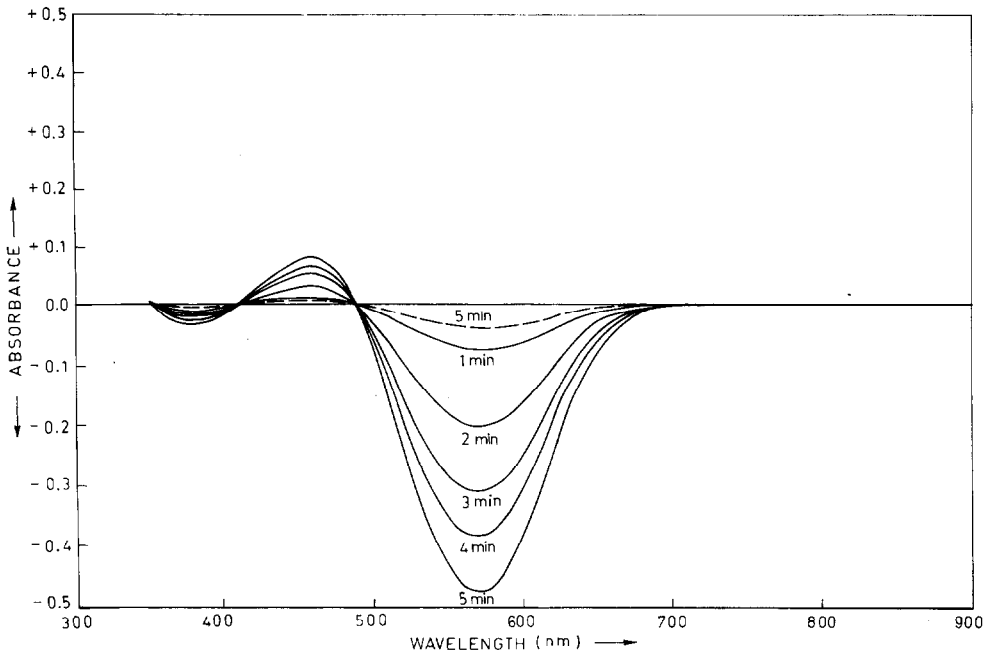

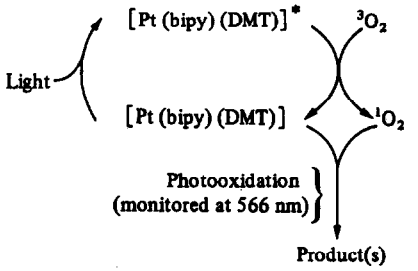

Fig. 2. Difference UV–visible spectra of DMF solutions of [Pt(bipy)(DMT)] (200 μm) (——) at different times of irradiation and of [Pt(bipy)(DMT)] (– – –) at 5 min of light irradiation in presence of sodium azide (500 μM) with light of wavelength greater than 400 nm.

difference absorption spectrophotometry in the visible region. The difference absorption spectra at different times of light irradiation (1–5 min) are given in Fig. 2. The photolysis was accompanied by bleaching of the colour of the complex. New positive (456 nm) and negative (378 and 570 nm) peaks were observed in the difference spectra. Thus, these spectral changes have been accounted for the loss of [Pt(bipy)(DMT)] complex as a result of photolysis. The above reaction was retarded by about 90% in presence of sodium azide, a known singlet oxygen quencher,[20] under similar light irradiation conditions.

The solution was quite stable when either molecular oxygen saturated solution of [Pt(bipy)(DMT)] was kept in dark or irradiated with light while oxygen free molecular nitrogen was bubbled through it. This suggests that the observed decay of [Pt(bipy)(DMT)] was due to the combined action of light and molecular oxygen. The quenching of reaction in presence of sodium azide indicates the involvement of singlet oxygen in the above reaction. This suggests that the [Pt(bipy)(DMT)] sensitizes the generation of singlet oxygen which in turn reacts with the [Pt(bipy)(DMT)] causing the observed change. Figure 3 shows a plot of log (logarithm) of concentration vs time of photolysis. This plot is linear which suggests a first order kinetics for the above reactions. A similar plot of self-sensitized photooxidation of bilirubin was observed earlier.[21,22] Thus the above observations can be explained by the following proposed mechanism.

All the efforts to isolate the product(s) of photolysis met with failure. The absorption spectra of [Pt(bipy)(DMT)] before photolysis and after all [Pt(bipy)(DMT)] complex has been converted to product(s) as a result of photolysis suggest that the LLCT band of [Pt(bipy)(DMT)] at 566 nm is shifted to 478 nm due to photolysis. Since the [Pt(bipy)(CAT)] and [Pt(bipy)(BCAT)] complexes are not photooxidized even after irradiation for five hours in presence of molecular oxygen, it suggests that 2,2'-bipyridine molecule is not photooxidized in [Pt(bipy)(DMT)] complex. The possibility left is the photooxidation of dimercaptotoluene molecule in [Pt(bipy)(DMT)]. The position of LLCT spectrum of [Pt(bipy)(TSA)] compares favourably with photooxidized product of [Pt(bipy)(DMT)],[5] and,

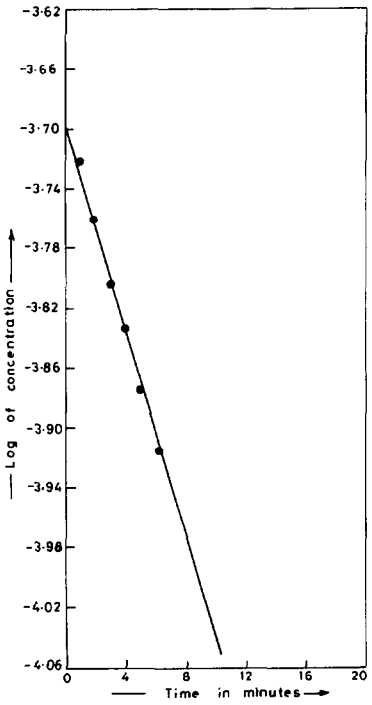

Fig. 3. Plot of log of concentration against time of light irradiation of DMF solution of [Pt(bipy)(DMT)] (200 μM) with light of wavelength greater than 400 nm.

thus, it seems one of the sulphur atoms of dimercaptotoluene is oxidized.[23]

(b) [*Pd(bipy)(DMT)*]. An oxygenated solution of [Pd(bipy)(DMT)] (200 μM) in DMF was quite stable to light during two hours of irradiation under identical irradiation conditions as used for [Pt(bipy)(DMT)] and [Pt(bipy)(TSA)]. The decrease of absorbance during irradiation for three hours was only 5% of initial absorbance. This suggests that [Pd(bipy)(DMT)] undergoes very poor self-sensitized photooxidation by singlet oxygen.

The neutral 2,2'-bipyridine-palladium(II) and -platinum(II) derivatives of catechol and 4-*tert*-butylcatechol are found to be good photosensitizers of the singlet oxygen while their 3,4-dimercaptotoluene derivatives are poor photosensitizers due to self-sensitized photooxidation.

FLUORINATED BARRELENE–RUTHENIUM(II) COMPLEXES WITH ANIONIC CHELATING LIGANDS

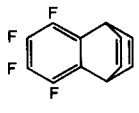
M. VALDERRAMA,* M. SCOTTI and A. ROJAS
Facultad de Química, Pontificia Universidad Católica de Chile, Casilla 6177, Santiago, Chile

(*Received* 31 *January* 1985; *accepted* 28 *February* 1985)

Abstract—Reaction of ruthenium(III) chloride with the barrelene diolefins (tetrafluorobenzobarrelene (TFB) or (trimethyltetrafluorobenzobarrelene) (Me_3TFB) leads to the formation of the polymeric complexes $[RuCl_2(barrelene)]_n$. These compounds react with anionic chelating ligands with formation of new hexacoordinated neutral complexes of the general formulae [Rh(chelate)$_2$(barrelene)], where chelate = acetylacetonate, tropolonate, salicylaldehydate and 8-oxyquinolinate. The IR and ^{1}H NMR spectra of the complexes are given and discussed.

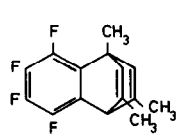
The synthesis of polymeric halogen bridged complexes of ruthenium(II) of the type $[RuX_2(diolefin)]_n$, where diolefin = 1,5-cyclooctadiene (COD) or bicyclo[2.2.1]hepta-2,5-diene (NBD) have been described by Wilkinson *et al.*[1,2] These complexes show a marked insolubility in most common organic solvents and only a few of their reactions have been reported.[1,3,4] Interestingly, hexacoordinated complexes of formula [Ru(acac)$_2$(diolefin)] (acac = acetylacetonate, diolefin = COD or NBD) have been prepared by Pannetier *et al.*[5,6] using an oxalate intermediate. On the other hand Powell[7] has reported an alternative and general route for the synthesis of [Ru(chelate)$_2$(diolefin)] complexes where the anionic chelating ligands present as donor atoms O–O, O–N, N–S or S–S. In particular the formation of geometrical isomers was found for the benzoylacetonate ligand.[7] As a continuation of studies on rhodium complexes containing tetrafluorobenzobarrelene ligands[8–11] we report new polymeric chloride ruthenium(II) complexes with tetrafluorobenzobarrelene (TFB) and trimethyltetrafluorobenzobarrelene (Me_3TFB) (see Fig. 1), along with a high yield synthesis under mild conditions of hexacoordinated barrelene ruthenium(II) derivatives with the anionic ligands acac, tropolonate (trop), salicylaldehydate (sal) and 8-oxyquinolinate (oq).

EXPERIMENTAL



Carbon and hydrogen analyses were made with a Heraeus Mikro Standard microanalyser. IR spectra were recorded on a Perkin–Elmer 567 spectrophotometer using Nujol mulls between KBr discs, or dichloromethane solutions between KBr plates. ^{1}H NMR spectra were recorded on a Varian XL-100 intrument relative to tetramethylsilane.

Molecular weight measurements were obtained in chloroform solutions at 37°C with a Knauer vapour pressure osmometer calibrated with benzil. Melting points were determined with a Büchi apparatus and are uncorrected.



Ruthenium(III) chloride hydrate was obtained from commercial sources. Reagent grade solvents were dried, distilled and stored under nitrogen. Tetrafluorobenzobarrelene (TFB), the trimethyl derivative (Me_3TFB) and the polymeric complex $[RuCl_2(NBD)]_n$ were prepared according to literature procedures.[12,13]

Preparation of the complexes $[RuCl_2(diolefin)]_n$ (diolefin = TFB, Me_3TFB)

1 g (3.83 mmol) of the starting compound $RuCl_3 \cdot xH_2O$ was treated with 2.6 g (11.5 mmol) of TFB in ethanol solutions, and the mixture was stirred

TFB

Me_3TFB

* Author to whom correspondence should be addressed.

for 4 h at room temperature. The red–brownish solid obtained was filtered and washed with ethanol, acetone and diethylether. Yield 98% (1.49 g). Refluxing conditions (24 h) were required for the Me_3 TFB derivative (1.5 g, 5.60 mmol), due to the low solubility of this diolefin.

Preparation of the complexes [Ru(chelate)$_2$(diolefin)]

The compounds were prepared by the two general routes described below:

(i) *Synthesis of* [Ru(chelate)$_2$(diolefin)] (chelate = trop; diolefin = TFB, Me_3TFB, NBD). To a suspension of the polymeric complex [$RuCl_2$(diolefin)]$_n$ (100 mg, 0.25 mmol) in chloroform (50 cm^3) was added the stoichiometric amount of Tltrop (163 mg, 0.50 mmol). The mixture was boiled under reflux for 2 h. The TlCl formed was filtered off through kieselguhr, and the red filtrate was evaporated to dryness. The solid obtained was crystallized from dichloromethane–diethylether.

(ii) *Synthesis of* [Ru(chelate)$_2$(diolefin)] (chelate = acac, sal, oq; diolefin = TFB, Me_3TFB). A slurry of [$RuCl_2$(diolefin)]$_n$ (100 mg, 0.25 mmol), a large excess of chelating ligand [0.5 cm^3 (acetylacetone), 0.5 cm^3 (salicylaldehyde), 0.75 mmol (8-hydroxyquinoline)] and an excess of sodium carbonate (0.25 g) in dimethylformamide (10 cm^3) was boiled under reflux for 10 min. The mixture was cooled to room temperature, filtered and the sodium salts washed with methanol. Careful addition of distilled water precipitated the complexes which were washed with water and dried *in vacuo*.

The acac complexes were purified by column chromatography on activated silica-gel using hexane as eluant.

RESULTS AND DISCUSSION

The reaction of an ethanolic solution of $RuCl_3 \cdot xH_2O$ with TFB or Me_3TFB gave rise to the formation of [$RuCl_2$(barrelene)]$_n$ complexes. These polymeric compounds react, in refluxing dimethylformamide, with the potentially bidentate ligands acetylacetone, tropolone, salicylaldehyde or 8-hydroxyquinoline, in the presence of sodium carbonate, yielding hexacoordinated neutral complexes of general formula [Ru(chelate)$_2$(barrelene)] (chelate = acac, trop, sal, oq).

An alternative high yield method used for the tropolonate derivatives, involves the reaction of chloroform or diethylether suspensions of [$RuCl_2$(barrelene)]$_n$ complexes with a slight excess of thallium(I) tropolonate.

All the complexes are stable in air at room temperature and are non-conducting in organic solvents. Molecular weight measurements in chloroform solutions confirm the mononuclear

Table 1. Analytical results, colour, melting points and yields of the isolated complexes

Complex	Colour	Found (calc.) % C	Found (calc.) % H	M.p. (°)	Yield (%)

formulation. Elemental analyses, melting points, colour and yields are collected in Table 1.

The IR spectra of the complexes (Table 2) show absorptions of the coordinated diolefins (TFB at 1500 s, 1040 s, 885 s, 850 s, 670 m; Me_3TFB at 1500 s, 1490 s, 1060 s, 970 s, 930 s, 850 s and NBD at 1310 s cm^{-1}) together with the bands due to the coordinated chelating ligands. The acetylacetonate complexes show two strong bands in the range 1505–1515 cm^{-1} and 1575 cm^{-1} which are probably due to the combination of ν(C=O) and ν(C=C).[14] In the same range, the tropolonate complexes show two absorptions tentatively assigned to ν(C=O) + ν(C=C) and ν(C=C), whereas the absorptions located in the *ca* 1330–1340 cm^{-1} range is assigned to ν(C–O).[15,16] The salicylaldehyde complex shows the expected bands ν(C–O) and ν(C=O) at 1330 and 1600 cm^{-1} respectively.[17,18] The 8-oxyquinolinate derivative shows bands at ~1110 and 1330 cm^{-1} assigned to ν(C=N) and ν(C–O) together with strong bands at 1560 and 1580 cm^{-1}, characteristic of the heteroaromatic ring.[19,20]

The ^{1}H NMR spectrum of the [Ru(acac)$_2$(TFB)] complex (III) shows the presence of non-equivalent methyl groups and the related tropolonate compound (IV) presents a multiplet for the protons of the tropolonate ring (Table 2). In both cases the coordinated TFB diolefin presents two resonances for the vinyl protons and one resonance corresponding to the protons bonded to the tertiary carbons. These non-equivalent methyl groups of the ligand (acac) and the resonances corresponding to the vinyl protons of the TFB are due to the unsymmetrical coordination of the anionic chelate ligands (Fig. 2).[21,22]

Lack of symmetry is generally observed for the Me_3TFB complexes, due to the 1,3,8 disposition of the methyl groups in the ligand [Me_3TFB = 1,3,8 - trimethyl(tetrafluorobenzo[5,6])bicyclo - [2.2.2]octa-2,5,7-trieno] (Table 2). Thus the ^{1}H

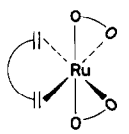

Fig. 2.

NMR spectrum of complex **V** show signals indicating non-equivalent acetylacetonate ligands. On the other hand, the tropolonate ligand in complex **VI** shows two multiplets of aromatic ring protons, whilst the complex obtained with NBD (**IX**) shows only one multiplet, indicating that the non-equivalence of the anionic bidentate ligands is probably due to the presence of the Me_3TFB diolefin.

Finally the complexes with the sal or oq ligand show an unsymmetrical coordination. In particular the ^1H NMR spectrum of the complex $[Ru(sal)_2(Me_3TFB)]$ (**VII**) shows two signals at δ 8.89 and 8.91 ppm, indicating the non-equivalence of the salicylaldehydate ligand. Although the presence of geometrical isomers cannot be completely excluded, we believe that only one geometric isomer is present because no chromatographic separation was observed (Fluorisil).[23] Therefore, the observed low symmetry has most probably the same origin as that in the above-mentioned complexes.

PREPARATION AND CHARACTERIZATION OF COPPER(II) AND NICKEL(II) COMPLEXES WITH NOVEL TETRAAZA-MACROCYCLIC SCHIFF BASES

MANABU FUJIWARA, YASUHIRO NAKAJIMA, TAKAYUKI MATSUSHITA* and TOSHIYUKI SHONO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565, Japan

(*Received* 9 *November* 1984; *accepted* 6 *March* 1985)

Abstract—Novel tetraaza-macrocycles with *N*-substituted carbamoyl groups were prepared by the reaction of 5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,5,7,12-tetraene with isocyanates (R–N=C=O, R = CH_3 and C_6H_5). Their copper(II) and nickel(II) complexes were characterized by magnetic susceptibilities, electronic absorption spectra, and electrochemical properties. The complexing abilities and extractabilities of the ligands for the metal ions were investigated.

Many reports on the displacement reactions of a methine hydrogen of β-diketone derivatives by various electrophilic reagents have been presented.[1–9] For example, the methine hydrogen can be displaced by several substituents such as nitro,[1] thiocyanate,[2] chloro, bromo,[3,4] alkyl[5] and carbonyl[6] groups. Recently, Tokumitsu *et al.*[7] have reported the preparation and characterization of the disubstituted derivatives of 5,7,12,14-tetramethyl-1,4,8,11 - tetraazacyclotetradeca - 1,5,7,12 - tetraene, $(N_4)H_2$, with Cl, $SC_6H_4NO_2(o)$, $N_2C_6H_5$ and COC_6H_5 and their complexes with copper(II), nickel(II) and palladium(II). On the other hand, Nelson *et al.*[8] have found that [*N*,*N*′-bis(1-methyl-3-oxo-1-butenyl) ethylenediaminato]copper(II) reacts with various isocyanates to give mono- and diamide derivatives. In a preceding paper,[9] we have described the preparation of the dinitro-substituted macrocycle of $(N_4)H_2$ which possesses an excellent extractability for copper(II).

In this paper, we wish to describe the preparation of novel tetraaza-macrocyclic Schiff bases having carbamoyl groups (Fig. 1) and their copper(II) and nickel(II) complexes. The complexing abilities and extractabilities of these ligands for the metal ions are also described.

EXPERIMENTAL

Materials

All reagents were of reagent grade, and isocyanates were distilled prior to use. Chloroform was refluxed over P_4O_{10} and distilled. Benzene was refluxed over sodium and distilled. *N*,*N*-dimethylformamide (DMF) was distilled over CaH_2 under reduced pressure prior to use. Other solvents were purified in the usual manner. Water was deionized.

Measurements

UV and visible absorption spectra were recorded on a Hitachi 340 recording spectrophotometer. IR

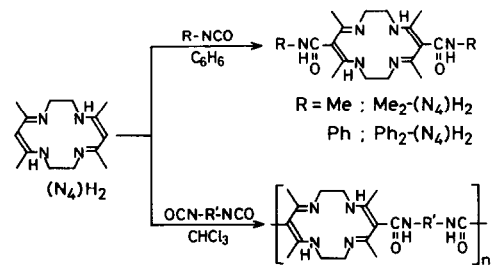

Fig. 1. Synthetic scheme for the novel tetraaza-macrocycles studied.

spectra were recorded on a Hitachi 215 grating spectrophotometer. Atomic absorption spectra were obtained using a Nippon Jarrell Ash AA-1. ^{1}H NMR spectra were taken with a JEOL JNM-PS 100 spectrometer, using DMSO-d_6 as the solvent and TMS as the internal standard. Polarograms were measured in DMF at 25°C by use of a Yanaco P-8 polarograph. A dropping mercury electrode and a mercury pool were used as the working and counter electrodes, respectively. Tetrabutylammonium perchlorate (0.1 mol dm^{-3}) was used as the supporting electrolyte. The pH of a sample solution was measured with a Shibata 671 pH meter. Magnetic susceptibilities were measured by the Gouy method at room temperature.

Procedure for solvent extraction

Solvent extractions were carried out by using a 10-cm^3 test tube with a stopper in which an aqueous solution (5 cm^3) of metal acetate (copper(II) and nickel(II)) and a chloroform solution (5 cm^3) of Me_2–$(N_4)H_2$ were contained as aqueous and organic phases, respectively. The test tube was shaken for an adequate time, from 2 min to 24 h, at room temperature by use of a shaker. After shaking, the concentrations of metal ions remained in the aqueous phase were determined by atomic absorption spectrometry.

The preparative scheme for tetraaza-macrocyclic Schiff base ligands is shown in Fig. 1.

Preparation of 6,13-*bis*(*N-methylcarbamoyl*)-5,7,12,14-*tetramethyl* - 1,4,8,11 - *tetraazacyclotetradeca* - 1,5,7,12 - *tetraene* (Me_2–$(N_4)H_2$)

To a benzene solution (20 cm^3) of the parent macrocycle[7] (1.0 g, 4.0 mmol) was added methyl isocyanate (0.57 g, 10 mmol). The mixture was stirred vigorously at room temperature for 24 h. The solution turned to milky yellow and then a turbidity appeared. It was collected on a glass filter and washed with dry benzene several times. The pale yellow solid was dissolved in a very small amount of ethanol and reprecipitated with benzene. It was filtered and dried *in vacuo*. The yield was 30%. This compound is very soluble in ethanol and DMF, slightly soluble in chloroform, and insoluble in ether and benzene. M.p.: 160.7–161.0°C (decomp.). Found: C; 59.21, H; 8.56, N; 23.48. Calc. for $C_{18}H_{30}N_6O_2$: C; 59.64, H; 8.34, N; 23.19%. MS found: *m/z* 362. Calc. for $C_{18}H_{30}N_6O_2$: 362. IR (in KBr disk): 3320, 1615, 1560, 1440, 1260, 1160, 810 and 730 cm^{-1}. ^{1}H NMR (in DMSO-d_6): δ 1.80 (6H, s, C$\underline{H}_3$), 2.48 (12H, s, C$\underline{H}_3$) and 3.36 (8H, s, C$\underline{H}_2$) ppm.

Preparation of 6,13 - *bis*(*N* - *phenylcarbamoyl*) - 5,7,12,14 - *tetramethyl* - 1,4,8,11 - *tetraazacyclotetradeca* - 1,5,7,12 - *tetraene* (Ph_2–$(N_4)H_2$)

To a benzene solution (100 cm^3) of the parent macrocycle (1.0 g, 4.0 mmol) was added phenyl isocyanate (1.2 g, 10 mmol). The mixture was stirred vigorously at room temperature for 48 h to give a precipitate gradually. It was collected on a glass filter, washed with dry benzene several times, and dried *in vacuo*. The yield was 55%. This compound is very soluble in ethanol and DMF, but insoluble in chloroform and benzene. M.p.: 254.5–256.0°C (decomp.). Found: C; 68.97, H; 7.24, N; 17.06. Calc. for $C_{28}H_{34}N_6O_2$: C; 69.10, H; 7.06, N; 17.27%. IR (in KBr disk): 3280, 1630, 1590, 1500, 1435, 1310, 1250, 1130, 750 and 690 cm^{-1}. ^{1}H NMR (in DMSO-d_6): δ 2.48 (12H, s, C$\underline{H}_3$), 3.36 (8H, s, C$\underline{H}_2$) and 7.30 (10H, m, $C_6\underline{H}_5$) ppm.

Preparation of copper(II) and nickel(II) complexes, Cu[Me_2–(N_4)], Cu[Ph_2–(N_4)], Ni[Me_2–(N_4)] *and* Ni[Ph_2–(N_4)]

The copper(II) complex, Cu[Me_2–(N_4)], was prepared by the reaction of Cu(N_4)[7] with methyl isocyanate as follows.

Cu(N_4) (1.0 g, 3.2 mmol) and methyl isocyanate (0.5 g, 8.7 mmol) were dissolved in a mixture of benzene and chloroform (1 : 1, 50 cm^3). It was stirred for 12 h at room temperature under a nitrogen atmosphere in the dark. A green precipitate formed gradually. It was collected on a glass filter, washed with dry benzene and then chloroform, and dried *in vacuo*. The yield was 50%. IR (in KBr disk): 3370, 1610, 1545, 1405, 1335, 1270, 1175, 800 and 720 cm^{-1}. Found: C; 50.92, H; 6.81, N; 19.64. Calc. for $CuC_{18}H_{28}N_6O_2$: C; 50.98, H; 6.67, N; 19.82%. Magnetic moment: μ_{eff} = 1.61 BM.

Other complexes were prepared by a method similar to that for Cu[Me_2–(N_4)].

Cu[Ph_2–(N_4)] was obtained in a similar manner to that described for Cu[Me_2–(N_4)], using phenyl isocyanate in place of methyl isocyanate. The yield was 70%. IR (in KBr disk): 3270, 1630, 1590, 1500, 1430, 1335, 1250, 1130, 750 and 690 cm^{-1}. Found: C; 61.09, H; 6.11, N; 15.17. Calc. for $CuC_{28}H_{32}N_6O_2$: C; 61.34, H; 5.90, N; 15.33%. Magnetic moment: μ_{eff} = 1.99 BM.

Ni[Me_2–(N_4)] was obtained in 55% yield. Found: C; 51.43, H; 6.99, N; 19.84. Calc. for $NiC_{18}H_{28}N_6O_2$: C; 51.57, H; 6.75, N; 20.05%. IR (in KBr disk): 3380, 1610, 1550, 1410, 1345, 1280, 1175, 800 and 725 cm^{-1}. The complex is diamagnetic.

Ni[Ph_2–(N_4)] was obtained in 80% yield. Found:

C; 62.02, H; 5.98, N; 15.21. Calc. for $NiC_{28}H_{32}N_6O_2$: C; 61.89, H; 5.95, N; 15.47%. IR (in KBr disk): 3280, 1625, 1590, 1500, 1425, 1345, 1255, 1135, 745 and 690 cm^{-1}. The complex is diamagnetic.

These complexes were also prepared by the reaction between copper(II) or nickel(II) acetate and the corresponding free ligands, and identified by the IR and UV spectra. However, their yields were lower than those obtained by the reaction between the metal complexes of $(N_4)H_2$ and the isocyanates, because it was difficult to purify the complexes.

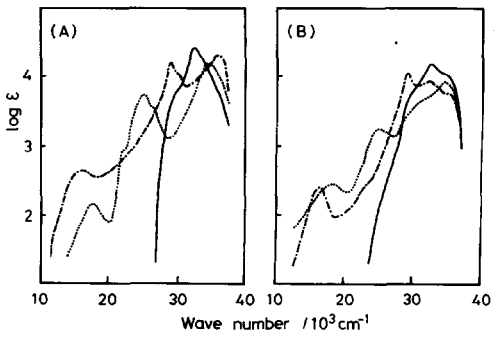

Fig. 2. Electronic spectra in DMF. (A) (——) Me_2–$(N_4)H_2$, (— · — · —) Cu[Me_2–(N_4)], (· · ·) Ni[Me_2–(N_4)]. (B) (——) Ph_2–$(N_4)H_2$, (— · — · —) Cu[Ph_2–(N_4)], (· · ·) Ni[Ph_2–(N_4)].

RESULTS AND DISCUSSION

Electronic spectra

Figure 2 shows the electronic spectra of the ligands Me_2–$(N_4)H_2$ (Fig. 2A) and Ph_2–$(N_4)H_2$ (Fig. 2B) and their copper(II) and nickel(II) complexes in DMF. The band positions of the absorption maxima are listed in Table 1, together with the molar extinction coefficients.

Both spectra of Me_2–$(N_4)H_2$ and Ph_2–$(N_4)H_2$ resemble that of the parent ligand.[9] The spectrum of Me_2–$(N_4)H_2$ exhibits three absorption bands centred at 309 nm, which can be assigned to π–π^* transitions.[10] The spectrum of either Cu[Me_2–(N_4)] or Ni[Me_2–(N_4)] shows an absorption band with moderate intensity in the visible region. The absorption band at 620 nm for Cu[Me_2–(N_4)] and at 558 nm for Ni[Me_2–(N_4)] can be assigned to the ligand field transitions. The band positions and intensities of the absorption bands of these complexes in the visible region are quite similar to those for the corresponding complexes of the parent macrocycle, indicating that the carbamoyl groups have little effect on the electronic state of the central metal ions.

The spectrum of Ph_2–$(N_4)H_2$ exhibits slightly broad absorption bands centred at 311 nm. The band positions and intensities are similar to those of Me_2–$(N_4)H_2$, suggesting that the phenyl rings of the ligand are not conjugated with the tetraaza ring. The spectra of Cu[Ph_2–(N_4)] and Ni[Ph_2–(N_4)] resemble those of Cu[Me_2–(N_4)] and Ni[Me_2–(N_4)], respectively, and the band positions for the former complexes due to the ligand field transitions are slightly shifted to shorter wavelengths than those for the latter.

Electrochemical properties

The reduction potentials of the complexes measured in DMF are summarized in Table 1. The polarograms of Cu[Me_2–(N_4)] and Ni[Me_2–(N_4)] show one cathodic wave at half-wave potentials of

Table 1. Absorption maxima and half-wave potentials of the macrocycles and their copper(II) and nickel(II) complexes

Compound	λ_{max} (log ε)[a] (nm)	$-E_{1/2}$ (vs Hg pool)[a] (V)
Me_2–$(N_4)H_2$	309 (4.42)	
Cu[Me_2–(N_4)]	620 (2.60), 346 (4.19), 269 (4.47)	2.05

[a] Measured in DMF at 25°C.
[b] Measured in chloroform. Previous work, Ref. 9.

−2.05 and −2.28 V (vs Hg pool), respectively. These values are slightly positive (*ca* 0.20 V) compared with those of the parent complexes. Moreover, the polarograms of Cu[Ph_2–(N_4)] and Ni[Ph_2–(N_4)] also show one cathodic wave at half-wave potentials of −2.09 and −2.26 V, respectively. These slightly positive shifts may be caused by the carbamoyl groups which were introduced into the parent ligand; they act as weakly electron-attracting groups, which cause a decrease in the electron density on the central metal ion of the complexes. Previously, we have pointed out that the introduction of nitro groups into $(N_4)H_2$ results in a large positive shift (*ca* 1.0 V) of the half-wave potentials of the copper(II) and nickel(II) complexes.[9] Therefore, it can be said that the carbamoyl derivatives are similar to the parent ligand based on the spectral and electrochemical properties.

Complexation of copper(II) and nickel(II) with Me_2–$(N_4)H_2$ *and* Ph_2–$(N_4)H_2$

The rates of complexation of copper(II) and nickel(II) with Me_2–$(N_4)H_2$ and Ph_2–$(N_4)H_2$ were spectrophotometrically determined in a homogeneous DMF solution at 25°C. A DMF solution of each ligand (8.0×10^{-5} mol dm^{-3}) and a DMF solution of the equimolar amount of each metal ion were mixed in a UV cell (light-path length: 10 mm) with a stopper under an atmosphere of prepurified nitrogen, and then its absorption spectra were measured in a closed system over the range 290–420 nm at regular time intervals. In the case of copper(II) with Me_2–$(N_4)H_2$, the absorption spectrum changes remarkably during the initial 2 min and then gradually until 120 min: the absorption maximum of the ligand at 309 nm decreases in intensity and the new absorption bands which appear at 269 and 346 nm increase in intensity, having isosbestic points at 292 and 322 nm (Fig. 3A). These spectral changes indicate the formation of Cu[Me_2–(N_4)] complex. Similar spectral changes were observed for other cases: with Ph_2–$(N_4)H_2$ and copper(II) the absorption maximum of the ligand was shifted from 311 to 346 nm, having an isosbestic point at 321 nm, with Me_2–$(N_4)H_2$ and nickel(II) it was shifted from 309 to 402 nm, having an isosbestic point at 357 nm (Fig. 3B), and with Ph_2–$(N_4)H_2$ and nickel(II) it was shifted from 311 to 401 nm, having an isosbestic point at 342 nm.

The extent of complexation for these systems was calculated from these spectral changes. The results are shown in Fig. 4. Clearly, the rates of complexation of copper(II) with both ligands were found to be much faster than those for nickel(II), and the rates of complexation of both metal ions with

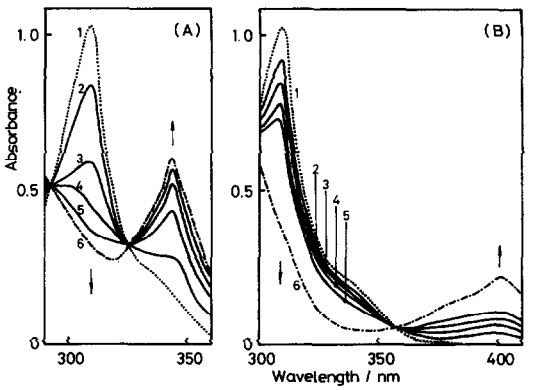

Fig. 3. Absorption spectral changes caused by complexation of copper(II) (A) and nickel(II) (B) with Me_2–$(N_4)H_2$ in DMF at 25°C. [Me_2–$(N_4)H_2$] = [metal]: 4.0×10^{-5} mol dm^{-3}; cell length = 10 mm. (A) 1, Me_2–$(N_4)H_2$; 2, 3, 4 and 5, after 2, 20, 60 and 90 min, respectively; 6, Cu[Me_2–(N_4)]. (B) 1, Me_2–$(N_4)H_2$; 2, 3, 4 and 5, after 20, 120, 240 and 360 min, respectively; 6, Ni[Me_2–(N_4)].

Me_2–$(N_4)H_2$ were faster than those with Ph_2–$(N_4)H_2$. The rate of the complexation of copper(II) with Me_2–$(N_4)H_2$ was fastest among them and its extent reached *ca* 100% (exactly 97%) after 2 h. This value is better than those observed for the complexation of copper(II) with $(N_4)H_2$ and its nitro derivatives.[9] The advantage of this tetraaza-macrocyclic ligand in the complex formation may arise from the formation of more stable complex than the parent macrocycle and the nitro derivative because the electron density on the nitrogen atoms of Me_2–$(N_4)H_2$ is richer than the nitro derivative and its copper(II) complex is more stable against oxygen and light than that of $(N_4)H_2$.

The extent of the complexation of copper(II) with

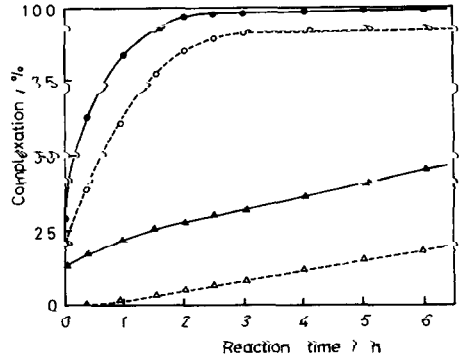

Fig. 4. The time-courses of complexation of copper(II) and nickel(II) with either Me_2–$(N_4)H_2$ or Ph_2–$(N_4)H_2$ in DMF at 25°C. [ligand] = [metal]: 4.0×10^{-5} mol dm^{-3}. (—●—) Cu(II)–Me_2–$(N_4)H_2$, (—▲—) Ni(II)–Me_2–$(N_4)H_2$, (– – ○ – –) Cu(II)–Ph_2–$(N_4)H_2$, (– – △ – –) Ni(II)–Ph_2–$(N_4)H_2$.

Ph_2-$(N_4)H_2$ reached *ca.* 90% after 3 h, which was slightly lower than that with Me_2-$(N_4)H_2$.

Generally, a nickel(II) ion is known to possess lower complexation rates and smaller formation constants with ordinary ligands than a copper(II) ion.[11–13] In fact, we have previously shown that with both of $(N_4)H_2$ and the nitro derivative ligands a copper(II) ion reached to the equilibrium of complexation faster than a nickel(II) ion.[9] And also the rates of the complexation of nickel(II) with the carbamoyl derivatives were late: after 6 h, the extent of the complexation of nickel(II) was 45 and 17% for Me_2-$(N_4)H_2$ and Ph_2-$(N_4)H_2$, respectively. These results suggest that the carbamoyl substituted tetraaza-macrocycles selectively form complexes with copper(II) rather than nickel(II). Thus, we have applied Me_2-$(N_4)H_2$, which can complex with copper(II) very fast and completely, as a selective extractant for copper(II).

Solvent extraction of copper(II) and nickel(II) by Me_2-$(N_4)H_2$

Solvent extractions of copper(II) and nickel(II) by Me_2-$(N_4)H_2$ were carried out under the conditions mentioned in the Experimental section. Figure 5 shows the plots of the percentages of two metal ions extracted by Me_2-$(N_4)H_2$ against the shaking time. The concentrations of Me_2-$(N_4)H_2$ in chloroform and of the metal ions in water were 2.0×10^{-3} and 2.0×10^{-4} mol dm^{-3}, respectively, and pH of the aqueous phase was adjusted to nearly 5.7 without using a buffer solution. Expectedly, the extraction rate of copper(II) by Me_2-$(N_4)H_2$ was found to be much faster than that of nickel(II). The copper(II) ion extracted into the chloroform phase was 78% within 30 min and its percentage was kept to be constant until 24 h. As for nickel(II), its extraction rate was late: after shaking for 30 min, the nickel(II) ion transferred into the chloroform phase was only 11%. The extraction equilibrium was not attained after 24 h, and the percentage of the extracted nickel(II) increased gradually.

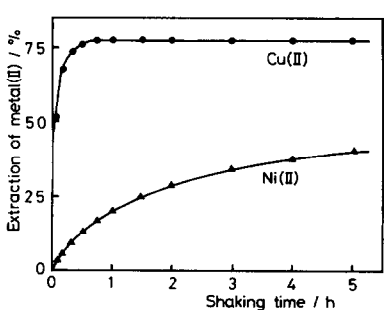

Fig. 5. Extractabilities of Me_2-$(N_4)H_2$ (2.0×10^{-3} mol dm^{-3}) for copper(II) and nickel(II) (2.0×10^{-4} mol dm^{-3}).

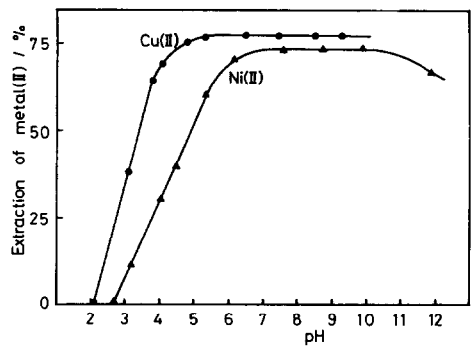

Fig. 6. Effect of pH on extraction of copper(II) and nickel(II) (2.0×10^{-4} mol dm^{-3}) by Me_2-$(N_4)H_2$ (2.0×10^{-3} mol dm^{-3}).

However, the percentage of the extracted copper(II) is lower than that expected from the results obtained on the complexation. This may be caused by the solubility of Me_2-$(N_4)H_2$ in water. In fact, the distribution ratio of Me_2-$(N_4)H_2$, ($[Me_2$-$(N_4)H_2]_{org}/[Me_2$-$(N_4)H_2]_{aq}$), was determined to be 0.02 and 0.85 at pH 5.0 and 7.7, respectively, after shaking for 2 h. Therefore, appreciable amounts of the ligand and the formed complex may be distributed into the aqueous phase.

Effect of pH on extraction

Figure 6 shows the effects of the pH of the aqueous phase on the extraction of copper(II) and nickel(II) by Me_2-$(N_4)H_2$. The extractions were made under the following conditions: the concentrations of the extractant and metal ions were 2.0×10^{-3} and 2.0×10^{-4} mol dm^{-3}, respectively, and the shaking time was 2 and 24 h for copper(II) and nickel(II), respectively. The pH of the aqueous solution was adjusted by addition of an adequate amount of

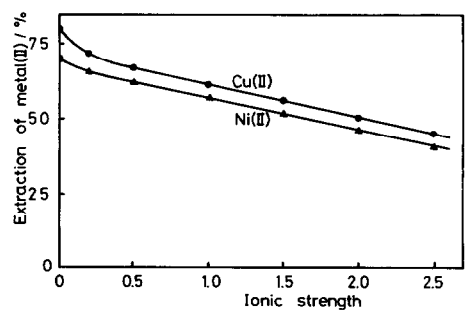

Fig. 7. Effect of ionic strength on extraction of copper(II) and nickel(II) (2.0×10^{-4} mol dm^{-3}) by Me_2-$(N_4)H_2$ (2.0×10^{-3} mol dm^{-3}). Ionic strength was adjusted by addition of sodium nitrate.

1.0 mol dm^{-3} hydrochloric acid, acetic acid, sodium acetate or sodium hydroxide. Because the extractability of Me_2–$(N_4)H_2$ was found to be influenced strongly by ionic strength, buffer solutions could not be used.

No extractions of copper(II) and nickel(II) were observed below pH 2.1 and 2.7, respectively. The percentage of the extracted copper(II) increased linearly with increasing pH of the aqueous phase, and came up to constant (78%) in the pH range from 5.7 to 9.0. On the other hand, the percentage of the extracted nickel(II) increased similarly with increasing pH of the aqueous phase in a higher pH region than the copper(II) case, and reached a constant value (73%) in the pH range from 7.5 to 10.0.

Effect of ionic strength on extraction

Figure 7 shows the effect of the ionic strength of the aqueous phase on the extractions of copper(II) and nickel(II) by Me_2–$(N_4)H_2$. The extractions were carried out under the following conditions: the concentrations of the extractant and metal ions and shaking time were the same as those described above. The pH of the aqueous phase was adjusted to be 5.7. The ionic strength of aqueous phase was varied from 0.0 to 2.5 by addition of sodium nitrate. Both extractions of copper(II) and nickel(II) were strongly influenced by the ionic strength of the aqueous phase. The percentage of the extracted copper(II) decreased linearly from 78 to 45% as the ionic strength was increased from 0.0 to 2.5. A similar behavior was obtained for the extraction of nickel(II).

SYNTHESIS AND SPECTRAL STUDIES ON PALLADIUM AND PLATINUM COMPLEXES WITH MONO- AND BIDENTATE *N*-DONOR ORGANIC LIGANDS AND THEIR INTERACTION WITH CALF THYMUS DNA IN SOLUTION*

P. UMAPATHY,† RASHIDA A. HARNESSWALA and C. S. DORAI
National Chemical Laboratory, Poona 411008, India

(*Received* 17 *September* 1984; *accepted after revision* 6 *March* 1985)

Abstract—Palladium(II) and platinum(II) complexes of the types $PdLX_2$, PdL_2X_2, PtL_2X_2 and the Pt(IV) complexes $PtLX_2Y_2$, $PtL_2X_2Y'_2$ (where L = mono- or bidentate organic ligand containing nitrogen donor atoms; X = Cl or Br; Y = Br and Y′ = OH) have been synthesized and characterized by elemental analysis, IR and X-ray photoelectron spectral data. The Pd $3d_{5/2}$ binding energies indicate that the 8-aminoquinoline ligand is a better electron donor to the metal than other ligands studied. The Cl $2p_{3/2}$ binding energies in the square planar Pd(II) complexes are observed in the range 198.0–199.56 eV. The ν(Pd–Cl) vibrations (*ca* 340 and 320 cm^{-1}) corresponding to two *cis*-Cl ligands were observed in the IR spectra. Binding through probably N-7 of the guanine residue and the phosphate oxygen in a chelate form is implied from UV difference spectral data.

The discovery that some platinum compounds, especially *cis*-$Pt(NH_3)_2Cl_2$, exhibit anti-tumour properties[1] has stimulated considerable research in the area of metal ion interactions with nucleic acid constituents.[2–4] A majority of the recent studies on platinum drugs have been directed towards an understanding of their biological mode of action and their toxic side-effects. Studies in cultured cells have indicated the relevance of platinum–DNA binding to cytotoxicity. The bulk of evidence at present favours the view that damage to DNA leads to the inhibition of DNA synthesis and that this in turn results in cell death.[5] The anticancer action of *cis*-$Pt(NH_3)_2Cl_2$ is thought to involve coordination to a guanosine residue in DNA. Little is precisely known about the specific covalent attachment sites of *cis*-$Pt(NH_3)_2Cl_2$ and platinum uracil blues on DNA. Nevertheless, numerous studies have implicated N-7 and possibly O-6 of guanine.[2,3,6,7] Other atoms in nucleic acid bases which have been shown to have affinity for platinum include the deprotonated N-1 and N-3 positions of guanine and thymine respectively, as well as the N-3 position of cytosine and the deprotonated NH_2 group of cytosine.[8] Furthermore, scant attention has been given to the binding of *cis*-$Pt(NH_3)_2Cl_2$ to the oxygen atoms of phosphate groups despite the fact that early experimental studies of the binding of platinum complexes to DNA and nucleosides produced evidence that suggested platinum–phosphate binding was a significant factor in these systems.[9–11] In order to further explore the nature of the metal ion binding sites in DNA, we have in continuation of our earlier work,[12] synthesized several new Pt(II) and Pd(II) complexes of the types PtL_2X_2, $PdLX_2$ PdL_2X_2 and Pt(IV) complexes $PtLX_2Y_2$, $PtL_2X_2Y'_2$ (where L = mono- or bidentate ligand, such as 8-aminoquinoline, 1,8-naphthalenediamine or a derivative of 1,10-phenanthroline, theophylline, cytidine, etc., X = Cl or Br, Y = Br and Y′ = OH) and studied in solution the reactions of two complexes, namely, *cis* - dichlorobis(theophyllinato) - *trans* - dihydroxoplatinum(IV), *cis*-$PtCl_2(theoph)_2(OH)_2$, and *cis*-dichlorobis(cytidine)palladium(II), *cis*-$Pd(cytd)_2Cl_2$, with calf thymus DNA by recording UV difference spectra at various concentrations, pHs and temperatures. Solubility problems precluded the study of other Pt- or Pd-complexes.

EXPERIMENTAL

K_2PtCl_4, K_2PdCl_4, K_2PtBr_4 and $K_2PtCl_4(OH)_2$ were prepared by the reported methods.[13–15] The cis- and trans-isomers of dichlorodiammine palladium(II) were prepared by following the procedure of Layton *et al.*[16] and later modified by Coe and Lyons.[17] The ligands 5-nitro-1,10-phenanthroline, theophylline, 7-methyltheophylline were synthesized by the known procedures.[18,19] Their purity was checked by elemental analysis, m.p.s and spectral data. Calf thymus DNA (Type 1), 8-aminoquinoline, 1,8-naphthalenediamine, *o*-phenylenediamine were purchased (Sigma Chemical Co., Fluka AG, Buchs SG, Switzerland, Aldrich Chemical Company, Inc., U.S.A. and E. Merck AG, Darmstadt). All other chemicals used were of reagent grade. Solvents were purified and dried prior to use. IR spectra were recorded on a Perkin–Elmer model 599B IR spectrophotometer.

X-ray photoelectron spectra were recorded using a VG Scientific ESCA-3MK-2 electron spectrometer. Powdered samples were mounted on a nickel sample holder. Magnesium K_α radiation (1253.6) was used as a source. Nitrogen 1*s*, Pt 4*f*, Pd 3*d*, Cl 2*p*, Br 3*p*, K 2*p* binding energies were referred to C 1*s* line of adventitious carbon at 285.0 eV. The final values of the binding energies for each sample were determined from measurements in triplicate on several sample preparations and their accuracy is within ± 0.20 eV. Visual examination of the samples after measurements revealed no evidence of radiation damage.

The experimental details concerning the preparation of stock solutions of DNA and the aquated platinum complex and recording of UV difference spectra were described before.[12] The difference spectra reported at 30°C were obtained on a 1.00 expanded absorbance scale on a Pye Unicam Model SP8-100 spectrophotometer.

The Pd(II) complexes of the type $Pd(II)LX_2$, $Pd(II)L_2X_2$ were synthesized by following the general procedure given below:

Clear (filtered if necessary) solutions of K_2PdCl_4 in water (10 cm^3) and the appropriate organic ligand in excess hot water (25–30 cm^3) in 1 : 1 or 1 : 2 mole ratios were mixed together and heated on a water bath for about 8–12 h. (In the case of 5-nitro-1,10-phenanthroline, solvent acetone–water mixture, 1 : 1, was used and refluxed for 8 h.) The solid products separated out were collected on a filter under suction, washed with hot water (5 cm^3 portions) and dried under vacuum. Yield ~ 80%.

The platinum complexes of the types $Pt(II)L_2X_2$, $Pt(IV)LX_2Y_2'$ were prepared in an analogous manner starting with K_2PtCl_4 or $K_2PtCl_4(OH)_2$ and refluxing the mixtures for about 8 h. The tetrabromo(8-aminoquinoline)platinum(IV) was obtained by bromination, in $CHCl_3$ solution, of Pt(8-aminoQ)Br_2.[12] The analytical data of platinum and palladium complexes are given in Table 1.

RESULTS AND DISCUSSION

The interactions of platinum and palladium complexes, *cis*-dichlorobis(theophyllinato) - *trans* - dihydroxoplatinum(IV) and *cis* - dichlorobis-(cytidine)palladium(II) with calf thymus DNA were followed by UV difference spectral technique. The UV difference spectrum for the DNA solution mixed with *cis*-$Pt(theoph)_2Cl_2(OH)_2$ did not change, indicating no reaction with DNA bases. However, when the aquated Pt-complex was mixed with DNA, the spectrum exhibited large hyperchromism with a wavelength shift of the peak absorption from 259 to 280 nm initially. Over several days, at the end of the reaction apparently, the observed shift was from 259 to 263–4 nm (Figs 1 and 2). It seems well established now[3,20] that the interaction between Pt-compounds and DNA takes place through the complex aquated charged species of platinum and the high concentration of chloride ions (> 0.01 M) inhibits the reaction to an appreciable extent. The aquo complexes bind more readily to cellular targets such as DNA since water is relatively a good leaving group. It was postulated[21,22] that reactions of compounds such as *cis*-$Pt(NH_3)_2Cl_2$ with DNA bases and even DNA itself *in vivo* go through an aquation product supposedly

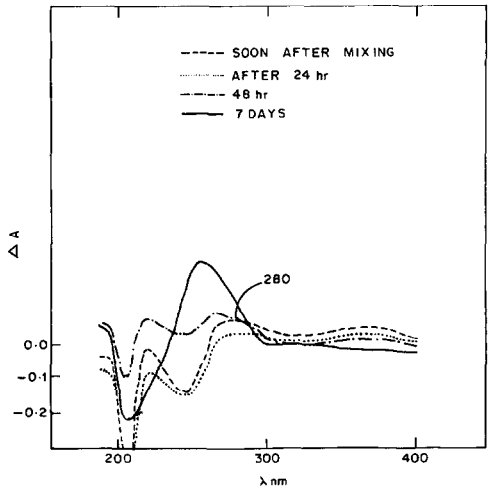

Fig. 1. UV difference spectra resulting from aquated *cis*-$Pt(theoph)_2(OH)_2(H_2O)]^{2+}$–DNA interaction: pH = 6.9, T = 30°C, 0.2 mg DNA/10 cm^3 phosphate buffer, Pt(IV) = 1×10^{-4} M (phosphate buffer).

$[Pt(NH_3)_2(H_2O)_2]^{2+}$. Rosenberg *et al.*[23–26] recently have shown that aqueous solutions of the aquation product are very complex and in addition to such species as above contain substantial amounts of hydroxide bridged species containing two, three or four platinum atoms. A ^{195}Pt and ^{15}N NMR spectral studies of aqueous solutions of *cis*-$Pt(NH_3)_2Cl_2$ and its hydrolysis and oligomerization products showed[27] that, in the blood substitute Hanks' medium, conversion of

$$cis\text{-}[Pt(^{15}NH_3)_2(H_2O)_2](NO_3)_2$$

into

$$cis\text{-}PtCl_2(^{15}NH_3)_2,$$

$$cis\text{-}[PtCl(H_2O)(^{15}NH_3)_2]^+,$$

$$[Pt(^{15}NH_3)_2(OH)_3]^{3+}$$

and

$$[Pt(^{15}NH_3)_2(OH)_2]^{2+}$$

takes place, the reaction taking several hours at 30°C. The aquated *cis*-$PtCl_2$(theoph)$_2$(OH)$_2$ solution may contain presumably *cis*-$[Pt(theoph)_2(OH)_2(H_2O)_2]^{2+}$ species. The extent of the reaction depends on pH, time, temperature and the mole ratio of Pt/DNA system. The time required to reach the end of the reaction under optimum conditions (pH 6.89–7.6, mole ratio 1 : 1) is of the order of 48 h at 30°C for the initial reaction and several days for the slow reaction. A rapid reaction occurred within hours and then a slow reaction extending over several days. The binding of a bifunctional Pt-complex to DNA probably occurs in two stages. The UV difference spectrum in the reaction with aquated species of Pt(IV) complex with DNA at pH 6.89 exhibits λ_{max} at *ca* 280 nm (broad band) probably consisting of two bands (the reaction mixture after 5 days showed a shoulder at 270 nm) while λ_{min} was observed at 248 nm and at *ca* 210 nm. ΔA at 280 nm increased with increased concentration of DNA as well as Pt-concentration. In citrate buffer, pH 7.59 the reactions of Pt(IV) and Pd(II) complexes with DNA appear to be sluggish. The DNA secondary structure undergoes a very profound alteration upon binding of *cis*-$[Pt(theoph)_2(OH)_2(H_2O)_2]^{2+}$ and the hyperchromism observed has been attributed to a denaturation of the double helical structure caused by breaking of one hydrogen bond at O-6-Guo for each Pt-bound by the first binding process.[28,29] The increments of ΔA at 280 nm (and at 263–4 nm) in the initial fast reaction and the final reaction may be due to change in the electron distribution of base moieties.[30,31] It is also possible that the aquated species binds to guanine residues at N-7 position with the resulting liberation of proton at N-1 position as has been postulated.[32] Scovell and O'Connor[33] observed in their studies of aquated *cis*-$Pt(NH_3)_2Cl_2$ with nucleic acid constituents that deprotonation of the guanosine does not occur and that in the complexation reaction monodentate coordination occurs with displacement of water. Millard *et al.*[34] have suggested that in the *cis*-Pt(II)$(NH_3)_2$ interaction with DNA, guanine acts as a chelate binding through the N-7 and O-6 positions. The shift of the 259 nm band of DNA to 280 nm (or 263–4 nm) in the UV difference spectrum of aquated *cis*-(theoph)$_2$(OH)$_2$Pt–DNA interaction is indicative of the involvement of N-7 of the guanine residues in DNA. The UV difference spectral pattern and the shift are similar approximately to those previously reported.[20,30,33]

It is interesting to note that the UV difference spectra in the reaction with aquated *cis*-Pt(IV)(theoph)$_2$(OH)$_2$Cl$_2$ with DNA recorded after several days (Fig. 2) exhibit a well defined intense positive peak at 208 nm. The UV spectrum of calf thymus DNA in buffer, pH 6.89 (recorded against appropriate blank) shows an intense absorption peak at 196 nm in the far UV region. The phosphate groups are known to absorb in this region.[35] The shift of the phosphate group absorption peak of DNA from 196 to 208 nm indicates

direct involvement of the phosphate oxygen with platinum in a Pt–OPO_3^{2-} type interaction. The formation of the charged aquo complex *cis*-$[Pt(theoph)_2(OH)_2(H_2O)_2]^{2+}$ equally may raise the affinity of the complex to phosphate group. The interaction between aquated *cis*-$[Pt(theoph)_2(OH)_2(H_2O)_2]^{2+}$ and DNA results in the denaturation of the double helical structure caused by breaking of the hydrogen bonds. The domain of this part of this helix can unwind itself over the planar base in such a way that the nitrogen of the base and the phosphate oxygen are in close proximity—an ideally placed configuration—for eventual coordination. Szent-Györgyi[36] has postulated a quadridentate chelate between ATP and Mg^{2+} in which the bonding involves the 6-amino group, the nitrogen atom at position 7 and one oxygen atom of each of the terminal phosphate groups.

FT–IR spectral studies[37] of the adenosine-5′-monophosphate complexes of Pt(II) and Mg(II) metal ions reveal that Mg(II) complexes synthesized in acid solution show direct Mg–phosphate interactions as well as N-7 bonding. However, no direct metal phosphate interaction was observed for the Pt(II) complexes. Crystal structure data for the complex $[Pt(en)(5'\text{-CMP})]_2 \cdot 2H_2O$ confirm the presence of direct platinum–phosphate bonding.[38] The CMP ligands are linked in a head-to-tail fashion by two Pt(en) fragments such that each Pt-atom is bonded to the N-3 atom of one nucleotide and to a phosphate oxygen of the other. The structure of this complex is consistent with those of other metal–CMP complexes.[39,40]

The UV difference spectrum for the DNA solution mixed with *cis*-$Pd(cytidine)_2Cl_2$, unlike the Pt(IV) complex, showed changes soon after mixing, indicating immediate reaction with DNA bases (Figs 3 and 4). The spectrum exhibited large hyperchromism with shift of the 259 nm band to 276 nm along with an additional positive peak at 220 nm. At the end of the reaction over several days, the observed shift was from 259 to 263 nm; the other peak appearing at 206 nm. The extent of the reaction depends on time, pH and the mole ratio of Pd/DNA system. The time required to reach the end of the initial reaction under optimum conditions (pH 6.8–7.6) mole ratio (1 : 1) is of the order of 24 h at 30°C. Although Pt- and Pd-complexes would be expected to exhibit similar reactivity towards DNA, the greater reactivity of Pd(II) towards heterocyclic nitrogen is a consequence of the lower affinity of Pd(II) towards Cl^-. Studies by Martin *et al.*[41] have indicated that, in the absence of Cl, Pt(II) is also reactive. The aquated *cis*-$Pd(cytidine)_2Cl_2$ may contain presumably the bifunctional *cis*-

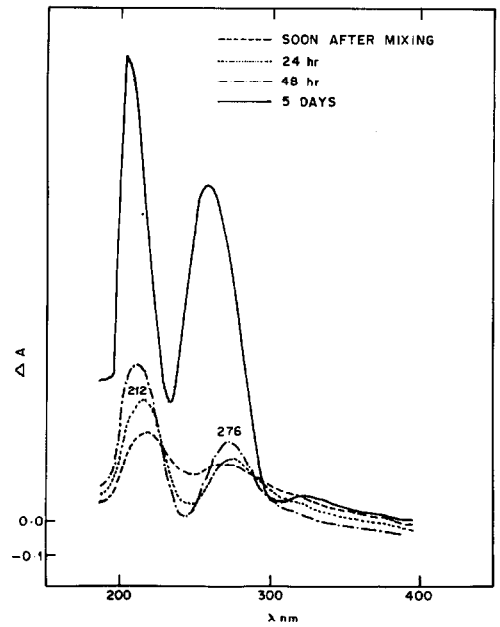

Fig. 3. UV difference spectra resulting from aquated *cis*-$(cytd)_2Pd(II)$–DNA interaction: pH = 6.8, T = 30°C, 0.2 mg DNA/10 cm^3 phosphate buffer, Pd(II) = 1×10^{-4} M (phosphate buffer).

$[Pd(cytidine)_2(H_2O)_2]^{2+}$ species which binds to the DNA in two stages. The shift of the 259 nm band of DNA to 276 nm (or to 263 nm) in the initial and final reactions is indicative of the perturbation of the electronic systems of the bases due to interaction of

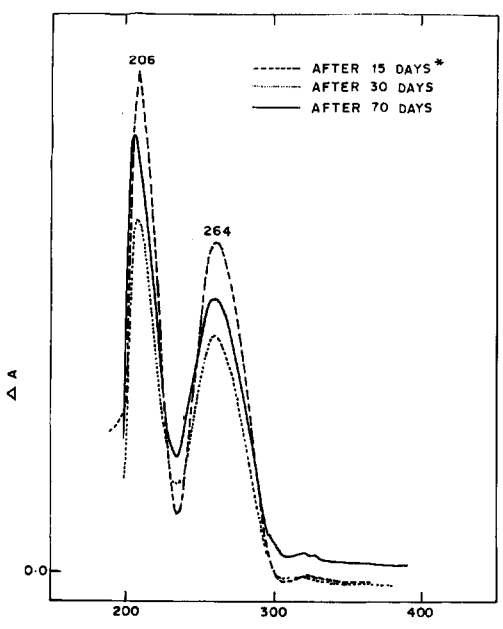

Fig. 4. UV difference spectra resulting from aquated *cis*-$(cytd)_2Pd(II)$–DNA interaction: concentrations same as in Fig. 3. *Recorded on 0.500 full scale.

cis-(cytidine)$_2$Pd^{2+}, possibly at the N-7 of the guanine residues. From a detailed study on the binding of (en)Pd^{2+} and (dien)Pd^{2+} to nucleic bases of nucleosides and nucleotides Martin[42,43] favoured a general rule for metal ion binding to N-7 of purine bases. Though the basicity of N-1 is much greater than that of N-7 in purines, (dien)Pd^{2+} only slightly favours N-1. In the region around neutral pH (en)Pd^{2+} coordinates to both N-7 and N-1 leading to possible polymeric complexes. The shift of the phosphate group absorption of DNA from 196 to 206 nm in the UV difference spectra recorded after several days (as in the case of Pt(IV)–DNA interaction) suggest involvement of phosphate oxygen with palladium. Recent interaction studies of *cysteinato - O - methylesterpalladium(II) - μ* - dichloro - cysteinato - *O* - methylesterpalladium(II) with adenosine-5'-monophosphate disodium, AMP–Na$_2$ indicate that in the complex [Pd(*O*-MeCys)(AMP)]Na, the nucleotide AMP coordinates to palladium through the N-7 atom of the purine ring and the phosphate group, most probably in a chelate form.[44]

The XPS data for the platinum and palladium complexes investigated are given in Tables 2 and 3. The Pd $3d_{5/2}$ binding energies of compounds nos. 2–6 imply a marked decrease in electron density on the metal relative to that in the 8-aminoquinoline complex. All the compounds are formally square planar Pd(II) complexes presumably containing the *cis*-PdCl$_2$ fragment. Variations in relaxation effect should be minimized in this series and the differences in metal binding energies should primarily be due to differences in the electron donating ability of the coordinated ligands.[45] A comparison of the Pd $3d_{5/2}$ binding energies for the complexes indicates that 8-aminoquinoline is a better electron donor, i.e. a better complexing agent, compared to 1,8-naphthalenediamine, 5-nitro-1,10-phenanthroline, theophylline or 7-methyltheophylline. The substantial shift in the binding energy of N(1*s*) clearly confirms a net electron transfer from nitrogen to palladium in these complexes. The change in the Pt $4f_{7/2}$ binding energies shows both the effect of oxidation state and of ligand character. The higher the formal oxidation state, the higher the binding energy. The platinum(II) and (IV) complexes of the type PtL$_2$X$_2$, PtLX$_2$Y$_2$ or PtLX$_2$Y$'_2$ investigated have Pt $4f_{7/2}$ binding energies within the range reported in the literature[46,47] for platinum complexes. The Cl(2*p*) binding energies of these complexes are lower than that of K$_2$PtCl$_4$ or K$_2$PtCl$_6$ indicating partial ionic character of the Pt–Cl bond.

The Cl(2*p*) binding energies for the palladium complexes studied are in the range 198.0–199.56 eV. The observed Cl(2*p*) binding energy for *cis*-Pd(NH$_3$)$_2$Cl$_2$ is lower than the *trans*-Pd(NH$_3$)$_2$Cl$_2$. In complexes where L = a bidentate ligand, the square planar geometry presumably implies *cis*-Cl configuration. The other complexes may also have *cis*-chlorines in view of the close range of observed

[a] Binding energies are in electron volts, eV, relative to adventitious carbon C 1*s*, 285 eV.

[b,c] Data from *Electron Spectroscopy*, D.A. Shirley (Editor), pp. 713, 725, North-Holland, Amsterdam (1972); and from W. M. Riggs, *Anal. Chem.* 1972, **44**, 830.

binding energies compared to *cis*-$Pd(NH_3)_2Cl_2$. The IR spectral data also confirm this. X-ray crystallographic data show quite clearly that there is a considerable increase in metal–halogen bond length in going from the *trans*- to *cis*-isomer in square planar Pt(II) and Pd(II) complexes of the type $(PR_3)_2MX_2$. For X = Cl, NQR data suggest[48] that the bond lengthening is accompanied by a considerable electron drift to chlorine. It is however observed[49] that in a given *cis–trans*-pair the binding energy of the metal is the same but that of the halogen is considerably lower in the *cis*-isomer. The ^{35}Cl resonance signals in the three *trans*-L_2PtCl_2 complexes are found at higher frequencies than in the corresponding *cis*-complex and this difference is related to the charge on the ligands. A tentative suggestion is that the *trans*-influence in the ^{35}Cl quadrupole resonance of the complexes of the type L_2MCl_2 [M = Pt(II) or Pd(II), Ni(II)] manifests itself in a general lowering of the frequencies on going from the *trans*- to the *cis*-complex and the difference being related to the position of the ligand L in the *trans*-series.

The IR spectra of Pd(II) complexes with organic ligands show two medium intense absorptions at *ca* 340 and *ca* 320 cm^{-1} ascribable to ν(Pd–Cl) vibrations—asymmetric and symmetric respectively corresponding to two Cl ligands in the *cis*-arrangement.[50,51] In the spectra of Pt(IV) complexes, the two Pt–Cl stretching vibrations are observed at *ca* 335 and *ca* 350 cm^{-1}. The Pt–Cl stretching vibrations absorb in the range observed for other complexes of Pt(IV) with chloroligands *trans* to (NH_3) group.[52,53] The IR ν(Pt–Cl/Pd–Cl) vibrations and XPS data (Cl $2p_{3/2}$ binding energies) support the view that both the complexes Pd(II) and Pt(IV), contain two Cl ligands in the *cis*-arrangement, in their respective geometries. XPS data also confirms the oxidation state of the metals involved in the study. It is well known that *cis*-$Pt(NH_3)_2Cl_2$ is effective against various tumour systems while *trans*-$Pt(NH_3)_2Cl_2$ is inactive. The activity of Pt(IV) complexes involves reduction inside the cell to the corresponding Pt(II) complex with the loss of the two *trans*-ligands. The profound spectral changes observed in the spectra of the interaction products of *cis*-Pt(IV) and *cis*-Pd(II) complexes with DNA are consistent with the observation[30] that the changes in the DNA secondary structure induced by antitumour active platinum complexes are greater than those of inactive platinum complexes.

Acknowledgements—The authors thank Dr. S. Badrinarayan for the help in recording the XP spectra. One of the authors, (Miss) R.A.H., thanks CSIR, New Delhi, for placement in the Scientist's Pool. The authors also thank the referees for helpful suggestions.

ROLE OF SECONDARY LIGANDS IN THE STRUCTURE AND STABILITY OF METAL–CYTIDINE COMPLEXES IN SOLUTION

PULIMAMIDI RABINDRA REDDY* and V. B. MALLESWARA RAO
Department of Chemistry, Osmania University, Hyderabad—500007, India

(*Received* 18 *February* 1985; *accepted* 27 *March* 1985)

Abstract—The interaction of Cu(II), Ni(II), Zn(II), Mn(II), Co(II), Mg and Ca ions with cytidine and the biologically important ligands histidine, histamine, glycine and oxalic acid in a 1:1:1 ratio have been investigated by potentiometric equilibrium measurements at 35°C and 0.10 M (KNO_3) ionic strength. These investigations were undertaken to assess the influence of the secondary ligands on the structure and stability of the 1:1 metal–cytidine system. The stability of the binary and ternary complexes has been compared. The enhanced stability of the ternary complexes was measured in terms of Δ log K, the difference between the ternary and binary complexes. The involvement of various donor sites of histidine in metal binding was specially discussed. A general conclusion drawn from this investigation is that aromatic ligands formed more stable complexes than aliphatic ligands. This is attributed to the stacking phenomenon.

Mixed-ligand complexes are gaining importance because they provide models for metalloenzyme reactions in biological systems.[1–3] The ternary complexes of nucleosides and nucleotides in particular have attracted the attention of many scientists throughout the world.[4–11] This is mainly because of the fact that metal ions participate in almost all biological processes involving nucleic acids, the winding and unwinding of the DNA helix being controlled by certain metal ions, apart from their being involved in other important biochemical processes like replication,[12,13] transcription[14,15] and translation[16] reactions. These studies (on the metal–nucleoside and metal–nucleotide interactions) have explained to some extent the specific and selective interactions that take place in many biological systems. However, much more information is needed before one can come to clear conclusions about the reactions that occur *in vivo*. One of the important aspects concerned with the ternary complexes is the influence of secondary ligands on the 1:1 metal–ligand complex. This influence becomes much more important when the secondary ligands are capable of participating in electrostatic,[17] hydrophobic[18] and stacking[19,20] interactions. We have been involved for some time in the study of ternary complexes involving nucleosides and nucleotides, which act as model systems for metal–nucleic acid interactions. The study of metal–nucleic acid interactions at the monomer level has a definite advantage over polymeric species because one can selectively eliminate or modify certain groups to obtain the necessary information about these reactions in solution.

Earlier work on the ternary complexes of cytidine was confined mainly to Th(IV) and UO_2(II),[21] and EPR and electronic absorption studies on the interaction of Cu(II)–glyglyglycine complexes.[22]

In the present paper we describe a detailed physicochemical investigation of the interaction of transition and alkaline earth metal ions with cytidine and biologically important secondary ligands to see the role of these ligands (secondary) on the structure and stability of metal–cytidine complexes in solution.

EXPERIMENTAL

Cytidine, glycine, histidine and histamine were obtained from Sigma (U.S.A.) and oxalic acid from Fluka (Switzerland). For every titration, fresh solid ligands were weighed out into the reaction cell to avoid possible hydrolysis. Transition and alkaline earth metal ions [Cu(II), Ni(II), Zn(II), Co(II), Mn(II), Mg and Ca] were of AnalaR grade and were standardized volumetrically by titration with the

* Author to whom correspondence should be addressed.

disodium salt of ethylenediamine tetraacetic acid in the presence of a suitable indicator as outlined by Schwarzenbach.[23] Carbonate-free sodium hydroxide was prepared by the method of Schwarzenbach and Biedermann.[24]

The experimental method employed consisted of potentiometric titration of the ligands with standard sodium hydroxide solution, in the absence and presence of the above-mentioned metal ions. The ionic strength was maintained constant by using 0.10 M (KNO_3) as the supporting electrolyte and relatively low concentrations of the ligand and metal ion (1×10^{-3} M). During the course of the titrations a stream of nitrogen was passed over the solution to eliminate the adverse effect of atmospheric carbon dioxide.

A Digisun digital pH meter (model DI-707) with a combination electrode was used to determine the hydrogen ion concentration. The electrode system was calibrated by direct titration of acetic acid, the observed pH meter reading was compared with the actual hydrogen ion concentration, and the pH regions below 3.5 and above 10.5 were calibrated by measurement in HCl and NaOH solutions, respectively.

CALCULATIONS

Dissociation constants

The acid dissociation constants of the primary ligand cytidine and the secondary ligands glycine, histidine, histamine and oxalic acid were calculated by the usual algebraic method.

Formation constants

To calculate the stability constants of the ternary complexes of Cu(II), Ni(II), Zn(II) and Co(II) with cytidine and histidine in a 1 : 1 : 1 ratio the following equations were employed [eqns (1)–(11)] (charges are omitted for clarity):

$$M + HL + H_2A \overset{K_1'}{\rightleftharpoons} MLA + 3H^+, \quad (1)$$

$$M + L + A \overset{K^M_{MLA}}{\rightleftharpoons} MLA, \quad (2)$$

$$K^M_{MLA} = \frac{T_M - [M]}{[M][L][A]}, \quad (3)$$

$$[M] = QL \quad \text{or} \quad PA \quad (4)$$

$$[L] = \frac{P\alpha}{QX + PY}, \quad (5)$$

$$[A] = \frac{Q\alpha}{QX + PY}, \quad (6)$$

$$\alpha = AX + LY, \quad (7)$$

$$X = \frac{3[H]^2}{K_aK_{2a}} + \frac{2[H]}{K_{2a}} \quad (8)$$

$$P = \frac{[H]^2}{K_aK_{2a}} + \frac{[H]}{K_{2a}} + 1 \quad (9)$$

(8), (9): using K_a and K_{2a} values of histidine

$$Y = \frac{3[H]}{K_a} + 2 \quad (10)$$

$$Q = \frac{[H]}{K_a} + 1 \quad (11)$$

(10), (11): using K_a values of cytidine

Equations (1)–(11) were also employed to calculate the stability constants of the ternary complexes of Cu(II), Ni(II), Zn(II) and Co(II) with cytidine and histamine, the ternary complex of Cu(II) with cytidine and glycine and the ternary complexes of Cu(II), Ni(II), Zn(II), Co(II), Mn(II), Mg and Ca with cytidine and oxalic acid in a 1 : 1 : 1 ratio.

For the ternary complexes of Mn(II), Ca and Mg with cytidine and histidine in a 1 : 1 : 1 ratio eqns (12)–(27) were used. In the buffer region between $a = 0$ and $a = 2$:

$$M + HL + H_2A \overset{K_2'}{\rightleftharpoons} [M(HA)L] + 2H^+, \quad (12)$$

$$M + HA + L \overset{K^M_{M(HA)L}}{\rightleftharpoons} [M(HA)L], \quad (13)$$

$$K^M_{M(HA)L} = \frac{T_M - [M]}{[M][HA][L]}, \quad (14)$$

$$[M] = QL \quad \text{or} \quad PA, \quad (15)$$

$$L = \frac{P\alpha}{QX + PY}, \quad (16)$$

$$A = \frac{Q\alpha}{QX + PY}, \quad (17)$$

$$\alpha = AX + LY, \quad (18)$$

$$X = \frac{2[H]^2}{K_aK_{2a}} + \frac{[H]}{K_{2a}} \quad (19)$$

$$P = \frac{[H]^2}{K_aK_{2a}} + \frac{[H]}{K_{2a}} \quad (20)$$

(19), (20): using K_a and K_{2a} values of histidine

$$Y = \frac{2[H]}{K_a} + 1, \quad (21)$$

$$Q = \frac{[H]}{K_a} + 1. \quad (22)$$

In the buffer region between $a = 2$ and $a = 3$ the following equations are used:

$$[M(HA)L] \overset{K_2'}{\rightleftharpoons} MLA + H^+, \quad (23)$$

$$M + L + A \overset{K^{M(HA)L}_{MLA}}{\rightleftharpoons} MLA, \quad (24)$$

$$K^{M(HA)L}_{MLA} = \frac{T_M - M}{[M][A]}, \quad (25)$$

$$[M] = A\left[\frac{H}{K_{2a}} + 1\right] \quad \text{using } K_{2a} \text{ values of histidine} \quad (26)$$

$$A = \frac{\alpha}{H/K_{2a}} \quad (27)$$

$$\alpha = (1-a)T_M - H^+ + OH^-. \quad (28)$$

In eqns (25) and (26) "M" equals M(HA)L.

For eqns (1)–(27) HL = monoprotonated cytidine, H_2A = monoprotonated histidine, and T_M = total metal ion species present in solution.

Equations (12)–(27) were also employed to calculate the stability constants of the ternary complexes of Mn(II), Mg and Ca with cytidine and histamine and the ternary complexes of Ni(II), Zn(II), Co(II), Mn(II), Mg and Ca with cytidine and glycine in a 1 : 1 : 1 ratio.

RESULTS

The proton dissociation constants of the ligands cytidine, glycine, histidine, histamine and oxalic acid are presented in Table 1.

Table 1. Acid dissociation constants of the ligands: temperature = 35°C, μ = 0.10 mol dm^{-3} (KNO_3)

Ligand	pK_a	pK_{2a}
Cytidine	4.15±0.04	—
Glycine	2.50±0.02	9.75±0.02
Histidine	6.00±0.04	9.00±0.04
Histamine	5.87±0.04	9.63±0.04
Oxalic acid	2.18±0.05	4.20±0.05

Metal : cytidine : glycine system (1 : 1 : 1)

The mixed-ligand titration curve of Cu(II)–cytidine–glycine given in Fig. 1(e) shows an inflection at m = 3 (where "m" is mol of base added per mol of metal ion), indicating simultaneous formation of a 1 : 1 : 1 mixed-ligand complex in the entire buffer region between m = 0 and m = 3. The constant K^M_{MLA} was calculated with the help of eqn (3) and presented in Table 2. The titration curve for all the other metal ions resulted in an inflection at m = 2, indicating the formation of a monopronated complex and the constant $K^M_{M(HA)L}$ was calculated with the help of the eqn (14). The constant $K^{M(HA)L}_{MLA}$ was, however, calculated in the buffer region between m = 2 and m = 3 using eqn (24). All the constants so calculated are listed in Table 2.

Metal : cytidine : histidine system (1 : 1 : 1)

The mixed-ligand titration curve of Cu(II) with cytidine and histidine in a 1 : 1 : 1 ratio is given in Fig. 1(d), resulting in an inflection at m = 3, indicating the simultaneous formation of a 1 : 1 : 1 complex in the

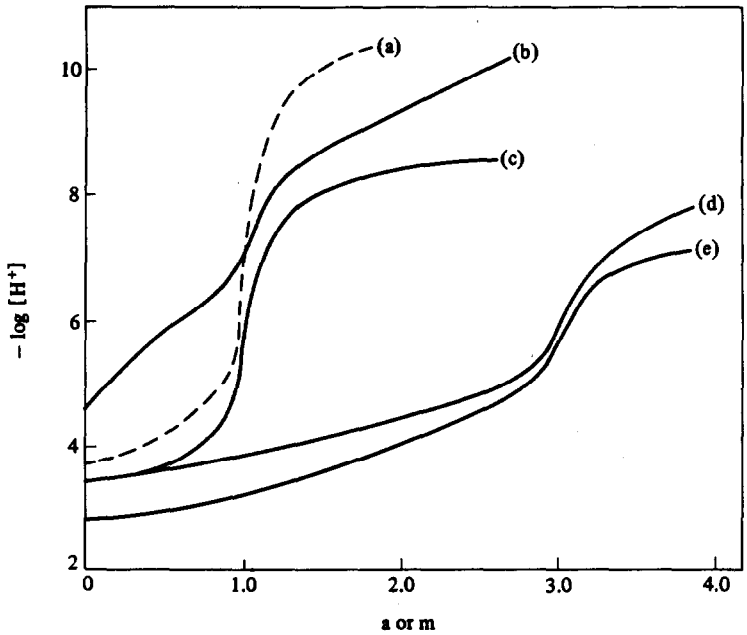

Fig. 1. Potentiometric titration curves for Cu(II)–cytidine–glycine and Cu(II)–cytidine–histidine systems in a 1 : 1 : 1 ratio at 35°C, μ = 0.10 M (KNO_3). (a) Free cytidine, (b) free histidine, (c) free glycine, (d) Cu(II)–cytidine–histidine, and (e) Cu(II)–cytidine–glycine. m, mol of base added per mol of metal ion [for curves (d) and (e); a, mol of base added per mol of ligand [for curves (a)–(c)].

Table 2. Stability constants[a] of the binary and ternary complexes of cytidine (HL) with glycine (H_2A) and oxalic acid (H_2A): temperature = 35°C, μ = 0.10 mol dm^{-3} (KNO_3)

Metal ion	Metal:cytidine (1:1)	Metal:glycine (1:1)	Metal:cytidine:glycine (1:1:1)			Metal:oxalic acid (1:1)	Metal:cytidine:oxalic acid (1:1:1)
	K^{M}_{ML}	K^{M}_{MA}	$K^{M}_{M(HA)L}$	$K^{M(HA)L}_{MLA}$	K^{M}_{MLA}	K^{M}_{MA}	K^{M}_{MLA}
Cu(II)	3.19	8.61			13.85	6.16	9.93
Ni(II)	2.94	5.92	8.56	5.72		5.23	9.31
Zn(II)	2.60	5.22	8.23	5.54		5.31	9.40
Co(II)	2.74	5.50	8.03	5.10		4.97	9.17
Mn(II)	2.51	3.85	8.16	3.79		5.14	9.53
Mg	2.42	3.40	8.19	3.59		4.65	8.81
Ca	2.47	3.58	8.24	3.63		4.85	8.80

[a] Deviations are omitted for clarity.

entire buffer region between $m = 0$ and $m = 3$. The constant K^{M}_{MLA} was calculated with the help of the eqn (3). Similar trends were observed for Ni(II), Zn(II) and Co(II). The constants so calculated are presented in Table 3.

However, in the case of the other metal ions [Mn(II), Mg and Ca] an inflection was obtained at $m = 2$, indicating the formation of a monoprotonated complex in the region between $m = 0$ and $m = 2$. The constant $K^{M}_{M(HA)L}$ was calculated using eqn (14). The constant $K^{M(HA)L}_{MLA}$ was also calculated in the buffer region between $m = 2$ and $m = 3$ with the help of eqn (24). All the constants thus calculated are listed in Table 3.

Metal:cytidine:histamine (1:1:1)

This system is exactly similar to the metal:cytidine:histidine system. The constants thus calculated are presented in Table 3.

Metal:cytidine:oxalic acid system (1:1:1)

The titration curve of all the metal ions showed an inflection at $m = 3$, indicating the simultaneous formation of a 1:1:1 mixed-ligand complex in the entire buffer region between $m = 0$ and $m = 3$. The constants were calculated with the help of eqn (3) and presented in Table 2.

DISCUSSION

In the ternary system there exist two types of complexes: (i) complexes in which interligand interactions (electrostatic, hydrophobic and stacking) occur; and (ii) complexes in which there is no such interaction. These interligand interactions have been found to be most effective in deciding the stability of the ternary complexes in solution along with other factors like the nature of the metal ion, the geometry of the metal complex and the solvent effects

Table 3. Stability constants[a] of the binary and ternary complexes of cytidine (HL) with histidine (H_2A) and histamine (H_2A): temperature = 35°C, μ = 0.10 mol dm^{-3} (KNO_3)

etc. These interactions (interligand) become more pertinent when the ligands participate in stacking interactions, but what is intriguing is that even this stacking interaction is neither automatic nor universal. Our experience[9–11,19] shows that this phenomenon (stacking) not only varies from ligand to ligand but also from metal ion to metal ion, indicating the high selectivity and specificity of the reactants in solution. Usually, the role of secondary ligands on the stability of 1:1 metal–ligand complexes is quantified in terms of $\Delta \log K$. $\Delta \log K$ is the difference between the overall 1:1:1 ternary complexes and the corresponding 1:1 binary complexes. Thus, if the $\Delta \log K$ values are positive, the ternary complexes are more stable than the binary complexes and, if they are negative, the binary complexes are more stable than the ternary complexes. However, it should be noted here that negative values of $\Delta \log K$ do not preclude the formation of ternary complexes in solution. A detailed discussion on the subject is found elsewhere.[11,25]

It was mentioned in one of the recent papers[26] that $\Delta \log K$ values are influenced by the stability constants of simple complexes. As there is no ambiguity about this observation (since ternary complexes are the combination of individual binary systems also) what is important here is the extent to which the two ligands influence the metal in the presence of each other compared to simple 1:1 parent complexes, affecting the coordination modes of the ligands and geometry of the complex as a whole. Therefore whatever information one gets out of $\Delta \log K$ values is still worthwhile.

Table 4 presents the $\Delta \log K$ values for the various systems studied. It can be seen that $\Delta \log K$ values are positive for all the systems studied. Various factors like charge neutralization, the π-accepting capacity of the secondary ligands and stacking interaction are reponsible for this extra stability found in ternary complexes.

First, let us compare the $\Delta \log K$ values for the

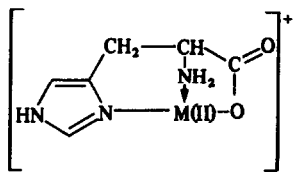

Fig. 2. Tentative structure of 1:1 metal–histidine showing the involvement of all available donor sites in metal coordination.

systems where interligand interactions are absent (glycine and oxalic acid systems). The $\Delta \log K$ values in the case of the glycine system are reported (Table 4) only for Cu(II) and the corresponding values for the other metal ions could not be computed owing to the formation of different types of complexes in binary and ternary systems. The $\Delta \log K$ value of the Cu(II)–cytidine–glycine system is more positive compared to the corresponding value of the oxalic acid system, although both ligands are aliphatic. This is due to the involvement of hetero-donor atoms in metal coordination in the case of the glycine system. The enhancement of the stability when mixed-donor atoms are involved has been reported for other related systems.[9,10,27] This is also supported by electrostatic molecular potential calculations.[28] In the case of the systems where interligand interactions are expected (the histidine and histamine systems), the $\Delta \log K$ values of histidine are less positive than the corresponding values of histamine complexes for all the metal ions investigated. This is exactly the reverse trend to that observed for their 1:1 complexes. In 1:1 complexes histidine forms more stable complexes than histamine, suggesting a different mode of coordination [involving amino, imidazole and carboxylate groups (Fig. 2)], but in ternary complexes the closeness in the values of $\Delta \log K$ (though a little more positive in the case of histamine) suggests that the mode of binding in ternary complexes is most probably similar in both of the ligands. This means

Table 4. $\Delta \log K$ values for various metal–ligand systems in solution: temperature = 35°C, $\mu = 0.10\ \text{mol dm}^{-3}$ (KNO_3)

Metal ion	Metal:cytidine: glycine (1:1:1)	Metal:cytidine: histidine (1:1:1)	Metal:cytidine: histamine (1:1:1)	Metal:cytidine: oxalic acid (1:1:1)
Cu(II)	+2.05	+2.02	+2.25	+0.58
Ni(II)	—	+2.12	+2.35	+1.14
Zn(II)	—	+2.98	+3.02	+1.49
Co(II)	—	+2.95	+3.15	+1.46
Mn(II)	—	—	+2.83	+1.88
Mg	—	+3.13	+3.62	+1.74
Ca	—	+3.15	+3.84	+1.48

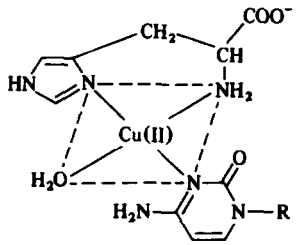

Fig. 3. Tentative structure of 1:1:1 Cu(II)–cytidine–histidine showing the histamine-like coordination: R = ribose.

that, in ternary complexes, histidine is acting in a histamine-like way, involving only amino and imidazole groups in metal coordination (Fig. 3). The interesting question that then arises is what is the status of the carboxylate group. It is likely that a hydrogen-bonding type of interaction between the

and NH_2 of cytidine takes place, as a result of

which the C—O group is kept away from the metal coordination.

It is significant to mention here the very recent work of Arena *et al.*,[26] where similar observations were made in the case of the Cu(II)–ATP–histidine system. Such an interaction disfavours the formation of ternary complexes in solution by an entropy factor, as the ligands become more rigid as a consequence of the bridge between the two-noncoordination groups and also due to the different degree's of solvent interaction with the metal ion. This may be the reason for the less positive values of $\Delta \log K$ in histidine complexes compared to those with histamine.

In general, for the systems under investigation, the $\Delta \log K$ values of Cu(II) are less positive than for the rest of the metal ions studied. This may be due to the lower coordination number of Cu(II) compared to other metal ions whose coordination number is more certain. Finally, the $\Delta \log K$ values are controlled and significantly contributed to by the nature of the secondary ligands, and the ligands which participate in stacking interaction (aromatic ligands) result in the formation of more stable ternary complexes (more positive $\Delta \log K$ values). Within the aromatic ligands the non-coordinating side chain affects the stacking interaction at least to some extent.

Based on the above conclusions we propose the following tentative structure for metal–cytidine–histamine complexes in solution (Fig. 4).

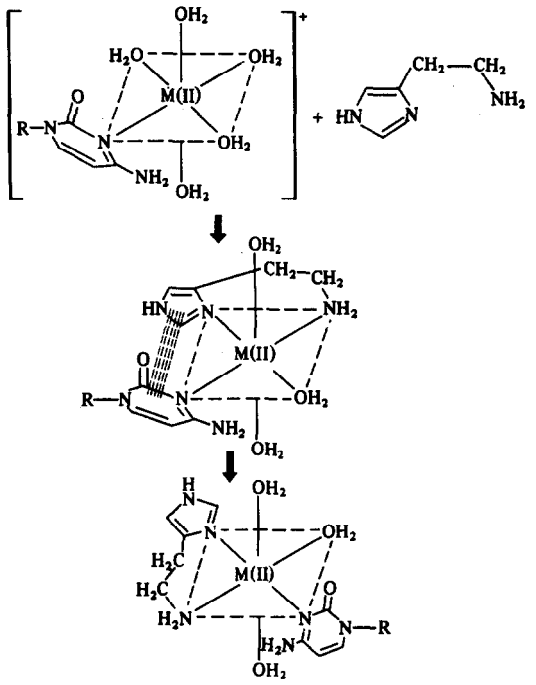

Fig. 4. Model illustrating the stacking interaction followed by coordination in H_2O: R = ribose (metal–cytidine–histamine complex).

(*Received* 30 *January* 1985; *accepted* 27 *March* 1985)

Abstract—A complete analysis of the temperature dependence (−30 to 52°C) of the ^{1}H NMR spectra in *d*-chloroform of the ternary complexes, bis-(8-quinolinato)tin(IV) dichloride and bis-(5,7-dichloro-8-quinolinato)tin(IV) dichloride has been performed. The intramolecular character of the exchange process has been established, and the spectra have been analyzed by the total lineshape method in terms of the interconversion of two isomers, the *cis–cis–trans* and the *cis–trans–cis* (with respect to Cl, N and O atoms), including the tin–proton couplings in the simulations. Arrhenius parameters of the process were $E_a = 54 \pm 1$ and $52 + 1$ kJ mol^{-1}, and log $A = 11.8 \pm 0.2$ and 11.7 ± 0.3, respectively, for the two complexes. The similarity of the activation parameters obtained for both complexes indicates that the presence of bulky Cl atoms in the 8-quinolinol ring had no appreciable energetic influence on the isomerization process. Data were compared with those reported for other chlorinated hexacoordinated complexes, involving ligands other than the 8-quinolinol ring.

Descriptions of chelates of tri- and tetravalent metals (including tin) with the ligand 8-quinolinol can be found in the literature.[1–11] However, no activation data on isomerization equilibria have been reported as far as we know, probably due to the difficulties in obtaining NMR spectra of such chelates that show limited solubility, specially when carbon–metal bonds are absent. The structure and ^{1}H NMR spectra at low temperature (−30°C) of the chlorotin(IV) ternary complexes with 8-quinolinol and derivatives have been characterized very recently,[12] and, in view of the scarcity of data, we considered it interesting to study the temperature dependences of the NMR spectra in order to obtain activation parameters of the isomerization equilibrium.

In this work, a complete analysis of the temperature dependence of the ^{1}H NMR spectra of the ternary complexes bis-(8-quinolinato)tin(IV) dichloride (Cl_2SnQ_2) and bis-(5,7-dichloro-8-quinolinato)tin(IV) dichloride [$Cl_2Sn(CQ)_2$] has been carried out and the activation parameters of the isomer exchange process obtained. The total-line shape method, with visual comparison between experimental and computed spectra, has been employed, and the whole ^{1}H NMR spectrum, including the tin–proton couplings, computed.

EXPERIMENTAL

Materials

Details of the preparation of the complexes have been reported previously.[13] Chloroform was chosen as the solvent because it represented a compromise between solubility, availability in a high degree of deuteration, thus reducing dynamic range problems in the NMR spectrum, and the absence of signals in the region of interest (Stholer Isotope Inc., 99.98% $CDCl_3$ was used).

NMR spectra

These were recorded at 360 MHz in a Bruker WM-360 Fourier spectrometer. Flip angles of 70°, 16 K of memory, 10,000 scans and 2-s relaxation delays were typical recording conditions. Saturated solutions of the complexes in *d*-chloroform were used. Variable-temperature spectra were obtained with a standard accessory by flushing the sample with cool N_2 or heated air, and the temperature was calibrated with a methanol thermometer.[14] The signal-to-noise ratio of exchange-broadened spectra was somewhat critical in the complex of lowest solubility (Cl_2SnQ_2), so that a moderate digital filtering (line-broadening factor of 1 Hz) was employed in that case.

Spectral simulations

These were carried out by the Binsch program,[15,16] modified by us to include the tin–proton couplings in the calculations. The NMR spectrum of the $Cl_2Sn(CQ)_2$ complex was simulated as the sum of three independent spin subsystems, $H_2H_3H_4H_6$, H_6Sn and $H_2H_3H_4Sn$, with relative intensities in accordance with natural isotopic abundances. In an analogous way, the Cl_2SnQ_2 spectrum was decomposed into four spin subsystems, namely $H_2H_3H_4$, $H_5H_6H_7$, $H_2H_3H_4Sn$ and $H_5H_6H_7Sn$. The whole ^1H NMR spectrum was computed for both complexes and, using an adequate expanded scale, visually compared with the experimental one. The introduction of the tin–proton couplings in the simulations has proved to be necessary to obtain a good agreement between experimental and computed line shapes. Static parameters and isomer populations were those given in Ref. 12; a 2-Hz linewidth in the absence of exchange was used. Tin–proton coupling constants that were not available for the Cl_2SnQ_2 complex were transferred from the $Cl_2Sn(CQ)_2$ one.

The low-temperature spectra evidenced that the chemical shifts were appreciably temperature-dependent only in the case of the Cl_2SnQ_2 complex, so that they were extrapolated in that case through the full temperature range, following the criterion of resemblance with the experimental spectrum recommended by Szymanski *et al.*[17]

RESULTS AND DISCUSSION

In the absence of exchange at low temperature, the NMR spectra of the complexes show sharp lines, corresponding to the presence in solution of only two appreciably populated isomers,[12] namely *cis–cis–trans* and *cis–trans–cis* with respect to the Cl, N and O atoms (see Fig. 1). As the temperature is raised, the NMR lines begin to broaden, indicating that an

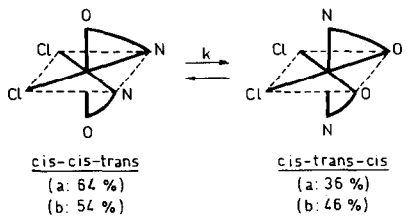

Fig. 1. Isomer exchange and populations of the Cl_2SnQ_2 (a) and $Cl_2Sn(CQ)_2$ (b) complexes.

exchange process is taking place. The intramolecular character of such an exchange is supported by two facts. First, the appearance of sharp NMR signals corresponding to protons of the free ligands when they are added to the complexes, at temperatures where signals of the complexes are extensively exchange-broadened. Second, the absence of appreciable changes in the linewidths of the NMR signals following a significant change in the concentration of the complexes (10-fold dilution, monitored at 2°C where lineshapes are sensitive to rate constant changes).

The analysis of the NMR spectra in terms of an intramolecular exchange between two unequally populated sites, gives the first-order rate constants, *k*, that provide the best fit between experimental and computed spectra. Table 1 lists the best-fit rate constants, at each temperature, obtained for both complexes. The degree of agreement between experimental and computed spectra is illustrated for some of the temperatures, in Figs 2 and 3. It can be seen that the agreement is good in all the spectral regions corresponding to the different protons of the ligand rings.

Arrhenius (see Fig. 4) and Eyring plots were obtained for both complexes. A good linearity was found for $Cl_2Sn(CQ)_2$ in the whole range of

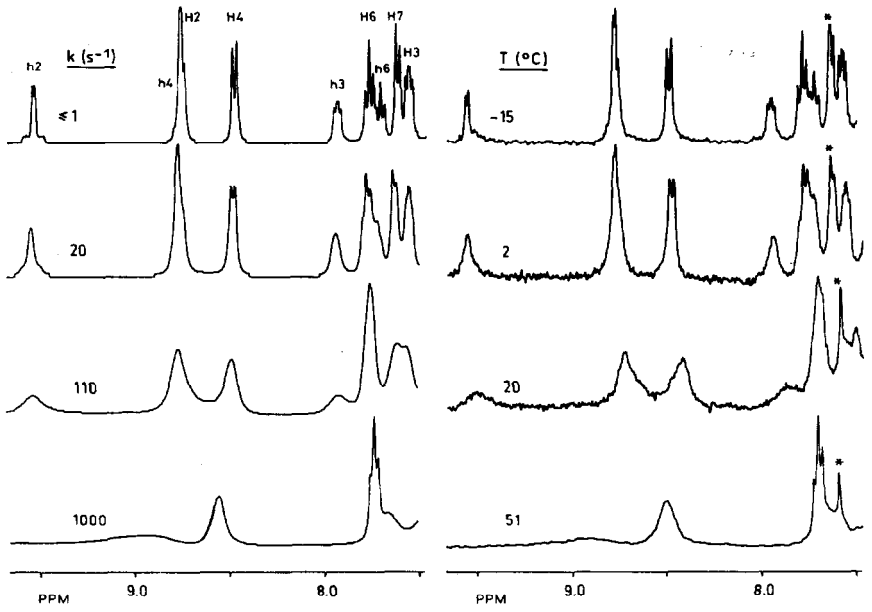

Fig. 2. Experimental and simulated ^{1}H NMR spectra of the Cl_2SnQ_2 complex at selected temperatures. Upper and lower case letters identify *cis–cis–trans* and *cis–trans–cis* isomers respectively. Signals from H5, h5 and h7 protons are not shown due to overlapping with the solvent line. The asterisk marks a solvent impurity.

temperatures, and for Cl_2SnQ_2 at temperatures higher than 2°C (correlation coefficient was 0.998 and 0.999, respectively). However, for the Cl_2SnQ_2 complex at temperatures below 2°C, a slight curvature of the plot can be seen. Although these temperatures are near the slow-exchange limit where rate constants are not very well determined, a change in the slope was apparent. The involvement of the solvent in the activated complex[18] or the existence of two consecutive exchange processes with different activation energies[18,19] are two possible explanations for convex curvatures in Arrhenius plots. It should be noted that an interaction with the solvent could explain the temperature dependence of the

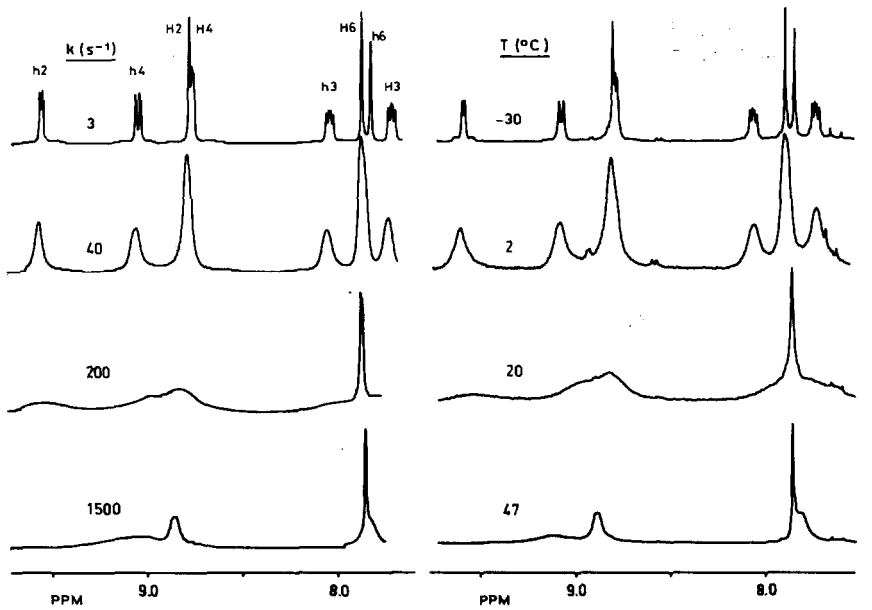

Fig. 3. Experimental and simulated ^{1}H NMR spectra of the $Cl_2Sn(CQ)_2$ complex at selected temperatures. Upper- and lower-case letters identify *cis–cis–trans* and *cis–trans–cis* isomers respectively.

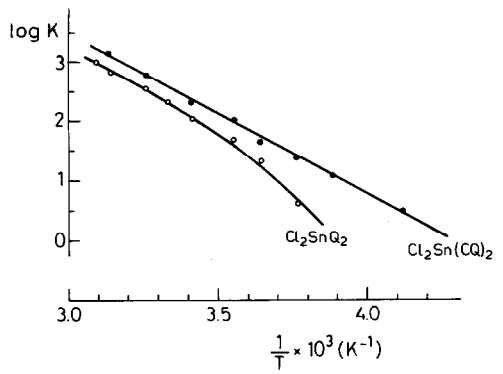

Fig. 4. Arrhenius plots of the Cl_2SnQ_2 and $Cl_2Sn(CQ)_2$ complexes.

chemical shifts in the slow-exchange region and the small curvature of the Arrhenius plots as well, both trends being shown by the same complex, Cl_2SnQ_2.

The Arrhenius (E_a and log A) and Eyring ($\Delta H^{\neq}$, $\Delta S^{\neq}$) parameters obtained are shown in Table 2, where activation data of related chlorinated hexacoordinated complexes of tetravalent metals (including tin) are also included for comparison purposes. It can be seen that the activation energies are very similar for the two complexes, $Cl_2Sn(CQ)_2$ and Cl_2SnQ_2, indicating that the presence of bulky Cl atoms in the 8-quinolinol ring had no appreciable influence on the isomer exchange around the tin atom. Even the substitution of the 8-quinolinol ring by acetylacetonate or dipivaloylmethanide (dpm) ligands, maintaining the Cl and tin atoms, causes only a moderate (~ 15 kJ mol^{-1}) change in activation energies. On the contrary, the substitution of the Sn(IV) atom by Ge(IV), maintaining the Cl and dpm ligands, practically doubled the activation energy of the exchange process.

We would like to point out that, as far as we know, this is the first time that an isomerization process involving a ligand as complex as the 8-quinolinol ring (seven coupled nuclear spins) has been studied by NMR techniques and the activation parameters obtained. Studies on the stereodynamics of complexes of 8-quinolinol with other metals are desirable to fully characterize its behaviour, and further work in that direction will be done in the future.

Acknowledgements—We thank A. Gómez, Mrs C. López and Mr L. de la Vega for excellent technical assistance.

COMPLEXES OF Pt(II) AND Pt(IV) WITH DISUBSTITUTED PURINES

BADAR TAQUI KHAN,* S. VIJAYA KUMARI, K. MURALI MOHAN and G. NARSA GOUD

Department of Chemistry, Osmania University, Hyderabad-7, India

(*Received* 5 *February* 1985; *accepted* 27 *March* 1985)

Abstract—Mixed-ligand complexes of Pt(II) and Pt(IV) with 2,6-diaminopurine and 6-thioguanine were synthesized and characterised. The complexes were prepared in acidic and basic media. The binding of the ligands to the metal ion varies according to the pH of the medium. Thus, in the complexes of 6-thioguanine, the ligand acts as a monodentate ligand coordinating through the neutral C_6-SH group in the acidic medium and in the basic medium as a bidentate ligand binding to the metal ion through C_6S^- and N_7, forming a five-membered chelate ring. In an acidic medium 2,6-diaminopurine forms mononuclear complexes with Pt(II) and Pt(IV) binding through N_7. In a basic medium binuclear hydroxobridged complexes are formed with Pt(IV) and the ligand is monodentate, coordinating through N_7.

There has been a growing interest in the study of various mixed-ligand complexes of platinum group metal ions because of their anti-tumour activity.[1–3] Earlier we have reported on platinum group metal complexes with purines, pyridimidines and nucleosides as ligands.[4–7] In the present paper the preparation and characterisation of Pt(II) and Pt(IV) complexes with 2,6-diaminopurine and 6-thioguanine are reported.

EXPERIMENTAL

Hexachloroplatinic acid was purchased from Alfa–Ventron (U.S.A.). 2,6-Diaminopurine and 6-thioguanine were purchased from Schwarzmann (U.S.A). Hexachloroplatinic acid was converted to potassium hexachloroplatinate(IV) and potassium tetrachloroplatinate(II) by reported procedures.[8] Elemental analysis of the samples was performed at Australian Mineral Development Laboratories (Australia). The percentage of chlorine in the complexes was estimated by a reported procedure.[9] The IR and UV spectra were recorded on Perkin–Elmer (377) and Beckman Model (DB) spectrophotometers, respectively. ^{1}H NMR spectra were recorded on a Varian A-60 spectrometer.

The insolubility of some of the complexes precluded the use of electronic and NMR spectra.

* Author to whom correspondence should be addressed.

Synthesis

Pentachloro-2,6-diaminopurinium platinum(IV) dihydrate. Potassium hexachloroplatinate (0.243 g, 0.5 mM) was dissolved in 10 cm^3 of water and to this a solution of 2,6-diaminopurine (0.075 g, 0.5 mM) in 10 cm^3 of 3 N HCl was added. The resulting solution was stirred at room temperature for 6 h. A yellow precipitate was obtained on cooling, which was filtered, washed with methanol and acetone, and dried.

Hexachloro - μ - dihydroxo - bis(2,6 - diaminopurine) diplatinum(IV). Potassium hexachloroplatinate(IV) (0.243 g, 0.5 mM) was dissolved in 10 cm^3 of water and to this a solution of 2,6-diaminopurine (0.075 g, 0.5 mM) in 10 cm^3 of 3 N KOH was added. The resulting solution was stirred at room temperature for 6 h, when a yellow precipitate was obtained. The precipitate was filtered, washed with methanol and acetone, and dried.

Trichloro 2,6-diaminopurinium platinum(II) dihydrate. Potassium tetrachloroplatinate(II) (0.207 g, 0.5 mM) was dissolved in 10 cm^3 water and to this a solution of 2,6-diaminopurine (0.075 g, 0.5 mM) in 10 cm^3 of 3 N HCl was added. The resulting solution was stirred for 5 h at room temperature, when a yellow-coloured precipitate was obtained. The complex was filtered, washed with water, methanol and acetone, and dried.

Tetrachloro bis(6-thioguanine) platinum(IV) trihydrate. Potassium hexachloroplatinate(IV) (0.243 g,

0.5 mM) was dissolved in 10 cm^3 of water and to this a solution of 6-thioguanine (0.167 g, 1 mM) in 10 cm^3 of acidified water was added. On stirring for 3 h a yellow precipitate was obtained. The compound was filtered, washed with methanol and acetone, and dried.

Dichloro bis(6-thioguaninato) platinum(IV) tetrahydrate. Potassium hexachloroplatinate(IV) (0.243 g, 0.5 mM) was dissolved in 10 cm^3 of water and to this a solution of 6-thioguanine (0.167 g, 1 mM) in 10 cm^3 of 2 N KOH was added. The resulting solution was stirred for 6 h, when a yellow precipitate was obtained. The complex was filtered, washed with methanol and acetone, and dried.

Dichlorobis(6-thioguanine) platinum(II). Potassium tetrachloroplatinate(II) (0.207 g, 0.5 mM) was dissolved in 10 cm^3 of water and to this a solution of 6-thioguanine (0.083 g, 0.5 mM) in 10 cm^3 of acidified water was added, when a yellow precipitate was obtained. The precipitate was stirred for 2 more hours at room temperature. The complex was filtered, washed with methanol and dried.

Bis(6-thioguaninato) platinum(II) pentahydrate. Potassium tetrachloroplatinate(II) (0.207 g, 0.5 mM) was dissolved in 10 cm^3 of water and to this a solution of 6-thioguanine (0.088 g, 0.5 mM) dissolved in 10 cm^3 of 2 N KOH was added. The resulting solution was stirred at room temperature for 15 min, when a yellow precipitate appeared. The stirring was continued for 3 more hours and the reaction mixture was kept in the refrigerator overnight. The precipitate was filtered, washed with methanol and dried.

RESULTS AND DISCUSSION

The analytical and other data for complexes **1**–**7** are presented in Table 1. The IR spectra of 2,6-diaminopurine and 6-thioguanine exhibit a strong band around 1600 cm^{-1} due to the NH_2 deformation mode. 6-Thioguanine exhibits a band at 1060 cm^{-1}, which may be assigned to skeletal vibrations of the pyrimidine ring. The S–H stretching frequency is observed as a strong band in the region around 2100 cm^{-1}. In the free ligands, the C=N and C=C frequencies are observed as strong bands at 1460, 1500 and 1580 cm^{-1}. The band at 1600 cm^{-1} remains unaffected in the spectra of all the complexes, indicating that the NH_2 group is not involved in coordination. Except for complexes **4** and **6** the peaks corresponding to C=N are shifted to a lower frequency by about 50–70 cm^{-1} indicating the involvement of ring nitrogen in bonding. The coordination of the metal ions of the ring nitrogen in these complexes is also ascertained by a band due to M–N vibrations observed around 500–600 cm^{-1}.

Complexes **1** and **3** are prepared in acidic medium at a pH of 3–4. In these complexes, 2,6-diaminopurine binds to the metal ion through N_7, as N_1 is preferentially protonated.[10] Complex **1** shows two M–Cl stretching modes at 340 and 360 cm^{-1}. The former corresponds to the equatorial chlorides in the plane of the metal ion and the latter to the chloride *trans* to the coordinated purine in the sixth position. In complex **3** two M–Cl stretching frequencies are observed around 350 and 330 cm^{-1}, indicating a meridional arrangement of three

Table 1. Analytical and conductivity data

[a] Abbreviations: 2,6-diampu, 2,6-diaminopurine; 2,6-diampuH$_2^+$, 2,6-diaminopurinium ion; 6-thioguH, 6-thioguanine; 6-thiogu$^-$, 6-thioguaninato ion.

chlorides in the square plane of the metal ion. The 2,6-diaminopurinium ion is coordinated to Pt(II) through N_7 at the fourth coordination position. In both complexes **1** and **3** the proton is associated with N_1, as verified by a peak around 2600 cm^{-1}, which is observed unaltered in the protonated 2,6-diaminopurinium ion.

The electronic spectrum of complex **1** exhibits two peaks at 370 nm ($\varepsilon_{max} = 567$) and 384 nm ($\varepsilon_{max} = 467$), which may be assigned to $^1A_1 \rightarrow {}^1B_2$ and $^1A_1 \rightarrow {}^1A_2$ transitions, respectively based on a C_{4v}-symmetry of the complex. In complex **3** the peaks at 384 nm ($\varepsilon_{max} = 275$) and 272 nm ($\varepsilon_{max} = 1.06 \times 10^4$) are assigned to $^1A_1 \rightarrow {}^1A_1(1)$ transition. The $\pi \rightarrow \pi^*$ transition of the ligand is observed in complexes **1** and **3** in the range of 265–275 nm.

Complex **2** was prepared in a basic medium. The complex is an insoluble hydroxo-bridged dimer with coordinated terminal chlorides and 2,6-diaminopurine coordinated through N_7. The presence of bridging hydroxo groups in the complex is supported by a broad peak at 2900–3000 cm^{-1}. The M–Cl stretch of the terminal chlorides is observed around 350 cm^{-1}.

Complexes **4** and **6** were prepared in an acidic medium. The IR spectra of these complexes exhibit NH_2 stretching modes as a broad band around 3040–3350 cm^{-1}. The NH_2 deformation mode is observed around 1610 cm^{-1}. This mode is not shifted to any appreciable extent in these complexes, indicating its non-involvement in coordination. The ring C=C and C=N stretching frequencies of 6-thioguanine are observed in these complexes around 1470 and 1450 and 1370–1385 cm^{-1}, respectively, and are not shifted to an appreciable extent when compared to the ligand, indicating that the ring nitrogen is not involved in coordination. In both complexes a medium band is observed around 480 cm^{-1}, which may be assigned to an M–S stretching vibration. In the IR spectra of complexes **4** and **6** a single intense peak is exhibited at 330 and 350 cm^{-1} respectively, indicating the presence of *trans*-chlorides in the complexes. In complexes **4** and **6** the S–H stretching frequency is shifted to a lower frequency by about 100 cm^{-1}, indicating the coordination of neutral S–H in these complexes. The NMR spectrum of free 6-thioguanine gives a peak around 7.8 ppm (δ) due to C_8H protons. In complexes **4** and **6** this peak is not shifted and exhibited at 7.75 (δ) and 7.9 ppm, respectively, indicating that N_7 is not involved in coordination. From the above data complex **4** is assigned an octahedral structure with four chlorides in the equatorial position and two 6-thioguanine ligands coordinating to the metal ion in the axial position. The electronic spectrum of complex **4** exhibits *d–d* transitions at 370 and 344 nm assigned to $^1A_{1g} \rightarrow {}^1B_{1g}$ and $^1A_{1g} \rightarrow {}^1B_{2g}$, respectively, in accord with a D_{4h}-symmetry of the complex. The $\pi \rightarrow \pi^*$ transition of 6-thioguanine is observed in complex **4** at 267 nm. In the electronic spectrum of complex, **6**, peaks are observed at 358 nm ($\varepsilon_{max} = 540$) and 370 nm ($\varepsilon_{max} = 700$) which are assigned to $^1A_{1g} \rightarrow {}^1A_{2g}$ and $^1A_{1g} \rightarrow {}^1A_{1g}(1)$ transitions, respectively, for a C_{4h}-symmetry. A band is also observed at 266 nm ($\varepsilon_{max} = 1.5 \times 10^4$) which is assigned to a $\pi \rightarrow \pi^*$ transition of the ligand.

The IR spectrum of complex **5** exhibits two peaks at 330 and 450 cm^{-1}, which may be assigned to stretching frequencies of *trans*-chlorides and ν(M–S) respectively. The insolubility of the complex precludes its studies by other physico-chemical techniques. The SH stretching frequency at 2100 cm^{-1} observed in the ligand disappears in the complex, indicating the coordination of the thiolato S^- group in the complex. Based on the analytical data, IR spectrum and the usual stereochemistry of Pt(IV), complex **5** is assigned an octahedral geometry with the chelated 6-thioguaninato ions in the equatorial position of Pt(IV) and the two axial positions occupied by the chloride ions with a C_{2v}-symmetry.

In complex **7** the coordination of 6-thioguaninato ion is through N_7 and C_6S^- as indicated by the presence of peaks corresponding to M–N and M–S stretching frequencies at 530 and 450 cm^{-1}, respectively. The ν(M–Cl) and ν(S–H) bands are absent in that complex.

THE OXIDATION OF THIOSULPHATE IONS BY OCTACYANOTUNGSTATE(V) IN WEAK ACIDIC MEDIUM

C. R. DENNIS,* J. G. LEIPOLDT, S. S. BASSON and G. J. LAMPRECHT
Chemistry Department, University of the Orange Free State, Bloemfontein (9300), Republic of South Africa

(*Received* 11 *December* 1984; *accepted* 3 *April* 1985)

Abstract—The kinetics of the oxidation of thiosulphate ions by octacyanotungstate(V) ions has been studied in the pH range 3.9–5.0. The reaction showed zero-order kinetics with respect to $[W(CN)_8^{3-}]$ and is consistent with the rate law $R = k[H^+][S_2O_3^{2-}]^2$. A reaction mechanism is proposed for the reaction with a third-order rate constant of 0.26 $M^{-2}\,s^{-1}$ at 25°C.

The oxidation of thiosulphate ions by mild oxidizing agents like iodine and iron(III) yields tetrathionate ions in neutral aqueous medium.[1] Stronger oxidizing agents such as bromine and chlorine yield sulphate ions, whilst hydrogen peroxide gives a mixture of sulphate and tetrathionate ions. In an alkaline medium oxidation by iodine produces some sulphate ions and the ratio of sulphate to tetrathionate increase with increasing pH of the reaction medium. This suggests that the oxidation product of thiosulphate ions is determined by two factors: (i) the reduction potential of the oxidizing agent, and (ii) the pH of the reaction medium.

The kinetics of the oxidation of thiosulphate ions by octacyanotungstate(V) ions in the pH range 3.9–5.0 were investigated as part of a research program on the redox properties of the cyano complexes of iron, molybdenum and tungsten. Sandved and Holte[2] reported the oxidation of thiosulphate by hexacyanoferrate(III) ions to be zero-order in $Fe(CN)_6^{3-}$ with a rate law:

$$-\frac{d[Fe(CN)_6^{3-}]}{dt} = k[H^+][S_2O_3^{2-}]^2. \quad (1)$$

The rate law for the oxidation by octacyanomolybdate(V) ions[3] in a weak acidic medium has been reported to be:

$$-\frac{d[Mo(CN)_8^{3-}]}{dt} = k[Mo(CN)_8^{3-}][S_2O_3^{2-}][M^+]. \quad (2)$$

(M^+ = alkali-metal ion)

A reinvestigation[4] of the oxidation of the thiosulphate by hexacyanoferrate(III) ions confirmed the zero-order kinetics in $[Fe(CN)_6^{3-}]$ and showed the rate to be consistent with a two-term rate law [eqn (3)] of which the second term represents an alkali-metal ion catalysis pathway:

$$R = k[H^+][S_2O_3^{2-}]^2 + k'[H^+][S_2O_3^{2-}]^2[M^+]. \quad (3)$$

The results of both Lamprecht *et al.*[3] and Howlett and Wedzicha[4] show the effect of the alkali-metal ion catalysis to be in the order $Na^+ < K^+ < Rb^+ < Cs^+$.

In view of the above-mentioned results the kinetic study of the octacyanotungstate(V) oxidation of thiosulphate ions was performed for a comparison with those of the hexacyanoferrate(III) and octacyanomolybdate(V) ions.

EXPERIMENTAL

The complex tricesium octacyanotungstate(V) dihydrate, $Cs_3[W(CN)_8]\cdot 2H_2O$, was prepared as described by Leipoldt *et al.*[5,6] All other reagents used were analytical grade and redistilled water was used throughout.

Kinetic measurements were made in acetate buffer solutions ($[CH_3COO^-]_T = 0.01$ M) by monitoring the decrease in $[W(CN)_8^{3-}]$ at 357 nm using a Pye–Unicam SP1700 spectrophotometer. The temperature was controlled to ±0.1°C. Stock solutions of sodium thiosulphate were renewed daily and standardised against potassium iodate.

The concentration of $W(CN)_8^{3-}$ at various times

* Author to whom correspondence should be addressed.

was calculated from the molar absorptivity of $W(CN)_8^{3-}$ and $W(CN)_8^{4-}$, which were determined as 1850 and 230 $M^{-1}\,cm^{-1}$ at 357 nm respectively.

The stoichiometry of the reaction at a pH of 4.5 was determined volumetrically by oxidation of the reaction product, $W(CN)_8^{4-}$, with a Ce(IV) solution using *N*-phenylanthranilic acid as indicator. This indicated that the overall reaction is represented by:

$$2W(CN)_8^{3-} + 2S_2O_3^{2-} \rightarrow 2W(CN)_8^{4-} + S_4O_6^{2-}.$$

RESULTS AND DISCUSSION

Reproducible zero-order reaction rates could only be obtained after addition of Na_2EDTA to reaction mixtures. Similar phenomena were observed for the reaction with $Fe(CN)_6^{3-}$ and $Mo(CN)_8^{3-}$. Addition of 6×10^{-6} M Na_2EDTA to reaction mixtures containing 5×10^{-4} M $W(CN)_8^{3-}$ and 0.10 M $S_2O_3^{2-}$ at 25°C and pH = 4.5 caused the reaction rate to drop by about 20% compared to the rate in the absence of EDTA. No further effect on the reaction rate was observed with a 50-fold increase in [EDTA]. All the reported runs were therefore 1×10^{-5} M in Na_2EDTA to eliminate catalysis by traces of multivalent cations. No reaction between $W(CN)_8^{3-}$ and EDTA was observed under the experimental conditions.

The kinetic results (Table 1) show that the reaction is second order with respect to $[S_2O_3^{2-}]$ and linearly dependent on $[H^+]$. The alkali-metal ion concentration and also the ionic strength of the reaction medium have no significant effect on the reaction rate. These results are consistent with the rate law:

$$R = k_{obsd}[H^+][S_2O_3^{2-}],^2 \quad (4)$$

which was also found for the uncatalysed reaction between $Fe(CN)_6^{3-}$ and thiosulphate ions.

According to the pK_a values of $H_3W(CN)_8$ ($pK_{a1} < 1$, $pK_{a2} = 1.70$, $pK_{a3} = 2.35$)[7] the main octacyanotungstate(V) species under the experimental conditions is the $W(CN)_8^{3-}$ ion. The K_{a2} value[8,9] (1×10^{-2} M) of $H_2S_2O_3$ and the observed hydrogen ion dependence indicate the existence of the association equilibrium:

$$S_2O_3^{2-} + H^+ \overset{K}{\rightleftharpoons} HS_2O_3^-. \quad (5)$$

The formation of colloidal sulphur in acidified thiosulphate solution[10] was found to involve a bimolecular reaction between $HS_2O_3^-$ and $S_2O_3^{2-}$ followed by a first-order decay of the resultant ionic

associate. The following reaction mechanism was proposed:

$$HS_2O_3^- + S_2O_3^{2-} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [HS_2O_3 \cdot S_2O_3]^{3-}, \quad (6)$$

$$[HS_2O_3 \cdot S_2O_3]^{3-} \overset{k_2'}{\rightarrow} HSO_3^- + SO_3^{2-} + 2S. \quad (7)$$

The rate constants k_1 and k_2' are comparable in magnitude.

The reduction of octacyanotungstate(V) by excess thiosulphate ions proceeds with a uniform rate until all the $W(CN)_8^{3-}$ has reacted. The excess $S_2O_3^{2-}$ then decomposes in the acidic medium as shown in eqns (6) and (7). The fact that the experimental rate constants for the oxidation of thiosulphate ions by hexacyanoferrate(III) ions ($k = 0.6\ M^{-2}\ s^{-1}$) and $W(CN)_8^{3-}$ ($k = 0.3\ M^{-2}\ s^{-1}$) are of the same order compared to that of the acid decomposition[10] of thiosulphate ions ($k = 0.5\ M^{-2}\ s^{-1}$), as well as the mutual second-order concentration dependence in $S_2O_3^{2-}$, show the first and rate-determining step of the reaction mechanism to be the same as depicted in reaction (6). This is followed by a series of fast reactions with $W(CN)_8^{3-}$ ions which can be represented by:

$$[HS_2O_3 \cdot S_2O_3]^{3-} + 2W(CN)_8^{3-} \underset{\text{fast}}{\longrightarrow} S_4O_6^{2-} + 2W(CN)_8^{4-}. \quad (8)$$

This reaction mechanism is consistent with a rate law:

$$-\frac{d[W(CN)_8^{3-}]}{dt} = 2k_1[HS_2O_3^-][S_2O_3^{2-}]. \quad (9)$$

From reaction (5) it follows that:

$$[HS_2O_3^-] = \frac{K[H^+][S_2O_3^{2-}]_T}{1 + K[H^+]}. \quad (10)$$

($[S_2O_3^{2-}]_T$ = total thiosulphate concentration)

Substitution of the latter into eqn (9) yields the rate law:

$$-\frac{d[W(CN)_8^{3-}]}{dt} = \frac{2k_1K[H^+][S_2O_3^{2-}]^2}{1 + K[H^+]}. \quad (11)$$

Since $1 \gg K[H^+]$ under the experimental conditions, eqn (11) simplifies to the observed rate law [eqn (4)] with $k_{obsd} = 2k_1K$.

From eqn (11) it is expected that a pH region would be found where the reaction is independent of hydrogen ion concentration. This region could not be reached experimentally because of the acid decomposition of thiosulphate ions.

Qualitative proof for the formation of tetrathionate was performed by comparing an IR spectrum of the yellow precipitate, formed by the reaction of tetrathionate with an excess mercurous nitrate, with that of a precipitate formed by adding an excess mercurous nitrate to a reaction mixture containing an excess of $W(CN)_8^{3-}$ relative to $S_2O_3^{2-}$. The only two peaks at 625 and 1125 cm^{-1} present in the first spectrum were also present in the second and were absent in a third recorded from a precipitate formed with an excess of mercurous nitrate added to a buffered solution of $W(CN)_8^{3-}$ in the absence of thiosulphate ions.

In addition to the above, the formation of a polythionate was proved by a method of Kolthoff and Belcher[11] using the reaction:

$$S_4O_6^{2-} + 3CN^- + H_2O \rightarrow S_2O_3^{2-} + SO_4^{2-} + SCN^- + 2HCN. \quad (12)$$

The polythionate formed by oxidation of thiosulphate ions with excess octacyanotungstate(V) ions was similarly reduced to $S_2O_3^{2-}$ using excess potassium cyanide. Determination of the formed thiosulphate ions yielded only half the originally reacted amount of thiosulphate ions, in accordance with reaction (12).

The reaction mechanisms for the oxidation of thiosulphate ions by the cyano complexes of iron(III) and tungsten(V) compared to that of molybdenum(V) in a weakly acidic medium are clearly different. This may be explained by the difference in the reduction potentials[12,13] of these complexes. Since the reduction potential of the molybdenum complex ($E = 0.80$ V) is high relative to those of the iron ($E = 0.42$ V) and tungsten ($E = 0.54$ V) complexes a difference in reaction pathway as discussed earlier, for the reduction of $Mo(CN)_8^{3-}$ ions by thiosulphate ions, can be expected.

REACTIONS OF XENON DIFLUORIDE: OXIDATIVE FLUORINATION OF METHYL DERIVATIVES OF THE *p*-BLOCK ELEMENTS

ALAN M. FORSTER and ANTHONY J. DOWNS*
Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 6 *January* 1985; *accepted* 20 *February* 1985)

Abstract—A survey has been carried out to determine how xenon difluoride reacts with methyl derivatives of *p*-block elements, Me_nX ($n = 3$, X = N, P, As, or Sb; $n = 2$, X = O, S, or Se; $n = 1$, X = Cl, Br, or I), on the basis of NMR measurements, tensimetric and IR analysis of the gaseous products, and mass balances. The reaction proceeds smoothly in most cases, although a Freon like CCl_3F may be needed as a moderator; the rate of the reaction seems to reflect the basicity of the substrate Me_nX. The difluoride Me_nXF_2 is formed in the cases where X = P, As, Sb, Se, or I. The scope of xenon difluoride in these conditions as a mild selective oxidative fluorinating agent is illustrated by the synthesis of the known compounds $(CF_3)_2XF_2$ (X = S or Se) and the novel compound $Me(CF_3)SeF_2$. By contrast, cleavage of C–H bonds, with the formation of CH_2F derivatives, is the predominant path in the cases where X = N, O, or S, and cleavage of C–X bonds, with the formation of MeF, occurs in the cases where X = Cl or Br.

Oxidative fluorination of an organic derivative of a *p*-block element X can take one of three courses: (i) difluorine-addition at X, (ii) fluorination at one or more carbon atoms of the organic groups with the formation of C–F bonds, and (iii) cleavage of X–C bonds. All three paths are liable to be followed more-or-less indiscriminately when such a derivative reacts with molecular fluorine in normal circumstances. Additional paths are created, moreover, by the increasing range of oxidation states open to the *p*-block elements in the later groups of the Periodic Table: situations such as these accentuate the need for selective methods of fluorination. The search for improved selectivity has led recently to the development of low-temperature procedures involving molecular fluorine diluted with an inert carrier,[1] albeit with varying degrees of success.[2] Receiving considerable attention too have been various fluorides, e.g. SF_4, halogen fluorides, and AgF_2, which have been used for example to promote changes of the type

$$R_nX \rightarrow R_nXF_2,$$

where R = alkyl, aryl, or perfluoro-organo groups; $n = 3$ for X = P, As, or Sb;[3] $n = 2$ for X = S, Se, or Te;[4] and $n = 1$ for X = I.[5] Such studies show that unsubstituted alkyl groups like CH_3 are the organic ligands most susceptible to fluorination.

Xenon difluoride[6] has much to commend it as a selective fluorinating agent of organic[7] as well as inorganic[8] derivatives: it can be prepared, purified, and manipulated with comparative ease and safety; when it acts as a fluorinating agent, moreover, it has the great attraction of affording in elemental xenon a highly volatile, inert co-product. On the other hand, it can be rather sluggish in its action. That it is capable of selective fluorination has been established by the reaction reported to occur with iodomethane,[9] viz.

$$MeI + XeF_2 \rightarrow MeIF_2 + Xe.$$

By contrast, we have shown that the reaction with dimethyl sulphide in a non-acidic medium results in fluorination at carbon with the formation of CH_2FSMe and hence the cation $[Me_2SCH_2SMe]^+$.[10]

$$Me_2S + XeF_2 \rightarrow \underset{\downarrow Me_2S}{\underline{CH_2FSMe + HF}} + Xe$$
$$[Me_2SCH_2SMe]^+[F(HF)_n]^-$$

* Author to whom correspondence should be addressed.

The difference between the behaviours of dimethyl sulphide and iodomethane prompted us to extend our initial investigation to determine the nature and scope of the reactions which occur between xenon difluoride and the methyl derivatives of *p*-block elements in Groups V (N, P, As, and Sb), VI (O, S, and Se), and VII (Cl, Br, and I). Here we report the results of this survey.

RESULTS

(i) *Methyl derivatives of group V elements*

(a) *Trimethylamine.* The attack of trimethylamine by molecular fluorine[11] or cobalt(III) fluoride[12] gives rise to a host of degradation products; with molecular chlorine or bromine, however, it is said to form an adduct formulated as $[Me_3NX]^+X^-$ (X = Cl or Br).[13] We have found that xenon difluoride reacts explosively with trimethylamine even when diluted with trichlorofluoromethane ($Me_3N:CCl_3F$ = *ca* 1:20) at room temperature. However, increased dilution ($Me_3N:CCl_3F$ = *ca* 1:400) results in a smooth reaction with the release of one mole of xenon gas for every mole of xenon difluoride taken. Evaporation of the solvent leaves a sticky solid product which dissolves in liquid sulphur dioxide; the ^1H and ^{19}F NMR spectra of the solution indicate the presence of a complex mixture of products in which the only components to be identified were $[Me_3NH]^+$ and HF arising presumably from attack of the C–H bonds. Chlorination of trimethylamine by vanadium tetrachloride results similarly in the formation of the $[Me_3NH]^+$ cation.[14] With xenon difluoride, as with vanadium tetrachloride, it is likely that trimethylamine is oxidised to the intermediate $[Me_2N{=}CH_2]^+X^-$ (X = F or Cl); this reacts in turn with an excess of the amine with elimination of HX to form $[Me_3NH]^+X^-$ and unidentified products derived possibly from the carbene Me_2NCH.[14,15]

(b) *Trimethyl-phosphine, -arsine, and -stibine.* Controlled oxidative fluorination of the trimethyl derivatives Me_3X (X = P, As, or Sb) to the corresponding difluoride Me_3XF_2 has not been described previously. Instead trimethylphosphorus difluoride has normally been prepared by metathesis involving a trimethylphosphorus(V) precursor, e.g. $Me_3PO + SF_4$[16] or $Me_3PS + SbF_3$,[17] although an unpublished report[18] alludes to its formation from Me_3P by the action of SF_4. Trimethylarsenic and trimethylantimony difluoride have been prepared by the action of aqueous silver fluoride on the corresponding dichloride[19] and dibromide[20] respectively, or, better, by the action of sodium fluoride on the dichloride in an acetonitrile medium.[21]

Xenon difluoride reacts explosively on contact with the liquid trimethyl compounds Me_3X (X = P, As, or Sb) at or near ambient temperatures. However, dilution of the trimethyl compound with trichlorofluoromethane (e.g. $Me_3X:CCl_3F$ = *ca* 1:100) results in a smooth reaction at room temperature with the quantitative evolution of one mole of xenon gas for every mole of xenon difluoride taken. Evaporation of the solvent leaves a colourless residue which is a liquid (X = P) or a solid (X = As or Sb) at room temperature, and which is shown by its ^1H and ^{19}F (and ^{31}P for X = P) NMR spectra to be the difluoride Me_3XF_2. The difluoride is free from any contaminant detectable by its NMR spectrum and a mass balance shows that it can be isolated in greater than 90% yield based on the amount of xenon difluoride taken (see Table 1). Hence xenon difluoride provides a highly efficient single-step route from Me_3X to the corresponding difluoride Me_3XF_2. Previous reports[9b] have established that similar reactions occur, not only with Ph_3P, but also with species like Ph_2PH and *cyclo*-$C_6H_{11}PH_2$ the P–H bonds of which remain intact during oxidative fluorination.

A deuteriochloroform solution of the difluoride Me_3XF_2 in contact with dry caesium fluoride and held in a Teflon-FEP cell[10,22] gives rise to well-resolved NMR spectra at ambient temperatures (35–40°C), as displayed for example in Fig. 1. Previous accounts of the NMR spectra disclosed only

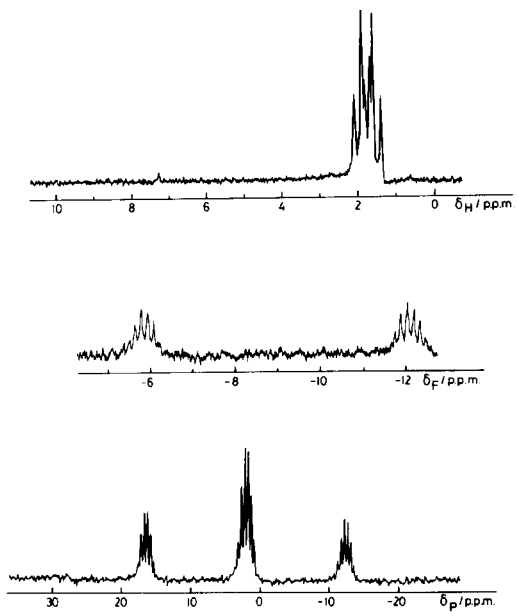

Fig. 1. 60 MHz ^1H, 84.6 MHz ^{19}F and 36.43 MHz ^{31}P NMR spectra of Me_3PF_2 in $CDCl_3$ solution.

unresolved features at ambient temperatures, although the NMR parameters quoted for all three species Me_3XF_2 (X = P,[17] As,[19] or Sb[23]) are close to those we have measured (see Table 2).

(c) *Behaviour in hydrogen fluoride solution.* As reported previously,[10] xenon difluoride reacts with a hydrogen fluoride solution of dimethyl sulphide or the adduct $Me_2S \cdot BF_3$ to form the cation $[Me_2SF]^+$. However, no similar reaction occurs with either trimethylamine or trimethyl-phosphine in hydrogen fluoride solution. No xenon is evolved when xenon difluoride is introduced into such a solution at room temperature, and the ^1H NMR spectrum of the solution shows that the cation $[Me_3XH]^+$ (X = N or P) survives unchanged. A hydrogen fluoride solution of trimethylphosphorus difluoride at ambient temperatures yielded ^1H and ^{19}F NMR spectra consisting of broad resonances; cooling the sample to 0°C caused the resonances to be resolved into the multiplets characteristic[17] of the fluorotrimethylphosphonium cation, $[Me_3PF]^+$ (Table 2). Hence trimethylphosphorus difluoride resembles dimethylsulphur difluoride[10] under these conditions in its ionisation in accordance with the equation

$$Me_3PF_2 + nHF \rightarrow [Me_3PF]^+[F(HF)_n]^-.$$

The immunity of four-coordinate phosphorus, as in the cation $[Me_3PH]^+$, to attack by xenon difluoride is also strikingly illustrated by the very recent report of the following reaction[24]

in which the coordinated PF_2 but not the PEt_3 ligands undergo oxidative fluorination. This is perhaps the most telling example yet of the selectivity which can be achieved through the use of xenon difluoride as a fluorinating agent.

(ii) *Methyl derivatives of group VI elements*

(a) *Dimethyl ether.* In contrast to the potentially explosive reaction between xenon difluoride and either dimethyl sulphide[10] or dimethyl selenide (q.v.), xenon difluoride reacts extremely slowly with liquid dimethyl ether in Teflon apparatus at ambient temperatures. Crystals of xenon difluoride are consumed by the liquid over a period of several days with the evolution of xenon gas. The ^1H and ^{19}F NMR spectra of the liquid showed, in addition to the ^1H resonance associated with the excess of dimethyl ether, resonances attributable to fluoromethyl methyl ether, CH_2FOMe. This compound has been prepared previously by the action of a metal fluoride on chloro- or bromomethyl methyl ether, and characterised by its vibrational and microwave spectra.[25] The relevant NMR parameters which we have determined are listed in Table 2 together with those of the related molecules CH_2FSMe and CH_2FSeMe.

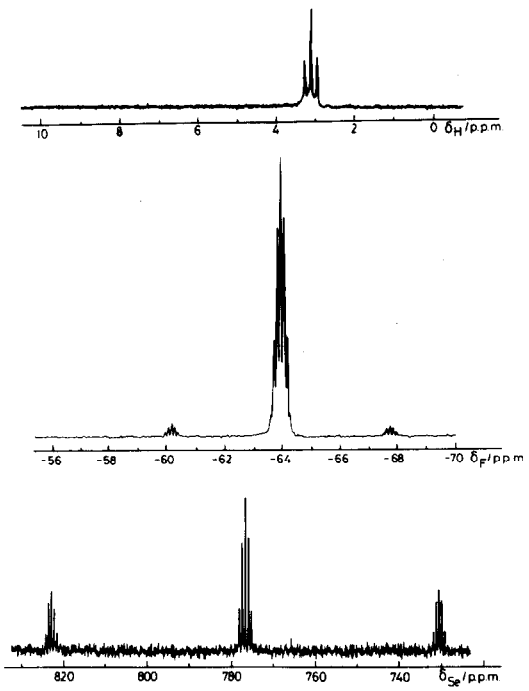
(b) *Methylsulphur compounds.* Xenon difluoride reacts with dimethyl sulphide diluted in trichlorofluoromethane in a matter of minutes at room temperature to form initially CH_2FSMe; the corresponding reaction in hydrogen fluoride solution yields $[Me_2SF]^+$.[10] On the evidence of the ^1H and ^{19}F NMR spectra, methyl trifluoromethyl sulphide, $MeSCF_3$, behaves in a similar fashion yielding either the hitherto unknown CH_2FSCF_3 in non-acidic conditions or the novel sulphonium cation $[Me(CF_3)SF]^+$ in hydrogen fluoride solution. Neat methyl trifluoromethyl sulphide reacts slowly with xenon difluoride at 20°C but not at all in the presence of caesium fluoride. Neat bis(trifluoromethyl) sulphide reacts quantitatively with xenon difluoride in 24 h at 20°C to yield the known compound $(CF_3)_2SF_2$[4(a),26] as the major sulphur-containing product formed in accordance with the reaction

$$(CF_3)_2S + XeF_2 \rightarrow (CF_3)_2SF_2 + Xe.$$

The sulphides Me_2S and $MeSCF_3$ react also with xenon difluoride in hydrogen fluoride solution in the presence of boron trifluoride to give adducts best formulated as $[Me_2SF]^+[BF_4]^-$[10] and $[Me(CF_3)SF]^+[BF_4]^-$;[27] a fuller account of these and related compounds will be given elsewhere.[28]

Thus, provided that neither of the substituents in an organic sulphide RR'S is susceptible to fluorination, xenon difluoride offers a route to the corresponding sulphur(IV) compound $RR'SF_2$, as shown previously in the cases where R = R' = Ph[29] and R = aryl group, R' = CF_3.[30]

(c) *Methylselenium compounds.* Dimethyl selenide has been shown to react with silver(II) fluoride affording dimethylselenium difluoride, Me_2SeF_2, in 22% yield.[4(c)] We have shown that the selenide dissolved in either trichlorofluoromethane or anhydrous hydrogen fluoride reacts with xenon difluoride at room temperature with the quantitative release of xenon and the formation of dimethylselenium difluoride in yields exceeding 90% (based on the amount of XeF_2 taken). At room temperature and in the presence of a small amount of caesium fluoride, a deuteriochloroform solution of the dimethylselenium difluoride gives rise to well-resolved first-order ^1H, ^{19}F, and ^{77}Se NMR spectra



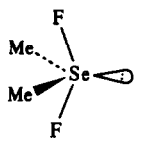


Fig. 2. 60 MHz ^{1}H, 84.26 MHz ^{19}F and 17.04 MHz ^{77}Se NMR spectra of Me_2SeF_2 in $CDCl_3$ solution.

(see Fig. 2). Where comparisons can be made, the NMR parameters thus derived tally closely with those reported earlier;[4(c)] the identity of the neat difluoride has also been confirmed by elemental analysis and Raman spectroscopy.[31] All the spectra are consistent with the presence of Me_2SeF_2 molecules having the structure I with the two methyl groups occupying equatorial sites and the two fluorine atoms axial sites of a trigonal bipyramid centred on the selenium atom, although the comparatively low volatility of the compound at room temperature[4(c)] points to strong intermolecular interactions in the condensed phases.

I

At ambient temperatures a very dilute hydrogen fluoride solution of dimethylselenium difluoride exhibited a single ^{1}H resonance ($\delta_H = 3.3$); at -40°C the resonance was resolved into a triplet ($\delta_H = 3.2$, J(FH) = 8.5 Hz); a more concentrated solution gave a resonance which remained unresolved even at temperatures as low as -70°C. Hence it appears that dimethylselenium difluoride, unlike its sulphur analogue,[10] exists in hydrogen fluoride solution as undissociated molecules.

In a non-acidic medium dimethylselenium difluoride is appreciably more stable than its sulphur analogue[10] with respect to the elimination of hydrogen fluoride. However, decomposition in accordance with the equation

$$Me_2SeF_2 \rightarrow CH_2FSeMe + HF$$

occurs very slowly at ambient temperatures. Thus, after a deuteriochloroform solution of the compound has been allowed to stand for 10 weeks, the ^{1}H and ^{19}F resonances due to Me_2SeF_2 are found to have broadened and lost the multiplicity originating in H–F coupling. In addition, the spectra reveal the simultaneous appearance of new resonances attributable to the novel compound CH_2FSeMe (see Table 2).

Neat methyl trifluoromethyl selenide reacts smoothly with xenon difluoride at room temperature with the near-quantitative formation of the novel compound methyl(trifluoromethyl)selenium difluoride, $Me(CF_3)SeF_2$, in accordance with the equation

$$MeSeCF_3 + XeF_2 \rightarrow Me(CF_3)SeF_2 + Xe.$$

A colourless mobile liquid scarcely volatile at room temperature, the product has been characterised by elemental analysis and by its ^{1}H, ^{19}F, and ^{77}Se NMR spectra (see Table 2 and Fig. 3) and vibrational spectra (see Table 3). It shows no sign of

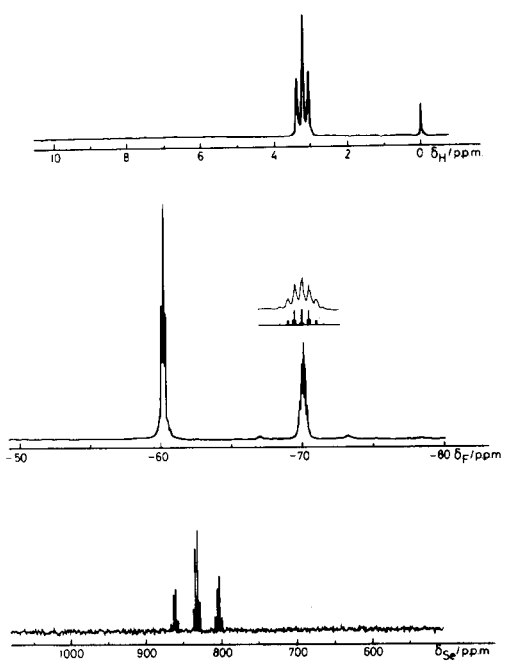

Fig. 3. 60 MHz ^{1}H, 84.26 MHz ^{19}F and 17.04 MHz ^{77}Se–{^{1}H} NMR spectra of $Me(CF_3)SeF_2$ in $CDCl_3$ solution.

decomposition over a period of 5 weeks at room temperature (cf. Me_2SeF_2).

Liquid bis(trifluoromethyl) selenide reacts slowly but quantitatively with xenon difluoride to yield bis(trifluoromethyl)selenium difluoride, $(CF_3)_2SeF_2$. This relatively volatile compound (vapour pressure *ca* 35 mmHg at room temperature) has been produced otherwise by fluorination of the selenide with either chlorine monofluoride[4b] or silver difluoride;[32] the electron-diffraction pattern of the vapour implies that the molecule has a skeleton derived from a trigonal bipyramid with equatorially sited CF_3 and axially sited F ligands.[32] We find that it reacts immediately on contact with borosilicate glass to give the white solid selenoxide $(CF_3)_2SeO$.

On the evidence of these experiments, xenon difluoride appears to be particularly well suited to the preparation of diorgano derivatives of selenium tetrafluoride, $RR'SeF_2$ (where R and R′ may be the same or different organic groups). Where the organic groups contain C–H bonds, the diorganoselenium difluoride is much slower to eliminate hydrogen fluoride than is the corresponding sulphur compound.

(iii) *Methyl derivatives of group VII elements*

Gibson *et al.* have detected methyliodine difluoride, $MeIF_2$, by its ^1H and ^{19}F NMR spectra as a product of the reaction between xenon difluoride and iodomethane.[9] We have confirmed that xenon difluoride reacts smoothly with an excess of liquid iodomethane in the presence of caesium fluoride at room temperature with the quantitative evolution of xenon gas and the development of the resonances associated with methyliodine difluoride[9]

$$MeI + XeF_2 \rightarrow MeIF_2 + Xe.$$

Standing at room temperature for several hours causes the initially colourless iodomethane solution to assume the deep purple colour characteristic of elemental iodine. The ^1H and ^{19}F NMR spectra of the solution testify to the decay of the methyliodine difluoride with the formation of fluoromethane;[33] there are no signs of higher iodine fluorides.

Xenon difluoride reacts much more slowly with liquid chloromethane or bromomethane at room temperature but there is no spectroscopic evidence of the species $MeXF_2$ (X = Cl or Br). The evolution of xenon gas is accompanied by the development of a yellowish-green (MeCl) or yellowish-brown (MeBr) colouration, and fluoromethane is identified as the sole hydrogen- and fluorine-containing product in each case by the ^1H and ^{19}F NMR spectra of the solution[33] and by the IR spectrum displayed by the vapour of the material volatile at −112°C.[34] The evidence available points to cleavage of the C–X bond in accordance with the equation

$$2MeX + XeF_2 \rightarrow 2MeF + X_2 + Xe.$$

DISCUSSION

Xenon difluoride is now well characterised with respect to certain aspects of its chemistry, e.g. in its ability to act as an electrophilic fluorinating agent[7] and its capacity to release fluoride ions with the formation of the cationic species $[XeF]^+$ and $[Xe_2F_3]^+$.[6] Some of its reactions are subject evidently to catalysis by traces of acid.[6,35] However, the response of xenon difluoride to donor species is relatively sparsely charted and attempts to exploit any acidic character in the formation of the trifluoroxenate(II) anion, $[XeF_3]^-$, have proved fruitless.[36]

Xenon difluoride reacts with donor molecules of the type Me_nX, where $n = 1$–3 and X is a *p*-block element belonging to Groups V–VII, and the facility of the reaction appears to parallel the base strength of Me_nX, as illustrated by the following variations of reaction rate: (a) $Me_3As > Me_2Se > MeBr$; (b) $Me_2X \gg MeXCF_3 > (CF_3)_2X$ (X = S or Se). With trichloro fluoromethane or the neat reagent as the solvent in the presence of caesium fluoride, the cation $[XeF]^+$ is unlikely to function as an intermediate. A more plausible mechanism involves interaction between the donor molecule and molecular XeF_2 functioning as a Lewis acid. The lowest unoccupied molecular orbital of XeF_2 possesses σ-symmetry and is anti-bonding in character (see Fig. 4).[6,37] The symmetry of this frontier orbital is expected to encourage the approach of the donor atom X along the principal axis of the F–Xe–F molecule. Such a model is consistent with the changes in energy exhibited by the antisymmetric Xe–F stretching mode when XeF_2 is exposed to different environments.[38] Thus, the energy is reported to decrease from 555 cm^{-1} for the gaseous molecule and 547 cm^{-1} for the solid to 538, 533, 532, or 530 cm^{-1} for the molecule dissolved in CCl_4, MeCN, $MeNO_2$, or dioxan respectively. As the donor capacity of the solvent increases and the molecule relaxes its grip on the electrons occupying the HOMO, the energy gap between this HOMO and the LUMO of XeF_2 is narrowed; as a result charge-transfer from the solvent to XeF_2 is enhanced, but at the expense of the Xe–F bond strength.

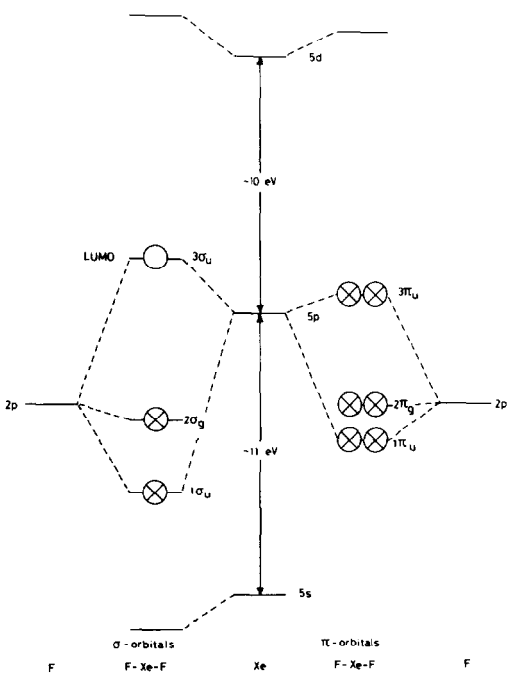

Fig. 4. One-electron orbital energy diagram for XeF_2, adapted from Ref. 37.

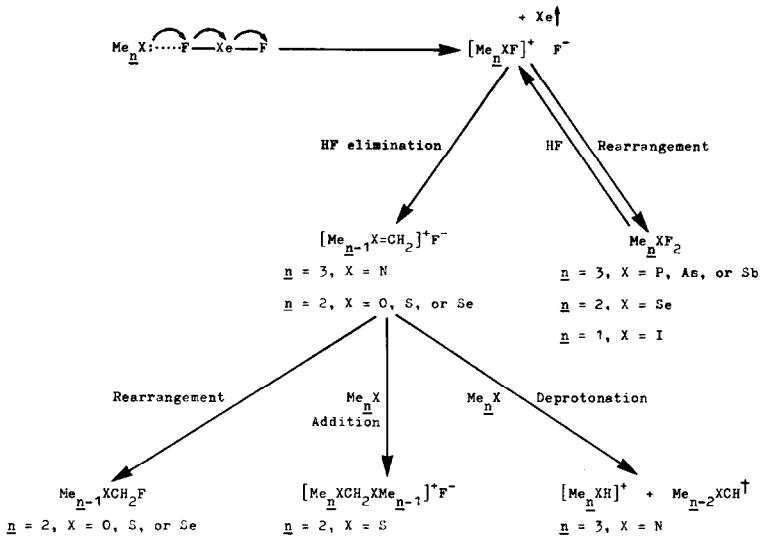

A possible sequence for the subsequent reactions between Me_nX and XeF_2 is depicted in Scheme 1. Transfer of charge proceeds with the formation of the ion-pair $[Me_nXF]^+F^-$ which may then rearrange to form the molecular difluoride Me_nXF_2. Alternatively, depending on the strength of the X–F bond and the basicity of Me_nX, the ion-pair may eliminate HF to form the intermediate $[Me_{n-1}X{=}CH_2]^+F^-$. This in turn may suffer one of three possible fates: (i) rearrangement to give the molecular monofluoromethyl derivative $Me_{n-1}XCH_2F$ (as when $n = 2$ and X = O, S, or Se); (ii) addition to another molecule of Me_nX to give a derivative of the cation $[Me_nXCH_2XMe_{n-1}]^+$ (as when $n = 2$ and X = S);[10] or (iii) elimination of HF in the presence of Me_nX to give the cation $[Me_nXH]^+$ and the carbene $Me_{n-1}XCH$ which is susceptible to polymerisation and other secondary reactions (as seems to be the case when $n = 3$ and X = N).[14,15]

If the molecular difluoride Me_nXF_2 is thermally fragile, there is the risk that the threshold temperature required to initiate selective but highly exothermic fluorination with xenon difluoride is too high to permit the survival of the desired product. Such is the case with X = S ($n = 2$).[10] With the most strongly basic substrates, like Me_3N and Me_3P, protonation yielding the cation $[Me_nXH]^+$ occurs to such an extent in acid solution as to leave insufficient free base to react at an appreciable rate with xenon difluoride.

On the other hand, the feebly basic haloalkane molecules MeX (X = Cl, Br, or I) react very slowly with xenon difluoride, and their pattern of reaction differs from that outlined above. Although iodomethane undergoes oxidative addition initially to form methyliodine difluoride, the mechanism for the overall reaction

$$2MeX + XeF_2 \rightarrow 2MeF + X_2 + Xe$$

(X = Cl, Br, or I)

† Polymerises or undergoes other secondary reactions; see Refs. 14 and 15.

Scheme 1.

is not immediately apparent. We propose that the underlying reaction with a haloalkane molecule involves a simple nucleophilic attack by fluoride anion, either real (formed for example via heterolytic fission of XeF_2) or incipient (in XeF_2 itself). Such a process, although slow at ambient temperatures, is favoured with the haloalkanes partly by default (i.e. for want of the basic properties needed to promote difluorine-addition), partly by the strength of the C–F bond formed and the ease of displacement of halide anions (cf. the corresponding leaving groups $[Me_{n-1}X]^-$; $n = 3$, X = N, P, As, or Sb; $n = 2$, X = O, S, or Se)

$$F^- + MeX \rightarrow MeF + X^-.$$

The halide anions are then oxidized by XeF_2 (or perhaps $MeIF_2$ where X = I) to the elemental halogen

$$2X^- + XeF_2 \rightarrow X_2 + Xe + 2F^-.$$

We cannot account for our results simply on the basis of the elimination of MeF by thermal decomposition of the halogen(III) fluoride $MeXF_2$ since this would be expected also to give rise to the appropriate halogen monofluoride, or at least its disproportionation products (e.g. $Br_2 + BrF_3$ or $I_2 + IF_5$).[39] Furthermore, the cleanliness of the reactions and the absence of molecules such as CH_2FX (X = Cl, Br, or I)[40] counter suggestions that fluorination with xenon difluoride takes place through a predominantly free-radical mechanism.[6,7]

Despite these complications, xenon difluoride emerges as a highly efficient and selective agent for the conversion of several organic derivatives of the *p*-block elements R_nX to the corresponding difluorides R_nXF_2. The specificity of the reactions, combined with the volatility and immunity to side-reactions of the co-product—elemental xenon—offer significant advantages over the use of reagents like elemental fluorine or the halogen fluorides.

EXPERIMENTAL

Caution. Xenon difluoride reacts explosively with the methyl derivatives Me_nX ($n = 3$, X = N, P, As, or Sb; $n = 2$, X = S or Se) in the absence of a diluent. Although the reactions are moderated with CCl_3F or HF as the diluent, suitable shielding should be employed at all times.

Apparatus. Experiments were carried out with a vacuum system constructed in Teflon-FEP tubing with PTFE couplings and needle valves (Production Techniques Ltd.). Apparatus was conditioned before use by exposure overnight to fluorine gas at a pressure of 1 atm.

A conventional glass vacuum system was available for the purification of other reagents and CCl_3F (B.D.H.) prior to its use as a diluent. A nitrogen-filled glove-box was used for the storage and transfer of xenon difluoride and other solid materials.

Chemicals. Xenon difluoride was prepared by exposure to sunlight of a Pyrex bulb containing an equimolar xenon–fluorine mixture, typically for about 1 week.[41] Caesium fluoride (Alfa, 99.9%) was

used as supplied, whereas hydrogen fluoride (B.D.H., 99.8%) was purified before use by double distillation from Teflon-FEP traps held at −63°C. The following reagents were obtained from commercial sources: trimethylamine (B.D.H.), dimethyl ether (B.D.H.), dimethyl sulphide (B.D.H.), dimethyl selenide (Alfa), and the haloalkanes MeX (X = Cl, Br, or I; all B.D.H.). Trimethyl-phosphine, -arsine, and -stibine were prepared by standard procedures.[42] The compounds $(CF_3)_2X$ and $Hg(XCF_3)_2$ (X = S or Se) were kindly made available by Professors A. Haas and W. Gombler; the monomethyl derivatives $MeXCF_3$ were prepared by the reaction between $Hg(XCF_3)_2$ and neat iodomethane at 70°C for 2–4 days. Each volatile reagent was typically purified by fractional condensation *in vacuo* and its purity checked by reference to its vapour pressure at an appropriate temperature and to the IR spectrum of its vapour.

Spectrometers. NMR spectra were recorded with the aid of four different spectrometers, a JEOL PMX-60 (^1H, 60 MHz), a Perkin–Elmer R32 (^1H, 90 MHz; ^{19}F, 84.6 MHz), a JEOL FX-90Q FT spectrometer (^1H, 89.56 MHz; ^{19}F, 84.26 MHz; ^{77}Se, 17.04 MHz), and a Brüker WH-90 FT instrument (^{31}P, 36.43 MHz). Each sample was normally sealed in a section of FEP tubing 5–10 cm long and 4 mm in external diameter which was inserted into a standard 5 mm precision NMR tube.[10,22] Chemical shifts were referenced, where possible, to internal $SiMe_4$ or CCl_3F; ^{77}Se and ^{31}P shifts were measured by sample interchange using as external standards neat Me_2Se and 85% H_3PO_4 in D_2O respectively. With hydrogen fluoride solutions, ^1H shifts were measured by sample interchange using CH_2Cl_2 ($\delta_H = 5.30$ ppm) as a secondary standard.

IR spectra of vapours were measured with a Pye Unicam Model SP 2000 spectrophotometer. Raman spectra of liquid samples, measured with a Spex Ramalog 5 spectrophotometer, were excited at $\lambda =$ 514.5 nm using the output from a Spectra-Physics Model 165 Ar^+ laser.

Reactions with XeF_2. A typical experiment was performed with a vessel constructed from PTFE components (Chemcon, Production Techniques Ltd.) and heat-moulded Teflon-FEP tubing, the internal capacity being 5–10 cm^3. The reaction chamber was loaded with 50–200 mg (0.3–1.2 mmol) of xenon difluoride and *ca* 50 mg (0.33 mmol) of finely powdered caesium fluoride; in addition, *ca* 5 mg of caesium fluoride was introduced into a side-arm intended to contain the NMR sample. The reagent was co-condensed with the xenon difluoride to give the proportions substrate: $XeF_2 > 1:1$, together with CCl_3F (2–5 cm^3) where necessary as a moderator. The mixture was then allowed to warm up to room temperature. With the completion of the reaction, material volatile at low temperatures (−45 to −95°C) could be removed and assayed by tensimetric and IR measurements. The less volatile component remaining in the reaction chamber could then be weighed before transfer either by distillation or by decanting the neat liquid or a solution into the side-arm which was sealed for analysis, typically by NMR spectroscopy. Essential details of the different experiments are summarised in Table 1.

Elemental analysis of some of the less volatile products was performed by the Analytische Laboratorien Elbach, Engelskirchen, West Germany with the following results (%).

Compound		C	H	F	Se
Me_2SeF_2	found	16.18	3.94	25.35	53.45
	calc.	16.34	4.11	25.84	53.70
$Me(CF_3)SeF_2$	found	11.95	1.59	47.11	39.04
	calc.	11.95	1.51	47.26	39.28
$(CF_3)_2SeO$	found	10.15	—	48.69	33.86
	calc.	10.31	—	48.93	33.89

Details of the IR and Raman spectra of liquid methyl(trifluoromethyl)selenium difluoride are given in Table 3; the features may be interpreted by analogy with the vibrational analyses carried out previously on the compounds Me_2SeF_2[31] and $(CF_3)_2SeF_2$.[4b]

Acknowledgements—We thank the S.E.R.C. for research grants and the award of a research studentship (to A.M.F.) and Christ Church, Oxford for the award of a Graduate Scholarship (also to A.M.F.); we are grateful also to Professors A. Haas and W. Gombler for providing samples of the trifluoromethyl compounds $(CF_3)_2X$ and $Hg(XCF_3)_2$ (X = S or Se), and to Dr. M. C. Grossel and Mr. D. R. Parkinson for practical assistance with some of the NMR measurements.

NMR STUDIES OF MIXED-LIGAND IRON(III) DITHIOCARBAMATES

KRZYSZTOF DRABENT* and LECHOSŁAW LATOS-GRAŻYNSKI
Institute of Chemistry, University of Wrocław, 50-383 Wrocław, F. Joliot-Curie 14, Poland

(*Received* 14 *November* 1984; *accepted* 20 *February* 1985)

Abstract—^{1}H NMR studies of mixed-ligand iron (III) dithiocarbamates have been carried out using the following ligands: *N*,*N*-diethyldithiocarbamate, morpholinyl-*N*-, and piperidyl-*N*-carbodithioate. The ligand exchange equilibria gave all species of the general formula $Fe(dtc)_n(dtc')_{3-n}$, where $n = 0$–3 with nearly random statistical distribution of $Fe(Et_2dtc)_n(morphdtc)_{3-n}$ complexes. Magnetic moments of the mixed-ligand complexes have been determined. Both the magnetic moment and isotropic shift temperature dependences confirmed the cross-over properties of these mixed-ligand complexes.

The possibility of preparing mixed-ligand iron(III) dithiocarbamates of type $Fe(dtc)_2(dtc')$ was first suggested by Wickman and Trozzolo.[1] The formation of such complexes in solution has been reported on the basis of NMR[2–6] and electrochemical[7] studies. It has been found that equilibration takes place in a few minutes leading to the mixture of complexes of general formula $Fe(dtc)_n(dtc')_{3-n}$ ($n = 0$–3).[2,6,7] The radioisotopic exchange studies of tris-dithiocarbamate iron(III) complexes had confirmed the previous kinetic observation.[8] Tsipis *et al.*[9] and Wajda *et al.*[10] had prepared the title complexes in the solid state according to the Wickman and Trozzolo's method[1] and had concluded that the discussed compounds showed the "cross-over" behaviour.

The problems in preparation of mixed-ligand dithiocarbamate complexes have been discussed recently.[5,6] Particularly it is not possible to investigate the magnetic properties of the title compounds in the solid. However, an attempt has been made to determine the solution magnetic properties of the mixed-ligand complexes. An application of the ^{1}H NMR spectroscopy makes possible, at least in principle, the determination of the magnetic susceptibility and composition of the equilibrium mixture of $Fe(dtc)_n(dtc')_{3-n}$ ($n = 0$–3) complexes. As a result, the magnetic properties of the particular form could be determined. Additionally, the temperature dependence of isotropic shifts provided some information related to the spin state of each species existing in solution.

* Author to whom correspondence should addressed.

The present investigation has been undertaken to determine the magnetic properties of the mixed-ligand iron(III) dithiocarbamates by means of the ^{1}H NMR spectroscopy.

EXPERIMENTAL

The sodium diethyldithiocarbamate was commercially available (Merck, F.R.G.) and used as received. Sodium morpholinyl-*N*-, and sodium piperidyl-*N*-carbodithioate were prepared as previously described.[11] $Fe(dtc)_2Cl$ complexes were prepared by the reaction of anhydrous $FeCl_3$ and the sodium salt of the dithiocarbamate ligand in anhydrous ethanol.[1] $Fe(dtc)_3$ complexes were prepared by a standard method[12] and recrystallized from chloroform. The mixed-ligand iron(III) dithiocarbamates were prepared by published methods[9,10] by reaction between stoichiometric amounts of the appropriate chloro complex, $Fe(dtc)_2Cl$, and a salt of dtc'. The isolated product was used without purification. The composition of the product is discussed in the Discussion section (see below).

^{1}H NMR spectra were recorded at 100 MHz on a JEOL PS 100 spectrometer. The pulse and/or CW techniques have been used depending on concentration. Magnetic moments were determined by Evans' method[13] with 2% v/v TMS as the internal reference. The corrections for the change in density of the solution with temperature were applied according to the literature.[14] The variable temperature probe was calibrated with ethanol and ethylene glycol using Van Geet's calibrations.[15] All the spectra were measured in $CDCl_3$ solutions with

concentration about 0.01 M of iron(III) complexes. The measurements were repeated three times at various concentrations.

The samples of mixed-ligand complexes were obtained in two ways: by dissolving a suitable quantity of isolated product and by dissolving appropriate $Fe(dtc)_3$ and $Fe(dtc')_3$ complexes in the required molar ratio (2:1 or 1:2). The spectrum pattern and magnetic properties did not depend on the method of the sample preparation.

RESULTS AND DISCUSSION

1. *Resonance assignments*

Equilibrium mixtures of $Fe(Et_2dtc)_3$ and $Fe(morphdtc)_3$ (denoted as FeE_3 and FeM_3, respectively) should contain four compounds with formula FeE_nM_{3-n}, where $n = 0$, 1, 2 or 3. Compounds with $n = 0$ or 3 are expected to exhibit one α-methylene proton resonance,[16] but two resonances with intensity ratio 1:2 and 2:1 are expected for compounds with $n = 1$ or 2, respectively. The metal centred intramolecular rearrangements are expected to be fast in the temperature range studied.[2,3] Therefore, a total of six α-methylene resonances should be observed for an equilibrium mixture, grouped in two groups of three, differing by their isotropic shifts. The α-methylene proton resonance spectra for the equilibrium mixtures of FeE_3 and FeM_3 in chloroform solutions at various values of ligand composition are shown in Fig. 1.

The ligand composition is specified by the quantity f_A which is defined as the molar fraction of total ligand present as Et_2dtc. The identical NMR spectra as those shown for $f_A = 0.333$ and $f_A = 0.666$ were measured for the products of the reactions aimed at the synthesis of the mixed-ligand complexes in the solid (see Experimental). A total of six α-methylene resonances are observed as expected.

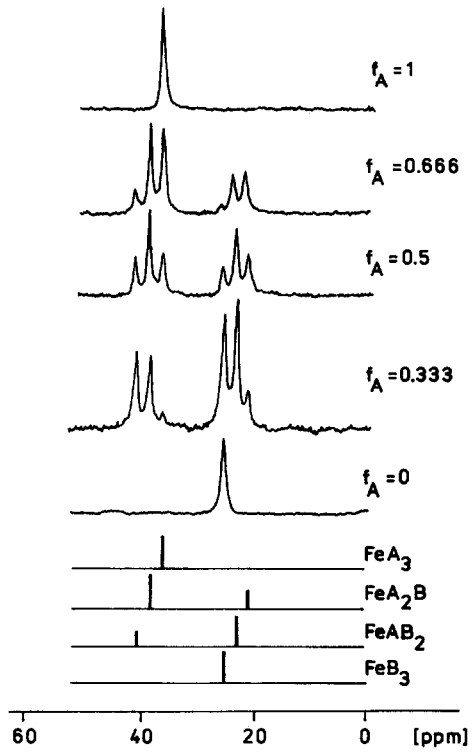

Fig. 1. α-Methylene proton resonance spectra and resonance assignments for equilibrium mixtures of $Fe(Et_2dtc)_3$ and $Fe(morphdtc)_3$ (denoted as FeA_3 and FeB_3, respectively) in $CDCl_3$ at 25°C.

The FeE_3 and FeM_3 singlets have been assigned by comparison with the respective spectra of pure complexes. Based on the dependence of signal intensities on ligand composition and the expected intensity ratios (see above) the resonance assign-

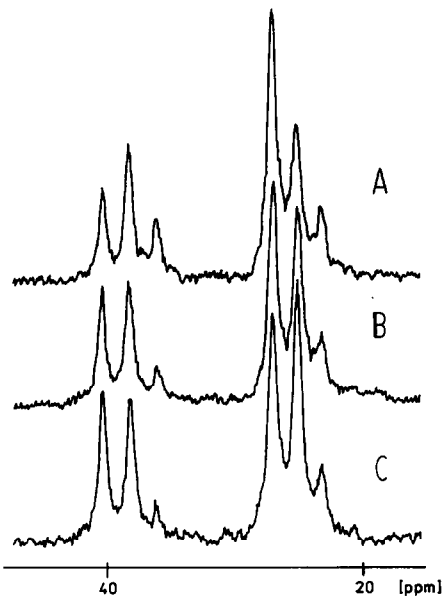

Fig. 2. ^{1}H NMR spectra of FeA_3 and FeB_3 mixture (molar ratio (1 : 2) in $CDCl_3$ at 25°C. A, 3 min; B, 5 min; C, 20 min after dissolving the sample in $CDCl_3$. Resonance assignments and notation—see Fig. 1.

ments have been made as shown in Fig. 1 and Table 1. The resonances due to CH_3 (Et_2dtc) and β-CH_2 (morphdtc) have been observed at -0.3 and -1.6 ppm, respectively (at 298 K). There is no shift differentiation depending on the form composition, so these resonances are of little interest in the present studies.

The assignment of resonances found its confirmation during the studies of equilibration process observed for the FeE_3–FeM_3 system. The NMR spectra of the FeE_3–FeM_3 mixture in $CDCl_3$ were clearly time dependent. The observed intensity changes (Fig. 2) resulted from the equilibration process. The mixed-ligand complexes were formed according to eqn (1):

$$FeE_3 + FeM_3 \rightleftharpoons FeE_2M + FeEM_2. \qquad (1)$$

The equilibrium was established during 20 min, and $t_{1/2}$ of the reaction was estimated to be less than 3 min. The resonance assignment, made in this work, allowed for the detailed determination of the equilibrium mixture composition not discussed before. The NMR spectra of the solid products (see Experimental) indicate that the exchange and equilibration have taken place during the preparation of the complexes.

The equilibrium concentrations of complexes were determined by numerical integration of their α-methylene proton resonance signals. For a completely random statistical distribution of ligands, the dependence of α_i [$i = (3-n)+1$] on ligand composition is given[17] by:

$$\alpha_i = f_A^n(1-f_A)^{3-n}\frac{3!}{n!(3-n)!}, \qquad (2)$$

where f_A is the total molar fraction of ligand A. The observed equilibrium molar fractions of FeE_nB_{3-n} complexes vs ligand composition are shown in Table 2. The values calculated for a random scrambling of ligands according to eqn (2) are also shown. It is readily seen that the FeE_3–FeM_3 system behaves nearly statistically at all temperatures studied.

2. *Magnetic susceptibility measurements*

It was shown in the previous section that the products of reactions between $Fe(dtc)_2Cl$ and Na dtc′ or of FeE_3 and FeM_3 are mixtures of all $Fe(dtc)_n(dtc')_{3-n}$ complexes according to random statistical distribution. As the molar fractions of particular compounds in the mixture were measured it was possible to determine the values and temperature dependence of magnetic moments for FeE_2M and $FeEM_2$ complexes. The magnetic moments of the FeE_3 and FeM_3 complexes as well as the magnetic moments of mixtures denoted $(FeE_2M)^{mix}$ and $(FeEM_2)^{mix}$ were measured for this purpose. Taking into account the determined distribution of compounds in the mixtures the magnetic moments of FeE_2M and $FeEM_2$ complexes were calculated by solution of two linear equations:

$$\mu^2_{(FeE_2M)^{mix}} = \alpha_1\mu^2_{FeE_3} + \alpha_4\mu^2_{FeM_3} + \alpha_2\mu^2_{FeE_2M} + \alpha_3\mu^2_{FeEM_2}$$

$$\mu^2_{(FeEM_2)^{mix}} = \beta_1\mu^2_{FeE_3} + \beta_4\mu^2_{FeM_3} + \beta_2\mu^2_{FeE_2M} + \beta_3\mu^2_{FeEM_2}$$

where α_i and β_i are the molar fractions of particular forms in the mixtures (see Table 2). The results obtained are shown in Table 3.

The magnetic moments for these complexes have shown the cross-over in the temperature range

[b] Error $\pm 0.25\ \mu_B$, calculated by the method of total differential (intensity measurement error assumed as in Ref. 22).

studied, typical for the parental tris-dithiocarbamate iron(III) compounds.[12] It is not possible to correlate the measured magnetic moments and the FeE_nM_{3-n} ($n = 0$–3) complex composition as the error in the magnetic moment calculation is too large.

The analysis of the dependence of isotropic shift vs temperature has shown the very characteristic deviation from the regular Curie behaviour. This conclusion is valid for all species present in the solution. A large increase in isotropic shifts as the temperature increased has been found (Fig. 3) whereas the Curie law requires a decrease in isotropic shifts as the temperature is increased.

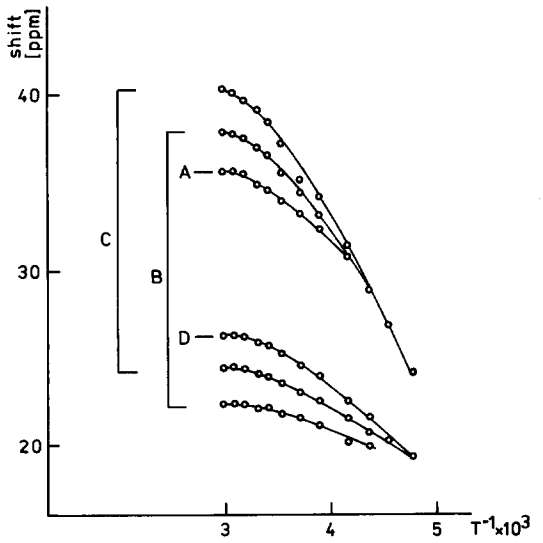

Fig. 3. Temperature dependence of the α-CH_2 chemical shifts for: A, FeA_3; B, FeA_2B; C, $FeAB_2$ and D, FeB_3 complexes. Notation—see Fig. 1.

The increase of the high spin term contribution in the ground state of iron(III) postulated for the cross-over phenomenon[16] is responsible for the observed isotropic shift dependences. This confirms explicitly the magnetic moment studies and provides a strong argument for the cross-over properties of the mixed-ligand complexes.

The pronounced dependence of the isotropic shifts on the complex composition has been found. It reflects the different distribution of the spin density between the A and B ligand depending on the iron dithiocarbamate bond characters, i.e. the total amount of spin delocalized remained constant but as the ligands were different it was shared unequally. It was observed that the sum of the differences of isotropic shifts of mixed-ligand and their parent complexes expressed by the equation:

$$\Delta = (\nu_{FeA_3} - \nu_{FeA_nB_{3-n}})n + (3-n)(\nu_{FeB_3} - \nu_{FeA_nB_{3-n}})$$

was close to zero for each system studied, as expected (see above). The sign of the difference was determined in each case by a pair of two dithiocarbamate ligands. The Et_2dtc α-CH_2 protons have been shifted upfield or downfield in the presence of morphdtc or pipdtc ligand, respectively. The influence of ligand character on the spin distribution has been determined for the variety of complexes of the formula $M(A_2A')$[18] or $M(AA')$.[19] The mechanism of the spin density delocalization of the mixed-ligand complexes is identical to that proposed for FeA_3 and FeB_3 (A and B are dithiocarbamate ligands) as the isotropic shift pattern is similar in each case[20] (see Table 1) and is determined mainly by the contact shift.

3. *Other systems*

The isotropic shifts and resonance assignments for $Fe(Et_2dtc)_n(pipdtc)_{3-n}$ and

$$Fe(pipdtc)_n(morphdtc)_{3-n}\ (n = 0\text{–}3)$$

are shown in Table 1. In this manner all binary systems including Et_2dtc–pipdtc–morphdtc ligands were investigated. The large overlapping of resonances made it impossible to study the magnetic properties of four of the six mixed-ligand complexes observed. The isotropic shift vs temperature dependences could be made in each case. The noted deviation from the Curie law allowed us to conclude that all systems studied belong to the class of cross-over complexes. The distribution of the species in the equilibrium could be measured only in a few cases. The small deviations from random statistical distributions have been found for $Fe(pipdtc)_n(morphdtc)_{3-n}$ and $Fe(Et_2dtc)_n(pipdtc)_{3-n}$ systems.

CONCLUSION

The NMR studies of the mixed-ligand iron(III) dithiocarbamate complexes have clearly demonstrated cross-over properties on the basis of magnetic susceptibility and isotropic shift analysis.

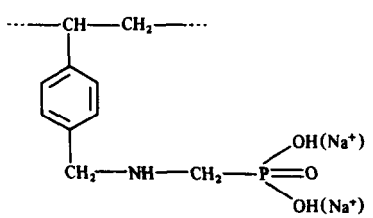
A SPECTRAL STUDY OF TRANSITION-METAL COMPLEXES ON A CHELATING ION-EXCHANGE RESIN CONTAINING AMINOPHOSPHONIC ACID GROUPS



SURESH K. SAHNI, RENE VAN BENNEKOM and JAN REEDIJK*
Department of Chemistry, Gorlaeus Laboratories, State University Leiden, P.O. Box 9502, 2300 RA Leiden, The Netherlands

(*Received* 13 *December* 1984; *accepted* 3 *April* 1985)

Abstract—The coordination mode of a commercial chelating ion-exchange resin, ES 467, containing aminomethylphosphonic acid groups anchored on a macroporous styrene–divinylbenzene copolymer, with several metal ions, such as chromium(III), cobalt(II), nickel(II), copper(II) and zinc(II) has been studied with the aid of IR, ligand field and ESR spectra. The chelating group of ES 467, aminomethylphosphonic acid, appears to bind different metal ions mainly through oxygen atoms of the phosphonic acid group, though, in the case of those species containing low-loading of metal ions, the secondary amine nitrogen atom also appears to take part in coordination. Most of the metal ions studied seem to be present as six-coordinated species in the polymeric matrix, whereas cobalt(II) species show electronic spectra which are consistent with the presence of both four-coordinated (tetrahedral) and six-coordinated (octahedral) structures of these species. The distribution coefficients for cobalt(II), nickel(II), copper(II) and zinc(II) have been determined and it appears that the resin ES 467 binds copper(II) ions selectively. An attempt has been made to find a possible relationship between the selectivity of the chelating resin and the stereochemistry of the adsorbed metal ions.

In recent years, a great deal of research effort has been expended to study the ion-selective properties of chelating ion-exchange resins and quite a few such resins are commercially available now.[1] Some of the salient features of a successful selective ion-exchange resin are its high capacity, selectivity and marked kinetics combined with its chemical and mechanical stability. The selectivity, among other things, depends on the nature of the donor atoms and different steric factors of the chelating group. However, it appears that no attempt has been made to develop a relationship between selectivity and different properties of a chelating group present in a selective ion-exchange resin. A possible approach to develop such a relationship consists in studying the stereochemistry of the chelated/adsorbed species (the term metal complexes will be used throughout this paper) on a selective ion-exchange resin with the aid of their spectral properties. Some scattered studies[2–5] on this subject are available, but much more data are required before any meaningful relationship between selectivity and various properties of ion-exchange resins could be evolved.

In continuation of our previous work on the spectral studies of metal complexes of chelating ion-exchange resins, Chelex-100[6] and Spheron Oxine,[7] the ligating behaviour of a commercial chelating ion-exchange resin (ES 467) containing aminomethylphosphonic acid groups attached to a macroporous styrene–divinylbenzene copolymer, with chromium(III), cobalt(II), nickel(II), copper(II) and zinc(II) ions has been described in this paper. The schematic tentative structure of ES 467 is depicted in Fig. 1.

ES 467

ES 467 is known to form stable complexes with low-atomic mass cations.[8] Several other chelating ion-exchange resins containing aminoalkylphosphonic acid groups anchored on different types of polymeric matrices have been developed in recent years to explore their potential in preconcentration and selective removal of certain cations and anions.[9,10] The synthesis and ion-selective properties of such chelating ion-exchange resins[11] and also those of several phosphonic acid resins, including their kinetics and ion-exchange equilibria, have been reported.[12–16] Recently, the capacity and ion-separation capabilities of ES 467 have been compared with several other commercially available chelating ion-exchange resins for its applications in hydrometallurgy.[17] It has been found that, like the picolylamine resins XF 4195 and XF 4196,[1] the aminophosphonic acid resin, ES 467, shows a moderate selectivity for copper(II) over iron(III) in acid sulfate solution compared with an iminodiacetic acid resin which shows no or limited selectivity depending on the pH. The thermodynamic aspects[18] and other applications such as maintaining the required level of calcium ions in feed brine for chlorine-alkali cells using ES 467 have recently been reported.[19]

EXPERIMENTAL

Elemental analysis, physical measurements and materials

The elemental analysis (C, H, N and P) was performed by Mikroanalytisches Laboratories of E. Pascher, Bonn, F.R.G., and P. van den Bosch, Technical University, Eindhoven, The Netherlands, and metal analyses were carried out by digesting the metal-containing beads of the resin with nitric and sulfuric acids, by atomic absorption spectroscopy, using a Perkin–Elmer 460 atomic absorption and flame emission spectrometer. IR spectra were recorded in KBr pellets on a Perkin–Elmer 580 spectrophotometer provided with an IR data station; the far-IR spectra were recorded in powdered polyethylene pellets using a freshly prepared polyethylene disc as a reference. The electronic spectra of various complexes have been recorded as diffuse reflectance on Perkin–Elmer 330 spectrophotometer also provided with a data station, using a zinc(II) complex of the same resin, ES 467, as a reference[3,6,7] for both the wet and the dried samples in the region 5000–33,000 cm^{-1}. The electronic spectra of the high-loaded (7–9% metal content) metal complexes have been recorded to find out the geometry around the metal ions under the different conditions of loading and synthesis. In the case of low-loaded complexes (*ca* 0.1–1% of metal content), the *d–d* transitions originating from the metal ions are overshadowed by intense intraligand bands and the assignments appeared to be impossible. However, in the case of high-loaded complexes, the *d–d* transitions could easily be discerned and lead to reliable conclusions. Electron spin resonance spectra at X-band frequencies at room and liquid nitrogen temperature were recorded on a Varian E-3 spectrometer.

Analytical metal salts have been used throughout and all metal-uptake experiments have been carried out in polyethylene bottles. The details of various buffer solutions used are: sodium chloride–hydrochloric acid (pH = 1–2.5), sodium acetate–acetic acid (pH = 3–6) and Tris [tris(hydroxymethyl) aminomethane]–hydrochloric acid (pH = 7). ES 467 was obtained from Duolite International Inc., France. The sodium form of the commercially available resin ES 467 was converted into its hydrogen form by a conventional method using dilute hydrochloric acid.

Determination of distribution coefficients

The distribution coefficients for cobalt(II), nickel(II), copper(II) and zinc(II) were determined by the following procedure. An accurately weighed sample of ES 467 (H^+-form) (200 ± 5 mg) was added to an appropriate metal salt solution (25 cm^3 of 0.001 M solution) buffered at a certain pH, using an appropriate buffer solution (25 cm^3) and the ionic strength of the solution was maintained at 0.3 by addition of potassium chloride or potassium nitrate. The reaction contents were shaken on an automatic shaker for *ca* 48 h at room temperature (*ca* 22°C). However, it was observed that the equilibration was generally achieved within 24 h. The metal-containing beads were filtered and washed with water, ethanol and ether, and dried *in vacuo* at *ca* 80°C for 60–72 h. Both the metal-containing solutions and metal-containing beads were analysed for their metal contents. The distribution coefficients (D) have been calculated using the following relationship:

$$D = \frac{\text{amount of metal ion per gram of dry resin}}{\text{amount of metal ion per cm}^3\text{ of solution}}.$$

Determination of capacity

The capacity of ES 467 for different metal ions was determined by a batch method. To a weighed amount of buffered ES 467 an appropriate metal salt was added in a quantity greater than its theoretical

capacity (*ca* 3 times). The reaction contents were shaken for *ca* 36 h at room temperature. The metal-containing beads were filtered and washed thoroughly with water, ethanol and ether, dried to a constant weight at *ca* 70–80°C *in vacuo* for 24 h, and analysed for their metal contents.

Preparation of different samples used for spectroscopic studies

These samples were prepared both from the sodium and hydrogen forms of ES 467. A general procedure has been adopted for the preparation of both low- and high-loaded samples. To a weighed amount of air-dried resin (200 ± 5 mg) was added the appropriate metal salt (100, 50, 25 and 10% of the theoretical capacity of the resin) and the reaction contents were buffered at a pH between 3 and 5, and shaken for 24–36 h. The samples were thoroughly washed and dried as described above. The samples used for the detection of the presence of counter ions of metal salts on the polymeric matrix were also prepared in demineralised water without using any buffer solutions. For low-loaded samples, the complexes isolated from *D* determination experiments were used.

RESULTS AND DISCUSSION

General

ES 467 has been claimed to be of general use in the removal and recovery of transition and alkaline-earth metal ions from process liquors and relatively dilute solutions.[8,17–19] Besides binding transition-metal ions, this resin also weakly binds calcium and magnesium ions, like Chelex-100 or Dowex A-1 resins containing iminodiacetic acid as functional groups.[1] The stability constants for several divalent metal with several monomeric aminoalkylphosphonic acids and their derivatives are known from the literature.[20–23] The stability constants for divalent metal ions with aminomethylphosphonic acid[20,22] and 2-aminoethylphosphonic acid,[21,23] which can be considered as ideal monomeric analogues for ES 467, have been found to follow the order: $Ca^{2+} < Mg^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Zn^{2+}$, which is in accord with the Irving–Williams order of chelate stability. The *D* for divalent cobalt, nickel, copper and zinc with ES 467 have been determined (Table 1) and the log *D* values for different metal ions appear to follow the same trend as observed in the monomeric systems. This observation has been confirmed by capacity determination of ES 467 for different metal ions. It has been found that this resin, ES 467, takes up the maximum amount of copper; however, more cobalt than nickel is taken up, despite the fact that the nickel chelate has a higher stability than the cobalt chelate[20,22] (Table 2). These results are in accord with those of Milling and West[17] who also found that ES 467 possesses a higher capacity for copper(II) ions compared to nickel(II) and iron(III), and that the capacity is lowered with the lowering of the pH and metal ion concentration of the solutions. The capacities for different metal ions are comparable when either chloride or nitrate salts of these metal ions are used, indicating that these anions do not play any significant role as far as the capacity of ES 467 is concerned.

The solution studies on metal complexes of monomeric analogues of ES 467 reveal that several types of complexes are formed in solution, although the species having a 1:1 metal:ligand stoichiometry have been found to be most stable.[20–23] On the basis of the magnitude of formation constants of copper(II), nickel(II), zinc(II), cobalt(II), magnesium and calcium ions, different binding modes of these monomeric aminoalkylphosphonic acids have been

proposed.[20,22,23] These studies were inconclusive, as no light is shed on the structure of the various metal complexes. The spectral properties of transition-metal complexes of aminoalkylphosphonic acids have been studied, but no attempt has been made to analyse the binding mode of the ligands with different metal ions under varied conditions.[24] With a view to ascertaining the binding sites in ES 467, several of its metal complexes have been prepared under different conditions of pH and concentration of metal ions. The extent of metal loading of different species is given in Table 3 and their spectral properties are discussed below.

IR spectra

The IR spectra of aminoalkylphosphonic acids[25,26] and phosphonic acids, including their polymeric derivatives,[27,28] have been reported. The IR spectra of some metal complexes of polymer-supported phosphonic acids,[29] aminoalkylphosphonic acids[24,30–34] and their metal complexes have also been reported. However, no attempt has been made to make a detailed analysis of polymer-supported aminoalkylphosphonic acids and their metal complexes. The important IR spectral bands of ES 467 and its metal complexes recorded under different conditions of pH are given in Tables 4 and 5, respectively. Aminoalkylphosphonic acids, like their carboxylic acid analogues (amino acids), also exist in zwitterion forms and have been shown to possess betaine structure as established on the basis of various analytical and spectral techniques.[33,34] The chelating ion-exchange resin ES 467, which incorporates aminomethylphosphonic acid groups anchored on a polymeric matrix has also been found to possess a zwitterion structure as established on the basis of IR spectra and is depicted in Fig. 2. The IR spectra of ES 467 samples conditioned at lower pH (less than 7) show strong bands at *ca* 1170 and 1070 cm^{-1} due to $\nu_{as}(PO_2)$ and $\nu_s(PO_2)$ vibrations of the PO_3H^- group.[25,26,31,32] A strong band appearing at *ca* 925 cm^{-1} can be assigned to a ν(P—OH) vibration.[25,26] The spectra of the samples conditioned above pH 10 show two strong bands at *ca* 1090 and 975 cm^{-1} assignable to $\nu_{as}(PO_3)$ and $\nu_s(PO_3)$ vibrations of the PO_3^{2-} group, respectively.[31,32,34] However, the spectrum of a sample conditioned between pH 7 and 10 (pH = 7.5) shows two strong bands at *ca* 1088 and 975 cm^{-1} due to asymmetric and symmetric stretching vibrations of the completely ionised PO_3^{2-} group, along with a shoulder at 1170 cm^{-1}, resembling the spectra of the samples conditioned at pH lower than 7. This indicates that the spectra of the samples conditioned between pH 7 and 10 possess the features of completely ionised and zwitterion-like forms of ES 467. The occurrence of asymmetric and symmetric stretching vibrations of the PO_3H group at higher frequencies in the samples conditioned at lower pH has been ascribed to the positive charge on the nitrogen atom.[31] The spectra of all these samples show a band at *ca* 1215 cm^{-1} due to ν(P=O) vibrations.[32] The presence of a protonated $\overset{+}{N}H_2$ group is indicated by the occurrence of bands at *ca* 1660 and 1570 cm^{-1} [24,34] in the spectra of the samples conditioned at lower pH. In fact, the resin acts as an anion-exchanger at lower pH, as indicated

by the IR spectrum of a sample of ES 467 treated with potassium nitrate which shows a strong band at *ca* 1380 cm^{-1} due to the ionic nitrate group. The spectra of the samples conditioned at higher pH show a distinct band at *ca* 3260 cm^{-1} due to ν(NH) vibrations of the unprotonated secondary amino group. On the basis of these observations, the dissociation of ES 467 is depicted in Fig. 3. These

[a] The spectra of the samples buffered at pH = 4.5 (acetate buffer) and pH = 1.0 (KNO_3) show bands at 1700 and 1380 cm^{-1}, due to the vibrations of acetate and nitrate groups, respectively.

observations are consistent with the two pK values (pK_1 = 5.38 and pK_2 = 10.4); the first one corresponds to the deprotonation of the hydroxyl group of the phosphonic moiety and the second one to the deprotonation of the amino group.[26] Thus, it appears that the possibility of coordination of the secondary nitrogen atom at lower pH seems extremely remote in view of its protonated nature and also for steric reasons, and the only potential donor or binding sites in ES 467 are the oxygen atoms of the phosphonic groups under these conditions.[32]

The important bands of the metal complexes of ES 467 prepared under different conditions are given in Table 5. It may be pointed out that only the spectra of high-loaded species have been icnluded. In the case of low-loaded samples hardly any discernible changes can be observed in the vibrations of the ligand (in this case polymer-supported aminomethylphosphonic acid) upon coordination to a metal atom. In the spectra of the metal complexes prepared with the acid form of ES 467 below pH 7, a doublet appears at *ca* 1120 and 1080 cm^{-1}, along with three more bands at *ca* 925, 985 and 1165 cm^{-1} due to different symmetric and asymmetric stretching vibrations of the phosphonic group. The occurrence of a doublet in a narrower range (*ca* 40–50 cm^{-1}) supports the coordination of the phosphonic group to the various metal ions.[24,28,29,31] The persistence of a band at *ca* 1165 cm^{-1} indicates that the betaine structure of ES 467 is also retained in the metal complexes prepared at lower pH. This again rules out the possibility of coordination of the secondary nitrogen atom to metal ions. The occurrence of several bands in the region characteristic of $\nu_{as}(PO_3)$ and $\nu_s(PO_3)$ vibrations indicates that the two hydroxyl groups of the phosphonic group are not alike.[24] The spectra of the complexes prepared from the disodium salt of ES 467 (at pH 10) also show a doublet at *ca* 1120 and 1060 cm^{-1} along with a strong band at *ca* 985 cm^{-1}, which supports the coordination of the phosphonic group to metal ions. The spectra of the air-dried samples show a broad band at *ca* 980–1120 cm^{-1}, which changes into a well-defined doublet in the spectra of the dried samples. The conspicuous absence of a band at *ca* 1170 cm^{-1} indicates the absence of a betaine structure of ES 467 in these complexes. In such cases (at higher pH) the possibility of coordination of the secondary nitrogen atom to metal ions cannot be ruled out.

The spectra of ES 467 show a number of bands in the lower region at *ca* 550–565 and 450 and 450–490 cm^{-1} which are assigned to $\delta_{as}(PO_3)$ and $\delta_s(PO_3)$ vibrations, respectively.[25,26] In the spectra of the metal complexes, the bands occurring at high

[a] The iron(III) and manganese(II) complexes have been included for comparison only.

frequencies shift to higher frequencies, whereas the band assigned to $\delta_s(PO_3)$ vibrations either remains stationary or disappears altogether. The $\delta_{as}(PO_3)$ band has been found to increase in frequency with the decrease in the ionic radii of divalent metal ions, i.e. Cu^{2+} (590 cm^{-1}) > Zn^{2+} (588 cm^{-1}) > Ni^{2+} (575 cm^{-1}) > Co^{2+} (565 cm^{-1}) ≥ Mn^{2+} (565 cm^{-1}), indicating that the strongest metal–oxygen bond is formed in the case of copper(II) ions, followed by zinc(II) and other metal ions in accord with the Irving–Williams order of metal stability. The band due to the ν(P—C) vibration occurring in the free ligand at *ca* 760 cm^{-1} remains unperturbed in the spectra of the metal complexes. From the preceding discussion, it is evident that the aminomethylphosphonic group of ES 467 exists in a zwitterion form in the lower range of pH and coordinates various metal ions mainly through the oxygen atoms (of the hydroxyl group) of the phosphonic group. The same trend has also been observed in the metal complexes prepared at higher pH; however, the possibility of the coordination of a secondary nitrogen atom cannot be ruled out as it will be shown below. In all these complexes, the possibility of coordination of the oxygen atom of the P=O group has been completely ruled out as no shift is observed in its position in the metal complexes.

An attempt has also been made to establish the presence of counter ions required to maintain the electrical neutrality of the metal complexes present in the polymeric matrix. It has been observed that the counter anions are generally washed away with buffer solutions used to maintain the pH of the reaction medium and, in turn, the electrical neutrality of the metal complexes is either maintained by deprotonation of the ligand or anions coming from the buffer solutions (for instance, acetate ions in the case of sodium acetate–acetic acid buffers) or hydroxide ions present in the polymeric matrix.[35] To solve this problem, some of the complexes of ES 467 have been prepared in an aqueous media without using any buffer solutions, using different salts of metal ions. The IR spectra of the metal complexes prepared from different salts show no trace of counter anions being present in the polymeric matrix. This is also confirmed by the elemental analysis of some of the metal chloride and nitrate complexes. This again indicates that the electroneutrality of the metal ions is maintained by deprotonation of the phosphonic acid moiety of the resin ES 467.

Electronic spectra of chromium(III) complexes

The spectral data of a few chromium(III) complexes of ES 467 are given in Table 6 and those of reference compounds in Table 7. The spectra of all complexes show well-defined, relatively strong bands in the regions 15,700–16,700 and 22,000–23,900 cm^{-1} and two shoulders are also observed on the low-energy side of these bands at *ca* 14,500 and 21,500 cm^{-1}, respectively. The spectra of these complexes bear a close resemblance to typical octahedral chromium(III) complexes, which generally show three spin-allowed bands and the highest-energy band due to the $^4T_{1g}(P) \leftarrow {}^4A_{2g}$ transition occurs above 30,000 cm^{-1}.[36,37] In addition to these spin-allowed transitions, two of the three spin-forbidden transitions have also been observed. In the present complexes, the two spin-allowed bands occurring at *ca* 16,000 and 22,500 cm^{-1} can be assigned to $^4T_{2g} \leftarrow {}^4A_{2g}$ and $^4T_{1g}(F) \leftarrow {}^4A_{2g}$ transitions, respectively.[36,37] The two bands which appear as shoulders can be assigned to the spin-forbidden transitions $^2E_g \leftarrow {}^4A_{2g}$ and $^2T_{1g} \leftarrow {}^4A_{2g}$, in increasing order of energy.[36] These spectra can further be rationalised in terms of various ligand field and nephelauxetic parameters ($10Dq$, B and β_{35}) and the values of these parameters have been computed through procedures given in the literature.[37,38] The values of $10Dq$ and B which lie in the ranges 15,740–16,720 and 593–665 cm^{-1} are comparable to those observed for the chromium(III) complexes of the monomeric aminoethylphosphonic acid and those of other oxygen-containing ligands.[24] This indicates that the functional group, aminomethylphosphonic acid, present in ES 467 coordinates or binds the chromium(III) ions through the oxygen atoms of the phosphonic acid moiety. In fact, the $10Dq$ values for the present complexes are even lower than those observed for the $[Cr(H_2O)_6]^{3+}$ complex which contains the chromosphore CrO_6. The lower $10Dq$ values have also been observed with metal complexes involving rather bulky ligands, as is the case here. In the present complexes, the exclusive coordination through oxygen atoms of the aminophosphonic acid moiety can be explained as follows. Most of the chromium(III) complexes have been prepared in the lower pH range (less than 3) conditions which are subjective to protonation of the secondary nitrogen atom and, moreover, chromium(III) ions have a pronounced tendency to bind to oxygen donors due to their "a"-class character. The monomeric analogue of ES 467, aminomethylphosphonic acid, is reported to form a chromium(III) complex having the formula $[Cr(AEP)(OH)]_2 \cdot 4H_2O$, which has been interpreted in terms of a dimeric structure having two hydroxo bridges as revealed by low magnetic moments (3.37 BM) and the IR spectrum showing characteristic bands for hydroxo bridges between 500 and 550 cm^{-1}.[20] No such observation has been made in the chromium(III) complexes of ES 467 and

Table 6. Electronic and ESR spectral data of a selection of chromium(III), cobalt(II), nickel(II) and copper(II) complexes, along with some reference compounds

[a] Chelex-100 and Dowex A-1 are commercial chelating ion-exchange resins containing iminodiacetic acid groups attached to styrene–divinylbenzene copolymers. UR-50 is also a commercial chelating resin containing (*o*-hydroxybenzyl)iminodiacetic acid incorporated into a phenol–formaldehyde condensate. BioRex-63 is a commercial resin having PO_3H_2 groups attached to a styrene–divinylbenzene copolymer and Zeo-Karb-226 is another commercial resin having carboxylic groups.

[b] AEP and PhPO stand for 2-aminoethylphosphonic and phenylphosphonic acids, respectively.

thus no exact structural analogy can be made with their monomeric analogue.

The electronic spectra of the chromium(III) complexes of ES 467 have also been compared with other chelating resins such as those containing iminodiacetic acid groups (Chelex-100 and ES 466) and multidentate aminoalkylphosphonic acid groups attached to a cross-linked polystyrene resins. The iminodiacetic acid resins and monomeric ethylenediaminotetrakis(methylenephosphonic) acids are well known to bind transition-metal ions through nitrogen and oxygen donor atoms present in these systems.[2,6,30,33,34] The values of $10Dq$ obtained for chromium(III) complexes of these resin lie around 17,240 (Chelex-100 and ES 466 with coordination of N-atoms) and 16,700 cm^{-1}, respectively, are slightly higher than those observed for our ES 467 complexes.

Electronic spectra of cobalt(II) complexes

The spectral data of a few representative complexes are given in Table 6, whereas some model and reference compounds are listed in Table 7. The ligand field spectra of most of these complexes show a cluster of bands at *ca* 6400–7500 and 15,800–21,000 cm^{-1}. It may be mentioned that most of the cobalt(II) complexes appear pink–purple when air-dried, but a distinct blue color is attained when the samples are dried *in vacuo*. This observation indicates that water may play an important role in the coordination geometry of cobalt(II) complexes of ES 467 and that water is lost upon heating. The spectra of these complexes cannot be rationalised in terms of either tetrahedral or octahedral or an intermediate coordination geometry. Instead, it appears that more than one type of cobalt(II) species is present in the polymeric matrix of ES 467. The presence of a band near 7000 cm^{-1} with multiple components (two–three) and another multi-component band near 16,500 cm^{-1} supports the presence of tetrahedral cobalt(II) species and these two bands can be assigned to $^4T_1(F) \leftarrow {}^4A_2\ (\sigma_2)$ and $^4T_1(P) \leftarrow {}^4A_2\ (\sigma_3)$ transitions in increasing order of energy.[37] Similar bands have also been observed in the spectra of the cobalt complex of monomeric aminoethylphosphonic acid which has been shown to possess a 1:2 metal:ligand stoichiometry and a tetrahedral geometry around the cobalt(II) ions.[24] The occurrence of another band at *ca* 18,500 cm^{-1} indicates that some octahedral cobalt(II) species are also present in the polymeric matrix, which is supported by the presence of a shoulder at *ca* 20,500 cm^{-1}.[37,39] In some of the complexes, the shoulder appears at higher energies, *ca* 21,500 cm^{-1}. The shifting of this band towards a higher energy indicates that cobalt(II) ions may not be exclusively coordinated to oxygen donor atoms (as is the case with chromium complexes), but some of the cobalt(II) ions may also be chelated by a nitrogen donor atom of the chelating group present in ES 467.[5,6,37] This nitrogen atom donor atom may not necessarily come from the aminoethylphosphonic acid group, but it cannot be ruled out that other nitrogen-containing species such as poly(aminomethylstyrene) or other species containing nitrogen used as a starting material for the synthesis of this resin may be present as impurities in the polymeric matrix might also coordinate to metal ions. A similar observation has also been made in the cobalt(II) and copper(II) species adsorbed on Dowex A-1 known to contain a small amount of quaternary nitrogen atoms.[5] The band appearing at *ca* 7500 cm^{-1} also appears to contain a component of octahedral cobalt(II) species, as this band splits to show a well-defined band at *ca* 9000 cm^{-1} in some of the cobalt(II) complexes. This band which occurs particularly in the case of low-loaded cobalt species prepared at relatively high pH also supports the involvement of a nitrogen atom in coordination.

Though there appears to be some overlap in the band position of the tetrahedral and the octahedral cobalt(II) species present in the polymeric matrix of ES 467, the band belonging to the tetrahedral species are clearly discernible because of their high intensity. Some ligand field and nephaulextic parameters (Dq and B) have been evaluated by taking the weighted average of the multiple bands.[37] The values of these parameters are consistently on the lower side (particularly those of Dq) of those observed for oxygen donor ligands and are comparable to those observed for the cobalt(II) complex of monomeric aminoethylphosphonic acid.[24] There is no particular trend in the Dq values of low- or high-loaded and air- or *in vacuo* dried cobalt(II) species. However, the high-loaded well-dried species show Dq values which are consistently lower (*ca* 4100 cm^{-1}) compared to those found for the low-loaded air-dried cobalt(II) samples (*ca* 4450 cm^{-1}). Thus, it appears that the high-loaded cobalt(II) species are exclusively coordinated to oxygen donor atoms, whereas in the case of relatively low-loaded species the coordination of the secondary nitrogen atom cannot be ruled out. One possible reason for the exclusive oxygen coordination in the case of high-loaded cobalt(II) species can be the additional cross-linking caused by cobalt ions resulting in the binding of the secondary nitrogen atom which is relatively close to the polymeric matrix.[40] The B values (700–800 cm^{-1}) of the cobalt complexes are about 20–30% lower than the free-ion value of cobalt and indi-

cate a moderately covalent nature for the metal–ligand bond.[37]

Electronic spectra of nickel(II) complexes

The band maxima for a selection of nickel(II) complexes are given in Table 6 and those of some reference and model compounds are given in Table 7. In general, four bands are observed in the regions 8000–9000, 12,900–13,510, 14,400–14,910 and 23,250–25,000 cm^{-1} which can be interpreted in terms of octahedral geometry for these nickel(II) complexes of ES 467. The band occurring at *ca* 14,500 cm^{-1} appears to have its origin in the spin-forbidden transition $^1E_g \leftarrow {}^3A_{2g}$ and three other bands can be assigned to $^3T_{2g} \leftarrow {}^3A_{2g}$ (σ_1), $^3T_{1g} \leftarrow {}^3A_{2g}(\sigma_2)$ and $^3T_{1g} \leftarrow {}^3A_{2g}(\sigma_3)$ transitions, respectively, in increasing order of energy.[37] The values of different ligand field parameters (*Dq* and *B*) have been calculated through the procedures documented in the literature.[6,37,38] The 10*Dq* values for most of the nickel(II) complexes lie in the range 8330–8700 cm^{-1}, except for two complexes prepared at a relatively higher pH, *ca* 7, with low-loading of the metal ions. The 10*Dq* values for these two complexes lie *ca* 9000 cm^{-1}. The lower 10*Dq* values of these nickel(II) complexes are comparable to those observed for the nickel(II) complexes of aminoethylphosphonic acid and phenylphosphonic acid in which nickel(II) ions have been postulated to be present as a NiO_6 chromophore.[24,29] In view of the comparable 10*Dq* values, it appears that the nickel(II) ions are mainly coordinated by oxygen donor atoms of ES 467 and also possess a chromophore NiO_6 (the coordination sphere is completed by water molecules like cobalt and chromium complexes). However, the 10*Dq* values of the order of *ca* 9000 cm^{-1} observed for two of the nickel(II) complexes are too high to be attributed to a chromophore NiO_6; these are rather close to nickel(II) complexes involving nitrogen and oxygen donor atoms.[6,7,41,42] It appears that, in the case of low-loaded nickel(II) complexes isolated at relatively higher pH, ES 467 behaves as a $(N, O_2)^-$ tridentate ligand. The *B* values observed for the nickel(II) complexes lie in the range 730–860 cm^{-1}, indicating a moderately covalent nature for the metal–ligand bonds present in the complexes of ES 467. However, the low-symmetry components present in these complexes can also be responsible for the very low values of *B*.[37]

Electronic spectra of copper(II) complexes

The spectral data for a selection of copper(II) complexes of ES 467 are given in Table 6 and those of some model and reference compounds in Table 7. Most of the copper(II) complexes show a broad band in the region 11,700–12,900 cm^{-1}, with one or two conspicuous shoulders on the low-energy side at *ca* 9000 and 7500 cm^{-1}. The position of the main broad band is comparable to one found in the copper(II) complexes of monomeric aminoethylphosphonic and phenylphosphonic acids.[24,29] Interestingly, the main *d–d* band assignable to the $^2T_{2g} \leftarrow {}^2B_{1g}$ transition for a distorted octahedral geometry of copper(II) complexes, occurs at a lower energy, *ca* 11,700 cm^{-1}, in the high-loaded complexes, whereas it occurs at a higher energy, *ca* 12,500 cm^{-1}, in the low-loaded complexes. This lowering in the position of the main band might possibly be due to exclusive oxygen donor coordination of the copper(II) ions, as it has been observed that the complexes having a low-loading of the metal content and isolated at higher pH show this band at a relatively higher energy at *ca* 12,900 cm^{-1}, possibly due to involvement of the secondary nitrogen atom in coordination to copper(II) ions.[43–46] Thus, it is apparent that ES 467 coordinates copper(II) ions exclusively through its oxygen donors in the high-loaded species and binds as $(N, O_2)^{2-}$ in a tridentate fashion in the low-loaded species (the coordination sphere is completed by water molecules). Tentative structures of metal complexes involving a bidentate and a tridentate ES 467 are depicted in Figs 4 and 5, respectively.

Electron spin resonance spectra

The electron spin resonance spectra of air-dried and vacuum-dried samples having different loadings of metal ions have been recorded both at room and at liquid-nitrogen temperature. The spectral data obtained for a selection of chromium(III) and copper(II) complexes are given in Table 6 and those of some model and reference compounds in Table 7. No significant difference in the ESR signal positions and their shapes has been observed in air-dried samples and in the samples dried *in vacuo* at 60°C for more than 24 h. The spectra recorded at liquid-

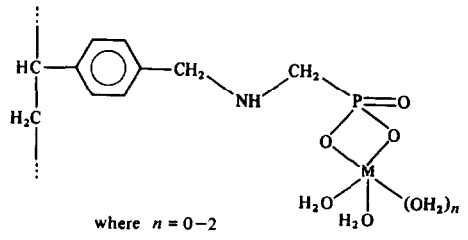

Fig. 4. Schematic structure of a metal complex of ES 467 acting as a bidentate ligand.

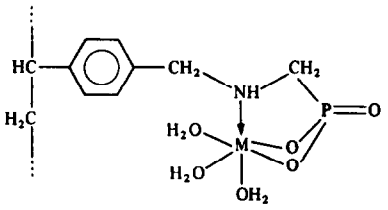

Fig. 5. Schematic structure of a metal complex of ES 467 acting in tridentate fashion.

nitrogen temperature do not show any better resolution than those recorded at room temperature. The low-loaded copper(II) samples show better resolved hyperfine splitting patterns compared to high-loaded samples, apparently because of some weak Cu–Cu interactions resulting in the disappearance of the fine structure in the latter species.

The chromium(III) complexes of ES 467 having different metal loadings show similar ESR spectra, having broad signals with $g = 5.10$–5.20 and 1.97–1.98 values, resulting from zero-field splitting.[2] It is, however, not possible to draw any useful conclusions about the bonding mode of ES 467 with chromium(III) ions.

In the case of copper(II) complexes, it has been found that the low-loaded copper(II) species (*ca* 0.1–1% metal content) show well-resolved spectra both at room and at liquid-nitrogen temperature, facilitating the evaluation of different ESR parameters. The species having a high loading of copper(II) ions (more than 1%) also show some hyperfine splitting which is rather poor and does not show any improvement even at lower temperatures. The values of $A_{\|}$, $g_{\|}$ and $g_{\perp}$ calculated for both the low- and the high-loaded species in air-dried and vacuum-dried states lie in the ranges 125–135 G, 2.31–2.35 and 2.06–2.14, respectively. The values observed for $A_{\|}$ are comparable to copper(II) species absorbed on Amberlite IRC-50 (a carboxylic acid containing resin), Dowex-50W (a resin with sulphonic acid group) and BioRex-63 (a resin having phosphonic acid groups attached to a cross-linked polystyrene copolymer) and hexaaquacopper(II) ions, all having a CuO_6 chromophore.[41,42,47] These values of $A_{\|}$ are much lower than those observed for copper(II) ions adsorbed or chelated to Dowex A-1,[46] Chelex-100,[6] ES 466[48] and Unicellex UR-50[2] (all having iminodiacetic acid or its derivative anchored on different types of polymeric matrices) possessing a common chromophore, $CuNO_5$. On the basis of the results obtained, it appears that ES 467 coordinates mainly through oxygen atoms, whereas the possibility of the secondary nitrogen atom coordinating as well in very low-loaded species cannot be completely ruled out. For such species, rather complex spectra have been obtained and the complexity appears to arise from the presence of more than one type of copper(II) species on the polymeric matrix, in which smaller $g_{\|}$ and larger $A_{\|}$ values can be distinguished, suggesting that some species with chromophore $CuNO_3O_2$ are also present.[7,30]

The fact that the g and A values of air-dried and vacuum-dried copper(II) species present in the ES 467 matrix do not differ significantly from each other indicates that copper(II) ions are chelated by aminomethylphosphonic acid groups of the resin. This behaviour of ES 467 resin differs from that of other resins containing phosphonic acid groups, such as BioRex-63 or Duolite C-63 (ES-63), in which copper(II) ions are present as $[Cu(H_2O)_6]^{2+}$, interacting only by means of electrostatic forces.[47] This is also confirmed by a kinetic study of BioRex-63 in which the rate-determining step for the exchange of uni- and divalent cations has been found to be diffusion through the particle bead.[12,49] The behaviour of copper(II) ions present in the matrix of ES 467 resembles to other chelating resins such as Dowex A-1 or Chelex-100 in which the presence of chelated copper ions has been established by ESR spectra showing almost similar g and A values for hydrated and dehydrated species.[6,46,47]

Stoichiometry and tentative structure of the metal complexes of ES 467

The elemental analysis of ES 467 reveals that it contains about 10% divinylbenzene which makes it a quite rigid structure. It has been pointed out in the case of Dowex A-1 or Chelex-100 containing iminodiacetic acid groups anchored on a styrene–divinylbenzene (2%) copolymer that it cannot form 1:2 (metal:ligand) complexes like monomeric iminodiacetic acid, because of the unfavourable position of two iminodiacetic acid groups caused by its cross-linked structure. Indeed, it has been observed and confirmed by several workers[2,6,41,46,47] that Dowex A-1 or Chelex-100 only form 1:1 (metal:ligand) complexes with several di- and trivalent metal ions. The possibility of the formation of 1:2 (metal:ligand) metal complexes in the case of ES 467 which contains a highly cross-linked matrix seems, therefore, even more unlikely. To confirm this, some of the high-loaded metal complexes of ES 467 have been analysed and it has been found that they conform to 1:1 metal:ligand stoichiometry, keeping in view that all the coordination or exchange sites are not accessible because of the highly cross-linked nature of the

polymeric matrix [10% cross-linking agent (divinylbenzene)]. It has been observed that with an increase in the cross-linking the exchange capacity of styrene–divinylbenzene copolymer-based ion-exchanger resins decreases appreciably and a 10% cross-linked sulfonated styrene–divinylbenzene copolymer takes up only *ca* 51% of tetrabutylammonium ion, for example, relative to Na^+ capacity.[50] In fact, the degree of cross-linking is generally higher than the known weight percentage of divinylbenzene content, because of some additional intrastrand cross-linking which creeps in during the modification of the polymers.[51]

The chelating group, aminomethylphosphonic acid groups present in ES 467, is potentially a tridentate ligand having two bonding sites at a phosphonic acid group and one coordination site at the secondary nitrogen atom. The structures of metal complexes of aminoalkylphosphonic acids have been discussed in detail elsewhere.[33,34] It has been observed that the amino-nitrogen atom normally does not participate under acidic conditions because of its protonated nature[31] and only phosphonic acid groups chelate the metal ions. One of the most favourable mode of chelation of the phosphonic acid group is the formation of a four-membered ring through the deprotonation of two P—OH groups, though the formation of a four-membered ring through bonding of one of the OH groups and the coordination of the oxygen atom (P=O) has also been reported.[29(a)] However, in the present complexes of ES 467, it has been found to be unaffected and thus it appears that it does not take part in coordination or bridging. These complexes are mainly formed by the chelation of two oxygen atoms of the OH groups of the phosphonic acid moiety forming a four-membered group and the rest of the coordination sphere is completed by three or four water molecules, as has been observed in the case of metal complexes of iminodiacetic acid resins.[2,6,41,42,46] This type of chelation by phosphonic acid results in the formation of more stable complexes compared to those formed by the corresponding carboxylic acids, because of the fact that the P—O bond lengths are longer than the C—O bond lengths, which results in a wider "bite", with a more favourable bond angle close to 90°. The higher stability of the metal complexes of the aminomethylphosphonic acid containing chelating resin, ES 467, is also augmented by the formation of hydrogen bonds between coordinated water molecules and the phosphono groups, as observed also in the case of alkylphosphate complexes.[27(b)] However, it appears that ES 467 can also act as a chelating agent in which the secondary nitrogen atom can participate in coordination as well, and the rest of the coordination sphere is again completed by water molecules as discussed in the preceding sections.

The selectivity and stereochemistry of metal complexes of chelating resins

The selectivity of chelating ion-exchange resins generally follows the same order as that of chelate stability suggested by Irving and Williams.[52] However, several deviations have been found from this order in the case of highly selective ion-exchange resins which bind almost exclusively only one metal ion over a given pH range.[48,53] This indicates that there are some other factors which play an important role in imparting selectivity to chelating ion-exchange resins. It is well known that the ultimate stereochemistry of metal complexes depends on several factors such as the denticity, the nature of the donor atoms, steric configurations, the rigidity and distribution of electrical charge on donor atoms of a ligand and the nature of a metal ion. A proper combination of all these factors can lead to enhanced selectivity of chelating systems and this appears to be more true for polymer-supported chelating ligands in which steric factors are expected to play an important role.

ES 467, containing aminomethylphosphonic acid groups, appears to combine some of these properties. This resin has been found to bind copper(II) ions selectively over a range of pH, but it also takes up other metal ions such as cobalt(II), nickel(II), zinc(II), iron(III) and chromium(III) like the chelating resins containing iminodiacetic acid groups. However, ES 467 appears to be more selective for copper(II) ions than iminodiacetic acid type resins because of some fundamental differences in the structure and stereochemistry of the phosphonic acid and carboxy groups. The phosphate ion is almost tetrahedral (distorted tetrahedron) with a three-fold symmetry axis. A carboxylate ion is planar with a two-fold symmetry and different valence angles and bond lengths. Besides, the phosphonic acid group possesses two hydroxyl groups and an extra oxygen atom in the P=O grouping which can coordinate to metal ions in different fashions than the carboxy groups, contributing to enhanced selectivity and coordination capacity.[33,34] The selectivity of ES 467 for copper(II) ions can be attributed to special steric and electronic factors present in aminoalkylphosphonic acid type ligands and also to the flexible nature of the copper(II) ion which can easily adapt different stereochemical features.[44,45] It is this flexibility of copper(II) ion which leads to the formation of different types of polyhedra around it under the different conditions of loading and pH which, in turn, lead to the formation of different types

of species in solution, some of which are taken up selectively and others are not.[48,53,54]

It has been found that the capacity of ES 467 for cobalt(II) ions is higher than that of nickel(II) ions at a given pH (Table 2), though the stability of nickel(II) complexes is higher than those of cobalt(II) complexes of the monomeric aminoalkylphosphonic acids.[21–23] This again points towards the role of some steric factors and the flexible nature of metal ions (in this case cobalt) which can make stable four- and six-coordinated complexes with equal ease with the same set of donor ligands.

THE INTERACTION OF SILVER IONS WITH THE ISOTHIOCYANATOPENTA-AMMINECHROMIUM(III) CATION

HERVINE MILLER
Chemistry Department, University of the West Indies, Cave Hill, Barbados

(*Received* 18 *January* 1985; *accepted* 3 *April* 1985)

Abstract—The reaction of the isothiocyanatochromium(III) ion with silver ions produces adducts of the type $[Cr(NH_3)_5NCSAg_n]X_{n+2}$. For X = ClO_4, $n = 1$ and for NO_3, $n = 2$.

There is significant interaction between silver ions and $[M(NH_3)_5NCS]^{2+}$ cations as in reaction (1):

$$M(NH_3)_5NCS^{2+} + nAg^+ \rightleftharpoons M(NH_3)_5NCAg_n^{(n+2)+}, \quad (1)$$

where M = Cr, Co, Rh. Values of log K for $n = 1$ are approximately 10^3.[1] The complexes thus formed are thought[2,3] to account for the enhanced rates of aquation of the penta-ammines in the presence of silver ions. For $[Cr(NH_3)_5NCS]^{2+}$ there is spectral evidence for the existence of intermediates with $n = 1$–3 at 25°C[2] and the silver-assisted aquation reaction has been reported[2] as proceeding through such an intermediate, with $n = 1$ at higher temperature (76.4°C). Similar observations have also been reported for $[Co(NH_3)_5NCS]^{2+}$[3] and $[Rh(NH_3)_5I]^{2+}$.[4]

The isolation and characterization of two solid adducts of the isothiocyanatopenta-ammine chromium(III) cation is reported here. These adducts are analogous to, but less stable than, those of cobalt previously reported.[3]

EXPERIMENTAL

Analytical grade reagents were used throughout and distilled water was passed through a column of Permutit "Biodeminrolit" before use. Silver perchlorate solution was prepared by neutralizing freshly prepared silver carbonate with perchloric acid. Isothiocyanatopenta-ammine chromium(III) perchlorate was prepared and analysed as previously reported.[1] All reactions were carried out in the dark or in diffused light.

Preparation and analysis of adduct

Silver adducts were precipitated as follows. Solid $[Cr(NH_3)_5NCS](ClO_4)_2$ was added to a 2 mol dm^{-3} solution of silver perchlorate in a mole ratio Cr : Ag of approximately 1 : 10. The resulting suspension was shaken vigorously and allowed to react at room temperature, approximately 25°C, for a few minutes. A peach-yellow powder precipitated. For the nitrate adduct a similar procedure was followed with silver nitrate being used instead of perchlorate. The resulting precipitate was yellow-buff in colour. The adducts were collected at pump, washed with dry ethanol and dried over silica gel in a darkened vacuum desiccator.

The freshly prepared adducts were analysed quantitatively for chromium and silver by atomic absorption spectrophotometry, after decomposition of an accurately known weight of adduct in aqueous perchloric acid (*ca* 10^{-3} mol dm^{-3}). Found: Cr, 8.72; Ag, 17.2. Calc. for $[Cr(NH_3)_5NCSAg](ClO_4)_3$: Cr, 8.64; Ag, 17.93%. Found: Cr, 7.9; Ag, 31.8. Calc. for $[Cr(NH_3)_5Ag_2](NO_3)_4$: Cr, 7.89; Ag, 32.75%. The ratio Cr : Ag in the adducts was confirmed by spectrophotometric analysis using dithiozone.

RESULTS AND DISCUSSION

The reaction of $[Cr(NH_3)_5NCS]^{2+}$ with silver ions in aqueous solution at 25°C is too fast for study by conventional stopped-flow spectrophotometry.[2] However, in the solid state there is very little evidence of reaction between the adducts.

The silver adducts are only partially soluble in

Table 1. Wavenumber (cm^{-1}) and assignments[5] of bands in spectra of silver adducts of $[ML_5NCS]^{2+}$ (L = NH_3) and silver thiocyanate

Compound	ν_{C-N}	ν_{C-S}	δ_{NCS}	Reference
AgSCN	2145	899, 749	445	3
$[CoL_5NCS](ClO_4)_2$	2110	853	502	3
$[CoL_5NCSAg](ClO_4)_3$	2135, 2185	839, 760	505–510	3
$[CoL_5NCSAg_2](NO_3)_4$	2120	825, 735	505, 458	6
$[CrL_5NCS](ClO_4)_2$	2070	858	458	This work
$[CrL_5NCSAg](ClO_4)_3$	2080, 2160	830, 784	492	This work
$[CrL_5NCSAg_2](NO_3)_4$	2080	840, 825	477, 463	This work

water, even at elevated temperatures, and decompose to give a pink solution and a black powder. After filtration and cooling, this solution corresponds quantitatively to $[Cr(NH_3)_5NCS]^{2+}$. The black powder is, presumably silver oxide since the solutions were not acidified.

In the solid state, decomposition of the adducts was evident in a relatively short time—the nitrate in 3 days, the perchlorate in about 2 weeks. This shows that the compounds are less stable than the cobalt(III) analogues. Analyses showed that the perchlorate and nitrate salts were 1 : 1 and 1 : 2,

$$[Cr(NH_3)_5NCSAg](ClO_4)_3$$

and

$$[Cr(NH_3)_5\ NCSAg_2](NO_3)_4,$$

respectively. The differences are probably due to solubility effects.

Special features of the IR KBr disc spectra compared to those of the cobalt(III) analogues and AgSCN are shown in Table 1. Assignments were made according to published data.[5]

Resolved bands in the region 3100–3300 cm^{-1} $[Cr(NH_3)_5NCS](ClO_4)_2$ are undoubtedly due to N–H stretches and, while unaltered in the 1 : 1 adduct, are significantly changed in the 1 : 2 compound. ν_{C-N} for the pure penta-ammine is at 2070 cm^{-1} and the splitting to 2080 and 2060 cm^{-1} for the 1 : 1 adduct is consistent with a simple bridging SCN group.[5,6] A single band at 2080 cm^{-1} is observed for the 1 : 2 adduct as for the analogous cobalt complex.[3] ν_{C-S} values between 830 and 860 cm^{-1} are assigned to MNC–S and lower values to M'S–CN. A large shift is observed for $\rho_{r(NH_3)}$, being 737 cm^{-1} in $[Cr(NH_3)_5NCS]^{2+}$, and 751 and 760 cm^{-1} in the 1 : 1 and 1 : 2 adducts respectively.

^{1}H AND ^{13}C NMR OF PLATINUM PORPHYRINS—III. PLATINUM DEUTEROPORPHYRIN IX DIMETHYL ESTER

LIONEL R. MILGROM
Imperial College of Science and Technology, Department of Chemistry, Exhibition Rd, London SW7 2AZ, U.K.

(*Received* 14 *November* 1984; *accepted* 3 *April* 1985)

Abstract—^{1}H and ^{13}C NMR spectra of the title compound are reported and peaks assigned by comparison with the free-base porphyrin. Long-range spin–spin coupling is observed between platinum and the macrocyclic protons and carbon atoms. *Meso*-protons are assigned from line-broadening observed for three of the peaks, possibly caused by residual coupling of these protons to the pyrrole β-protons. Allylic coupling of the pyrrole β-protons to adjacent methyl groups is also noted, and supports the tautomeric model of an 18-atom delocalisation pathway around the macrocycle. The ^{1}H NMR spectrum of the title compound is more concentration-dependent than that of the free-base porphyrin and probably reflects additional macrocyclic interactions via the platinum atoms.

Previous papers in this series[1,2] described long-range coupling in the NMR of the symmetric platinum porphyrins, PtTPP[1] and PtOEP.[2] An attempt to observe similar couplings in the NMR of platinum protoporphyrin IX dimethyl ester [PtPPIXDME (**1**)] was unsuccessful,[2] owing to excessive line-broadening of all the peaks. Those due to the internal reference and solvent were, however, sharp and well-defined. These observations were rationalised in terms of the aggregation of **1** in solution to an oligomer of unknown constitution.

If monomers of **1** aggregate via their platinum atoms, then attempts to prepare platinum complexes of other type IX porphyrins should also yield oligomers with line-broadened NMR spectra. If, on the other hand, oligomerisation is due to some, as yet, unspecified interaction involving platinum and porphyrin vinyl groups, then oligomerisation should be confined to **1** only: other type IX platinum porphyrins should give sharp, well-defined NMR spectra.

To test this hypothesis, platinum deuteroporphyrin IX dimethyl ester [PtDPIXDME (**3**)] was chosen because it should demonstrate in the same molecule all the couplings found separately in the NMR of PtTPP[1] and PtOEP.[2] This paper, therefore, reports the ^{1}H and ^{13}C NMR of the type IX platinum porphyrin, **3**.

RESULTS AND DISCUSSION

Platinum was inserted into **2** using the method of Büchler and Puppe[3] and the product (**3**) gave a clear melting point, unlike **1**. In addition, the FAB spectrum of **3** exhibited a discrete molecular ion, (M^+, m/z = 731). The UV/visible spectrum of the orange-coloured **3** gave sharp, well-defined bands, in contrast to the less-intense and broadened bands of the brown-coloured **1**. These data would indicate much less aggregation in solution for **3**, in contrast to that supposed for **1**.

Assignment of the ^{1}H NMR spectrum of **3** depended on data obtained for the free-base porphyrin (**2**) in these laboratories and elsewhere. This will be discussed first.

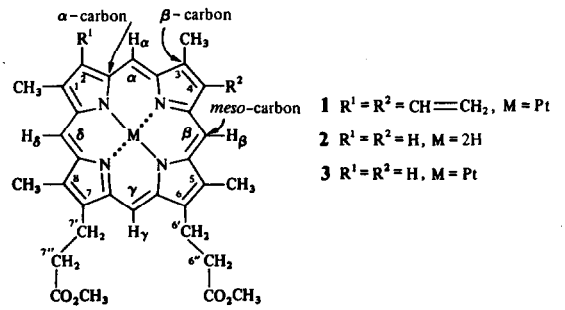

Fig. 1.

Proton assignments for the peripheral substituents and the pyrrole β-positions are in broad agreement with previous results.[5–7] The 5- and 8-methyl groups are to higher field than the 1- and 3-methyls, the latter identifiable by allylic coupling to the pyrrole β-protons (1 Hz). This leads to clearly resolved doublets for these methyl groups in dilute (4 mM) solution and as broadened peaks at a higher (20 mM) concentration. This confirms the results of Clezy *et al.*[6] and Sano *et al.*,[7] but is a feature unremarked on by Janson and Katz[5] who, in the present view, wrongly assign the 1- and 3-methyl groups to higher field.

The pyrrole β-protons appear as two partly-resolved overlapping quartets in dilute solution (allylic coupling to the 1- and 3-methyls), and as a broadened singlet at higher concentration. The *meso*-protons appear as four singlets around 10 ppm (see Table 1).

With this data, the ^{1}H NMR spectrum of **3** can be assigned (see Table 1). In dilute solution (4 mM), the methyl groups appear as a triplet and two singlets at a slightly lower field (assigned to those at the 5- and 8-positions). The triplet, 1- and 3-methyls, arises from two overlapping doublets (J = 1.1 Hz), caused by allylic four-bond coupling to the 2,4-pyrrole β-protons.[6,7] At a higher concentration (20 mM), the triplet becomes two broadened singlets, this time at a lower field to the 5- and 8-methyls.

Again, in dilute solution, the 2,4-pyrrole β-protons are a well-defined quartet[7] (J = 1.2 Hz), presumably due to allylic coupling to the 1,3-methyl groups. Flanking the quartet are partly-resolved Pt satellites ($^4J_{^1H-^{195}Pt}$ = 12.5 Hz) as reported earlier for PtTPP.[1] At a higher concentration, the quartet broadens into two poorly-resolved overlapping quartets (J = 1.2 Hz). Only the Pt satellites outside of them are resolved, giving an apparently larger ^{1}H–^{195}Pt four-bond coupling constant (15.3 Hz).

Assignment of the *meso*-protons is tentative. Three

[h] As *g*, Pt satellites, J = 15.3 Hz.
[i] Broad.
[j] Broad + Pt satellites, J = 4.5 Hz.

of the peaks are broader than the fourth by about 0.5 Hz. This may be due to concentration effects or residual long-range coupling of the three *meso*-protons to the 2,4-pyrrole β-protons. If the latter, the γ-*meso*-proton is assigned to the narrower peak as being furthest from the 2,4-pyrrole β-protons. At low concentration, the γ-*meso*-proton appears to higher field than the α-, β- and δ-*meso*-protons while at higher concentrations the assignment is reversed. In addition, at a higher concentration, Pt satellites are observed on all the *meso*-protons, the coupling constant ($^4J_{^1H-^{195}Pt}$ = 4.5 Hz) being in agreement with the value reported earlier for PtOEP.[2] In dilute solution, the *meso*-protons are too close for individual Pt satellites to be resolved.

Practically all the proton resonances are deshielded by dilution, but the effect is approximately twice as great for the platinum complex (**3**) as for the free-base porphyrin (**2**). This agrees with an earlier report on nickel mesoporphyrin IX dimethyl ester[5(b)] and probably reflects increased dimer formation in solution, presumably mediated via platinum d_{z^2}-orbitals.

The allylic coupling constant, J = 1.2 Hz (cf. 1.5–1.7 Hz in model systems[8]) points to a significantly diminished bond-order for the β–β pyrrolic linkage of **3**.[6] This would implicate the periphery of the molecule in an 18-atom delocalisation pathway,[6] which favours the tautomeric model[9–11] for the platinum porphyrin skeleton as opposed to a 16-atom pathway involving a formal porphyrin dianion.[12] This contradicts the usual dianion formalism for the macrocycle in metalloporphyrins.

The ^{13}C NMR spectrum of **3** differs from **2** in two respects. Firstly, Pt satellites are observed and clearly resolved on all the *meso*-carbons, the 2,4-pyrrole β-carbons, and the 5,6,7,8-pyrrole β-carbons. The coupling constants are similar to those reported for PtTPP[1] and PtOEP[2] (see Table 2). Secondly, the pyrrole α-carbons are shifted upfield so that they overlap with the 1,3-pyrrole β-carbons. Consequently it proved impossible to distinguish the various two- and three-bond ^{13}C–^{195}Pt couplings for these carbons.[1,2]

The *meso*-carbons appear in two groups. The higher-field group is close to that observed for the γ- and δ-carbons of TIDPIXDME(OH,H_2O),[13] themselves assigned on the basis that substitution of the neighbouring pyrrole β-carbons by alkyl groups shifts the *meso*-carbons upfield. The lower-field group are, therefore assigned to the α- and β-*meso*-carbons.

That **3** gives well-defined UV/visible and NMR spectra compared to **1**[2] implies that the latter's vinyl groups are involved in some, as yet, unspecified interaction with Pt. As **1** could be a useful NMR probe for haemoproteins (beause of its potential coupling of Pt to the porphyrin's protons and carbons), synthetic efforts to **1** will in future be directed to modification of 2,4-substituents of an already-existing type IX platinum porphyrin.[14]

EXPERIMENTAL

NMR spectra were obtained in the FT mode on a Bruker WM 250 NMR spectrometer. UV/visible spectra were obtained on a Pye–Unicam SP8-400 spectrophotometer in $CHCl_3$ using approximately 10^{-5} M solutions. The melting point was obtained using a hot-stage microscope. The FAB spectrum was obtained using a Vacuum Generators VG 7070 in a matrix of 2,2′-thiodiethanol. Platinum was

N-METHYL-2,2′-BIPYRIDYLIUM ION (bpyMe) COMPLEXES: SYNTHESIS AND CYCLOMETALLATION OF $[Pd(bpyMe)_2Cl_2]^{2+}$

FRANZ L. WIMMER* and SMITA WIMMER
School of Natural Resources, University of the South Pacific, Suva, Fiji

(*Received* 14 *January* 1985; *accepted* 3 *April* 1985)

Abstract—On prolonged heating in water $Pd(bpyMe)Cl_3$ (bpyMe = *N*-methyl-2,2′-bipyridylium cation) cyclometallates to give monomeric $Pd(bpyMe\text{-}H)Cl_2$, whereas the immediate products are a mixture of *trans*-$[Pd(bpyMe)_2Cl_2]^{2+}$ and anionic palladium species. $[Pd(bpyMe)_2Cl_2]^{2+}$ was synthesised directly from Na_2PdCl_4 and on heating gives $Pd(bpyMe\text{-}H)Cl_2$ with the elimination of bpyMe and H^+.

Two areas of current interest are the metal complexes of cationic ligands[1,2] and cyclometallated compounds.[3] We describe here the facile cyclopalladation of the cationic ligand, the *N*-methyl-2,2′-bipyridylium ion [bpyMe (**1**)]. We have previously shown that **1** forms zwitterionic complexes of the type $M(II)(bpyMe)Cl_3$ with both 3*d* metals[4] and palladium (**2**) and platinum (**3**).[5] $Pt(bpyMe)Cl_3$ (**3**) slowly cyclometallates on heating to give $Pt(bpyMe\text{-}H)Cl_2$ (**5**).[5]

$Pd(bpyMe)Cl_3$ (**2**) is insoluble in all solvents except very hot water, from which it can be recovered unchanged on cooling as brownish orange crystals. However, when the heating is prolonged† **2** cyclometallates readily to give pale yellow needles of $Pd(bpyMe\text{-}H)Cl_2$ (**4**) which is sparingly soluble in boiling water and insoluble in all other solvents.‡

The IR spectrum of **4** is identical to that of **5**.§‖ The medium intensity bands at 335 and 265 cm^{-1} are assigned as Pd—Cl stretching modes. This is consistent with the dichloro ligands being *trans* to a sigma C-donor and an N-donor ligand respectively. However, it is not possible to distinguish between the two isomeric structures for **4** shown in Fig. 1. Both the neutral monomer (**I**) and the dicationic dimer (**II**) should give rise to similar frequencies for their respective Pd—Cl stretching absorptions.[6]

The molar conductivity of a 3.73×10^{-3} M aqueous solution of **2** at 298 K is 1.26×10^{-2} S m^2 mol^{-1}, which is typical of a 1 : 1 electrolyte. Aquation of either **1** or chloride will account for this. Ion-exchange chromatography on Sephadex C25 and

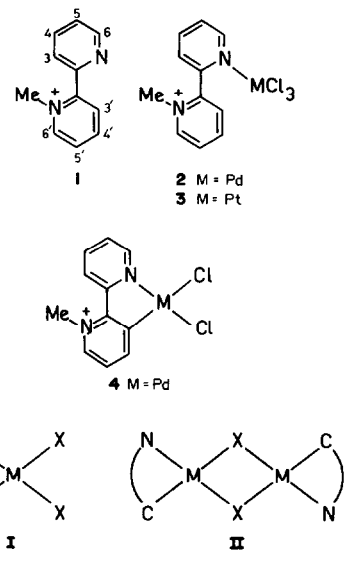

Fig. 1. Generalized structures for cyclometallated compounds of Pd(II).

* Author to whom correspondence should be addressed.

† In a typical experiment $Pd(bpyMe)Cl_3$ (0.36 mmol) is heated under reflux in water (20 cm^3) for 22 h to give $Pd(bpyMe\text{-}H)Cl_2$ in 85% yield. The mother liquor is acidic and gives a positive test for chloride with $AgNO_3$.

‡ Water is necessary for cyclometallation to occur. $Pd(bpyMe)Cl_3$ is recovered unchanged after heating under reflux in solvents with varying boiling points such as ethanol and 2-methoxyethanol (**5**).

§ The IR spectrum on cyclometallation shows changes in both the ring-stretching (1650–1400 cm^{-1}) and the C–H out-of-plane (800–700 cm^{-1}) regions, suggesting cyclometallation at $C^{3'}$ rather than in the methyl group.

‖ Far-IR region: 335 m, 290 wm, 280 wm and 265 m cm^{-1}.

A25 resins shows that the solution contains both cationic and anionic palladium species.

The cationic species was isolated by adding sodium perchlorate to a hot solution of **2**; this gave an immediate pale yellow precipitate which was recrystallized as pale yellow plates from water/acetone (1 : 1) by slow evaporation at room temperature (25–30°C). The elementary analyses indicate the formulation $[Pd(bpyMe)_2Cl_2](ClO_4)_2$ (**6**). The IR spectrum shows a strong band at 348 cm^{-1} which is assigned as a Pd—Cl stretching mode, suggesting that the complex has the *trans*-configuration.

The crude yield of **6** is about 48% based on **2**. The rest of palladium remains in solution as either $[PdCl_4]^{2-}$ or $[Pd(H_2O)Cl_3]^-$ and was not isolated. Presumably the primary process in the dissolution of **2** is aquation of **1** [eqn (1)] followed by substitution [eqn (2)]:

$$Pd(bpyMe)Cl_3 \rightarrow [Pd(H_2O)Cl_3]^- + bpyMe^+ \quad (1)$$

$$Pd(bpyMe)Cl_3 + bpyMe^+ \rightarrow [Pd(bpyMe)_2Cl_2]^{2+} + Cl^-. \quad (2)$$

It should be possible to prepare the bis-complex $[Pd(bpyMe)_2Cl_2]^{2+}$ by direct synthesis. Addition of 2 mol of $(bpyMe)NO_3$ to a warm aqueous solution of Na_2PdCl_4 results initially in an orange precipitate of **2**, which dissolves to a yellow solution. Addition of a dilute sodium perchlorate solution precipitates **6** in 85% yield.* Similarly, treatment of a warm solution of **2** with $(bpyMe)ClO_4$ (1.5 mol) followed by sodium perchlorate gives **6** in 75% yield.†

The facile formation of a four-coordinate bis(bpyMe) complex is unexpected since most complexes with cationic ligands (L) are insoluble zwitterions of type $MLCl_3$. The limited number of first-row transition-metal complexes with two cationic ligands are mainly five-coordinate.[7] There are no known Pd(II) or Pt(II) complexes with two cationic ligands.

On heating **2** in water, the overall reaction is cyclometallation to give **4**, whereas the immediate products are $[Pd(bpyMe)_2Cl_2]^{2+}$ and anionic species [eqns (1) and (2)]. It follows that $[Pd(bpyMe)_2Cl_2]^{2+}$ should cyclometallate with elimination of **1**. Heating **6** under reflux in water for 5 h gives **4** in 88% yield. The **1** produced in the reaction was recovered by precipitation with sodium tetraphenylborate. The IR spectrum of the cyclometallated complex formed in this reaction is free from perchlorate bands, indicating that **4** is monomeric (i.e. has structure **I**) and neutral overall. The cyclometallated bpyMe ligand is now behaving as an internal zwitterion. If **4** was dimeric (i.e. **II**) it would bear a dipositive charge and would be expected to separate from solution as the perchlorate salt if the normal solubility difference between chloride and perchlorate salts is followed.

Most complexes formed as a result of cyclopalladation of a neutral ligand have the dimeric structure **II** so as to produce a neutral compound.[3] In some cases[8] the dimer can be cleaved by halide ions to the monomer **I** which is now anionic.

These results are of interest in the light of recent X-ray studies[9] of $Ir(bpy)_3Cl_3 \cdot 4H_2O$, which have shown the presence of a cyclometallated C^3,N'-bpy ligand similar to cyclometallated bpyMe.‡

* Mixing hot solutions of K_2PtCl_4 and $(bpyMe)ClO_4$ (2 mol) gives a yellow solution. Cooling in the presence of excess perchlorate yields $Pt(bpyMe)Cl_3$ with only a very small amount of $[Pt(bpyMe)_2Cl_2](ClO_4)_2$ which can be extracted with acetone/water (1 : 1).

† The soluble salt $[Pd(bpyMe)_2Cl_2](NO_3)_3$ was prepared by treating $Pd(bpyMe)Cl_3$ with warm $(bpyMe)No_3$ followed by $AgNO_3$ (1 mol), filtering and evaporating to dryness at room temperature. $Pd(bpyMe)Cl_3$ gives a clear solution when treated with (bpyMe)Cl, but on cooling the starting compound crystallises.

‡ Attempts to obtain the crystal structure of $Pt(bpyMeH)Cl_2$ have been unsuccessful due to an unusually large unit cell (M. R. Snow, personal communication). The crystal structure of $[Pd(bpyMe)_2Cl_2](ClO_4)_2$ is currently under investigation.

AZIDES OF HEAVIER MAIN GROUP ELEMENTS: THE RELUCTANCE OF PHOSPHINE AZIDES TO UNDERGO A CURTIUS-TYPE REARRANGEMENT

EDGAR OCANDO, SAMIA MAJID and JEAN PIERRE MAJORAL*
U.A. 454, Université Paul Sabatier, 118 route de Narbonne, 31062 Toulouse, France

and

ANTOINE BACEIREDO and GUY BERTRAND*
U.A. 477, Université Paul Sabatier, 118 route de Narbonne, 31062 Toulouse, France

(*Received* 18 *December* 1984; *accepted* 3 *April* 1985)

Abstract—Under thermolytic or photolytic conditions, phosphine azide complexes $Ph_2PN_3M(CO)_5$ (M = W, Cr) gave rise to the corresponding isocyanato complexes and not to the expected iminophosphane complexes.

Recently, Curtius-type rearrangements involving an azide group bonded to boron,[1] silicon,[2] germanium[3] or tetracoordinated pentavalent,[4] tetracoordinated tetravalent[5] and pentacoordinated pentavalent[6] phosphorus atoms have been reported. On the other hand, although phosphine azides have received considerable attention in recent years,[7–9] no Curtius rearrangement:

$$R_2PN_3 \xrightarrow[-N_2]{h\nu \text{ or } \Delta} R{-}P{=}N{-}R,$$

which would lead to dicoordinated trivalent phosphorus derivatives, has been observed. Depending on the nature of the substituents, three types of reactions have been described previously:[7–9]

$$Ph_2PN_3 \xrightarrow{\Delta} (Ph_2PN)_{3,n}$$

$$[(Me_3Si)_2N]_2PN_3 \xrightarrow{\Delta} (Me_3Si)_2N{-}P(=N{-}SiMe_3)(=N{-}SiMe_3)$$

$$[(iPr)_2N]_2PN_3 \xrightarrow{h\nu} [(iPr)_2N]_2P{\equiv}N$$

Since all of these reactions involve the phosphorus lone pair electrons, one might anticipate that the complexation of the phosphorus atom might encourage the Curtius-type rearrangement and thereby provide a facile route to iminophosphane complexes (**2**).[10]

Because of the great instability of diphenylphosphine azide which explodes when shocked at −13°C, compounds **1a** and **1b** were prepared by reaction of diphenylchlorophospine complexes with sodium azide [**1a**: ^{31}P NMR (CH_3CN): +88 ppm, $^1J_{PW}$ = 273 Hz; IR (CH_3CN): 2130 cm^{-1} (P—N_3); **1b**: ^{31}P NMR (CH_3CN): +134 ppm; IR (CH_3CN): 2130 cm^{-1} (P—N_3)]:

$$Ph_2PCl \xrightarrow{NaN_3} Ph_2PN_3 \qquad \begin{matrix}\textbf{1a}: M = W\\ \textbf{1b}: M = Cr\end{matrix}$$
$$\quad | \qquad\qquad |$$
$$M(CO)_5 \qquad M(CO)_5$$

Irradiation of a toluene or acetonitrile solution of complexes **1a** and **1b** at 254 nm and ambient temperature for 9 h, using a Rayonet photochemical reactor or heating at 70°C (6 h) gave new complexes, **3a** and **3b**, with release of nitrogen:

$$Ph{-}P{=}N{-}Ph \quad \leftarrow\!\times\!- \mathbf{1} -\!\rightarrow \quad Ph_2P{-}N{=}C{=}O$$
$$\quad | \qquad\qquad\qquad\qquad\quad |$$
$$M(CO)_5 \qquad\qquad\qquad\qquad M(CO)_5$$
$$\mathbf{2} \qquad\qquad\qquad\qquad\quad \mathbf{3}$$

3a: M = W
3b: M = Cr

*Authors to whom correspondence should be addressed.

Complexes **3a** and **3b** were obtained in 33 and 42% yields respectively, as pale yellow powders; **3a**: m.p. 50°C; ^{31}P NMR (CH_3CN): +70 ppm, $^1J_{PW}$ = 276 Hz; IR (CH_3CN): 2250 (N=C=O) 2080, 1950 (CO) cm^{-1}; mass spectrum: M^+ and successive eliminations of CO groups; **3b**: m.p. 42°C; ^{31}P NMR (CH_3CN): +118 ppm; IR (CH_3CN): 2280 (N=C=O), 2080, 1930 (CO) cm^{-1}; mass spectrum: M^+ and successive eliminations of CO groups. Confirmation of the structural assignments of **3** were obtained by their independent synthesis by uniquely different routes:

$$Ph_2PN{=}C{=}O \xrightarrow{M(CO)_5THF} \mathbf{3} \xleftarrow{NaOCN} Ph_2PCl \mid M(CO)_5$$

It seems reasonable that the reaction **1** → **3** proceeds via the transient formation of a phosphinonitrene intermediate, **4**, which combines with carbon monoxide:

$$Ph_2P{-}N \mid M(CO)_5$$

4

Addition of CO to an aryl nitrene has been observed but under drastic conditions (160°C, 150 atm).[11] However, all attempts to trap **4** by classical nitrene reagents failed; in each case **3a** or **3b** was formed.

In conclusion, in marked contrast with other heavier main group element azides, free or complex phosphine azides are reluctant to give Curtius-type rearrangement, although a nitrene type intermediate seems to be formed.

THE STRUCTURE OF (DICHLORO) (DI-μ-ACETATO)(BIS-TRIPHENYL PHOSPHINE) DIMOLYBDENUM(II)

F. ALBERT COTTON* and GREGORY L. POWELL
Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A & M University, College Station, TX 77843, U.S.A.

(*Received* 25 *February* 1985; *accepted* 19 *April* 1985)

Abstract—The title compound was obtained in crystalline form suitable for X-ray structure determination. It forms crystals in the monoclinic space group $P2_1/c$ with two centrosymmetric molecules in a unit cell of dimensions, $a = 10.888(1)$ Å, $b = 10.182(2)$ Å, $c = 17.929(4)$ Å, $\beta = 104.33(1)°$. The central $Mo_2Cl_2(O_2C—)_2P_2$ core has effectively C_{2h}-symmetry with the following principal dimensions: Mo—Mo = 2.091(1) Å, Mo—Cl = 2.405 Å, Mo—P = 2.566(2) Å, Mo—O(av.) = 2.103[4] Å, Mo—Mo—P = 104.38(7)°, and Mo—Mo—Cl = 116.23(8)°.

Molecules of type $Mo_2(O_2CR)_2X_2L_2$, in which X is a halogen and L a phosphine, have been known since the first ones were synthesized by San Filippo *et al.*[1,2] in 1976. At that time the structure of $Mo_2(O_2CC_6H_5)_2Br_2(PBu^n_3)_2$ was determined.[2] In 1982 there were three further reports of the preparation of such compounds[3–5] and structures were reported for $Mo_2(O_2CMe)_2Cl_2(PBu^n_3)_2$[3] and $Mo_2(O_2CCMe_3)_2Cl_2(PEt_3)_2$.[5] Three preparative methods have been used:

$$Mo_2(O_2CMe)_4 + AlCl_3 + PPh_3 \rightarrow Mo_2(O_2CMe)_2Cl_2(PPh_3)_2 \quad \text{(McCarley)},$$

$$Mo_2(O_2CMe)_4 + Me_3SiCl + PR_3 \rightarrow Mo_2(O_2CMe)_2Cl_2(PR_3)_2 \quad \text{(Green } et\ al.\text{)},$$

$$Mo_2X_4(PR_3)_4 + RCOOH \rightarrow Mo_2(O_2CR)_2X_2(PR_3)_2 \quad \text{(San Filippo)}.$$

In two of the earlier studies the title compound of this paper was prepared. This was first done by Ryan and McCarley[4] who characterized it by elemental analysis, visible absorption spectrum and IR spectrum. Green *et al.*[3] also obtained it by their method and added ^1H and ^{31}P NMR data to the characterization. We now report its structure and compare it with the three other structures mentioned above.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

The preparation was by the method of Green *et al.*,[3] but relatively greater amounts of Me_3SiCl and PPh_3 were used, and a technique for obtaining the crystalline compound directly from the reaction mixture was employed. Me_3SiCl (1.0 cm^3, 7.9 mmol) was added to a stirred mixture of $Mo_2(O_2CMe)_4$ (0.42 g, 0.98 mmol) and PPh_3 (1.04 g, 3.97 mmol) in 50 cm^3 of THF. After 2 h of stirring at 22°C the mixture was filtered through a glass frit and the filtrate collected in a large Schlenk tube. A layer of toluene was carefully placed over this solution and after a few days slow interdiffusion of the two liquid phases had caused the formation of red crystals suitable for X-ray analysis.

The crystal structure was determined in the usual way by methods that are routine.[6] The pertinent crystallographic facts are summarized in Table 1. There was no evidence of crystal decay during data collection and absorption corrections were made empirically by scanning nine reflections with χ near 90° at 10° intervals in ψ. The structure was solved and refined without difficulty or any indication of disorder and the final difference map contained no feature of chemical significance. Atomic positional and thermal parameters, structure factors and complete lists of bond angles and distances have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

Table 1. Summary of crystal data, data collection parameters, and refinement residuals for $Mo_2(OAc)_2Cl_2(PPh_3)_2$

Formula	$Mo_2Cl_2P_2O_4C_{40}H_{36}$

$^a R = \sum ||F_o| - |F_c|| / \sum |F_o|$.
$^b R_w = [\sum w(|F_o| - |F_c|)^2 / \sum w|F_o|^2]^{1/2}$; $w = 1/\sigma^2(|F_o|)$.
^{c} Quality of fit $= [\sum w(|F_o| - |F_c|)^2 / (N_{obs} - N_{parameters})]^{1/2}$.

RESULTS AND DISCUSSION

A labelled drawing of the molecular structure is presented in Fig. 1. There is a crystallographic inversion center at the midpoint of the Mo—Mo bond. Table 2 lists the important bond lengths and angles. The molecule is qualitatively very similar to the others of the same type whose structures have been reported. In all cases, the virtual symmetry of the central $Mo_2X_2(O_2C—)_2P_2$ core is C_{2h} with the plane of symmetry containing the $Mo_2X_2P_2$ atoms.

We present in Table 3 a comparison of the present structure with the three others. It is clear that changes in the R group of the carboxylic acid, the halogen or the R′ groups in the phosphine have only

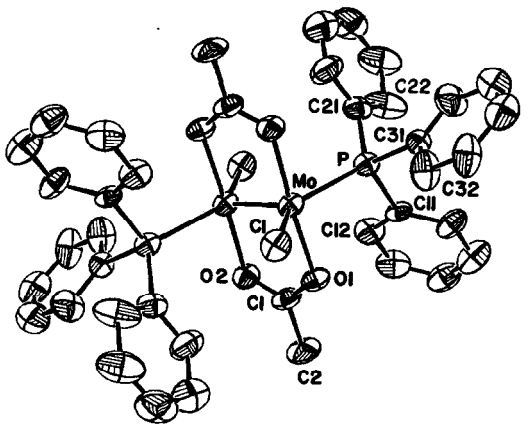

Fig. 1. An ORTEP drawing of the $Mo_2(O_2CCH_3)_2Cl_2(PPh_3)_2$ molecule. Atoms are represented by displacement ellipsoids at the 40% probability level. Unlabeled atoms in one half of the molecule are related by an inversion center to those that are labeled. The numbering of unlabeled ring atoms, C13–C16, C23–C26 and C33–C36, should be evident.

slight effects on the structures. Indeed in comparing compounds **1** and **3** it appears that the change from $MeCO_2^-$ to $Me_3CCO_2^-$ is without any detectable effect. Nor does the replacement of Cl^- by Br^- seem to have any important consequences. Only changes in the bulk and/or the basicity of the phosphines appear to have structural consequences of any size.

The variation in Mo—Mo—P angles correlates with the increasing bulk of the PR_3 ligands. While the variation in Mo—P distances from **1** to **3** is virtually negligible, there is an appreciable increase for **4**. This could be due to the lower basicity of the aryl phosphine but it may also be partly of steric origin since the bulkier PPh_3 ligand may be sterically repelled by the other ligands.

CATIONIC DIHYDRIDOIRIDIUM(III) COMPLEXES OF NITRILES

CHONG SHIK CHIN* and HWA-KUN PARK
Department of Chemistry, Sogang University, CPO Box 1142, Seoul, 121 Korea

and

WAN-CHUL JOO
Department of Chemistry, Sung Kyun Kwan University, Suwon, 170 Korea

(*Received* 15 *February* 1985; *accepted* 19 *April* 1985)

Abstract—The reaction of $[IrL(CO)(PPh_3)_2]ClO_4$ (PPh_3 = triphenylphosphine) with H_2 produces new cationic dihydridoiridium(III) complexes of nitriles (L), $[Ir(H)_2L(CO)(PPh_3)_2]ClO_4$ [L = CH_3CN (**1**), CH_3CH_2CN (**2**), $CH_3CH_2CH_2CN$ (**3**) and C_6H_5CN (**4**)], where nitriles are coordinated through the nitrogen atom. Proton NMR spectral data for complexes **1–4** suggest that the two hydrides in each complex are *cis* to each other and *trans* to CO and nitrogen (nitrile), and the two PPh_3 are *trans* to each other.

We recently prepared dihydridoiridium(III) complexes of unsatured nitriles,

$$[Ir(H)_2L(CO)(PPh_3)_2]ClO_4$$

(L = unsaturated nitriles coordinated through the nitrogen) and examined their physical properties and catalytic activities.[1] In this paper, we wish to report the synthesis of new cationic dihydridoiridium(III) complexes of saturated and aromatic nitriles and suggest their structures on the basis of the spectral data.

Stirring the yellow solution of

$$[IrL(CO)(PPh_3)_2]ClO_4$$

(L = CH_3CN, CH_3CH_2CN, $CH_3CH_2CH_2CN$ and C_6H_5CN)† in dichloromethane under hydrogen (P_{H_2} = 1 atm) at 25°C yielded a beige precipitate within 5 min. The addition of hexane to this beige suspension resulted in a more beige solid of $[Ir(H)_2L(CO)(PPh_3)_2]ClO_4$[eqn (1):‡

$$[IrL(CO)(PPh_3)_2]ClO_4 + H_2 \rightarrow [Ir(H)_2L(CO)(PPh_3)_2]ClO_4 \quad (1)$$

[L = CH_3CN (**1**), CH_3CH_2CN (**2**), $CH_3CH_2CH_2CN$ (**3**) and C_6H_5CN (benzonitrile) (**4**)].

Complexes **1–4** are stable in the solid state in air at room temperature, and slightly soluble in chloroform and dichloromethane and insoluble in benzene and hexane. The conductance measurements (110–120 ohm^{-1} cm^2 mol^{-1} for **1–4**)‡ indicate that the complexes are 1:1 electrolytes.§

* Author to whom correspondence should be addressed.

† $[IrL(CO)(PPh_3)_2]ClO_4$ (L = CH_3CN and C_6H_5CN) were prepared as before.[2] $[IrL(CO)(PPh_3)_2]ClO_4$ (L = CH_3CN, CH_3CH_2CN, $CH_3CH_2CH_2CN$ and C_6H_5CN) used in this study, have been prepared in the same manner as described in Ref. 2. The newly prepared compounds, $[IrL(CO)(PPh_3)_2]ClO_4$ (L = CH_3CH_2CN and $CH_3CH_2CH_2CN$) have been identified by the elemental analyses, solution conductance measurements and spectral data (IR, ^1H NMR and electronic absorption) and will be reported elsewhere.

‡ 0.2 mmol (0.18–0.19 g) of $[IrL(CO)(PPh_3)_2]ClO_4$ (L = CH_3CN, CH_3CH_2CN, $CH_3CH_2CH_2CN$ and C_6H_5CN) was used to prepare 0.18 mmol (0.16–0.17 g) of **1–4** whose molar conductance ranged from 110 to 120 ohm^{-1} cm^2 mol^{-1} ($[Ir] = 4.0 \times 10^{-5}$ M) in dichloromethane at 25°C. Calc. for **1** ($IrC_{39}H_{35}NO_5P_2Cl$): C, 52.81; H, 3.98; N, 1.58. Found: C, 52.48; H, 4.11; N, 1.59%. Calc. for **2** ($IrC_{40}H_{37}NO_5P_2Cl$): C, 53.31; H, 4.14; N, 1.55. Found: C, 52.94; H, 4.21; N, 1.51%. Calc. for **3** ($IrC_{41}H_{39}NO_5P_2Cl$): C, 53.81; H, 4.30; N, 1.53. Found: C, 52.98; H, 4.42; N, 1.49%. Calc. for **4** ($IrC_{44}H_{37}NO_5P_2Cl$): C, 55.63; H, 3.93; N, 1.48. Found: C, 55.01; H, 4.02; N, 1.40%.

§ Molar conductance of a standard 1:1 electrolyte $[(C_3H_7)_4N]PF_6$ in dichloromethane is 110 ohm^{-1} cm^2 mol^{-1} at 25°C.

Table 1. IR (Nujol) and ^1H NMR ($CDCl_3$) spectral data for $[Ir(H)_2L(CO)(PPh_3)_2]ClO_4$ [L = CH_3CN (**1**), CH_3CH_2CN (**2**), $CH_3CH_2CH_2CN$ (**3**) and C_6H_5CN (**4**)]

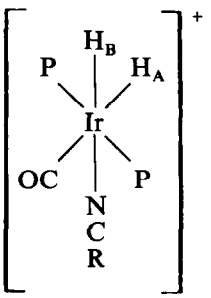
[a] Weak. ν_{CN} = ν_{CN} of coordinated nitrile $-\nu_{CN}$ of free nitrile. [b] Very strong. [c] Strong. [d] Medium.

[e] In air at 25°C at 60 MHz (Varian 60 MHz EM-360A) for free nitriles and at 80 MHz (Bruker WP 80 MHz FT-NMR) for **1–4**. Chemical shifts are relative to TMS and coupling constants are in Hz.

[f] $J(P, H_A) = 16.5$, $J(H_A, H_B) = 3.9$. [g] $J(P, H_B) = 13.6$, $J(H_A, H_B) = 3.9$.

[h] $J(P, H_A) = 16.5$, $J(H_A, H_B) = 3.9$. [i] $J(P, H_B) = 13.6$, $J(H_A, H_B) = 3.9$.

[j] $J(P, H_A) = 16.5$, $J(H_A, H_B) = 3.9$. [k] $J(P, H_B) = 13.7$, $J(H_A, H_B) = 3.9$.



[l] $J(P, H_A) = 16.5$, $J(H_A, H_B) = 3.8$. [m] $J(P, H_B) = 13.6$, $J(H_A, H_B) = 3.8$.

IR spectral data (see Table 1) clearly suggest that the nitriles are coordinated to iridium through the nitrogen atom, rather than through the π-system of the nitrile group. It is well-known that ν_{CN} of a nitrile increases upon coordination through the nitrogen atom,[3–5] and decreases significantly upon coordination through the π-system of the nitrile group,[4,5] A strong and broad absorption band at 1100 cm^{-1} (not listed in Table 1) observed for all complexes is attributable to the tetrahedral (C_{4v}) anion ClO_4^-,[6] which suggests that **1–4** are 1:1 electrolytes as confirmed by the conductance measurements. It is seen in Table 1 that ν_{CO} of **4** is higher than those of **1–3**, which is readily understood by the relative basicity of the nitrogen atoms of the nitriles. It is also noticed in Table 1 that the substituents of the nitriles do not significantly affect the ν_{Ir-H} (ν_{M-H} varies widely from 1700 to 2250 cm^{-1} among various metal complexes[7]).

Electronic absorption spectra of **1–4** show no bands in the visible region as observed for the related six-coordinated dihydridoiridium(III) complexes, $[Ir(H)_2L(CO)(PPh_3)_2]ClO_4$ (L = unsaturated nitrile coordinated through the nitrogen atom).[1]

Proton NMR spectral data (see Table 1) provide more conclusive information on the characterization of **1–4**. The ratios of protons observed clearly indicate that each compound contains the $Ir(H)_2L(PPh_3)_2$ moiety. Practically no changes in coupling constants have been observed in this study for the protons of the nitriles upon coordination to $Ir(H)_2(CO)(PPh_3)_2$ as observed for the unsaturated nitrile complexes.[1] The coupling constants between hydride and *trans* phosphorus are relatively large (53–154 Hz) compared with those between hydride and *cis* phosphorus (10–20 Hz).[1,8–14] The relatively small coupling constants (13.6–16.5 Hz) observed for **1–4** (Table 1) indicate that both hydrides are *cis* to

both phosphorus atoms. The large difference in the chemical shifts of the hydrides implies that the two hydrides are *trans* to different groups, respectively. Accordingly the two hydrides are *cis* to each other and *trans* to CO and nitrogen (nitrile), respectively. For the series of related hydridoiridium(III) complexes, it is well-known that the chemical shift of a hydride depends on the *trans* donor atom.[1,8–16] The shielding at the hydride *trans* to nitrogen (nitrile) is higher (−17 to −20 ppm relative to TMS)[1,11,15] that than at the hydride *trans* to carbon (CO, $C_6H_{11}NC$) (−7 to −13 ppm).[1,10,16] Accordingly the signals at *ca* −8 ppm observed for **1–4** are due to the hydride (H_A) *trans* to CO and those at *ca* −18 ppm are due to the hydride (H_B) *trans* to nitrogen of the nitrile. Accordingly, the following structure is suggested for **1–4**:

P = PPh_3,

R = CH_3— (**1**), CH_3CH_2— (**2**),

$CH_3CH_2CH_2$— (**3**) and C_6H_5— (**4**).

(*Received* 15 *November* 1983; *accepted after revision* 4 *May* 1984)

Abstract—The reaction of $[RhCl(COD)]_2$ (COD = 1,5-cyclooctadiene) with sodium *N*-phenylanthranilate leads to the formation of the new crystalline rhodium(I) complex $[RhFA(COD)]_2$ (FA = *N*-phenylanthranilate anion). The compound is a dimer with two *N*-phenylanthranilate ions bridging and COD ligands terminally bonded to rhodium with an Rh . . . Rh distance equal to 3.424(3) Å. Strong intramolecular hydrogen bonding occurs between the hydrogen of the NH group and the closest carbonyl oxygen in the FA ligands. The crystals are monoclinic, space group $P2_1/c$, with $a = 11.246(8)$, $b = 14.999(9)$, $c = 21.82(2)$ Å, $\beta = 105.11(6)°$. The structure was solved by the heavy-atom method and refined by least squares to $R = 0.035$ for 4260 diffractometer data.

Only a few Rh(I) compounds with aminoacids are known.[1] The complex with *N*-phenylanthranilic acid with the formula $H[Rh_2(FA)_2Cl]$ (FA = *N*-phenylanthranilate anion) was synthesized for the first time by Khidekel *et al.*[2] Their studies, as well as the results reported in Ref. 3, revealed it to be a catalyst active in the hydrogenation of aromatic hydrocarbons. The complexes with anthranilic acid, asparagine and L-tyrosine were synthesized by a similar procedure to $H[Rh_2(FA)_2Cl]$.[4] The structural investigations which could resolve their spatial structures have not been made. The formulae were proposed on the basis of analytical studies.[4] Recently, the Rh(I) dicarbonyl complex with anthranilic acid, $Rh(AA)(CO)_2$ (AA = anthranilate ion) has been synthesized and spectroscopically examined.[5] The Rh(I) compounds with aminoacids are still attractive as potential hydrogenation catalysts. Thus, it was reasonable to establish the spatial structure of the complex obtained by us.

RESULTS AND DISCUSSION

The overall structure of the $[Rh(FA)(COD)]_2$ (COD = 1,5-cyclooctadiene) complex is shown in Fig. 1; selected bond distances and angles are listed in Table 1. The compound is a dimer with two bridging *N*-phenylanthranilate ions and two COD molecules terminally coordinated to each rhodium atom via π-olefin interactions.

The complex molecule has approximate C_2-symmetry. The idealized two-fold axis is perpendicular to the plane of four oxygen atoms. Each rhodium atom is tetracoordinated; two sites are occupied by the carboxyl oxygen atoms and two sites by the olefin units of cyclooctadiene. The Rh...Rh distance of 3.424(3) Å is comparable to the Rh...Rh distances in the other dimeric Rh(I) complexes in which there is no direct metal–metal bonding, e.g. 3.5[6] for $[RhCl(COD)]_2$, 3.12[7] for $[Rh(CO)_2Cl]_2$, and 3.396(1) Å[8] for

$$Rh(CO)Cl[(C_6H_5)_2AsCH_2As(C_6H_5)_2]_2.$$

In the Rh(I) and Rh(II) complexes with single metal–metal bonds the Rh—Rh distance is shorter and equal to 2.752(2)[9] and 2.618(5) Å[10] for

$$[(Et_3P)_2Rh(\mu\text{-}PPh_2)_2Rh(COD)]$$

and

$$[Rh(CH_3CO_2)(DMG)(PPh_3)]_2.$$

Two *N*-phenylanthranilate ligands are bonded to Rh

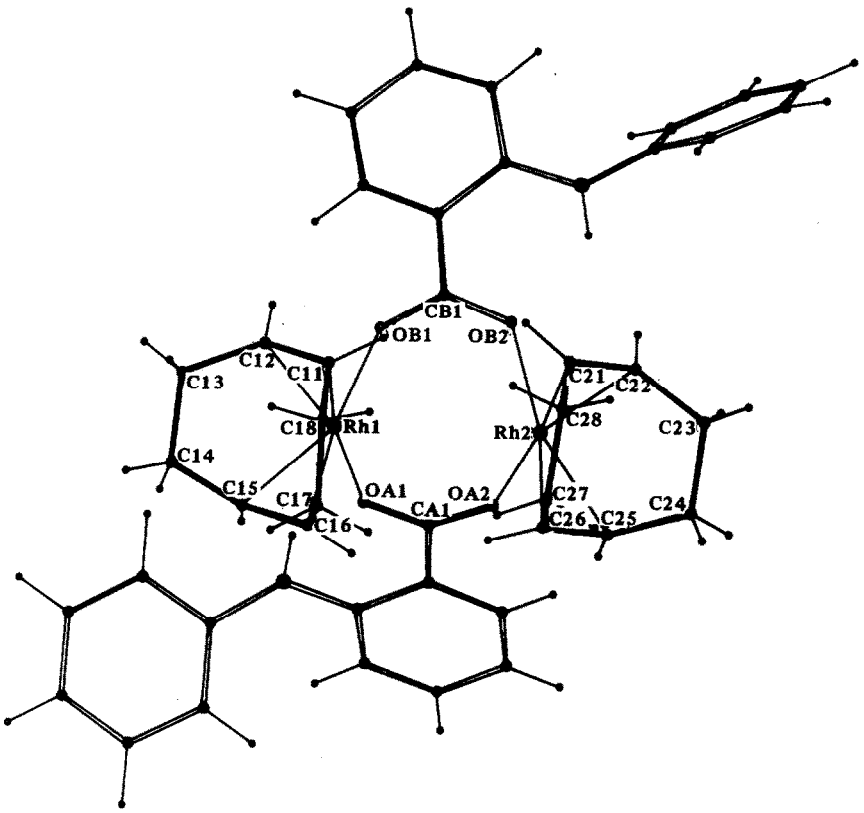

Fig. 1. A view of the complex molecule with the atom core numbering.

atoms via carboxyl oxygens. Comparison of the Rh—O bonding distances shows a small non-equivalence of the two Rh atoms.

Rh(1)—O(A1) and Rh(1)—O(B1) distances are 2.078(4) and 2.062(5) Å, respectively, while the bonds formed by Rh(2) are a little longer, with Rh(2)—O(A2) being 2.107(4) and Rh(2)—O(B2) 2.115(3) Å. These distances are comparable with the Rh—O distances found for Rh(II) carboxylate complexes.[10,11] X-ray studies allowed us to exclude the formation of bonding between the rhodium and the nitrogen of the *N*-phenylanthranilate ligand. The presence of hydrogen bonding within the carboxylic ligand causes the complete disability of nitrogen to the bonding formation with metal ion. Rh—C(COD) bond distances are between 2.080(6) and 2.098(6) Å and are similar to Rh—C(COD) distances in the other complexes of that type.[13,16]

For

$$Rh(C_5H_4CO_2Me)(COD),$$

$$[Rh(Ph_3PC_5H_4)(COD)]BPh_4,$$

$$B(pz)_4Rh(COD)$$

[where $B(Pz)_4$ = poly(1-pyrazolyl)borate] and Rh(ACA)(COD)(ACA = acetylacetone), the Rh—C(COD) bond distances are 2.101(5)–2.129(5),[13] 2.13(1)–2.28(2),[14] 2.124(3)–2.139(2)[15] and 2.092(8)–2.115(7) Å,[16] respectively. The view of *N*-phenylanthranilate ligands respective to the plane of one of two phenyl rings is shown in Fig. 2. Two phenyl rings in each FA molecule are arranged towards each other by approximately equal angles of 50.8(25)° for the A-molecule and 55.0(22)° for the B-molecule, respectively, but the direction of the rotation is the reverse. The hydrogen bond between N and the nearest oxygen atom of the carboxyl group is shown by dotted lines in Fig. 2. The N(1)...O(A1) distance is 2.623(6) and that of N(2)...O(B2) is 2.660(5) Å. These distances are comparable with N...O distances in systems in which hydrogen bonding was classified as strong.[17,19]

In 3,4,6-trichloro-2-diethylamino-methylphenol the N...O distance is 2.58(1),[17] in 2,2′-bis(6-methyl-3-piridinol) 2.568[18] and in salicylaldehyde azine 2.645(3) Å.[19] The C—N—C angles are 128.2(5) [C(A7)—N(1)—C(A8)] and 127.4(6)° [C(B7)—N(2)—C(B8)], respectively. That suggests that hybridization of nitrogen orbitals in *N*-phenylanthranilate ligands is sp^2 rather than sp^3.

Repulsion between two phenyl rings causes an increase in the C—N—C angle to over 120°. The

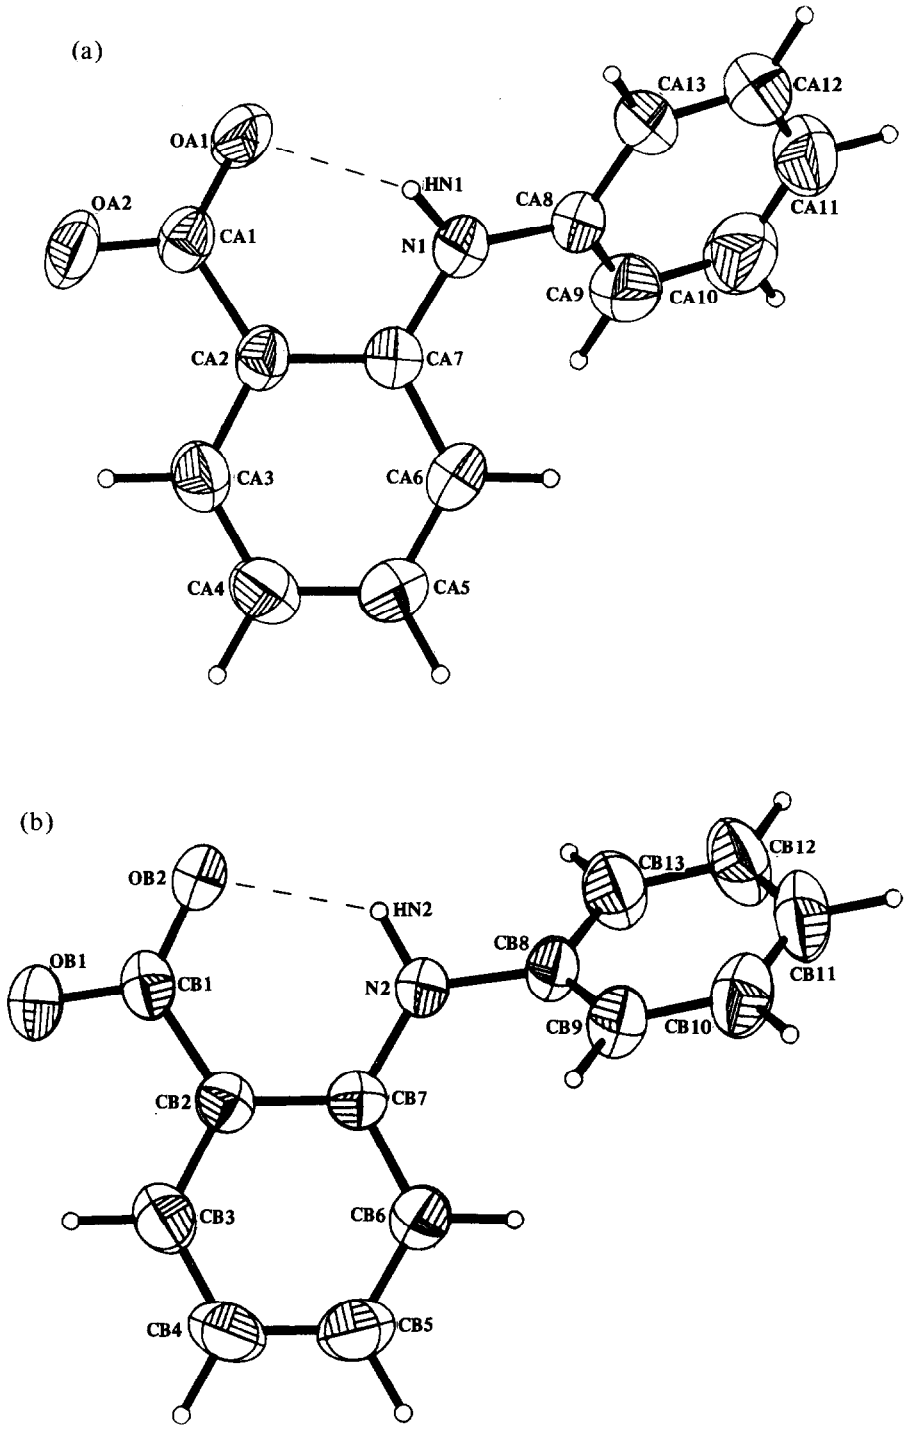

Fig. 2(a) and (b). ORTEP drawings showing different conformations of two *N*-phenylanthranilate crystallographically independent ligands.

N—C bonds are non-equivalent; the nitrogen atoms in both *N*-phenylanthranilate ligands are closer to the carbon adjacent to the carboxyl group. The respective distances are N(1)—C(A7) 1.372(7) and N(2)—C(B7) 1.367(6) Å. The N—C distances to the second phenyl rings are longer, 1.395(7) and 1.414(7) Å, respectively. In both FA ions differences in the C—C bond length in phenyl rings closer to rhodium ions are observed. The longest C—C distances are C(A2)—C(A7) [1.406(7) Å] and C(B2)—C(B7) [1.416(7) Å]. The shortest C—C distances are C(A5)—C(A6) [1.355(8) Å] and C(B5)—C(B6)

[1.352(8) Å]. This indicates a disproportionate electron density distribution in these phenyl rings. The distortion of the phenyl rings and non-equivalence of the N—C distances are caused by electron density delocalization on the carboxyl group, the first phenyl ring and the nitrogen atom. The carboxyl group, two carbon atoms from the phenyl ring and nitrogen atom with hydrogen are almost planar. The phenyl ring and the ring with hydrogen bonding may be treated as conjugated because they are almost coplanar. This is the explanation for the shortening of the C—C bond distances in phenyl rings closer to rhodium ions. The further phenyl ring is not conjugated with the first one, because it is twisted towards its plane. For that reason the electron density delocalization over two phenyl rings in each FA ion does not take place. Therefore the N—C distances to the second phenyl rings are longer and no differences in C—C bond distances are observed.

EXPERIMENTAL

Synthesis

$[RhCl(COD)]_2$ (0.49 g), obtained as reported by Chatt and Venanzi[20] and sodium *N*-phenylanthranilate (0.71 g) were heated in boiling ethanol for 3 h. The precipitate was washed with water until the reaction on Cl^- ceased, then with ethanol, and dried *in vacuo*. Recrystallization of the compound from chloroform and ethyl ether produced yellow crystals suitable for the X-ray examination.

Elemental analysis. Found: C, 59.3; N, 3.1; H, 5.2; Rh, 24.8. Calc. for $C_{42}H_{44}N_2O_4Rh_2$: C, 59.0; N, 3.3; H, 5.2; Rh, 24.8%.

X-ray structure analysis of $[Rh(FA)(COD)]_2$

Crystal data. $C_{42}H_{44}N_2O_4Rh_2$, $M = 846.7$, monoclinic, $a = 11.246(8)$, $b = 14.999(9)$, $c = 21.82(2)$ Å, $\beta = 105.11(6)°$, $U = 3553$ Å^3, $Z = 4$, $D_c = 1.58$ g cm^{-3}, $D_o = 1.54$ g cm^{-3}, space group $P2_1/c$ Mo-K_α radiation $\lambda = 0.71069$ Å, $\mu = 9.5$ cm^{-1}.

A specimen ($0.6 \times 0.4 \times 0.3$ mm) was cut from a large crystal. A Syntex $P2_1$ diffractometer, Mo-K_α radiation and a graphite monochromator were used for lattice-parameter and intensity measurements at $T = 298 \pm 2$ K. Intensities were measured only for reflections above background with a 2θ–ω scan technique. The structure was solved by the heavy-atoms method using 4260 reflections with $I > 3\sigma(I)$. All calculations were performed with the Syntex XTL/XTLE programs.[21] The carbon-bonded hydrogen atoms were placed in geometrically calculated positions at a distance of 1.0 Å and fixed. The nitrogen-bonded hydrogen atoms were found from a difference Fourier synthesis and were not refined. Block-diagonal least-squares refinement, with anisotropic thermal parameters for Rh, N, O and C gave a final R_1 ($\sum ||F_o| - |F_c|| / \sum |F_o|$) of 0.035 and an R_w [$(\sum w\Delta F^2 / \sum wF_o^2)^{1/2}$] of 0.041.

The final difference Fourier synthesis showed the highest peaks located around the Rh atoms with an electron density in the range 0.4–0.7 e Å^{-3}. All other peaks had lower densities. Final atomic positional and thermal parameters and a list of F_o and F_c values have been deposited as supplementary data with the Editor from whom copies may be obtained on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

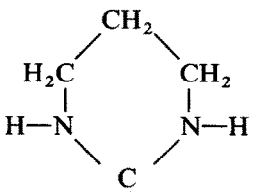
SYNTHESIS, ^{13}C NMR AND IR SPECTROSCOPIC STUDIES OF GOLD(I) COMPLEXES OF IMIDAZOLIDINE-2-THIONE AND ITS DERIVATIVES

ANVARHUSEIN A. ISAB* and M. SAKHAWAT HUSSAIN
Department of Chemistry, University of Petroleum and Minerals, Dhahran, Saudi Arabia

(*Received* 22 *March* 1984; *accepted* 9 *May* 1984)

Abstract—The gold(I) complexes of imidazolidine-2-thione and its derivatives were synthesized and their ^{13}C NMR and IR spectroscopic studies were carried out. When gold(III) was reacted with the ligands using a 1 : 4 metal to ligand ratio, gold(III) was reduced to gold(I), the bis complexes of the general formula AuL_nX (where $n = 2$) were formed. However, when gold(III) was reduced to gold(I) by a reducing agent followed by an addition of the ligand to an aqueous or methanolic solution of gold(I), only mono complexes of the type AuLX were obtained. The structures of the reported complexes are proposed on the basis of their spectroscopic measurements.



Imidazolidine-2-thione, Imt (**Ia**), its six-membered analog, Eapt (**II**), and its derivatives MeImt (**Ib**) and PrImt (**Ic**) are interesting ligands because of their potential binding sites such as —NH and —C=S. These ligands exist in —N=C—SH or —NH—C=S form exhibiting thiol ⇌ thione equilibrium. However, it has been established that the thione form dominates in the solid state.[1,2] The coordination chemistry of these ligands with various transition metal ions such as Cu(I), Zn(II), Pd(II), Co(II), Ni(II) and Hg(II) has been studied.[1,5]

(**Ic**) PrImt: R = $-CH_2CH_2CH_3$; *N*-propyl-imidazolidine-2-thione

By reacting copper(II) chloride or bromide with these ligands, an immediate reduction of copper(II) to copper(I) takes place in MeOH or in aqueous solution[4,6] and the mono as well as the bis complexes of the general formulas CuLX and CuL_2X are formed. The mono complexes are polymeric in nature whereas the bis complexes are dimeric.[4,6] The reduction of gold(III) to gold(I) with Imt was studied by Morgan and Burstall.[7] Usually a gold(III) to ligand ratio of 1 : 4 resulted in a bis complex of the formula AuL_2X ($X = Cl^-, Br^-$). However, we have recently demonstrated[8] that, if the reduction of gold(III) is carried out in aqueous solution using SO_2 gas, gold(I) is stabilized by the ligand forming only monomeric AuLX species.

*Author to whom all correspondence should be addressed.

We have extended our studies on gold(I)–Imt systems, as a part of our continuing research program on synthetic and structural studies of crystalline gold(I)–thiol complexes as model compounds for anti-arthritic drugs[9,10] such as Myocrisin or Solganol which are polymeric in nature as identified by NMR and CD spectroscopy.[11,12] In the present paper we report the synthesis and spectroscopic studies of some mono and bis gold(I)–imidazolidine-2-thione complexes. Most of these complexes were obtained in pure crystalline forms and the single crystal X-ray studies on some of them are currently in progress.

EXPERIMENTAL

All chemicals were obtained from Fluka Chemical Co. except $^{12}CD_3OD$ which was obtained from BDH. The ligands were prepared by the procedures described in the literature.[13,14]

Preparation of complexes of formula L_nAuX

The ligands were dissolved in MeOH and the gold(III) halides were dissolved in double deionized distilled water. The L : M ratio was kept at 4 : 1. As soon as gold(III) was added to the ligand, an orange coloured residue was immediately formed which dissolved on stirring to give a colourless precipitate. The precipitate was dissolved in boiling MeOH to obtain crystalline products. In some cases the complexes could only be obtained in the form of a powder.

Preparation of mono complexes of formula LAuX

The gold(III) halides were reduced to gold(I) by passing SO_2 gas as described earlier.[15] As soon as the solution became colourless, the ligand was added, keeping the gold(I) to ligand ratio close to 1 : 1. Usually a white residue was obtained. The elemental analyses of the products were carried out on a Carlo Erba (Italy) elemental analyzer.

Using the above general procedures the following complexes were prepared:

Gold(I)–imidazolidine - 2 - thione bromide: (Imt)AuBr.

Bis(imidazolidine - 2 - thione)gold(I) chloride hydrate: $(Imt)_2AuCl \cdot H_2O$.

Gold(I)–*N* - methyl - imidazolidine - 2 - thione chloride: (MeImt)AuCl.

Gold(I)–*N* - methyl - imidazolidine - 2 - thione bromide: (MeImt)AuBr.

Bis(*N* - methyl - imidazolidine - 2 - thione)gold(I) chloride: $(MeImt)_2AuCl$.

Bis(1,3 propyl - imidazolidine - 2 - thione)gold(I) chloride: $(Eapt)_2AuCl$.

Bis(*N* - propyl - imidazolidine - 2 - thione)gold(I) chloride: $(PrImt)_2AuCl$.

Spectroscopic measurements

IR spectra of the pure ligands and their gold(I) compounds were obtained on a Perkin–Elmer IR 180 or on a Beckman Microlab IR spectrophotometer using KBr pellets. ^{13}C NMR spectra were obtained on a Varian XL-200 NMR spectrometer operating at a 50.3 MHz frequency. The ligands and gold(I) complexes were dissolved in a 50 : 50 (v/v) $D_2O/^{12}CD_3OD$ solvent. The complexes were not very soluble but enough dissolved to yield spectra except $(Eapt)_2AuCl$ and (MeImt)AuCl which are extremely insoluble in the above solvents. The chemical shifts were measured relative to 1,4-dioxane as internal reference having resonance at +67.4 ppm relative to DSS. ^{13}C NMR spectra of PrImt, (PrImt)AuCl and $(PrImt)_2AuCl$ were measured in d_6-acetone.

RESULTS AND DISCUSSION

Mono and bis gold(I) complexes were formed by Imt and its *N*-methyl derivative, all of which were in pure crystalline state. In the case of Eapt only the bis complex was formed as indicated by the analytical data given in Table 1.

^{13}C *NMR studies*

A representative ^{13}C NMR spectrum is shown in Fig. 1 and Table 2 lists the ^{13}C NMR chemical shifts of the ligands and their complexes. As reported earlier,[8] in the case of mono complexes, the C-2 resonance is shifted by about 8 ppm compared to the free ligand but a less dramatic shift (−0.768 ppm) was observed for C-4 and C-5 resonances. In the bis Imt complexes, the C-2 resonance is shifted by +6.764 ppm whereas the C-4,5 resonance shows a slight shift of only −0.836 ppm. The most significant shift for the $(MeImt)_2AuCl$ complex is also for the C-2 resonance (+7.644 ppm). The C-4, C-5 and CH_3 resonances are only shifted by −1.43, −0.96 and −0.627 ppm, respectively. The shift in the C-2 resonance of the $(PrImt)_2AuCl$ complex is only about 2 ppm, which is significantly less than 8.292 ppm observed for the mono complex (PrImt)AuCl or about 7 ppm observed for any of the bis complexes. This variation in the C-2 shift (Fig. 2) can be explained on

Table 1. Analytical data for the ligands and gold(I) complexes*

Complex	Melting point (°C)	Colour	H	C	N
(Imt)AuBr	198–199	Pale yellow powder	1.53	9.22	7.86
			(1.58)	(9.55)	(7.38)
$(Imt)_2AuCl \cdot H_2O$	247–249	White crystalline	2.98	15.70	12.80
			(3.08)	(15.84)	(12.32)
(MeImt)AuCl	186–187	White powder	2.33	14.36	13.92
			(2.29)	(13.77)	(14.92)
(MeImt)AuBr	167–168	Yellow powder	1.98	12.29	7.21
			(2.04)	(12.21)	(7.12)

			(3.44)	(20.66)	(12.05)
$(Eapt)_2AuCl$	286–288	White crystalline	3.39	20.64	11.94
			(3.44)	(20.66)	(12.05)
$(PrImt)_2AuCl$	92–93	White crystalline	4.75	28.08	11.03
			(4.66)	(27.66)	(10.76)

* The corresponding calculated values are given in parentheses.

the basis of the shielding effects on C-2 which is least shielded in the bis complexes and is most shielded in the mono compounds. An appreciable shift of the C-2 resonance in the ^{13}C NMR spectra clearly indicates that, in all of these complexes, gold(I) is bonded to the ligand through sulfur atom only and the —NH group is not involved in any kind of bonding. Any bonding through —NH would have resulted in a considerable shift of the C-4 resonance in the $(MeImt)_2AuCl$ complex. A significant shift in ^{13}C NMR for C=S carbon atoms consistently observed in these complexes can be used as a diagnostic NMR observation for the location of bonding sites in solution phase of these and similar gold(I) complexes. The sulfur coordination of gold(I) in chloro (*N* - ethyl - 1,3 - imidazolidine - 2 - thione)gold(I) and chloro(*N* - propyl - 1,3 - imidazolidine - 2 - thione) gold(I) complexes[8] was confirmed by the single crystal X-ray analysis in the solid state and a similar ^{13}C shift for the C=S carbon was observed in both complexes. The +1 oxidation state for gold in the $(PrImt)_2AuCl$ was assumed on the basis of its white

* ^{13}C NMR resonances are assigned as given in Faure *et al.*, *Org. Magn. Reson.* 1977, **9**, 688. The numbers in parentheses indicate shifts with respect to the free ligands. A positive value indicates a high-field shift whereas a negative value shows a low-field shift. The spectrum of (MeImt)AuBr could not be recorded due to its insolubility in the 50/50 (v/v) CD_3OD/D_2O solvent.

† The resonance could not be detected in the spectrum.

colour. Both mono and bis complexes are white in colour. In the case of the mono complexes the reduction of gold(III) to gold(I) was carried out by SO_2, whereas an excess of the ligand was used for the reduction of the bis complexes. The Mössbauer and single crystal X-ray studies are planned to identify the oxidation state of gold and to elucidate the solid state structures of these complexes.

The $(Eapt)_2AuCl$ complex is very insoluble in water and its analytical data (Table 1) show that no

H_2O molecule is present. In contrast to this, the 5-membered analog of Eapt forms the complex $(Imt)_2AuCl \cdot H_2O$ which is water soluble[16] and its X-ray analysis revealed an ionic structure with linear gold(I) coordination through sulfur atoms. Due to the high insolubility of $(Eapt)_2AuCl$, its ^{13}C NMR spectrum could not be recorded.

IR absorption spectral studies

The IR spectra of the free ligands and their gold(I) complexes (Table 3) do not show S—H absorption in the region of 2500 cm^{-1} nor a C=N band at 1700–1590 cm^{-1} but exhibit a strong absorption around 3300 cm^{-1} corresponding to N—H stretch.[17] The presence of the band at 3300 cm^{-1} in the free ligand as well as in the gold(I) complexes clearly indicates the existence of thione forms in the solid state.

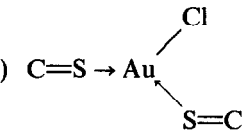
A band at 375 w cm^{-1} in the gold(I)–diisobutyl dithiocarbamate dimer[18] and a band at 342 cm^{-1} for $Au(SMe)_2^-$ anion[19] have been assigned to the Au—S vibration. On a correlative basis the band at 345 cm^{-1} found in all complexes of the present study can be assigned to the Au—S vibration. A shift of about 40 cm^{-1} in the C=S band in all complexes is consistent with our conclusion that the gold(I) is bonded through sulfur. The band at 210 cm^{-1} for (Imt)AuBr and at 225 cm^{-1} for (MeImt)AuBr can be assigned to the Au—Br stretching.[20] The Au—Cl absorption is usually found in the region of 310–320 cm^{-1} for various gold(I) complexes[20] with coordinated chloride ion. This band was observed in the (MeImt)AuCl complex but was absent for $(Imt)_2AuCl$, $(MeImt)_2AuCl$ and $(PrImt)_2AuCl$ complexes. This is consistent with the ionic nature of the chloride in the last three complexes which, of course, will not exhibit any Au—Cl stretching vibrations.[16] The presence of an Au—Cl vibration at 315 cm^{-1} in $(Eapt)_2AuCl$ complex indicates that the gold(I) is three coordinated. The fact that this complex is insoluble in water/methanol solvent further indicates that the complex is neutral or polymeric in nature.

CONCLUSIONS

On the basis of ^{13}C NMR and IR spectral data, the following conclusions can be drawn for gold(I) geometries in its complexes with imidazolidine-2-thiones and its derivatives:

(1) Imt and its derivatives exist in the thione forms both in the solution as well as in the solid phase.

(2) When these ligands react with gold(I), different complexes of types AuLX and AuL_2X are formed, in all of which the ligands exist in the thione form.



(3) The IR and ^{13}C NMR spectral studies revealed three coordination of the following kinds for the gold(I) complexes with the above ligands:

(a) C=S → Au—X

for all mono complexes.

(b) $[C{=}S \rightarrow Au \leftarrow S{=}C]^+$

for all bis complexes which are soluble in water or methanol.

(c)

for L_2AuX neutral complex such as $Au(Eapt)_2Cl$.

SYNTHESIS OF DINUCLEAR PHOSPHIDO OR ARSENIDO BRIDGED COMPLEXES OF MOLYDENUM VIA REACTION OF SECONDARY PHOSPHINES OR ARSINES WITH $[Mo(\eta^5\text{-}C_5H_5)(CO)_3]_2$: X-RAY STRUCTURES OF $\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}ER_2)\}$ (E = P, R = *t*-Bu; OR E = As, R = Me)

RICHARD A. JONES,* STUART T. SCHWAB, ANTHONY L. STUART, BRUCE R. WHITTLESEY and THOMAS C. WRIGHT
Department of Chemistry, The University of Texas at Austin, Austin, TX 78712, U.S.A.

(*Received* 17 *July* 1984; *accepted* 8 *October* 1984)

Abstract—Reaction of $[Mo(\eta^5\text{-}C_5H_5)(CO)_3]_2$ with $t\text{-}Bu_2PH$ or Me_2AsH yields $\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}ER_2)\}$, where E = P, R = *t*-Bu (**1**) (45%); or E = As, R = Me (**2**) (35%). The X-ray crystal structures of **1** and **2** have been determined. Each complex contains a central planar $Mo_2(E)(H)$ core and the co-ordination geometry about each Mo is best described as a "four-legged stool" in which adjacent H and P (or As) atoms are shared. The positions of the bridging hydrogen atoms are symmetrical to within experimental error.

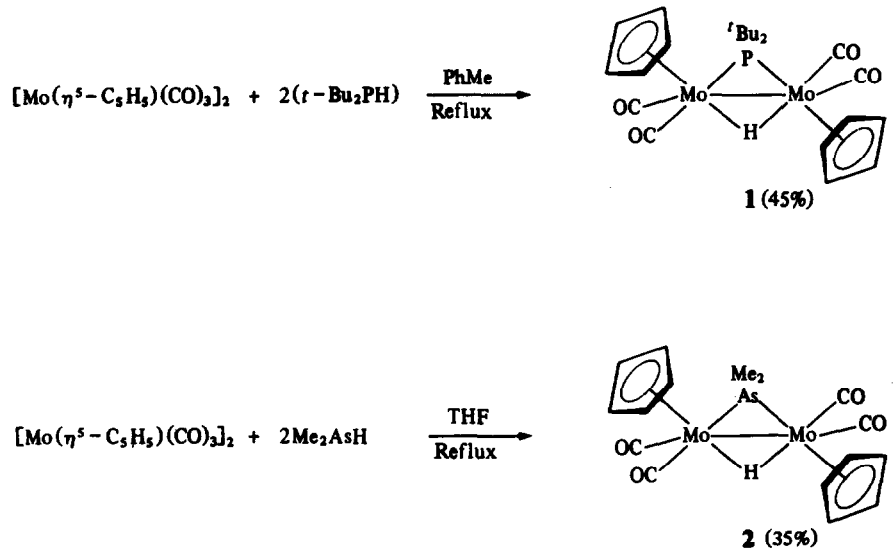
A variety of dinuclear phosphido or arsenido bridged complexes of molybdenum have been reported. These include

$[Mo(CO)_4PR_2]_2$ (R = Me,[1] Et,[2] Ph[2]),
$[Mo(CO)_5]_2PMe_2$,[3] $[Mo(CO)_4(AsPh_2)]_2$,[2]
$[Mo(CO)_3(PR_3)(PMe_2)]_2$,[4]
$[Mo(\eta^5\text{-}C_5H_5)(CO)_2(EMe_2)]_2$ (E = P,[5] As[6]),
$[Mo(\eta^5\text{-}C_5H_5)(CO)_2As(CF_3)_2]_2$,[7]
$[Mo(\eta^5\text{-}C_5H_5)(CO)_2(PMe_3)(\mu\text{-}AsMe_2)Mo(PMe_3)(CO)_2(\eta^5\text{-}C_5H_5)]^+[Mo(CO)_3(\eta^5\text{-}C_5H_5]^-$,[8]
$[Mo(CO)_3(\eta^5\text{-}C_5H_5)(\mu\text{-}AsMe_2)Mo(CO)_5]$,[9]
$\{CpMo(CO)_2[\mu\text{-}o\text{-}C_6H_4\text{-}(PPh)(PPhH)](\mu\text{-}H)(MoCp(CO)]\}$,[10]

and

$[Mo(\eta^5\text{-}C_5H_5)(CO)_2(\mu\text{-}H)(\mu\text{-}Me_2P)]$.[5] The last two complexes in this list are two of a number of dinuclear phosphido bridged complexes of the *d*-block transition metals in which the two metals are bridged both by an R_2P^- (or R_2As^-) group and by a hydrogen atom. Other examples include

$\{[Fe(\eta^5\text{-}C_5H_5)CO]_2(\mu\text{-}H)(\mu\text{-}PR_2)\}$,[6]
$\{[Mn(CO)_4]_2(\mu\text{-}H)(\mu\text{-}Ph_2P)\}$,[11]
$\{[Mn(CO)_4]_2(\mu\text{-}H)[\mu\text{-}P(CF_3)_2]\}$,[12]
$\{[Co(\eta^5\text{-}C_5H_5)(\mu\text{-}PMe_2)]_2(\mu\text{-}H)\}^+BF_4$,[13]



and $[Mn_2(\mu\text{-}H)(\mu\text{-}PPh_2)(CO)_8]$.[14]

$\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}Me_2P)\}$ was originally prepared by Hayter[5] via the interaction of Me_2PH with $[Mo(\eta^5\text{-}C_5H_5)(CO)_3]_2$ and several structural studies have also been reported.[15–17] The key structural feature of this molecule is a central, planar $Mo_2P(H)$ core with an Mo–Mo distance of *ca* 3.2 Å consistent with a fairly long single metal–metal bond. This is bridged by both the PMe_2 unit and the H atom. We felt that complexes of this type might prove to be useful starting materials for further studies of the chemistry of dinuclear phosphido or arsenido bridged complexes. However, we were surprised to find that, to our knowledge, the Me_2P bridged complex is the only one of this type for Mo to have been reported so far.[10]

In order to prepare other analogues we investigated the reaction of $[Mo(\eta^5\text{-}C_5H_5)(CO)_3]_2$ with $t\text{-}Bu_2Ph$ and Me_2AsH. Under refluxing conditions both the phosphine and arsine gave complexes analogous to

$\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}PMe_2)\}$

* Author to whom all correspondence should be addressed.

Scheme 1.

(see Scheme 1) suggesting that this may be a general reaction for the preparation of complexes of this type.

Neutron diffraction studies[16] on

$$\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}PMe_2)\}$$

have shown that the bridging hydrogen atom occupies a symmetrical position between the two molybdenum atoms. We expected our X-ray studies on **1** and **2** to reveal similar symmetrical μ-H atoms if they could be detected. In both cases the X-ray studies show symmetrical bridging hydrides.

We report here the syntheses, characterizations and X-ray crystal structures of **1** and **2**.

RESULTS AND DISCUSSION

Synthesis of $\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}ER_2)\}$ (**1** *and* **2**)

The reaction of t-Bu_2PH or Me_2AsH with $[Mo(\eta^5\text{-}C_5H_5)(CO)_3]_2$ in refluxing toluene or THF yields the phosphido or arsenido bridged dinuclear complexes **1** and **2** in 45 and 35% yields respectively (see Scheme 1). These red (**1**) or orange (**2**) crystalline materials are air-stable both in the solid state and in solution for prolonged periods. Spectroscopic data are in accord with the solid state structures as determined by X-ray diffraction studies. Thus IR spectra for both **1** and **2** show two strong bands in the terminal CO region (see Experimental). The ^1H NMR spectra are also quite straightforward with the unique bridging hydrides giving high field resonances: (**1**) δ −13.1 d ($^2J_{P-H}$ = 35.4 Hz), (**2**) δ −12.09 s (C_6D_6, RT). The $^{31}P\{^1H\}$ NMR spectrum of **1** shows a low field resonance (δ 267.53 ppm) indicative of a phosphide bridging a metal–metal bond.* Both complexes are also sufficiently volatile to yield molecular ions as the highest observable peaks in their mass spectra. In order to confirm the geometries and formulations of each complex and to study the $Mo_2E(H)$ cores in these molecules, single-crystal X-ray diffraction studies were undertaken for both **1** and **2**.

X-ray structures of $\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}ER_2)\}$ (**1** *and* **2**)

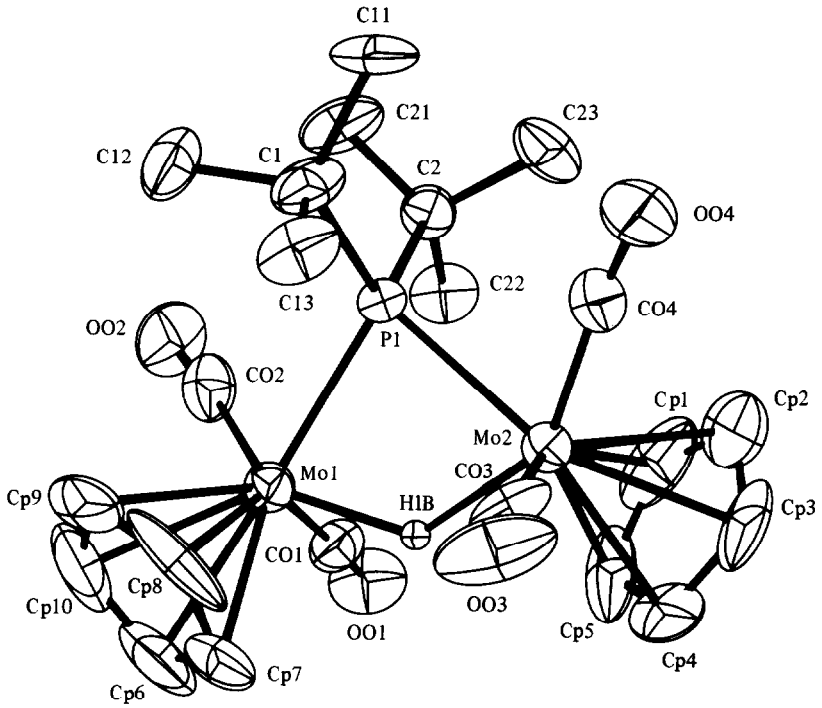
General views of each molecule are shown in Figs 1 and 2. Relevant bond lengths and angles are presented in Tables 1–4. As found for

$$\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}Me_2P)\}$$

the structures of **1** and **2** consist of a central $Mo_2(R_2E)(H)$ core (E = P, As) which is virtually planar.† Each molybdenum atom bears one η^5-C_5H_5 ligand and two carbonyls. Ignoring the position

* Downfield shifts in the δ 50–200 range in the ^{31}P NMR of Ph_2P groups bridging metal–metal bonds have been noted by several groups of workers. See Ref. 18. Similar downfield shifts have been noted for μ-t-Bu_2P complexes, see Ref. 1 and references therein.

† Deviations from the least-squares plane through Mo1–Mo2–H1B–P1 are Mo1 −0.074(1), Mo2 −0.080(1), H1B 0.10(9), P1 0.046(2). (**2**) Deviations (Å) from the least-squares plane through Mo1–As–Mo2–HY1 are Mo1 −0.002(1), As −0.001(1), Mo2 −0.002(1), HY1 0.003(1).



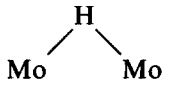


Fig. 1. General view of $[Mo(\eta^5\text{-}C_5H_5)(CO)_2](\mu\text{-}H)(t\text{-}Bu_2P)$ (**1**). Hydrogen atoms except for the bridging hydride have been omitted for clarity.

of the μ-H atom there is a pseudo-two-fold axis passing through the P or As atom and the mid-point of the Mo–Mo vector. The geometry about each Mo atom can be described in terms of a "four legged stool"[15] with the overall dinuclear geometry resulting from a sharing of adjacent H and P (or As) atoms. A reasonable electron-counting scheme for each Mo has been proposed for

$$\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}Me_2P)\}$$

which involves a bent 3*c*–2*e*

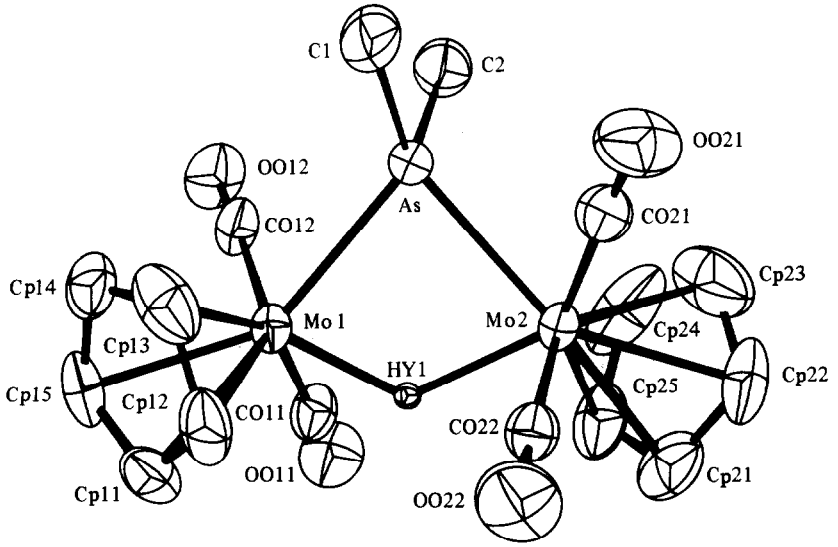

Fig. 2. General view of $[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}Me_2As)$ (**2**). Hydrogen atoms, except for the bridging hydride have been omitted for clarity.

interaction involving a substantial Mo–Mo bonding component despite the fairly long Mo–Mo distances [e.g. 3.247(1) Å in **1**]. The key structural features of the central cores of **1** and **2** are similar to those of $\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}Me_2P)\}$ and are tabulated in Table 5. In both cases the X-ray data was of sufficient quality to permit the location and isotropic thermal refinement of the bridging hydrides. It is well known that the apparent positions of the hydrogen nuclei in metal hydrides when obtained from X-ray data may deviate substantially from their true positions obtained via neutron diffraction studies.[17] For both **1** and **2** however the μ-H atoms *appear* to occupy fairly symmetrical positions (to within the limits of error inherent in locating them). This is consistent with the more reliable positions of the non-hydrogen atoms in **1** and **2**, which also adopt quite symmetrical positions and we feel that this is a reasonably good indication that the μ-H units are symmetrically bridging.

The chemistry of these and related complexes will be described in future papers.

EXPERIMENTAL

All reactions were performed under oxygen-free nitrogen. Microanalyses were by the Schwartzkopf Microanalytical Laboratory (Woodside, NY). Hexane and THF were dried over sodium and distilled from sodium/benzophenone under nitrogen before use. Toluene was distilled from sodium under nitrogen. Melting points were in sealed capillaries under nitrogen (1 atm) and are uncorrected.

Instruments

IR: Perkin–Elmer 1330. NMR: Nicolet NT200 (^{1}H and ^{31}P), Varian EM-390 (^{1}H, 90 MHz), FT80 (^{31}P, 32.384 MHz). IR spectra were as Nujol mulls (KBr plates) or in solution (matched KBr or CaF_2

filtered. Cooling the red Et_2O solution (−20°C) yielded red prisms of **1** over 72 h which were collected and dried under vacuum. The compound is air-stable in solution and in the solid state. Yield 0.53 g (45%); m.p. 177–185°C (dec); IR (CaF_2, toluene) 1935 *s*, 1857 *s*, 1800 *w* (cm^{-1}); IR (Nujol, NaCl) 1915 *s*, 1831 *s*, 1257 *m*, 1009 *m*, 807 *s* (cm^{-1}). ^1H NMR (C_6D_6, 200 MHz) δ 4.95 *s* (10 H) (C_5H_5), δ 1.28 *d*, J = 13.5 Hz (18H), (μ-P^{t}Bu$_2$), δ −13.1 *d*, $^2J_{PH}$ = 35.4 Hz (μ-H); $^{31}P\{^1H\}$ NMR (C_6D_6) δ 267.53 *s*, (μP^tBu_2); M.S. using fast atom bombardment; positive ion, thioglycerol matrix. The molecular ion (M^+) was observed as the highest peak at 580.08(58) a.m.u. (based on $_{42}Mo^{96}$). $^{92}Mo_2PC_{22}H_{29}O_4$ peak matching was also good: m/z measured = 571.9926; m/z calculated = 571.9940. Other peaks (relative intensity in parentheses): 552 (78) ($M^+ - CO$); 525 (32) ($M^+ - 2CO$); 495 (20) ($M^+ - 3CO$); 467 (50) ($M^+ - 4CO$); 437 (100) [$M^+ - (t\text{-}Bu_2P)$]; 407 (70) [$M^+ - (t\text{-}Bu_2P$, $CO)$]; 382 (75) [$M^+ - (t\text{-}Bu_2P$, $2CO)$]; 353 (70) [$M^+ - (t\text{-}Bu_2P$, $3CO)$]; 323 (40) [$M^+ - (t\text{-}Bu_2P$, $4CO)$]. Found: C, 45.43; H, 4.89%. Calc. for $C_{22}H_{29}Mo_2O_4P$: C, 45.53; H, 5.04%.

$\{[Mo(\eta^5\text{-}C_5H_5)(CO)_2]_2(\mu\text{-}H)(\mu\text{-}Me_2As)\}$ (**2**)

To a solution of $[Mo(\eta^5\text{-}C_5H_5)(CO)_3]_2$ (1.23 g, 2.50 mmol) in THF (100 cm^3) was added two equivalents (0.437 cm^3, 5.0 mmol) of neat Me_2AsH. The mixture was then heated under reflux 40 h. Volatile materials were removed under vacuum, the dark brown residue extracted with toluene (30 cm^3) and the solution filtered. The volume was reduced (*ca* 20 cm^3) and cooled overnight (−20°C). **2** is obtained as air-stable orange rods. Yield 0.51 g (35%), m.p. 185–192°C (dec); IR (THF solution, CaF_2 cells) 1935 *s*, 1870 *s* (cm^{-1}); (Nujol, KBr plates) 1920 *s*, 1850 *s*, 1260 *w*, 890 *w*, 850 *vw*, 810 *m*, 790 *m*, 710 *vw*, 590 *m*, 555 *vw*, 525 *vw*, 500 *m*, 460 *m* (cm^{-1}). NMR: ^1H δ 4.65 *s* (10H) (C_5H_5); δ 1.54 *s* (6H) (Me_2As); δ −12.09 *s*, 1 *H* (μ-*H*) M.S. (EI). The parent ion (M^+ = 540 a.m.u.) was the highest observable peak. Found: C, 35.62; H, 3.10%. Calc. for $C_{16}H_{17}AsMo_2O_4$: C, 35.58; H, 3.17%

X-ray experimental data

X-ray quality crystals of **1** and **2** were grown from toluene solutions at −20°C. Crystals were mounted in thin-walled glass capillaries under nitrogen. Data were collected by the $\omega/2\theta$ scan technique at 23 ± 2°C on an Enraf–Nonius CAD-4 diffractometer. Final lattice parameters were determined from 25 carefully centered high angle reflections ($26.0 > 2\theta > 30.0$). Details of crystal data and a summary of intensity data collection parameters for **1** and **2** are given in Table 1. Details of data collection were similar to those outlined in Ref. 21. For **1** the space group was uniquely determined by systematic absences to be *Pbca* and this was confirmed by the successful refinement. For **2** the stucture was solved successfully in $P\bar{1}$. The data for **1** and **2** were corrected for Lorentz and polarization effects. Both structures were solved using standard heavy-atom methods or direct methods and successive difference Fourier maps using the Enraf–Nonius software package "SDP-PLUS" (B. A. Frenz and Associates, College Station, TX 77840, 4th edition, 1981) on a PDP 11/44 computer. Scattering factors were taken from Ref. 22. Empirical absorption corrections (psi scans) were applied [% trans: min. 73.6, max. 99.9 (**1**); min. 64.9, max. 99.8 (**2**)]. Hydrogen atoms on the Cp rings were placed in idealized positions with fixed temperature factors (sp^2 geometry, 0.95 Å bond lengths) and were used in structure factor calculations but not refined. The bridging hydride was located and refined isotropically in both cases. The methyl hydrogen atoms in both structures were not located. Crystal data: (**1**) $C_{22}H_{29}Mo_2PO_4$, M = 580.33, orthorhombic, *Pbca* (No. 61), a = 18.085(7) Å, b = 16.637(5) Å, c = 15.423(6) Å, U = 4640.5(5) Å^3, D_c = 1.661 g cm^{-3}, Z = 8, λ(Mo-K_α) = 0.71069 Å (graphite monochromator), μ(Mo-K_α) = 11.47 cm^{-1}, from 2064 observed reflections [$I > 2\sigma(I)$], 4548 measured. (**2**) $C_{16}H_{17}AsMo_2O_4$, M = 540.11, triclinic, $P\bar{1}$ (No. 2), a = 9.246(1) Å, b = 9.493(1) Å, c = 11.625(1) Å, α = 83.04(9)°, β = 82.239(9)°, γ = 61.976(10)°, U = 890.9(5) Å^3, D_c = 2.013 g cm^{-3}, Z = 2, λ(Mo-K_α) = 0.71069 Å (graphite monochromator), μ(Mo-K_α) = 32.29 cm^{-1}, 3120 observed reflections [$I > 3\sigma(I)$], 3332 measured. Final full-matrix least-squares refinements with anisotropic thermal parameters for all non-hydrogen atoms gave final values of R = 0.0407 and R_w = 0.0463 for **1** and R = 0.0258 and R_w = 0.0373 for **2**

$$\{R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$$

and

$$R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}\}.$$

Final difference Fourier maps showed no chemically significant peaks. Tables of atomic coordinates, thermal parameters, complete bond lengths and angles and F_o/F_c values (65 pages) have been deposited as supplementary materials with the Editor from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Acknowledgements—We thank the Robert A. Welch Foundation (F-816) and the National Science Foundation

(CHE82-11883) for support. The X-ray diffractometer was purchased with funds from the NSF (CHE82-058712) and the University of Texas. We thank Professor E. P. Kyba of this Department for helpful discussions of his work prior to publication.

COMPLEXING PROPERTIES OF 1,2-DIHYDROXY-3,4-DIKETOCYCLOBUTENE WITH IRON AND NICKEL IN ETHANOL

O. ST. C. HEADLEY and L. A. HALL*
Department of Chemistry, University of the West Indies, St. Augustine, Trinidad

(*Received* 29 *August* 1983: *accepted after revision* 19 *February* 1985)

Abstract—The divalent chlorides of iron and nickel were reacted with 1,2-dihydroxy-3,4-diketocyclobutene (squaric acid) in ethanolic solution to form complexes of molecular formula $[M(HC_4O_4)(Cl)(C_2H_5OH)]_2 \cdot C_2H_5OH$ in which the metal ions show penta-coordination. Both complexes are hygroscopic and on exposure to air undergo changes indicating change of coordination number. However, only the iron complex undergoes a change in oxidation state as well.

A number of complexes of squaric acid have been reported previously, but so far all have been octahedral and have been obtained from aqueous solution.[1–5] Tetrahedral complexes have been obtained by the vacuum dehydration of their octahedral analogues,[6] but, as far as we know, this is the first direct synthesis of five-coordinate inorganic squarate complexes.

EXPERIMENTAL

Chemicals. The squaric acid was obtained from the Aldrich Chemical Company, Milwaukee, Wisconsin. It was recrystallised once from water and dried at approximately 100°C. The ethanol used was absolute ethanol (which was redistilled over calcium oxide) obtained from BDH. The nickel(II) and iron(II) chlorides were used in their hydrated form.

Preparation of the complexes (squarate chlorides). The method of preparation of the iron(II) and nickel(II) squarate chlorides is identical and therefore only the preparation of the nickel(II) complex is described.

Approximately 1.48 g (6.2 mmol) of nickel(II) chloride-6-water was dissolved in 200 cm^3 of hot ethanol through which a continuous stream of nitrogen was being passed. A hot ethanolic solution (200 cm^3) containing 0.71 g (6.3 mmol) of squaric acid was then added to the nickel(II) chloride solution and the resulting mixture evaporated for a few minutes in an atmosphere of nitrogen. The mixture was then quickly transferred to a dry bag filled with nitrogen, filtered and the complex placed in a vacuum manifold, which was then removed from the dry bag and connected to a drying pistol containing phosphorus pentoxide. The complex was then dried at approximately 0.1 mm pressure for four hours and sealed *in vacuo*.

Yield: nickel(II) squarate chloride, 2.10 g (61.3%); iron(II) squarate chloride, 2.25 g (66.4%).

Found: C, 30.32; H, 5.12; Cl, 13.20; Ni, 21.18. Calc. for $C_{14}H_{20}Cl_2Ni_2$: C, 30.38; H, 3.62; Cl, 12.84; Ni, 21.34%.

Found: C, 30.16; H, 5.02; Cl, 13.05; Fe, 20.18. Calc. for $C_{14}H_{20}Cl_2Fe_2$: C, 30.71; H, 3.66; Cl, 12.98; Fe, 20.48%.

Instrumentation. A Perkin–Elmer 237B grating spectrophotometer was used to record the spectra between 4000 and 625 cm^{-1} while the spectra in the 600–180 cm^{-1} region were done with a Perkin–Elmer model 983 spectrophotometer. Nujol was used in the preparation of the mulls for both types of spectra and "saran wrap" was used as window material for the spectra between 600 and 180 cm^{-1}. The UV–visible–near IR reflectance spectra were recorded on a Varian 2300 spectrophotometer. The magnetic susceptibility measurements were done on a Newport magnetic balance using mercury tetrathiocyanatocobalt(II) as calibrant. Thermal weight loss curves were obtained on a Netzsch STA 409 thermogravimetric analyser.

* Author to whom correspondence should be addressed.

Analyses. The carbon and hydrogen microanalyses were done by Huffman Laboratories, Inc., Colorado, U.S.A. The metal determinations were done with the use of a Pye–Unicam SP9 atomic absorption spectrophotometer, while the chlorine was determined gravimetrically as silver chloride using the method described by Vogel.[7]

RESULTS AND DISCUSSION

Iron(II) squarate chloride and nickel(II) squarate chloride

The IR spectra of the two complexes are almost superimposable (Table 1). The peak at 1775 cm^{-1} in the IR spectrum of both complexes is attributed to C=O stretching and the fact that it is observed a few wave numbers below 1800 cm^{-1} where it is expected is most likely due to hydrogen bonding involving the ketonic oxygen. The broad band around 3400 cm^{-1} is characteristic of hydrogen bonded hydroxyl groups and has been assigned to the O–H stretch in ethanol and the hydroxyl groups on the squarate rings. The peaks at 884, 1050, 1100, 1270 and 1925 cm^{-1} are due to ethanol since they all appear in the spectrum of neat ethanol.[8] The peak at 2200 cm^{-1} is an overtone of the peak at 1100 cm^{-1}. The band between 2600 and 2700 cm^{-1} and the peak at 725 cm^{-1} are also present in the spectra of the both complexes and have been identified as squarate bands.[9] The broad band between 1500 and 1700 cm^{-1} is due to a mixture of C–C and C–O stretchings.[3] The strong absorption at 525 cm^{-1} is assigned to M–O stretching.[10] The peaks at 180–250, 280 and 300 cm^{-1} in the iron complex and those at 225–250, 305, 317 and 330 cm^{-1} in the nickel complex are assumed to be due to the bridging chlorine atoms.[11]

Ciampolini[12] calculated the splittings of the terms of the free nickel(II) ion in the fields of five point dipoles arranged in trigonal–bipyramidal configurations. The predicted electronic spectrum resembles closely the observed spectra of [Ni(dienMe)Cl]Cl,[13] to which a distorted trigonal–bipyramidal structure has been assigned (see Fig. 1), and $[Ni(HC_4O_4)(Cl)(C_2H_5OH)]_2 \cdot C_2H_5OH$. The band at 8000 cm^{-1} in the electronic spectrum of nickel(II) squarate chloride has been assigned to $^3E' \rightarrow {}^3E''$, the band at 12,500 cm^{-1} to $^3E' \rightarrow {}^3A_1''$, and the shoulders at 14,300 and 20,600 cm^{-1} to $^3E' \rightarrow {}^3A_2'$ and $^3E' \rightarrow {}^3E''$ respectively. The band at 23,500 cm^{-1} has been assigned to $^3E' \rightarrow {}^3A_2'$.

The electronic spectrum of the iron(II) complex shows bands which can be interpreted in terms of the ligand-field model for trigonal–bipyramidal iron(II) proposed by Norgett *et al.*[14] The broad band between 8700 and 12,500 cm^{-1} has been assigned to $(e'')^4(e')^2 \rightarrow (e'')^3(e')^3$. The bands at 20,000 and 26,300 cm^{-1} have been assigned to $(e'')^4(e')^2 \rightarrow (e'')^4(e')^1a_1'$ and $(e'')^4(e')^2 \rightarrow (e'')^3(e')^2a_1'$ respectively. In addition, the spectrum compares favourably with that of the five-coordinate iron(II) complex $[Fe(NO_3)(QP)]^+$; $[QP = (OPh_2P \cdot C_6H_4)_3P]$. The electronic spectra of the two complexes appear in Fig. 2.

The evidence tends to suggest that both the iron(II) and nickel(II) complexes are five-coordinate and most likely trigonal–bipyramidal. The following structure is therefore proposed.

The thermal weight loss curve for

$$[Fe(HC_4O_4)(Cl)(C_2H_5OH)]_2 \cdot C_2H_5OH$$

shows an inflection at about 150°C which corresponds to a 19.4% weight loss and another at about 200°C which corresponds to a weight loss of 9.9%. The first weight loss probably corresponds to the loss of coordinated ethanol while the second is apparently due to the loss of "lattice" ethanol.

Wrobleski and Brown[15,16] have postulated that hydrogen bonding between squarate and lattice solvent may be so strong that solvent coordinated to the metal is more easily lost from the complex.

The calculated weight losses of 16.8% and 8.4% are lower than those observed. This disparity may possibly be attributed to contamination by ethanol and/or water molecules, an occurrence which would also lead to the high H analysis recorded. A similar solvent contamination was observed[17] when $NiC_4O_4 \cdot 2H_2O$ was prepared from a 50:50 ethanol/water mixture. In that case, H analysis yielded values that were 50% higher than calculated.

The first inflection in the thermal weight loss curve for $[Ni(HC_4O_4)(Cl)(C_2H_5OH)]_2 \cdot C_2H_5OH$ occurs at about 175°C and corresponds to a weight loss of 28%. The theoretical weight loss for 3 molecules of ethanol is 25%. It appears that nickel(II) squarate chloride looses the coordinated and "lattice" ethanol simultaneously. This could be due to a weaker binding of the "lattice" ethanol in this complex. The disparity between the theoretical and experimental weight loss is again attributed to solvent contamination which could also explain the difference between the calculated and found H values.

Subsequent steps in the decomposition of the two squarate complexes seem to follow a complicated mechanism as observed for other squarates.[15] On exposure to the atmosphere, the nickel(II) complex changes from yellow to green. The electronic spectrum of the exposed complex shows the bands shifting with time until the spectrum becomes similar to that of $[Ni(H_2O)_6]^{2+}$.[18] The nickel(II) complex thus appears to become octahedral on taking up water from the atmosphere.

Iron(II) squarate chloride, when exposed to the atmosphere, undergoes two colour changes. The first change from faint yellow–brown to brown is accompanied by a weight loss and probably corresponds to the replacement of ethanol by water. Some atmospheric oxidation to iron(III) also takes place. The second colour change to deep red–brown is definitely due to rapid atmospheric oxidation to iron(III) since addition of hydrogen peroxide to the original faint yellow–brown complex produces the same change immediately.

The two complexes are apparently high spin since they have magnetic moments of 3.25 and 4.96 BM at 298 K which suggest spin-free Ni^{2+} and Fe^{2+} respectively.

Relative molecular mass and conductivity measurements could not be done since the complexes are insoluble in all the common solvents. Work is now being done to prepare crystals suitable for X-ray investigation.

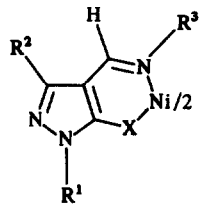
Abstract—Novel bis-chelate Ni(II) complexes with a series of 1,3-disubstituted 4-aminomethylenepyrazole-5-thion(seleno) derivatives have been prepared. An inversion of the tetrahedral configuration at the metal centre in these complexes proceeds in solution *via* the intramolecular diagonal twist rearrangement on the NMR time scale which was followed by coalescence studies on several pairs of diastereotopic protons. The activation barriers are: $\Delta G^{\ddagger}(T_c) = 41$–$74$ kJ mol^{-1}, $T_c = 218$–373 K. The bulky substituents R_3 at the aldimine nitrogen give rise to significant increases in the energy barriers to enantiomerization of tetrahedral complexes owing to the steric hindrance involving an intermediate square planar form.

Inversion of tetrahedral configuration ($\Delta \rightleftarrows \Lambda$) at four-coordinated metal centres in the MN_2X_2 (X = O, S, Se; M = Zn, Cd, Be) complexes **I** derived from unsymmetrical ligands has been studied in detail using dynamic NMR spectroscopy, without requiring the separation of enantiomers.[1–5] The same method was also found to be efficient in evaluation of the energy barriers to enantiomerization of tetrahedral B (**III**) mono-chelates with similar ligands.[6,7]

Two competing reactions were found to occur to complexes **I** in solution, both leading to the $\Delta \rightleftarrows \Lambda$ interconversion. These include the degenerate bond rupture-bond closure ligand exchange process and more rapid intramolecular digonal twist rearrangements via square planar *trans* **IIa** or *cis* **IIb** configurational isomers.

By applying the quantitative line-shape analysis and the two-dimensional FT–NMR technique to the study of ^{111}Cd isotopomeric complexes it became recently possible to evaluate rate constants and activation parameters for each of these reactions.[8,9] It was shown that the digonal twist rearrangements **IΔ** ⇄ **IΛ** are the purely intramolecular processes which are 10^2–10^3 times faster than the degenerate



ligand exchange reactions. Unlike the Be(II), Zn(II) and Cd(II) type **I** chelates isoligand Ni(II) complexes exist in solution as equilibrium mixtures of

* Author to whom correspondence should be addressed.

diamagnetic square planar **II** and paramagnetic tetrahedral **I** isomers, free energy of equilibrium (ΔG°_{298}) lying ordinarily in the range of 4–12 kJ mol^{-1}.[10] The rates of interconversion between planar and tetrahedral forms and, therefore, of the enantiomerization processes **IΔ** ⇄ **IΛ** are normally extremely high and are beyond the limits of the NMR time scale.

An approach to paramagnetic Ni(II)bis-chelates with sufficiently rigid chiral tetrahedral structure was first presented by Knorr *et al.*[11,12] By substituting X in **I** by the NR group these authors succeeded in destabilizing the square planar structure **II** as compared to the tetrahedral isomer **I** which led to the increase of square planar–tetrahedral energy gap up to 70–120 kJ mol^{-1}. Another way to achieve such a high energy difference between these isomeric forms of Ni(II) complexes was found in annelating various π-acceptor moieties (benzofurane, benzothiophene, pyrazole) to their chelate rings which results in a complete shift of the **I** ⇆ **II** equilibria to the left.[13–16] Therefore a considerable thermodynamic contribution to the energy barriers for the interconversion of the Ni(II)bis-chelate complexes might be expected. In the present paper the results of dynamic ^1H NMR investigation of enantiomerization kinetics of previously unknown paramagnetic tetrahedral Ni(II) complexes **III** are reported.

RESULTS AND DISCUSSION

The presence of prochiral isopropyl and benzyl groups R^1 and R^2 in chiral tetrahedral complexes **III** allows the investigation of the tetrahedral inversion by use of the NMR method without prior separation of enantiomers. Any process which leads to the inversion at the metal centre on the ^1H NMR time scale will result in averaging signals belonging to the diastereotopic methyl groups (*i*-Pr) or to the methylene protons (CH_2Ph). The ^1H NMR spectra of paramagnetic Ni(II) complexes **III** exhibit moderately broadened lines ($\Delta\nu^0_{1/2} \simeq 10$ Hz). The values of isotropic contact shifts originated from delocalization of the electron spin density to the ligands are very near to those measured earlier for some of type **IIIa** Ni(II) complexes.[15]

The typical spectrum for one of the complexes is given in Fig. 1.

In the slow exchange region at low temperatures diastereotopic methyls in both isopropyl groups R^3

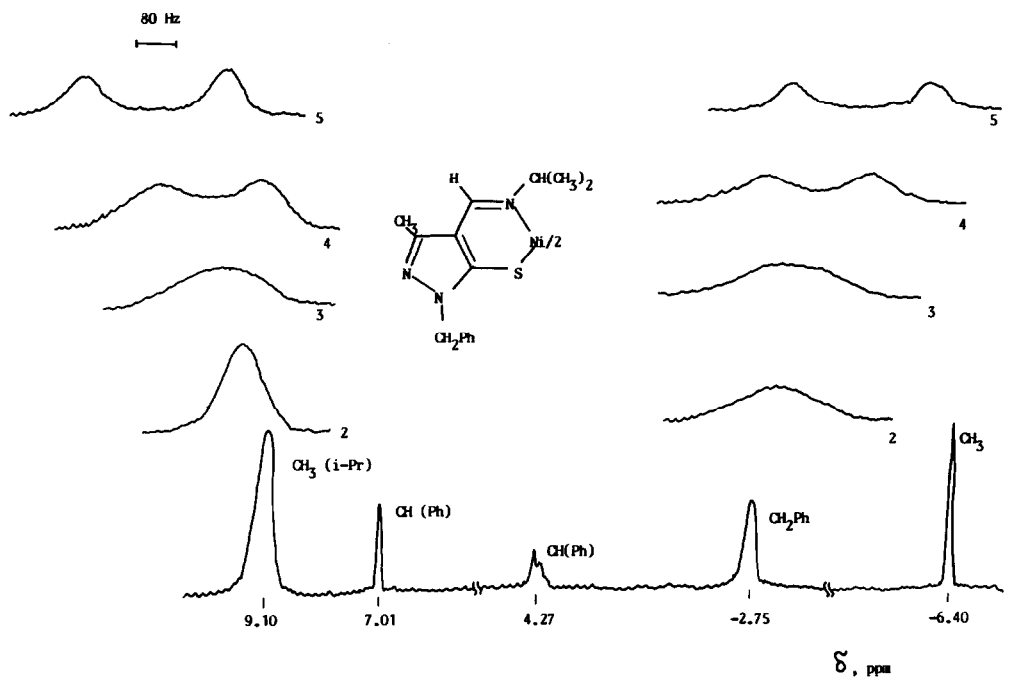


Fig. 1. ^1H NMR spectrum of bis-chelate complex **IIIc** (R^3 = *i*-Pr) in $CDCl_3$ solution at 25°C (1) and temperature dependent methyl (R^3 = *i*-Pr, X = S) and methylene ($R^1 = CH_2Ph$) resonances in the intermediate-exchange region: −10° (2), −20° (3), −30° (4) and −50° (5).

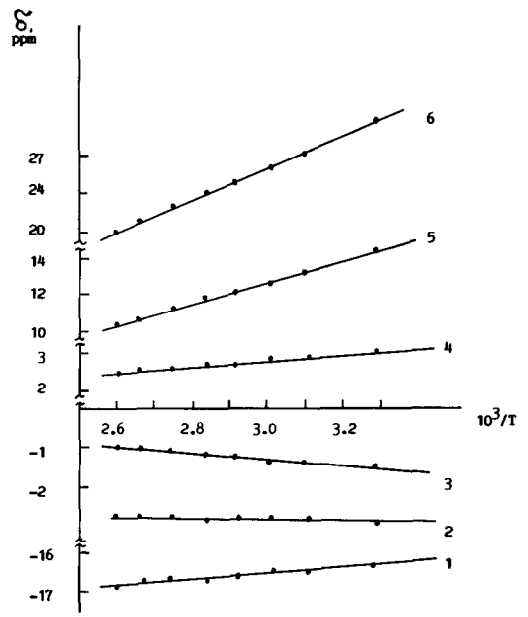

Fig. 2. Temperature dependence of isotropic chemical shifts of protons for bis-chelate complex **IIId** (R^3 = *t*-Bu, X = S) in DMSO solution: (1) CH, (2) CH_3 (*i*-Pr), (3) *m*-H, (4) *p*-H, (5) *o*-H, (6) CH_3 (*t*-Bu).

are rendered anisochronic, showing two unresolved six-proton peaks. Such broadened lines are typical for paramagnetic Ni(II) complexes ($\Delta\nu^0_{1/2} > {}^3J_{HH}$), while characteristic splitting (${}^3J_{HH}$ = 6.5–7 Hz) is observed in ^{1}H NMR spectra of both free ligands and diamagnetic tetrahedral complexes of Zn(II) and Cd(II). A linear contact shift vs 1/T dependence was observed for various protons in **III** in accordance with the Curie law. This is shown in Fig. 2.

At elevated temperatures the methyl proton peaks become broadened and then coalesce. A similar reversible temperature dependence was observed for the N_1-benzyl diastereotopic methylene protons. The AB type spectrum of this pair of protons is perturbed by significant paramagnetic broadening and a loss of terminal components of the AB quartet due to very large AB chemical shift. Thus, the dynamic ^{1}H NMR spectra of paramagnetic tetrahedral Ni(II) complexes **III** reveal the existence of the $\Delta \rightleftarrows \Lambda$ interconversions in solution manifesting themselves in a loss of chirality of the tetrahedral structure.

Since the total line-shape analysis of the temperature dependent NMR spectra of Ni(II) complexes **III** could not be carried out because of paramagnetic broadening and of large signal drifts (see also[17,18] for similar cases) the free energies of activation for the $\Delta \rightleftarrows \Lambda$ interconversion $\Delta G^{\ddagger}(T_c)$ were calculated at coalescence temperatures. They are listed in Table 1. The table includes also the values of magnetic moments of complexes **III** which were determined in chloroform solution by Evans' method.

The measured values of effective magnetic moments remained constant over a temperature interval covering the range of reversible line-shape evolution of prochiral group signals which indicates that no appreciable amounts of equilibrium diamagnetic isomers of **III** appeared. Neither contact shifts, even more sensitive to rather small concentrations of diamagnetic isomer,[17] nor coalescence temperatures depended on the concentration in the accessible range of 10^{-2}–10^{-4} mol l^{-1}. These values were not influenced either by varying solvent polarity ($CDCl_3$, CH_2Cl_2, acetone-d_6, DMSO-d_6). It may be concluded, therefore, that the mechanism and kinetics of the **III**(Δ) $\rightleftarrows$ **III**(Λ) interconversion is determined by the intramolecular digonal twist rearrangement, while the intermolecular degenerate ligand exchange reactions, if they proceed, are slow enough relative to the former process.

Although the free energies of activation for **III**(Δ) $\rightleftarrows$ **III**(Λ) interconversion could not have been calculated and compared at a single temperature relatively small differences in the coalescence temperatures and a compensation effect (see ref. 19) make possible a comparison of the energy barrier values given in Table 1. This is also justified by a good coincidence of the $\Delta G^{\ddagger}(T_c)$ values calculated for different pairs of diastereotopic groups within the same molecule (compounds under numbers 2, 3, 22 in Table 1).

It may be seen from the data given in Table 1 that the main structural factor influencing the height of the energy barrier against the digonal twist in tetrahedral complexes **III** is a steric volume of the R^3 substituent attached to the aldimine nitrogen atom coordinated to the metal centre. The bulkier the R^3 substituent the higher the **III**(Δ) $\rightleftarrows$ **III**(Λ) energy barrier. The following sequence of the energy barriers was found, for instance, for complexes relating to the **IIIb** series (X = S)

R^3 = *t*-Bu (no. 1 in Table 1);	*i*-Pr (no. 2);	CH_2Ph (no. 4);	aryl (nos. 10–15);	Me (no. 8)
73.6 kJ mol^{-1}	50.6	47.7	45.6–47.7	44.4

This sequence is similar to the one proved for the increasing relative stability of the square planar isomeric forms of various bis-chelate Ni(II)

complexes **I** with respect to their tetrahedral forms.[10,20,21]

In contrast to the steric factors, electronic properties of R^3 substituents slightly affect the rates of **III**(Δ) $\rightleftarrows$ **III**(Λ) interconversion which are almost insensitive to the origin of *para*-substituent in *N*-aryl ring (R^3 = aryl). The only exceptions are complexes nos. 17, 18 (**IIIb**) and no. 27 (**IIIc**) containing very strong π-donor groups (*p*-OMe, *p*-NMe_2) in *N*-aryl moieties. It is noteworthy, however, that a nonlinear contact shift vs $1/T$ plot and a small decrease of the effective magnetic moment values upon cooling the solution were observed in the cases of all the above mentioned complexes which may be accounted for by the presence of measurable quantities of polymeric associates in an equilibrium with tetrahedral monomeric forms. Replacement of the sulphur atom in the chelate rings of complexes **IIIb,c**

by selenium results in a small increase in the energy barriers to the tetrahedral inversion. This trend, however, is not observed in the case of complexes **IIId**.

EXPERIMENTAL

^{1}H NMR spectra were obtained using a Varian XL-100 (100 MHz) spectrometer equipped with a variable-temperature probe. The temperature in the samples was controlled with an accuracy of ± 1 K. The rate constants at coalescence temperatures were calculated according to the usual equation: $k(T_c) = \pi/\sqrt{2}\Delta\nu_{1/2}$, where $\Delta\nu_{1/2}$ stands for a linewidth at half height for diastereotopic group signals.

Magnetic moments of complexes in solution were determined by Evans' method.[22]

Complexes **III** were prepared by refluxing (5–10 min) equimolecular quantities of nickel acetate with the respective 4-aminomethylene derivatives of 1,3-substituted 5-thio(seleno)pyrazoles in ethanol solution. All the complexes thus obtained were purified by repeated crystallization from benzene. The experimental details of synthetic procedure and some additional characteristics of complexes **III** will be reported elsewhere.[23]

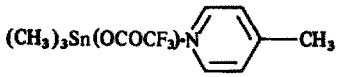
REACTIONS OF THE PYRIDINE ADDUCTS OF ORGANOTIN HALIDES: SYNTHESIS AND SPECTRAL PROPERTIES OF SOME SUBSTITUTED PYRIDINE ADDUCTS OF $(CH_3)_3SnOCOCF_3$ AND $(CH_3)_2Sn(OCOCF_3)_2$



J. J. BONIRE

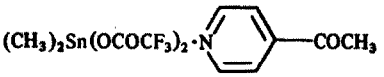
(*Received* 23 *November* 1984; *accepted after revision* 3 *April* 1985)



Abstract—A study of the reactions of the pyridine aducts of organotin halides has led to the synthesis of

and

which were characterised by elemental analysis and spectroscopy.

Studies of the substitution reactions of organotin and organosilicon halides and pseudohalides[1–5] have indicated that the reactions occur by an associative route. Therefore, while triorganotin halide pyridine adducts might undergo associative substitution reactions, the hexacoordinated diorganotin dihalide pyridine adducts might not, due to steric factors. However, Van der Berghe's observation[6] that the trimethyltin chloride pyridine adduct ionizes in polar media suggests that organotin chloride pyridine adducts could undergo dissociative substitution reactions.

Reactions of organotin halide pyridine adducts have not attracted much interest apparently because of their poor solubility in many organic solvents.

Organotin carboxylate pyridine adducts appear to be a new class of compounds. Graddon and Rana[7] have reported their apparent existence in solution, and Saxena *et al.*[8] have reported the synthesis of some tridentate Schiff base complexes of Sn(IV) acetate.

This paper reports the synthesis and some spectroscopic properties of some methyltin trifluoroacetate pyridine adducts in the study of the reactions of organotin halide adducts.

EXPERIMENTAL

"Dry" acetone was prepared by refluxing the analytical grade of acetone with *p*-toluenesulphonylchloride (2 g l^{-1}) for $\frac{3}{4}$ h and distilling the acetone.

All m.p. temperatures (°C) are uncorrected.

IR spectra (KBr disc) were obtained using Perkin–Elmer SP 700 and 800 spectrometers.

^1H NMR spectra were obtained using a T-60 spectrometer at an operating temperature of 38°C; the δ values (ppm, reference TMS) were recorded.

Elemental analyses (C, H and N) were done by the Scandinavian Analytical Laboratories. Sn contents were determined locally, using the methods reported by Farnsworth and Pekola.[9]

All reagents were obtained from BDH, Alfa or Aldrich.

$Me_3Sn(OCOCF_3)\cdot L$: L = *4-acetylpyridine* (*4-AcPy*), *4-benzoylpyridine* (*4-BzPy*) *or* *4-picoline* (*4-Pic*)

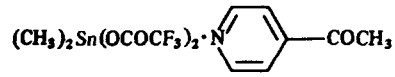
Equimolar amounts (0.01 mol) of Me_3SnCl and L were mixed after dissolving both solutes in CCl_4 (10 and 15 cm^3 respectively). Each mixture was cooled (5°C) overnight. Crystals of $Me_3SnCl\cdot L$ separated out, and were removed, washed with the cold solvent, and dried over silica gel. Each product was recrystallized twice from CCl_4.

Equimolar amounts (0.005 mol) of $Me_3SnCl\cdot L$ and $AgO\cdot CO\cdot CF_3$, both in portions of dry acetone (30 cm^3), were mixed. The ensuing white precipitate was coagulated by boiling the mixture under reflux for 10 min under a covering of aluminium foil, and then removed by filtration. The filtrate was concentrated by evaporation until a yellow oil was left. This solidified on standing, and was dried *in vacuo*. The product was recrystallised 3 times from CCl_4 and dried *in vacuo*.

$Me_2Sn(OCOCF_3)_2\cdot 4$-AcPy

Me_2SnCl_2 (2.21 g, 0.01 M) in CH_2Cl_2 (50 cm^3) and 4-AcPy (2.42 g, 0.02 M) in CH_2Cl_2 (50 cm^3) were mixed. The resulting clear solution was left to stand overnight. Light yellowish granular crystals of $Me_2SnCl_2\cdot$ bis-4-AcPy were produced. The product was removed by filtration, dried *in vacuo*, and recrystallised 3 times from dry acetone (m.p. 117–118°C, lit.[10] 117–118°C).

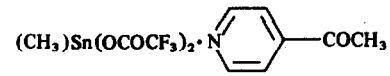
$Me_2SnCl_2\cdot$bis-4-AcPy (2.32 g, 0.005 M) and $AgOCOCF_3$ (2.21 g, 0.01 M) each in (50 cm^3) of hot, dry acetone, were mixed. The ensuring white precipitate of AgCl was coagulated by boiling the mixture under reflux for 10 min under aluminium sheet cover, and filtered off. The filtrate was evaporated until a thick brownish oil was left. This, on cooling (5°C), yielded yellowish crystals. The mass of crystals was removed and dried *in vacuo* (2.05 g, dry), and recrystallised 3 times from toluene.



RESULTS AND DISCUSSION

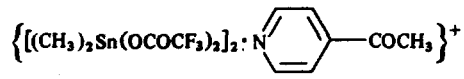
The reactions of the methyltin chloride pyridine adducts with silver trifluoroacetate occurred smoothly in hot, dry acetone. The insoluble silver chloride, after coagulation by boiling, was easily removed by filtration.

Elemental analysis results show all the complexes (Table 1) to be 1:1 complexes, including $Me_2Sn(OCOCF_3)_2\cdot 4$-AcPy. They generally have lower m.ps than the corresponding methyltin chloride adducts.



The ^1H NMR spectra of the complexes, obtained in deuterodimethyl sulphoxide and shown in Table 2, show that the chemical shift (δ) values for the Sn—CH_3 protons are generally lower for the methyltin carboxylate than for the methyltin chloride pyridine adducts. The other signals are not remarkably different from those given by the independent Lewis acids and bases, except that the shift values for the pyridyl protons decreased slightly with the complexation of the pyridine.

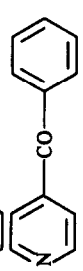
Table 3 shows the IR spectra. The pronounced bands at ~1650 and 1200 cm^{-1}, assignable to OCO and C—F stretch respectively, confirm the presence of the trifluoroacetate group in the complexes. The broad OCO band in the spectrum of



suggests that the OCO is of a bridging type.

A mass spectrum of the

gave the highest mass unit of 873, assignable to



which is twice the molecule of the complex minus a molecule of the Lewis base. This strongly suggests that the adduct exists as a dimer with the structural

formula shown in Fig. 1, which explains why the 4-AcPy adduct of $(CH_3)_2Sn(OCOCF_3)_2$ is obtained as a 1 : 1 Lewis acid : Lewis base.

This work therefore shows that at least some organotin halide pyridine adducts can undergo associative substitution reactions, and also establishes the existence of at least some organotin carboxylate pyridine adducts. It also suggests that interconversion reactions between the adducts of methyltin (and perhaps other organotin) halides and pseudohalides might be possible, as commonly known[1–5] with organosilicon and organotin halides and pseudohalides.

The route of synthesis of the complexes given in this report could be summarized as follows:

$$(CH_3)_3SnCl\cdot L + AgOCOCF_3 \xrightarrow{\text{in hot, dry acetone}} (CH_3)_3Sn(OCOCF_3)\cdot L + AgCl, \quad (1)$$

where L = 4-AcPy, 4-BzPy or 4-Pic.

$$(CH_3)_2SnCl_2\cdot \text{bis-4-AcPy} + AgOCOCF_3 \xrightarrow{\text{in hot, dry acetone}} (CH_3)_2Sn(OCOCF_3)_2\cdot \text{4-AcPy} + AgCl. \quad (2)$$

However, the complexes were also synthesized by the direct reaction of the methyltin trifluoroacetate with the Lewis base in a dry acetone medium. Equimolar amounts of the Lewis acid and Lewis base when mixed in hot dry acetone (heated to ensure the dissolution of the reactants) yielded the complexes, which were obtained from the medium in the manner described above for the complexes prepared from the organotin chloride adducts. Alternatively, the methyltin trifluoroacetates, prepared from the reaction of the methyltin chloride with silver trifluoroacetate in dry acetone, reacted *in situ* with the Lewis bases to yield the complexes.

The route of synthesis of the organotin carboxylate complexes from the organotin chloride complexes being reported cannot be called a general

one; attempts to isolate the $(CH_3)_2Sn(OCOCF_3)_2$ complexes of other pyridine Lewis bases than 4-AcPy have so far failed. Also, only organotin trifluoroacetate complexes have so far been isolated; there is not enough evidence to believe at this stage that all organotin carboxylates complex with the pyridines to give isolable products.

PREPARATION AND PROPERTIES OF VANADYL(IV) HYPOPHOSPHITE, $VO(PO_2H_2)_2 \cdot H_2O$

ENRIQUE J. BARAN* and SUSANA B. ETCHEVERRY
Departamento de Química, Facultad de Ciencias Exactas, Universidad Nacional de La Plata, 1900-La Plata, Argentina

and

EKKEHARD DIEMANN
Fakultät für Chemie der Universität Bielefeld, D-4800 Bielefeld 1, F.R.G.

(*Received* 9 *October* 1984; *accepted in revised form* 3 *April* 1985)

Abstract—The preparation of $VO(PO_2H_2)_2 \cdot H_2O$ was possible by direct reduction of V_2O_5 with hypophosphorous acid or by interaction of $VOSO_4$ and H_3PO_2 solutions, and subsequent crystallization. The compound was characterized by IR, electronic and ESR spectroscopy and X-ray powder diffractometry. Magnetic susceptibilities were measured in the temperature range between 100 and 300 K. The thermal decomposition was also investigated in detail, showing a very complex sequence of degradation steps which finally generate a polymeric V(III) phosphite.

As part of a current research program devoted to the study of simple and not well-characterized compounds of the vanadyl(IV) cation, VO^{2+}, we have recently prepared and investigated the corresponding hypophosphite.

This research is also of more general interest, because very little is known up to now about the structural, spectroscopic and thermal properties of transition-metal hypophosphites. On the other hand, it extends previous work of our laboratory on different complex compounds containing other phosphate ligands (cf, for example, Refs 1–3).

EXPERIMENTAL

The only earlier literature reference about vanadyl hypophosphite is a 1907-dated paper by Mawrow.[4] He prepared this compound by direct reaction between V_2O_5 and hypophosphorous acid. By subsequent crystallization, a blue powder of composition $VO(PO_2H_2)_2 \cdot H_2O$ was obtained. We could also obtain the same product by direct interaction between vanadyl sulfate and hypophosphorous acid solutions. The following procedure, which we have worked out, allows an easy and quick preparation of the compound.

* Author to whom correspondence should be addressed.

Method A

1.5 g of V_2O_5 are suspended in 10 cm^3 of distilled water. 4 cm^3 of a 50% H_3PO_2 solution are dropwise added to this suspension under continuous stirring. The solution is heated until all the V_2O_5 is dissolved and the heating continued for a few minutes more. The resulting blue solution is then concentrated in a vacuum desiccator over conc. H_2SO_4. After a few days a blue compact mass is deposited. It is filtered, washed 3 times with hot water and finally dried again over H_2SO_4.

Method B

4.5 g of $VOSO_4 \cdot 5H_2O$ are dissolved in 20 cm^3 of hot distilled water. 4.5. cm^3 of a 50% H_3PO_2 solution are dropwise added to this solution. The mixture is heated for 10 min and then stored in a vacuum desiccator over conc. H_2SO_4. The remaining steps of the operation are similar to those described in method A.

The solid product is very insoluble in water. Chemical analyses of the obtained samples, performed as described in Ref. 4, confirm the formula $VO(PO_2H_2)_2 \cdot H_2O$. Found: V, 23.7; P, 28.7. Calc.: V, 23.72; P, 28.83%.

Spectroscopic measurements

IR spectra were recorded with a Perkin–Elmer 580 B spectrophotometer, using the KBr pellet technique. The UV/VIS spectra were recorded with a Shimadzu UV-600 model spectrophotometer. The ESR spectrum was obtained by means of a Brucker-ER 10 type spectrometer, working at room temperature and employing a microwave frequency of 9.6 GHz; DPPH was used as an internal calibration standard.

Magnetic measurements

Magnetic susceptibility measurements were performed using the Gouy method in the temperature range between 100 and 300 K. The instrument was calibrated with $HgCo(SCN)_4$. The molar magnetic susceptibilities were corrected by the diamagnetism of the sample.[5]

Diffractometric measurements

X-ray powder data were obtained on a Philips 1732/10 diffractometer using Cu-K_α radiation (Ni filter) and employing NaCl as an external calibration standard.

Thermal studies

The TG/DTA measurements were performed with a Linseis L-81 thermoanalytical system, working in air, at a heating rate of 5°C/min. Al_2O_3 was used as a DTA standard. Studies were also performed at constant controlled temperatures in a crucible furnace in air.

RESULTS AND DISCUSSION

The formula of the compound and the physicochemical properties clearly support the structural arrangement shown in Fig. 1.

This implies that the $H_2PO_2^-$ anion acts as a bidentate ligand of the vanadyl ion occupying four coordination positions about the vanadium atom. The fifth position is obviously occupied by the oxygen atom and the remaining one by the water molecule. The free hypophosphorous acid has a C_{2v} point symmetry,[6,7] but this symmetry is probably reduced in the complex.

Physicochemical studies

IR spectrum. The IR spectrum of the compound is reproduced in Fig. 2 and the corresponding band assignment is given in Table 1.

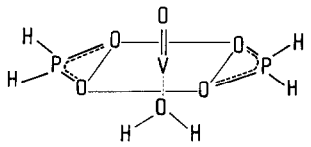

Fig. 1. Proposed structural arrangement for vanadyl(IV) hypophosphite.

Some interesting features of this spectrum are worth further comments.

In this case, the values of the P—H frequencies are displaced to higher wavenumbers, whereas those of the P—O bonds show a shift to lower wavenumbers, in comparison with that reported for the free hypophosphorous acid and for some ionic hypophosphites.[7,8] This behaviour clearly indicates that the $H_2PO_2^-$ moieties act as bidentate ligands of the metallic centre. Its coordination produces a weakening of the P—O bonds and a concomitant increase of the strength of the P—H bonds.

The shift of the $\nu_{as}(PO_2)$, which in the free acid is found at 1184 cm^{-1},[7] produces a partial overlap with the PH_2-scissor band, which appears only as a weak shoulder on the higher-frequency side of the $\nu_{as}(PO_2)$ band.

It is very interesting to observe a weak band placed at 912 cm^{-1} assignable to the PH_2-twisting mode.

412	$\nu(V–OH_2)$

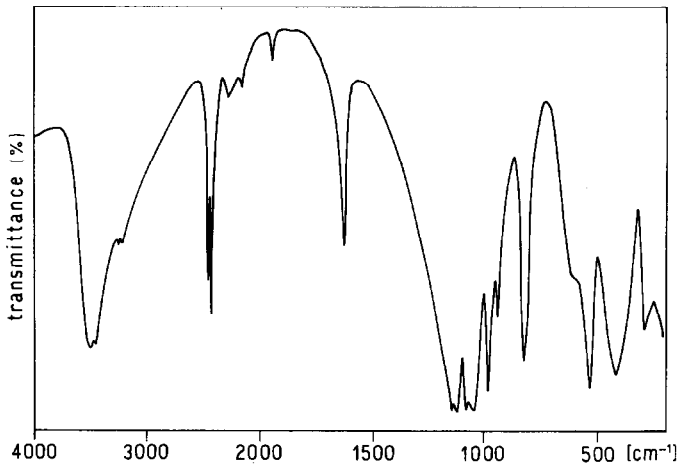

Fig. 2. IR spectrum of $VO(PO_2H_2)_2 \cdot H_2O$.

This band is forbidden for C_{2v}-symmetry[7] and its appearance is indicative of a further lowering in symmetry of the ligands in the complex.

One of the two very weak bands at 3242 and 3218 cm^{-1} can be assigned to the first overtone of the water bending mode, whereas the origin of the other one remains uncertain.

The fact that the $\delta(H_2O)$ band shows a certain asymmetry (a weak shoulder is clearly identified at *ca* 1623 cm^{-1}) can probably be related to the presence of two crystallographically non-equivalent water molecules in the unit cell. If this were true, the presence of two overtones of this bending mode could be explained.

The bands due to the coordinated water (wagging, rocking and V–OH_2 stretch) have been assigned by comparison with the spectra of other aquo complexes.[8,9]

The typical V=O stretching band appears as a very well defined and intense band at 975 cm^{-1}. For comparative purposes we have also measured the IR spectrum of pure $VOSO_4 \cdot 5H_2O$ under the same experimental conditions; in this case the ν(VO) band was found at 980 cm^{-1}. The variations of this stretching mode are commonly associated with changes in the electronic density in the metal *d*-orbitals due to ligand-to-metal $p_\pi \rightarrow d_\pi$ donation (cf. for example, Ref. 10) which indirectly affects the strength of the V—O bond. The present results would imply that the $p_\pi \rightarrow d_\pi$ donation of the $H_2PO_2^-$ ligands is not very different from that of the water oxygen atoms, although a little stronger.

Electronic spectrum. Although the band assignments of the electronic spectra of vanadyl complexes are still not settled (cf. Refs 11 and 12) there seems to be enough evidence favouring the level ordering proposed by Ballhausen and Gray.[13,14] According to their treatment, three "*d–d*" bands related to the $b_2 \rightarrow e_\pi^*$, $b_2 \rightarrow b_1^*$ and $b_2 \rightarrow a_1^*$ transitions, could be observed, although the third one is frequently obscured by the tail of more intense, charge-transfer bands. This is also the situation in our case, in which only two "*d–d*" transitions located at 12,300 cm^{-1} ($\varepsilon = 19.5$) and 15,600 cm^{-1} ($\varepsilon = 8.9$) are observed. In addition, two change-transfer bands, placed at 40,160 cm^{-1} ($\varepsilon \sim 270$) and 48,310 cm^{-1} ($\varepsilon \sim 700$), have been measured.

The crystal field splitting parameter $10Dq$ can be directly obtained from the $b_2 \rightarrow b_1^*$ transition.[13,14] The observed value of 15,600 cm^{-1} is in agreement with those obtained for other simple VO^{2+} complexes with a similar VO^{2+} environment.[15]

ESR spectrum and magnetic susceptibility. In order to obtain a wider insight into the electronic properties and the metal–ligand interactions in this complex, we have also measured its ESR spectrum and investigated its magnetic behaviour at different temperatures.

The first derivative of the ESR spectrum of a powdered sample gives practically an isotropic pattern from which a g_0 value of 1.97 is obtained. This value clearly lies in the region which is considered as typical for a $VO(O_4)$ environment (cf. Ref. 16).

The magnetic susceptibilities were measured in the range between 100 and 300 K. The substance obeys the Curie–Weiss law and a least-squares refinement of the experimental data shows that the Weiss constant, θ, has a value of -7.86 K, whereas the Curie constant is equal to 0.373.

X-ray diffraction measurements. The compound shows a very complex powder pattern, which is given in Table 2. The intensities of the peaks included in Table 2 are relative values, obtained by setting the

Table 2. X-ray powder diagram of $VO(PO_2H_2)_2 \cdot H_2O$

value of the most intense line as equal to 100 and referring the intensity of all other lines to this value. No attempts have been done to index this powder diagram.

Thermal behaviour. TG and DTA diagrams have been recorded and the spectroscopic behaviour of the decomposition residues and intermediates, collected at different temperatures, were investigated.

As it has been already shown by Mawrow,[4] the heating of the vanadyl hypophosphite at 135–145°C causes a colour change from the characteristic bluish coloration to a light green tint, which he associates with the release of water. A further heating, up to 180°C, should produce the decomposition of the substance, which is accompanied with a new colour change from greenish to grey.

The DTA curve shows a very strong endothermic peak at 170°C, which is associated with a mass loss of *ca* 9.5%. This loss extends up to *ca* 200°C in the TG curve; above this temperature and up to 400°C neither new mass changes nor clearly defined DTA signals could be observed.

The controlled heating of samples in a crucible furnace in air, at different temperatures between 130 and 500°C, shows the following behaviour.

The mass loss is strongly dependent on the heating time, heating rate and final temperature.

If one places a sample in the warm furnace at 400°C a very violent reaction with spontaneous inflammation is observed, suggesting the rapid generation of PH_3 and/or H_2.

The characteristic $\nu(OH)$ and $\delta(H_2O)$ IR bands are present, even if the mass loss was greater than 8.4% (which is the percentage of H_2O in the compound). Although it is impossible to formulate a stoichiometric schema for the overall decomposition process, it is evident that, simultaneously with the loss of water, part of the $H_2PO_2^-$ ligand is decomposed, generating HPO_3^{2-} (or $H_2PO_3^-$) and PH_3 in a similar way as for pure H_3PO_2 (cf. Ref. 17).

In a second stage, the remaining hypophosphite is also transformed to phosphite, whereas the primarily generated phosphite is further degraded, probably with the loss of H_2. In this stage the VO^{2+} is probably reduced to V(III) and as a final consequence of this process some type of polymeric V(III) phosphite is formed. These last possibilities are in agreement with the well-known behaviour of V_2O_5 when it is heated with conc. H_3PO_4,[18–20] a process in which its gradual reduction to V(IV) and V(III) takes place. On the other hand, the IR spectra of the residues collected after heating treatments of $VO(PO_2H_2)_2 \cdot H_2O$ at 400°C closely resemble that of $V(PO_3)_3$.[20]

Acknowledgements—This work is supported by CONICET (Programa QUINOR) and CIC–PBA and is also a part of a special research program devoted to the chemistry and biochemistry of vanadium which is sponsored by the Foundation Volkswagenwerke (Hannover, F.R.G.). We are also indebted to G. Minelli (Istituto di Chimica Generale ed Inorganica, Universitá di Roma, Italy) for the magnetic susceptibility measurements.

DITHIOPHOSPHINATES OF TRIVALENT IRON, RUTHENIUM AND OSMIUM

R. N. MUKHERJEE,* S. SHANKAR, V. S. VIJAYA and P. K. GOGOI
Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400 076, India

(*Received* 31 *January* 1985; *accepted* 3 *April* 1985)

Abstract—Dithiophosphinates of Fe(III), Ru(III) and Os(III) have been prepared and their ESR studies indicate distortion from octahedral geometry. The tetragonal and rhombic splittings and the orbital reduction factors were calculated from the experimental g values for low-spin Ru(III) and Os(III) complexes. The metal–ligand covalency increases in the order Ru < Os.

There are few reports on ESR studies of low-spin d^5 Ru(III) and Os(III) complexes[1,2] and, in particular, complexes of these metals with sulphur donors have received much less attention.[3,4] These investigations are of interest because of the sensitive nature of the g values to small changes in the structure and also to the metal–ligand covalency and are found to be a good probe for molecular structure and bonding. In continuation of our earlier work[5,6] on dithiophosphinates of transition metals, we wish to report the synthesis and spectral studies on di-(2,4-dimethylphenyl)dithiophosphinato derivatives of trivalent iron, ruthenium and osmium. Detailed ESR studies were also carried out on a few other dithio compounds of ruthenium and osmium (doped in the corresponding rhodium matrix) which were briefly reported earlier.[7,8]

EXPERIMENTAL

All the chemicals used were of chemically pure grade. Dithiophosphinic acids were prepared by the procedure reported in the literature.[9]

Preparation of the complexes

$Fe(2,4\text{-}Me_2dtpi)_3$. A concentrated aqueous solution of ferric chloride was treated with a slight excess of $Na(2,4\text{-}Me_2dtpi)$ in methanol. The dark green complex which separated out was washed with a water–methanol (80:20) mixture and dried in vacuum. Found: C, 59.12; H, 5.26; S, 19.62; Fe, 5.66; $C_{48}H_{54}P_3S_6Fe$ requires: C, 59.31; H, 5.60; S, 19.79; Fe, 5.75%.

$Ru(2,4\text{-}Me_2dtpi)_3$. Ruthenium trichloride trihydrate (0.5 g) in methanol was mixed with a methanolic solution of sodium salt of the ligand (2 g). On evaporation a chocolate brown complex was precipitated out. This was filtered, washed with methanol and recrystallised from a chloroform–methanol mixture. Found: C, 56.32; H, 5.25; S, 18.68; $C_{48}H_{54}P_3S_6Ru$ requires: C, 56.67; H, 5.35; S, 18.91%.

$Os(2,4\text{-}Me_2dtpi)_3$. The chocolate brown complex was prepared by mixing a methanolic solution of $(NH_4)_2OsCl_6$ (0.5 g) and the sodium salt of the ligand (1.5 g). The complex which separated out was washed with methanol and recrystallised from a chloroform–methanol mixture. Found: C, 51.87; H, 4.70; S, 17.32; $C_{48}H_{54}P_3S_6Os$ requires: C, 52.11; H, 4.92; S, 17.39%.

Physical measurements

The electronic spectra were recorded on a Varian Super Scan 3 UV visible spectrophotometer. The IR spectra were obtained on a Pye–Unicam SP-2000 IR spectrophotometer. ESR spectra of the powdered samples were carried out at $\approx$ 77 K on a Varian E-112 ESR spectrometer (X-band) by using TCNE ($g = 2.00277$) as g marker. Magnetic measurements were made either by Gouy's method or by Evan's NMR technique.

RESULTS AND DISCUSSION

$Fe(2,4\text{-}Me_2dtpi)_3$

The room temperature magnetic moment is 5.80 BM, indicating a d^5 high-spin complex. The

Os(MeCldtpi)$_3$	2.054	2.019	1.939
Os(Medtpi)$_3$	2.059	2.007	1.965

[a] 2,4-Me_2dtpi, di(2,4 - dimethylphenyl)dithiophosphinate; 3,4-Me_2dtpi, di(3,4 - dimethylphenyl)dithiophosphinate; MeCldtpi, di(2 - methyl - 5 - chlorophenyl)-dithiophosphinate; Cl_2dtpi, di(3,4 - dichlorophenyl)dithiophosphinate; Medtpi, di(p - tolyl)dithiophosphinate.

electronic spectrum shows bands at 16,300, 19,100, 23,250, 28,250, 28,600 and 40,650 cm^{-1} and is similar to that of other dithio complexes.[10,11] The spectra of Fe(III) complexes are likely to be influenced by charge-transfer transitions in the visible region[12] and therefore no attempt has been made to assign the observed bands. The IR spectrum shows a P—S stretching frequency at 632 cm^{-1}.

ESR spectrum of the complex at liquid-nitrogen temperature gave a broad signal at $g = 8.24$; in addition, a signal at $g = 4.46$ and a weak signal at $g = 1.87$ were obtained. This observation is similar to those reported for high-spin octahedral Fe(III) complexes.[13]

M(2,4-Me_2dtpi)$_3$ (M = Ru *or* Os)

The room-temperature magnetic moments for these complexes were observed to be 1.67 and 1.79 BM, respectively. The absorption spectrum of the ruthenium compound shows bands at 23,600, 28,500, 34,700 and 40,000 cm^{-1}, while for the osmium compound bands were observed at 17,500, 21,750, 25,600 and 39,400 cm^{-1}. The electronic spectra of Ru(III) and Os(III) complexes have not been fully understood and in most cases it is dominated by charge-transfer bands.[14,15] The bands at 640 and 638 cm^{-1} in the IR spectrum were assigned to P—S stretching vibrations for ruthenium and osmium compounds, respectively.

The ESR data have been interpreted by using the theory described by various authors.[16–18] The observation of three principal g values showed magnetic anisotropy, with $g_1 = 2.080$–2.257, $g_2 = 2.026$–2.077, and $g_3 = 1.948$–1.987 for ruthenium complexes and $g_1 = 2.054$–2.084, $g_2 = 2.007$–2.029, and $g_3 = 1.939$–1.965 for osmium complexes. The g values are given in Table 1.

The paramagnetic resonance experiments give only the absolute principal g values and so neither their signs nor the correspondence of g_1, g_2 or g_3 to g_x, g_y or g_z are known. There are 48 possible combinations depending on the labelling (x, y, z) and signs chosen for the experimental g values. We consider all the possible combinations of experimental g values and their signs for acceptable results. In the present case we have taken g_1 and g_2 to be negative, g_3 to be positive and $g_1 > g_2 > g_3$ to get a reasonable value of k (< 1.0). For other solutions k values are not within the limit and have been rejected. This yielded values of A (0.048–0.094), B (0.995–0.999), C (-0.010 to -0.038), k (0.33–0.76), V/λ (-4.68 to -11.09), Δ/λ (9.57 – 16,14), V/Δ (0.36–0.86), $\Delta E_1/\lambda$ (10.44–16.60) and $\Delta E_2/\lambda$ (12.56–18.50) for ruthenium complexes and A (0.085–0.117), B (0.993–0.996), C (-0.017 to -0.028), k (0.20–0.29), V/λ (-2.08 to -6.86), Δ/λ (6.57–9.85), V/Δ (0.32–0.70), $\Delta E_1/\lambda$ (6.37–10.45) and $\Delta E_2/\lambda$ (7.46–12.48) for osmium complexes. All of these values have been calculated by using a Fortran-IV computer programme and are given in Table 2.

[a] Abbreviations as in Table 1.

[b] In units of spin–orbit coupling constant, λ.

The orbital reduction factor, k, cannot be equated purely with delocalisation or covalency but other unaccounted for effects are to be considered.[19] These effects were taken into account by some authors[1,20,21] and, in particular, Cotton[22] has shown that for $Fe(dtc)_3$ and $Fe(exan)_3$ complexes k can be reduced from 1.07–1.08 to 0.83–0.87 by considering $t_2^4(^3T_1)e$ and $t_2^4(^1T_2)e$ configurations mixed into $t_{2g}^5(^2T_2)$ by electrostatic interactions. However, spin–orbit and charge-transfer mixing have not been taken into account. Further, Desimone[4] has concluded that out of two fits for some ruthenium and osmium dithio compounds the one with a lower value of k is more likely to be an acceptable solution, even though the second one cannot be rejected out of hand. It is clear from Table 2 that the low values of k for Os(III) complexes compared to their corresponding Ru(III) analogues indicate that the metal–ligand covalency increases in the order Ru < Os.

X-ray and Mössbauer studies of iron dithio compounds[23,24] show considerable distortion from O_h-symmetry. Ru(III) and Os(III) complexes show low, relatively temperature-independent magnetic moments,[2,14] indicating a considerable distortion from idealised symmetry. From hyperfine splitting analysis Desimone[4] has concluded that the sulphur compounds of ruthenium and osmium have distorted structures. The ratio V/Δ gives information about the rhombicity of the complex. In the present case V/Δ is less than 1.0 indicating that the tetragonal splitting is greater than the rhombic splitting. Table 2 shows that ruthenium compounds have larger V/Δ values compared to their corresponding osmium analogues. The V/λ and Δ/λ values also follow the same trend except for $Ru(Medtpi)_3$ and $Os(Medtpi)_3$ in which Δ/λ value is almost equal. The high values of Δ/λ indicate considerable distortion of the complexes and the ground state consists of the d_{xy}-hole. Geometric factors and anisotropy in covalent bonding may contribute for this distortion. The latter factor probably plays an important role in distorting the molecules.

The relative energies of the ground and two excited Kramer's doublet states were calculated and it is found that the orbital reduction factor decreases as ΔE_2 decreases. As ΔE_2 is related to bond length,[3] the lower value of k is indicative of the increased covalency of the metal–ligand bond. For these compounds the values of $\Delta E_1/\lambda$ and $\Delta E_2/\lambda$ are in the order Ru > Os, which confirms that osmium complexes are somewhat more covalent than the corresponding ruthenium analogues.

CAN THE PENTAZOLE ANION (N_5^-) BE ISOLATED AND/OR TRAPPED IN METAL COMPLEXES?

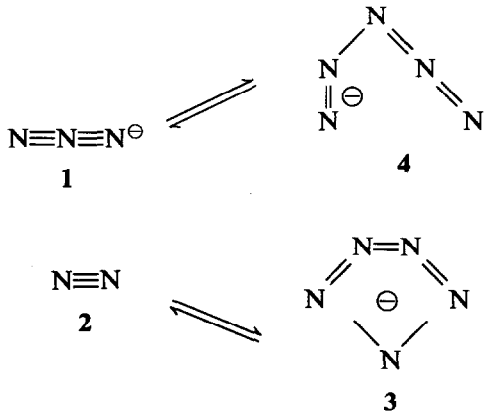
(*Received* 19 *February* 1985; *accepted* 3 *April* 1985)

Abstract—The 1,3-dipolar cycloreversion pathway of the pentazole anion (N_5^-) to the azide anion (N_3^-) plus dinitrogen (N_2) has been investigated using *ab initio* methods. At the MP4SDQ/6-31 + G* level of theory plus zero-point energy contributions, the pentazole anion is predicted to lie at 31 kcal mol^{-1} above the $N_3^- + N_2$ system but the energy barrier for decomposition is 22 kcal mol^{-1}. This indicates that the pentazole anion could be isolated in an inert matrix at low temperature. Comparison between extended Hückel calculations on the $(N_5)M(CO)_3$ and $(C_5H_5)M(CO)_3$ complexes (with M = Fe^{2+}, Mn^+ and Cr) suggests that the N_5^- complexes would be formed if the fragments could be brought together. Predicted vibrational frequencies of the N_5^- anion are also reported.

The chemistry of homocycles containing exclusively nitrogen atoms is only in its first stage of development. For instance, triaziridines (**I**)[1–3] and pentazoles (**II**)[4,5] are at present the only stable or isolable saturated and unsaturated *N*-homocycles, respectively, for which some spectroscopic data and *ab initio* calculations on model molecules (N_3H_3[6] and N_5H[7]) are available.



I **II** **III**

The question of whether hexazine (**III**), the all-nitrogen analogue of benzene, is stable enough to be detected has recently attracted the interest of several groups.[8–13] However, experimental[8] and theoretical[9–13] studies have as yet been inconclusive as to the existence of this intriguing species.[12]

We have recently reported an *ab initio* study of the structure and reactivities towards cycloreversion and cycle-chain isomerisation of the pentazole anion, N_5^- (**3**) (the all-nitrogen analogue of the cyclopentadienyl anion) (Scheme 1).

This study suggested that **3** is of higher energy than the azide anion (**1**) plus molecular nitrogen (**2**) system, but much more stable than the pentazene anion (**4**) and might constitute a reasonable synthetic target. Nevertheless, this prediction should be regarded with caution, because the calculations on

1 **4**

2 **3**

Scheme 1.

† Author to whom correspondence should be addressed.

which it is based were performed at the SCF level using a rather limited basis set (4-31G).

In order to gain further insight into the stability of the pentazole anion, it seems useful to reinvestigate the **3** supersystem at higher levels of accuracy by extending the basis set and including the effects of electron correlation in the wave functions.

In addition, the possibility of trapping the anion in a metal complex such as $(N_5)Mn(CO)_3$ (mentioned in our earlier work,[14] but with theoretical support) is also worth examining.

The aims of the present work are twofold: firstly, to determine the effects of basis set and electron correlation on the energy differences between stationary points in the 1,3-dipolar cycloaddition (or cycloreversion) pathway connecting fragments N_3^- (**1**) plus N_2 (**2**) to the anion **3**. Because of the large energy differences between **3** and **4** (68 kcal mol^{-1} at 4.31 G[14]), we have excluded the two remaining pathways of Scheme 1 involving **4** from this study. Secondly, to examine whether **3** is a possible candidate for metal complexation by performing some extended Hückel (EH) calculations[15] on the systems $(N_5)M(CO)_3$ with M = Fe^{2+}, Mn^+ and Cr.

We used the Gaussian-82 program[16] for *ab initio* calculations and the FORTICON-8 program[17] for EHT calculations. Details of the choice of semi-empirical parameters used for the latter calculations are given in the appendix. We will present the results obtained in two separate sections.

RESULTS AND DISCUSSION

Ab initio *calculations*

The molecular geometries of stationary points in the N_5^- (**3**) supersystem determined using the force method with analytical gradients and the 3-21 G basis set[18] are displayed in Fig. 1. This basis set has been shown to provide reasonable geometries for anions.[19]

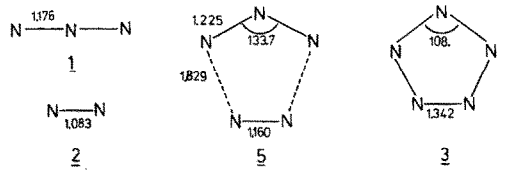


Fig. 1. 3-21G optimized geometries of species considered: N_3 (**1**), N_2 (**2**), transition state (**5**) and pentazole anion (**3**). Bond lengths in Å and bond angles in degrees.

Structure **5** is the transition state connecting isolated fragments **1**+**2** to **3**. The N—N bond lengths of 1.176 Å in **1** are comparable to the experimental values of 1.15–1.18 Å found in various ionic azides.[20] By comparison with previous 4-31 G geometries,[14] the 3-21G N—N bond lengths are somwhat shorter for **1** (4-31G: 1.20 Å), but slightly larger in both **3** (4-31G: 1.32 Å) and **5**.

It is also worth noting that the energy surface near the D_{5h}-minimum of **3** is not flat, in contrast to that of the corresponding point for the hexazine (N_6) molecule.[11] An energy increase of about 2 kcal mol^{-1} accompanies a shift of 0.02 Å in the N—N bond length.

In order to obtain improved relative energies, we have carried out single point SCF calculations on **1**, **2** and **5** employing the 3-21G optimized geometries and three basis sets: 6-31G, 6-31+G[21] (6-31G plus a set of diffuse *s*- and *p*-functions), 6-31G*[22] (plus a set of polarization *d*-functions) and 6-31+G* (including both diffuse and polarization functions; this basis set thus consists of 19 contracted Gaussian functions for each nitrogen atom). The correlation energies have been taken into account using Møller–Plesset perturbation theory to second, third and fourth order[23] (denoted MP2–MP4) making use of the HF/6-31G wave functions as references. The calculated total energies of the species considered at

[b] Including MP4SDQ/6-31+G* and ZPVE. The corrected zero-point vibrational energies are (kcal mol^{-1}): **1**, 6.1; **2**, 3.3; **4**, 12.1 and **5**, 10.5. The imaginary frequency of **5** is 646*i* (cm^{-1}).

different levels are collected in Table 1. The relative energy differences between stationary points as well as the energy barrier for the cycloreversion of **3** to fragments **1** and **2** are summarized in Table 2.

Firstly one sees that at all levels, the separate **1**+**2** system is calculated to be of lower ion energy than **3**. The 3-21G basis set overestimated the stability of the ring. In comparison with that determined by 6-31G for **3**, it is seen that diffuse functions and polarization functions act in opposite directions: the former destabilizes by 5.5 kcal mol^{-1} with respect to **1**+**2** whereas the latter stabilizes by 2.5 kcal mol^{-1}. The trend in the Møller–Plesset calculations is not continuous: MP2 raises the energy appreciably (16.2 kcal mol^{-1}), MP3 reduces it significantly (7.9 kcal mol^{-1}), while MP4SDQ raises it again (5.3 kcal mol^{-1}).

The situation concerning **5** is rather more homogeneous, both diffuse and polarization functions increasing the energy barrier for the 1,3-dipolar cycloaddition of **1** to **2**, while the correlation energies at all orders tend to reduce it.

For both structures **4** and **5**, we can note a certain additivity of the basis set effect. For example, the global modifications found at the HF/6-31+G* level are slightly smaller than the sum of the changes observed in separate calculations.

More interesting perhaps is the variation in magnitude of the energy barrier for the 1,3-dipolar cycloreversion of **4** ($\Delta E^{\neq}$, Table 2). An interesting feature is that diffuse functions do not modify this quantity. As is usually observed, the modifications created by polarization functions and correlation energies cancel each other, the former increasing the barrier while the latter decreases it.

As an estimation considering both basis set and electron effects, the MP4SDQ/6-31G* values reported in Table 2 were obtained from the additivity relationship:[24,25]

$$\Delta E(\text{MP4SDQ/6-31G*}) \approx \Delta E(\text{MP4SDQ/6-31G}) + \Delta E(\text{HF/6-31+G*}) - \Delta E(\text{HF/6-31G}).$$

These values, together with the addition of a contribution for zero-point vibrations, thus constitute our best relative energies. The zero-point vibrational energy contributions have been determined from HF/3-21G and scaled by a factor of 0.95 (see Table 3). Hence our best values in this work predict that **3** lies about 31 kcal mol^{-1} above the **1**+**2** system and can be decomposed to the latter by means of an energy barrier of 22 kcal mol^{-1}. This indicates that **3** could hardly be isolated in solution or even in the gas phase. Nevertheless, such an energy barrier seems to be sufficiently large for this species to be isolated, for example in an ethanol matrix at low temperature.[8] Under such conditions, intermolecular hydrogen bonds of the O—H...N type

Table 3. Predicted vibrational frequencies (cm^{-1}) for **3** compared with those of **1**

[b] Taken from Ref. 26.

might be expected to occur, reducing the destabilizing interaction between nitrogen lone pairs of **3** and hence favouring the existence of the anion.

On the other hand, the energy barrier for the 1,3-dipolar cycloaddition turns out to be 53 kcal mol^{-1}. It can be concluded that **3** would not be involved in a hypothetical process of molecular nitrogen fixation by azide.

This discussion raises the question to what extent the above estimation is definitive. The answer to this is somewhat equivocal, because the geometries of stationary points were not optimized at higher levels of accuracy. As seen in Table 2, the energy differences change significantly and unhomogeneously in going from one level to another. A definite estimation can only be provided from a determination of stationary-point geometries at the MP4SDQ/6-31G* level (diffuse functions can be omitted). At the present time, our computational resource precludes such calculations.

In summary, the present theoretical study suggests that **3** could be isolated in a matrix at low temperature. In order to assist eventual further experiment, the predicted vibrational frequencies for **3** are collected in Table 3. A comparison between HF/3-21G and experimental frequencies of **1** (see Table 3) emphasizes that the calculated frequencies were overestimated by about 4–5%. To provide more realistic frequencies, the HF/3-21G values can thus be reduced by an average scale factor of 0.95. The N—N stretching frequencies in **3** are a little smaller than those relevant to the symmetric stretching mode of **1**. The out-of-plane mode (E_2'') frequency is about twice those in the hypothetical hexazine (318 cm^{-1}, DZP[11]) or benzene (404 cm^{-1}, IR).

EH calculations

The results of EH calculations show that in transforming the cyclopentadienyl into **3** by successive replacement of the C—H groups by N atoms, the σ-character MOs become destabilized by "lone pair–lone pair" type repulsions, while there is a steady decrease in the energy of the π-MOs. In consequence, the $1e_1''$ MO, which constitutes the HOMO of $(C_5H_5)^-$ lies below the occupied $2e_2'$ and $2e_1'$ σ-type MOs in **3** (Fig. 2). The σ-character of the pentazole anion HOMO is in agreement with the results of the *ab initio* study, but the ordering of the $1e_1''$ and $2e_2'$ levels is the reverse of that obtained from the more rigorous treatment (see Table 4).

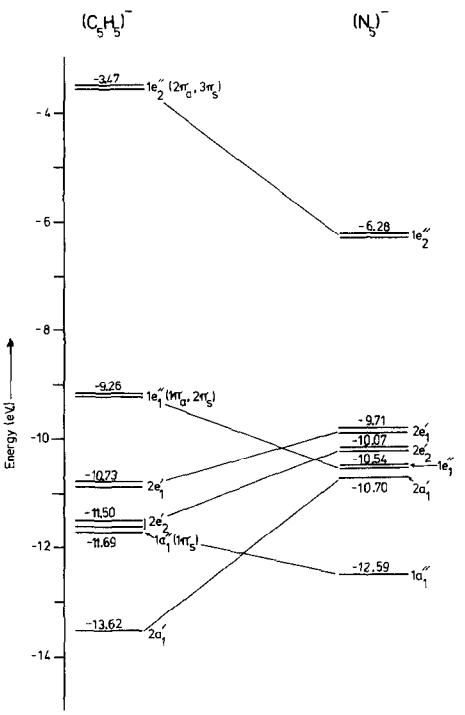

Fig. 2. Energy level diagram comparing the ordering of frontier MOs for $(C_5H_5)^-$ and N_5^-, calculated using the EH method (energies in eV).

The ability of transition metal bearing fragments to "trap" otherwise unknown organic species by formation of isolable complexes is well known, the

classic example being that of cyclobutadienes, which may be isolated as the cationic complexes $[(C_4R_4)Fe(CO)_3]^+$.[27] To determine whether such a stabilization of **3** would be possible, calculations were performed on $(N_5)M(CO)_3$ complexes where $M = Fe^{2+}$, Mn^+ and Cr [analogous to the $(C_5H_5)M(CO)_3$ complexes which are known to exist]. An energy level diagram comparing the cyclopentadienyl and pentazole tricarbonyliron structures is shown in Fig. 3, with the levels traced to show their parentage in the MOs of the ring and $M(CO)_3$ fragments. The important frontier levels are labelled "s" or "a" depending upon whether they are symmetric or antisymmetric with respect to the plane of symmetry of the complex.

The bonding in $(C_5H_5)M(CO)_3$ species has been the subject of previous discussions.[28,29] A fragment MO analysis shows that the principal interaction occurs between the $1\pi_a$, $2\pi_s$ ($1e_1''$) HOMOs of the ring and the $2e_{a,s}$ and $1e_{a,s}$ LUMOs and HOMOs of the $M(CO)_3$ fragment. In the case of the iron complex, where the energy gap between these levels is ~ 0.5 eV, the stabilization is ~ 1 eV (see Table 5). In comparison, in the pentazole complex, the drop in energy of the $1\pi_a,2\pi_s$ MOs of **3** relative to $(C_5H_5)^-$ widens the energy separation from the $2e$ levels to 1.5 eV, and this reduces the stabilization to 0.75 eV. Nevertheless, this suggests that such a complex would be stable. Note that the HOMOs of $[(N_5)Fe(CO)_3]^+$ are composed of the non-bonding σ-HOMOs of **3**.

The calculations on the pentazole complex also show a very strong stabilisation of the $2a_1'$ ("σ_s") level of N_5 which has a very strong contribution from the nitrogen lone pairs by interaction with the $1a_s$ and another low-lying $M(CO)_3$ orbital of *s*-symmetry. This should be treated with caution in view of the fact that the EH method is known to underestimate the degree to which filled orbitals repel each other. However, if it is a genuine effect, it would greatly enhance the stability of the pentazole system.

The bonding pattern exhibited by the analogous chromium and manganese complexes is identical to the iron complex, but because the *e* LUMO lies at higher energy in the $Cr(CO)_3$ and $Mn(CO)_3^+$ fragments, they are predicted to be less stable (see Table 5).

These results suggest that the complexes would be stable if the fragments could be brought together, possibly by diffusion in an inert matrix at low temperature.

Table 5. Energy separation between $2e$ (LUMO) of $M(CO)_3$ and $1\pi_a,2\pi_s$ ($1e_1''$) MOs of $(C_5H_5)^-$ and N_5^- vs stabilization (eV)

Complex	ΔE $[2e_{a,s}-(1\pi_a,2\pi_s)]$	Stabilization from interaction of $2e_{a,s}$ and $1\pi_a,2\pi_s$
$[(C_5H_5)Fe(CO)_3]^+$	0.5	1.0
$[(N_5)Fe(CO)_3]^+$	1.5	0.75
$[(C_5H_5)Mn(CO)_3]$	1.25	0.65
$[(N_5)Mn(CO)_3]$	2.15	0.40
$[(C_5H_5)Cr(CO)_3]^-$	2.05	0.40
$[(N_5)Cr(CO)_3]^-$	2.75	0.25

APPENDIX

Semi-empirical parameters used in the EH calculations

Geometrical parameters. For the N_5^- ring, r(N–N) = 1.342 Å, and, in $(C_5H_5)^-$, r(C–C) = 1.418 Å and r(C–H) = 1.083 Å. The $M(CO)_3$ fragments were assumed to be octahedral with r(M–C) = 1.820 Å (Fe), 1.790 Å (Mn) and 1.840 Å (Cr) with r(C–O) = 1.150 Å in each case. The distance from the metal atom to the centroid of the ring was fixed at 1.712 Å for the Fe complexes, 1.821 Å for Mn and 1.686 Å for Cr.

Basis sets and diagonal coulomb terms. The basis set for the metal atoms consisted of valence Slater-type 3*d*, 4*s* and 4*p* atomic orbitals, and, for the first-row atoms, 2*s* and 2*p* AOs were used. 1*s* orbitals were included on the hydrogen atoms. The radial wave functions computed by Fitzpatrick and Murphy[30] as a least-squares fit to the SCF functions of Herman and Skillman[31] were chosen (double-zeta functions were used to represent the *d*-orbitals). A value of 1.3 was used as the exponent for the hydrogen 1*s* orbital. Valence orbital ionisation potentials for nine configurations of the metal atoms and two configurations of the first-row atoms were taken from the work of Basch *et al.*[32] as approximation to the diagonal terms of the coulomb matrix. Off-diagonal terms were calculated using the "weighted" Wolfsberg–Helmholz parameterisation.[33]

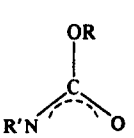
PREPARATION, STRUCTURES AND REACTIVITY OF TWO NEW ADDITION COMPOUNDS OF CARBODIIMIDES WITH DITUNGSTEN HEXA-*t*-BUTOXIDE

F. ALBERT COTTON* and EDWAR S. SHAMSHOUM
Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A & M University, College Station, TX 77843, U.S.A.



(*Received* 6 *February* 1985; *accepted* 19 *April* 1985)

Abstract—The reactions of ditungsten hexa-*t*-butoxide, $W_2(OCMe_3)_6$, with dicyclohexylcarbodiimide, $C_6H_{11}NCNC_6H_{11}$, and diisopropylcarbodiimide, $Me_2CHNCNCHMe_2$, afford the 1:1 adducts, $[W(OCMe_3)_3]_2(\mu\text{-}C_6H_{11}NCNC_6H_{11})$, **1**, and $[W(OCMe_3)_3]_2(\mu\text{-}C_3H_7NCNC_3H_7)$, **2**, respectively. These products were each shown by X-ray crystallography to be structurally homologous to the previously reported $[W(OCMe_3)_3]_2(\mu\text{-}CH_3C_6H_4NCNC_6H_4CH_3)$ and similar to $[W(OCMe_3)_3(\mu\text{-}C_6H_5NCO)$. It has been shown that the $[W(OCMe_3)_3]_2(\mu\text{-RNCNR})$ compounds fail to react with further RNCNR, with PhNCO, PMe_3, $LiOCMe_3$ or $LiOCHMe_2$, CO or CO_2, and also that $[W(OCMe_3)_3]_2(\mu\text{-PhNCO})$ does not afford any defined product when treated with $C_6H_{11}NCNC_6H_{11}$. Compounds **1** and **2** were fully characterized by IR and NMR spectroscopy and by X-ray crystallography. Compound **1** crystallizes in space group $C2/c$ with unit cell dimensions $a = 13.481(3)$ Å, $b = 18.129(4)$ Å, $c = 18.244(2)$ Å, $\beta = 97.54(1)°$, $V = 4420(2)$ Å^3, $Z = 4$. It was refined to $R = 0.0375$, $R_w = 0.0475$. Compound **2** crystallizes in space group $P2_1/c$ with unit cell dimensions $a = 14.752(2)$ Å, $b = 12.157(3)$ Å, $c = 22.189(3)$ Å, $\beta = 97.03(2)°$, $V = 3949(2)$ Å^3, $Z = 4$. The structure was refined to $R = 0.053$, $R_w = 0.059$. Each molecule has C_2-symmetry, with two $W(OCMe_3)$ units united by RNCNR bridges across W—W distances of 2.490(1) and 2.485(1) Å for **1** and **2**, respectively.

It has recently been reported[1] that $W_2(OCMe_3)_6$ as well as several $Mo_2(OR)_6$ compounds react with organic isocyanates to give products in which two RNCO molecules have been inserted into M—OR bonds, as shown in eqn (1):

$$W_2(OCMe_3)_6 + 2PhNCO \rightarrow W_2(OCMe_3)_4[\mu\text{-PhNC(OCMe}_3)O]_2. \quad (1)$$

The products have the molecular formulas $M_2(OR)_4[\mu\text{-R'NC(OR)O}]_2$, where R' originates from the R'NCO reactant. The bridging ligands are of type **a**. We then used a related "heterocumulene" molecule, R'N=C=NR', where R' = *p*-tolyl with $W_2(OCMe_3)_6$ and found that the only product is an adduct, $[W(OCMe_3)_3]_2(\mu\text{-}C_7H_7NCNC_7H_7)$, in which no insertion into W—O bonds has occurred.[2] We have also shown[3] that the reaction of $W_2(OCMe_3)_6$ with PhNCO proceeds by way of an initial 1:1 adduct much like that obtained as the only product with $C_7H_7NCNC_7H_7$. This has led us: (a) to examine the reactions of other carbodiimides with $W_2(OCMe_3)_6$; (b) to determine whether the $[W(OCMe_3)_3]_2(\mu\text{-RNCNR})$ adducts would react further with reagents such as excess RNCNR, RNCO, PMe_3, CO or CO_2; and (c) to see whether $[W(OCMe_3)_3]_2(\mu\text{-PhNCO})$ would react with RNCNR. The results of all of these studies, carried out to improve our understanding of the capacity of $W_2(OCMe_3)_6$ to react with heterocumulene type molecules in general, are reported here.

a

EXPERIMENTAL

Ditungsten hexa-*t*-butoxide was prepared[4] by reduction of WCl_4 with Na/Hg in THF at −10°C in

* Author to whom correspondence should be addressed.

the presence of $LiOCMe_3$. The product was recrystallized from hexane at $-10°C$. Dicyclohexylcarbodiimide was obtained from Aldrich Chemical Co. and diisopropyl carbodiimide was purchased from Pfaltz & Bauer Chemical Co.

IR spectra were measured on a Perkin–Elmer 783 spectrometer using KBr pellets. Proton NMR spectra were measured on C_6D_6 solutions at 25°C using a Varian XL-200 PFT spectrometer. Chemical shifts (δ) are specified in ppm downfield from TMS. The ^{13}C NMR spectrum of **2** was measured on a Varian FT-80 spectrometer in C_6D_6 solution. Chemical shifts are again given in ppm downfield from TMS.

Preparation of $[W(OCMe_3)_3]_2(\mu\text{-}C_6H_{11}NCNC_6H_{11})$ **(1)**

Under an argon atmosphere $W_2(OCMe_3)_6$ (0.41 g, 0.50 mmol) was dissolved in toluene and dicyclohexyl carbodiimide (0.206 g, 1.0 mmol) was added from a side-arm tube. After about 2 h a color change from red to brown had occurred, but the reaction mixture was stirred for a further 10 h. It was then filtered into a storage tube, concentrated by vacuum distillation to about 4 cm^3 volume and allowed to stand for about 12 h at $-10°C$. Blue crystals were obtained in 70–80% yield reproducibly, and the products always appeared to be homogeneous. The dry solid is stable in air for a few minutes.

IR. 2952(s), 2914(m), 2847(s), 1710(s), 1465(w), 1450(m), 1377(w), 1370(m), 1350(s), 1260(s), 1225(s), 1170(s), 1004(m), 985(m), 960(s), 925(s), 895(m), 840(w), 787(m), 765(m), 570(m), 550(w) and 524(w).

^1H *NMR* (*see Fig. 1A*). Singlets at δ 1.577 (a_6) and 1.805 (a_3) with relative intensities of 2:1. These signals are assigned to two types of $OCMe_3$ methyl groups, four which are *cis* and two which are *trans* to the carboximide ligand. Multiplets at δ 3.9 (not shown), δ 2.24 (a_1, a_2) and δ 1.18 (a_4, a_5) are assigned to the cyclohexyl groups. There was also an impurity peak ($LiOCMe_3$) at δ 1.034 (not shown).

Preparation of $[W(OCMe_3)_3]_2(\mu\text{-}C_3H_7NCNC_3H_7)$ **(2)**

Under argon $W_2(OCMe_3)_6$ (0.20 g, 0.25 mmol) was dissolved in toluene at room temperature and diisopropyl carbodiimide (0.15 cm^3, 1.0 mmol) was added by syringe. The solution was stirred for 4 h, although a color change from red to brown-purple appeared to be complete within the first 15 min. The solvent was completely removed under vacuum and the solid residue extracted with 10 cm^3 of hexane. This solution was concentrated by vacuum distillation to a volume of *ca* 3 cm^3 and *ca* 3 cm^3 of THF was added. During a period of 2 days at $-10°C$, blue crystals of **2** were deposited. This preparation was reproduced several times and found to give consistently yields of 60–70% of a homogeneous crystalline product. This compound is much more air-sensitive than compound **1** and must be protected at all times.

IR. 2950(m), 2905(s), 2822(w), 1687(m), 1450(s), 1375(m), 1352(m), 1259(s), 1227(w), 1167(m), 1100(m), 1020(m), 1310(w), 982(w), 965(w) and 800(s).

^1H *NMR* (*Fig. 1B*). Singlets at δ 1.519 (b_3) and 1.778 (b_2) with relative intensities of *ca* 2:1. These signals are assigned to two types of $OCMe_3$ methyl groups as for **1**. A doublet at δ 1.339 (J = 6.5 Hz) (b_4, b_5) assigned to the methyl protons of the isopropyl groups and a septet at δ 4.211 (b_1) assigned to the proton on the secondary carbon of the isopropyl group were also observed. There was an impurity peak at δ 1.033 ($LiOCMe_3$) (not shown).

^{13}C *NMR.* The following resonances, with their proposed assignments, were observed: δ 25.85 $[CH(\underline{C}H_3)_2]$, δ 32.14 $[OC(\underline{C}H_3)_3]$, δ 33.38 $[CH(\underline{C}H_3)_3]$, δ 79.22 $[O\underline{C}(CH_3)_3]$, δ 82.16 $[O\underline{C}CH_3)_3]$, and δ 160.32 ($C_3H_7N\underline{C}NC_3H_7$).

Reactions of **1** *and* **2** *with* PhNCO

A weighed amount of **1** or **2** was dissolved in 20 cm^3 of toluene and an excess (two-fold or greater) of

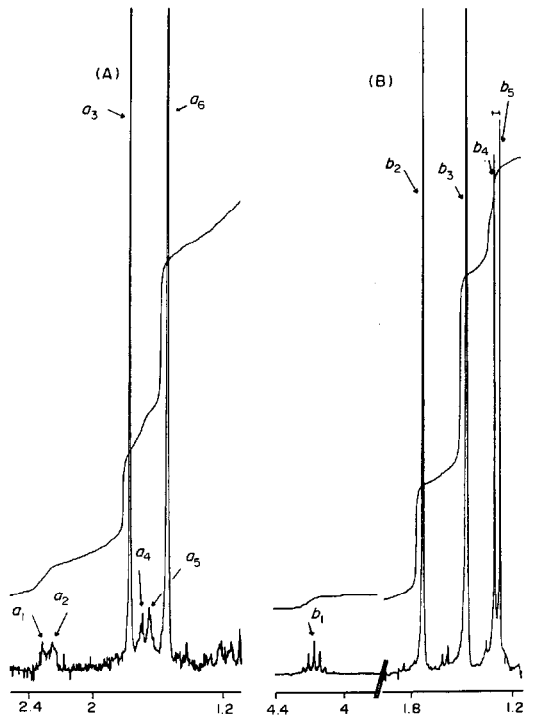


Fig. 1. ^1H NMR spectra of the $OCMe_3$ groups for: (A) $[W(OCMe_3)_3]_2(\mu\text{-}C_6H_{11}NCNC_6H_{11})$, and (B) $[W(OCMe_3)_3]_2(\mu\text{-}C_3H_7NCNC_3H_7)$ molecules.

PhNCO was added. These solutions were stirred at 27°C for 48 h, during which time little if any change was visible. It was possible to recover at least 85% of the starting materials, together with a small amount of a dark insoluble solid, presumably a decomposition product. Repetition of these reactions at 65°C for 15 h also allowed recovery of most of the starting materials (*ca* 70%), but somewhat more of the presumed decomposition products were also observed (but not identified).

Reaction of **2** *with* PMe_3

A weighed amount of **2** was dissolved in 20 cm^3 of toluene, and a 10-fold molar amount of PMe_3 was added. After the reaction mixture had been stirred for 24 h the color was unchanged and **2** was recovered essentially quantitatively upon evaporation of solvent and PMe_3.

Reactions of **1** *and* **2** *with lithium alkoxides*

To weighed amounts of **1** and **2** dissolved in 20 cm^3 of toluene were added 10-fold molar amounts of $LiOCMe_3$ or $LiOCHMe_2$. These mixtures were stirred at 27°C for 15 h. There was no visible evidence that reactions had occurred and starting material was recovered.

Reactions of **2** *with* CO_2 *and* CO

To a solution of **2** in toluene CO_2 was added at liquid nitrogen temperature. The mixture was allowed to warm to room temperature and then

stirred for 3 h. Essentially the same procedure was repeated with CO. In neither case was there any visible indication that a reaction had occurred.

Reaction of $[W(OCMe_3)_3]_2(\mu\text{-PhNCO})$ *with* $C_6H_{11}NCNC_6H_{11}$

One hundred milligrams of $[W(OCMe_3)_3]_2(\mu\text{-PhNCO})$ in 15 cm^3 of toluene was treated with a five-fold molar ratio of dicyclohexyl carbodiimide for 24 h at 25°C. About 15% of the starting ditungsten compound was recovered, but no other product could be isolated.

X-ray crystallographic procedures

The structures of single crystals of compounds **1** and **2** were determined by applying general procedures already described elsewhere.[5] Some details concerning each of the structure determinations are given below. The crystal parameters and basic information pertaining to data collection and structure refinement for both compounds are summarized in Table 1.

Crystal structure of **1**

Three standard reflections which were checked after every 100 measurements showed a 53% uniform drop in intensity over a period of 69.9 h of exposure to the X-ray beam. An appropriate linear, uniform correction was applied to the data. Absorption corrections were calculated based on azimuthal (ψ) scans of nine reflections with Eulerian angles (χ) near 90°. Systematic absences were consistent with space groups *Cc* and *C2/c*. The latter was provisionally assumed and proved to be correct according to the successful refinement. The position of the one independent tungsten atom was inferred from a three-dimensional Patterson function and the rest of the structure then developed by a succession of alternating cycles of least-squares refinements and difference electron density maps. All atoms were ultimately treated anisotropically and the refinement converged uneventfully.

Crystal structure of **2**

Three standard reflections showed an 11.6% uniform decay during 34.3 h of measurements, and a suitable correction was applied. Empirical absorption corrections, as for **1**, were also made. The space group was uniquely defined as $P2_1/c$ by the systematic absences. Positions for the tungsten atoms were derived from a Patterson function and the remaining non-hydrogen atoms then located as before. Carbon atoms (2), (4) and (6) did not refine well anisotropically, showing weak residual peaks (*ca* 0.7 *e* $Å^{-3}$) nearby, suggesting some disorder. However, no physically reasonable disorder model was found and these three atoms were simply refined isotropically while all others were treated anisotropically.

Tables 2 and 3 give important bond distances and angles for **1** and **2** respectively. Complete tables of anisotropic thermal parameters and structure factor

data are available as supplementary material.* Figures 2 and 3 show the structures and atom numbering schemes.

RESULTS

The reactions of the two carbodiimides, RNCNR, R = cyclohexyl and isopropyl, with $W_2(OCMe_3)_6$ proceed just as did the reaction of di-*p*-tolyl carbodiimide. The formation of the 1:1 adduct appears to occur promptly but there is no apparent tendency to proceed further. Moreover, it appears to be generally true that these blue adducts, $[W(OCMe_3)_3]_2(\mu\text{-RNCNR})$, are not reactive toward any other ligands of interest, viz. CO, CO_2, PMe_3 and PhNCO.

The structures of the two new compounds, as shown in Figs 2 and 3, are quite analogous to those previously reported for $[W(OCMe_3)_3]_2(\mu\text{-}C_7H_7NCNC_7H_7)$[2] and $[W(OCMe_3)_3]_2(\mu\text{-PhNCO})$.[3] In compound **1** the molecule has rigorous crystallographic C_2-symmetry, with the symmetry axis passing through the carbodiimide carbon atom and the midpoint of the W=W bond. In compound **2**

* Supplementary material available: tables of structure factors, anisotropic thermal vibration parameters, complete tables of bond lengths and angles, and more detailed accounts of the crystallographic work for both structures (39 pp.) have been deposited with the Editor at Queen Mary College. Positional parameters and isotropic thermal parameters have been forwarded to the Director, Cambridge Crystallographic Data Centre.

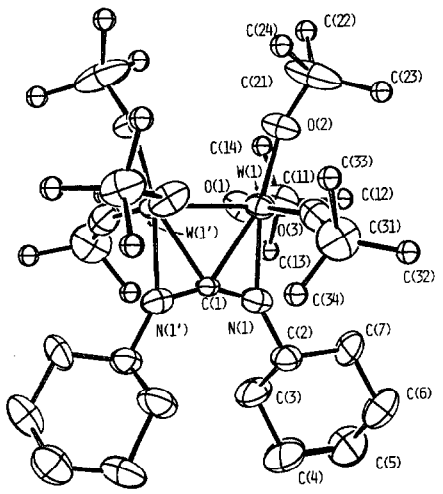

Fig. 2. An ORTEP drawing of the molecule $[W(OCMe_3)_3]_2(\mu\text{-}C_6H_{11}NCNC_6H_{11})$, giving the atomic labelling scheme. All methyl carbon atoms of $OCMe_3$ groups are represented by arbitrarily small spheres to avoid covering up other atoms. All other atoms are represented by their ellipsoids of thermal vibration at the 40% level.

there is no crystallographically rigorous symmetry, but the effective symmetry is again C_2.

DISCUSSION

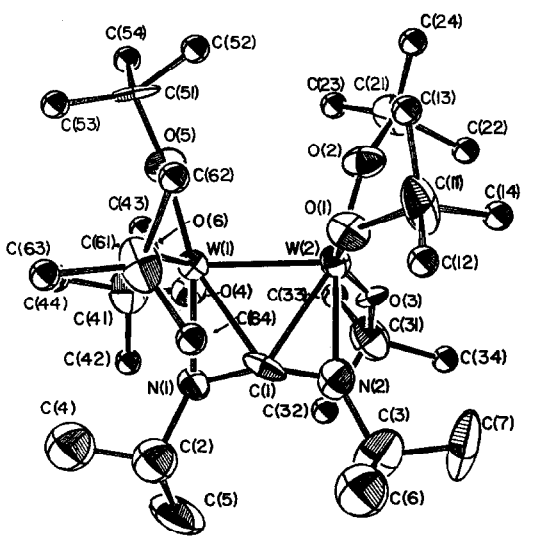
We have shown that our previous observations[2] concerning the preparation, structure and reactivity of the di-*p*-tolyl carbodiimide adduct of $W_2(OCMe_3)_6$ apply to carbodiimides more generally, including those with alkyl rather than aryl groups on the nitrogen atoms. As before, the use of an excess of carbodiimide over the 1 : 1 mole ratio does not lead to any further reaction. In the two new compounds the mode of attachment is essentially identical to that previously observed in $[W(OR_3)_2]_2(\mu\text{-}C_7H_7NCNC_7H_7)$ and also, *mutatis mutandis*, to that in the 1:1 adduct of PhNCO with $W_2(OCMe_3)_6$.[3]

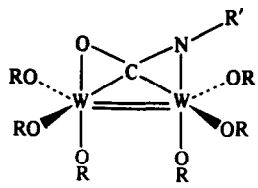
In all four molecules of this 1 : 1 adduct type the W=W distances are the same to within less than 0.01 Å and the bonding can be accounted for in the same way, as previously explained.[2] In the case of compound **2** we have, for the first time, been able to observe the ^{13}C NMR signal for the central carbon atom of the bound RNCNR (or RNCO) group. We find it at 160.32 ppm, which is within the general region where it might have been expected.

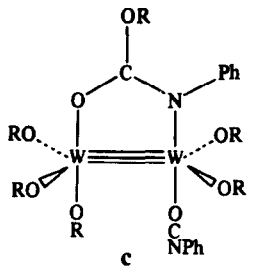
We have now established that not only are these carbodiimide adducts unreactive toward additional carbodiimide, they are unreactive towards a number of other reagents, specifically PnNCO, PMe_3, LiOR, CO_2 and CO. We have also shown that the PhNCO adduct, $[W(OCMe_3)]_2(\mu\text{-PhNCO})$, which reacts very readily with additional PhNCO, or with PMe_3, will not react with $C_6H_{11}NCNC_6H_{11}$. The relationship of these observations to our previously proposed[3] mechanism for reaction (1) must now be considered.

We proposed that the key, established features of the overall process represented by eqn (1) were the initial formation of the mono-adduct, of structure **b**, followed by a migratory insertion induced by the attack of a second molecule of PhNCO, or the nucleophile PMe_3 to form **c** or **d**. In the case of **d**, whose structure is known, no further reaction occurred, whereas **c**, the structure of which remains to be discussed, cannot be isolated (or even positively detected) because it immediately rearranges to afford the final product (**e**). Since the carbodiimide adducts (**f**) are very similar to **b**, why is it that they are not subject to further reaction so as to allow an overall process analogous to that described by eqn (1)?

Clearly, part of the problem is simply that a second molecule of RNCNR appears to be in itself an unsuitable reactant; it cannot act as a nucleophile, as can PhNCO or PMe_3. This is shown by the fact that **b** is unreactive toward $C_6H_{11}NCNC_6H_{11}$. This naturally prompts the thought that if PhNCO or PMe_3 were to be used the $[W(OCMe_3)_3]_2(\mu$-RNCNR) molecules might react, at least to the extent of forming analogs of **c** or **d**, if not further. Again, however, there is no reaction, and this poses an interesting question. While it is obvious that an







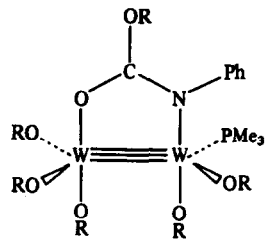


Fig. 3. An ORTEP drawing of the molecule $[W(OCMe_3)_3]_2(\mu\text{-}C_3H_7NCNC_3H_7)$, giving the atomic labelling scheme. All other atoms are represented by their ellipsoids of thermal vibration at the 40% level.

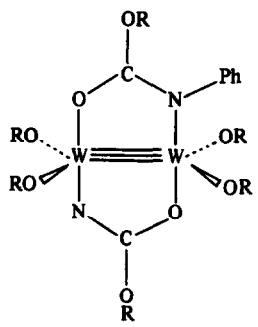
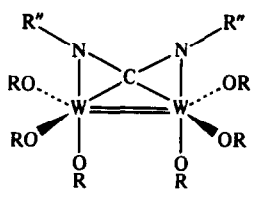
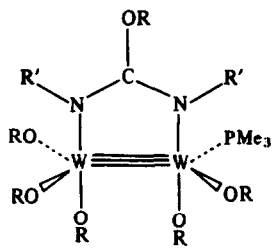


b



c

d



e

f

RNCNR molecule is much less suited than an RNCO or PMe_3 molecule, the present question is more subtle. It does not seem likely that a molecule such as **g**, the carbodiimide analog of **d**, or a carbodiimide analog of **c**, should be inherently unstable once formed. It thus seems more likely that we are dealing with a kinetic inhibition, i.e. there is a kinetic barrier to the process of getting from molecule **f** to molecule **g** that does not exist, or at least does not assume the same importance, in getting from **b** to **c** or **d**.

g

We believe that this barrier may be steric in nature. In the molecules of type **f** both ends of the attached molecule, R'NCNR', are sterically encumbered, whereas in **b** one end, the oxygen end, is relatively undemanding sterically. This could mean that a pathway close to the O atom, that is sterically open for migration of an $OCMe_3$ group in **b**, is not readily available in **f**. However, since it is also true that in **b** there is a type of polarity, due to the unsymmetrical nature of PhNCO, that does not exist in **f** with its symmetrical R'NCNR' ligand, we cannot rule out the possibility that polarity too is important.

Finally, we must say something about the possible structure of the posited intermediate, **c**, about which we have so far been silent. If we assume that the key difference between the reactive molecule **b** and the unreactive molecule **f** is the presence of O rather than R'N (for either steric or electronic reasons, but especially for steric reasons) we might tend to suppose that the transferred OR group would come from W(1), the W atom bonded to the isocyanate oxygen atom of **b**. This *might*, then, lead us to expect that **f**, and also **c**, would have the incoming nucleophilic ligand on that same tungsten atom, whereas in **d** it does not.

Does the actual structure of **d**, with its PMe_3 on the "wrong" metal atom refute our mechanistic reasoning? We think not. There is no logical need to believe that the added PMe_3 group must occupy the

very place vacated by the migrating OR group. It is entirely possible to imagine an OR group from one of the two closest positions on the W(1) atom of **b** moving to the carbon atom of PhNCO, either before, during or after an attack by PMe_3 (or PhNCO) on either of the W atoms, followed by migrations of PMe_3 and/or OR groups from one metal atom to the other to give **d**. It has been noted before in the chemistry of these multiply-bonded ditungsten and dimolybdenum alkoxide species that the alkoxide groups and other ligands are labile,[6] even to the point of making the molecules fluxional on the NMR time scale.[7] Thus, we have no right to conclude either that the observed structure of **d** is inconsistent with our proposal that **b** is transformed to **e** via a transient intermediate **c**, or that the stereochemistry (including the regiostereochemistry) of **c** is necessarily the same as that of **d**. After all, **d** is a kinetic dead end, whereas **c** is a very lively and unisolable kinetic intermediate.

Acknowledgements—We thank the Robert A. Welch Foundation for support. We are grateful to Drs L. Falvello and W. Schwotzer for advice and assistance with the X-ray crystallography.

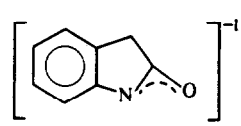
(*Received* 28 *January* 1985; *accepted* 26 *April* 1985)

Abstract—The title compound has been prepared by reaction of $(C_5H_5)_2Cr$ with oxindole (indole with C=O in place of CH_2 at the 2-position). Red single crystals belong to space group $P2_1/c$ with $a = 10.107(4)$ Å, $b = 22.496(7)$ Å, $c = 9.210(3)$ Å, $\beta = 93.26(3)°$, $V = 2091(2)$, and $Z = 2$. The centrosymmetric molecule has a Cr—Cr distance of 2.495(4) Å. The mean Cr—O and Cr—N distances for the bonds to bridging oxindolate anions are 2.024(7) and 2.065(8) Å, respectively. There is an oxindole molecule bound at each end with a Cr—O axial bond of length 2.341(8) Å and a hydrogen bond from the oxindole N—H group to an equatorial oxygen atom of length 2.83(1) Å. The significance of this compound with respect to Cr—Cr bonding is discussed.



The enormous range of metal–metal distances (*ca* 1.83–2.54 Å) spanned by molecules containing two Cr(II) atoms interacting to give a singlet ground state has provoked considerable interest and activity, both experimental and theoretical.[1–9] The general structural situation is illustrated in **I**. In virtually all cases the adjacent pairs of L_{eq} ligands are parts of bridging bidentate ligands. Two factors are clearly pertinent: (1) the effect of the ligands that fill the eight "equatorial" positions, denoted in **I** as L_{eq}; and (2) the effect of the axial ligands, denoted in **I** as L_{ax}. While it is generally accepted that both play a significant role, views differ as to whether the L_{eq} or the L_{ax} influence is predominant.

I

It has been established unequivocally that when axial ligands are *entirely* absent the Cr—Cr distance is *always* short.[1] It has recently been shown that even when the eight L_{eq} atoms are derived from four acetate ions, if there are no axial ligands, the Cr—Cr distance is well under 2.00 Å.[9] There has, however, been the suggestion that, for an equatorial ligand set consisting of 4N + 4O or another combination not consisting exclusively of oxygen atoms, there would be a pronounced tendency to develop strong and short Cr—Cr bonding even in the presence of axial ligands.[6]

To test this suggestion, we have prepared and structurally characterized a compound in which the equatorial ligand set is of the 4N + 4O type, but two axial ligands are also present. This was done by employing the bridging bidentate ligand derived by deprotonation of oxindole, namely **II**. The conditions of preparation led to the crystallization of a crystalline product in which the Cr_2(oxindolate)$_4$ unit has two adjoined axial ligands, each of which is an oxindole molecule, coordinated to a chromium atom through its oxygen atom and also held in place by an N—H···O hydrogen bond to one of the equatorially coordinated oxygen atoms.

−20°C. After 1 week, large single crystals had formed in about 50% yield.

Structural solution of $Cr_2(C_8H_6NO)_4 \cdot 2C_8H_7NO$. X-ray data were collected in the monoclinic crystal system on a CAD-4F diffractometer. Systematic absences uniquely determined the space group as $P2_1/c$. The chromium atom position was obtained from a Patterson map. Alternate cycles of least-squares refinement and difference Fourier maps allowed location of all remaining non-hydrogen atoms. Refinement proceeded smoothly with all atoms finally treated anisotropically. General information concerning the crystallography is given in Table 1. No detectable diminution in the scattering by standard reflections was observed and, in view of the low absorption coefficient and the crystal dimensions, no absorption correction was made.

The atomic positional parameters and tables of thermal vibration parameters and structure factors are available as supplementary material.

RESULTS

The crystal consists of equivalent discrete centrosymmetric $Cr_2(C_8H_6NO)_4(C_8H_7NO)_2$ molecules. One such molecule is depicted in Fig. 1. It can be seen that the central portion consists of a Cr_2 unit bridged by four oxindolate anions arranged so that two mutually cisoid ones point in one direction and two in the other. This gives a *cis*-CrN_2O_2 coordination at each metal atom and gives the entire $Cr_2(C_8H_6NO)_4$ unit a virtual C_{2h}-symmetry. The addition of the axial C_8H_7NO ligands abolishes all but one of the symmetry operations of C_{2h} so that the complete molecule has as its highest possible symmetry the crystallographically rigorous inversion symmetry.

A list of bond distances and angles is given in Table 2, and Fig. 2 displays some of these that are important in discussing the arrangement of ligands about the Cr_2 core.

The way in which the axial oxindole molecules are

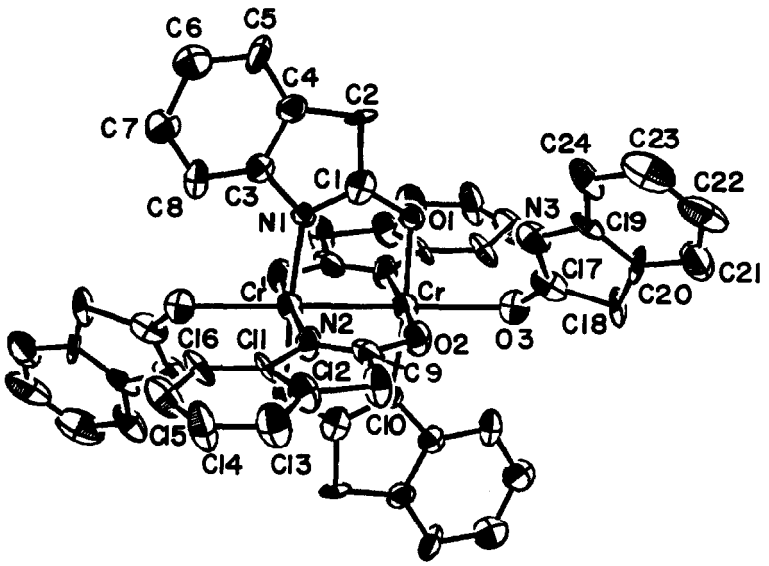

Fig. 1. An ORTEP drawing of the Cr_2(oxindolato)$_4$(oxindole)$_2$ molecule. Atoms are represented by thermal vibration ellipsoids drawn at the 40% level. Only the crystallographically independent ligand atoms are labelled in this centrosymmetric molecule.

held in place, by a combination of coordination from O to Cr as well as by N—H ··· O hydrogen bonding, is clearly displayed in Fig. 2. It is an efficient way to anchor axial ligands in place which might be usefully employed in a deliberate way in the future. It is not, however, unique to this structure. Previously, in $Rh_2(CH_3COS)_4(CH_3CSOH)_2$[10] and in $Ru(hp)_4Cl(Hhp)$,[11] where hp is the anion derived from 2-hydroxypyridine (Hhp), similar "two-prong" attachments have been observed.

DISCUSSION

In the structure reported here we have one of the longest Cr—Cr distances known within the general type of structure under consideration. This occurs despite the fact that the bridging ligands are of the N—C—O type, that is, the amidato type, that has been alleged to favor the shortest Cr—Cr bonds. Indeed, the Cr—Cr bond length here, 2.495(4) Å, is nearly as long as those found in three

carboxylato-bridged compounds, as the following comparison shows: $Cr_2(oxindolato)_4(oxindole)_2$ (**1**) 2.495(4) Å, $Cr_2(O_2CCF_3)_4(Et_2O)_2$ (**2**) 2.541(3) Å,[12] $[Cr_2(O_2CCH_2NH_3)_4Cl_2]^{2+}$ (**3**) 2.513(1) Å,[13] and $Cr_2(O_2CCH_2NH_3)_4Br_2]^{2+}$ (**4**) 2.524(1) Å.[13] These three carboxylato compounds are those containing the least basic carboxylato anions.

What our study of the structure of **1** shows is that if there is good axial coordination a long Cr—Cr distance will be obtained, without regard to whether the four bridging ligands are of the amidato ion (N—C—O$^-$) type or the carboxylato type.

It can even be argued that the reason why the Cr—Cr distance in **1** is a little shorter than those in **2**–**4** is because the axial donation is not as strong in **1** as in the others. If we take the Cr—L_{ax} distances in each of the four compounds and subtract the accepted single bond radii of the coordinated atom, we have the following results (Å): (**1**) 2.34 − 0.66 = 1.68, (**2**) 2.24 − 0.66 = 1.58, (**3**) 2.58 − 0.99 = 1.59, and (**4**) 2.74 − 1.14 = 1.60. Clearly, with due allowance for the inherently different atomic sizes, the axial ligands approach less closely in **1** than in the other three cases.

The idea that the basicity of the equatorial ligands has a dominant role and the presence or absence of axial ligands only a secondary role in determining Cr—Cr bond lengths in compounds of the class under consideration is flatly contradicted by the experimental results for compounds **1**–**4**, as well as by the experimental results recently obtained for the structure of $Cr_2(O_2CCH_3)_4$. There is evidently a need for new and reliable calculations concerning the electronic properties and resultant structures of molecules of this class.

DIRECT SYNTHESIS AND NMR SPECTRA OF $[(C_6H_5)_2PCH_2]_2CuB_5H_8$: COMMENTS ON THE SOLUTION STRUCTURE OF 2,3-μ-METALLOPENTABORANES

PAMELA K. RUSH and LAWRENCE BARTON*
Department of Chemistry, University of Missouri—St-Louis, St. Louis, MO 63121, U.S.A.

(*Received* 2 *January* 1985; *accepted after revision* 19 *April* 1985)

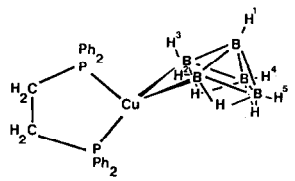
Abstract—The species $[(C_6H_5)_2PCH_2]_2CuB_5H_8$ has been prepared directly from $[(C_6H_5)_2PCH_2]_2CuI$ and $K[B_5H_8]$. NMR spectra unequivocally indicate that the species has a static structure in solution and an argument is presented that all 2,3-μ-metallopentaboranes have similarly static solution structures.

A recent study[1] described the synthesis of (dppe)CuB_5H_8 (**I**) by ligand exchange between solutions of $[(C_6H_5)_2PCH_2]_2$ and $[(C_6H_5)_3P]_2CuB_5H_8$ (**II**) [dppe = 1,2-bis(diphenylphosphino)ethane]. Apparently **I** is stabilized by the chelate effect. **I** is of comparable stability to **II** in the solid state but, in CH_2Cl_2 solution at 25°C, **II** decomposes completely after 4 days, whereas **I** is essentially unchanged under the same conditions. Since metalloboranes and metallocarboranes are useful in the synthesis of larger metalloboranes and borane clusters,[2] we decided to investigate the possibility of synthesizing directly the more stable species (**I**) from a dppe-ligated Cu(I) halide and $K[B_5H_8]$ as part of our continuing studies of dppe-ligated metalloboranes.[3] Furthermore, since we had access to high-field NMR, we though we might be able to provide some insight into some unresolved aspects of the solution dynamics of 2,3-μ-metallopentaboranes.

EXPERIMENTAL

Standard high-vacuum and inert-atmosphere techniques were employed in this work. B_5H_9 (Callery Chemical Co.) was distilled on the vacuum line before use, dppe (Pressure Chemicals Inc.) was used without purification and (dppe)CuI was prepared by literature methods.[4] KH (Alpha Products) was washed with pentane on the vacuum line until it was a free flowing white powder. Solvents were dried and distilled on the vacuum line before use. (dppe)CuB_5H_8 was prepared as follows. In the dry-box a two-neck 50-cm^3 reaction flask attached to an extractor was charged with KH (0.11 g, 2.6 mmol) and sealed with a rotatable solid addition tube containing (dppe)CuI (1.52 g, 2.61 mmol). After evacuation on the vacuum line B_5H_9 (0.27 cm^3, 2.61 mmol) and $(CH_3)_2O$ (10 cm^3) were condensed at −196°C. Stirring at −35°C for 45 min afforded H_2 (2.15 mmol) which was measured and removed using a Toepler pump. CH_2Cl_2 (20 cm^3) was condensed at −196°C and the (dppe)CuI was added. The solution was allowed to warm, stirred at −35°C for 1 h and at −78°C overnight. The solution was filtered at −78°C to remove KI, and the filtrate was frozen at −196°C and transferred to a clean extractor under a positive flow of N_2. $(CH_3)_2O$ was removed at −78°C, and the volume of CH_2Cl_2 was reduced by half at −35°C. The addition of $(C_2H_5)_2O$ (5 cm^3) and C_5H_{12} (5 cm^3) resulted in the isolation of (dppe)CuB_5H_8. The product was washed with $(C_2H_5)_2O$ followed by C_5H_{12} and identified by its IR and ^{11}B NMR spectra, which compared well with those reported previously. NMR spectra were run on a Nicolet NT 300 at 300.1 and 96.25 MHz for ^1H and ^{11}B observations respectively. IR spectra were run as KBr discs on a Perkin–Elmer 337 spectrometer.

RESULTS AND DISCUSSION



(dppe)CuB_5H_8 was prepared from the following series of reactions:

$$B_5H_9 + KH \xrightarrow[(CH_3)_2O]{-35°C} KB_5H_8 + H_2,$$

$$KB_5H_8 + [(C_6H_5)_2PCH_2]_2CuI \xrightarrow[CH_2Cl_2/(CH_3)_2O]{-35°C} [(C_6H_5)_2PCH_2]_2CuB_5H_8 + KI.$$

* Author to whom correspondence should be addressed.

Yields were in the same range as those reported earlier although our yields may be higher, based on B_5H_9 as the limiting reagent. The solid product was off-white in color and in the presence of traces of solvent and excess $[(C_6H_5)_2PCH_2]_2CuI$ at room temperature it turned bright orange yellow and specks of Cu(0) were observed, presumably due to reduction of the ligated Cu(I) iodide by borane complex. The species did not melt sharply but turned dark yellow at 145°C and decomposed at 156°C. The 96.25-MHz ^{11}B NMR spectra provided more information than those previously reported and are shown in Fig. 1 along with the proposed structure. The coupled spectrum indicates overlap of resonances due to the two sets of basal borons; however the $^{11}B\{^1H\}$ spectrum clearly resolves the spectrum into two resonances arising from two sets of two equivalent basal borons at $\delta = -11.33$ and -15.05 ppm and a single resonance arising from the apical boron at $\delta = -47.52$ ppm. The assignment of the basal resonances is based on that of Greenwood and Staves[5] for the analogous species $[(C_6H_5)_3P]Cd(Cl)B_5H_8$. The basal resonances are not resolved enough for the accurate measurement of the coupling constants, presumably due to quadrupolar broadening from the Cu atom; however, they are in the expected range. The value of $J_{^{11}B^1-^1H^1}$ is 161 Hz. These data confirm that this species has a static structure in solution and this is discussed later. The proton spectrum, which has not been reported previously, is complicated by the presence of ligand resonances. Thus resonances assigned to the phenyl Hs are seen at $\delta = 7.29$ and 7.13 ppm and the methylene Hs seen at $\delta = 2.4$ ppm show no significant splitting by the P atoms. This latter observation has been made for other dppe-ligated metallopentaboranes.[6,3] In addition, a resonance seen at $\delta = 1.2$ ppm is due presumably to the free dppe ligand which arises from dissociation. Such dissociation in solution has been observed[7] for other phosphine-ligated cuprioboranes. A broad resonance centered at 2.2 ppm, in the expected position for basal terminal Hs, is obscured by ligand resonances. The higher-field region of the spectrum is more informative and is repreduced in Fig. 2 along with that[8] for $[(C_6H_5)_3P]_2Cu\text{-}1\text{-}(CH_3)B_5H_7$. The small peak at $\delta = -0.8$ ppm in the spectrum of $(dppe)CuB_5H_8$ is the upfield member of a 1:1:1:1 quartet due to the apical hydrogen. The observed $^{11}B^{11}-^1H^1$ coupling constant is 163 Hz and, from the positions of the two upfield members of the quartet, the center of the multiplet is located at $\delta = -0.11$ ppm. The two resonances, in approximate area ratio 1:2, seen at $\delta = -2.7$ and -3.28 ppm respectively are assigned to the bridging hydrogens and compare well to those shown in Fig. 2b for $[(C_6H_5)_3P]_2Cu\text{-}1\text{-}(CH_3)B_5H$ which fall at $\delta = -2.45$ and -3.01 ppm

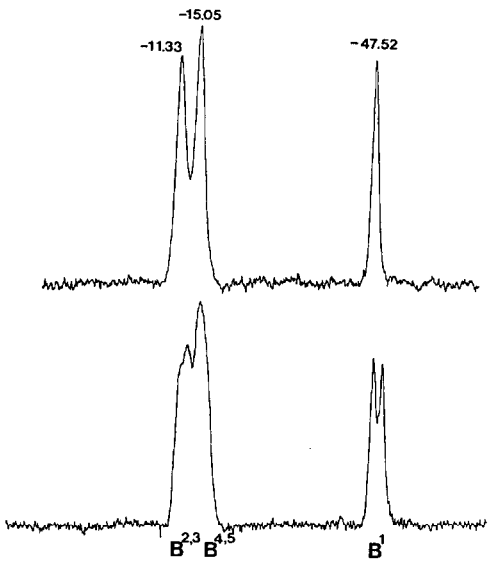


Fig. 1. 96.25-MHz ^{11}B NMR spectrum of $(dppe)CuB_5H_8$ in CD_2Cl_2 at -78°C. The upper trace is ^1H-decoupled and chemical shifts are in ppm.

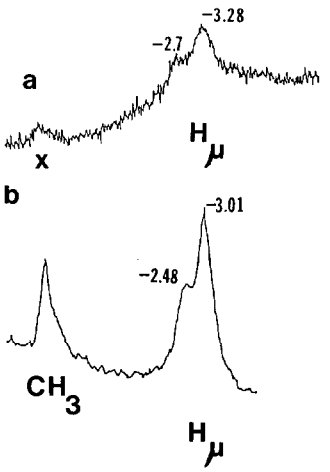

Fig. 2. (a) 300.1-MHz ^1H NMR spectrum of $(dppe)CuB_5H_8$ in the $H\mu$ region. (b) 100-MHz ^1H NMR spectrum of $[(C_6H_5)_3P]_2Cu\text{-}1\text{-}(CH_3)B_5H_7$ in the $H\mu$ region (from Ref. 8, reproduced with permission). (x) See text.

respectively. The observation of two resonances for the bridging hydrogens confirms that the species is not fluxional.

This work demonstrates the utility of the more direct method for the preparation of (dppe)Cu(I) complexes of boranes and confirms that the series of metalloboranes derived from insertion of ligated transition metal moieties into the boron–boron bond in the basal plane of $[B_5H_8]^-$ are not fluxional in solution. Previous attempts to resolve resonances due to basal B atoms in ^{11}B NMR spectra of cupriopentaboranes have been unsuccessful[1,8] and this has been attributed to the influence of the copper quadrupole. The related series of (dppe)NiX (X = Cl, Br or I) complexes of $[B_5H_8]^-$ were described[9] as fluxional based on the observation of a single broad ^{11}B resonance for the basal boron atoms in the ^{11}B NMR spectrum and single resonances for basal and bridging hydrogens in the ^1H NMR spectrum. Subsequently the same authors[10] concluded that the analogous Pd(II) and Pt(II) complexes were not fluxional on the basis of a more detailed NMR study and they surmised that all the complexes in the series (dppe)MXB_5H_8 (M = Ni, Pd or Pt) were probably[6,10] not fluxional. The data presented herein confirm that the cupriopentaboranes also have static structures as was originally suggested.[8] For such *nido*-pyramidal boranes and metalloboranes to be fluxional, it appears that it is necessary for there to be at least one formal B—B σ-bond which does not contain a bridging hydrogen in the basal plane of the species. This provides a site into which bridging hydrogens may move and also provides a mechanism whereby the borane cage in metalloboranes may move relative to the metal moiety. Thus species such as B_6H_{10},[11] $B_6H_9^-$,[12] $(THF)_2MgB_6H_9$,[13] $B_5H_8^-$[14] and $C_2B_4H_7^-$[15] are fluxional whereas $B_6H_{10}Fe(CO)_4$,[16] $[(C_6H_5)_3P]CdClB_5H_8$,[5] μ-$[\eta^5$-$C_5H_5)Fe(CO)_2]C_2B_4H_7$[17] and $[B_6H_{11}]^+$[18] are not. The former contain B—B bonds and the latter do not. Thus it is reasonable to expect that 2,3-μ-metallopentaboranes would have static structures.

A CONVENIENT SYNTHESIS OF COPPER(I) CARBOXYLATES

THOMAS P. LOCKHART* and DEBORAH A. HAITKO
General Electric Corporate Research & Development Center, P.O. Box 8, Schenectady, NY 12301, U.S.A.

(*Received* 22 *February* 1985; *accepted* 19 *April* 1985)

Abstract—A simple procedure is described for the synthesis of aliphatic and aromatic copper(I) carboxylates by the reduction of copper(II) carboxylates with commercially available tin(II) 2-ethylhexanoate. In this way copper(I) acetate, benzoate and stearate have been prepared in good yield and purity from the corresponding copper(II) carboxylates.

Copper(I) carboxylates have found wide application as catalysts and stochiometric reagents in organic chemistry,[1] and have served as starting materials in the synthesis of novel copper(I) complexes.[2] These air- and moisture-sensitive compounds are usually prepared by one of the methods described by Edwards and Richards.[3] One procedure involves the reaction of copper(I) oxide with a carboxylic acid, with azeotropic removal of the water by-product. Reaction times are long (*ca* 12 h) and the several manipulations must be carried out under inert atmosphere. A second route involves treating a carboxylic acid solution of the copper(II) carboxylate with a reductant such as copper(0) or hydrazine hydrate. To employ this procedure, however, the acid must be a liquid at ambient conditions. Further, non-volatile carboxylic acids can be difficult to remove from the copper(I) product.

Recently several examples of the *in situ* generation of catalytically active copper(I) by the tin(II) reduction of copper(II) compounds have been reported.[4,5] In our study of the copper-catalyzed decomposition of diaryliodonium salts,[5] we employed tin(II) 2-ethylhexanoate to generate copper(I) carboxylate catalysts from the corresponding copper(II) carboxylates. The subject of this report is our development of the tin(II) reduction of simple copper(II) carboxylates as a convenient method for preparing copper(I) carboxylates of good purity in good isolated yield:

$$2\text{Cu(II)}(O_2CR)_2 + \text{Sn(II)}(O_2CR')_2 \xrightarrow[CH_2Cl_2]{25^\circ C} 2\text{Cu(I)}(O_2CR) + \text{Sn(IV)}(O_2CR')_2(O_2CR)_2.$$

RESULTS AND DISCUSSION

We have prepared three copper(I) carboxylates [copper(I) acetate, stearate and benzoate] in good yield (65–85%) from the corresponding commercially available copper(II) salts by reduction with tin(II) 2-ethylhexanoate in CH_2Cl_2 solution under an inert atmosphere. The occurrence of carboxylate exchange between copper and tin was ruled out by the IR spectrum of copper(I) benzoate which showed only strong absorbances due to aromatic C—H stretching; no absorbance due to aliphatic C—H stretching was observed. In addition, elemental and mass spectroscopic analyses indicated that the desired products were obtained in high purity.

Relative to the procedures of Edwards and Richards,[3] advantages of the method described here include the short reaction time and the simple apparatus and work up. Critical for some applications[5] is the fact that the reaction product produced by this method is obtained free of excess carboxylic acid or coordinating solvent. The tin(II) reductant, further, is inexpensive and readily available.

Isolation of a product of high purity requires the use of copper(II) carboxylates free of insoluble impurities such as copper oxides or halides.[6] Some commercially available copper(II) carboxylates are of modest purity; thus, the reduction of a commercial copper(II) caprylate gave the copper(I) salt (identified by FDMS and high-resolution EI mass spectroscopic experiments) in good yield, but elemental analysis revealed the presence of about 10% of a copper-containing impurity, presumably a copper(I) halide. The presence of small amounts of impurities may be of less concern in some application of the copper(I) carboxylates as a reaction catalyst.[4]

The method described here applies only to copper(II) carboxylates which have at least slight

* Current address: Central Research and Development Department, E. I. DePont de Nemours and Company, Experimental Station, Wilmington, DE 19898, U.S.A.

solubility in the organic solvent. Our attempts to reduce copper(II) gluconate and glycolate, which are extremely insoluble in CH_2Cl_2 and $CHCl_3$, were unsuccessful. Conversely, it appears that high solubility of the copper(I) carboxylate may result in over-reduction of the product [to copper(0)]. Therefore, in reactions involving substituted carboxylates it may be necessary in some instances to substitute other reaction solvents.

EXPERIMENTAL

Commercially available copper(II) carboxylates were dried in a vacuum oven at 80°C overnight and used without further purification. Tin(II) 2-ethylhexanoate (stannous "octoate") was used without purification (except for degassing) in the synthesis of copper(I) benzoate and stearate, but was distilled under vacuum (*ca* 0.005 torr, b.p. 155–165°C) through a short fractionating column for the synthesis of copper(I) acetate. A good commercial grade of CH_2Cl_2 was used after degassing on a vacuum line. We preferred to carry out the syntheses in an inert atmosphere glove box, but the reaction has also been carried out in a three-neck flask with a nitrogen blanket over the solution. Removal of the reaction and wash solvents from the copper(I) product can be accomplished with a cannula or a filtering side arm. Loss of the very fine copper(I) product through the fritted filter appears to be the major factor lowering the isolated yield. The representative synthesis of copper(I) benzoate is described below.

Copper(I) benzoate

In an inert atmosphere glove box, a mixture of copper(II) benzoate (0.016 mol) and tin(II) 2-ethylhexanoate (0.009 mol) in 25 cm^3 CH_2Cl_2 was prepared. While stirring at room temperature, the color of the solution changed from blue [due to copper(II)] to a faint grey-green color over about 4 h. The very fine whitish precipitate [copper(I) benzoate] was isolated by suction filtration [the tin(II) reagent and the tin(IV) product are very soluble in the organic solvent]. The product was washed 4 times with CH_2Cl_2, leaving a whitish-grey solid which was dried *in vacuo* for several hours. The moderately air-sensitive copper(I) benzoate was isolated in 84% yield and stored under nitrogen.

Found: Cu, 34.20; C, 45.30; H, 2.73. Calc. for $CuC_7H_5O_2$: Cu, 34.4; C, 45.5; H, 2.73%. IR (KBr) major bands at 3050(m), 1590(s), 1530(br, s), 1490(m), 1410(br, sh, 845(m), 710(s), 690(s) and 555(m) cm^{-1}.

Copper(I) acetate

Isolated as a very pale yellow solid in 75% yield. Found: Cu, 51.60; C, 19.59; H, 2.41. Calc. for $CuC_2H_3O_2$: Cu, 51.83; C, 19.60; H, 2.47%.

Copper(I) stearate

Isolated as a pale yellow solid in 65% yield: Found: Cu, 18.15; C, 62.08; H, 9.95. Calc. for $CuC_{18}H_{35}O_2$: Cu, 18.33; C, 62.33; H, 10.10%.

TETRAHEDRAL AND OCTAHEDRAL COORDINATION FOR COBALT(II) COMPLEXES OF *N*-ISOPROPYL-2-PYRROLIDINONE

BRUCE A. WILSON and STANLEY K. MADAN*
Department of Chemistry, State University of New York at Binghamton, Binghamton, NY 13901, U.S.A.

(*Received* 14 *February* 1985; *accepted* 19 *April* 1985)

Abstract—Complexes of the formulas $[Co(NIPP)_4](ClO_4)_2$ and $[Co(NIPP)_6](ClO_4)_2$ have been synthesized and isolated (NIPP = *N*-isopropyl-2-pyrrolidinone). IR spectra and conductance data are presented as proof that perchlorate coordination in $[Co(NIPP)_4](ClO_4)_2$ does not occur. Vibrational spectra indicate that coordination occurs through the NIPP carbonyl oxygen for both complexes. Spectral parameters obtained from the electronic spectra and magnetic moments indicate tetrahedral and octahedral coordination for $[Co(NIPP)_4](ClO_4)_2$ and $[Co(NIPP)_6](ClO_4)_2$, respectively. The powder X-ray diffraction data appear to support the assignments of these two geometries. The crystal-field prediction that $\Delta(T_d)/\Delta(O_h) = 0.44$ is in reasonably good agreement with the experimental results.

The best-known examples of mixed neutral ligand–anion complexes of a metal ion in two different symmetries are the four-coordinate $Co(py)_2X_2$ and the six-coordinate $Co(py)_4X_2$ (py = pyridine, X = halide).[1,2] Tetrahedral and octahedral symmetries for nickel(II)[3] and cobalt(II)[4] doped into ZnO and MgO lattices have also been investigated. The formation of octahedral and tetrahedral complexes from a single metal ion and anion has been reported by Foster and Goodgame.[5,6] Wayland *et al.*[7] were the first to report the synthesis and isolation of a transition-metal ion complex with different numbers of the same neutral ligand [*N*,*N*-dimethylacetamide (DMA)] as the only coordinated species. Madan[8] has provided a second example of this phenomenon by preparing and isolating perchlorate salts of *N*-methyl-2-pyrrolidinone (NMEP) (also known as *N*-methyl-γ-butyrolactam), in both tetrahedral and octahedral geometries.

This paper reports the third definite isolation of complexes of the form $[Co(NIPP)_4](ClO_4)_2$ and $[Co(NIPP)_6](ClO_4)_2$, where NIPP = *N*-isopropyl-2-pyrrolidinone is the only coordinated species and is a neutral ligand like DMA and NMEP. Magnetic susceptibility data, electronic spectra and powder X-ray diffraction data indicate the Co(II) possesses a tetrahedral field in $[Co(NIPP)_4](ClO_4)_2$, and an octahedral field in $[Co(NIPP)_6](ClO_4)_2$. For both complexes, the IR spectra show the NIPP ligand is coordinated to cobalt(II) through the carbonyl oxygen. Vibrational spectra and conductance measurements are utilized to demonstrate that the perchlorate ion is not coordinated in $[Co(NIPP)_4](ClO_4)_2$. Calculations made on the basis of regular symmetry for these complexes give $\Delta(T_d)/\Delta(O_h) = 0.52$, which compares favorably with the value of 0.44 predicted by the crystal-field theory.[9,10]

EXPERIMENTAL

Physical measurements

Electronic absorption spectra were determined using a Carey Model 14 recording spectrophotometer. IR spectra were obtained from a Perkin–Elmer Model 283B recording spectrophotometer. The conductance measurements were made on an Industrial Instrument Model RD 16B2 conductivity bridge, utilizing a conventional conductivity cell containing platinum electrodes. The magnetic susceptibilities were measured utilizing a Faraday magnetic balance. Mercury(II) tetrathiocyanate cobaltate(II) was used as the magnetic susceptibility standard. X-ray diffraction patterns were obtained on a Norelco (Phillips Electronics Instruments)

wide-range gioniometer type 150-100-00 with a direct reading diffractometer. The *K*-alpha X-ray line from a nickel-filtered copper source was employed. The relative peak heights were determined by estimating the relative intensities.

Chemicals

The Co(II) perchlorate hexahydrate was of reagent grade. NIPP was obtained from GAF coporation in technical grade form and purified using vacuum distillation (84°C, 5 mm).

Synthesis

All syntheses were performed in a nitrogen atmosphere, utilizing glove box techniques.

$[Co(NIPP)_6](ClO_4)_2$ (*raspberry*). Cobalt(II) perchlorate hexahydrate, $Co(ClO_4)_2$ (0.3538 g), was added to a 500% excess of 2,2-dimethoxypropane (3.060 g). The resulting solution was stirred on a magnetic stirrer for 2 h at room temperature. A stoichiometric amount of NIPP (0.7475 g) was added to the resulting anhydrous solution dropwise while the solution was being stirred. This mixture was stirred for an additional 15 min. An equal volume of anhydrous ethyl ether was then added to the mixture with stirring. Vigorous trituration of the raspberry oil that formed upon the addition of NIPP did not result in the formation of crystals. Additional NIPP was added dropwise with continuous trituration until raspberry-colored crystals had formed. The crystals were then filtered, washed with anhydrous ethyl ether, and dried over P_4O_{10} for 48 h in a nitrogen atmosphere. The complex is extremely hygroscopic.

$[Co(NIPP)_4](ClO_4)_2$ (*violet*). The four-coordinate complex of NIPP coordinated to Co(II) was obtained by keeping the six-coordinate complex *in vacuo* at 80°C over P_4O_{10} in a drying pistol for 96 h. This complex is also extremely hygroscopic.

Analyses

Carbon and hydrogen analyses were performed by MicAnal Organic Microanalysis of Tucson, AZ. Metal ion analyses were performed by complexometric titration with EDTA, as described by Flaschka.[11] Perchlorate analyses were completed utilizing a gravimetric procedure based upon the precipitation of nitron perchlorate.[12]

RESULTS AND DISCUSSION

The analytical data for the complexes are summerized in Table 1. The electronic spectral data for the complexes are given in Table 2, with assignments for the transitions. The molar absorbtivity of $[Co(NIPP)_4](ClO_4)_2$ in CH_2Cl_2 is low for a tetrahedral complex. However, it was found that the

[b] Data from Ref. 8.

spectra of the complex in Nujol and CH_2Cl_2 were not significantly different. Further, it was found that addition of NIPP to the complex in CH_2Cl_2 had no effect on the spectra. This indicates that the primary absorbing species in solution is $[Co(NIPP)_4]^{2+}$.

The conductance data are presented in Table 3 and magnetic susceptibility data are given in Table 4. X-ray data are displayed in Tables 5 and 6.

The IR spectrum of $[Co(NIPP)_4](ClO_4)_2$ may be used to determine if the perchlorate ion is coordinated to the cobalt(II) ion. It has been shown[13] that, for a unidentate coordinated perchlorate, the symmetry of the perchlorate ion is lowered from T_d to C_{3v} in the complex. This results in the splitting of the broad band into two intense peaks in the 1200–900 cm^{-1} region. However, the IR spectrum of $[Co(NIPP)_4](ClO_4)_2$ in the 1200–900 cm^{-1} region shows a broad band with a maximum at 1090 cm^{-1}, which is indicative of ionic perchlorate. The conductance data in Table 3 clearly indicate that $[Co(NIPP)_4](ClO_4)_2$ is an electrolyte. Hence, the perchlorate ion can not be coordinated.

The magnetic moments for crystalline $[Co(NIPP)_4](ClO_4)_2$ and $[Co(NIPP)_6](ClO_4)_2$ are within the acceptable ranges for tetrahedral and octahedral cobalt(II) complexes, respectively.[14] The magnetic moments for $[Co(DMA)_4](ClO_4)_2$, 4.62 B.M.,[7] and $[Co(NMEP)_4](ClO_4)_2$, 4.80 B.M.,[8] are considerably higher than the magnetic moment for $[Co(NIPP)_4](ClO_4)_2$, 4.42 B.M.

The electronic spectra for $[Co(NIPP)_4](ClO_4)_2$ and $[Co(NIPP)_6](ClO_4)_2$ compare favorably with spectra previously reported for tetrahedral[15] and octahedral[16] Co(II) complexes, respectively. For $[Co(NIPP)_6](ClO_4)_2$, the $^4T_1(F) \rightarrow {}^4A_2(F)$ transition, which is essentially a two-electron transition, is absent. The splitting of the ν_2 bands observed in the spectra of $[Co(DMA)_4](ClO_4)_2$[7] and $[Co(NMEP)_4](ClO_4)_2$[8] is not observed in the spectrum of $[Co(NIPP)_4](ClO_4)_2$.

It is expected that $[Co(NIPP)_4](ClO_4)_2$ is highly distorted, since it is formed from $[Co(NIPP)_6](ClO_4)_2$. Support for distortion from regular tetrahedral symmetry comes from consideration of the spin–orbit coupling constant, λ', for the tetrahedral complex. The λ' for the coordinated Co(II) are decreased in magnitude from that of the free ion value of -178 cm^{-1}. The λ' for a tetrahedral cobalt(II) complex can be calculated using the magnetic and spectral data, according to the relationship: $\mu_{obs} = \mu_{so} - 15.59\lambda'/10Dq = 3.89 - 15.19\lambda'/10Dq$.[7,8,15,17] Values of λ' for complexes of regular tetrahedral symmetry calculated from this relationship have been found to be in the range -130 to -160 cm^{-1}.[17] Wayland *et al.*[7] and Madan[8] have reported λ' for $[Co(DMA)_4](ClO_4)_2$ and $[Co(NMEP)_4](ClO_4)_2$ of -200 to -220 and -296 to -316 cm^{-1}, respectively. The authors have attributed these large negative λ' to the inappropriateness of the above equation in calculating the λ' for a distorted tetrahedral complex. For $[Co(NIPP)_4](ClO_4)_2$, the λ' has been found to be ir

the range of -138 to $-158\ cm^{-1}$, which is in the range of Co(II) complexes exhibiting regular tetrahedral geometry. This is a rather surprising result, considering that the NIPP ligand has a bulkier alkyl substituent than either the DMA or NMEP ligands. However, Wayland *et al.*[7] and Madan[8] attribute the distortion from regular tetrahedral geometry to a weak bonding interaction between the nitrogen atom and the metal ion. It is possible that the isopropyl group prevents this interaction from occurring in $[Co(NIPP)_4](ClO_4)_2$.

The shift in the NIPP carbonyl stretching frequency to a lower frequency upon complexation is generally used to indicate coordination through the carbonyl oxygen.[18] The centers of intensity for the NIPP carbonyl stretching frequency in $[Co(NIPP)_4](ClO_4)_2$ and $[Co(NIPP)_6](ClO_4)_2$ are at 1610 and 1630 cm^{-1}, respectively. The carbonyl stretching frequency for neat NIPP is 1687 cm^{-1}. The carbonyl frequency shifts indicate that the carbonyl oxygen is the principal donor site.

Underhill and Billing[19] have shown that the calculations of the spectral parameters for the octahedral and tetrahedral d^7 Co(II) complexes can be determined using simplified quadratic equations for the Tanabe and Sugano energy expressions. The values for $[Co(NIPP)_6](ClO_4)_2$ and $[Co(NIPP)_4](ClO_4)_2$, in Nujol, are 8230 ± 100 and $4200 \pm 100\ cm^{-1}$, respectively. The ratio $\Delta(T_d)/\Delta(O_h)$ is 0.52 in Nujol for $[Co(NIPP)_{4,6}](ClO_4)_2$, compared to the value of 0.44 predicted by the crystal-field theory. There are several effects that should be considered in interpreting this slightly higher ratio for the Co(II) complexes of NIPP: (1) the steric interaction of the isopropyl group will lower the splitting energy of the octahedral complex, and (2) the increased covalency of the tetrahedral complex, as seen in the β values, should increase the crystal-field splitting energy of the tetrahedral complex. Foster and Goodgame[5,6] have determined $\Delta(T_d)/\Delta(O_h)$ for the pairs of complexes

$$Ni(NCS)_4^{2-}/Ni(NCS)_6^{4-}$$

and

$$Co(NCS)_4^{2-}/Co(NCS)_6^{4-},$$

to be 0.51 and 0.49, respectively. Wayland *et al.*[7] have determined $\Delta(T_d)/\Delta(O_h)$ for the pair $[Co(DMA)_4]^{2+}/[Co(DMA)_6]^{2+}$ to be 0.64, and Madan[8] found $\Delta(T_d)/\Delta(O_h)$ for the pair $[Co(NMEP)_4]^{2+}/[Co(NMEP)_6]^{2+}$ to be 0.60.

The powder X-ray diffraction patterns indicate that

$$[Co(NIPP)_4](ClO_4)_2$$

and

$$[Zn(NIPP)_4](ClO_4)_2{}^{20}$$

are isomorphous and that these patterns are significantly different from those for

$$[Cu(NIPP)_4](ClO_4)_2.{}^{20}$$

Although Co(II) and Zn(II) are known to form square-planar complexes with bidentate ligands, they predominantly form tetrahedral complexes with monodentate ligands. Conversely, Cu(II) is known to form a variety of square-planar complexes, as well as tetrahedral complexes. Therefore, it would be expected that the complexes of Co(II) and Zn(II) are tetrahedrally coordinated, whereas the Cu(II) complex is evidently a square-planar complex. A comparison of the X-ray diffraction patterns indicates that

$$[Co(NIPP)_6](ClO_4)_2$$

and

$$[Ni(NIPP)_6](ClO_4)_2{}^{20}$$

are isomorphous, whereas

$$[Cd(NIPP)_6](ClO_4)_2$$

is not isomorphous with either. A possible explanation of this may be that the steric interaction of the isopropyl group of NIPP results in the distortion of the complexes of Co(II) and Ni(II) from octahedral configuration. The larger ionic radius of Cd(II) may relieve some of these steric interactions, resulting in a "purer" octahedral geometry.

CYCLIC AND OPEN-CHAIN TAUTOMERISM AND COMPLEX FORMATION BEHAVIOUR OF THE CONDENSATION PRODUCT OF 2-AMINO-3-AMINOMETHYL-4-METHOXYMETHYL-6-METHYLPYRIDINE WITH SALICYLALDEHYDE

Z. CIMERMAN and Z. ŠTEFANAC*
Laboratory of Analytical Chemistry, Faculty of Science, University of Zagreb, Strossmayerov trg 14, 41000 Zagreb, Yugoslavia

(*Received* 7 *November* 1984; *accepted* 19 *April* 1985)

Abstract—The crystalline product obtained by the condensation of 2-amino-3-aminomethyl-4-methoxymethyl-6-methylpyridine and salicylaldehyde was characterized by spectrometric methods (UV, IR, ^{1}H NMR and MS). It was shown that the dissolution of the crystalline cyclic diamine afforded its tautomeric conversion to the enolimine form of the Schiff base [2-amino-4-methoxymethyl-6-methyl-3-(salicylideneaminomethyl)pyridine] with a rate of the process and a ratio of both forms attained at equilibrium dependent upon the solvent. The presence of the ketoamine form was not evidenced. The behaviour of the condensation product as the ligand in formation of complexes with Cu(II), Ni(II), Co(II) and Cd(II) was investigated in methanolic solution. Coordination with Cu(II) and Ni(II) caused partial hydrolysis of the ligand and the formation of complexes of the bis Schiff base [4-methoxymethyl-6-methyl-2-(salicylideneamino)-3-(salicylideneaminomethyl)pyridine] characterized after their isolation by elemental analyses and spectrometric data.

Condensation of diamines with aldehydes or ketones yield products which form stable complexes with various metal ions with characteristic properties interesting from several points of view.[1,2]

The course of condensation depends on the reactants in question and on the reaction conditions, so that different intermediates, isomeric compounds or mixtures of tautomeric forms might be involved. Schiff bases are mostly obtained as mono and bis derivatives[1–3] but the presence in solution of cyclic diamines[4,5] and/or carbinolamines[5] has also been reported. Metal ions influence in some cases the course affording products unobtainable in their absence.[3,6]

Anticipating in the first place an improved analytical applicability of the product, the condensation of 2-amino-3-aminomethyl-4-methoxymethyl-6-methylpyridine with salicylaldehyde has been undertaken in the broadened frame of the study concerning the related amines.[7]

The behaviour of the condensation product and formation of some transition metal complexes have been pursued in solution and the structures of isolated solid species determined.

EXPERIMENTAL

Apparatus

Vibrational and electronic absorption spectra were recorded on Perkin–Elmer instruments. Models 598 with data station and 580B were used for recording IR spectra in solution ($CHCl_3$) and Model 283 for solid-state samples (KBr or CsBr pellets). UV/VIS spectra were recorded on Model 200. Mass spectra were recorded on an Hitachi Perkin–Elmer RMU-6M spectrometer. ^{1}H NMR spectra of saturated solutions [$CDCl_3$, CD_3OD and $(CD_3)_2SO$] were taken at various temperatures (20, 25, 40 and 50°C) on a JEOL JNM-FX-100FT instrument, using tetramethylsilane as internal standard.

Materials

2 - Amino - 3 - aminomethyl - 4 - methoxymethyl - 6 - methylpyridine was obtained as dihydrochloride by courtesy of Dr D. Korunčev, Pliva,

* Author to whom correspondence should be addressed.

Pharmaceutical and Chemical Works, Zagreb, Yugoslavia. Free amine was prepared and purified to analytical grade according to the procedure described in Ref. 8. Salicylaldehyde and metal salts of analytical purity grade, were purchased from Kemika, Zagreb, Yugoslavia. All solvents used were of analytical purity grade (E. Merck, Darmstadt, F.R.G.).

Procedures

Condensation of 2 - amino - 3 - aminomethyl - 4 - methoxymethyl - 6 - methylpyridine with salicylaldehyde. Equimolar amounts of amine and salicylaldehyde, both dissolved in ethanol ($\sim$ 1 mol dm^{-3} solution) were mixed and the resulting yellow solution was stirred thoroughly for 30 min at room temperature. The pale yellow precipitate which had formed during the stirring was separated and recrystallized from hot methanol.

Preparation of complexes with Cu(II) *and* Ni(II). Slow evaporation of a methanolic solution containing equimolar amounts of the condensation product and metal(II) sulphate resulted in the formation of white crystals of dibasic tetrasubstituted pyridine sulphate along with the coloured crystals of complexes, green with copper or dark brown with nickel. The water-soluble salt of the amine was removed by washing the crystals with large amounts of water after filtration. The remaining water-insoluble complex was recrystallized from a chloroform/methanol mixture.

The Cu(II) complex was also prepared by reaction of the condensation product with Cu(II) acetate and Cu(II) nitrate, respectively. The isolation procedure was the same as in the case of Cu(II) sulphate.

Characterization of solid compounds. Condensation product, $C_{16}H_{19}N_3O_2$, pale yellow crystals, m.p. 158–160°C, 80% yield.

Found (calc.): C, 67.26 (67.34); H, 6.85 (6.71); N, 14.74 (14.73)%.

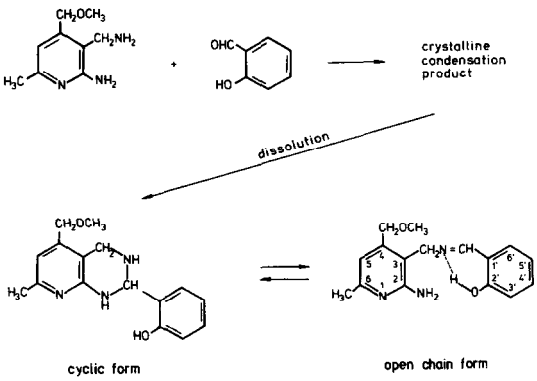
Spectrophotometric determination of metal: ligand ratio in solution. The modified continuous-variation method of Job[9] was pursued throughout.

RESULTS AND DISCUSSION

Tautomeric equilibrium of the condensation product in solution

The investigation of the complexation ability in diluted solutions of the product obtained by condensation of 2-amino-3-aminomethyl-4-methoxymethyl-6-methylpyridine with salicylaldehyde afforded the evidence for very slow changes of UV/VIS spectrometric characteristics. For better understanding of the formation course of complex species we pursued also the behaviour of the ligand itself in solution. The more so, as in addition to the usual ketoenamine–enolimine tautomeric equilibria, some other resemblant systems have been considered.[4,5,10]



The absorption maxima (λ_{max}) (245, 283 and 312 nm) in the UV spectrum showed in methanolic solution an almost imperceptible incipient increase of absorbances which was more pronounced in chloroform and continued for 6 h. Nevertheless, this

information was a useful hint to prolong the measurement procedures with the other spectrometric methods.

The most striking new strong absorption band at 1630 cm^{-1} in the IR spectrum taken of the condensation product in chloroform solution after 14 h, corresponds by its position, intensity and feature to ν(C=N) vibration. Additional bands emerging at 3500 and 3390 cm^{-1} are joint with C_2—NH_2 asymmetric and symmetric stretching vibrations, respectively. This can be considered as an indication for the enolimine form of the Schiff base appearing only successively in solution, although the presence of a strong intramolecular hydrogen bond is not evident in the spectrum.

The fact that immediately after dissolution only the bands at 3420 and 3320 cm^{-1}—positions characteristic of Ar-NH-R and R-NH-R—are present in the spectrum points at the incipient absence of primary amino group on the pyridine ring.

Comparison of this latter spectrum with the one recorded with the crystalline product shows that the strongest absorption bands at 1600 and 1580 cm^{-1} as well as those in the range 1500–1450 cm^{-1} have analogous positions and features. Small differences in the positions of the bands at 1300–1200 and 1150–1100 cm^{-1}, as well as the fact that the range above 3000 cm^{-1} is better differentiated in solution while

Scheme 1.

this stands for the fingerprint region of the crystalline state spectrum, could be ascribed to intermolecular association and crystal lattice.

^{1}H NMR has been applied as more adequate for structure determinations of the involved species. The results are given in Scheme 1 and Tables 1 and 2. The assignments of the chemical shifts are based on a series of spectra recorded under different systematically varying conditions, on deuteration experiments, on the effect of different solvents and on the comparison with the literature data.[8,11,12]

The obtained information can logically be linked with the cyclic structure as the incipient tautomeric form (Table 1) attaining equilibrium with the

enolimino form after dissolution (Table 2). The rate of the attainment and the ratio of tautomeric forms at equilibrium depends on the solvent used as well as on the concentration and the temperature. Thus, a 1:1 ratio is reached after 24 h in saturated $CDCl_3$ solution at room temperature. Such slowly attaining equilibria but with an inverse course, i.e. conversion of the initially present Schiff base to the cyclic diamine form, have been reported for the condensation of pyridoxal with ornithine and two amino acids bearing an α and a terminal amino group.[4]

There is no evidence in the spectrum of any interaction with the proton bound to nitrogen and so only the presence of the enolimino form is obvious.[13,14] The absence of the ketoenamine form is evident also in the IR spectra taken in chloroform and in methanolic solution since the absorption band characteristic of the ν(C=O) vibration of the quinoid structure is missing.[15]

The hydroxyl proton sharing in a strong intramolecular hydrogen bond to imino nitrogen has a signal with a chemical shift conformable to the usual values.[13]

Complexes with Cu(II), Ni(II) *and* Co(II)

The complex formation behaviour of the condensation product (ligand) has been studied in methanolic solution and the solid species isolated from the methanolic medium have been characterized.

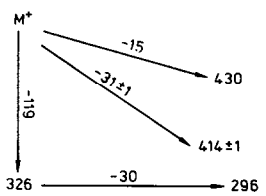
Preliminary spectrophotometric experiments with the series of metal ions comprising Cu(II), Ni(II), Co(II), Cd and Zn indicated complex formation of the ligand only in the cases of Cu(II), Ni(II) and Co(II).

UV/VIS spectra of complexes with these metals in methanolic solution are shown in Table 3.

Table 3. UV/VIS spectrometric characteristics of complexes with Cu(II), Ni(II) and Co(II) in methanolic medium 1 h after the preparation of solutions

M	$C_M = C_L$ (mol dm^{-3})	$\lambda_{max}(A)$ (nm)
Cu(II)	1.0×10^{-4}	238(1.226), 269(0.941), 356(0.582)
	7.1×10^{-2}	650(0.630)
Ni(II)	2.0×10^{-4}	236(1.130), 270sh(0.650), 278(0.720), 372(0.521)
	1.0×10^{-3}	430sh(0.140)
Co(II)	3.0×10^{-4}	236(1.052), 266(1.163), 285sh(0.800), 351sh(0.728), 370(0.672)
	6.6×10^{-2}	650(0.532)

The reaction of ligand with Co(II) proceeds very slowly. Continuous changes of the UV spectrum, including not only increases in but also variable shifts of maxima in the course of time, indicate the presence of unstable complex species which make detailed measurements uninterpretable.



Complexes with Cu(II) and Ni(II) are formed immediately and their UV/VIS spectrometric characteristics do not change during 24 h in dilute solutions. The interacting molar ratio of the ligand with Cu(II) has been found to be 1 : 1, measured at all absorption maxima in the spectrum.

The metal : ligand ratio of 1 : 2 obtained for Ni(II) at 372 nm could not be confirmed by measurements at other wavelengths, thus indicating a more composed complex formation course.

The standing of a dilute (1×10^{-4} mol dm^{-3}) solution of the Cu(II) complex for more than 24 h is followed by formation of a new species evidenced through appearance of shoulders at 280 and 380 nm in the UV spectrum. Similarly, with the prolonged standing of a dilute methanolic solution of the Ni(II) complex hyper- and bathochromic shifts of the 430-nm shoulder accompanied by a hypsochromic shift of the 270-nm shoulder and the appearance of a new band at 348 nm have been noted. The arising of this last band, characteristic of the complex of the original aminopyridine with Ni(II), was linked with partial decomposition of the ligand. The structures of solid species obtained by isolation are in accordance with the mentioned changes proceeding very slowly in dilute but faster in concentrated methanolic solutions of Cu(II) and Ni(II) complexes.

One of the two solid compounds obtained during the isolation of the Ni(II) complex was characterized as a salt of 2-amino-3-aminomethyl-4-methoxymethyl-6-methylpyridine. Characterization of the other compound showed that Ni(II) is coordinatively bound in a 1 : 1 ratio to the bis Schiff base [4-methoxymethyl-6-methyl-2-(salicylideneamino)-3-(salicylideneaminomethyl)pyridine].

Fully conformable with such a structure are the elemental analyses and mass spectrometric data (Scheme 2). The most striking feature of the corresponding IR spectrum is the absence of absorption bands in the region 3100–3500 cm^{-1}, proving formation of two imino bonds. The assignment of absorption bands at 1620 and 1610 cm^{-1} to C=N stretching vibrations is based on the presumption that they are shifted to lower frequencies by coordination.[13] The UV spectrum of the solid complex solved in methanol shows λ_{max} of 440, 310 and 266 nm also appearing successively in a methanolic solution of the ligand in the presence of Ni(II) as mentioned before.

Scheme 2.

The same behaviour as in the case of Ni(II) was observed in the course of isolation of the Cu(II) complex formed in the methanolic medium containing incipient ligand and copper. In this case, the isolated species was characterized also by X-ray determination,[16] while IR and mass spectrometric data are in accordance with those obtained for the crude Ni(II) complex.

The features of the IR spectra of both isolated complexes, together with the values of C—N bond lengths at condensation sites determined by X-ray analysis[16] for the Cu(II) complex (1.277 and 1.282 Å) show unambiguously the enolimino character of the bis Schiff base.

The coordination sphere of Cu was found to be partially tetrahedral,[16] consisting of two N and two O atoms from two salicylaldimine moieties. On the basis of remarkable similarity of the IR spectra the same coordination mode can be presumed for the Ni(II) complex.

The formation of a tetradentate ligand has been reported previously[5] for the system comprising Zn(II) or Ni(II), ethylenediamine and glyoxylate in the ratio 1 : 1 : 2. The proposed course starts with the incipiently formed cyclic diamine, 2-carboxylate imidazolidine. In the presence of a complexing metal ion the ring opens up to form with the excess of glyoxylate for the complex species a tetradentate ligand, likely a carbinolamine. Analogously, in our case, the presence of the complexing metal ion plays the essential role.

Apart from different constitution of the ligand, added as the condensation product in the cyclic diamine form, there is no salicylaldehyde present in excess. Therefore the opening of the cyclic diamine ring is accompanied also by the decomposition to condensating components of a share of added ligand. Indeed, the salt of the 2-aminopyridine moiety has been separated during the preparation of the complexes. The free salicylaldehyde is condensed with the C_2 amino group to a bis Schiff base, affording simultaneously in the enolimine form the tetradentate ligand of the isolated complexes.

The formation of complexes with bis Schiff base proceeds in diluted solutions at an extremely slow rate as already mentioned.

Acknowledgements—We are indebted to Professor J. Seibl, ETH Zentrum, Zürich, for taking the mass spectra and

helping with interpretation. Thanks are also due to members of the Ruder Bošković Institute, Zagreb, and to Drs Z. Meić and N. Brničević for recording the ^{1}H NMR spectra and a part of IR spectra.

Abstract—Complexes of Cu(II) with the polydentate diacetylazine dioxime ligand $C_8H_{14}N_4O_2$ have been synthesized by template and non-template reactions. The crystal structure of $[Cu(C_8H_{13}N_4O_2)]_2[ClO_4]_2(C_2H_5OH)_2$ has been determined to establish the conformation of the ligand and the coordination of the oxime function. The structural analysis shows that the nearly planar $[C_8H_{13}N_4O_2]^-$ group behaves as a bridging tetradentate ligand. The distorted square-pyramidal coordination about each Cu atom includes three N donors from two oxime and azine and one O donor from the other oxime, the ethanol molecule occupying the apical position. A perchlorate anion is loosely bonded to Cu. The intramolecular Cu...Cu separation is 3.725(2) Å. The compound crystallizes in the centrosymmetric space group $P\bar{1}$ triclinic lattice with refined lattice parameters of a = 11.963(8) Å, b = 9.784(7) Å, c = 7.501(6) Å, α = 90.69(4)°, β = 104.53(4)°, γ = 90.83(4)°, V = 849.7 Å^3 and Z = 2. Full-matrix least-squares refinement of 1490 independent reflexions led to final discrepancy indices, R = 0.059, and R_w = 0.065. The Cu centres are highly coupled as indicated by the ESR spectrum. There is no evidence that the $C_8H_{14}N_4O_2$ ligand stabilizes unusual oxidation states of Cu.

Macrocyclic ligands able to coordinate two or more metal ions offer the possibility of studying unusual electronic and chemical properties depending upon the proximity of the metal centres. An advantage of macrocyclic systems for this type of investigation is that the variation of ring size or other geometric constraints should allow the separation and disposition of the metal ions to be controlled in a systematic manner.[1,2]

The ketazine complexes are attractive systems[3] for structural and magnetic studies because the close proximity of the metal(II) ions implies a strong likelihood of magnetic coupling. During the investigation of new ketazine polymetallic compounds obtained by simple condensation between hydrazone and ketonato complexes,[4] the template reaction of 1,3-butanedione monoxime monohydrazone with 1,3-butanedione monoxime was studied. It should be noted that the non-template reaction produces diacetylazine dioxime,[4] which can be used as a dinucleating polyaza ligand in coordination chemistry.[5] Binuclear Cu(II) and Ni(II) complexes of the ketazine ligands have been known for several years;[6,7] unfortunately, to our knowledge, no X-ray structure has yet been published.

The ligand diacetylazine dioxime is likely to be sterically unstable and several stereoisomers are possible. In addition, oximes are widely recognized as versatile ligands that can be bound in different ways by O and/or N atoms.[8–10]

The compounds reported in this investigation result from the template reaction of 1,3-butanedione monoxime and 1,3-butanedione monoxime monohydrazone with copper perchlorate. We have

undertaken an X-ray diffraction study of $[Cu(C_8H_{13}N_4O_2)]_2[ClO_4]_2(C_2H_5OH)_2$ to establish the nature of the oxime and azine coordination and the conformation of the polydentate ligand.

EXPERIMENTAL

Reagents

2,3-Butanedione monoxime, $C_4H_7NO_2$ (99%), was purchased from Merck. Hydrazine and hydrazine hydrate were purchased from Vendron. Copper perchlorate, $Cu(ClO_4)_2 \cdot 6H_2O$, was purchased from Fluka.

Syntheses

The 2,3-butanedione monoxime monohydrazone was obtained by mixing 2,3-butanedione monoxime (0.1 mol) and hydrazine hydrate (0.098 mol) in 100 cm^3 of ethanol. After 24 h, white needle crystals were obtained. The product was recrystallized by dissolving in ethanol, adding water and cooling. Found: C, 41.9; H, 7.9; N, 36.5; O, 14.0. Calc. for $C_4H_9N_3O$: C, 41.74; H, 7.82; N, 36.52; O, 13.91%.

The diacetylazine dioxime was obtained by the method of Stratton.[6] The product was recrystallized from hot ethanol yielding yellow needle crystals. Found: C, 48.3; H, 7.3; N, 27.9; O, 16.4. Calc. for $C_4H_9N_3O$: C, 48.48; H, 7.07; N, 28.28; O, 16.16%.

$[Cu(C_8H_{13}N_4O_2)]_2[ClO_4]_2$ (**A**). (1) Stoichiometric quantities of 2,3-butanedione monoxime monohydrazone (0.043 mol) and $Cu(ClO_4)_2 \cdot 6H_2O$ (0.043 mol) were dissolved in 50 cm^3 of ethanol, then 2,3-butanedione monoxime (0.043 mol) was added to the solution which was allowed to react at 60°C. The solution was filtered (removing a small amount of green precipitate) and allowed to stand in a covered beaker. The product crystallized as dark green crystals, which were separated by filtration, washed by cold ethanol and diethyl ether, and dried *in vacuo*. Found: Cu, 16.8; C, 27.8; H, 4.0; N, 13.8; O, 27.1; Cl, 9.4. Calc. for $C_8H_{13}ClCuN_4O_6$: Cu, 17.64; C, 26.67; H, 3.63; N, 15.55; O, 26.65; Cl, 9.84%. Single crystals suitable for crystal structure determination were obtained by mixing 2,3-butanedione monoxime monohydrazone (0.005 mol), 2,3-butanedione monoxime (0.005 mol) and $Cu(ClO_4)_2 \cdot 6H_2O$ (0.005 mol) in 50 cm^3 of ethanol. The solution was allowed to stand at 0°C. Well-developed dark green single crystals were obtained after several days.

(2) A stoichiometric amount of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.043 mol) in ethanol was added to a refluxing solution of diacetylazine dioxime (0.043 mol) in ethanol and the solution was refluxed for several hours. After cooling the product crystallized immediately as a fine powder. The product was separated by filtration, washed by cold ethanol and ether, and dried *in vacuo*. Found: Cu, 16.3; C, 28.5; H, 4.4; N, 13.6; O, 27; Cl, 9.1. Calc. for $C_8H_{13}ClCuN_4O_6$: Cu, 17.64; C, 26.67; H, 3.63; N, 15.55; O, 26.65; Cl, 9.84%. The IR and UV–visible spectra are analogous for the products obtained by the template (1) and non-template (2) reactions.

$[Cu(C_8H_{13}N_4O_2)][ClO_4]$ (**B**). Five grams (0.043 mol) of diacetyl monohydrazone monoxime were dissolved in 50 cm^3 of hot ethanol with 8.055 g (0.0217 mol) of $Cu(ClO_4)_2 \cdot 6H_2O$. The dark red solution was refluxed for several hours, then the solution was allowed to stand at 0°C. The product crystallized as dark red crystals which were isolated by filtration, washed with cold ethanol and ethyl ether, and dried *in vacuo*. Found: Cu, 17.3; C, 28.0; H, 3.9; N, 15.1; O, 26.3; Cl, 9.4. Calc. for $C_8H_{13}ClCuN_4O_6$: Cu, 17.64; C, 26.67; H, 3.63; N, 15.55; O, 26.65; Cl, 9.84%.

Instrumentation

UV–visible spectra were run at room temperature in solution or in the solid state (Nujol mull) with a Jobin–Yvon DUOSPAC 203 spectrophotometer. IR spectra were recorded from Nujol mulls and KBr pressed discs (4000–400 cm^{-1}) and polyethylene discs (400–50 cm^{-1}) by use of a Bruker IFS 113 V Fourier-transform spectrometer. ESR spectra of solutions and powder samples were obtained on a Varian E-109 spectrometer operating at 9.315 GHz between 20 and −160°C. Electrochemistry was performed with a Tacussel PRT 20-10 potentiostat in combination with a Tacussel UAP4 universal programmer equipped with a current to voltage converter. Cyclic voltammograms were recorded on a Sefram TGM 164 X–Y recorder or a Tektronik R 5111 storage oscilloscope. The electrochemical experiments were carried out under argon with a conventional three-electrode system. The reference electrode used is the SCE (saturated calomel electrode). The solvent, $(CH_3)_2CO$, was distilled over a "molecular sieve" (4 Å) under argon prior to use. The supporting electrolyte, tetraethyl ammonium perchlorate, was purchased from Agfa and dried *in vacuo* at 50°C over P_4O_{10}.

CRYSTALLOGRAPHIC STUDIES

Cell dimensions were determined from the angular settings of 25 accurately centred reflections during diffractometer measurements.

Crystal data

$Cu_2C_{20}H_{38}N_8O_{14}Cl_2$; $M = 405.3$, triclinic space group $P\bar{1}$, $a = 11.963(8)$ Å, $b = 9.784(7)$ Å, $c = 7.501(6)$ Å, $\alpha = 90.69(4)°$, $\beta = 104.53(4)°$, $\gamma = 90.83(4)°$, $V = 849.7$ Å^3. $D_m = 1.56(3)$ g cm^{-3}, $D_c = 1.58$ g cm^{-3}, $Z = 4$, and μ(Mo-K_α) = 15.32 cm^{-1}.

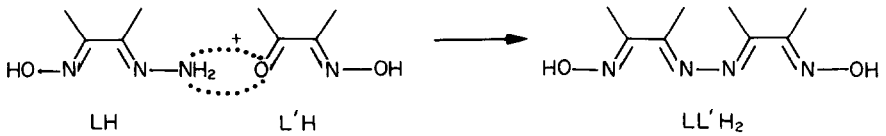
Data collection

Data were obtained from a dark green crystal of dimensions $0.3 \times 0.2 \times 0.25$ mm^3 on a Philips PW 1100 diffractometer equipped with a graphite monochromator which isolates Mo-K_α radiation ($\lambda = 0.7107$ Å). The intensities of 1624 independent reflexions were collected for $2° < \theta < 30°$; 1499 reflexions were classified as observed with $I > 3\sigma(I)$. Background, Lorentz and polarization corrections were applied. No absorption corrections were applied.

Structure solution and refinement

The structure was solved by the heavy-atom method. Refinement and subsequent difference synthesis located the remaining non-H atoms. Three unexpected peaks were attributed to an ethanol solvate molecule which was not detected during elemental analysis of samples dried *in vacuo*. All atoms were refined anisotropically by a full-matrix least-squares program. Considerable difficulty was encountered in locating and refining the perchlorate O atoms: one of them is statistically disordered over two positions and all have abnormally high thermal motion.

Convergence was achieved with $R = 0.059$, and $R_w = 0.065$. The final Fourier difference function was featureless and does not permit the localisation of the H atoms. Unit weights were assumed for all reflections.



Scattering factors were taken from Cromer and Waber[11] for Cu^{2+}, C, N, O and Cl, and the anomalous dispersion corrections from Cromer and Liberman.[12] Final atomic coordinates, thermal parameters and F_o/F_c values have been deposited with the Editor as supplementary data.*

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre for inclusion in their data base. Copies of all deposited data are available, on request, from the Editor at Queen Mary College.

RESULTS AND DISCUSSION

Syntheses

1,3-Butanedione monoxime monohydrazone, denoted LH, reacts with 1,3-butanedione monoxime, denoted L'H, in ethanol to give the diacetylazine dioxime ligand, denoted $LL'H_2$.[5,6]

LH L'H $LL'H_2$

The coordination of Cu(II) perchlorate with this ketazine ligand gives a dark green product corresponding to the $Cu(LL'H)ClO_4$ composition (compound **A**). If the reaction is performed under "template" conditions the same product is obtained, as evidenced by analytical, spectral and crystallographic results. If LH is mixed with Cu(II) perchlorate in refluxing ethanol a dark red compound (**B**) is isolated, which exhibits the same elemental analysis as **A**. We suspect that the elimination of one hydrazine molecule between the hydrazone function of two LH in the coordination sphere of Cu(II) can lead to the formation of the $LL'H_2$ ligand. The $LL'H_2$ ligand in compound **B** possesses a different conformation than that in compound **A**.

UV, visible and IR spectra

It is difficult to make an unequivocal assignment of the IR bands; nevertheless, some similarities exist in the IR absorptions of the free $LL'H_2$ ligand in compounds **A** and **B**. In particular, the broad absorption near 3400 cm^{-1} corresponds to the OH group of the oxime function involving inter- or intramolecular hydrogen bonding. Three bands corresponding to the ν(C=N) vibrations are found at 1658, 1598 and 1567 cm^{-1} for **A** whereas the IR spectrum of **B** exhibits two absorptions at 1640 and 1612 cm^{-1}; it should be noted that the spectrum of the free ligand possess two ν(C=N) bands at 1643 and 1602 cm^{-1}. However, several differences are observed near 1250 and 750 cm^{-1} particularly in the relative intensities of the IR absorption. The expected ν_3 and ν_4 IR bands of the ClO_4^- anion with T_d-symmetry are observed at 1108 and 628 cm^{-1} and 1092 and 632 cm^{-1} for **B** and **A** respectively. Nevertheless, the weak band observed at 932 cm^{-1} for **A** and the broadness of the ν_3-bands indicates that the symmetry may be lowered.

Compound **A** is sparingly soluble in ethanol and

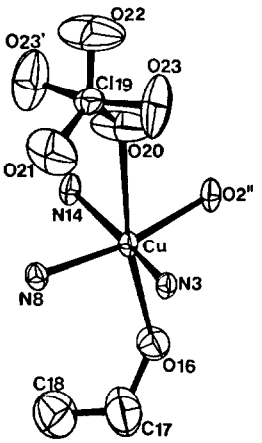


Fig. 1. View of the inner coordination sphere of Cu(II) showing the atom-labelling scheme.

its UV and visible absorption spectra exhibit a broad band centred at 360 nm and a shoulder at 460 nm. The electronic absorption spectra of **A** and **B** in the solid state exhibit an intense band centred at 360 and 340 nm, while the visible absorption peaks occur at 610 and 480 nm respectively.

Structure of $[Cu(LL'H)]_2[ClO_4]_2(C_2H_5OH)_2$ (**A**)

Since spectroscopic data could not decide the stereochemistry of complexes **A** and **B**, an X-ray investigation was necessary. While stable single crystals of **A** were easily obtained, attempts to crystallize product **B** by slow reaction or slow cooling led to well-shaped crystals which rapidly lose solvent when they are extracted from reaction mixture.

Coordination of the Cu(II) *ion*

Figure 1 shows the Cu atom coordination sphere along with the numbering scheme. The coordination polyhedron around Cu^{2+} comprises five atoms forming a square-pyramidal arrangement. The basal plane is formed by the N(3), N(8) and N(14) atoms of one LL'H ligand and the O(2) atom of the second $LL'H^-$ ligand. The apical position is occupied by the O(16) atom of ethanol. The "basal plane" is essentially planar with the largest deviation from the best least-squares planes being 0.03 Å. The Cu atom is displaced 0.165(1) Å from the basal plane in the direction of the O(16) atom of ethanol.

The Cu—N bond lengths are 2.008(8), 1.963(8) and 1.957(9) Å; the shortest corresponds to the N(4) azine atom, the intermediate to the N(3) atom (deprotonated oxime group) and the largest to the N(14) atom (non-deprotonated oxime function). The bond angles of the Cu atom coordination sphere (Table 1) are in the range of those found for the Cu complex derived from 2,6-diacetylpyridinedioxime (DAPDH).[13] An ethanol molecule is located above each Cu atom with a Cu—O(16) distance of 2.279(9) Å. This distance can be compared to the corresponding Cu—H_2O distances of 2.249(3) and 2.317(4) Å in the DAPDH complex.[13]

A distorted octahedral geometry around the Cu atom is obtained by a long Cu...O (perchlorate) contact. This interaction is clearly weak: the Cu—O(20) distance is 2.760(15) Å and may best be described as what Hathaway and coworkers[14] have called "semicoordination". The geometry of the ClO_4^- anion is not well defined because of the disorder. Two kinds of ClO_4^- anions are present with only half-occupancy, so that the interatomic angles and distances within a ClO_4^- tetrahedron are not significant.

Conformation of the LL'H ligand

As shown in Fig. 2, the complex is in fact a dimer, $[CuLL'H]_2^{2+}$; the two parts are related by the

inversion centre. The dimeric fragment composed of O(2), N(3), N(8), N(14), O′(2), N′(3), N′(8) and N′(14) is essentially planar with a largest deviation from the best least-squares plane of 0.014(8) Å (Table 2). This planarity was also observed in several dimeric copper complexes with μ-dihydroxo bridges[15,16] but not in the $[CuDAPDH]_2^{2+}$ dimer which contains a dihedral angle of 169.6° between pyramidal units.[13] The bond lengths and angles for this portion of the complex, as given in Table 1, are consistent with those found in similar complexes. The intramolecular Cu–Cu separation is 3.725(2) Å, longer than in the $DAPDH_2$ complex [3.5453(7) Å]. The tetradentate ligand gives two kinds of chelate rings with a Cu atom: a diaza five-membered ring and a triaza six-membered ring.

The $LL'H^-$ tetradentate ligand adopts the *cis–trans* conformation in the dimeric complex. The coordination of the Cu^{2+} ion induces appreciable deviations in the N—C—C, C—N—N, C—C—C and O—N—C angles. As noted in Ref. 14, deprotonation of the O oxime site is accompanied by a reduction in the N—O bond distance from 1.397(13) to 1.314(10) Å, and a lengthening of the Cu—N (oxime) distance.

Crystal structure

The unit cell contain only one dimer and the planes of dimeric ions, $[Cu(LL'H)]_2^{2+}$, related by lattice translations are of course parallel. The interdimer contacts are more than 3.4 Å, between the O atom of

the ClO_4^- group and the C atom of the methyl group, and correspond to Van ver Waals' contacts.

Electrochemistry

The electrochemical study of the dimeric complex $[Cu(LL'H)]_2[ClO_4]_2$ was undertaken in dry acetone and under argon with the hope of obtaining Cu(III) and/or Cu(I) oxidation states. The reduction of the dinuclear Cu(II) complex occurs at +0.02 V vs SCE electrode. However, when measured by cyclic voltammetry, the Cu(II)/Cu(I) redox process is irreversible at all the scan rates used. The reason for this is not well understood, but could be due to chemical reaction or rearrangement subsequent to charge transfer. The oxidation of the two copper centres occurs nearly simultaneously at +0.84 V vs SCE (Fig. 3) and the two expected sequential oxidations are not clearly observed. In addition the cyclic voltammograms indicate the chemical decomposition of the Cu(III) species generated at the platinum electrode. There is no evidence that the $LL'H_2$ ligand stabilizes high or low oxidation states of Cu as occurs in the case of dinuclear macrocyclic ligands.[17]

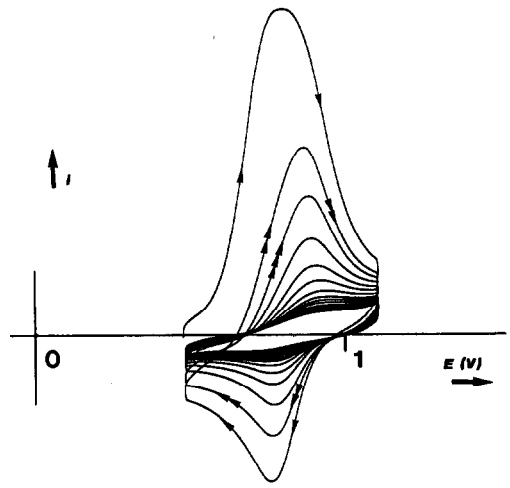

Fig. 3. Multiple scans of cyclic voltammetry of 10^{-3} M $[Cu(C_8H_{13}N_4O_2)]_2^{2+}$ in $(CH_3)_2CO$ with 0.1 M $[(C_2H_5)_4N][ClO_4]$ at 0.1 V s^{-1}.

ESR spectra

The dimeric structure of $[Cu(LL'H)]_2[ClO_4]_2$ is retained in nondonor solvents such as ethanol. Unfortunately, the red (**B**) and green (**A**) products are sparingly soluble in nondonor solvents and the ESR spectra obtained in ethanol at room temperature are poorly resolved with a bad signal: noise ratio. The ESR spectrum of compound **B** exhibits a signal centred at 3600 G with no obvious sign of coupling, whereas the spectrum of product **A** shows a more complicated signal near 2000 and 3600 G.

The difference between the ESR spectra of the two products is more evident with powder samples. The powder spectra of product **B** (Fig. 4) is typical of an isolated Cu(II) ion.[18] Lowering the sample temperature to 77 K produces no significant effect on

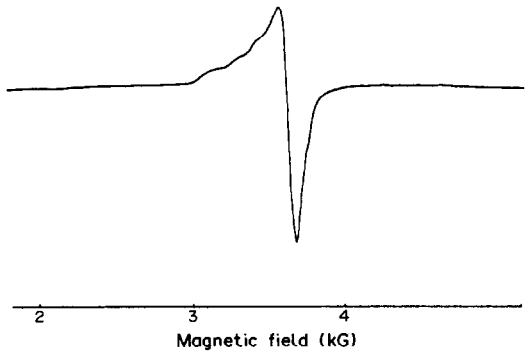

Fig. 4. Powder X-band ESR spectrum of **B** $[Cu(C_8H_{13}N_4O_2)(ClO_4)]$ at room temperature.

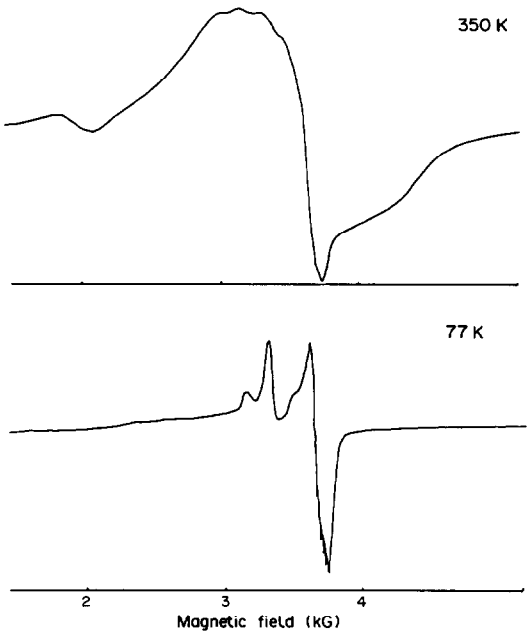

Fig. 5. Powder X-band ESR spectrum of binuclear A $\{[Cu(C_8H_{13}N_4O_2)]_2[ClO_4]_2\}$ compound at room temperature and 77 K.

the shape of the signal. The ESR spectra of powdered sample A are reported in Fig. 5: the spectra are typical of that shown by other highly coupled Cu dimers.[14,16,19,20] Lowering the temperature to 77 K produces a dramatic effect on the shape of the low-field signal. The usual Cu(II) and ^{14}N hyperfine couplings are observed in the spectrum recorded at 77 K.

The ESR spectra of the Cu(II) complexes derived from diacetylazine dioxime indicated a dramatic effect of the coordination mode of the ligand upon the magnetic properties.

In the light of the structure determination, it is apparent that electron exchange between the Cu(II) centres of the $[Cu(LL'H)]_2$ dimers is mediated through oximato bridges and gives a highly coupled system. The $LL'H_2$ appears to be a versatile polydentate ligand and confirmation of different stereoisomeric forms of the ligand coordinated to Cu(II) is under investigation. A detailed study of the magnetic properties in connection with the structural determination is currently being carried out.

(*Received* 2 *January* 1985; *accepted* 26 *April* 1985)

Abstract—The synthesis of a new class of two-dimensional triazole compounds is described, including the crystal structure of $[Co(NCS)_2(btr)_2]H_2O$ [btr stands for 4,4'-bis-1,2,4-triazole ($C_4H_4N_6$)]. Crystals are monoclinic, space group $C2/c$, $a = 11.159(1)$ Å, $b = 13.047(4)$ Å, $c = 12.993(3)$ Å, $\beta = 91.81(2)°$, $Z = 4$. The structure has been solved by Fourier and direct methods and refined by full-matrix least squares to $R = 0.0229$, $R_w = 0.0283$. The structure consists of layers of six-coordinated cobalt atoms, each having two *trans*-oriented *N*-bonded thiocyanate groups [Co—NCS 2.098(2) Å] and linked together in the equatorial plane by single bridges of btr to a two-dimensional network. The btr ligand coordinates through its N(1) and N(1') atoms [Co—N 2.128(1) and 2.142(1) Å]. The intralayer Co—Co distance is 9.207(2) Å, and the inter-layer Co—Co distance is 8.584(1) Å. The magnetic susceptibilities of the compound and of the isostructural nickel and iron compounds are discussed. The iron compound exhibits a high-spin–low-spin crossover at liquid-nitrogen temperatures, as shown by magnetic susceptibility.

Derivatives of 1,2,4-triazole are now well known to act as polynucleating ligands to first-row transition metals.[1,2] Unsubstituted 1,2,4-triazole has been demonstrated to coordinate in several ways: monodentate;[3] 1,2-bidentate,[4] leading to chains; and 2,4-bidentate,[5] leading to two-dimensional layer structures. 4-Substituted triazoles coordinate mainly via N(1) and N(2) producing again one-dimensional chains[6–8] of dimers, trimers and polymers (dinuclear etc.). These compounds show interesting magnetic properties,[1,2] not only by the fact that they are polynuclear, but also because this type of ligand coordinates rather strongly and may cause iron(II) compounds to become low-spin and spin transitions may occur above or below room temperature.[8,9] In a previous paper,[10] the preparation of the ligand 4,4'-bis-1,2,4-triazole (btr) and of two of its metal complexes were reported. One of the conclusions was that btr was a rather strong ligand among the triazoles and comparable in ligand-field strength to 1,2-diaminoethane, as deduced from ligand-field spectra. The free ligand btr has a remarkable structure, that was determining by Domiano.[11] The torsional angle around the N—N bond connecting the two triazole rings appeared to be 91.9°, and the two rings are, therefore, nearly perpendicular to each other. The four peripheral nitrogen atoms are chemically equivalent and in principle liable to coordinate to four metal ions which should afford three-dimensional coupled systems. Preliminary results showed the compounds $M(NCS)_2(btr)_2(H_2O)$ for M = Fe, Co and Ni to be mutually isomorphous, with interesting magnetic and spectroscopic properties. In order to investigate the mode of coordination of btr in the compound $[Co(NCS)_2(btr)_2]H_2O$ an X-ray crystal structure determination was done, the results of which are also reported in the present paper.

EXPERIMENTAL

Syntheses and X-ray structure determination. The ligand btr and its metal coordination compounds were prepared as described earlier.[10] Orange

crystals of $[Co(NCS)_2(btr)_2]H_2O$ were grown by slowly cooling a hot (70°C) solution of the reactants to room temperature. The experimental density, determined in a mixture of 1,2-dibromoethane and trichloromethane, was 1.65 Mg m^{-3}. A rod-shaped single crystal suitable for analysis was mounted on an Enraf–Nonius CAD-4 diffractometer and data were measured at room temperature. Crystallographic and experimental data are tabulated in Table 1. The experimental intensities were corrected for Lorentz and polarisation effects and transmission coefficients ranged from 0.69 to 0.94. An absorption correction was calculated using the program ABSCOR[12] [μ(Mo-K_α) = 11.51 cm^{-1}]. After reduction to structure factors a Wilson plot afforded starting values for the scaling parameter and the overall isotropic thermal parameter. The position of the cobalt was located by means of a Patterson synthesis, the other non-hydrogens were found successively with the direct methods program MULTAN.[13] The hydrogen atoms could be located in a difference Fourier synthesis. Anisotropic refinement for the non-hydrogens and isotropic refinement for the hydrogens yielded $R = 0.0229$ and $R_w = 0.0283$, with omission of unobserved reflections. The scattering factors were taken from the *International Tables*.[14] All computer programs used were written or modified by Dr R. A. G. de Graaff and Mrs E. Rutten-Keulemans. The function minimized during the least-squares refinement was $\sum w(\Delta F)^2$, with $\Delta F = |F_o| - |F_c|$ and $w = (\sigma_F)^{-2}$. Reliability indices referred to in Table 1 are $R = \sum|\Delta|/|F_o|$ and $R_w = [\sum w(\Delta F)^2/\sum w|F_o|^2]^{1/2}$. Secondary extinction did not appear to be significant, therefore no correction for this effect was made. The thiocyanate sulphur atom and the water hydrogen atoms were found to be in disordered positions. Two positions with different occupancy numbers were refined. The occupancy numbers for S and S* are 0.82 and 0.18 respectively; the occupancy numbers for HW and HW* are 0.73 and 0.27 respectively.

Table of atomic coordinates, temperature factors and F_o/F_c values have been deposited with the Editor as supplementary materials and are available on request. Atomic coordinates have also been

deposited at the Cambridge Crystallographic Data Centre.

Magnetic measurements. The magnetic susceptibility measurements from 80 to 300 K were made by means of a Faraday balance.

$CoHg(SCN)_4$ was used as a calibrant.

RESULTS AND DISCUSSION

Description of the structure

Figure 1 gives an ORTEP[15] view of a part of the network structure of the compound. It also shows the thermal ellipsoids of the non-hydrogens at 50% probability and the numbering of the atoms as used in the structure determination. Table 2 gives the bond distances and bond angles of the compound. Some dihedral angles and information about the hydrogen bridging system are also given. As Fig. 1 shows, the coordination polyhedron around cobalt is a distorted octahedron with two thiocyanate N atoms *trans* to each other. Because the cobalt atoms are on centres of inversion the N—Co—N angles are 180°. The Co—NCS distance is 2.098(2) Å, in agreement with literature values.[16,17] The Co—N—C angle, 154.9(1)°, differs significantly from 180°; such a large deviation for an M—N—C angle in isothiocyanates is rare, but has been observed before.[1,2,7,17–20] The remaining four positions of the coordination polyhedron are occupied by ligand N atoms. Each ligand constitutes a bridge between two adjacent cobalt atoms by coordination through N(1) and N(1') [in the tables and Fig 1 named as N(11) and N(21) respectively]. In this way two-dimensional arrays of cobalt atoms are formed that are planar and nearly square: angles 89.76(2) and 90.24(2)°. These layers are parallel to the *bc* plane of the unit cell. Each cobalt atom of a layer is just between the centers of the "holes" of the two neighbouring layers, as imposed by the space group symmetry (see Fig. 2). The Co—Co distance in the layers is 9.207(2) Å, whereas between the layers the shortest Co—Co distance is 8.584(1) Å. The layers are connected to each other by means of Van der Waals' forces and weak hydrogen bridges through the water molecules. As there is only one water molecule on two ligands, each with two non-coordinating nitrogen atoms, only half of these nitrogen-free electron pairs can take part in hydrogen bonding. The disorder in the position of the water hydrogen atom is in agreement with this weak hydrogen bridge. The geometry of this bridge is detailed in Table 2 and illustrated in Fig. 2.

The H-bond interaction is rather weak indeed, as is illustrated by the comparatively narrow OH-stretching absorptions in the IR spectrum at 3500 cm^{-1}.[10] The position of the disordered hydrogens makes them unavailable for this hydrogen bond. The direction in which the disordering of this atom has taken place suggests instead that some additional H-bonding interaction may be present with the other

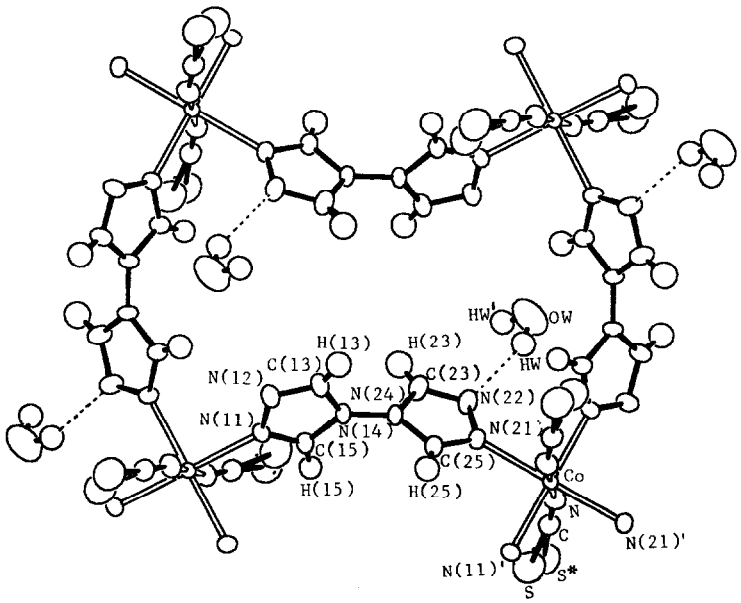

Fig. 1. Part of the two-dimensional layer structure of $[Co(NCS)_2(btr)_2]H_2O$ showing coordinating polyhedra, ligand bridging, part of hydrogen bonding (dotted lines) and numbering system used. ORTEP[15] drawing. HW' is related to HW by symmetry operation $-x, y, \frac{1}{2}-z$; N(11)' is related to N(11) by symmetry operation $x, 1-y, -\frac{1}{2}z$; N(12)' is related to N(12) by symmetry operation $1\frac{1}{2}-x, 1\frac{1}{2}-y, -z$.

Both positions of the disordered hydrogen atoms of the water molecules are given. These hydrogen atoms are drawn with small temperature factors. The ligand hydrogen atoms have been omitted for clarity.

free electron pair on N(12), despite the long O...N bond of 3.75 Å. The disorder in the position of S is unusual for a nearly linear NCS geometry: angles N—C—S [176.5(2)°] and N—C—S* [164.5(5)°]. There was no disorder observed in the N or C positions. This sulphur disorder may be brought about by the fact that the NCS groups point to spaces between the layers where no active hydrogens are available to fix their position by means of hydrogen bonding.

Symmetry considerations do not give any support to a splitting of the ν(C—N) in the IR spectrum of $[Co(NCS)_2(btr)_2]H_2O$ and the isomorphous iron and nickel compounds.[21] Nevertheless, a splitting of about 18 cm^{-1} is observed.[10] This splitting can be attributed to the disorder in the position of the sulphur atoms. The splitting in the ν(C—S) (at 796 cm^{-1}) may also originate from this disorder. If this explanation is valid, the reported splitting of the NCS-bending mode into four absorptions could be ascribed to the deviation from linearity, as well as to the disorder in the sulphur atoms.

The geometry of the ligand btr, compared to that of the free molecule, shows a systematic decrease in all ligand bonds. Such an effect has been demonstrated before[5] for complexes of unsubstituted 1,2,4-triazole. The difference between the longest and the shortest endocyclic bonds, which is the largest found so far for 1,2,4-triazoles and their coordination compounds is quite remarkable. Domiano[11] inferred from this a more defined localisation of double-bond character between the N(1), C(5) and N(2), C(3) atoms. Apparently this localisation effect has been retained in the title compound. A comparable effect, although smaller, was observed in coordination compounds of 4-alkyl-substituted 1,2,4-triazoles.[2]

The torsional angle around the central N—N bond of the ligand is 93.60(8)°, which is almost equal to the angle in the free ligand (90.9°), allowing the conclusion that the molecular geometry of the ligand is retained in the complex.

Magnetic measurements

To investigate a possible magnetic interaction between the metal ions through the ligands, magnetic susceptibility measurements of the three isomorphous compounds were recorded. The results are summarised in Table 3. All compounds show

Table 3. Magnetic data for $[M(NCS)_2(btr)_2]H_2O$ (M = Fe, Co or Ni)

	M		
	Fe	Co	Ni
μ_{300K}	5.28	—	—

$\theta_{80-150K}$	−9.5	—	—
$\theta_{150-300K}$	12.5	—	—

only small magnetic interactions, as could already be expected from the rather long metal–metal distances.

Much to our surprise, the iron(II) compound shows a high-spin–low-spin transition at 153 K, although a residual paramagnetic fraction of about 60% remains (Fig. 3). Preliminary analysis of this phenomenon indicates a relationship between crystal quality and magnitude of the residual paramagnetic fraction.

This effect, which has been observed before for several other compounds,[22–25] is the subject of further investigations, including magnetic susceptibility and Mössbauer measurements (to be published at a later stage[26]). Haasnoot and Groeneveld[10] have already reported a strengthening of the ligand field upon cooling to liquid-nitrogen temperature in the cobalt(II) and nickel(II) compounds.

The observed spin transition in

$$[Fe(NCS)_2(btr)_2]H_2O$$

is highly unusual and, in fact, has not been observed before in iron(II) compounds with *trans*-oriented thiocyanate groups. A variety of iron(II) compounds is known, showing an HS–LS transition; however, all have *cis*-oriented thiocyanate anions.[22–25] The very few iron(II) *trans*-thiocyanate compounds which are known[18,27–29] do not exhibit a spin transition upon cooling. It appears that $[Fe(NCS)_2(btr)_2]H_2O$ is the first compound with a spin transition in which the iron(II) is coupled weakly antiferromagnetically by ligand bridges, thus forming a two-dimensional network.

Concluding remarks

The structure of the title compound, which was proposed from analytical and spectroscopic data,[10] has been confirmed by the X-ray structure determination. The ligand indeed has *C*2 symmetry with 1,1′-coordination.

The splitting of the NCS IR vibrations have been explained mainly by the disorder found in the position of the sulphur atoms. This emphasizes that care must be taken in drawing conclusions about the coordination mode of thiocyanate from the positions of the NCS absorptions.

The conclusion that btr is a very strong ligand has been proven by the HS–LS transition in the X-ray isomorphous iron(II) compound. This makes it also worthwhile to continue the investigations on this ligand because of the fact that btr is a potentially tetradentate tetranucleating ligand.

Acknowledgements—We wish to thank W. G. Haije, R. C. M. de Groot and G. Renes for operating the Faraday balance. The present investigations have been carried

SPECTROSCOPIC AND STRUCTURAL PROPERTIES OF HOMONUCLEAR Fe(II) PYRAZINE-BRIDGED POLYMERIC COMPLEXES $[Fe(PYRAZINE)_2X_2]_n$ (X = Cl, Br OR I)

K. RACHLEWICZ,* J. PIETRZYK and K. DRABENT
Institute of Chemistry, University of Wrocław, 50-383 Wrocław, F. Joliot-Curie 14, Poland

(*Received* 23 *November* 1984; *accepted after revision* 26 *April* 1985)

Abstract—The reactions of FeX_2 (X = Cl, Br or I) with pyrazine (pyz) yield the $Fe(pyz)_2X_2$ compounds. Examination of IR and Raman spectra in the medium- and far-IR region as well as studies of electronic and Mössbauer spectra suggests that the complexes contain six-coordinate high-spin Fe(II) in the FeN_4X_2 chromophore. The complexes have a polymeric pseudo-octahedral pyz-bridged structure. The magnetic moments are independent of temperature and low-temperature magnetic measurements do not indicate any magnetic ordering above 4.2 K in these compounds. The π-acceptor properties of pyz are reflected both in the electronic spectra evaluated in terms of the angular overlap model and the Mössbauer parameters.

There are many papers dealing with the physico-chemical properties of transition metal compounds containing pyrazine (pyz) as one of the ligands. In most cases these studies refer to the compounds where pyz is a ligand bridging two metal ions,[1–4] although it also occurs as a unidentate ligand.[4–6]

Polymeric compounds with the formula FeL_2X_2 (where L = pyridine)[7,8] or $FeLX_2$ (where L = 2,2-bipyridyl or 1,10-phenanthroline, and X = halide or pseudo-halide ion)[9,10] containing halide or pseudo-halide bridges have been recently thoroughly studied because of their magnetic properties. These compounds were found to possess a pseudo-octahedral polymeric structure. A group of compounds of that composition with a monomeric pseudo-tetrahedral structure were reported.[7,11–14]

It seemed interesting to prepare and to investigate the structure and properties of the FeL_2X_2 compounds (X = Cl, Br or I), with the ligand L containing two coordination sites capable of bridge bond formation. The present paper shows the results obtained for compounds where the ligand L is pyz. The compound $Fe(pyz)_2Cl_2$ has been prepared previously[15,16] and on the basis of IR studies its structure was described as polymeric pseudo-octahedral, containing chloride bridges. The spectroscopic (IR, Raman, UV–Vis and Mössbauer) and magnetic results presented here do not confirm such a structure.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

$Fe(pyz)_2Cl_2$ was prepared by the modified method of Bayer and Ferraro.[15] A solution of 2 mmol of $FeCl_2 \cdot 4H_2O$ in 10 cm^3 of water was added to a solution of 2 mmol of pyz in 10 cm^3 of water under a stream of nitrogen. A red precipitate formed immediately, which was filtered, washed with water, ethanol and ethyl ether, and dried in a desiccator over $CaCl_2$ in a nitrogen atmosphere. Found: Fe, 19.52; C, 33.56; H, 2.91; N, 19.44; Cl, 24.63. Calc. for $Fe(pyz)_2Cl_2$: Fe, 19.46; C, 33.48; H, 2.82; N, 19.53; Cl, 24.71%.

$Fe(pyz)_2Br_2$. An excess of iron powder was dissolved in 5 cm^3 of 40% HBr in a nitrogen atmosphere. After 12 h the solution was filtered to remove all traces of iron. A methanol solution of pyz was added to this solution (Fe : pyz = 1 : 1). A red precipitate formed immediately and was purified and dried as a chlorine derivative. Found: Fe, 14.92; C, 25.58; H, 2.24; N, 14.82; Br, 42.44. Calc. for $Fe(pyz)_2Br_2$: Fe, 14.86; C, 25.56; H, 2.15; N, 14.91; Br, 42.52%.

$Fe(pyz)_2I_2$ was prepared in a similar way to the bromine complex, except that 40% HI was used instead of HBr. Found: Fe, 11.88; C, 20.54; H, 1.86; N, 11.87; I, 53.93. Calc. for $Fe(pyz)_2I_2$: Fe, 11.89; C, 20.45; H, 1.72; N, 11.92; I, 54.02%.

Physical measurements. The X-ray powder patterns were obtained with a DRON-1 and Ni-filtered Cu radiation.

Diffuse reflectance electronic spectra in magnesium oxide were recorded on a Beckman 5240.

The IR spectra in the region 4000–20 cm^{-1} were obtained on a Perkin–Elmer 180 spectrometer in both KBr pressed pellets and Nujol mulls.

The Raman spectra were measured by means of a JEOL IRS-S1 Spectrophotometer using the 488 and 514.5 nm exciting lines of an Ar-ion laser. The magnetic measurements were made on either a Gouy or a Faraday balance calibrated with $HgCo(NCS)_4$.

The diamagnetic corrections were applied using Pascal's constants. The Mössbauer effect measurements of powders were done on a Mössbauer 2330 spectrometer (Polon, Poland). Measurements were made at 80 and 295 K. The isomer shift values were related to a sodium nitroprusside (SNP) standard. ^{57}Co in the Cr matrix of 20 mCi activity was used as the source. The source and SNP during all measurements were stored at room temperature. The spectra were processed numerically by distribution into Lorentz curves.

Carbon, hydrogen, nitrogen and halide analyses were performed by the Analytical Laboratory of the Institute of Chemistry, University of Wrocław.

Iron was determined by using dichromate titrimetry.[17]

RESULTS AND DISCUSSION

The reactions of FeX_2 (X = Cl, Br or I) with pyz in neutral or acid aqueous solutions at room temperature yield the $Fe(pyz)_2X_2$ compounds, irrespective of the metal : pyz concentration ratio. All compounds were prepared in the form of powders. The compounds were kept in a desiccator under nitrogen over $CaCl_2$. The compounds are stable under such conditions and no changes in their spectral characteristics were found to occur after several months.

Powder X-ray diffraction patterns of the chloride compounds were made. It was found that the compound is not isomorphous with $Co(pyz)_2Cl_2$, whose single-crystal structure is known[1] to be polymeric with pyz bridges. The pyz compound is also not isomorphous with the pyridine iron compounds $Fe(py)_2Cl_2$ and $Fe(py)_4Cl_2$.

Magnetic studies

The magnetic susceptibility was examined as a function of temperature over the 4.2–293 K range for the chloride compound and over 77–293 K for the bromide and iodide compounds. Over that temperature range the $Fe(pyz)_2X_2$ complexes obey the Curie–Weiss law.

The magnetic moment is independent of temperature over the temperature range studied. The magnitude of the magnetic moment is characteristic of the pseudo-octahedral high-spin Fe(II) complexes with the ground state $^5T_{2g}$, whose degeneracy is eliminated by the low ligand field symmetry. Low-temperature magnetic measurements of pyz complexes do not indicate any magnetic ordering above 4.2 K, which distinguishes these complexes with respect to pyridine compounds with the same composition, $Fe(py)_2X_2$.[7]

Electronic spectra

Diffuse reflectance spectra of the complexes examined were measured over the region from 4000 to 50,000 cm^{-1}. The electronic spectra of the chloride and bromide complexes over the NIR region exhibit one band with a shoulder in the low-frequency part of the spectrum. On the other hand, the spectrum of the iodide complex contains two well-resolved bands. The visible region shows one broad strong band corresponding to the charge-transfer transition at about 20,800 cm^{-1}, whose energy varies slightly depending on the ligand X (X = Cl, Br or I). One can also observe a band at 35,000 cm^{-1} which corresponds to the inner π–π^* transition of pyz. The bands found in the NIR region should be assigned to the *d–d* transitions for high-spin Fe(II) of the d^6-structure surrounded by a disturbed octahedron. These transitions are from the ground state $^7T_{2g}$ (with O_h-symmetry) to the excited level E_{2g}, which becomes split into the $^5A_{1g}$ and $^5B_{1g}$ levels in the field of lower symmetry. Characteristics of the *d–d* bands found in the NIR region are presented in Table 1.

The $\nu_1 - \nu_2$ parameter defines the magnitude of the *d–d* band splitting, whereas ν_{av} is the arithmetic mean of both *d–d* band energies.

Table 1. Experimental electronic spectral results[a]

Compound	$^5T_{2g} \xrightarrow{\nu^1} {}^5A_{1g}$	$^5T_{2g} \xrightarrow{\nu^2} {}^5B_{1g}$	$\nu_1 - \nu_2$	ν_{av}
$Fe(pyz)_2Cl_2$	9800	11,600	−1800	10,700
$Fe(pyz)_2Br_2$	8800	11,200	−2400	10,000
$Fe(pyz)_2I_2$	7200	11,200	−4000	9200

[a] All data in cm^{-1}.

The parameters presented in Table 1 are similar to those found for $Fe(py)_4X_2$[7] which indicates the presence of the FeN_4X_2 chromophore for iron(II) in the pyz complexes. For the compounds with the formula $Fe(pyz)_2X_2$ such an environment may be achieved only by bridge bonding. The splitting in the spectra may be related to the σ-bonding of the ligands by using the angular overlap model:[18,19]

$$\delta_{e\sigma} = E(d_{x^2-y^2}) - E(d_{z^2}) = -(\nu_1 - \nu_2) = 2(e_{\sigma pyz} - e_{\sigma X}).$$

The $\delta_{e\sigma}$ value for the chloride compound is, within experimental error, identical to that found for the pyridine complex ($-1800\ cm^{-1}$). On the other hand, for the pyz compounds with bromide and iodide this value is lower than that for the corresponding compounds with pyridine.

The differences in the splitting energy and e_σ values of ligand interactions should be interpreted with allowance for differences in π-acceptor interactions of pyridine and pyz. The π-acceptor properties of pyz modify the σ-donor properties of X, increasing them in the case of the bromide and iodide (with respect to the pyridine compounds), or, which is more probable, the interactions of both ligands mutually change their σ-donor properties. One could note that the difference between the σ-interactions of pyz and ligand X for bromide and iodide is smaller in the pyz compounds (compared to those of pyridine), which can also be observed in the Mössbauer spectral parameters.

Similar conclusions may apply to the magnitude of splitting in the σ- and π-orbitals of the metal. This splitting is measured by the ν_{av} parameter (equivalent to the $10Dq$ parameter in the crystal field approximation). The value of ν_{av} is higher for the pyz complexes. The formation of π-back bonding in pyz compounds results in a decrease in the t_{2g} orbital energy of the metal and, thus, an increase in the separation of the t_{2g}- and e_g-orbitals which is manifested by an increase in the ν_{av} parameter. ν_{av} decreases in the series Cl > Br > I according to the position of the ligand X in the spectrochemical series. However, the decrease in that parameter is lower in pyz than in pyridine compounds.[7] The increase in the σ-donor properties of bromide and iodide is responsible for increasing the e_g orbital energy and, as a result, the separation of the t_{2g}- and e_g-orbitals is larger compared to the pyridine counterparts.

IR and Raman spectra

Mid-IR and Raman spectra exhibit internal pyz fundamentals.[20–22]

In complexes where pyz is coordinated through a bridge with two identical acceptors, the symmetry centre is preserved and pyz bonded in this manner as well as that isolated has a D_{2h}-symmetry.[4,23,24] In effect there is no coincidence of bands in the IR and Raman spectra.

As shown in Table 2 a lack of coincidence is observed for the compounds under examination. This fact indicates that the assumed structure of the complexes is polymeric with pyz bridges. Most fundamental IR bands of pyrazine are slightly shifted (several by a dozen cm^{-1}) towards higher frequencies upon coordination. Exceptions are bands 19a and 9a (Table 2).

It is not possible to evaluate the σ- and π-interactions on the basis of those shifts since they are related above all with the interactions of rings in the lattice.

Far-IR spectra in the region from 400 to 50 cm^{-1} are characteristic of the D_{4h}-symmetry.[23,24] As predicted, there are two bands for such a symmetry of the metal environment. One of these bands should be assigned to the ν_{Fe-X} mode (X = Cl, Br or I) and one to $\nu_{Fe-N(pyz)}$ (see Table 3).

The ν_{Fe-N} frequency in the pyz complexes investigated is comparable with the ν_{Fe-N} frequency in monomeric pyridine complexes of formula $Fe(py)_4X_2$.[7] The ν_{Fe-X} frequency for the chloride and bromide compound is higher than that[7] for the monomeric compounds $Fe(py)_4Cl_2$ ($+37\ cm^{-1}$) and $Fe(py)_4Br_2$ ($+17\ cm^{-1}$) but is lower for the iodide compound with respect to $Fe(py)_4I_2$ ($-22\ cm^{-1}$). The high band frequency ν_{Fe-X} is more evidence that the halides occur in terminal positions in the compounds investigated by us. In the pyz compounds the Fe—X bond becomes stabilized in the chloride and bromide complex compared to the pyridine compounds. On the other hand, there is a certain destabilization of the Fe—I bond in the pyz compound which is manifested by a decrease in the ν_{Fe-I} frequency compared to the pyridine complex.

In terms of the hard and soft acids and bases principle[25–27] a shift of electron density from the metal ion as a result of π-acceptor interactions of pyz increases the hard nature of the metal ion and thus the bond with a hard base chloride becomes stabilized and that with a soft iodide becomes destabilized.

Mössbauer spectroscopy

The magnitude of the quadrupole splitting (QS), isomeric shift (IS) and line-width for the compounds measured at 80 and 295 K are presented in Table 4. The powder Mössbauer spectra for all the compounds under examination consist of a single quadrupole doublet with narrow resonance lines.

[a] All data in cm^{-1}.

The values of QS and IS for the compounds examined are characteristic of high-spin iron(II) compounds with a distorted octahedron symmetry and for the chloride compound are close to the values observed for the $Fe(py)_4Cl_2$ complex and not $Fe(py)_2Cl_2$, which is further evidence that iron is bonded with four nitrogen atoms in the plane and with two chlorine atoms in the axial positions. The value of IS at room temperature does not depend on the type of X in the $Fe(pyz)_2X_2$ compounds, which indicates that *s*-electron density on the iron nucleus does not vary in these compounds. In addition, in the $Fe(py)_4X_2$ compounds no significant changes in the value of IS in the series (X = Cl, Br or I) are observed.

The value of QS reflects a change in substituent X in $Fe(pyz)_2X_2$ to a much less extent than in tetrakis(pyridine)[7,28–30] and tetrakis(isoquinoline)-iron(II)[28–30] complexes of general formula FeL_4X_2. However, significant differences occur in the QS values for the latter compounds. The value of QS as a measure of spherical charge distribution around the Mössbauer nucleus decreases in the series Cl > Br > I which is in agreement with expectations and reflects an increase in covalency of the Fe—X bond. In the case of the $Fe(pyz)_2X_2$ compounds the situation is different. No change in QS is found on transition from chloride to bromide and introduction of the iodide ion as X results in a much smaller change in QS than in the case of a similar substitution in the FeL_4X_2 complexes.

The absence of any differences in QS is consistent with the variations in the parameters of electronic spectra, $\nu_1 - \nu_2$ and ν_{av}. We believe that a slight change in QS results from the same reasons which were discussed in the description of the electronic spectra, that is, a decrease in the covalent nature of the Fe—X bond (X = Br and I) with respect to the analogues of formula FeL_4X_2. This effect results in the absence of significant changes in the electric field gradient on the nucleus in the bromide and iodide compound compared to the chloride compound. Therefore, no change in the QS parameter is found on passing from chloride to bromide and a slight decrease in this parameter (compared to the respective pyridine compound) for the iodide complex. A similar slight change in QS was observed

for the $Fe(phen)_2X_2$ complexes.[28] However, in this case there is a symmetry effect apart from the π-back-bonding effect of phenanthroline donation since this compound is a *cis* isomer.

PREPARATION AND ELECTRICAL RESISTIVITIES OF TETRATHIAFULVALEN (TTF) AND TETRASELENAFULVALEN SALTS WITH THE $[SnR_2Cl_n]^{2-n}$ ANIONS ($n = 3$ OR 4: R = Et OR Ph) and X-RAY CRYSTAL STRUCTURE OF $[TTF]_3[SnEt_2Cl_4]$

(*Received* 1 *March* 1985; *accepted* 3 *May* 1985)

Abstract—Tetrathiafulvalen (TTF) and tetraselenafulvalen (TSF) salts with diorganochlorostannate anions, $[TTF][SnEt_2Cl_3]$ (**1**), $[TTF]_2[SnPh_2Cl_4]$ (**2**), $[TTF]_3[SnEt_2Cl_4]$ (**3**), $[TTF]_{3.3}[SnPh_2Cl_4]$ (**4**), $[TSF]_2[SnPh_2Cl_4]$ (**5**) and $[TSF]_{3.3}[SnPh_2Cl_4]$ (**6**), were prepared by the reactions of $[TTF \text{ or } TSF]_3[BF_4]_2$ with SnR_2Cl_2 (R = Et or Ph) in the presence of $[Ph_3PCH_2Ph]Cl$ and by electrocrystallization of TTF or TSF in acetonitrile containing SnR_2Cl_2 and $[Ph_3PCH_2Ph]Cl$. All the salts behave as semiconductors with electrical resistivities of the order of $10–10^8$ Ω cm as compacted samples at 25°C. Electronic reflectance spectra of the simple salts **1**, **2** and **5**, show a band due to the dimeric $(TTF^+)_2$ or $(TSF^+)_2$ unit in the 12,200–12,800-cm^{-1} region. The complex salt **3** exhibits a TTF^+/TTF^0 charge-transfer (CT) band at 8700 cm^{-1}, and the remaining complex salts, **4** and **6**, both display CT bands between the radical cations and between the radical cation and the neutral donor molecule. The crystal structure of **3** was determined by a single-crystal X-ray diffraction. The tetragonal crystal, space group *I4cm*, has cell dimensions $a = 11.710(3)$ Å, $c = 25.242(7)$ Å, and $Z = 4$. The structure was solved by the heavy-atom method and refined to a final R value of 0.082 for 479 independent reflections with $|F_o| > 3\sigma(F)$. TTF molecules exist as trimers, in which a slight lateral shift from the eclipsed TTF overlap occurs, although TTF molecules are arranged with equal spacing between them. The trimer units are located perpendicularly to each other, forming a two-dimensional layer. The $[SnEt_2Cl_4]^{2-}$ anion is disordered with respect to the two Sn—Et and two Sn—Cl bonds.

Tetrathiafulvalen (TTF) and tetraselenafulvalen (TSF) are known as good electron donors and can easily be oxidized to stable radical cations, forming electrically conductive salts with various anions.[1] Metal halide anions may be of much interest as the counterparts of TTF^+ or TSF^+ radical cation salts since they assume various geometries and different formal charges which can affect the packing of donor molecules in crystals. Recently, we reported the crystal structures and the electrical properties of $[TTF]_3[SnCl_6]$,[2] $[TTF]_3[SnMe_2Cl_4]$[3] and $[TTF][SnMe_2Cl_3]$.[3] Of those, $[TTF]_3[SnMe_2Cl_4]$ has a novel TTF packing, consisting of trimer units forming a two-dimensional layer, and exhibits a low electrical resistivity (16 Ω cm at 25°C as a compacted pellet).[3] Thus, we have undertaken an investigation of the TTF and TSF salts with more bulky diorganochlorostannate(IV) anions.

This paper reports the preparation and electrical resistivities of TTF and TSF salts with some diorganochlorostannate anions, $[SnEt_2Cl_n]^{2-n}$ ($n = 3$ or 4) and $[SnPh_2Cl_4]^{2-}$. The arrangements of TTF and TSF molecules in crystals are also discussed, based on electronic reflectance spectra of the salts, together with an X-ray crystallographic analysis of $[TTF]_3[SnEt_2Cl_4]$.

EXPERIMENTAL

Materials

TTF,[4] and TSF,[5] $[TTF]_3[BF_4]_2$,[6] $[TSF]_3[BF_4]_2$,[7] $SnEt_2Cl_2$[8] and $SnPh_2Cl_2$,[9] were prepared according to the literature. $[Ph_3PCH_2Ph]Cl$

* Author to whom correspondence should be addressed.

was obtained from an equimolar mixture of triphenylphosphine and benzylchloride in benzene.

Preparation of the TTF salts

To an acetonitrile (30 cm^3) solution of $[TTF]_3[BF_4]_2$ (50 mg, 0.064 mmol) was added an acetonitrile (20 cm^3) solution containing both $SnEt_2Cl_2$ (470 mg, 1.9 mmol) and $[Ph_3PCH_2Ph]Cl$ (50 mg, 0.13 mmol) under a nitrogen atmosphere. The mixture was allowed to stand in a refrigerator overnight to yield the simple salt $[TTF][SnEt_2Cl_3]$ (**1**), which was filtered and dried *in vacuo*, 44% yield based on the TTF^+ radical cation. A similar reaction, with $SnPh_2Cl_2$ in the place of $SnEt_2Cl_2$, afforded the simple salt $[TTF]_2[SnPh_2Cl_4]$ (**2**), 18% yield.

On the other hand, the reaction of an acetonitrile (5 cm^3) solution containing both $SnEt_2Cl_2$ (95 mg, 0.38 mmol) and $[Ph_3PCH_2Ph]Cl$ (30 mg, 0.077 mmol) with $[TTF]_3[BF_4]_2$ (30 mg, 0.038 mmol) in the same solvent (30 cm^3) in the presence of TTF (20 mg, 0.098 mmol) under a nitrogen atmosphere afforded the complex salt $[TTF]_3[SnEt_2Cl_4]$ (**3**), 16% yield. The same salt was also obtained by electrolysis of an acetonitrile (10 cm^3) solution containing TTF (51 mg, 0.25 mmol), $SnEt_2Cl_2$ (250 mg, 1.0 mmol) and $[Ph_3PCH_2Ph]Cl$ (190 mg, 0.50 mmol) for 11 days under conditions described elsewhere,[10] 8% yield based on TTF. By using $SnPh_2Cl_2$ in the place of $SnEt_2Cl_2$, electrocrystallization under the same conditions gave the complex salt $[TTF]_{3.3}[SnPh_2Cl_4]$ (**4**), 16% yield.

Preparation of the TSF salts

In contrast to the TTF salt electrocrystallization from an acetonitrile (10 cm^3) solution containing TSF (51 mg, 0.13 mmol), $SnPh_2Cl_2$ (340 mg, 1.0 mmol) and $[Ph_3PCH_2Ph]Cl$ (190 mg, 0.50 mmol) for 11 days afforded the simple salt $[TSF]_2[SnPh_2Cl_4]$ (**5**), 33% yield based on TSF. On the other hand, the reaction of an acetonitrile (5 cm^3) solution containing $SnPh_2Cl_2$ (190 mg, 0.56 mmol) and $[Ph_3PCH_2Ph]Cl$ (14 mg, 0.037 mmol) with $[TSF]_3[BF_4]_2$ (50 mg, 0.037 mmol) in the same solvent (30 cm^3) in the presence of TSF (20 mg, 0.51 mmol) under a nitrogen atmosphere gave the complex salt $[TSF]_{3.3}[SnPh_2Cl_4]$ (**6**), 36% yield.

Ratios of the TTF^+ radical cation to neutral TTF^0 in the salts were determined from electronic absorption spectra in acetonitrile. The involvement of diorganostannate groups in the salts obtained was confirmed from ^1H NMR spectra in conc. HNO_3. The analyses and properties of the salts are listed in Table 1.

Physical measurements

Electronic absorption spectra in acetonitrile and powder reflectance spectra were recorded as described elsewhere.[2] Electrical resistivities were measured as compacted samples by the conventional two-probe method.[11]

X-ray crystal structure determination of salt **3**

Crystal data for **3**. $C_{22}H_{22}Cl_4S_{12}Sn$, $M = 931.6$, tetragonal, space group *I4cm*, $a = 11.710(3)$ Å, $b = 25.242(7)$ Å, $U = 3461(2)$ Å^3, $Z = 4$, $D_c = 1.789(1)$ g cm^{-3}, μ(Mo-K_α) = 17.6 cm^{-1}.

A specimen (0.25 × 0.30 × 0.10 mm) was selected to collect intensities on a Rigaku four-circle diffractometer using graphite-monochromated Mo-K_α

Table 1. Analyses and physical properties of the salts

No.	Salt	Colour	M.p. (dec.) (°C)	Found (calc.) % C	% H

radiation ($\lambda = 0.71070$ Å) and employing the ω–2θ scan technique.[3]

The positions of the Sn atoms were determined by the heavy-atom method on the basis of 479 reflections of $|F_o| > 3\sigma(F)$ among the 926 independent reflections. Although three possible space groups, $I\bar{4}c2$, $I4cm$ and $I4/mcm$, were suggested on the basis of the extinction rule, $I4cm$ was proved to be correct by the successful analysis, and the positions of all non-hydrogen atoms except for the methyl-carbon atoms of ethyl groups were given by the Fourier maps. The positions of the methyl carbons were not found, due to a disorder between two chlorine and two methylene-carbon atoms. Structure refinement was performed by the block-diagonal least-squares method assuming anisotropic thermal parameters for the nonhydrogen atoms to give residual indices of

$$R = \sum ||F_o| - |F_c|| / \sum |F_o| = 0.082$$

and

$$R' = [\sum w(|F_o| - |F_c|)^2 / \sum w|F_o|^2]^{1/2} = 0.11.$$

The weighting scheme was $1/w = \sigma^2(F_o) + 0.01(F_o)^2$. Atomic scattering factors were taken from *International Tables*.[12] The final atomic co-ordinates, temperature factors, and observed and calculated structure factors have been deposited as supplementary data with the Editor, from whom copies are available on request.*

Crystallographic calculations were performed on an ACOS 900S computer at the Crystallographic Research Centre, Institute for Protein Research, Osaka University. Figures 1–3 were drawn by the local version of the ORTEP-II program.[13]

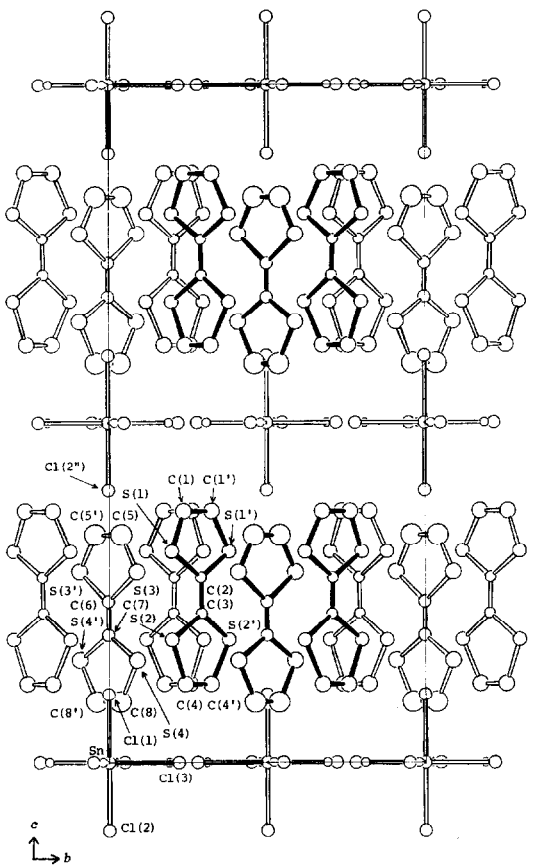

Fig. 1. Crystal structure of **3** projected along the *a*-axis. The atoms are drawn with arbitrary isotropic thermal factors for simplification.

RESULTS AND DISCUSSION

The crystal structure of **3**

The crystal structures of **3** projected along the *a*- and *c*-axes are shown in Figs 1 and 2, respectively, where the atoms are drawn by using arbitrary isotropic thermal parameters for simplification. Bond lengths and angles as well as relevant intermolecular atom–atom contacts are summarized in Table 2.

The tin atoms located in a distorted octahedral $[SnEt_2Cl_4]^{2-}$ anion occupy the positions (0, 0, 0), ($\frac{1}{2}$, $\frac{1}{2}$, 0), (0, 0, $\frac{1}{2}$) and ($\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$), where four-fold axes exist parallel to the *c*-axis. Two chlorine atoms as well as two methylene-carbon atoms of the ethyl groups are almost on the (001) and (002) planes and they are

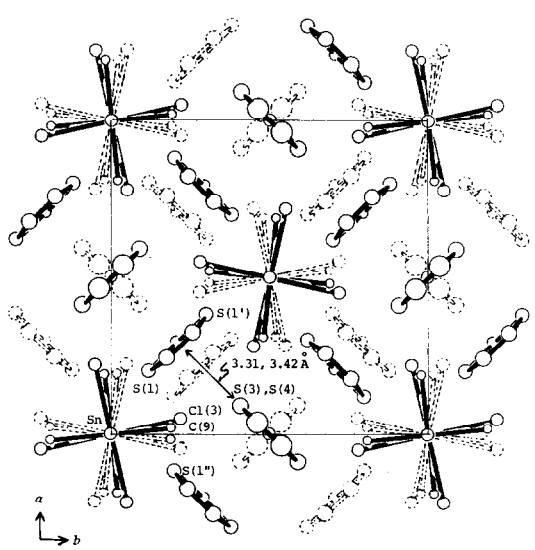

Fig. 2. Crystal structure of **3** projected along the *c*-axis. The atoms are drawn with arbitrary isotropic thermal factors for simplification.

* Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

disordered on these planes. A similar disorder with respect to chlorine atoms and methyl groups has been reported for $[TTF]_3[SnMe_2Cl_4]$[3]. The positions of the methyl-carbon atoms of the ethyl groups have not been determined. The Sn—Cl distances [2.58(2), 2.62(2) and 2.67(1) Å are close to those of $[TTF]_3[SnMe_2Cl_4]$ [2.599(5) and 2.600(3) Å][3] and $[pyridinium]_2[SnMe_2Cl_4]$ [2.603(2) and 2.625(2) Å].[14] The Sn—C(9) bond [2.21(7) Å] is slightly longer than those reported for $[pyridinium]_2[SnMe_2Cl_4]$ [2.109(9) Å],[14] $[SnMe_2Cl(terpyridyl)][SnMe_2Cl_3]$ [2.11(5) and 2.12(4) Å for the anion moiety],[15] and $[Mo_3(h^5\text{-}C_5H_5)_3S_4][SnMe_3Cl_2]$ [2.12(1) Å],[16] whereas it is shorter than that for $[EtSn(OH)Cl_2 \cdot H_2O]_2$ [2.304(30) Å].[17]

TTF moieties exist as a trimer unit, where the co-facial molecular planes are located parallel to the *c*-axis, separated by the same distance. The molecular overlap of the TTF moieties within the trimer unit has a considerable lateral shift (0.79 Å) along the long molecular axis, as shown in Fig. 3. This is in marked contrast to the eclipsed overlap of the TTF moieties in $[TTF]_3[SnCl_6]$[2] and $[TTF]_3[SnMe_2Cl_4]$.[3]

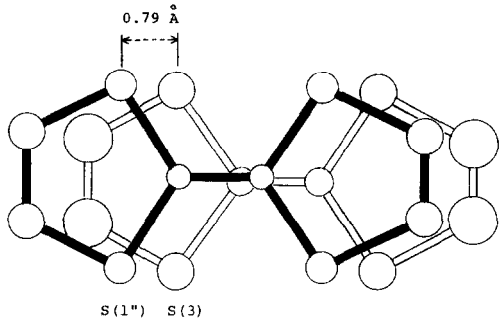

Fig. 3. Overlap scheme of the TTF moieties in the trimer unit.

Moreover, the TTF trimers are arranged perpendicularly to one another, the centres of terminal TTF molecules of the trimer unit being at $z = 0.245$ and 0.745 (Fig. 1). Thus, the two-dimensional TTF layers are constructed parallel to the *c*-plane, and are very similar to those of $[TTF]_3[SnCl_6]$ and $[TTF]_3[SnMe_2Cl_4]$, except for a significant shift of the TTF-eclipsed overlap within the trimer unit in **3**.

The intermolecular spacing [3.46(2) Å] within the TTF trimer units is close to those of $[TTF]_3[SnCl_6]$ [3.493(2) Å][2] and $[TTF]_3[SnMe_2Cl_4]$ [3.499(2)

Table 2. Selected bond distances (Å) and angles (°)[a] of **3** with the estimated standard deviations in parentheses

Non-bonded distances[c]			
S(1)–S(3)	3.69(3)	S(2)–Cl(1)	3.36(2)
S(1″)–S(3)	3.62(3)	S(1)–Cl(2″)	3.52(3)

[a] The atoms with a prime are in mirror symmetry with respect to the atoms with the same number (see Figs 1 and 2).

[b] Atom C(9) is the methylene-carbon atom of the ethyl group.

[c] See Figs 1 and 2.

Å].[3] The sulphur–sulphur distance [3.62(3) Å] within the trimer unit is somewhat longer than those of the $[SnCl_6]^{2-}$ and $[SnMe_2Cl_4]^{2-}$ analogues [3.493(2) and 3.498(3) Å, respectively],[2,3] owing to the considerable lateral shift of the TTF overlap in the present salt. The closest sulphur–sulphur contact between the TTF trimer units is 3.69(3) Å, which is almost equal to the sum of van der Waals' radii of sulphur atoms,[18] and is slightly longer than that of $[TTF]_3[SnMe_2Cl_4]$ [3.649(3) Å][3] and rather close to that of $[TTF]_3[SnCl_6]$ [3.705(2) Å].[2] On the other hand, the distances between the sulphur atoms [S(3) and S(4)] of the central TTF molecule and the neighbouring TTF molecular plane are 3.31(2) and 3.42(2) Å, respectively (see Fig. 2), which are similar to the corresponding sulphur–TTF plane distances in $[TTF]_3[SnCl_6]$ (3.40 Å)[2] and $[TTF]_3[SnMe_2Cl_4]$ (3.34 Å). Thus, **3** also forms a two-dimensional layer, consisting of the TTF trimer units, and a higher electrical conductance through the layer may appear, as mentioned later.

Although a weak interaction is observed between Cl(2) and S(1) atoms [3.52(3) Å], the Cl(1)–S(2) distance [3.36(2) Å][2] is appreciably shorter than the sum of the van der Waals' radii of sulphur and chlorine atoms (3.65 Å),[18] and is close to the shortest sulphur–chlorine distances reported for $[TTF]_3[SnCl_6]$ [3.367(2) Å][2] and $[TTF]_3[SnMe_2Cl_4]$ [3.344(2) Å].[3] This may be due to the electrostatic interaction between the rather positively polarized TTF sulphur and the negatively polarized chlorine atoms. In accordance with the short Cl(1)---S(2) distance, the Sn—Cl(1) bond [2.67(1) Å] is somewhat elongated in comparison with the Sn—Cl(2) bond [2.58(2) Å].

Electronic spectra

Figure 4 illustrates the powder electronic reflectance spectra of salts **1**, **3**, **4** and **5**. In the frequency region higher than 15,000 cm^{-1} local-excitation (LE) bands are observed for the TTF^{+} or TSF^{+} radical cations and the neutral TTF^{0} or TSF^{0} molecules.[19,20] Salt **1**, containing the TTF^{+} radical cation, exhibits a band around 12,500 cm^{-1}, which is assigned to the charge-transfer (CT) transition within the TTF^{+} radical cation dimer.[20,21] The same CT band was observed at 12,800 cm^{-1} in salt **2** (see Table 3). Analogously, salt **5** displays the band due to the $(TSF^{+})_2$ dimer, the frequency being lower than that of the $(TTF^{+})_2$ dimer. This is compatible with the fact that salt **5** has a considerably lower resistivity than the other simple salts, **1** and **2**, as described later.

Salt **3** in the solid state exhibits a broad band at 8700 cm^{-1} as well as LE bands with higher

Table 3. Powder electronic reflectance spectra of the salts

Salt	LE band (10^3 cm^{-1})			CT band (10^3 cm^{-1})	
				D^{+}/D^{+}[a]	D^{+}/D^{0}[a]
1	30.1	22.9	19.4	12.5	
2	26.6	[b]	19.1	12.8	
3	28.1	[b]	18.2		8.7
4	28.1	[b]	19.1	12.8	8.8
5	27.2	22.3	16.1	12.2	
6	27.8	21.6	16.0	12.2	8.8

[a] D = TTF or TSF.

[b] Not determined owing to being obscured by the high-frequency bands.

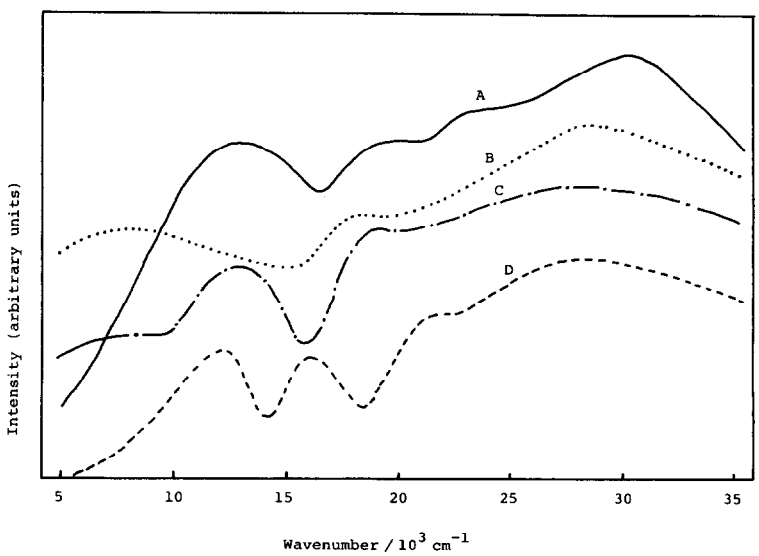

Fig. 4. Powder electronic reflectance spectra of **1** (A), **3** (B), **4** (C) and **5** (D).

Table 4. Electrical resistivities at 25°C ($\rho_{25°C}$) and activation energies (E_a) of the salts

Salt	$\rho_{25°C}$ (Ω cm)	E_a (eV)
1	2.1×10^8	0.53
2	9.0×10^8	0.60
3	4.2×10^1	0.13
4	2.9×10^3	0.28
5	7.1×10^3	0.10
6	3.0×10^3	0.18

frequencies. The low-frequency band is ascribed to the CT transition between the TTF^{+} radical cation and neutral TTF^0 within the TTF trimer, suggesting arrangement of the $TTF^{+}/TTF^0/TTF^{+}$ trimer. The same arrangement has been reported for $[TTF]_3[SnCl_6]$[2] and $[TTF]_3[SnMe_2Cl_4]$.[3] On the other hand, salt **4** displays two broad bands around 12,800 and 8800 cm^{-1} besides the LE bands in the higher-frequency region. These bands in the near-IR region can be ascribed to the CT transitions due to TTF^{+}/TTF^{+} and TTF^{+}/TTF^0, respectively. In view of this result, together with a relatively low resistivity, as described later, **4** may assume a columnar structure involving both TTF^{+}/TTF^{+} and TTF^{+}/TTF^0 interactions. A similar TSF columnar structure is suggested for salt **6**, based on the similarity between the spectra of these salts (Table 3).

Electrical resistivities

The temperature dependence of the the electrical resistivities of compacted samples has indicated that all the salts behave as typical semiconductors in the −20 to +30°C range.* Table 4 summarizes the resistivities at 25°C and activiation energies for electrical conduction. Salt **1** involving the TTF^{+} radical cation dimers exhibits a large resistivity and a high activation energy, indicating that each $(TTF^{+})_2$ dimer is located separately in the crystals, as was seen in $[TTF][SnMe_2Cl_3]$.[3] A large resistivity is also displayed in salt **2**, containing the TTF^{+} radical cation dimer, whereas the TSF^{+} radical cation analogue, **5**, exhibits a very small resistivity. A similar result has also been reported by us between the TTF and TSF salts with tris(oxalato)metallate anions (M = Si, Ge and Sn).[10]

Salt **3** displays a fairly small resistivity and a low activation energy. The electrical conduction in this salt may occur through the two-dimensional layer consisting of the TTF trimer units, as clarified by X-ray crystallographic analysis. On the other hand, the resistivity and the activation energy of **4** are larger than those of **3**, although **4** involves neutral TTF^0 as well as the TTF^{+} radical cation. This is indicative of the TTF stack not being suitable for the appearance of a high conductivity, while both the TTF^{+}/TTF^{+} and the TTF^{+}/TTF^0 CT bands have been observed. The TSF analogue, **6**, also displays electrical and spectroscopic properties similar to **4**.

* All the salts exhibit deviations of the log ρ–$1/T$ plots from a straight line above 40–60°C, due to some phase transitions.

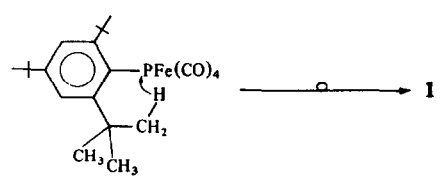
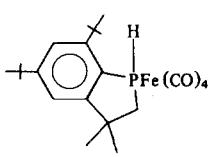
REACTION OF A PHOSPHAKETENE WITH DIIRON ENNEACARBONYL: POSSIBLE INTERMEDIACY OF A TERMINAL PHOSPHINIDENE COMPLEX

DONALD H. CHAMPION and ALAN H. COWLEY*
Department of Chemistry, The University of Texas at Austin, Austin, TX 78712, U.S.A.



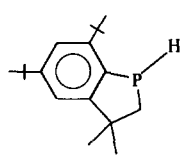
(*Received* 24 *April* 1985; *accepted* 28 *May* 1985)

Abstract—Evidence is presented for the intermediacy of a terminal phosphinidene complex, $[2,4,6\text{-}(t\text{-Bu})_3C_6H_2]PFe(CO)_4$, in the reaction of $[2,4,6\text{-}(t\text{-Bu})_3C_6H_2]P{=}C{=}O$ with $Fe_2(CO)_9$.



Compounds with phosphorus–phosphorus double bonds (diphosphenes, PR=RP) have received considerable attention recently.[1] Given the availability of species with metal–metal double bonds,[2,3] $L_nM{=}ML_n$ the obvious next step is to explore the chemistry of the phosphorus–metal double bond, viz. $RP{=}ML_n$. Elegant experiments by Mathey and co-workers[4] have established the intermediacy of $PhPW(CO)_5$, and recent reports by Bertrand, Gladysz *et al.*[5] and Roper *et al.*[6] have provided evidence for short-lived cationic phosphinidene complexes† of the type $[RPML_n]^+$. We report a potential route to neutral phosphinidene complexes starting with a phosphaketene.

Treatment of $ArP{=}C{=}O$[7] [Ar = 2,4,6-(*t*-Bu)$_3C_6H_2$] with $Fe_2(CO)_9$ in toluene at 25°C for 1–2 h, followed by chromatography (silica gel/*n*-hexane) resulted in a 39% yield of a yellow, crystalline product [m.p. 114°C (decomp.)] of empirical composition, $ArPFe(CO)_4$ (**1**). The 70 eV EI-MS of **1** revealed a low-intensity parent peak at *m/z* 444 and peaks corresponding to the sequential loss of 4 COs. However, the ^{31}P NMR spectrum of **1** (toluene, 32.2 MHz) featured a one-bond P—H coupling (δ + 14.8 ppm, $^1J_{PH}$ 360 Hz). The bicyclic structure of **1** was established by ^1H and ^{13}C–{^1H} NMR spectroscopy. ^1H NMR ($CDCl_3$, 90 MHz): δ 1.32 (s, 9H, *t*-Bu), δ 1.43 (s, 3H, 3-Me), δ 1.51 (s, 3H, 3-Me), δ 1.53 (s, 9H, *t*-Bu), δ 2.2–2.9 (m, 2H, 2-CH_2), δ 6.30 (d of m, 1H, P—H, $^1J_{PH}$ 360 Hz), δ 7.12 (br.s, 1H, aromatic), δ 7.47 (m, 1H, aromatic). ^{13}C–{^1H} NMR ($CDCl_3$, 20 MHz): δ 30.4 (s, 3-Me), δ 31.2 [s, $C(CH_3)_3$], δ 31.9 (s, 3-Me), δ 32.3 [s, $C(CH_3)_3$], δ 35.1 [s, $C(CH_3)_3$], δ 37.8 [s, $C(CH_3)_3$], δ 39.7 (d, C-2, $^1J_{PC}$ 35.8 Hz), δ 213.9 (d, CO, $^2J_{PC}$ 18.9 Hz). Confirmation of the above structure for **1** was provided by its independent synthesis from **2**[8] and $Fe_2(CO)_9$.



The most likely precursor to **1** is the terminal phosphinidiene complex, **3**, which rearranges to **1** via insertion of P into a C—H bond of an *ortho*-*t*-Bu group. We[8,9] and others[10] have reported ring closures of $[2,4,6\text{-}(t\text{-Bu})_3C_6H_2]$–phosphorus compounds. Reactions of this type occur when the phosphorus center is two- or three-coordinate and electropositive. In principle, **1** could be formed via a free radical pathway. However, this is unlikely because no P—D bond formation was detected when the reaction was conducted in toluene-d_8.

COMMUNICATION

SPECTROCHEMICAL PROPERTIES OF MOLYBDO- AND TUNGSTO-HETEROPOLYANIONS CONTAINING Ce(IV) OR Ce(III) AS A HETEROATOM

KENJI NOMIYA, HIROYUKI MURASAKI and MAKOTO MIWA*
Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180, Japan

(*Received* 30 *January* 1985; *accepted* 1 *May* 1985)

Abstract—The absorption and MCD spectra in the VIS–UV region of the traditional Silverton-type polyanion $[Ce(IV)Mo_{12}O_{42}]^{8-}$ and Weakley-type polyanions, $[X(W_5O_{18})_2]^{n-}$ [X = Ce(IV) and Ce(III)], have been measured and two charge-transfer transitions, ligand-to-heteroatom and intra-ligand, are discussed.

In the chemistry of heteropoly compounds, 12- and 8-coordinations of rare-earth heteroatoms have been elucidated; the former is found in the Silverton-type molybdopolyanion $[XMo_{12}O_{42}]^{8-}$ [X(IV) = Ce, U, Th or Np] and the latter in the two Weakley-type polyanions, $[X(W_5O_{18})_2]^{n-}$ [$n = 9$ for X(III) = Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Ho, Er or Yb; $n = 8$ for X(IV) = Ce, U or Th] and $[XL_2]^{n-}$ (L is lacunary derivatives of the Keggin and Dawson polyanions such as $[SiW_{11}O_{39}]^{8-}$ and $[P_2W_{17}O_{61}]^{10-}$).[1] The Silverton-type polyanion has been described as an XO_{12} icosahedron surrounded by six face-shared Mo_2O_9 units linked together by corner-sharing.[2] Two Weakley-type polyanions have been described as an XO_8 square antiprismatic complex, one is formed by two quadridentate W_5O_{18} groups viewed as "hypothetical" lacunary derivatives of the $[W_6O_{19}]^{2-}$ structure and the other by two quadridentate ligands.[3,4] As for spectrochemical characteristics of the skeleton structure of polyanions, we have paid attention to the MCD spectral pattern in the UV region due to the M ← O charge-transfer (CT) transition.[5–7] In this paper, we wish to report the optical and MCD spectra of the Silverton-type $[Ce(IV)Mo_{12}O_{42}]^{8-}$ and Weakley-type $[X(W_5O_{18})_2]^{n-}$ [X = Ce(IV) or Ce(III)] polyanions.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

Spectral measurements were performed by previously reported methods.[5–7]

The Silverton-type polyanion of Ce(IV) was prepared according to the literature[8] and obtained as yellow crystals. Found: N, 3.49; H, 1.68. Calc. for $(NH_4)_6H_2[CeMo_{12}O_{42}] \cdot 8H_2O$: N, 3.78; H, 1.90%. The Weakley-type polyanions, $[Ce(IV)(W_5O_{18})_2]^{8-}$ and $[Ce(III)(W_5O_{18})_2]^{9-}$, were prepared according to the literature,[9] recrystallized many times from water, and obtained as yellow crystals for the Ce(IV) polyanion and as orange–yellow crystals for the Ce(III) one. All of the spectra were independent of concentration.

RESULTS AND DISCUSSION

The VIS–UV absorption and MCD spectra of the Silverton-type $[Ce(IV)Mo_{12}O_{42}]^{8-}$ and Weakley-type $[Ce(IV)(W_5O_{18})_2]^{8-}$ polyanions are presented in Figs 1 and 2, respectively. The former polyanion shows an intense band near 41,000 ($\varepsilon \sim 40{,}000$) and a very broad band near 30,000 cm^{-1} ($\varepsilon \sim 3000$) in the absorption spectrum, and a positive intense band near 41,000, and a positive broad band near 27,000, and a negative small band near 34,000 cm^{-1} in the MCD spectrum. The latter polyanion shows two absorption maxima at 38,000 ($\varepsilon \sim 19{,}000$) and 30,000 ($\varepsilon \sim 5600$), and an A-term shape MCD near

38,000, a positive broad MCD at 27,000 and a negative small MCD at 33,000 cm^{-1}. All of absorptions and MCD observed should be attributed to the CT transition in the polyanions. In the lower-frequency region, the MCD pattern of the former polyanion is very similar to that of the latter one. This fact indicates that there exist at least two types of CT transition. They are probably the ligand-to-Ce(IV) and the intra-ligand CT transitions. This stems from two empirical facts;[5-7] (1) the MCD pattern due to the intra-ligand CT is more influenced by exterior "homoatoms" such as Mo and W than by heteroatoms, and (2) the ligand-to-heteroatom CT in the polyanion is generally observed in the lower-frequency region rather than the intra-ligand CT. Thus, the absorption and MCD in the lower-frequency region are attributed to the ligand-to-Ce(IV) CT. The absorptions due to such a transition have been observed in other type of polyanions; at 27,000 cm^{-1} ($\varepsilon \sim 1000$) in the Evans–Showell-type $[Co(III)_2Mo_{10}O_{38}H_4]^{6-}$ polyanion[10] and at 25,000 cm^{-1} ($\varepsilon \sim 1180$) in the Keggin-type $[Co(III)W_{12}O_{40}]^{5-}$ polyanion,[5] and their MCD bands observed as a B-term shape with positive sign.[5,11] In the higher-frequency region, the absorption of the Silverton-type Ce(IV) molybdopolyanion is necessarily attributed to the CT within the $Mo_{12}O_{42}$ ligand. This is significantly more shifted to the high-frequency region than those of the usual Keggin-type dodecamolybdopolyanions, and,

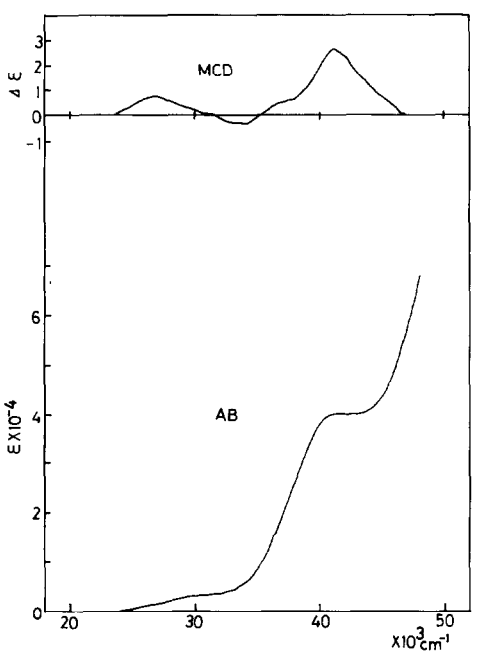

Fig. 1. VIS–UV absorption and MCD spectra of the Silverton-type $[Ce(IV)Mo_{12}O_{42}]^{8-}$ polyanion in aqueous solution.

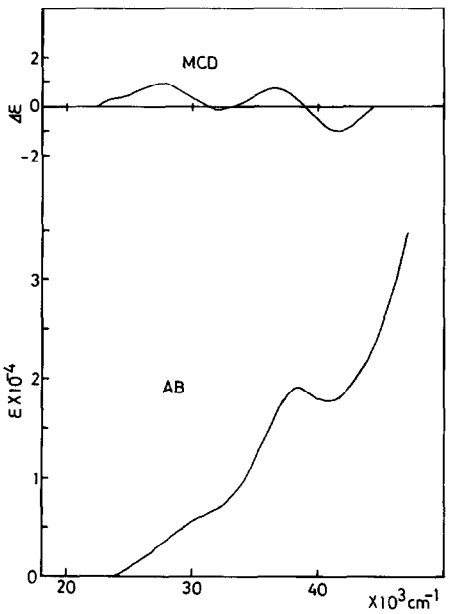

Fig. 2. VIS–UV absorption and MCD spectra of the Weakley-type $[Ce(IV)(W_5O_{18})_2]^{8-}$ polyanion in aqueous solution.

moreover, its MCD pattern is quite different from them. This is presumably caused by a participation of the face-sharing oxygen in a Mo ← O CT within the $Mo_{12}O_{42}$ ligand. On the other hand, the intra-ligand CT absorption of the Weakley-type Ce(IV) tungstopolyanion and the MCD with an apparent A-term shape seem consistent with those of the $[W_6O_{19}]^{2-}$ isopolyanion comprised only of edge-sharing WO_6 octahedra.

The absorption spectrum of the other Weakley-type polyanion, $[Ce(III)(W_5O_{18})_2]^{9-}$, is very similar to that of the Ce(IV) analogue, except that the intensities at 38,000 ($\varepsilon \sim 11{,}500$) and 30,000 cm^{-1} ($\varepsilon \sim 500$) decrease markedly (Fig. 3). However, the MCD is quite different, comprised only of positive bands. The electronic configurations of Ce(III) and Ce(IV) ions are $4f^1$ and $4f^0$, respectively. The only f–f transition of Ce(III) ion cannot contribute to the MCD and absorption in the VIS–UV region, because of its small energy difference. Rather, a contribution from an inter-shell ($5d \leftarrow 4f$) transition of Ce(III), besides the ligand-to-metal CT and intra-ligand CT transitions, should be taken into account in such a region. Recently, Okada *et al.*[12] have measured the absorption and MCD spectra due to the $5d \leftarrow 4f$ transition of the $[Ce(III)(H_2O)_8]^{3+}$ ion, which is formed by dissociation of one water molecule from $[Ce(III)(H_2O)_9]^{3+}$ in aqueous solution. They have found in the 34,000–51,000 cm^{-1} region five positive MCD bands in the crystals of the $[Ce(III)(H_2O)_9]^{3+}$ compound and six positive ones in the aqueous solution, in the latter the extra

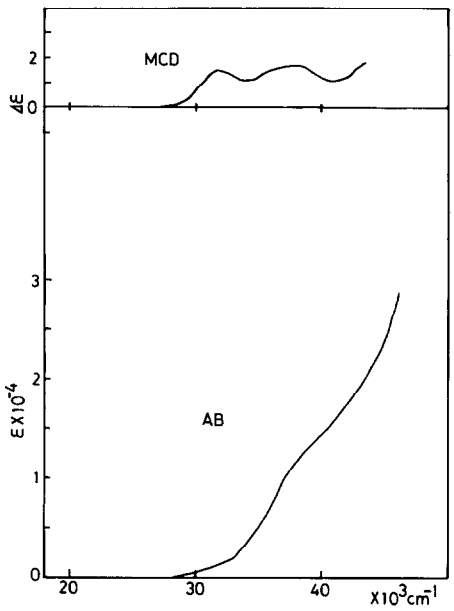

Fig. 3. VIS–UV absorption and MCD spectra of the Weakley-type $[Ce(III)(W_5O_{18})_2]^{9-}$ polyanion in aqueous solution.

band at 34,000 cm^{-1} being assigned to the lowest component of the $5d \leftarrow 4f$ transition of the $[Ce(III)(H_2O)_8]^{3+}$ species. This is consistent with the earlier assignment of the absorptions of the colourless Ce(III) aqua ion by Jørgensen and Brinen.[13] The intensity ratios of those MCD to absorptions ($\Delta\varepsilon \sim 10^{-3}$–$10^{-2}$) are sufficiently large. If this is the case for the $[Ce(III)(W_5O_{18})_2]^{9-}$ polyanion, the contribution of the $5d \leftarrow 4f$ transition should reflect markedly the MCD rather than the absorption. Thus, the MCD observed in the Weakley-type Ce(III) polyanion will be a superposition of such a contribution on the MCD due to the ligand-to-heteroatom CT and intra-ligand CT transitions as observed in the Ce(IV) analogue.

IMPROVED SYNTHESIS OF *ARACHNO*-6,9-$C_2B_8H_{14}$ AND ITS HALOGENATION UNDER ELECTROPHILIC CONDITIONS

ZBYNĚK JANOUŠEK, JAROMÍR PLEŠEK, STANISLAV HEŘMÁNEK and BOHUMIL ŠTÍBR*

Institute of Inorganic Chemistry, Czechoslovak Academy of Sciences, 250 68, Řež near Prague, Czechoslovakia

(*Received* 24 *April* 1985; *accepted* 20 *May* 1985)

Abstract—A convenient synthesis of *arachno*-6,9-$C_2B_8H_{14}$, based on the reduction of *nido*-5,6-$C_2B_8H_{12}$ with sodium tetrahydroborate, is reported. Electrophilic halogenation of the former carborane produced a series of 1-X-6,9-$C_2B_8H_{13}$ (X = Cl, Br and I) derivatives whose constitution was established on the basis of their ^1H and ^{11}B NMR spectra.

The first representative of the 10-vertex *arachno*-dicarbaborane family, 6,9-dicarba-*arachno*-decaborane(14), 6,9-$C_2B_8H_{14}$ (**I**), was prepared in our laboratory[1] by treatment of *nido*-5,6-$C_2B_8H_{12}$ (**II**)[2] with sodium amalgam in ethanol. For some still obscure reasons, this reaction sometimes fails and therefore we have searched for a more reliable method for preparing carborane **I**. We report herein a more convenient synthesis of the latter compound along with the preparation of its 1-halogenated derivatives.

Treatment of carborane **II** with sodium tetrahydroborate in an ethanolic solution of potassium hydroxide at higher temperatures, followed by the acidification of the reaction mixture, resulted in the isolation of 6,9-$C_2B_8H_{14}$ in higher than 35% yields. The product thus obtained is contaminated with less than 5% of 5-C_2H_5O-6,9-$C_2B_8H_{13}$ (**Ia**) {m.p. 48–50°C; *m/z* 166 (dehydrogenation); ^1H NMR (200 MHz, $CDCl_3$): δ 3.69 (2H, q, J = 7 Hz, CH_2), 1.16 (3H, t, J = 7 Hz, CH_3), 0.74 (2H, s, CH_{eq}), −0.61 (2H, s, CH_{ax}), −2.94 (2H, s, μH); ^{11}B NMR spectrum (64.18 MHz, $CDCl_3$): δ_B 5.45 [1B, s, B(5)], 2.10 [1B, d, 160, B(2)], 0.65 [1B, d, 166, B(4)], −20.60 [1B, d, 150(52), B(10)], −22.70 [1B, d, 144, B(8)], −24.10 [1B, d, 144, B(7)], −38.75 [1B, d, 147, B(1)], −40.85 [1B, d, 142, B(3)]}, which can be easily removed either by crystallization or by column chromatography on silica gel in benzene–hexane (1 : 2).

As proposed earlier,[1] formation of carborane **I** is consistent with a reductive cleavage of the

[c] Singlet.

C(5)—C(6) bond in the cage of 5,6-$C_2B_8H_{12}$, followed by moving the C(6) vertex into a new position. This type of rearrangement of the 10-vertex borane skeleton strongly parallels the mechanism proposed by Bould *et al.*[3] for the 6 → 5 rearrangement in the 6-irida-*nido*-decaborane series. The reduction of **II** to **I** represents a typical *nido*–*arachno* transformation and, in this respect, it is analogous to the well-known reduction[4] of $B_{10}H_{14}$ to $[B_{10}H_{14}]^{2-}$.

Halogenation of **I** with carbon tetrachloride, bromine in carbon disulphide, and iodine in benzene under reflux in the presence of anhydrous $AlCl_3$ produced a series of 1-halogenated derivatives, 1-X-6,9-$C_2B_8H_{13}$ (**Ib**, X = Cl; *Ic*, X = Br; and **Id**, X = I), as the main products. The explicit preference for electrophilic attack at the B(1) site fits well with the previously reported[1] results of the deuteration of carborane **I** in the DCl–$AlCl_3$–CS_2 system.

^1H NMR spectra of compounds **Ib–d** (Table 1) consist of two sharp singlets of intensity 1, assigned to two pairs of equatorial and axial CH groups, and one broad unresolved B–H–B singlet. ^{11}B NMR spectra of **Ib–d** (Table 2) exhibit one B(1) singlet along with four 2:2:2:1 patterns of doublets, while the corresponding spectrum of the ethoxoderivative **Ia** displays seven doublets and one low-field B(5) singlet of equal intensities. Besides the signals of the C_2H_5O group, the ^1H NMR spectrum of **Ia** shows three coincidentally overlapping singlets of two CH_{eq} and CH_{ax} groups and two bridging hydrogens.

The above NMR data for **Ib–d** are in agreement with the proposed 1-X-6,9-$C_2B_8H_{13}$ geometry and the relevant data for **Ia** are consistent with the asymmetrical structure[5] of 5-substituted derivatives of 6,9-$C_2B_8H_{14}$. We are presently engaged in the research aimed at preparing other substituted derivatives of **I**.

BOOK REVIEWS

Chemistry of the Elements. By N. N. Greenwood and A. Earnshaw, Pergamon Press, Oxford, 1984, over 3000 illustrations, 1542 pp., £53.00 (hardcover), £19.50 (flexicover).

The advent of a major new textbook on inorganic chemistry is an important event for all readers of this journal, more especially when it combines the virtues of scholarship, topicality and wide-ranging interest found here. The title evokes that of N. V. Sidgwick's magisterial volumes, *The Chemical Elements and Their Compounds*, published some 35 years ago, but still a fertile source of curious and fascinating information. This comparison is not a superficial one, as will appear later.

The book begins with two introductory chapters, the first being on the origin of the elements, isotopes and atomic weights, and the second dealing with chemical periodicity and the Periodic Table (37 pp.). Then follow 16 descriptive chapters on the *s*- and *p*-block or main-group elements (1021 pp.). After another general chapter on coordination compounds (41 pp.) come 12 further descriptive chapters on the *d*- and *f*-block metals (318 and 63 pp. respectively), and a series of appendices on such matters as orbital wave functions, point group symmetry, SI units, elemental abundances, ionic radii, and Nobel Prize winners in Chemistry and in Physics; nearly 1500 literature references are given throughout the text. Finally, there is a commendably full and detailed index of 36 pp.

Such a catalogue gives little idea of the distinctive flavour of this book, however. To begin with its most obvious characteristic, it is avowedly fact-based: there are no long sections on "general chemistry" or theoretical topics, no discussions of the niceties of electronegativity scales or atomic radii, and no entries in the index about hard/soft acids and bases or close-packing. So what kinds of facts are here? In essence, those of interest to inorganic chemists, construed in the broadest possible way. Besides the necessary information on preparations and properties and a good deal on structural aspects (illustrated by clear and attractive diagrams), there is also much on the human, social and industrial aspects of chemistry. People involved in the isolation of elements and the historical development of the subject, up-to-date and well-illustrated descriptions of important industrial processes, annual productions and costs, applications of inorganic materials (including both high-tonnage chemicals and such new developments as xerography, solid-state devices, non-asbestos fibres and high-performance ceramics), environmental factors in the manufacture and use of inorganic compounds, inorganic biochemistry, organometallic compounds and even cosmochemistry are all represented. Because of this wealth of interesting facts, it is possible to read this book as a voyage of discovery as well as a detailed reference work.

How about its use as a teaching text? It is not surprising, particularly in view of the senior author's long concern with chemical education and education through chemistry, that this has been taken carefully into account. Not so much explicitly—the student will find no ready-made list of 17 ways in which nitrogen differs from phosphorus—but implicitly in the wealth of factual

[c] Special topics (chiefly transition-metal chemistry).

material from which the student can make his own list. The clear style and organisation of the text, coupled with extensive cross-referencing and the good index, will make this book the natural first point of reference for a student writing an essay or a literature project. Equally one hopes that many lecturers' sets of notes will be enhanced from this source.

What about the balance of topics? Here it is interesting to compare the amount of space given to certain areas in some well-known texts (Table 1). It is clear that the present book gives proportionately far more coverage to main-group elements, particularly to non-metals such as boron and sulphur. This is certainly consistent with the present resurgence of interest in main-group chemistry, and compensates to some extent for the emphasis on transition-metal chemistry in some modern text-books. It suggests too that "Greenwood and Earnshaw" is complementary to the latest edition of "Cotton and Wilkinson", rather that directly overlapping with it, and that students will have to buy one or the other, while needing access to both.

To sum up, this is a notable and refreshingly different new text, which can significantly influence the future direction of the subject. In many ways, it is a new Sidgwick for the 1980s, which is high praise indeed.

Gmelin Handbook of Inorganic Chemistry. Uranium Supplement Vol. C4: Uranium Dioxide, Preparation and Crystallographic Properties. Published by the Gmelin Institute for Inorganic Chemistry of the Max Planck Society for the Advancement of Science, Springer, Berlin, 8th edition, 1984, xii + 140 pp., DM544.

This book on the preparation and crystallography of uranium dioxide is one of at least 27 supplementary volumes on uranium. The series, when completed in the near future, will comprise an authoritative and exhaustive account on all aspects of uranium chemistry. Uranium chemists with ready access to the series are in a particularly fortunate position and will be delighted by the excellent production qualities, the first-class use of English, and the outstanding scholarship.

Uranium dioxide is the most important compound in nuclear technology because it is the fuel of nearly all water nuclear power reactors. Volume C4 deals only with the preparation and crystallography while two others, C5 and C6, will deal with the physical and chemical properties. Two-thirds of volume C4 is devoted to the preparation of uranium dioxide and the production of pellets and other shapes. All of the well-characterised methods of preparation are included, the whole is well-illustrated, and contains 660 references. The crystallographic properties are also properly covered and no important results appear to be omitted. The literature is comprehensively covered to the end of 1982 and important results since then are also included.

One would normally expect a very large library to buy the entire Supplement but for specialised libraries, such as those covering nuclear technology, a selection from the many volumes would be well-worth considering, notwithstanding the high volume cost.

V. CONCLUSIONS 1836

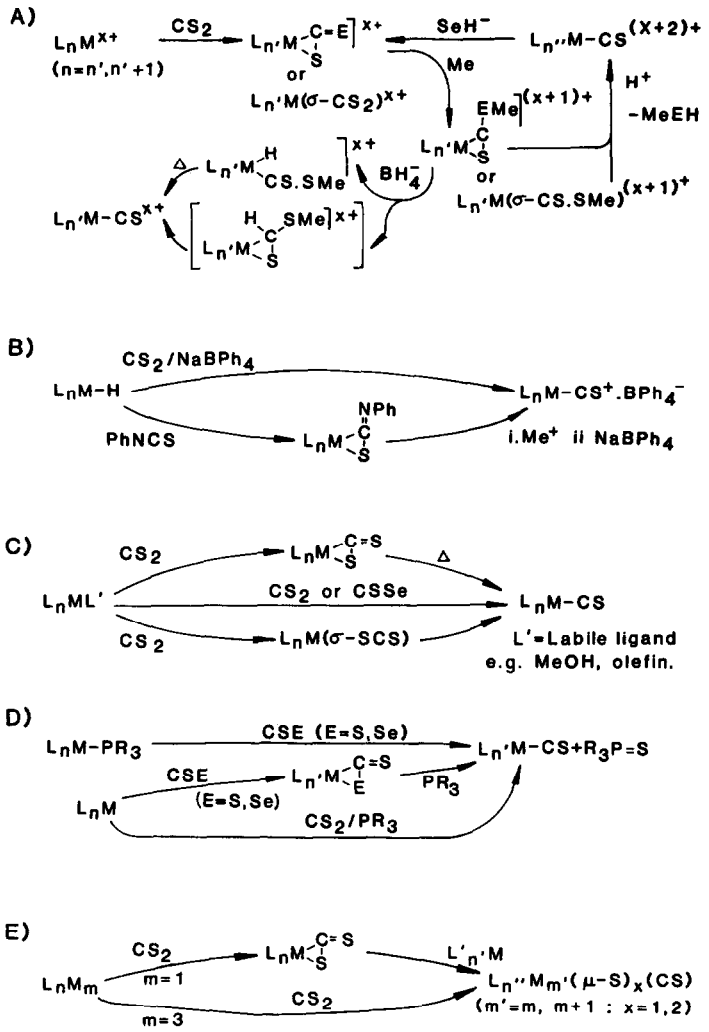
I. INTRODUCTION

Although a very large number of examples occur of CO ligation of metal centers, relatively few exist of the isoelectronic CS. Undoubtedly this arises from the lack of stable molecular CS. Although CS can be prepared[1] by subjecting CS_2 to a high voltage a.c. discharge *in vacuo*, it polymerizes above $-160°C$. Syntheses of thiocarbonyl complexes have used necessarily indirect routes, mostly via CS_2.

However, examples of the thiocarbonyl ligand are not uncommon. In the last review of this area published in 1977,[2] Butler pointed out that "CS can be stabilized by coordination to many transition metals, and well over 100 thiocarbonyl complexes have been reported . . .". Since then, many more examples have been identified, displaying some novel coordination modes, showing an increased range of reactivity and using some different preparative methods. This article surveys the literature up to the end of 1984, classifying thiocarbonyl complexes by preparative method, followed by a discussion of the reactivity and of the bonding, spectroscopic and structural properties of such complexes.

Two other reviews should be noted, by Yaneff[3] and by Butler and Fenster,[4] which appeared in 1977 and 1974, respectively. In particular, these document thoroughly much of the spectroscopic data pertinent to the CS ligand in its then known complexes.

The nature of the transition-metal–thiocarbonyl interaction is considered below, especially in comparison to the carbonyl ligand. For now, it is sufficient to state that these interactions are largely analogous so that the CS ligand exhibits synergic bonding and has π-acid character. Differences in the chemistries of these ligands arise from the relative abilities for σ-donation of electrons to and π-acceptance of electrons from metal centers and from the relative strength of C—O and C—S π- and σ-bonding.



II.1. TERMINAL CS LIGANDS—PREPARATIVE METHODS

i. Direct reaction of CS

A single example of CS usage exists.[5] Microwave discharge through CS_2 vapour yields CS which is cocondensed with Ni atoms at 10 K in an argon matrix. The product was identified as $[Ni(CS)_4]$ by IR spectroscopy, assigning a ν(CS) mode to the 1305 cm^{-1} absorption, and by mass spectroscopy of the intractable black solid obtained at room temperature which displayed a $[Ni(CS)_4]$ molecular fragment and was proposed to be polymeric $[\{Ni(CS)_4\}_n]$.

ii. Preparations using heteroallenes

The use of CS_2 or its complexes comprises the most important means of generating thiocarbonyl ligands by far. In some cases, complexes of the heteroallenes CSSe and PhNCS may be used. When the coordination chemistry of the heteroallenes CSE (E = O, Se or NR) is investigated, the products often do not contain CS ligands. However, information can be gained on the mechanism in the derivation of CS ligands from CS_2. Aspects of this heteroallene work have been summarized recently.[6,7] Also, carbon

Scheme 1. Routes to CS ligands via CS_2.

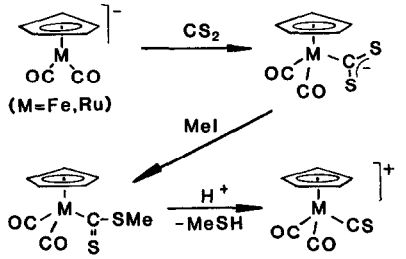
diselenide is known to yield the selenocarbonyl ligand, CSe, by some routes that apply to CS_2 for the CS ligand.

The heteroallene-based preparations of the CS ligand, summarized in Scheme 1, are various. Many reactions give a number of other products and give only modest yields of the thiocarbonyl product. These methods are discussed in turn, as detailed in Scheme 1.

(A) Two related routes use the same initial steps. Coordination of CS_2 or CSSe to a metal center in either σ-dithiocarboxylate or η^2-fashion is followed by methylation, giving the corresponding σ- or η^2-chalcogen-methylated moiety. The two pathways differ hereon in that H^+ or H^- attack is employed, although both result in MeEH elimination (E = S or Se).

Protonation is used on the σ-dithiocarboxylate methyl ester examples. In work by Angelici and co-workers, $[\{(\eta^5\text{-}C_5H_5)M(CO)_2(CS)\}^+]$ (M = Fe[8] or Ru[9]) results from $[\{(\eta^5\text{-}C_5H_5)M(CO)_2\}^-]$ by using CS_2 to give $[\{(\eta^5\text{-}C_5H_5)M(CO)_2(CS_2)\}^-]$, then MeI, yielding a ($\sigma$-$CS_2Me$) unit, assigned by IR spectroscopy, and lastly H^+ attack (Fig. 1).

Analogous reagents were used by Roper and co-workers in conversions through (η^2-CSE)(E = S or Se) intermediates. Reaction of CS_2 with $[M(CO)_2(PPh_3)_3]$ (M = Ru or Os) yields $[M(CO)_2(PPh_3)_2(\eta^2\text{-}CS_2)]$ upon which attack by MeI, giving an η^2-CS_2Me ligand, and then HCl results in $[MCl_2(PPh_3)_2(CO)(CS)]$ (M = Ru or Os).[10] Starting from $[M(CO)(CS)(PPh_3)_3]$ (M = Os) allows $[MX_2(PPh_3)_2(CS)_2]$ (M = Os, X = Cl or Br) to be prepared analogously.[11] The same method is effective for the preparation of $[RuX_2(PPh_3)_2(CO)(CSe)]$ (X = Cl) from CSe_2 and $[Ru(CO)_2(PPh_3)_3]$.[12] These reactions are summarized in Fig. 2. The η^2-CSSe ligand in



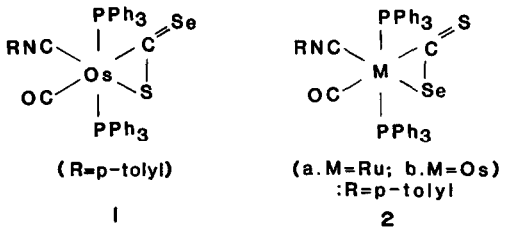


Fig. 1. σ-Dithiocarboxylate intermediates in CS ligand synthesis from CS_2.

$[Os(\eta^2\text{-}CSSe)(CO)(CNR)(PPh_3)_2]$ (R = *p*-tolyl) (**1**), although produced indirectly by SeH^- attack on $[\{OsCl(CS)(CO)(CNR)(PPh_3)_2\}^+]$, is reverted to this thiocarbonyl species by sequential attack of Me^+ (as MeI) at the uncoordinated Se atom and then HCl, eliminating MeSeH.[13] The analogous Ru compound $[\{RuCl(CS)(CO)(CNR)(PPh_3)_2\}^+]$ gives $[Ru(\eta^2\text{-}CSeS)(CO)(CNR)(PPh_3)_2]$ (**2a**) with SeH^- which MeI and HCl convert to $[RuCl_2(CSe)(CNR)(PPh_3)_2]$ in good yield.[13] Thus, the coordinated chalcogen of the η^2 ligand is retained in the chalcogenocarbonyl ligand but SeH^- attack on the CS ligand is able to give different η^2 connectivity in the $(\eta^2\text{-}CSSe)$ precursor depending on the individual case. However, this method is unable to convert $[Os(\eta^2\text{-}CSeS)(CO)(CNR)(PPh_3)_2]$ (**2b**) to a CSe species as HCl attack on the $(\eta^2\text{-}CSe \cdot SMe)^+$ methylation product is ineffective.[13]

Halide ligand coordination at the protonation step, sometimes displacing CO groups, causes a variable net charge on the product moiety but the metal has experienced a two-unit increase in its formal oxidation state through the CS ligand preparative sequence. This increased oxidation state coupled with an array of good π-acceptor ligands competing for metal electron density will render the CO more labile and promote its displacement by halide.

Hydride attack at $\eta^2\text{-}CS \cdot EMe$ (E = S or Se) ligands, prepared by methylation at η^2-CSE, can cause MeEH elimination resulting in CS groups. Overall, there is no change in the formal oxidation state of the metal. In two examples, the same $\eta^2\text{-}CS \cdot EMe$ compound may be used that gives a CS ligand through H^+ attack.[13,14] Thus, $[Os(\eta^2\text{-}CSSe)(CO)(CNR)(PPh_3)_2]$ (R = *p*-tolyl) (**1**) is methylated at Se upon which BH_4^- attack yields $[Os(CS)(CO)(CNR)(PPh_3)_2]$ and MeSeH,[13] and $[Os(CO)_2(PPh_3)_2(\eta^2\text{-}CS_2)]$ proceeds analogously to $[Os(CO)_2(PPh_3)_2(CS)]$ via $[\{Os(CO)_2(PPh_3)_2(\eta^2\text{-}CS_2Me)\}^+]$.[14] This

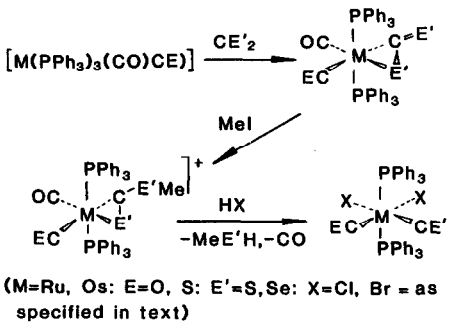

Fig. 2. η^2-Dichalcocarboxylate intermediates in CS ligand synthesis from CS_2.

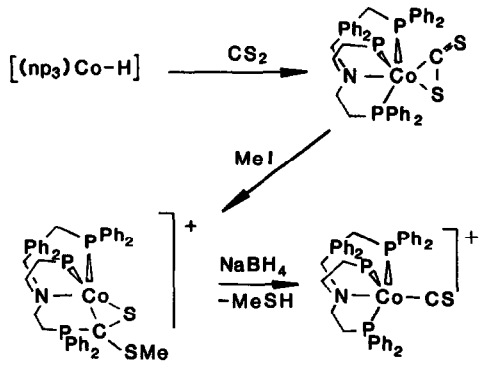

Fig. 3. A route to $[\{(np_3)Co(CS)\}^+]$.

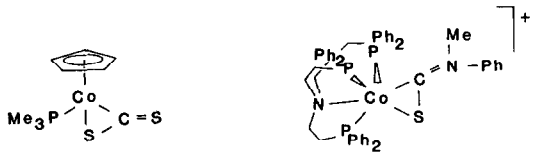
method works on $[IrCl(CO)(PPh_3)_2(\eta^2\text{-}CS_2)]$ to give $[IrCl(PPh_3)_2(CS)]$ with additional CO loss[14] and can be applied directly to the analogous CSe_2 conversion.[15] In the last two cases an $[L_nM(H)(\sigma\text{-}CS_2Me)]$ intermediate (3) was isolated which is heated to induce MeSH elimination.[14]



3 4

A different intermediate (4) has been proposed in a closely related system.[16,17] The η^2-CS_2 complex $[(np_3)Co(\eta^2\text{-}CS_2)]$, made by CS_2 attack upon $[(np_3)CoH]$, is methylated to give a phosphoniodithiomethyl ester moiety in $[\{Ph_2PCH_2CH_2N(CH_2CH_2PPh_2)_2Co(CS_2Me)\}^+]$. This undergoes hydride attack producing $[\{(np_3)Co(CS)\}^+]$ (Fig. 3).

The alteration in oxidation state between Co(0) and Co(I) in these reactions differs in pattern from the changes for the Os and Ir systems, and the modest yield of some steps suggests redox reactions occur with non-isolated cobalt species involved.

Sequential attack by Me^+ and H^- on an η^2-CSE ligand (E = S, Se or NR) resulting in a CS ligand is not a general reaction. For example, $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(\eta^2\text{-}CS_2)]$ (5) does methylate with $[Me_3O\cdot BF_4]$ to an η^2-CS_2Me^+ ligand but reacts with NaH to give CH_4 and 5 rather than MeSH and $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(CS)]$.[6]

5 6

(B) There are two related ways to make $[\{np_3)Co(CS)\}^+\cdot BPh_4^-]$, both via $[(np_3)CoH]$. The simultaneous use of CS_2 and $NaBPh_4$ gives[16] a low yield of $[\{(np_3)Co(CS)\}^+\cdot BPh_4^-]$ which equates to the formal loss of NaSH. Similarly, $[(np_3)CoH]$ reacts with PhNCS giving $[(np_3)Co(\eta^2\text{-}CS\cdot NPh)]$. Methylation is presumed to give $[\{(np_3)Co(\eta^2\text{-}CS\cdot NMePh)\}^+]$ (6) *in situ*, then $NaBPh_4$ addition produces $[\{(np_3)Co(CS)\}^+\cdot BPh_4^-]$.[17] Formally, NaNMePh is eliminated and the coordinated chalcogen of the η^2-ligand retained.

Both H^- and BPh_4^- addition to $[\{L_nM(\eta^2\text{-}CS\cdot EMe)\}^+]$ species result nominally in EMe^- elimination. Thus, other anions, X^-, may produce $[\{L_nM(CS)\}^+]$ similarly. Indeed, the use of HCl on the methylated ligand, discussed above, may be viewed as Cl^- acting in this role.

(C) These routes tend to give low yields of the CS complex either as the single isolated product or as one of a number of products. Also, the distinction in some cases from preparations involving phosphine ligands becomes tenuous [see Section II.1.ii(D)].

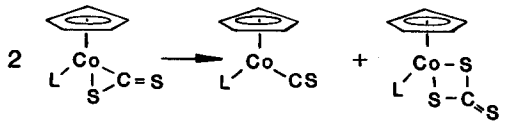


Fig. 4. The proposed disproportionation reaction of $[(\eta^5\text{-}C_5H_4R)CoL(\eta^2\text{-}CS_2)]$.

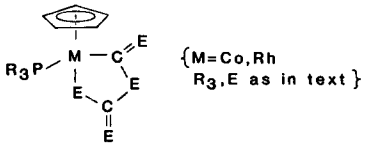

Cyclooctene loss from $[(\eta^5\text{-}C_5H_4R)Mn(CO)_2(C_8H_{14})]$ (R = H or Me) on reaction with CS_2 gives low yields of $[(\eta^5\text{-}C_5H_4R)Mn(CO)_2(CS)]$.[18,19] Cyclooctene was proposed to remove sulphur as cyclooctene sulphide but no evidence for this was found.[18] A $\eta^2\text{-}CS_2$ intermediate was proposed and the compound identified. Attack by CS_2 on $[(\eta^6\text{-}C_6H_5R)Cr(CO)_2(THF)^*]$ (R = H or CO_2Me) produces $[(\eta^6\text{-}C_6H_5R)Cr(CO)_2(CS)]$[20] and on [Os(OEP)$(N_2)$(THF)] in py gives [Os(OEP)(CS)py]:[21] both yields are fairly low and the sulphur's fate is unknown. These three CS complexes can be prepared in good yield by other routes (see below).

An intermediate in the reaction of CS_2 and $[RuBr_3(EPh_3)_2(MeOH)]$ (E = P or As) which produces $[RuBr_3(EPh_3)_2(CS)]$ is the σ-SCS compound $[RuBr_3(EPh_3)_2(\sigma\text{-SCS})]$. A mixture of these compounds occurs until a 30-min reflux has elapsed, when the former remains. The chloride analogue is stable at the σ-SCS stage.[22]

Reacting excess CS_2 with equimolar mixtures of $[(\eta^5\text{-}C_5H_5)Co(CO)_2]$ and L or with preformed $[(\eta^5\text{-}C_5H_5)Co(CO)L]$ (L = PR_3, *t*-BuNC; R_3 = Et_3, *n*-Pr_3, *n*-Bu_3, $PhMe_2$, Ph_2Me or Ph_3) gives four products, $[(\eta^5\text{-}C_5H_5)CoL(CS)]$, $[(\eta^5\text{-}C_5H_5)CoL(\eta^2\text{-}CS_2)]$, $[(\eta^5\text{-}C_5H_5)CoL(CS_3)]$ and $[(\eta^5\text{-}C_5H_5)_3Co_3(\mu_3\text{-}CS)(\mu_3\text{-}S)]$ in 5–25% yield each.[23] Refluxing $[(Cp)CoL(\eta^2\text{-}CS_2)]$ (L = PPh_3, Cp = $\eta^5\text{-}C_5H_5$ or $\eta^5\text{-}C_5H_4Me$; L = PPh_2Me, Cp = $\eta^5\text{-}C_5H_5$) in toluene mostly yields the Co_3 species with equal low yields of [CpCoL(CS)] and $[CpCoL(CS_3)]$. A disproportionation of the CS_2 ligand was proposed (Fig. 4). Involvement of dissociated PR_3 was ruled out as added PPh_3 did not have any effect.[23]

A closely related system of Werner's may proceed analogously in part. When $[(\eta^5\text{-}C_5H_5)Co(PR_3)_2]$ (R_3 = Me_3 or Me_2Ph) and excess CSSe react, $[(\eta^5\text{-}C_5H_5)Co(PR_3)(CS)]$ and $[(\eta^5\text{-}C_5H_5)Co(PR_3)(Se_2CS)]$ are isolated.[24] However, displaced or added phosphine abstracts Se from $[(\eta^5\text{-}C_5H_5)M(PR_3)(\eta^2\text{-}CSeS)]$ (M = Co or Rh) as discussed below. As yields of $[(\eta^5\text{-}C_5H_5)Co(PR_3)(Se_2CS)]$ are lower than for $[(\eta^5\text{-}C_5H_5)Co(PR_3)(CS)]$, a disportionation reaction between two molecules of $[(\eta^5\text{-}C_5H_5)Co(PR_3)(\eta^2\text{-}CSeS)]$ might account for equal yields of each, with displaced PR_3 abstracting Se to account for the remainder of the CS complex.

Both authors proposed the possible intermediacy of C_2S_4 or $C_2S_2Se_2$ groups in the rearrangement. Indeed, under certain conditions $[(\eta^5\text{-}C_5H_5)M(PR_3)_2]$ and CE_2 (E_2 = S_2, SSe or Se_2) gives $[(\eta^5\text{-}C_5H_5)M(PR_3)(C_2E_4)]$ (7) (M = Co, R_3 = Me_3, E_4 = Se_4;[24] M = Rh, R_3 = Me_3, E_4 = S;[25]

7

R_3 = Me_2Ph, E_4 = S_2Se_2).[24] Also, rearrangements via C_2S_4 groups have been proposed in routes to CS ligands involving phosphine ligands (see below).

(D) Three differing routes to CS ligands involve the abstraction of sulphur or selenium from CSE (E = S or Se) by PR_3 producing $R_3P{=}E$. Firstly, a CS_2–PR_3 mixture is used which is presumed to form an $\eta^2\text{-}CS_2$ complex which is attacked by PR_3. Secondly, coordinated PR_3 is displaced from a metal

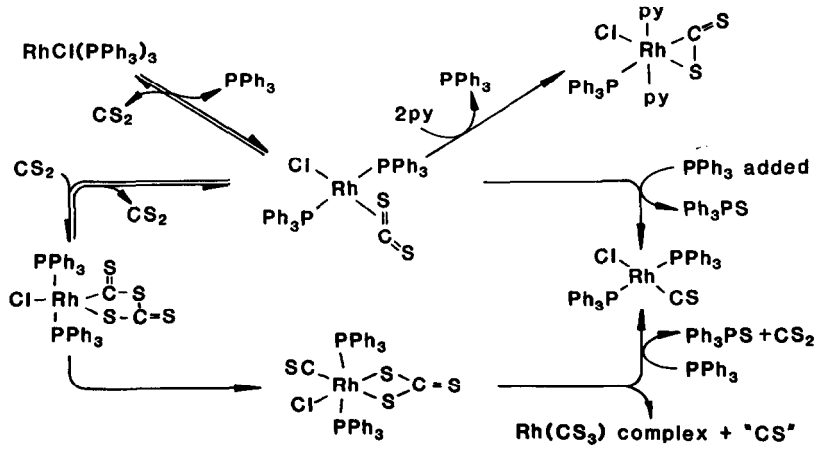
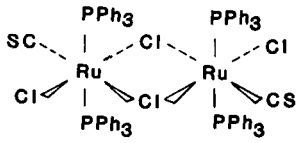
center and used as the abstracting molecule for the newly formed η^2-CES ligand or more complicated CSE-derived ligands. Thirdly, an isolated η^2-CES complex is attacked by added PR_3. Yields are variable, depending upon the exact system involved, and there is much overlap between these regimes.

The one-pot usage of excess CS_2 and PPh_3 converts $[MCl_2(PPh_3)_3]$ (M = Ru or Os) into *trans*-$[RuCl_2(CS)(H_2O)(PPh_3)_2]$[26] or $[OsCl_2(CS)(PPh_3)_3]$,[27] $[RhCl(PPh_3)_3]$ to $[RhCl(CS)(PPh_3)_2]$[28–30] and $[\{Ir(\mu\text{-}Cl)(cod)\}_2]$[31] or $[IrCl(PPh_3)_2(N_2)]$[32] into $[IrCl(CS)(PPh_3)_2]$. For these Rh and Ir cases, Wilkinson and co-workers[28,29,31] and Kubota and Carey[32] indicated that MeOH addition was needed with CS_2 and PPh_3 for good yields of the CS complex. Using CS_2, PPh_3 and MeOH individually allowed Kubota and Carey[32] to isolate intermediates and propose structures based on IR spectroscopy (Fig. 5). They suggested that these were unidentified compounds cited in Wilkinson's work.[31] Both groups identified $Ph_3P{=}S$ and inferred sulphur removal from CS_2 by PPh_3. Wilkinson observed[28,29] that without PPh_3 $[RhCl(PPh_3)_3]$ and CS_2 give a product assigned as $[RhCl(PPh_3)_2(\eta^2\text{-}CS_2)(\sigma\text{-}SCS)]$ which rearranges to $[RhCl(CS)(PPh_3)_2]$ in $CHCl_3$ solution. Figure 6 summarizes Wilkinson's work with $[RhCl(PPh_3)_3]$.

Reinvestigating this reaction, Thewissen proposes[30] that $[RhCl(PPh_3)_2(\eta^2\text{-}CS_2)]$ is formed first, identified spectroscopically, from which $[RhCl(CS)(PPh_3)_2]$ results on addition of excess PPh_3 in good yield *without* MeOH addition. With no added PPh_3, a slow reaction sequence occurs which was followed by IR and NMR spectroscopy and is shown in Fig. 7. The initially formed $[RhCl(PPh_3)_2(\eta^2\text{-}$





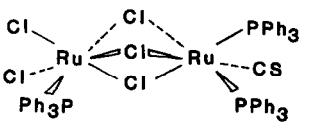


Fig. 7. The reaction of $[RhCl(PPh_3)_3]$ and CS_2 (py = pyridine). Products assigned by Thewissen.

CS_2)] reacts with CS_2 giving [$RhCl(PPh_3)_2(C_2S_4)$], which Thewissen suggests is the same compound as Wilkinson's [$RhCl(PPh_3)_2(\eta^2\text{-}CS_2)(\sigma\text{-}SCS)$]. This rearranges to [$RhCl(PPh_3)_2(CS)(S_2CS)$], which either loses "CS" to give unidentified $Rh(CS_3)$ products or loses CS_3 as CS_2 and $Ph_3P{=}S$ to give [$RhCl(CS)(PPh_3)_2$], the PPh_3 being derived from the original [$RhCl(PPh_3)_3$] reactant. This sequence is similar to Kubota and Carey's (Fig. 5) and the pathways are likely the same. Thewissen's later work gave him more literature IR data for his C_2S_4 and CS_3 assignments while Kubota and Carey's proposed C_2S_5 and CS_3 coordination modes remain unique. Also, Thewissen's work suggests *two routes* operate, excess PPh_3 directly abstracting sulphur from the η^2-CS_2 ligand but displaced PPh_3 eliminating the CS_3 group (as CS_2 and $Ph_3P{=}S$) after metal-centered CS_2 dimerization and disproportionation. The latter mechanism could operate in some of Werner's systems with [$(\eta^5\text{-}C_5H_5)Co(PR_3)_2$] and CSE (E = S or SE), although an attack of displaced PR_3 on an η^2-CES ligand is usually invoked,[6,24] as is discussed below.

8

9

Reacting [$RuCl_2(PPh_3)_3$] with excess CS_2 results in PPh_3 displacement and the isolation of three products, [$RuCl_2(S_2CPPh_3)(PPh_3)_2$], [$\{Ru(CS)Cl(PPh_3)_2\}_2(\mu\text{-}Cl)_2$] (**8**) and [$(PPh_3)_2ClRu(\mu\text{-}Cl)_3Ru(CS)(PPh_3)_2$] (**9**).[33–36] Mechanistic proposals suggested that [$RuCl_2(PPh_3)_2(CS)$] dimerizes to **8** or reacts with [$RuCl_2(PPh_3)_3$] giving **9**,[34,35] the latter by analogy with [$RuCl_2(PPh_3)_2(CO)$] behaviour.[35]

Another set of examples using either simultaneous or sequential use of CS_2 and PPh_3 are summarized in Fig. 8 and Table 1.[19,20,37–39] Generally, [(ring)$M(CO)_3$] (M = Mn, Re or Cr; ring = η^5- or η^6-ligand, as appropriate) is UV irradiated in the presence of a labile ligand L (L = THF or cyclooctene) producing [(ring)$M(CO)_2L$]. Then, CS_2 and PPh_3 are reacted with this, together or sequentially. The isolation of [(ring)$M(CO)_2(\eta^2\text{-}CS_2)$] in certain cases suggests the intermediacy of this in all cases, with PPh_3 abstracting sulphur as $Ph_3P{=}S$ to yield [(ring)$M(CO)_2(CS)$].

The same reaction sequence enables [$(\eta^5\text{-}C_5H_5)Cr(CO)_2(NO)$] to be converted to [$(\eta^5\text{-}C_5H_5)Cr(CO)(CS)(NO)$] using C_8H_{14} as labile ligand and CS_2–PPh_3 simultaneously.[40] This method applied twice over to [$(\eta^5\text{-}C_5H_5)Mn(CO)_2(CS)$] produces first [$(\eta^5\text{-}C_5H_5)Mn(CO)(CS)_2$] and finally [$(\eta^5\text{-}C_5H_5)Mn(CS)_3$].[19] Analogous usage of CSe_2–PPh_3 leads to the CSe analogues for the same Mn, Re and Cr reactants.[41,42]

The use of an excess of CS_2 and PPh_3 is *not* a general route to CS complexes. For instance, a wide range of analogues of [$Fe(CO)_2(PR_3)_2(\eta^2\text{-}CS_2)$] are made by reacting these reagents with appropriate Fe(0) precursors.[43,44]

Added P^nBu_3 is known to abstract sulphur from two η^2-CS_2 complexes. However, with [$W(CO)_3(R_2PC_2H_4PR_2)(\eta^2\text{-}CS_2)$] (R = Me or Ph), the reaction gives [$W(CO)_3(R_2PC_2H_4PR_2)(\sigma\text{-}SC(S)P^nBu_3)$] as well as [$W(CO)_3(R_2PC_2H_4PR_2)(CS)$][45] and, with [$Fe(CO)_2\{P(OPh)_3\}_2(\eta^2\text{-}CS_2)$], the yield of [$Fe(CO)_2\{P(OPh)_3\}_2(CS)$] proved variable.[46] The ready exchange of phosphine ligands in [$Fe(CO)_2(PR_3)_2(\eta^2\text{-}CS_2)$] indicates that the latter reaction is not general.[43,44]

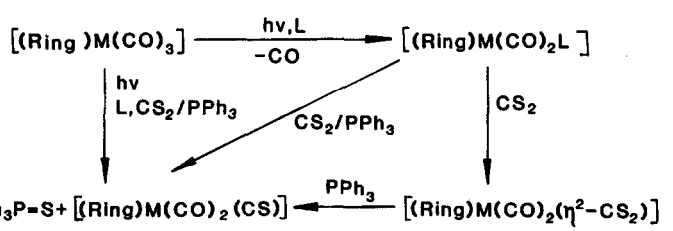

Fig. 8. The routes to prepare [(ring)$M(CO)_2(CS)$] using CS_2–PPh_3 (refer to Table 1).

Table 1.

M	L	Ring	η^2-CS_2 isolated	Reference
Mn	C_8H_{14}	η^5-C_5H_5	√	19, 37
Mn	C_8H_{14}	η^5-C_5H_4Me	√	19

Cr	C_8H_{14}	η^6-C_6Et_6	√	39
Mn	THF	η^5-C_5H_5	×	20
Mn	THF	η^5-C_5H_4Me	×	20
Re	THF	η^5-C_5H_5	×	20

Werner's work with $[(\eta^5\text{-}C_5H_5)M(PR_3)L]$ species (M = Co or Rh) involves the use of either displaced or added phosphine to give CS ligands by chalcogen abstraction from η^2-CES units. Sensitivity to the nature of M, PR_3 and CE_2 (E_2 = OS, S_2, SSe or Se_2) is indicated.[6,24,47] Reactions are summarized in Fig. 9. Reactions involving CS_2 give only $[(\eta^5\text{-}C_5H_5)M(PR_3)(\eta^2\text{-}CS_2)]$ [M = Co, R_3 = Me_3 or $(OMe)_3$; M = Rh, R_3 = Me_3 or Me_2Ph]. This was shown to be stable to added PPh_3 in some cases. Using COS, a near quantitative yield of $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(CO)]$ results from $[(\eta^5\text{-}C_5H_5)Co(PMe_3)_2]$ when displaced PMe_3 was proposed to remove sulphur as $Me_3P{=}S$ from the unidentified intermediate $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(\eta^2\text{-}CSO)]$. With CSSe or CSe_2, a variety of products result, the nature of which depends on the amount of this reagent used and the phosphine substituent. Stoichiometric quantities of CSSe with $[(\eta^5\text{-}C_5H_5)Co(PR_3)_2]$ (R_3 = Me_3) yield

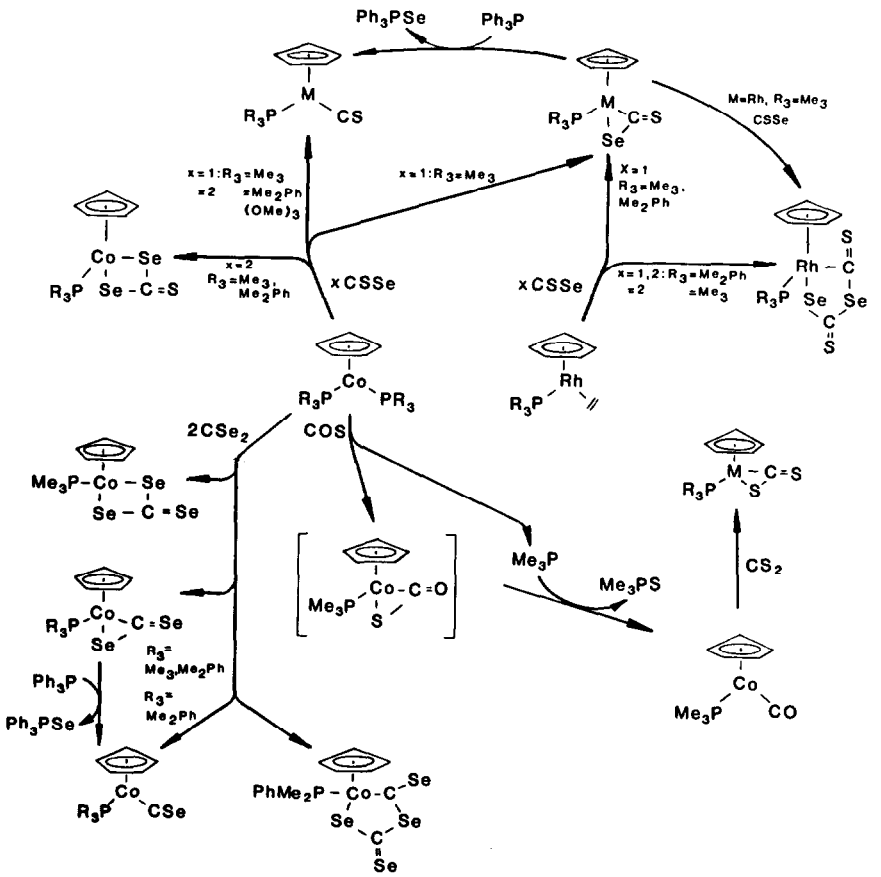

Fig. 9. Werner and co-workers results on the $[(\eta^5\text{-}C_5H_5)ML_2]$ (M = Co or Rh)–CEE′ (E and E′ = O, S or Se) system.

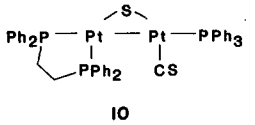
$[(\eta^5\text{-}C_5H_5)Co(PMe_3)(CS)]$ and $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(\eta^2\text{-}CSeS)]$, the displaced PMe_3 being proposed to abstract selenium. Excess CSSe (two–three-fold) gives $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(\eta^2\text{-}CSeS)]$ and $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(Se_2CS)]$ but, when $R_3 = (OMe)_3$, results in $[(\eta^5\text{-}C_5H_5)Co\{P(OMe)_3\}(CS)]$ and $(MeO)_3P{=}SE$ or, for $R_3 = Me_2Ph$, yields $[(\eta^5\text{-}C_5H_5)Co(PMe_2Ph)(CS)]$ and $[(\eta^5\text{-}C_5H_5)Co(PMe_2Ph)(Se_2CS)]$. Using two equivalents of CSe_2 with $[(\eta^5\text{-}C_5H_5)Co(PR_3)_2]$ ($R_3 = Me_3$) is analogous to using CSSe, but, for $R_3 = Me_2Ph$, $[(\eta^5\text{-}C_5H_5)Co(PMe_2Ph)(C_2Se_4)]$ occurs in addition to the CSe and η^2-CSe_2 compounds. With one equivalent of CSSe, $[(\eta^5\text{-}C_5H_5)Rh(PR_3)(C_2H_4)]$ produces $[(\eta^5\text{-}C_5H_5)Rh(PR_3)(\eta^2\text{-}CSeS)]$ when $R_3 = Me_3$ but a mixture of this and $[(\eta^5\text{-}C_5H_5)Rh(PR_3)(C_2S_2Se_2)]$ when $R_3 = Me_2Ph$. Two equivalents give the $C_2S_2Se_2$ compound only for both $R_3 = Me_3$ and Me_2Ph. The lack of CS products in the rhodium cases coincides with the absence of displaced phosphine ligands, suggesting the intermediacy of these in the cobalt cases. All the above η^2-CSeS and η^2-CSe_2 products react with PPh_3, giving the respective CS and CSe complexes, with the identification of $Ph_3P{=}Se$ in some cases. In summary, these pathways are variable and do not reliably yield CS complexes.

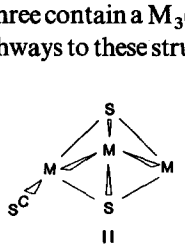
In cases, where PR_3 abstracts a chalcogen from an η^2-CE_2 ligand, removal of the coordinated chalcogen atom is proposed.[6,24,46] This contrasts with reactions discussed in Section II.1.ii(A) whereby methylation at the uncoordinated chalcogen followed by H^+ or H^- attack eliminates this atom in MeEH (E = S or Se).

(E) A few examples exist whereby free or η^2-coordinated CS_2 is fragmented giving rise to terminal CS ligands and μ_2- or μ_3-sulphide groups. The metal core is bi- or trimetallic.



Reacting $[Pt(Ph_2PC_2H_4PPh_2)(\eta^2\text{-}CS_2)]$ and $[Pt(\eta^2\text{-}C_2H_4)(PPh_3)_2]$ gives

$$[(Ph_2PC_2H_4PPh_2)Pt(\mu\text{-}S)Pt(PPh_3)(CS)]$$



(**10**),[48] via a proposed $\overline{Pt\{S\text{-}C(S)\}Pt}$ intermediate. Free CS_2 interacts with $[Fe_3(CO)_{12}]$,[49,50] $[Os_3(CO)_{12}]$[50,51] or $[Os_3(CO)_8SH_2(MeCN)]$[52] to yield the clusters

$$[Fe_3(CO)_8(CS)S_2],\ [Os_3(CO)_8(CS)S_2] \quad \text{and} \quad [Os_3(CO)_7(CS)S_2(\mu\text{-}H)_2],$$

respectively, as one of a number of products in each case. All three contain a $M_3(\mu_3\text{-}S)_2(CS)$ core (**11**) for M = Os. Different CS positions give isomers in the iron case. Pathways to these structures were not proposed.

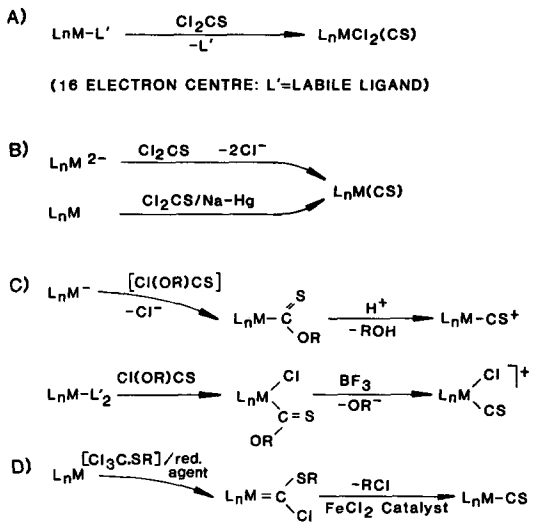
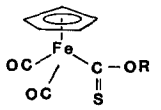
11

iii. Preparations using [Cl(X)CS] (X = Cl *or* OR) *and* $[Cl_3C\cdot SR]$



The uses of these reagents are summarized in Scheme 2 and are discussed in turn.

(A) Thiophosgene, Cl_2CS, reacts with the 16-electron Rh(I) and Ir(I) complexes $[RhCl(PPh_3)_3]$, $[IrCl(PPh_3)_2(N_2)]$ and $[\{Ir(PPh_3)_2(CO)(MeCN)\}^+]$. A neutral ligand is displaced (PPh_3, N_2 and MeCN, respectively) and Cl_2CS oxidatively adds to give the M(III) 18-electron complexes $[RhCl_3(PPh_3)_2(CS)]$, $[IrCl_3(PPh_3)_2(CS)]$ and $[\{IrCl_2(PPh_3)_2(CO)(CS)\}^+]$.[53] Similarly, $[Ru_3(CO)_{12}]$ fragments and loses one CO ligand from each Ru to give $[RuCl_2(CO)_3(CS)]$ with a two-unit increase in the formal metal oxidation state.[54]



(B) Chlorine is removed from Cl_2CS in two differing ways. Two equivalents of chloride are eliminated in the reaction of Cl_2CS with $[\{Fe(CO)_4\}^{2-}]$[55] or $[\{M(CO)_5\}^{2-}]$ and $[\{M_2(CO)_{10}\}^{2-}]$ (M = Cr, Mo or W)[56] to produce $[Fe(CO)_4(CS)]$ and $[M(CO)_5(CS)]$ in low yield. A better preparation of $[Cr(CO)_5(CS)]$ is known,[57] as discussed in Section II.1.v.

Either Fe powder or Na–Hg is used to remove chlorine from Cl_2CS. The thiocarbonyl products are metal porphyrin species and [M(OEP)(CS)L] (M = Fe,[21] Ru,[58] or Os;[21] L = solvent EtOH, THF or py) are prepared as shown in Fig. 10. Both Na–Hg and Fe powder have been used to prepare [Fe(TPP)(CS)] from [Fe(TPP)Cl].[59]

(C) Two differing two-step routes to CS ligands have been noted using $[Cl(OR)\cdot CS]$. Using $[(\eta^5\text{-}C_5H_5)Fe(CO)_2\}^-]$ and $[Cl(OR)\cdot CS]$ (R = Me,[8] or Et[60]) produces $[(\eta^5\text{-}C_5H_5)Fe(CO)_2\{CS(OR)\}]$ (**12**) by chloride elimination. Attack by H^+ on this causes ROH loss, giving $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2(CS)\}^+]$.

Scheme 2. Routes to CS ligands from [Cl(X)CS] (X = Cl or OR) and [Cl_3CSR].

12

Alternatively, with [$Pt(PPh_3)_4$], [Cl(OMe)·CS] oxidatively adds to the Pt center to give [$PtCl(PPh_3)_2${CS(OMe)}]. Abstraction of OMe^- is achieved using BF_3 and *trans*-[{$PtCl(PPh_3)_2(CS)$}$^+BF_4^-$] is isolated. Addition of MeOH reverses the second step.[61]

(D) The reaction with [Cl_3C-SR] (R = Ph, CH_2Ph or NR'_2) is related to those with Cl(X)CS. With [Fe(II)(TPP)] in the presence of either sodium dithionite or Fe powder, [Fe(TPP){C(Cl)SR}] results. Elimination of RCl is caused by adding catalytic amounts of $CuCl_2$ or $FeCl_2$ to give [Fe(II)(TPP)(CS)].[62] Differing porphyrin ligands such as OEP, TTP and tetrakis(*p*-chlorophenyl)porphyrin were employed with [Cl_3C-SCH_2Ph].[62]

iv. Preparations via dichlorocarbene or chlorocarbyne complexes

These methods boast only one set of examples each, but yields are relatively high and these routes may prove more widely useful. Also, both routes lead not only to the CS complex but also to the CSe and CTe analogues.

Reacting [$OsCl_2(PPh_3)_2(CO)(CCl_2)$] with EH^- (E = S, Se or Te) caused the elimination of Cl^- and HCl to yield [$OsCl_2(PPh_3)_2(CO)(CE)$][63] (Fig. 11). Similarly, the chlorocarbyne ligand in [Mo(CCl)$(CO)_2$L] [L = $HB(3,5\text{-}Me_2\text{-}C_3HN_2)_3$] reacts with E^{2-} (E = S, Se or Te) giving [{Mo(CE)$(CO)_2$L}$^-$][64] (Fig. 12).

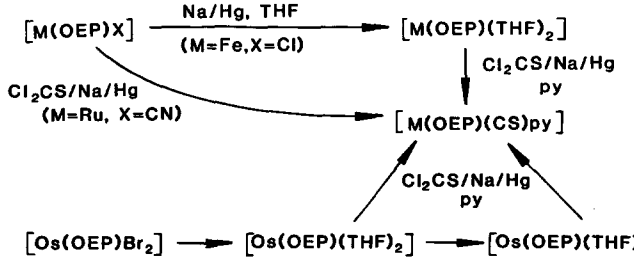


Fig. 10. [Cl_2CS]-based routes to [M(OEP)(CS)py] (M = Fe, Ru or Os: OEP = octaethylporphyrin).

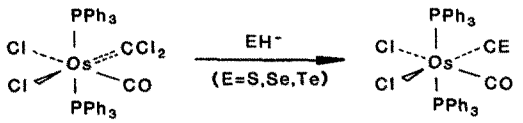

Fig. 11. The conversion of the dichlorocarbene ligand in $[OsCl_2(PPh_3)_2(CO)(CCl_2)]$ to CE using EH^- (E = S, Se or Te).

v. Modification of thiocarbonyl complexes

Novel thiocarbonyl complexes are often formed by ligand substitution or addition reactions of thiocarbonyl-containing species. Substitutions include those of neutral ligands (e.g. CO and PPh_3) often under the influence of heat or UV irradiation, anion exchange reactions and the displacement of a neutral ligand by an anion or vice versa. Addition reactions occur with sub-18-electron species which take on donor ligands (e.g. CO and PPh_3) or undergo oxidative addition of molecules such as H_2 or Cl_2. However, the discussion is not structured around reaction types but instead moves across the *d*-block, concentrating in turn on the major series of modification reactions which have been developed from certain thiocarbonyl complexes.

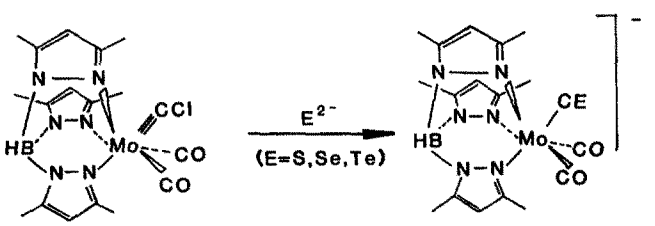
(a) Cr *triad*. UV irradiation of $[(\eta^5\text{-}C_5H_5)Cr(CO)(CS)(NO)]$ in the presence of cyclooctene eliminates CO to produce $[(\eta^5\text{-}C_5H_5)Cr(CS)(NO)(C_8H_{14})]$.[40] Both PMe_3 and NO^+ can displace the labile cyclooctene to give $[(\eta^5\text{-}C_5H_5)Cr(CS)(NO)(PMe_3)]$ and $[\{(\eta^5\text{-}C_5H_5)Cr(CS)(NO)_2\}^+]$.[40] Similarly, irradiation of $[\{\eta^6\text{-}o\text{-}C_6H_4(CO_2Me)R\}Cr(CS)(CO)_2]$ with PR'_3 in benzene leads to $[\{\eta^6\text{-}o\text{-}C_6H_4(CO_2Me)R\}Cr(CS)(CO)(PR'_3)]$ [R = H, $R'_3 = (OEt)_3$ or Me_2Ph: R = Me; R' = Ph, OEt or OPh][38,65–67] which when (R = Me, R' = OEt) can be reduced by $LiAlH_4$–$AlCl_3$ at the arene ligand to

$$[(\eta^6\text{-}o\text{-}C_6H_4Me_2)Cr(CS)(CO)\{P(OEt)_3\}].^{65,67}$$

These products are chiral, and optical isomers have been resolved in some cases.

At elevated temperature and pressure, CO displaces the arene ligand from $[(\eta^6\text{-}C_6H_5R)Cr(CO)_2(CE)]$ (R = H, E = S or Se; R = CO_2Me, E = S) to give $[Cr(CO)_5(CE)]$.[5] This is a higher-yield route than using $[\{Cr(CO)_5\}^{2-}]$ and Cl_2CS.[56]

The chemistry of $[M(CO)_5(CS)]$ (M = Cr or W) has been investigated and is mostly shown in Scheme 3. Spectroscopic investigation of the UV irradiation product of $[M(CO)_5(CS)]$ isolated in a gas matrix at 20 K indicates that *cis*-CO loss gives rise to C_{4v}- and C_s-isomers of $[M(CO)_4(CS)]$ (M = Cr or W).[68,69] Thermal ligand substitution results in $[M(CO)_4(CS)L]$ [M = Cr; L = PPh_3, *cis*- and *trans*-: M = W; L = PPh_3 (*cis*- and *trans*-), py (*trans*-)] and *mer*-$[M(CO)_3(CS)(dppe)]$ (M = Cr or W).[70–72] Further CO substitution in molten dppe produces *cis*-$[W(CO)(CS)(dppe)_2]$,[70–72] which is protonated by CF_3SO_3H at the metal giving $[\{WH(CO)(CS)(dppe)_2\}^+]$.[73,74] Halide substitution of CO in $[W(CO)_5(CS)]$ by using $^nBu_4NX$ gives [*trans*-$\{W(CO)_4(CS)X\}^- \cdot {}^nBu_4N^+$] (X = Cl, Br or I)[70,72,74] from which, when X = I, Ag^+ abstracts I^- and allows its replacement by a neutral ligand.[72,75] This gives a route other than thermal substitution of $[W(CO)_5(CS)]$ to a wider range of *trans*-$[W(CO)_4(CS)L]$ (L = ^{13}CO, CyNC, 4-Me-py or PR_3; R = Ph, tolyl, ^{n}Bu, OMe or OPh) without coproduction of the *cis*-isomer,[72,75] and also allows the preparation of *mer*-$[W(CO)_3(CS)(bipy)]$.[72] As I^- abstraction is performed in acetone solvent before ligand addition,[72,75] the intermediacy of *trans*-$[W(CO)_4(CS)(Me_2CO)]$ can be inferred. Heating *trans*-$[W(CO)_4(CS)L]$ (L = CyNC, 4-Me-py or PR_3) at 65°C in cyclohexane solution causes isomerization to a *cis–trans*-isomer mixture.[75] Anionic



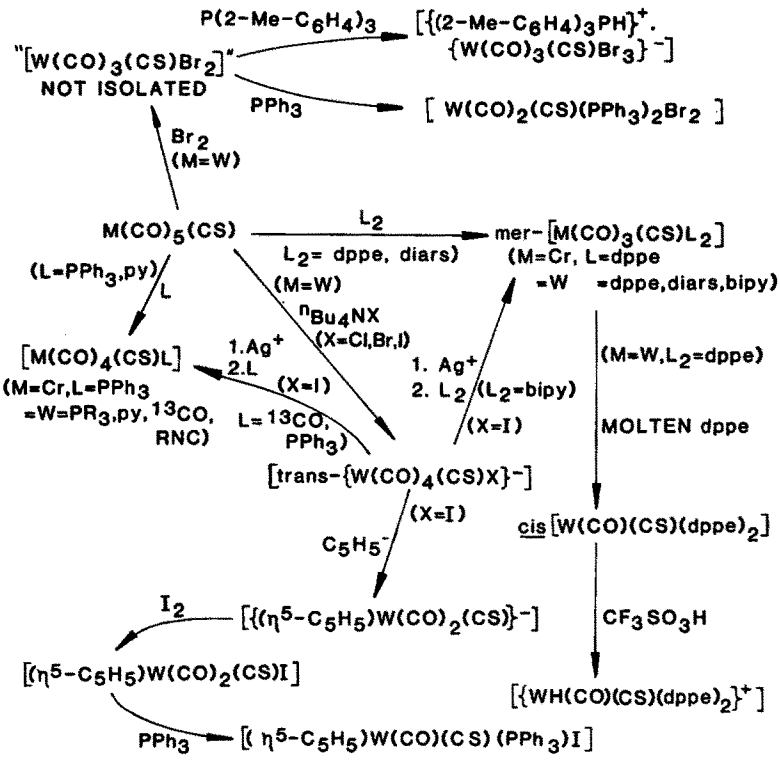


Fig. 12. Conversion of a chlorocarbyne ligand to CE by E^{2-} (E = S, Se or Te).

Scheme 3. CS complexes derived from $[M(CO)_5(CS)]$ (M = Cr or W) by ligand substitution.

substitution of I^- in [*trans*-$\{W(CO)_4(CS)I\}^-$] by $C_5H_5^-$ gives [$\{(\eta^5\text{-}C_5H_5)W(CO)_2(CS)\}^-$] to which I_2 nominally introduces I^+, yielding [$(\eta^5\text{-}C_5H_5)W(CO)_2(CS)I$] containing *trans*-CS and I ligands.[76,77] This stereochemistry is retained on CO substitution in refluxing toluene which produces [$(\eta^5\text{-}C_5H_5)W(CO)(CS)(L)I$] [L = PPh_3,[76] PMe_2Ph, $P(OPh)_3$, $P(NMe_2)_3$ or MeNC] although [$\{(\eta^5\text{-}C_5H_5)W(CO)(CS)L_2\}^+I^-$] (L = PMe_2Ph) is obtained using a lower reflux temperature.[77] Halide elimination between [$\{(\eta^5\text{-}C_5H_5)W(CO)_2(CS)\}^-$] and the substrates Ph_3SnCl, Ph_3PbCl, PhSeBr and HgI_2 gives [$(\eta^5\text{-}C_5H_5)W(CO)_2(CS)X$] {X = $SnPh_3$, $PbPh_3$ [*cis*-(CS)(X)], SePh or HgI [*cis*- and *trans*-(CS)(X)]}.[77] Reacting [$K\cdot\{HB(pz)_3\}$] and [*trans*-$\{W(CO)_4(CS)I\}^-$] eliminates I^- also to form [$\{W\{HB(pz)_3\}(CO)_2(CS)\}^-$] which, with I_2, yields [$W\{HB(pz)_3\}(CO)_2(CS)I$].[77] Other uses of halogen include Br_2 attack on $[W(CO)_5(CS)]$ when the formation of $[W(CO)_3(CS)Br_2]$ was inferred from the isolation of $[W(CO)_2(CS)(PPh_3)_2Br_2]$ and [$\{(2\text{-}Me\text{-}C_6H_4)_3PH\}^+\cdot\{W(CO)_3(CS)Br_3\}^-$] when the relevant phosphine is present.[73] Similarly, excess I_2 reacts with *mer*-$[W(CO)_3(CS)(dppe)]$ giving [$\{W(CO)_2(CS)(dppe)I\}^+\cdot I_3^-$], whereas stoichiometric amounts give a product assigned tentatively as $[W(CO)_2(CS)(dppe)I_2]$.[73]

(b) Mn *triad*. The substitution reactions of [$(\eta^5\text{-}C_5H_4R)Mn(CO)_2(CS)$] (R = H or Me) utilize UV irradiation extensively. The labile cyclooctene ligand is introduced thus into

$$[(\eta^5\text{-}C_5H_5)Mn(CO)(CS)(C_8H_{14})],$$

which reacts with CS_2–PPh_3 to form [$(\eta^5\text{-}C_5H_5)Mn(CO)(CS)_2$], on which the sequence of reactions can be repeated giving [$(\eta^5\text{-}C_5H_5)Mn(CS)_3$] via

$$[(\eta^5\text{-}C_5H_5)Mn(CS)_2(C_8H_{14})].^{19}$$

Cyclooctene may be displaced by PPh_3 or dppe also, producing

$$[(\eta^5\text{-}C_5H_5)Mn(CO)(CS)(PPh_3)]^{19,78} \quad \text{and} \quad [(\eta^5\text{-}C_5H_5)Mn(CS)(dppe)],^{79}$$

respectively. Irradiating [$(\eta^5\text{-}C_5H_5)Mn(CO)_2(CS)$] in THF leads to the *in situ* preparation of

$$[(\eta^5\text{-}C_5H_5)Mn(CO)(CS)(THF)].^{19,79,80}$$

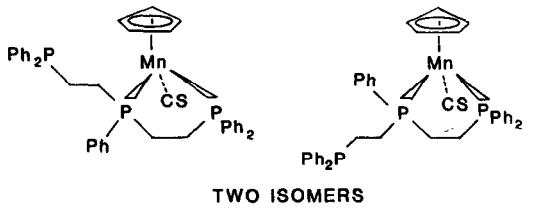

Fig. 13. The two isomeric forms of $[(\eta^5\text{-}C_5H_5)Mn(CS)(triphos)]$.

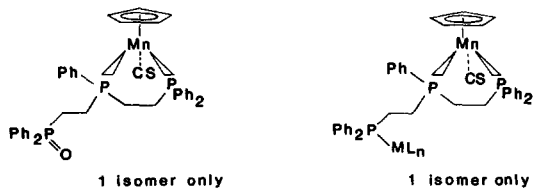
Production in the presence of or subsequent addition of a ligand displaces THF giving

$$[(\eta^5\text{-}C_5H_5)Mn(CO)(CS)L]$$



[L = PMe_2Ph, PCy_3, $P(OR)_3$, $AsPh_3$ or $SbPh_3$; R = Me, Et, Ph or CH_2CH_2Cl][80] and

$$[(\eta^5\text{-}C_5H_5)Mn(CS)(dppe)].^{19,79}$$

In benzene solvent with an excess of ligand, irradiation converts $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(CS)]$ into $[(\eta^5\text{-}C_5H_5)Mn(CS)L_2]$ (L = PMe_2Ph or PR_3; R = Ph, OMe, OEt, OPh or OCH_2CH_2Cl; L_2 = triphos).[80] For $[(\eta^5\text{-}C_5H_5)Mn(CS)(triphos)]$, diastereomers exist through different orientations of the uncoordinated third phosphine functionality (Fig. 13). This functionality is converted to a phosphine oxide by ozone or coordinates to another metal center on reaction with

$$[ML_n(THF)]\ [ML_n = Cr(CO)_5 \text{ or } (\eta^5\text{-}C_5H_5)Mn(CO)_2]$$

(**13** and **14**), these compounds existing also in two diastereometric forms.[80]

Reaction of $[(\eta^5\text{-}C_5H_4R)Mn(CO)_2(CS)]$ (R = H or Me) with NO^+ gives

$$[\{(\eta^5\text{-}C_5H_4R)Mn(CO)(CS)(NO)\}^+].^{81}$$

In refluxing CH_2Cl_2, this readily produces

$$[\{(\eta^5\text{-}C_5H_4R)Mn(CS)(NO)L\}^+]$$

(R = H; L = PPh_3: R = Me; L = PPh_3, $AsPh_3$ or $SbPh_3$) and with KI in THF yields

$$[(\eta^5\text{-}C_5H_5)Mn(CS)(NO)I].^{82}$$

(c) Fe *triad*. For $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2(CS)\}^+ \cdot PF_6^-]$, which is isoelectronic to

$$[(\eta^5\text{-}C_5H_5)Mn(CO)_2(CS)],$$

CO substitution occurs without UV irradiation or heating using an excess of ligand in acetone to prepare

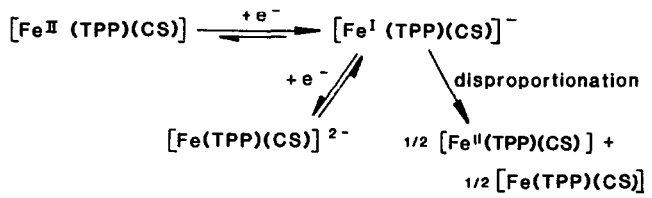
$$[\{(\eta^5\text{-}C_5H_5)Fe(CO)(CS)L\}^+ \cdot PF_6^-]$$

(L = PR_3, $AsPh_3$ or $SbPh_3$; R = Ph, Cy, C_6H_4F or C_6H_4OMe) or

$$[\{(\eta^5\text{-}C_5H_5)Fe(CS)(CNPh)_2\}^+ \cdot PF_6^-].^{83}$$

With irradiation,

$$[\{(\eta^5\text{-}C_5H_5)Fe(CS)(Me_2CO)\{MeC(CH_2As)_3\}\}^+]$$



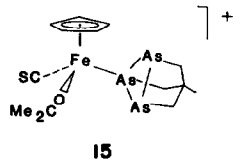


Fig. 14. The electrochemical behaviour of [Fe(II)(TPP)(CS)] (TPP = tetraphenylporphyrin).

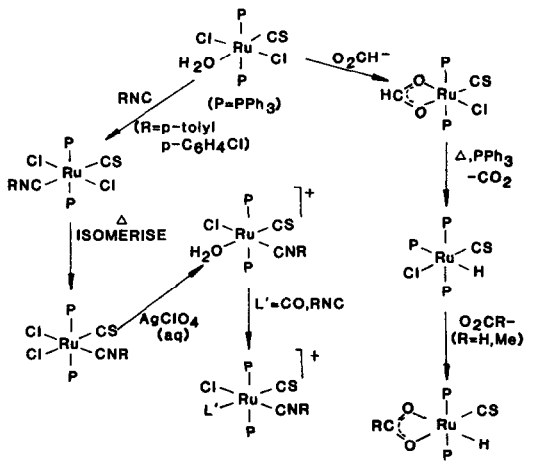
15

(**15**) is prepared from the ligand and [{(η^5-C_5H_5)Fe(CO)$_2$(CS)}$^+$] in acetone.[84] For the related [{(η^5-C_5H_5)Fe(CO)(CS)}$^-$], reaction with Ph_3SnCl eliminates chloride, giving



$$[(\eta^5\text{-}C_5H_5)Fe(CO)(CS)(SnPh_3)].^{85}$$

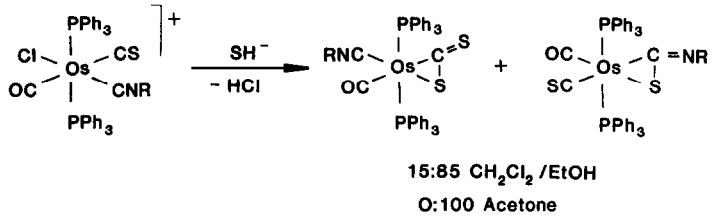
Petz has reacted [Fe(CO)$_4$(CS)] with $HgCl_2$ and Hg^{2+}(aq) to yield, respectively, [(CO)$_4$(CS)Fe → $HgCl_2$] containing an iron to mercury donor bond and polymeric [Hg{Fe(CO)$_3$(CS)}] in which Fe–Hg interactions are proposed to link the structure. The former is converted to the latter by H_2O.[86]

The porphyrin species [Fe(OEP)(CS)] is ligated *trans*- to CS by piperidine or 1-methyl-imidazole.[21] Addition of S^{n}Bu$^-$ to [Fe(TPP)(CS)] is reversible, the adduct stable only at low temperature,[87,88] and electrochemical modifications of [Fe(TPP)(CS)][87,88] are described in Fig. 14. A number of ligands form adducts of [Fe(TPP)(CS)] to give the six-coordinate [Fe(TPP)(CS)L] (L = py, ^{i}PrNH$_2$, *N*-methylimidazole, morpholine, PEt_3, MeOH or EtOH).[62]

Reacting PPh_3 with [Ru(CO)$_3$(CS)Cl$_2$] displaces CO to produce [Ru(CO)$_2$(CS)Cl$_2$(PPh$_3$)].[54] Chloride is also displaced by CyNC which yields [{Ru(CO)$_2$(CS)(CNCy)$_2$Cl}$^+$], as occurs on using [$Ph_2AsC_2H_4AsPh_2$] to yield [{Ru(CO)$_2$($Ph_2AsC_2H_4AsPh_2$)(CS)Cl}$^+$].[54] Both are isolated as BPh_4^- salts.

Much of the extensive work which Roper and co-workers have performed with *trans*-[M(PPh$_3$)$_2$(CS)L$_n$] (M = Ru or Os) species has been substitution chemistry with the L$_n$ ligands.[13,26,89–91] These reaction series begin with [MCl$_2$(CS)L(PPh$_3$)$_2$] (M = Ru, L = H_2O; M = Os, L = PPh_3) in which L is labile. Scheme 4 illustrates the reactions of [RuCl$_2$(CS)(H_2O)(PPh$_3$)$_2$],[13,26] to which the osmium cases are related. Conversion of [OsCl$_2$(CS)(PPh$_3$)$_3$] to [{OsCl(CS)(CO)(CNR)(PPh$_3$)$_2$}$^+$·ClO_4^-] (R = *p*-tolyl) is analogous to the ruthenium case[89] (refer to Scheme 4). Attack by RNC displaces PPh_3,

Scheme 4. CS complexes derived from [RuCl$_2$(CS)(H_2O)(PPh$_3$)$_2$] by ligand substitution.



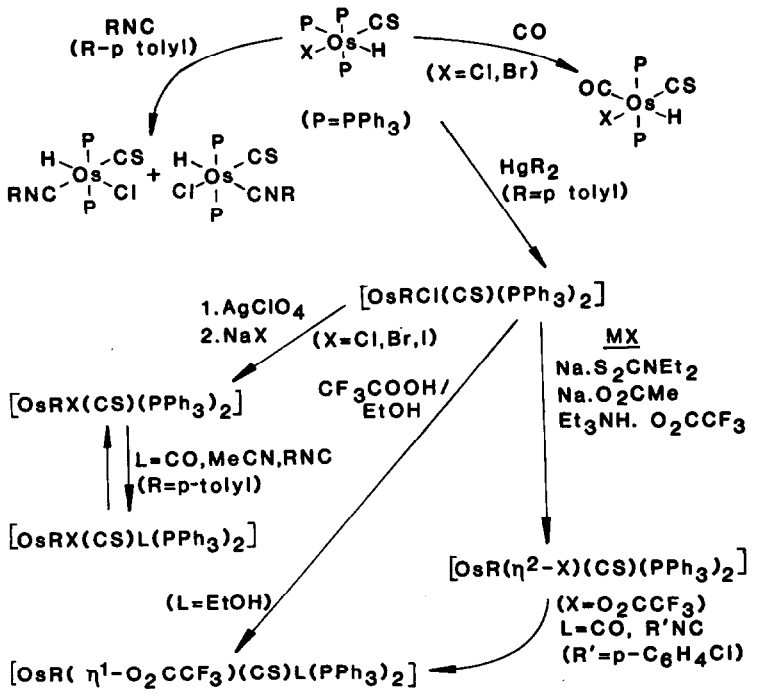


Fig. 15. The alternative sites of SH^- attack on $[\{OsCl(CS)(CO)(CNR)(PPh_3)_2\}^+]$ (R = *p*-tolyl).

giving $[OsCl_2(CS)(CNR)(PPh_3)_2]$ from which $AgClO_4$ removes Cl^- producing $[OsCl(CS)(CNR)(OClO_3)(PPh_3)_2]$; CO then displaces ClO_4^- to give the product. The analogous coordinated ClO_4^- species was proposed in the ruthenium system earlier[13] rather than H_2O ligation following $AgClO_4$ usage.

The osmium product, $[\{OsCl(CS)(CO)(CNR)(PPh_3)_2\}^+ \cdot ClO_4^-]$, reacts with SH^- at either the CS or CNR ligands to give $[Os(CS)(CO)(\eta^2\text{-}CS \cdot NR)(PPh_3)_2]$ or $[Os(CO)(CNR)(\eta^2\text{-}CS_2)(PPh_3)_2]$. The former is favoured, the ratio being solvent-dependent (Fig. 15).[89]

Other reactions of $[OsCl_2(CS)(PPh_3)_3]$ include the use of OH^- in EtOH which produces $[OsHCl(CS)(PPh_3)_3]$ or OH^- in $MeOCH_2CH_2OH$ with both of these to give $[OsH_2(CS)(PPh_3)_3]$.[90] The stepwise introduction of hydride can be reversed using HCl in stoichiometric or excess quantities for the mono- or dichloro species.[90] Also, $[OsH_2(CS)(PPh_3)_3]$ and HBr give $[OsHBr(CS)(PPh_3)_3]$.[90] The compounds $[OsHX(CS)(PPh_3)_3]$ (X = Cl or Br), containing *mer*-$(PPh_3)_3$ and *cis*-(H)(CS) groups, are a starting point for various reactions.[90,91] This substitution chemistry is shown in Scheme 5.

(d) Co *triad*. For Rh and Ir species, the reaction pathways begin with *trans*-$[MCl(CS)(PPh_3)_2]$ (M = Rh or Ir). In less polar solvents (e.g. $CHCl_3$) phosphine exchange occurs to give *trans*-$[MCl(CS)(PR_3)_2]$ (M = Rh; $R_3 = Me_2Ph$,[92] or Cy_3;[92,93] M = Ir; R = Cy[94]), while reaction with RLi or RMgX produces $[MR(CS)(PPh_3)_2]$ (M = Rh or Ir; R = C_6F_5 or C_6Cl_5).[95] For $[RhR(CS)(PPh_3)_2]$ (R = C_6F_5 or C_6Cl_5), HCl converts this back to $[RhCl(CS)(PPh_3)_2]$. However, the Ir analogues undergo a number of oxidative additions to form $[IrR(X)(Y)(CS)(PPh_3)_2]$ (R = C_6Cl_5; XY = HCl: R = C_6F_5; XY = HCl, Br_2, I_2 or $HgCl_2$), the addition of HCl being reversed by refluxing $[IrR(H)(Cl)(CS)(PPh_3)_2]$ in EtOH.[95]

Scheme 5. CS complexes derived from *mer*-$[OsHX(CS)(PPh_3)_3]$ (X = Cl or Br) by ligand substitution.

Substitution of Cl^- by $C_5H_5^-$ is achieved for $[MCl(CS)(PPh_3)_2]$ (M = Rh or Ir).[96] The resulting $[(\eta^5\text{-}C_5H_5)M(PPh_3)(CS)]$ react with halogens to form $[\{(\eta^5\text{-}C_5H_5)M(PPh_3)X(CS)\}^+ \cdot X^-]$ (X = Cl, Br or I).[96] For M = Rh, the reaction is performed at −78°C, the room-temperature reaction giving $[(\eta^5\text{-}C_5H_5)Rh(PPh_3)X_2]$, and $[\{(\eta^5\text{-}C_5H_5)Rh(PPh_3)X(CS)\}^+ \cdot X^-]$ is stable only at low temperature. Exchange of X^- by BPh_4^- increases stability somewhat. With dry HCl, $[(\eta^5\text{-}C_5H_5)Ir(PPh_3)(CS)]$ forms

$$[\{(\eta^5\text{-}C_5H_5)Ir(PPh_3)H(CS)\}^+ \cdot Cl^-],$$

but the Rh analogue eliminates the $\eta^5\text{-}C_5H_5$ ligand to give $[\{Rh(\mu\text{-}Cl)(CS)(PPh_3)\}_2]$, the dimeric nature indicated by its reaction with PPh_3 to regenerate $[RhCl(CS)(PPh_3)_2]$.[96] The sequential reaction of $ClCH_2CN$ and $NaBPh_4$ with $[(\eta^5\text{-}C_5H_5)Ir(PPh_3)(CS)]$ produces

$$[\{(\eta^5\text{-}C_5H_5)Ir(PPh_3)(CH_2CN)(CS)\}^+ \cdot BPh_4^-]$$

which indicated that $[\{(\eta^5\text{-}C_5H_5)Ir(PPh_3)Me(CS)\}^+ \cdot I^-]$ is the likely initial product of MeI addition which produces $[\{(\eta^5\text{-}C_5H_5)Ir(PPh_3)I\{C(S)SMe\}\}^+ \cdot I^-]$.[96]

In polar solvents which can ligate the metal center, ionization of $[RhCl(CS)(PPh_3)_2]$ occurs. Thus, $[RhCl(CS)(PPh_3)_2]$ in MeOH or Et_2O reacts with phosphorus-donor ligands to form $[\{Rh(CS)L_n\}^+]$ isolated as the BPh_4^- or PF_6^- salts [$n = 3$; L = PMe_2Ph, PEt_2Ph or $PPh(OPh)_2$: $n = 4$; L = $PMePh_2$, $PPh_2(OMe)$, $PPh(OMe)_2$, $PPh(OEt)_2$ or $\frac{1}{2}$dppe].[97] Similarly, $[\{Ir(CS)(dppe)_2\}^+]$ results from $[IrCl(CS)(PPh_3)_2]$.[94]

Uson and co-workers have furthered the chloride removal chemistry, using $AgClO_4$ to abstract AgCl. Earlier work in the presence of acetone indicated that $[\{Rh(CS)(PR_3)_2(Me_2CO)_n\}^+ \cdot ClO_4^-]$ (R = Ph or Cy) results from $[RhCl(CS)(PR_3)_2]$.[98,99] For R = Ph, donor ligands displace acetone to give

$$[\{Rh(CS)(PPh_3)_2L\}^+ \cdot ClO_4^-]$$

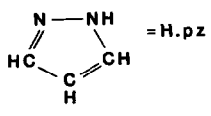
[monodentate L = py, 4-Et-py, 2-Et-py or PPh_3; bidentate L = bipy, phen or $o\text{-}C_6H_4(CN)_2$].[98] Without acetone, in CH_2Cl_2 solution,

$$[Rh(OClO_3)(CS)(PCy_3)_2]$$

is formed which converts to

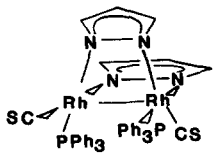
$$[\{Rh(CS)(PCy_3)_2(Me_2CO)\}^+ \cdot ClO_4^-]$$

reversibly on addition and removal of acetone.[92] This coordinated ClO_4^- is displaced by donor ligands yielding $[\{Rh(CS)(PCy_3)_2L\}^+ \cdot ClO_4^-]$ [monodentate L = py, 4-Me-Py, phthaln, $p\text{-}(MeO)C_6H_4CN$ or $o\text{-}ClC_6H_4CN$; bidentate L = bipy or phen] or dppe giving a mixture of $[\{Rh(CS)(dppe)_2\}^+]$ and $[\{Rh(CS)(PCy_3)(dppe)\}^+]$.[92] The mixed-phosphine species $[Rh(OClO_3)(CS)(PPh_3)(PCy_3)]$ and $[\{Rh(CS)(PPh_3)_2(PCy_3)\}^+ \cdot ClO_4^-]$ result from reacting $[RhCl(CS)(PPh_3)_2]$ and $AgClO_4$ with PCy_3 present.[92] These form the donor ligand adducts



$$[\{Rh(CS)(PCy_3)(PPh_3)L\}^+ \cdot ClO_4^-]$$

[L = py, bipy, phen, phthaln or $P(OPh)_3$] and



$$[\{Rh(CS)(PPh_3)_2L\}^+ \cdot ClO_4^-]$$

(L = py or bipy) respectively.

The pz ligands have been introduced to Rh-(CS) species by two routes (Fig. 16). The parent H · pz compound is illustrated (**16**). From $[RhCl(CS)(PR_3)_2]$ (R = Ph or Cy) and Na · L (L = pz or 3,5-Me_2-pz), $[Rh(CS)L(PR_3)_2]$ results, which is unstable when R = Ph and dimerizes to $[\{Rh(\mu\text{-}L)(CS)(PPh_3)\}_2]$ (**17**) with PPh_3 loss.[100] Using HL and $[\{Rh(CS)(PR_3)_2(Me_2CO)_n\}^+ \cdot ClO_4^-]$ gives

16

17

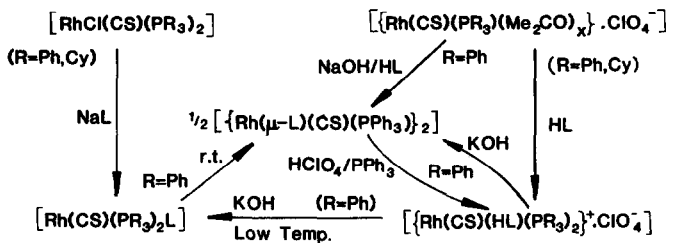


Fig. 16. Preparation and interconversions of Rh–CS–L systems (L = pyrazolate ligand).

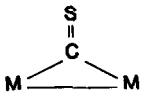
$[\{Rh(CS)(HL)(PR_3)_2\}^+ \cdot ClO_4^-]$ (R = Ph; L = pz, 3-Me-pz or 3,5-Me_2-pz: R = Cy; L = pz or 3,5-Me_2-pz) whereas use of NaOH–HL when R = Ph proceeds to the dimer (**17**).[99] Base treatment of $[\{Rh(CS)(HL)(PPh_3)_2\}^+ \cdot ClO_4^-]$ causes the dimer (**17**) to form, this reaction being reversed by $HClO_4$ and PPh_3.[99] The py-bridged mixed bimetallic $[\{(R_3P)_2(CS)Rh(\mu\text{-}L)Au(PPh_3)\}^+ \cdot ClO_4^-]$ is formed from $[\{Rh(CS)(PPh_3)_2(Me_2CO)_n\}^+ \cdot ClO_4^-]$ and [Au(pz)(PPh_3)].[99]



Turning to $[IrCl(CS)(PR_3)_2]$, other reactions include, when R = Ph, $[IrH(CS)(PPh_3)_3]$ formation using $NaBH_4$ and PPh_3,[31] 1 : 1 adducts with $[C_2(CN)_4]$ or fumaronitrile,[101] and 1 : *n* adducts with BX_3 (X = Cl or Br).[101] Attack by NO^+ yields $[\{IrCl(CS)(NO)(PR_3)_2\}^+]$ (R = Ph or Cy) and by CO gives $[\{Ir(CO)_2(CS)(PR_3)_2\}^+ \cdot Cl^-]$ (R = Ph or Cy), this product reacting with OMe^- forming [Ir(CO)(CS)$(PR_3)_2$(COOMe)] (R = Ph or Cy) or H_2 forming $[\{Ir(CO)_2(CS)(H)_2(PCy_3)_2\}^+ \cdot Cl^-]$.[94]

The only cobalt thiocarbonyl species which undergoes modification remote from the CS ligand is $[(\eta^5\text{-}C_5H_5)Co(PPh_3)(CS)]$. This forms adducts with HgX_2 (X = Cl or Br) in which there is a Co–Hg interaction.[23] Rhodium and iridium analogues are known.[96]

In summary, there are a large number of modification reactions of thiocarbonyl complexes. In a sense, it is the most prevalent synthetic method for terminal thiocarbonyl containing complexes. That other ligands are often substituted in preference to CS is indicative of its stability as a ligand. This point will be discussed further.

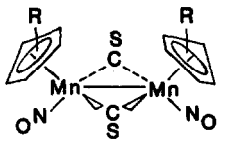
II.2. BRIDGING CS LIGANDS—PREPARATIVE METHODS

The thiocarbonyl ligand is known to bridge two metal centers in two ways, namely the thioketonic (μ-CS) (**18**) and linear (σ-C · σ-S) (**19**) bonding modes.

18

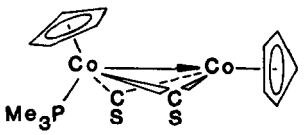
19

i. Linear bridging (σ-C · σ-S)



The few examples arise from reactions of *cis*-$[W(CO)(CS)(dppe)_2]$ with electrophilic metal compounds. The only case in which two transition-metal centers are linked is $[(dppe)_2(CO)W(\sigma\text{-}C \cdot \sigma\text{-}S)W(CO)_5]$ obtained by displacing acetone from $[W(CO)_5(Me_2CO)]$ on reaction with *cis*-$[W(CO)(CS)(dppe)_2]$.[70,73] This thiocarbonyl species also forms S-donor adducts to Ag^+ or HgX_2 (X = Cl or I) to give $[\{(dppe)_2(CO)W(\sigma\text{-}C \cdot \sigma\text{-}S)\}_2Ag^+]$ and $[(dppe)_2(CO)W(\sigma\text{-}C \cdot \sigma\text{-}S)HgX_2]$.[70,73] In all cases the sulphur donation is readily displaced by PPh_3 to regenerate *cis*-$[W(CO)(CS)(dppe)_2]$.[70,73] In the preceding section, it was noted that HgX_2 does not form adducts with other terminal CS complexes but rather shows M → HgX interactions,[23,86] oxidative addition giving (X)(HgX) ligands[95] or halide elimination forming an (HgX) ligand.[77]

From their work on these (σ-C · σ-S) species and on the reactivity of other $[L_nW(CS)]$ complexes with assorted electrophiles (see Section III.3.i),[70,73,74] Dombek and Angelici[70,73,74] suggested that a C—S stretching frequency, ν(CS), of below 1200 cm^{-1} is needed for sulphur donation to electrophiles. Thus, *cis*-$[W(CO)(CS)(dppe)_2]$, with ν(CS) at 1161 cm^{-1}, forms the linear bridging compounds, whereas *mer*-$[W(CO)_3(CS)(dppe)]$, with ν(CS) at 1215 cm^{-1}, does not. So, the ligand array must maintain a high electron density at the metal to encourage π-back donation to the CS ligand and make



the sulphur more nucleophilic for donation to electrophiles, when ν(CS) will be below 1200 cm^{-1}. This criterion is upheld in the formation of other CS sulphur adducts (see Sections II.3 and III.2).

ii. Thioketonic bridging (μ-CS)

(a) *Formation from monometallic compounds.* Syntheses mostly use terminal CS complexes as a starting material. Some reactions are a dimerization of sorts, with $[(\eta^5\text{-}C_5H_4R)Mn(NO)(CS)I]$ (R = H or Me) reacting with Zn dust to remove iodine and give $[\{(\eta^5\text{-}C_5H_4R)Mn(NO)(\mu\text{-}CS)\}_2]$ (**20**),[82] reduction of $[\{(\eta^5\text{-}C_5H_5)M(CO)_2(CS)\}^+]$ (M = Fe or Ru) by NaH causing CO loss in forming $[\{(\eta^5\text{-}C_5H_5)(CO)M(\mu\text{-}CS)\}_2]$ (M = Fe[102] or Ru[9]), and $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(CS)]$ and CH_2I_2 reacting to produce $[(\eta^5\text{-}C_5H_5)(PMe_3)Co(\mu\text{-}CS)_2Co(\eta^5\text{-}C_5H_5)]$ (**21**).[103] This cobalt compound results when $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(\eta^2\text{-}CSeS)]$ is allowed to stand in toluene solution,[6] the mechanism of formation being unclear for either route. An X-ray diffraction study showed a non-planar $Co_2(\mu\text{-}CS)_2$ core in which a Co → Co donor bond allows both centers to achieve an 18-electron configuration.[103]

20

21

On reacting $[\{(\eta^5\text{-}C_5H_5)Ru(CO)_2(CS)\}^+]$ with NaH, a secondary product is

$$[\{(\eta^5\text{-}C_5H_5)(CO)Ru\}_2(\mu\text{-}CO)(\mu\text{-}CS)].^9$$

Its iron analogue results in good yield from

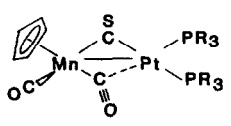
$$[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2\}^-Na^+]$$

and $[(PhO)_2CS]$ in 2:1 ratio through OPh^- elimination, with $[(\eta^5\text{-}C_5H_5)Fe(CO)_2\{CS(OPh)\}]$ produced with a 1:1 ratio.[85,104] In solution $[\{(\eta^5\text{-}C_5H_5)(CO)M\}_2(\mu\text{-}CS)(\mu\text{-}CE)]$ (M = Fe or Ru, E = O or S) all exist as interconverting mixtures of *cis-* and *trans*-isomers of $(\eta^5\text{-}C_5H_5)$ ligands about the M—M bond,[9,85,102,104] although crystal structures of both iron cases show the *cis*-isomer.[102,105]

Examples of heterobimetallic (μ-CS) complexes are made by reacting a terminal CS species with a metal complex from which a labile ligand is readily lost. The interaction of $[(\eta^5\text{-}C_5H_5)M(CO)_2(CS)]$ (M = Mn or Re) with $[Pt(PR_3)_2(C_2H_4)]$ displaces C_2H_4 to produce

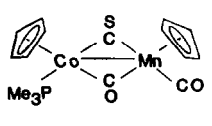
$$[(\eta^5\text{-}C_5H_5)(CO)_2M(\mu\text{-}CS)Pt(PR_3)_2]$$

(M = Mn, R_3 = Me_2Ph or $MePh_2$; M = Re, R_3 = Me_2Ph).[106,107] When M = Mn and R_3 = $MePh_2$, X-ray crystallography indicates a structure (**22**) with a semibridging CO which NMR spectroscopy indicates as the low-temperature solution structure for all cases. At higher temperatures, a fluxional process occurs involving bridge ⇌ terminal (CO)(CS) site exchange.[106,107]



In an equimolar reaction, $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(CS)]$ displaces THF from

$$[(\eta^5\text{-}C_5H_5)Mn(CO)_2THF)]$$



to give

$$[(\eta^5\text{-}C_5H_5)(PMe_3)Co(\mu\text{-}CS)(\mu\text{-}CO)Mn(CO)(\eta^5\text{-}C_5H_5)]$$ (**23**).[108]

Larger amounts of the Mn reagent lead to a sulphur-bound $(\eta^5\text{-}C_5H_5)Mn(CO)_2$ adduct of this product, which is displaced by PMe_3 to regenerate **23**.[108]

22

23

It is interesting to note that the terminal CS complexes used to form these heterobimetallic systems,[4,20] or some closely related analogues,[23] show ν(CS) above 1200 cm^{-1} and do not form stable linear (σ-C · σ-S) bridges, in line with the proposal of Dombek and Angelici[70,73,74] (see Section II.2.i). However, many of the bimetallic species with single (μ-CS) ligands do form sulphur-donor adducts to electrophilic centers and display ν(CS) below 1200 cm^{-1}, which is in agreement with the Dombek–Angelici proposal. This reactivity is discussed in Sections II.3.i and III.3.ii.

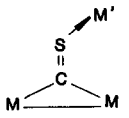
(b) *Carbonyl substitution reactions of* $[\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CS)(\mu\text{-}CE)]$ (E = O *or* S). Single carbonyl substitution in $[\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CO)(\mu\text{-}CS)]$ occurs under reflux conditions with 1–2 equivalents of certain ligands. In MeCN solvent, phosphine substitution yields

$$[\{(\eta^5\text{-}C_5H_5)Fe\}_2(CO)L(\mu\text{-}CO)(\mu\text{-}CS)]$$

[L = PEt_3, PMe_2Ph, $PMePh_2$ or $P(OMe)_3$] as a mixture of *cis-* and *trans-*(η^5-C_5H_5) isomers.[109] Isocyanide ligands substitute for CO and introduce the possibility of this ligand occupying a bridging position. Under benzene reflux, $[(\eta^5\text{-}C_5H_5)_2Fe_2(CO)_2(CS)(CNR)]$ (R = Me, Et, ^{i}Pr or ^{t}Bu) are formed which NMR spectroscopy shows to be present as interconverting (μ-CO)(μ-CS) and (μ-CNR)(μ-CS) isomers with both *cis-* and *trans-*(η^5-C_5H_5) ring orientations, the *cis-*$[\{(\eta^5\text{-}C_5H_5)Fe\}_2(CO)(CNR)(\mu\text{-}CO)(\mu\text{-}CS)]$ isomer being favoured increasingly as R becomes more bulky.[110] In refluxing THF, MeNC gives $[(\eta^5\text{-}C_5H_5)_2Fe_2(CO)_2(CS)(CNMe)]$, but in MeCN solvent the disubstituted product $[(\eta^5\text{-}C_5H_5)_2Fe_2(CO)(CS)(CNMe)_2]$ results, mostly as the (μ-CS)(μ-CNMe) isomer with a little of the (μ-CO)(μ-CS) isomer.[109] Introducing two MeNC ligands by UV irradiation is said to give only

$$[\{(\eta^5\text{-}C_5H_5)Fe\}_2(CO)(CNMe)(\mu\text{-}CS)(\mu\text{-}CNMe)].^{110}$$

Substitution of CO in $[\{(\eta^5\text{-}C_5H_5)(CO)Fe(\mu\text{-}CS)\}_2]$ by MeNC leads to the



$$[\{(\eta^5\text{-}C_5H_5)Fe(\mu\text{-}CS)\}_2(CO)(CNR)]$$

isomer.[110]

II.3. CS LIGANDS COORDINATED TO THREE OR MORE METAL CENTERS—PREPARATIVE METHODS

i. (μ-C · σ-S) *bonding*

This bonding mode links three metal centers (**24**), wherein the sulphur of a (μ-CS) ligand forms a donor bond to another metal center.

24

Quick and Angelici[111] identified both transition- and non-transition-metal adducts at the sulphur of

$$[\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CO)(\mu\text{-}CS)].$$

From a *cis–trans* mixture, the *cis-*(η^5-C_5H_5) adduct is favoured in the products

$$[\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CO)\{\mu\text{-}C\cdot\sigma\text{-}SML_n\}]$$

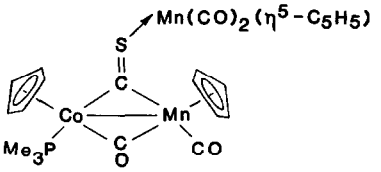
[ML_n = $M'(CO)_5$ (M' = Cr or W), $\{(\eta^5\text{-}C_5H_5)Fe(CO)_2\}^+$, HgX_2 (X = Cl, Br or I), $HgMe^+$], the labile Me_2CO or THF ligands having been displaced from the transition-metal compounds $[M'(CO)_5(Me_2CO)]$ and $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2(THF)\}^+ \cdot BF_4^-]$. Spectroscopic evidence was obtained for analogous adducts on reaction with BX_3 (X = F, Cl or Br), $AlCl_3$,

$$[Fe(CO)_4(THF)],\quad [Mo(CO)_5(Me_2CO)],\quad [W(CO)_4(CS)(Me_2CO)]$$

and

$$[\{M(CO)_5(MeCN)\}^+ \cdot PF_6^-]$$

(M = Mn or Re).[111] An earlier report indicated that some



$$[\{\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CO)\{\mu\text{-}C\cdot\sigma\text{-}SFe(CO)_2(\eta^5\text{-}C_5H_5)\}\}^+\cdot BF_4^-]$$

results when

$$[\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CO)(\mu\text{-}CS)]$$

is exposed to O_2 and HBF_4.[85]

When $[(\eta^5\text{-}C_5H_5)Co(PMe_3)(CS)]$ and two equivalents of $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(THF)]$ interact, the product is $[(\eta^5\text{-}C_5H_5)(PMe_3)Co(\mu\text{-}CO)\{\mu\text{-}C\cdot\sigma\text{-}SMn(CO)_2(\eta^5\text{-}C_5H_5)\}Mn(\eta^5\text{-}C_5H_5)(CO)]$ (**25**).[108] As

25

a 1:1 ratio yields $[(\eta^5\text{-}C_5H_5)(PMe_3)Co(\mu\text{-}CO)(\mu\text{-}CS)Mn(\eta^5\text{-}C_5H_5)(CO)]$ cleanly,[108] the 1:2 reaction seems likely to proceed via this compound.

ii. (μ_3-CS) *bonding and* (μ_3-C·σ-S) *derivatives*

One series of examples of the (μ_3-CS) ligand exists in $[(\eta^5\text{-}C_5H_5)_{3-x}(\eta^5\text{-}C_5H_4Me)_xCo_3(\mu_3\text{-}S)(\mu_3\text{-}CS)]$ (x = 0–3).[6,23,112,113] The various routes to $[\{(\eta^5\text{-}C_5H_5)Co\}_3(\mu\text{-}S)(\mu_3\text{-}CS)]$ are summarized in Fig. 17. The intermediacy of $[(\eta^5\text{-}C_5H_5)CoL(\eta^2\text{-}CS_2)]$ is indicated by its use as a starting material, and that in reactions between $[(\eta^5\text{-}C_5H_5)Co(CO)L]$ and CS_2 the yield of $[(\eta^5\text{-}C_5H_5)CoL(\eta^2\text{-}CS_2)]$ decreases and of the Co_3 species increases with reaction time.[23] The routes reported to

$$[(\eta^5\text{-}C_5H_5)_{3-x}(\eta^5\text{-}C_5H_4Me)_xCo_3(\mu_3\text{-}S)(\mu_3\text{-}CS)]$$

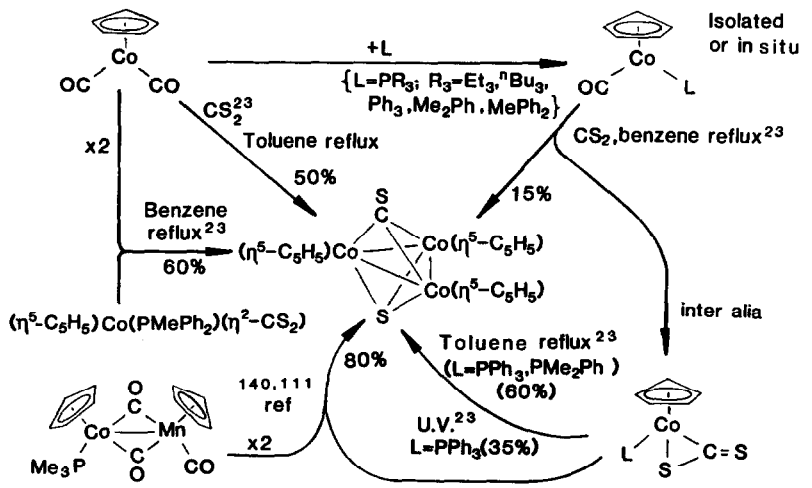
are the reflux in toluene of, for $x = 1$,

$$[(\eta^5\text{-}C_5H_4Me)Co(PMePh_2)(\eta^2\text{-}CS_2)] \quad \text{and} \quad [(\eta^5\text{-}C_5H_5)Co(CO)_2]$$

(1:2); for $x = 2$, use the reverse η^5 groups; and for $x = 3$, use $[(\eta^5\text{-}C_5H_4Me)Co(PPh_3)(\eta^2\text{-}CS_2)]$ alone.[23]

These (μ_3-CS) ligands can coordinate other metal centers via the sulphur. Thus,

$$[\{(\eta^5\text{-}C_5H_5)Co\}_3(\mu_3\text{-}S)(\mu_3\text{-}CS)] \quad \text{reacts with} \quad [Cr(CO)_5(THF)]$$



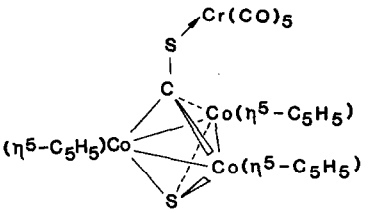


Fig. 17. The assorted reactions which give rise to $[\{(\eta^5\text{-}C_5H_5)Co\}_3(\mu_3\text{-}S)(\mu_3\text{-}CS)]$.

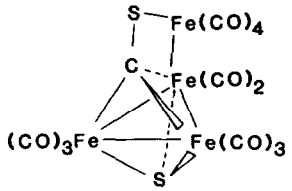
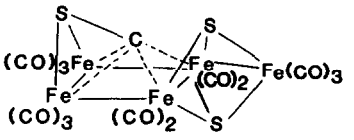
to give

$$[\{(\eta^5\text{-}C_5H_5)Co\}_3(\mu_3\text{-}S)\{\mu_3\text{-}C\cdot\sigma\text{-}SCr(CO)_5\}]$$

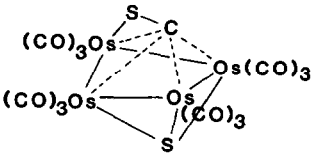


(**26**)[112,113] and forms Lewis acid–base pairs with $[ZnCl_2\cdot 2H_2O]$, $[CdI_2\cdot 2H_2O]$ or HgX_2 (X = Cl, Br or I)[23] as does Ag^+ with $[\{(\eta^5\text{-}C_5H_4Me)Co\}_3(\mu_3\text{-}S)(\mu_3\text{-}CS)]$.[23] Similar adducts to nonmetallic moieties are discussed in Section III.3.



26

iii. Other $M_4(CS)$ *interactions*



Three more ways are known for a CS ligand to interact with four metal atoms, the single examples of each characterized structurally by X-ray crystallography. The compounds are $[Fe_4(CO)_{12}(CS)S]$ (**27**)[50,114] containing a $(\mu_3\text{-}C\cdot\sigma\text{-}S)$ moiety, $[Fe_5(CO)_{13}(CS)S_2]$ (**28**)[50,115] with a $(\mu_4\text{-}C\cdot\mu_2\text{-}S)$ group and $[Os_4(CO)_{12}(CS)S]$ (**29**)[116] with a $(\mu_4\text{-}C\cdot\sigma\text{-}S)$ unit. The iron compounds are low-yield products of

27

28

29

the reaction of $[Fe_3(CO)_{12}]$ and excess CS_2 at elevated temperature under a modest CO–Ar pressure,[50,114,115] whereas an 8% yield of the osmium compound results from $[Os_6(CO)_{18}]$ and excess CS_2 at rather higher temperature and pressure.[116] For these clusters to be electron precise, the CS ligand formally donates four electrons in the Fe_4 and Os_4 cases but six in the Fe_5 example. This bonding is discussed more in Section IV.

III.1. REACTIVITY OF THE CS LIGAND

Modification reactions of CS complexes which do not involve the CS ligand were discussed in Sections II.1.v and II.2.ii. In this section, reactions occurring at the CS ligand are considered. This reactivity may be categorized into, firstly, CS substitution; secondly, attack by electrophiles at the CS sulphur; thirdly, nucleophilic attack at the CS carbon; fourthly, insertion reactions of the CS ligand; and lastly, the incidental reactions which do not correspond directly to these categories. Each category is discussed in turn.

III.2. SUBSTITUTION REACTIONS OF CS LIGANDS

There are few examples of displacement of a CS group from a metal center. The room-temperature reaction of $[(\eta^5\text{-}C_5H_5)Rh(PPh_3)(CS)]$ with the halogens X_2 (X = Cl, Br or I) causes CS elimination and $[(\eta^5\text{-}C_5H_5)Rh(PPh_3)X_2]$ is formed.[96] Addition of X_2 to $[\{Rh(CS)(PCy_3)_2(py)\}^+\cdot ClO_4^-]$ or $[RhCl(CS)(PCy_3)_2]$ gave spectroscopic evidence for CS ligand elimination, but the products were not characterized.[91] Treatment of $[\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CO)(\mu\text{-}CS)]$ with X_2 (X = Br or I) led to traces of $[(\eta^5\text{-}C_5H_5)Fe(CO)_2X]$, although a dimer cleavage is suggested rather than CS displacement as low amounts of $[(\eta^5\text{-}C_5H_5)Fe(CO)(CS)X]$ result also.[85] The porphyrin species [Fe(TPP)Cl] results from

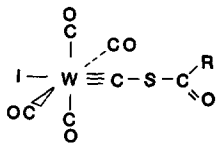
[Fe(TPP)(CS)] and $FeCl_3$.[62] One nonhalogen substitution involves $[Os_3(CO)_7(CS)H_2S_2]$ and PEt_3 when CS is smoothly replaced, the PEt_3 ligand in $[Os_3(CO)_7(PEt_3)H_2S_2]$ occupying the same position on the $M_3(\mu\text{-}S)_2$ core as the CS ligand had done (**11**).[117]

The lack of CS substitution reactions is indicative of the strength of the M–CS interaction. This is discussed in Section IV.

III.3. ELECTROPHILIC ATTACK AT CS SULPHUR

A subset of these reactions, discussed in Sections II.2 and II.3, has another metal center as the electrophile, receiving electron donation from the nucleophilic sulphur. Thus, examples of (σ-C · σ-S), (μ-C · σ-S) and (μ_3-C · σ-S) thiocarbonyl bonding result from terminal, μ_2 and μ_3-CS ligands respectively. Interactions with other electrophiles are now considered for terminal, (μ-CS) and (μ_3-CS) compounds. In many cases, the same compounds react which display reactivity with metallic electrophiles.

i. Terminal CS *ligands*



The electrophiles which interact with terminal CS ligands are R^+ (R = alkyl or acyl). Thus, $[\{Mo(CE)(CO)_2L\}^-]$ [E = S or Te, L = $HB(3,5\text{-}Me_2\text{-}C_3HN_2)_3$] with MeI gives

$$[Mo(\equiv CEMe)(CO)_2L].^{64}$$

Similarly, [*trans*-$\{W(CO)_4(CS)I\}^-$] and RX produces

$$\textit{trans}\text{-}[W(CO)_4(CSR)I] \ (RX = MeSO_3F \text{ or } Et_3O \cdot BF_4)$$

whereas acylation giving *trans*-$[W(CO)_4\{CSC(O)R\}I]$ (R = Me or CF_3) (**30**) is accomplished by acetic anhydride with BF_3 or trifluoroacetic anhydride alone.[73,74] Alkylation of *cis*-$[W(CO)(CS)(dppe)_2]$

30

produces [*cis*-$\{W(CO)(CSR)(dppe)_2\}^+X^-$] (R = Me or Et; X = SO_3F and BF_4, respectively), although CF_3SO_3H protonates at the tungsten.[73,74] With $MeSO_3F$,

$$[\{(\eta^5\text{-}C_5H_5)Co(PPh_3)(CSMe)\}^+]$$

results, although the weaker reagent MeI and the reactant $[(\eta^5\text{-}C_5H_5)Co(PPh_3)(CS)]$ do not react.[23] A double addition of MeI occurs to $[Ir(C_6F_5)(CS)(PPh_3)_2]$ producing

$$\textit{trans}\text{-}[Ir(C_6H_5)\{C(SMe)Me\}I_2(PPh_3)_2],$$

which was proposed to go through

$$[\{Ir(C_6H_5)(CSMe)(PPh_3)_2\}^+].^{95}$$

However,

$$[(\eta^5\text{-}C_5H_5)Ir(PPh_3)(CS)]$$

and MeI form

$$[\{(\eta^5\text{-}C_5H_5)Ir(PPh_3)I\{C(SMe)Me\}\}^+ \cdot I^-]$$

when the intermediates

$$[\{(\eta^5\text{-}C_5H_5)Ir(PPh_3)Me(CS)\}^+ \cdot I^-] \quad \text{and} \quad [(\eta^5\text{-}C_5H_5)Ir(PPh_3)I\{C(S)Me\}]$$

are proposed.[96]

Spectroscopic and structural data for the Mo and Co cases[23,64] indicate a large degree of carbyne character, M≡C-SR, to the metal–carbon interaction. In the Mo and W reactants, ν(CS) is below 1200 cm^{-1}, which Dombek and Angelici[70,73,74] suggested as a criterion for sufficient CS sulphur basicity to obtain electron pair donation. However, $[(\eta^5\text{-}C_5H_5)Co(PPh_3)(CS)]$ has ν(CS) at 1275 cm^{-1},[23] the only breakage of the suggested rule (including subsequent discussions).

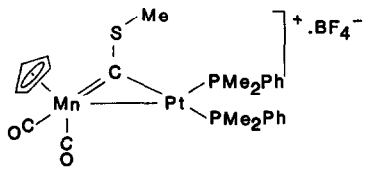
ii. Bridging (μ-CS) *ligands*

Some bimetallic species with one (μ-CS) ligand are alkylated or arylated at this sulphur. Both

$$[(\eta^5\text{-}C_5H_5)(PMe_3)Co(\mu\text{-}CO)(\mu\text{-}CS)Mn(CO)(\eta^5\text{-}C_5H_5)]$$

(23) and

$$[(\eta^5\text{-}C_5H_5)(CO)_2Mn(\mu\text{-}CS)Pt(PMe_2Ph)_2]$$



(22) are methylated, by $MeSO_3F$ and $Me_3O\cdot BF_4$, respectively, giving

$$[\{(\eta^5\text{-}C_5H_5)(PMe_3)Co(\mu\text{-}CO)(\mu\text{-}CSMe)Mn(\eta^5\text{-}C_5H_5)\}^+\cdot CF_3SO_3^-]^{108}$$

and

$$[\{(\eta^5\text{-}C_5H_5)(CO)_2Mn(\mu\text{-}CSMe)Pt(PMe_2Ph)_2\}^+\cdot BF_4^-]^{106,107}$$

(31). The (μ-CSMe) ligands are described as bridging methylthiocarbynes, although the CoMn case is drawn with delocalized bonding[108] and MnPt with localized [Mn=C(SMe)—Pt] bonding.[106,107] In

31

the latter, **31**, the CO ligands are terminal whereas one is semi-bridging in the reactant's limiting structure **(22)**.

A broader range of examples result from $[\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CO)(\mu\text{-}CS)]$ and organic halides, R.hal. The products

$$[\{\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CO)(\mu\text{-}CSR)\}^+]$$

were isolated, usually as PF_6^- salts, after using R.hal (R.hal = MeI, EtI, ^{n}PrI, ^{n}BuI, allyl.Br, $PhCH_2Br$ or EtO_2CCH_2Br), although $MeSO_3F$ or $Et_3O\cdot BF_4$ were also used.[104,109] Ligand exchange leads to

$$[\{(\eta^5\text{-}C_5H_5)_2Fe_2(CO)L(\mu\text{-}CO)(\mu\text{-}CSR)\}^+\cdot PF_6^-]$$

[L = PR'_3 or MeNC; R'_3 = Et_3, Me_2Ph, $MePh_2$ or $(OMe)_3$] which, for L = PEt_3 and R = $PhCH_2$, is accessible by $PhCH_2Br$ and PF_6^- treatment of

$$[(\eta^5\text{-}C_5H_5)_2Fe_2(CO)(PEt_3)(\mu\text{-}CO)(\mu\text{-}CS)].^{109}$$

Methylation of $[(\eta^5\text{-}C_5H_5)_2Fe_2(CO)(CS)(CNMe)_2]$ is reagent-dependent, an excess of MeI giving

$$[\{(\eta^5\text{-}C_5H_5)_2Fe_2(CNMe)(CO)(\mu\text{-}CNMe)(\mu\text{-}CSMe)\}^+]$$

but an excess of $MeSO_3F$ producing

$$[\{(\eta^5\text{-}C_5H_5)_2Fe_2(CNMe)(CO)(\mu\text{-}CNMe_2)(\mu\text{-}CSMe)\}^{2+}].^{109}$$

iii. Triply-bridging (μ_3-CS) *ligands*

The compounds $[\{(\eta^5\text{-}C_5H_4R)Co\}_3(\mu_3\text{-}S)(\mu_3\text{-}CS)]$ are alkylated by R'I to form

$$[\{\{(\eta^5\text{-}C_5H_4R)Co\}_3(\mu_3\text{-}S)(\mu_3\text{-}CSR')\}^+]$$

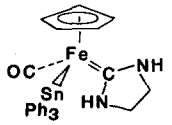
(R = H; R' = Me, Et or ^{i}Pr:[112,113] R = R' = Me[23]). Reacting $[\{(\eta^5\text{-}C_5H_5)Co\}_3(\mu_3\text{-}S)(\mu_3\text{-}CS)]$ with an equivalent of I_2 gives $[\{\{(\eta^5\text{-}C_5H_5)Co\}_3(\mu_3\text{-}S)(\mu_3\text{-}CSI)\}^+\cdot I^-]$.[23]

III.4. NUCLEOPHILIC ATTACK AT CS CARBON

Reactions have been reported only for terminal CS ligands which are classified by type of nucleophile.

i. Reactions with amines or amides

The reaction types observed are shown in Fig. 18. Primary amines, RNH_2, usually produce an isocyanide ligand through H_2S elimination. Examples, derived from the appropriate amine and terminal CS ligand, include $[W(CO)_5(CNR)]$ (R = Me, ^{n}Bu, ^{t}Bu, Cy, CH_2Ph or CH_2CO_2Et),[71] *cis*-$[W(CO)_4(PPh_3)(CNMe)]$,[71] $[Ir(C_6F_5)(CN\text{-}p\text{-tolyl})I_2(PPh_3)_2]$,[95] $[Fe(TPP)(^nBuNH_2)(CN^nBu)]$, which acquires an $^nBuNH_2$ ligand also,[62]



$$[(\eta^5\text{-}C_5H_5)Fe(CO)(CNMe)(SnPh_3)],^{85} \quad [\{(\eta^5\text{-}C_5H_5)Fe(CO)(CNR)(PR'_3)\}^+ \cdot PF_6^-]$$

(R = Me; R′ = Ph, Cy or C_6H_4F: R = Ph or Cy; R′ = Ph)[82] and $[Ru(CO)_2(CNR)Cl_2L]$ (L = CO; R = Ph, Cy or *p*-tolyl: L = PPh_3; R = Cy, *p*-tolyl or *p*-C_6H_4OMe).[54] Similarly,

$$[(\eta^5\text{-}C_5H_5)Fe(CO)(CS)(SnPh_3)]$$

and $H_2NCH_2CH_2NH_2$ eliminate H_2S, producing

$$[(\eta^5\text{-}C_5H_5)Fe(=\overline{CNHCH_2CH_2NH})(CO)(SnPh_3)] \ (\mathbf{32}).^{85}$$

32

The carbene {=C(SH)(NHR)} is a likely intermediate from which H_2S is eliminated. Evidence comes from the reaction of $[Fe(CO)_4(CS)]$ with $[C(NMe_2)_4]$ giving

$$[\{Fe(CO)_4\{C(S)NMe_2\}\}^- \cdot \{C(NMe_2)_3\}^+]$$

which then reacts with Me^+ forming the carbene-containing $[Fe(CO)_4\{C(SMe)NMe_2\}]$.[118]

Unlike its phosphine derivatives,[83] $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2(CS)\}^+]$ reacts with $MeNH_2$ eliminating H^+ and giving $[(\eta^5\text{-}C_5H_5)Fe(CO)_2\{C(S)NHMe\}]$, a reaction reversed by HCl.[119] Similarly, the secondary amine Me_2NH eliminates H^+ on reaction with $[\{PtCl(CS)(PPh_3)_2\}^+]$ and yields $[PtCl\{C(S)NMe_2\}(PPh_3)_2]$.[61]

Other reactions of secondary amines are $[W(CO)_5(CS)]$ with R_2NH [R = Me or $\frac{1}{2}(CH_2)_5$]. Here, the σ-thioaldehyde complexes $[W(CO)_5\{S{=}CH(NR_2)\}]$ result,[71] presumably through rearrangement of a $\{C(SH)(NR_2)\}$ carbene intermediate.

ii. Reactions with alcohols, alkoxides and water

Excepting the use of water, all examples display OR^- addition to the CS carbon. Thus, $[(\eta^5\text{-}C_5H_5)Fe(CO)_2\{C(S)OR\}]$ (R = Me or Et) results from $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2(CS)\}^+]$ and OR^-, a reaction reversed by HCl,[119] with the derivatives $[(\eta^5\text{-}C_5H_5)FeL_2\{C(S)OMe\}]$ [L_2 = (CO)(PPh_3) or $(CNMe)_2$] produced by OMe^- attack on the relevant precursors.[83] In EtOH solution, $[(CO)_4(CS)Fe$

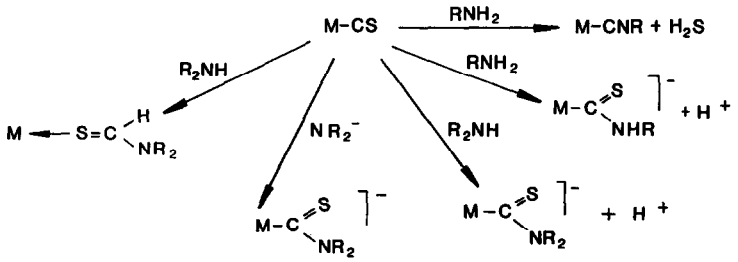


Fig. 18. The types of reaction known between terminal CS ligands and amines (1 and 2°) or amides (NR_2^-).

$\rightarrow HgCl_2$] liberates HCl to form [$(CO)_4Fe(HgCl)\{C(S)OEt\}$], which is obtained directly from [$Fe(CO)_4(CS)$] using $HgCl_2$ in EtOH.[86] Also, the cation [$\{PtCl(CS)(PPh_3)_2\}^+$] and MeOH react giving [$PtCl\{C(S)OMe\}(PPh_3)_2$].[61]

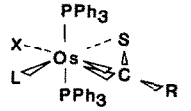
The conversion of a CS ligand to a CO ligand is achieved by H_2O in one case. When [$\{PtCl(CS)(PPh_3)_2\}^+$] and H_2O react, the product is [$\{PtCl(CO)(PPh_3)_2\}^+$]. The carbene group, $\{=C(SH)(OH)\}$, is proposed which eliminates H_2S to form the product.[61]

iii. The use of NCO^-, NCS^-, N_3^- *and* N_2H_4

Azide, N_3^-, converts CS ligands to NCS^- groups in five instances whereby [$\{(\eta^5\text{-}C_5H_5)M(CO)(CS)L\}^+$] (M = Fe[119] or Ru[9], L = CO; M = Fe,[83] L = PPh_3 or PCy_3) or [$W(CO)_5(CS)$][71] are transformed into [$(\eta^5\text{-}C_5H_5)M(CO)L(NCS)$] or [$\{W(CO)_5(NCS)\}^-$]. Initial formation of a $\{C(S)N_3\}^-$ group is proposed, losing N_2 and rearranging to the NCS^- unit.[117] The same iron reactants give [$(\eta^5\text{-}C_5H_5)Fe(CO)L(NCS)$] (L = CO,[117] PPh_3[83] or PCy_3[83]) on reaction with hydrazine when H^+ elimination is proposed to give a $\{C(S)\cdot NHNH_2\}$ intermediate which loses NH_3 and rearranges to the product.[119]

Although NCO^- might react like N_3^- with the elimination of CO rather than N_2, both NCO^- and NCS^- take a different path on reaction with [$\{(\eta^5\text{-}C_5H_5)M(CO)_2(CS)\}^+$] (M = Fe or Ru). The products, [$(\eta^5\text{-}C_5H_5)M(CO)_2(CN)$] (M = Fe[119] or Ru[9]), result by CSE (E = O or S) loss from the initially formed [$(\eta^5\text{-}C_5H_5)M(CO)_2\{C(S)\cdot NCE\}$].

iv. Reactions with EH^- (E = S *or* Se)



When [$\{MCl(CS)(CO)(CNR)(PPh_3)_2\}^+$] (M = Ru or Os, R = *p*-tolyl) and EH^- (E = S or Se) react, HCl is eliminated and (η^2-CS_2), (η^2-CSSe) or (η^2-CSNR) ligands are obtained. The products are dependent on M and E, so that SeH^- gives both (η^2-CS·Se) and (η^2-CSe·S) coordination isomers for M = Ru, but only (η^2-CSe·S) for M = Os in [$M(\eta^2\text{-}CSSe)(CO)(CNR)(PPh_3)_2$].[13] However, when M = Os, SH^- gives mostly [$Os(\eta^2\text{-}CS\cdot NR)(CO)(CS)(PPh_3)_2$] with some [$Os(\eta^2\text{-}CS_2)(CO)(CNR)(PPh_3)_2$].[89] These reactions are also discussed in Sections II.1.i and v. The mechanism may involve EH^- attack at the CS carbon followed by HCl elimination, although EH^- could substitute for Cl^- giving [$\{M(EH)(CS)(CO)(CNR)(PPh_3)_2\}^+$] which undergoes intramolecular rearrangement with H^+ loss. The former route could lead to all products but the latter could not give (η^2-CS·Se) connectivity from SeH^- attack without further rearrangement.

v. Reactions with other nucleophiles

Reaction of $NaBH_4$ with [$\{IrCl_2(CO)(CS)(PPh_3)_2\}^+$] gives [$IrCl_2(CO)(CHS)(PPh_3)_2$].[120] Formation of the thioformyl group by direct H^- attack at the CS carbon is likely as the Ir reactant has an 18-electron configuration and there is no other change in the ligand array.

III.5. INSERTION REACTIONS OF CS LIGANDS

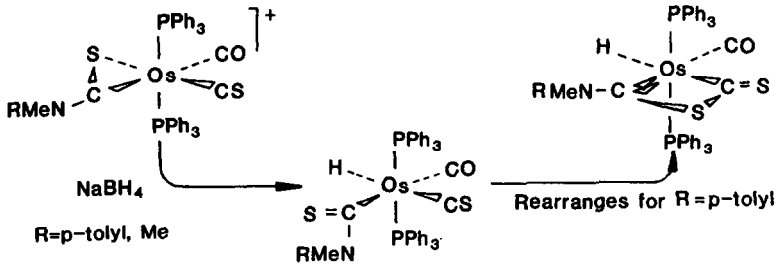
Examples have been almost exclusive to osmium complexes. Insertion of CS into the Os—aryl bond of [$OsRX(CS)L(PPh_3)_2$] (R = *p*-tolyl: L = CO; X = Cl, Br, I or σ-O_2CCF_3: L = RNC; X = Cl: L = *p*-ClC_6H_4CN; X = O_2CCF_3) on warming produces an η^2-thioacyl ligand in [$OsXL(\eta^2\text{-}CS\cdot R)(PPh_3)_2$] (**33**).[91] Further reactivity of these compounds was demonstrated.[91]

(For L,X,R-see text)

33

On treatment of [$\{Os(CO)(CS)(\eta^2\text{-}CS\cdot NMeR)(PPh_3)_2\}^+$] (R = Me or *p*-tolyl) with $NaBH_4$,

[$Os(CO)(CS)H\{\sigma\text{-}C(S)\cdot NMeR\}(PPh_3)_2$]



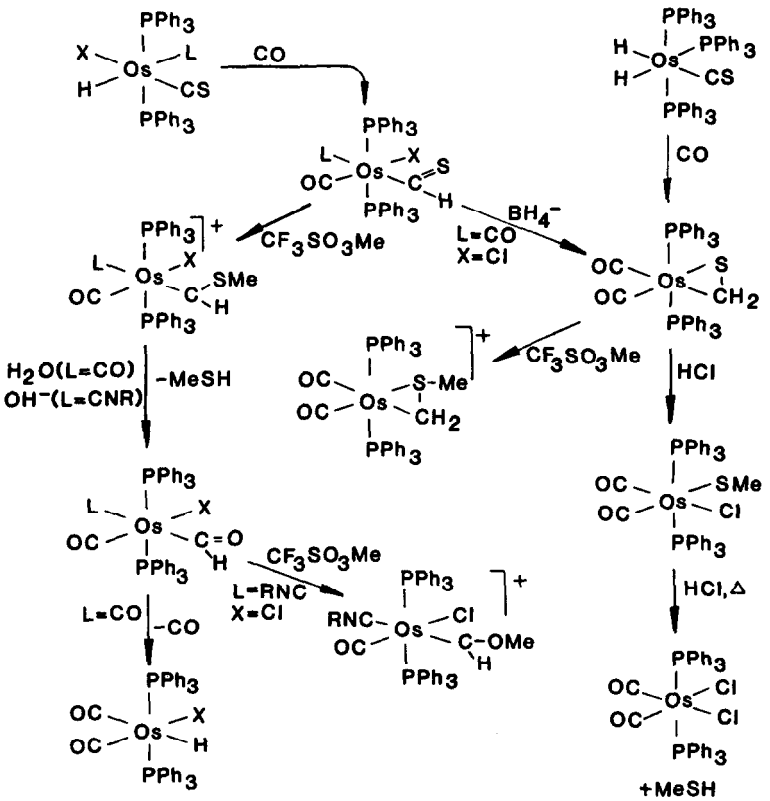


Fig. 19. The reaction of $[\{Os(CO)(CS)(\eta^2\text{-}CS\cdot NMeR)(PPh_3)_2\}^+]$ (R = Me or *p*-tolyl) with $NaBH_4$.

results. When R = *p*-tolyl, thermal rearrangement yields

$$[\overline{Os\{=C(NMeR)\cdot S\cdot C(S)\}}(CO)H(PPh_3)_2]$$

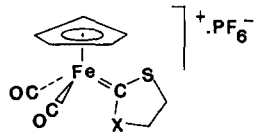
through CS insertion (Fig. 19).[89]

Elevated CO pressure induces CS insertion to the Os–H bond in various compounds. For $[Os(CS)L(H)X(PPh_3)_2]$ (X = Cl; L = PPh_3, CO or CN-*p*-tolyl: X = Br; L = PPh_3 or CO), 40 psig of CO gives $[Os(CHS)(CO)LX(PPh_3)_2]$ (L = CO or CN-*p*-tolyl: when L = PPh_3, CO substitutes).[90] When X = Cl and L = CO, BH_4^- converts the σ-thioformyl ligand to $(\eta^2\text{-}CH_2S)$ forming $[Os(CO)_2(\eta^2\text{-}CH_2S)(PPh_3)_2]$, but this product is accessible also by CO treatment (4 atm, 140°C) of $[Os(CS)H_2(PPh_3)_3]$ when a double insertion occurs.[90] Scheme 6 shows this and some subsequent chemistry, including the remaining steps in CS ligand conversion to MeSH. The cluster species $[Os_3(CO)_7(CS)H_2S_2]$ under CO pressure forms the thioformyl species $[Os_3(CO)_8H(CHS)S_2]$, which also displays reactivity at the (CHS) ligand.[117] The insertion reactions are especially relevant as these comprise thio-analogues of some of the first steps possible in the catalyzed reduction of CO by H_2, especially for MeOH production.

Scheme 6. Reaction pathways using CS insertion to Os–H bonds.

The one nonosmium system is an insertion reaction by inference when $[Ir(CS)H(PPh_3)_3]$ is converted into $[Ir(SMe)H_2(PPh_3)_3]$ under H_2 pressure.[120] Roper and Town[120] proposed that sequential insertion steps occur to Ir–H bonds derived by the oxidative addition of H_2 which are analogous to the characterized osmium sequence. Reaction of $[Ir(SMe)H_2(PPh_3)_3]$ with HCl forms $[IrCl(PPh_3)_3]$ and MeSH, completing the reduction of a CS ligand to MeSH.[120]

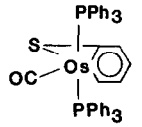
III.6. OTHER REACTIONS AT CS LIGANDS



These reactions do not fit obviously into the preceding categories.

Sequential addition of MeLi and Me_3O^+ to $[W(CO)_5(CS)]$ results in low yields of $[W(CO)_5(SMe_2)]$ by an uncertain mechanism.[71] Also at tungsten, LiPh reacts with $[(\eta^5\text{-}C_5H_5)W(CO)(CS)(PPh_3)I]$ eliminating LiI to produce $[(\eta^5\text{-}C_5H_5)W(CO)(CSPh)(PPh_3)]$ in which a carbyne interaction $\{W{\equiv}CSPh\}$ is indicated.[76] Formally, this is nucleophilic attack by Ph^- at the CS sulphur, although a less simple mechanism may operate.

Electrochemical studies of $[Fe(TPP)(CS)]$ show spectroscopic evidence for the reversible conversion by H^+ of $[\{Fe(TPP)(CS)\}^-]$ and $[\{Fe(TPP)(CS)\}^{2-}]$ into $[Fe(TPP)(CHS)]$ and $[\{Fe(TPP)(CHS)\}^-]$.[87,88] The di-iron species, $[\{(\eta^5\text{-}C_5H_5)(CO)Fe\}_2(\mu\text{-}CO)(\mu\text{-}CS)]$, is cleaved by Na–Hg to give $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2\}^-]$ and $[\{(\eta^5\text{-}C_5H_5)Fe(CO)(CS)\}^-]$,[85] and less cleanly by X_2 (X = Br or I) when traces of $[(\eta^5\text{-}C_5H_5)Fe(CO)_2X]$ and $[(\eta^5\text{-}C_5H_5)Fe(CO)(CS)X]$ are obtained.[85]



Interacting $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2(CS)\}^+ \cdot PF_6^-]$ with $[\overline{XCH_2CH_2}]$ (X = NH or S) in the presence of Br^- leads to $[\{(\eta^5\text{-}C_5H_5)Fe(=\overline{C \cdot S \cdot CH_2CH_2X})(CO)_2\}^+ \cdot PF_6^-]$ (**34**).[121] It was proposed that Br^- opens the aziridine or thiirane ring either before or after coordination of X at the CS carbon.[121] However, other mechanisms may operate such as a nucleophilic ring opening by CS sulphur.

An osmabenzene ring is derived from two C_2H_2 molecules, a CS ligand and an osmium atom when C_2H_2 reacts with $[Os(CO)(CS)(PPh_3)_3]$ to give $[\overline{Os\{CH(CH)_3CS\}}(CO)(PPh_3)_2]$ (**35**).[122]

35

IV.1. BONDING, SPECTROSCOPIC AND STRUCTURAL PROPERTIES OF CS COMPLEXES

In most discussions of the physicochemical properties of the CS ligand comparisons are made to the carbonyl ligand. The deliberate spectroscopic studies have focussed upon the CS ligand when bonded terminally. For other bonding modes, some observations have been made from the available data which, although valid, are not as wide ranging as those for terminal CS coordination.

This section begins by summarizing the conclusions reached concerning CS bonding to metal centers. A discussion follows of the data derived by each analytical technique, of how these lead to the conclusions on CS bonding and of some other trends which may be noted. In the appendices, ν(CS) IR and ^{13}C NMR data are tabulated where they have not been compiled beforehand.

IV.2. THE NATURE OF CS COORDINATION—A SUMMARY

In broad terms, the terminal CS ligand interacts with a metal center analogously to CO. There is σ-donation of electrons from a filled non-bonding orbital located at the carbon to a vacant metal orbital of σ-symmetry and π-acceptance by a vacant π^* CS orbital from a filled metal orbital of π-symmetry. The M–C–S interaction is linear, the bonding synergic and the ligand π-acid in character.[3,123]

Detailed comparison of the M–CO and M–CS interactions reveals differences. The bonding orbitals of CS π-bonding are sufficiently unstable and high in energy that an appreciable π-donation to

the metal may occur.[124,125] The σ-donor and π-acceptor ability of CS are deemed better than those of CO,[126] but the contribution of the π-donor interaction in tying up metal *d*-orbital electron density should be noted.[125] Overall, this leads to a stronger M–C interaction for M–CS over M–CO.[123] These interactions allow CS to show a "charge-buffering effect" as it can donate and accept more or less electrons as the ligand sphere around the metal is altered.[75,123] As a result, the π-acceptor: $(\pi+\sigma)$-donor ratio is wider for CS than for CO and varies to either side of it, an effect manifested in the range of C–S bond lengths.[123] These effects should be more marked for CSe ligands, although the biggest difference is between CO and CS.[126]

The μ_2- and μ_3-CS ligands show increasingly weaker C–S bonding which, by analogy to CO, may be attributed to increasing back donation to the CS π^*-orbitals. In the μ_2-C · σ-S, μ_3-C · σ-S, μ_4-C · σ-S and μ_4-C · μ-S bonding modes when four or six electrons are donated formally, weaker C—S bonding is indicated. However, when the sulphur coordination is to metal atoms also attached to the carbon, a comparison to similar CO ligands suggests independent M_n–C, M_n–S and C–S interactions with a more extensive loss of the weaker $p\pi$–$p\pi$ bonding in CS.[116] For the CO cases, a retention of CO π-bonding and η^2-type interactions of this with metal centers is in evidence.[116]

IV.3. THEORETICAL STUDIES

Richards' *ab initio* calculations on CS and CO suggest that CS should be a more stable ligand.[127] The HOMO for CS, the 7σ orbital, constitutes the σ-donor lone pair at carbon and is largely antibonding and *C2p* in character. The corresponding orbital in CO, 5σ, is of lower energy and the electrons are less available for σ-donation, suggesting that CS should be the better σ-donor. Conversely, the CS LUMO, the 3π level, is the π-accepting π^* CS orbital and is of lower energy than the corresponding CO 2π level. This indicates that CS should be a more effective π-acceptor. Indeed, calculation at elongated equilibrium bond lengths for CS and CO, closer to those observed when the moieties are ligating, indicate little effect on donor ability but a marked drop in CS LUMO energy which would favour its π-accepting properties.

Lichtenberger and Fenske[124] performed MO calculations in conjunction with photoelectron spectroscopy (PES) studies on $[Cr(CO)_5(CS)]$ and $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(CS)]$ and the tricarbonyl analogues. Although the absolute energy values for calculation and experiment do not agree, the ordering of occupied levels assigned is the same. Generally, results agree with those of Richards. The slightly better σ-donation of CS occurs because sulphur's lower electronegativity over oxygen leaves more charge at carbon and the better π-acceptor ability of CS. These destabilize the 7σ lone pair over the 5σ in CO. The better π-acceptance by CS results from the smaller metal *3d*-ligand π^* separation as the orbital overlap in both CO and CS cases is comparable. However, the *e* set of orbitals arising from this *3d*–π^* interaction is calculated at slightly higher energy than the non-interacting *3d*-derived b_2-orbital. This results from *3d* interaction with the filled CS 2π-orbitals offsetting the *e*-set stabilization, but the combined π-donor and π-acceptor interactions strengthen M–C and weaken C–S bonding.[124] This pair of effects explains both Raman and ^{13}C NMR observations (see Sections IV.8 and 9).[124] The metal (*d*)–CS (2π) interaction is mostly of *d*-orbital character in its filled antibonding combination and is more favourable than the *d*-orbital itself for interaction with the π^* set on CS, whereas the *d*-orbital electron density in the largely ligand character bonding combination is unavailable through this orbital's stability. These interactions cause a removal of metal *d*-orbital electron density to orbitals with much less *d*-character.[125] For CO the filled bonding π-orbitals are too stable to indulge in these interactions and, hence, none of the effects are manifested.[123,124]

Other *ab initio* calculations[126] agree with Richards' work. In $[(\eta^6\text{-}C_6H_5CO_2Me)Cr(CO)_2(CE)]$ (E = O, S or Se), the σ-donor and π-acceptor ability of CE increases from CO to CSe, the σ-donor and π-acceptor orbitals being calculated to increase and decrease in energy respectively. The increasing σ-donation is said to be mitigated by the decreasing localization of this orbital at the carbon. The calculations were rationalized against spectroscopic and structural data for the complexes.[126]

Lichtenberger and Fenske noted that, whereas nucleophiles react at the CS carbon, their calculations suggest an increasing electron density at this carbon over the less reactive CO ligand. They suggest that the attack is "lumophilic" and that the reaction is frontier orbital controlled, the HOMO being the nucleophile lone pair and the LUMO in the CS complex is an antibonding CS π^*-orbital.[124]

IV.4. PHOTOELECTRON SPECTROSCOPY STUDIES

Studies are limited to $[M(CO)_5(CS)]$ (M = Cr or W), $[(\eta^6\text{-}C_6H_6)Cr(CO)_2(CE)]$ (E = S or Se) and $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(CS)]$, probably as these are relatively volatile and, therefore, lend themselves to the technique. Comparisons are made to the carbonyl analogues.

For $[M(CO)_5(CS)]$ (M = Cr or W),[128] the $C(1s)$ binding energy is some 2 eV lower than for $[M(CO)_6]$. This is attributed to the lower sulphur electronegativity, indicates a higher carbon electron density for CS and suggests a stronger σ-donation by CS. The lack of difference in the rest of the PES spectra of $[M(CO)_5(CE)]$ (E = O or S) indicated increased π-back donation to CS so that other electron distributions are unaffected. A suggestion that the CO O(1s) and CS $S(2p_{3/2})$ binding energies provide a measure of metal π-back donation is backed by the correlation of this value with the respective stretching force constant, k, for the CO or CS bond.[128]

The high-energy bonding orbital of $[M(CO)_5(CS)]$ (M = Cr or W) and $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(CS)]$ were probed by He(I) photoelectron spectroscopy.[124] Binding energies at 8–9 eV derive from electrons in the largely metal d-character e- and b_2-levels, at about 11 eV from a CS (7σ) derived orbital, and at some 12 eV from a level derived largely from the CS (2π) level. From the relative ionization cross-sections of bands in $[M(CO)_5(CS)]$ (M = Cr or W) discrepancies between the 7σ and 2π-derived levels suggest different metal character of these orbitals, the 7σ derived having more. That the CS (2π) derived orbital has metal character indicates its interaction with metal orbitals. The many peaks at 13–17 eV derive from the σ- and π-levels of other ligands.

For $[(\eta^6\text{-}C_6H_6)Cr(CO)_2(CE)]$ (E = O, S or Se), the first ionization potential increases on going from CO to CSe[129] unlike $[Cr(CO)_5(CE)]$.[124,129] Also, the binding energies are some 1 eV lower for the $[(\eta^6\text{-}C_6H_6)Cr(CO)_2(CE)]$ series. A significant ring to chromium electron transfer is inferred.[129]

IV.5. ELECTRONIC OR UV–VIS SPECTROSCOPY

Only $[Cr(CO)_5(CE)]$ and $[(\eta^6\text{-}C_6H_6)Cr(CO)_2(CE)]$ (E = O, S or Se) have been studied, the data indicating more electron withdrawal by CE from CO to CSe.[130] An energy level diagram constructed for $[Cr(CO)_5(CE)]$ is shown (Fig. 20) and assignments of electronic transitions were made from the gas

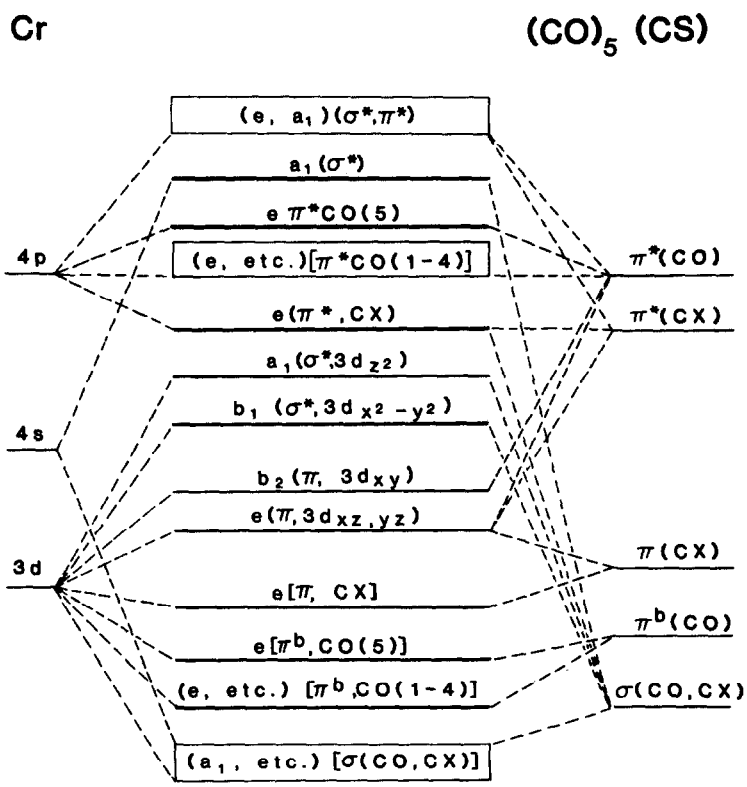

Fig. 20. A molecular orbital diagram for $[Cr(CO)_5(CS)]$.

phase or solution spectra. Increasing π-acceptor ability of CE from CO to CSe was deduced from the increasing energy of the lowest energy M → CO (π^*) charge-transfer band (36,000 → 36,600 cm^{-1}), although the high-energy bands do not adhere to this; from the increasing energy of the M → *trans*-CO (π^*) transition; and from the decreasing energy of the M → CE charge-transfer band ($b_2 \rightarrow e$ levels) backed by the greater intensity for CSe indicating a greater transition probability. However, a $[Cr(CO)_5(CS)]$ photoelectron spectrum indicates different energy differences for the M–CE charge transfer.[124] Two $d \rightarrow d$ transitions are observed ($b_2 \rightarrow b_1$, $e \rightarrow b_1$ or $e \rightarrow a_1$) out of the four possible ($b_2 \rightarrow b_1$, $b_2 \rightarrow a_1$, $e \rightarrow b_1$ or $e \rightarrow a_1$), at 27,000 and 24,000 cm^{-1}. Spectra of $[(\eta^6\text{-}C_6H_6)Cr(CO)_2(CE)]$ are comparable (with additional ring–Cr bands) although some discrepancy of the absolute energy of the HOMOs occurs from PES results.[129]

IV.6. MASS SPECTROSCOPIC STUDIES

As CO ligands are usually "lost" before CS in mass spectral fragmentation patterns, the M–CS linkage appears to be stronger. Some examples include $[(\eta^5\text{-}C_5H_4R)Mn(CO)_2(CS)]$ (R = H or Me),[131] $[Cr(CO)_5(CS)]$,[57] $[(\eta^6\text{-}C_6H_5CO_2Me)Cr(CO)(CS)L]$ [L = CO, $P(OEt)_3$ or $P(OPh)_3$],[2] $[Os_3(CO)_8(CS)S_2]$,[51] $[Os_3(CO)_7(CS)S_2(\mu\text{-}H)_2]$[52] and $[(\eta^5\text{-}C_5H_4Me)Mn(CO)(CS)L]$ (L = $AsPh_3$ or $SbPh_3$).[132] In the last case, the later loss of ligand L suggests that the Mn–As or Mn–Sb bonds are stronger.[132] The NO ligand is less enduring than CS in $[\{(\eta^5\text{-}C_5H_4R)Mn(NO)(\mu\text{-}CS)\}_2]$.[82]

Appearance potential data for $[(\eta^5\text{-}C_5H_4R)Mn(CO)_2(CS)]$ (R = H or Me) was used to suggest that CO is a better π-acceptor ligand and CS primarily a σ-donor,[131] an interpretation which has been questioned.[2,3] These arguments used only the σ-donor : π-acceptor ratio without reference to any π-donor effect of CS. Indeed, $[(\eta^6\text{-}C_6H_5CO_2Me)Cr(CO)(CS)L]$ [L = CO, $P(OEt)_3$ or $P(OPh)_3$] results were interpreted as showing better CS σ-donor and π-acceptor ability than CO.[2] Such differences may be explained by Andrews' "charge-buffering" concept.[123]

IV.7. MÖSSBAUER SPECTROSCOPY

In the compounds $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2L\}^+]$ (L = CO, CS, PPh_3, CN^-, NCO^-, NCS^- or Br^-), the electron density at iron increases in the order $Br^- < NCS^- < NCO^- < PPh_3 < CN^- < CO < CS$, suggesting CS as the best π-acceptor.[133] The iron electron density is augmented by σ-donation, increasing *s*-level electron density, and by π-acceptance, which decreases the shielding *d*-orbital electron density. As the π-accepting ligands increase iron's electron density most, π-acceptance is implied as the dominant effect.[133] The good σ-donor characteristics of CS over CO[123] and any Fe(3*d*)–CS(2π) interaction[125] will also contribute to these effects, the former in a σ-donor sense and the latter because this interaction augments the removal of *d*-orbital electron density by CS from the metal.

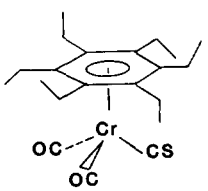
IV.8. ^{13}C NMR STUDIES

The ^{13}C NMR chemical shifts for CS ligands which have been reported are gathered in Appendix 1. These resonances occur at a lower field than their CO counterparts[2,3] generally in the range observed for metal–carbene species.[134] This suggests the importance of a carbenoid resonance form in the M–CS interaction in support of the proposal for a strong metal–carbon interaction,[124] although Yaneff suggested the importance of the polar resonance structure $M—C^+{=}S^-$.[3] Inspection of the appended data shows a range for terminal CS ligands of 286–442 ppm and for μ-CS ligands of 353–396 ppm. No data are reported for other bonding modes.

The effect of CS on other ^{13}C NMR chemical shifts has been considered. Bodner investigated the ^{13}C chemical shifts of two CO ligands in $[\{(\eta^5\text{-}C_5H_5)Cr(CO)_3\}^-]$, $[(\eta^5\text{-}C_5H_5)Mn(CO)_2L]$ [L = CS, CO, $P(OPh)_3$, $P(OMe)_3$, PPh_3, P^nBu_3, $C_5H_{10}NH$ or C_8H_{14}] and $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2L\}^+]$ (L = CS, CO, PPh_3 or NH_3).[135] The ^{13}C chemical shift of CO is deshielded more as π-acceptance by CO increases due to higher metal electron density. Deshielding is least when L = CS, indicating that, of the ligands L, CS most effectively reduces metal electron density. Hence, CS was deemed to have the highest π-acceptor : σ-donor ratio of these ligands.[135] For

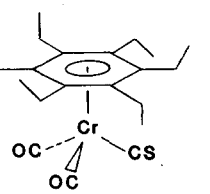
$$[\{(\eta^5\text{-}C_5H_5)Fe(CO)(CS)L\}^+ \cdot PF_6^-] \text{ [L = CO, } PPh_3\text{, } P(C_6H_4F)_3 \text{ or } PCy_3\text{]},$$

$$[\{(\eta^5\text{-}C_5H_5)Fe(CS)(CNPh)_2\}^+ \cdot PF_6^-] \quad \text{and} \quad [\{(\eta^5\text{-}C_5H_5)Fe(CO)(PPh_3)_2\}^+ \cdot PF_6^-]$$



the CS ^{13}C chemical shift is similarly influenced as ligand L changes, indicating that iron electron density reduces in the order CNPh < PCy_3 < PPh_3 < $P(C_6H_4F)_3$ < CO.[83]

The very low field ^{13}C chemical shift of CS in [(η^5-C_5H_5)Mn(CO)$_2$(CS)] indicates a high positive charge at carbon and a prevalent M—$^{\delta+}$C=S$^{\delta-}$ resonance structure is suggested, which was related to Raman spectroscopy data.[136] The CE ^{13}C chemical shifts for [(η^6-C_6H_5R)Cr(CO)$_2$(CE)] (R = H or CO_2Me), [(η^5-C_5H_4R')Mn(CO)$_2$(CE)] (R' = H or Me) and [(η^5-C_5H_5)Re(CO)$_2$(CE)] (E = O, S or Se) suggest that the π-acceptor : σ-donor ratio increases from CO to CSe.[137] Downfield movement of ring resonances indicates decreased metal electron density, and increased carbonyl carbon shielding agrees with Bodner's arguments for increasing electron acceptance from CO to CS,[135] which continues with CSe. Changes in the metal or ring substituent affect the CO, CS and CSe ^{13}C resonance similarly, indicating related bonding criteria for these ligands.[137] Thus, substituting NO^+ for CO in [(η^5-C_5H_5)Mn(CO)$_2$(CE)] or going from manganese to rhenium analogues shows upfield chemical shift changes.[137]



The downfield shift of CE from CO to CSe can be rationalized[137] by Pople's ^{13}C paramagnetic shielding expression.[138] Shielding is reciprocally related to the average electronic excitation energy, ΔE_{av}, which for CE is said to approximately equal the π–π^* energy difference which decreases from CO to CS, and probably also to CSe.[137]

The compounds *cis*- and *trans*-[W(CO)$_4$(CS)L] (*cis*- and *trans*-L = CO, 4-Me-py, CyNC or PR_3; R = Ph, ^{n}Bu, *p*-tolyl, OMe or OPh : *trans*-L = Cl^-, Br^- or I^-) have ^{13}C CS chemical shifts near 300 ppm which correlate well with CE (E = O or S) bond force constants, k_{CE}.[75] For *cis*-CO in *trans*-[W(CO)$_4$(CS)L] and CS in *cis*-[W(CO)$_4$(CS)L], k decreases linearly as $\delta(^{13}C)$ increases, and a method for calculating δ(CO) in other [W(CO)$_4$(CS)L] systems was proposed.[75] In *cis*-[W(CO)$_4$(CS)L], δ(CS) varies more than δ(CO) of the *trans*-CO ligand, suggesting that CS "buffers" CO against the electronic effects of altering the ligand L, with both δ(CS) and δ(CO) moved downfield by increased metal electron density.[75]

Controversy has arisen over the interpretation of the ^{13}C NMR spectrum of [(η^6-C_6Et_6)Cr(CO)$_2$(CS)]. McGlinchey *et al.*[39] infer slow tripodal rotation on the NMR time scale at low temperature with a 1,3,5-*distal*-2,4,6-*proximal* η^6-C_6Et_6 structure (**36**), as is observed in the solid state. Reinterpreting this data, Hunter and Mislow[139] prefer a 1,2,3,5-*distal*-4,6-*proximal* isomer (**37**), which

36

37

still undergoes rapid tripodal rotation, fluxional behaviour being explained by ethyl group *distal*, *proximal* exchange. Reaffirming their proposal, McGlinchey *et al.*[140] offered a more detailed spectral interpretation backed by a solid-state ^{13}C spectrum which is comparable to the limiting-solution spectrum, indicating that the same structure is present.

IV.9. RAMAN SPECTROSCOPIC STUDIES

As part of complete vibrational spectroscopic characterizations, Raman spectroscopy studies exist for [M(CO)$_5$(CE)] (M = Cr or W, E = S or Se), [(η^5-C_5H_5)Mn(CO)$_2$(CE)] (E = O or S) and [(η^6-C_6H_6)Cr(CO)$_2$(CE)] (E = O, S or Se).[136,141–143] The ν(CS) bands occur at 1250–1300 cm^{-1} but have very low intensity. In explanation, Lichtenberger and Fenske[124] argue that CS π- and π^*-levels (2π and 3π) are coupled as both interact with the same metal *d*-orbital set which reduces the polarizability change, and so Raman intensity, as the CS bond stretches. Both ν(M–CS) and δ(M–C–S) modes are Raman-active but tend to overlap with the equivalent M–CO modes. Tentative assignments have been made for ν(M–CS), 350–400 cm^{-1}, and δ(M–C–S), 300–500 cm^{-1}, which are more metal-dependent than ν(CS).

Table 2.

IV.10. IR SPECTROSCOPIC STUDIES

Assignment of the CS stretching vibration, ν(CS), is common although both ν(M–CS) and δ(M–C–S) IR-active modes have been reported.

In Table 2, the ν(CS) range for different CS coordination modes is noted.

Earlier reviewers[3,4] tabulated the known ν(CS) values. This listing has been updated (see Appendix 2) since the latter review.[3]

The ν(CS) value for "free" CS, trapped in a low-temperature matrix of CS_2, is 1274 cm^{-1}.[144] When ligating, ν(CS) falls to either side of this value. With the noted π-acceptor properties of CS an increase is unexpected but was rationalized from normal coordinate calculations on $[M(CO)_5(CE)]$ (M = Cr or W, E = O or S) which invoked a mixing of ν(CS) and ν(M–CS) stretching modes and showed that the ν(CE) force constant indeed decreases for E = S.[4,136] The MO calculations, which indicate both CS π- and π^*-orbitals overlap with metal d-orbitals,[124] lend support to the mixing of stretching modes. Also, correlating ν(CS) in $[ML_n(CS)]$ with k_{CO} for $[ML_n(CO)]$, Andrews[123] noted that other π-donor ligands cause a high ν(CS) with respect to a linear correlation and π-acceptor ligands a low value, again suggesting a complex interrelation of ν(CS) with M–CS interactions. As the d–π interaction tends to augment d-electron removal from the metal, increase M–C and decrease C–S bond strength,[125] π-donor ligands which will reduce this interaction will lead to stronger C–S bonding and higher ν(CS).

As carbon or sulphur becomes increasingly coordinated to metal centers, the ν(CS) ranges tend to decrease (see Table 2). The change from μ_4-C · σ-S at 843 cm^{-1} in $[Os_4(CO)_{12}(CS)S]$[116] to μ_4-C · μ-S at 921 cm^{-1} in $[Fe_5(CO)_{13}(CS)S_2]$[115] is an exception, but takes no account of ν(CS) and ν(M–CS) mixing nor of the change in metal.

Returning to terminal CS ligands, ν(CO) for the series of compounds $[\{(\eta^5\text{-}C_5H_5)Fe(CO)_2L\}^+]$ (L = CS, C_2H_4, PPh_3, MeCN or py) is greatest when L is CS which was taken to indicate that CS is the best π-acceptor amongst these ligands.[60] The largely analogous nature of metal–ligand interaction between CO and CS is shown by the similar direction of shift of ν(CO) and ν(CS) in $[\{(\eta^5\text{-}C_5H_5)Fe(CO)(CS)L\}^+]$ (L = CO, PR_3, $AsPh_3$ or $SbPh_3$; R = Ph, Cy, C_6H_4F or C_6H_4OMe), which both decrease as L has better σ-donor and worse π-acceptor properties.[83] However, ν(NO) and $\nu(CO)_{max}$ for $[\{(\eta^5\text{-}C_5H_5)Mn(CO)_2(NO)\}^+]$ are higher than for $[\{(\eta^5\text{-}C_5H_5)Mn(CO)(CS)(NO)\}^+]$, suggesting less π-acceptance by CS than CO, whereas replacing CO by CS in $[\{(\eta^5\text{-}C_5H_5)Mn(CE)(NO)L\}^+]$ (E = O or S; L = PPh_3, $AsPh_3$ or $SbPh_3$) causes slight increases in ν(NO), suggesting the opposite.[81]

Such conflicting data from various spectroscopic studies of CS complexes were rationalized by Andrews.[123] For numerous CS complexes, he compared ν(CS) in $[M(CO)_n(CS)]$ (M = metal with rest of ligand array) with k_{CO}, the stretching force constant for CO, in $[M(CO)_{n+1}]$ and k_{CO} in $[M(CO)_nL_1]$ and $[M(CO)_nL_2]$, where L_1 = CO and L_2 = CO, CS or PEt_3. Statistically significant correlations were found and some rationalization was made for deviation from exactitude of the correlations. He concluded that the basic interaction with metal of CO and CS is similar; σ-donor and π-acceptor. On correlating ν(CS) and k_{CO}, however, ν(CS) is lower than the ideal correlation when other good π-acceptor ligands are present but higher with good π-donor ligands, which will affect metal–ligand d–π

and d–π^* interactions. Estimation of ν(CS) of an unknown CS complex from k_{CO} of its CO analogue was suggested. The CS ligand was said to exhibit a "charge-buffering effect" as k_{CO} in $[M(CO)_n(CS)]$ varies less than in $[M(CO)_{n+1}]$, so that CS absorbs more of the charge differences between complexes. Hence, CS displays a wider donor : acceptor ratio range than CO, this ratio being higher than CO when k_{CO} in $[M(CO)_{n+1}]$ exceeds 17.1 mdyn $Å^{-1}$ and is lower below this value.[123]

In a similar vein, Dombek compared IR and ^{13}C NMR parameters for $[W(CO)_5L]$ and *cis*- and *trans*-$[W(CO)_4(CS)L]$ (*cis*- and *trans*-L = CyNC, 4-Me-py or PR_3; R = OMe, OPh, Ph, ^{n}Bu or tolyl : *trans*-L = Cl^-, Br^- or I^-).[75] For *trans*-$[W(CO)_4(CS)L]$, CS seems more effective at removing electron density from tungsten than CO in $[W(CO)_5L]$, with k_{CS} less variable than k_{CO} for the equivalent CO ligand. The availability of the opposing M–CS d–π and d–π^* interactions explains this. Also, decreasing k_{CS} correlates with decreasing CS ^{13}C shielding [increasing δ(CS)].[75]

The meticulous IR and Raman studies of Butler and co-workers are confined to $[(\eta^5\text{-}C_5H_5)Mn(CO)_x(CS)_y]$ ($x+y=3$, x and y = 1 or 2),[141,145] $[(\eta^6\text{-}C_6H_6)Cr(CO)_2(CE)]$ (E = O, S or Se)[143,146] and $[M(CO)_5(CE)]$ (M = Cr or W; E = O, S or Se).[136,142] Aided by isotopic labelling, detailed assignments have been made. The IR ν(CS) modes are strong, occurring at 1175–1300 cm^{-1}, although the Raman ν(CS) intensity is low, as discussed above. Both ν(M–CS) and δ(M–C–S) modes are IR- and Raman-active, varying significantly because of the changing metal atom. The manganese systems show ν(M–CS) modes at 359–404 cm^{-1} with δ(M–C–S) at the low end of 450–650 cm^{-1}, but undistinguishable from δ(M–C–O).[141] In $[(\eta^5\text{-}C_5H_5)Mn(CS)L_2]$ (L_2 = dppe or triphos), δ(M–C–O) IR-active modes occur from 530 to 555 cm^{-1}.[79] For the chromium complexes, ν(M–CS) occurs at 350–435 cm^{-1} with δ(M–C–S) assigned at 340 cm^{-1} for $[Cr(CO)_5(CS)]$, but at 490–520 cm^{-1} for $[(\eta^6\text{-}C_6H_6)Cr(CO)_2(CS)]$.[136,142,143] Values for $[W(CO)_5(CS)]$ are a little below the chromium analogue.[136,142,143]

Bond dipoles have been calculated from the absolute integrated IR intensity data for $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(CS)]$[145] and $[(\eta^6\text{-}C_6H_6)Cr(CO)_2(CE)]$ (E = O, S or Se).[146] Increasing π-acceptor ability of CE in the order E = O < S < Se was assigned as the M–C–E dipole increases in this order also.

As noted already, no similarly detailed IR studies have been reported for CS ligands in bonding modes other than terminal.

IV.11. X-RAY CRYSTALLOGRAPHIC DATA

Data on the X-ray crystallographic studies of CS complexes is gathered in Table 3 with some related information on M–C bond lengths for comparable CO ligands and ν(CS) values.

Twelve cases contain terminal CS ligands and five μ-CS, the remainder being single examples of the μ_3-CS, the two μ_3-C · σ-S, μ_4-C · σ-S and μ_4-C · μ-S bonding modes. The shorter M–CS distance than M–CO in comparable structures indicates that the M–CS interaction is stronger.[3] Generally, this holds for the terminal CS complexes characterized structurally since (see Table 3), although in the cases of $[(\eta^5\text{-}C_5H_4Me)Mn(CO)(CS)I]$,[149] $[Os_3(CO)_8(CS)S_2]$[50,51] and $[Os_3(CO)_7(CS)S_2(\mu\text{-}H)_2]$[52] these distances are close to equal. However, in Andrews' correlation of IR data, the CS ligand in $[\{(\eta^5\text{-}C_5H_5)Mn(CO)(CS)(NO)\}^+]$ is determined to have a worse acceptor : donor ratio than CO in $[\{(\eta^5\text{-}C_5H_5)Mn(CO)_2(NO)\}^+]$.[123] Substituting CO by I^-, a good π-donor ligand, should reduce the Mn–CS d–π interaction, which itself augments the d–π^* interaction,[125] worsening the acceptor : donor ratio further and leading to a long Mn–CS bond due to the low π-component to this interaction. Examination of all M–CS bond lengths against the IR parameters used by Andrews might prove interesting. Where M–CS is shorter than M–CO, C–S bond elongation is greater. Notably, the cases where M–CS and M–CO are close display the three shortest C–S distances, indicative of relatively low CS π-acceptance.

In the few structural studies of μ-CS systems, the tendency for longer M–CS than M–CO of comparable μ-CO ligands is not marked, M–CS being both longer and shorter. In $[\{(\eta^5\text{-}C_5H_5)Fe\}_2(CO)(CN^iPr)(\mu\text{-}CO)(\mu\text{-}CS)]$ where M–CS is longer than M–CO, the C–S bond is short.[110] Carbonyl analogues are unknown for the compounds with other CS bonding modes so no judgment on M–C distances can be made.

The C–S bond length generally increases as more metal atoms are bonded to carbon with ν(CS) decreasing (Fig. 21). For the two electron donor σ-, μ- and μ_3-CS ligands increasing back donation to

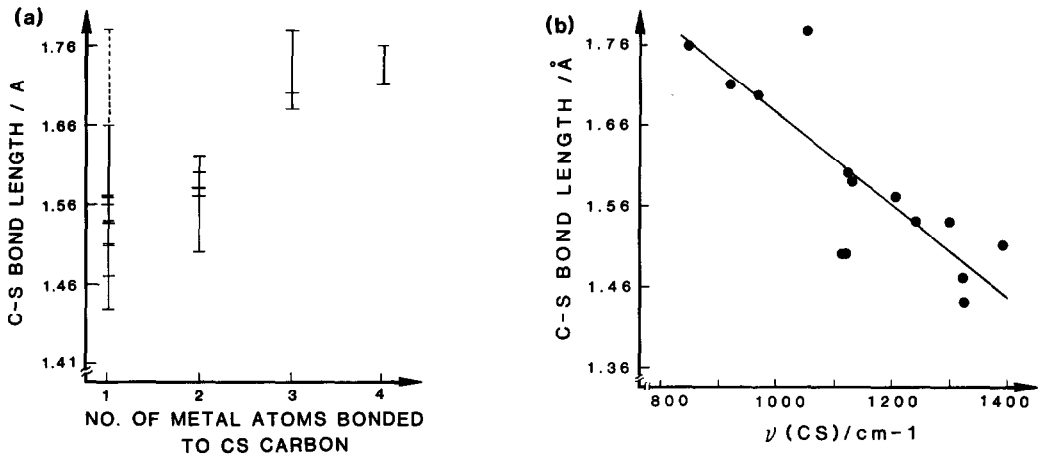
the CS π^*-orbitals should weaken the C–S bond and lower ν(CS) like the behaviour of CO analogues.

When CO and CS donate more than two electrons, bonding differences have been noted.[116] For $[Fe_5(CO)_{13}(CS)S_2]$ (**28**) and $[Os_4(CO)_{12}(CS)S]$ (**29**), formal electron counting requires CS to donate six and four electrons respectively. However, for $[Os_4(CO)_{12}(CS)S]$, the C–S bond is longer and ν(CS) lower. In both cases, the M_n–CS distances are effectively equal with the sulphur bonded to metal atoms also involved in the M_n–C interaction. Considering CO ligands which donate four or six electrons and have shared metal atoms between C and O, the CO bond orders are slightly greater than for CS cases and M_n–CO is shorter for the "nearest-to-linear" M–CO interaction. These data suggested largely independent M_n–C, M_n–S and C–S bonding whereas CO retains more π-bonding and tends to have separate linear M–CO and Chatt–Dewar η^2-CO interactions with metal centers. That the C–S bond length does not increase nor ν(CS) decrease on increasing donation from four to six electrons suggests that the extra two electrons are nominally donated from a sulphur-localized lone pair and that at the four-electron donor stage C–S π-bonding is effectively sundered. This indicates the weaker CS $p\pi$–$p\pi$ bonding.[116]

When carbon and sulphur do not share metal atoms, these effects are not observed. In $[\{(\eta^5\text{-}C_5H_5)Co\}_3(\mu_3\text{-}S)\{\mu_3\text{-}CSCr(CO)_5\}]$ (**26**) the Co–C distances are equal[113] and in $[Fe_4(CO)_{12}(CS)S]$ (**27**)



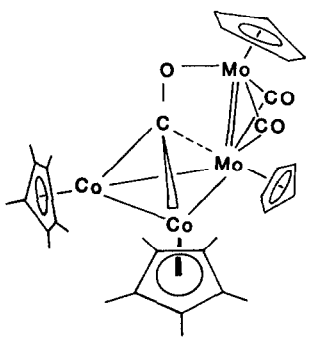


Fig. 21. Graphical comparison of the C–S bond length to : (a) the number of metal atoms bonded to the CS carbon, and (b) ν(CS).

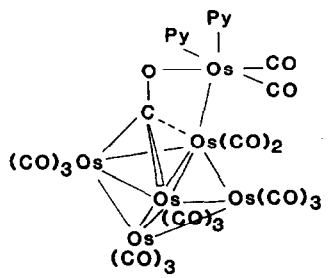

the μ_3-C · σ-S ligand is closer to the iron atom in the Fe_3 triangle which is attached to the $Fe(CO)_4$ group which is σ-bonded to the CS sulphur.[115,116] Two μ_3-C · σ-O analogues are known, in

$$[\{(\eta^5\text{-}C_5Me_5)Co\}_2\{(\eta^5\text{-}C_5H_5)Mo\}_2(\mu\text{-}CO)_3(\mu_3\text{-}C\cdot\sigma\text{-}O)]$$

(**38**)[154] and $[Os_6(CO)_{16}(\mu_3\text{-}C\cdot\sigma\text{-}O)(py)_2]$ (**39**).[155]

38

39

X-ray crystallography has proved vital in determining the structure of CS-containing complexes, especially those containing the more complex bonding modes.

In summary to this section, although CS displays a variety of two-, four- and six-electron donor bonding modes much like CO, differences do become apparent. The bonding of the terminal CS ligand has been studied in relative detail by a wide range of techniques and a reasonably good understanding of its bonding exists relative to that of CO.

In contrast, although the broad IR and ^{13}C NMR spectroscopic properties of μ-CS ligands are known, there is a paucity of data for the more complex bonding modes. This must arise, however, from the small number of such complexes which have been isolated.

V. CONCLUSIONS

This review encompasses the literature on thiocarbonyl complexes since the first identification in 1966, until approximately the end of 1984. The diversity of synthetic routes and the lack of general applicability of these become apparent, thus making the deliberate synthesis of thiocarbonyl complexes a fickle business.

Although there are a good number of terminal thiocarbonyl ligands of which a diverse reactivity has been demonstrated, there are rather few examples of other CS ligand bonding modes. Consequently,

the chemistry of these species remains uninvestigated to any extent. For the same reasons, detailed study of the bonding in such cases remains limited.

In 1977, Butler[2] concluded his account on this area by suggesting that "the chemistry of transition metal chalcocarbonyls will continue to be a fertile area of research... it is anticipated that the catalytic potential of these complexes will become an important research area." I suggest that the areas which remain fallow lie in the synthesis and study of the thiocarbonyl ligand in more complex bonding modes and in the consequent better understanding of the bonding in these species with respect to similarly coordinated carbonyl and selenocarbonyl ligands. It may also be noted that the catalytic potential of thiocarbonyl complexes remains an area lacking significant report.

Acknowledgements—This review was originally drafted while PVB was a research student at the University of Cambridge. Acknowledgement is made of Professor Sir J. Lewis and Dr B. F. G. Johnson for their support then and since towards the preparation of this review. The S.E.R.C. is acknowledged for a maintenance grant to PVB while at Cambridge. The Union Carbide Corporation is acknowledged for permission to update and publish this work and for providing the facilities necessary to research the material and to prepare the manuscript. The encouragement and interest of Drs G. L. O'Connor, S. W. Kaiser and J. R. Briggs is noted. I am indebted to Dr B. D. Dombek for his constructive criticism of draft manuscripts.

ESR AND ELECTRONIC ABSORPTION SPECTRA OF CHROMIUM ACETYLACETONATO NITROSYL COMPLEXES

A. KELLER* and B. JEŻOWSKA-TRZEBIATOWSKA
Institute of Chemistry, University of Wrocław, Poland

(*Received* 18 *September* 1984; *accepted* 27 *March* 1985)

Abstract—The *cis*- and *trans*-chromium nitrosyl complexes with formulae $[Cr(NO)(acac)_2L]$ ($L = H_2O$, NH_3, pyridine and imidazole) and $[Cr(NO)(acac)_2]_2(N\text{–}N)$ (N–N = bridge ligands, i.e. ethylenediamine and 4,4′-bipyridyl) were investigated by magnetic and spectroscopic (ESR and UV–VIS) methods. The character of metal–ligand bonding and the influence of the coordinated ligands on the electron density distribution within the molecular unit {CrNO} were determined.

Many papers concerning nitrosyl complexes of transition metals proved that the structure and properties of the coordinated NO group may be affected by a suitable choice of additionally coordinated ligands. Using acetylacetonate as the aditional ligand, nitrosyl *cis*-and *trans*-complexes of chromium of types $[Cr(NO)(acac)_2L]$ [where $L = H_2O$, NH_3, pyridine (py) and imidazole (imid)] and $[Cr(NO)(acac)_2]_2(N\text{–}N)$ [where N–N are bridge ligands ethylenediamine (en) and 4,4′-dipyridyl (bpy)] were obtained.[1] The structure of those complexes was determined on the grounds of X-ray powder diffractograms and IR spectra.

This paper concerns the electronic and ESR spectra of those complexes from which the nature of the metal–ligand bonding and the effect of the ligands on the electron density distribution within the {CrNO} molecular group were determined.

EXPERIMENTAL

Synthesis of trans-$[Cr(NO)(acac)_2(H_2O)]$ **(I)**

Ten grams of Na_2CO_3 was added to a solution of 7 g CrO_3 in 20 cm^3 H_2O previously cooled to 0°C. Then an aqueous solution of thiourea (5 g) and sodium carbonate (10 g) dissolved in water were added and subsequently 15 cm^3 of acetylacetone were added dropwise. This solution was then heated to room temperature and a solution containing 9 g of hydroxylamine hydrochloride in a minimum amount of water was added. After a few hours, the brown crystal precipitate was filtered off, washed with water and dried in a vacuum over P_4O_{10}.

Synthesis of trans-$[Cr(NO)(acac)_2(NH_3)]$ **(II)**

A solution of 7 g of CrO_3 in 15 cm^3 H_2O was cooled to about 0°C and neutralized with a concentrated sodium carbonate solution. Next, 10 cm^3 of a concentrated ammonia solution was added. To this solution 15 cm^3 of acetyloacetone and 9 g of hydroxylamine hydrochloride in a minimum amount of H_2O were added dropwise. The solution was left for 24 h at 0°C for crystallization. The orange precipitate was filtered off, washed with H_2O and dried over P_4O_{10}.

Synthesis of cis-$[Cr(NO)(acac)(NH_3)]$ **(IIa)**

To 7 g of CrO_3 dissolved in a small amount of H_2O and cooled to 0°C, 50 cm^3 of a 35% solution of KOH, 15 cm^3 of acetylacetone and 18 cm^3 of a concentrated NH_3 solution were added.

The solution was heated up to 70–80°C and then 9 g of hydroxylamine hydrochloride was added dropwise. The solution was cooled to room temperature. After 30 min, the light-brown non-crystalline precipitate was filtered off, washed with the H_2O–NH_3 mixture and with H_2O and dried over P_4O_{10}.

Synthesis of trans-$[Cr(NO)(acac)_2py]$ **(III)**

A known amount of the complex **I** was dissolved in methanol and treated with py, the molar ratio of the complex to py being 1:5. The red-brown crystal precipitate was next filtered off, washed with H_2O and dried over P_4O_{10}.

* Author to whom correspondence should be addressed.

Synthesis of cis-[Cr(NO)(acac)py] (**IIIa**)

A solution containing 7 g of CrO_3, 20 g of Na_2CO_3, 15 cm^3 of acetylacetone and 5 cm^3 of py dissolved in 50 cm^3 H_2O was heated to 70°C. Next, a solution of 10 g of hydroxylamine hydrochloride in a small amount of H_2O was added dropwise. After a dozen or so minutes of heating, the solution was cooled. The light-brown crystal precipitate was filtered off, washed with H_2O and dried over P_4O_{10}.

Synthesis of trans-{[Cr(NO)(acac)$_2$]$_2$en} (**IV**)

En was added to a methanol complex (**I**) solution, the molar ratio being 2:1. The solution was concentrated in a vacuum. The crystallized orange precipitate was washed with H_2O and dried over P_4O_{10}.

Synthesis of cis-{[Cr(NO)(acac)$_2$]$_2$en} (**IVa**)

Complex **IVa** was prepared similarly to complex **IIIa**, but 3 cm^3 of en was added instead of py. After reduction the solution was cooled and left for crystallization. The crystallized yellow-green precipitate was filtered off, washed with H_2O and dried over P_4O_{10}.

Synthesis of trans-{[Cr(NO)(acac)$_2$]$_2$(bipy)} (**V**) *and* trans-[Cr(NO)(acac)$_2$(imid)] (**VI**)

Complexes **V** and **VI** were prepared just like complex **III**, bipy and/or imid being added respectively, instead of py.

Instrumentation

Magnetic susceptibility measurements within the temperature range 77–295 K were made by the Gouy method. The ESR spectra were recorded with a JES-ME-3X X-band spectrometer at 125 and 295 K using Mn^{2+} in HgO and Fremi's salt as ESR standards and the JES-SH-3CX superheterodyne for microwave frequency measurement. The electronic absorption spectra were recorded within the range 50,000–10,000 cm^{-1} with a Cary 14 spectrophotometer.

RESULTS AND DISCUSSION

All the studied complexes are paramagnetic with magnetic moments corresponding to a single unpaired electron (Table 1). Typical ESR spectra are shown in Fig. 1. These spectra give no evidence of rhombic deformations and do not differ from those of complexes of $[Cr(NO)L_{5-n}X_n]^{m+}$ type.[1–4] In the spectra of complexes **II–VI**, in which the ligands are coordinated through nitrogen, no hyperfine interaction from the ^{14}N of the ligands is observed. A rather significant effect of the solvent on the ESR parameter values was noticed, particularly on the isotropic parameters. In Table 2 the spin Hamiltonian parameters of complex **I** in a few solvents are collected. For the other complexes under test those parameters depend on the solvent in the same way.

The spin Hamiltonian and bonding parameters of all the tested complexes, determined and calculated from the ESR spectra recorded for solutions in anhydrous ethanol, are given in Table 3. The ESR parameters indicate that the unpaired electron occupies the molecular orbital $\psi = c_{xy}d_{xy} - c\phi$ lig. For such an electronic configuration, the c_{xy}^2-coefficient and the isotropic contact term, K, were calculated from the McGarvey relationships.[5] The

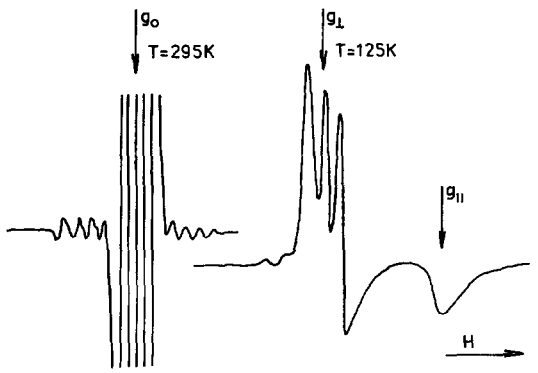

Fig. 1. The typical ESR spectrum for the chromium acetylacetonato nitrosyl complexes.

spin density of the *s*- and *p*-electrons of $^{14}N(NO)$ were estimated to be $c^2_{2s} = A_{iso}/A^o_{iso}$ and $c^2_{2p} = T_{zz}/T^o_{zz}$ (where A_{iso} is the isotropic part of the hyperfine interaction, and T_{zz} is the component of the anisotropic hyperfine tensor).[6] The signs of the hyperfine parameters of the complexes investigated were postulated from the general properties of those parameters[5] and from the results of zero-field spectroscopy investigations of similar complexes.[7] The $A_{iso}[^{14}N(NO)] < 0$ and $T_{zz}[^{14}N(NO)] > 0$ values are due to the negative spin density on the p_π-orbital of the nitrosyl nitrogen because of spin polarization of the nitrogen containing the $\pi^*(NO)$ orbital through the $\pi(d_{xz,yz})$ proper ligand system).[8,9]

The results indicate rather clearly the effect of the cordinated ligands L and N–N on the electron density distribution within the complex molecules. The variation of the K, T_{zz} and c^2_{xy} parameters (Table 3), the lowering of which may be considered to be a measure of the increase in the covalent character of the chemical bond, are consistent with the positions of those ligands in the nephelauxetic series. At the same time, those ligands exhibit their donor properties toward the strong acceptor NO. Those interactions are reflected in the variations of the c^2_{2s}- and c^2_{2p}-coefficients and of the c^2_{2p}/c^2_{2s} ratio (Table 3).

Acac as the ligand may exhibit both π-acceptor and π-donor properties toward the central ion since both the occupied bonding and the unoccupied antibonding π molecular orbitals are energetically suitable for overlap with the metal π-orbitals.[10] Which one of those interactions prevails depends on the population of the d_π-orbitals and on the relative orbital energies.[11,12] Therefore, those interactions will be considerably affected by the strongly π-acceptor properties of the NO group. A comparison of the experimental and calculated ESR parameter values of the *trans*- and *cis*-complexes (Table 3) indicates a stronger electron delocalization through π-bonding Cr → acac in the latter than in the *trans*-isomers. This is evidenced by the following sequences: $c^2_{2p}/c^2_{2s}(cis) < c^2_{2p}/c^2_{2s}(trans)$, $T_{zz}(cis) < T_{zz}(trans)$, $K(cis) < K(trans)$ and $g_\perp(cis) > g_\perp(trans)$ since the π M—L bonds contribute to the $g_\perp$ value due to the unpaired d_{xy}-electron interacting in the perpendicular orientation with the filled d_{xz}, d_{yz} orbitals, the positions of the latter depending on the donor–acceptor properties of the ligands.[13]

The above conclusions are consistent with the results of IR spectroscopic studies,[1] particularly when the frequencies of the Cr–O and NO vibrations are compared. For example, the ν(NO) frequency is lower for the *cis*-complexes than for the *trans*-isomers (Table 1). The correlation between ν(NO) and the structure of the M–NO group has been considered in many papers.[14–18] It is well known that the strength of the M–NO bond is related to the density of *s*- and *p*-electrons of the nitrogen of the NO group, the latter depending on the filling of the metal *d*-orbitals, on the character of the M–NO bonding and on the donor–acceptor abilities of the other coordinated ligands. Figure 2, in which the variation of the ν(NO) frequency is drawn as a function of the c^2_{2s}- and c^2_{2p}-coefficients, illustrates the global effect of donor–acceptor interactions of the coordinated ligands on the frequency ν(NO) in the complexes studied.

The diagram of molecular orbitals interpreting the ESR parameters of the complexes under test is shown in Fig. 3. The sequence of the δ^*-orbitals is determined by the δ-donor properties of the coordinated ligands. The diagram also explains the

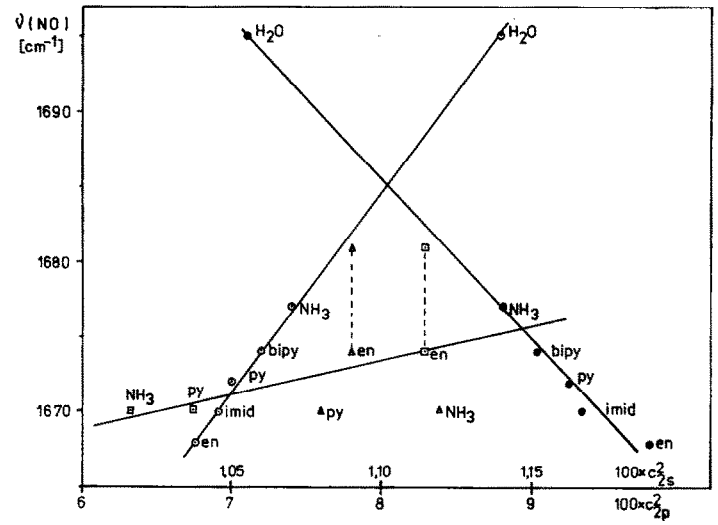

Fig. 2. The relationship between c^2_{2s}- and c^2_{2p}-coefficients and ν(NO) for the chromium acetylacetonato nitrosyl complexes. (○—○) $\nu(NO) = f(c^2_{2s})$ for *trans*-isomers, (●—●) $\nu(NO) = f(c^2_{2p})$ for *trans*-isomers, (△—△) $\nu(NO) = f(c^2_{2s})$ for *cis*-isomers, and (□—□) $\nu(NO) = f(c^2_{2p})$ for *cis*-isomers.

spectroscopic properties of the compounds discussed. Table 4 shows the electronic absorption spectra of complexes **I–IVa** in ethanol. The following electronic transitions were attributed to bands appearing in the spectra: the $^2B_2 \rightarrow {}^2E$ [$e(d_{xz,yz} + \pi^*NO) \rightarrow b_2(d_{xy})$] transition to the bands in the vicinity of 17,500 cm^{-1}, the $^2B_2 \rightarrow {}^2B_2$ [$e(d_{xz,yz} + \pi^*NO) \rightarrow e(\pi^*NO + d_{xz,yz})$] to the 22,000 cm^{-1} band (the energy of that transition is almost independent of the type of ligand in mononitrosyl complexes of chromium[2,19]), the $^2B_2 \rightarrow {}^2B_1$ [$b_2(d_{xy}) \rightarrow b_1(d_{x^2-y^2})$] transition to bands within 25,350–26,600 cm^{-1} and the $b_2(d_{xy}) \rightarrow [\pi^*_4(acac)]$ transition to bands within 30,150–30,700 cm^{-1}. The highest bands, i.e. those situated somewhat above 39,000 cm^{-1}, correspond to $\pi_3 \rightarrow \pi^*_4$ transitions of the coordinated acetylacetonates. For complexes **III** and **IIIa** (where L = py) $\pi \rightarrow \pi^*$(py) transitions are also observed at about 40,000 cm^{-1}. The above transitions were attributed to the bands assuming a C_{4v}-symmetry. This assumption is doubtless correct for the *trans*-isomers. In spectra of the *cis*-complexes, there are three additional bands at approximately 47,000, 36,000 and 24,000 cm^{-1} (Table 4). A $\pi_3 \rightarrow \pi^*_4$(acac) transition should be ascribed to the first one and a similar transition, or a transition of $d_\pi \rightarrow \pi^*_4$(acac) type, to the second one. The appearance of those bands is due to the coordination inequality of the acac ligands. The third band corresponds undoubtedly to a *d–d* type transition. Thus, it may be concluded that, because of the considerably lower symmetry of the central ion surroundings than in the *trans*-isomers with an unchanged degeneration of the d_{xz}, d_{yz} orbitals and sequence of molecular orbitals, the ground state of the *cis*-isomers is the ^2A-term (symmetry C_1). This means that all the electronic *d–d* type transitions ($^2A \rightarrow {}^2A$) are allowed. The relatively high energies of the $\pi_3 \rightarrow \pi^*_4$(acac) and $d_\pi \rightarrow \pi^*_4$(acac) transitions compared to those in M(acac)$_3$ type complexes,[12] confirm the previous considerations concerning π-interactions of {CrNO}—acac. A contribution to the high energy

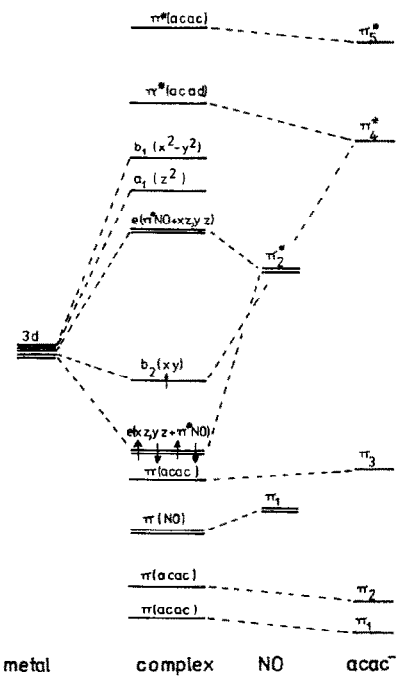

Fig. 3. Proposed molecular orbital scheme for *trans*-[Cr(NO)(acac)$_2$L].

of the $\pi_3 \rightarrow \pi_4^*$(acac) transitions may be caused by the M → L π-bonding (raising the π-antibonding level) as well as by L → M (lowering the π-bonding level). However the relatively high $d_\pi \rightarrow \pi_4^*$(acac) transition energy can result only from a significant contribution of πM → L bonding to the net π-interactions.

^{119m}Sn MÖSSBAUER SPECTROSCOPY AND ^{31}P AND ^{119}Sn NMR OF MIXED AQUEOUS 1-HYDROXY ETHYLIDENE-1,1-DISODIUM PHOSPHONATE (EHDP) AND TIN(II) CHLORIDE SOLUTIONS: EVIDENCE FOR EHDP–Sn COMPLEXES

N. ALBEROLA
Département de Radiologie Expérimentale, Hôpital Cardiologique, BP Lyon Montchat, 69394 Lyon Cedex 3, France

(*Received* 31 *October* 1984; *accepted after revision* 3 *May* 1985)

Abstract—1-Hydroxy ethylidene-1,1-disodium phosphonate (EHDP) labelled with ^{99m}Tc is well suited for human-bone scintigraphy. Before adding pertechnetate ions, the first step of the labelled-phosphorus procedure requires the preparation of a mixed aqueous EHDP and tin(II) solution. This mixture was investigated by both ^{119m}Sn Mössbauer spectroscopy and ^{31}P and ^{119}Sn NMR. ^{119m}Sn Mössbauer spectroscopy performed on mixed aqueous 0.1 M EHDP and 0.01 M $SnCl_2$ solutions at pH 6 and immediately frozen at −196°C after mixing showed the presence of an EHDP–Sn(II) complex. ^{31}P NMR spectra of freshly prepared solutions showed the weighted average of the signals of the free EHDP ligand and of the EHDP–Sn(II) complex. When the EHDP concentration was 10 times as large as the Sn(II) concentration, about 90% of the EHDP was present as the free ligand and the average NMR signal deviated little from the signal of the free ligand. ^{119m}Sn Mössbauer spectroscopy and ^{31}P NMR performed on these mixtures allowed to stand for 3 h at room temperature confirm the presence of a structure in which Sn(IV) atoms are included, in agreement with ^{119}Sn NMR results which show the presence of an $(EHDP)_2$–Sn(IV) complex.

1-Hydroxy ethylidene-1,1-disodium phosphonate (EHDP) labelled with ^{99m}Tc is used for human-bone scintigraphy.[1] A reducing agent such as tin(II) chloride is added to the aqueous compound before adding pertechnetate ions ($^{99m}TcO_4^-$). The reaction which occurs is unknown. However, in addition to ^{99m}Tc(Sn)–EHDP complexes, gel chromatography[2,3] of a mixed aqueous EHDP, tin(II) chloride and $^{99m}TcO_4^-$ solution has shown intermediates such as EHDP–Sn complexes. These observations suggest that an EHDP complexation with tin should occur in the intermediate EHDP and $SnCl_2$ solution. Moreover, the association constants of Sn(II) ions with EHDP and other diphosphonates have been measured by potentiometric titration.[4] Furthermore, ^{31}P NMR[5] and ^{119m}Sn Mössbauer[6] spectra obtained on analogous mixtures such as mixed aqueous pyrophosphate and tin(II) solutions only show a pyrophosphate–Sn(II) complex.

In the present work, ^{119m}Sn Mössbauer spectroscopy and ^{31}P and ^{119}Sn NMR were performed on mixed aqueous EHDP and tin(II) chloride solutions in order to confirm the presence of EHDP–Sn complexes and to get information on their molecular structures. EHDP and $SnCl_2$ molar concentrations and pH of the investigated mixtures, respectively, are very close to those used for bone tracer preparation: 0.1 M EHDP, 0.01 M $SnCl_2$ and pH 6.

EXPERIMENTAL

Chemicals

EHDP was provided by Procter & Gamble Co. (U.S.A.). $SnCl_2 \cdot 2H_2O$ and $SnCl_4 \cdot 5H_2O$ were purchased from Prolabo Co. (France). Deuterated solvents for NMR experiments and ^{119}Sn-enriched metallic tin (93% of ^{119}Sn) were from CEA-CEN Saclay (France). Distilled water was used as solvent for ^{119}Sn Mössbauer analyses. Other chemicals are commercial reagent grade materials.

Preparations of mixed aqueous 0.1 M *EHDP and* 0.01 M *tin(II) chloride solutions at pH* 6

$SnCl_2 \cdot 2H_2O$ (1.410 g) is dissolved in 12.5 M HCl (0.200 cm^3) and diluted (25 cm^3 H_2O and 25 cm^3 D_2O for Mössbauer and NMR experiments,

respectively). At this step, the $SnCl_2$ molar concentration is 0.12 M. EHDP (0.777 g) is solubilized in 25 cm^3 H_2O or D_2O. The EHDP molar concentration is 0.12 M. Some (0.200 cm^3) of the $SnCl_2$ solution is added to 4.167 cm^3 of the EHDP solution. The pH is adjusted to 6 with 1 and 0.1 M NaOH.

^{119}Sn NMR experiments require the use of ^{119}Sn-enriched tin. The preparation of the mixed aqueous solution with ^{119}Sn-enriched metal was as follows: ^{119}Sn-enriched metal (6 mg) was dissolved in 12.5 M HCl (0.400 cm^3) under nitrogen, then 0.391 cm^3 of this mixture was added to 0.12 M EHDP (4.167 cm^3) and the pH raised to 6 with NaOH.

For comparison purposes, reference solutions were prepared for Mössbauer and NMR experiments.

Reference aqueous solutions

0.01 M $SnCl_2$ *solution at pH* 1. 0.25 M $SnCl_2$ solution (0.200 cm^3) was added to distilled water (4.2 cm^3) and the pH raised to 1 with NaOH.

0.12 M *EHDP solution at pH* 6. EHDP (0.777 g) was dissolved in 25 cm^3 D_2O. In order to adjust the pH to 6, 12.5 M HCl (0.200 cm^3) was added to this aqueous EHDP solution (4.5 cm^3).

0.01 M $SnCl_4$ *solution at pH* 1. $SnCl_4 \cdot 5H_2O$ (2.191 g) was dissolved in 12.5 M HCl (0.200 cm^3) and diluted in distilled water (4.167 cm^3) and the pH adjusted to 1 with NaOH.

Mixed 0.1 M *EHDP and* 0.01 M $SnCl_4$ *solution at pH* 6. 0.01 M $SnCl_4$ (0.200 cm^3) was added to the 0.12 M EHDP solution (4.167 cm^3) and the pH adjusted to 6 with NaOH.

Instruments

Mössbauer spectroscopy was performed on the aqueous mixtures frozen at −196°C. The Mössbauer experiments were carried out using a constant-acceleration electromechanical drive system (Halder) together with a multichannel analyzer (Promeda, Inel) for collecting data. ^{119m}Sn in $CaSnO_3$ (Amersham Co.) was used as the gamma source. The velocity calibrations were done with a $CaSnO_3$ absorber. All the isomer shifts given in this paper refer to the Sn singlet of $CaSnO_3$ at −196°C.

NMR spectra were recorded on a Bruker WP 80 FT spectrometer equipped with a tunable multinuclear probe. ^{31}P and ^{119}Sn NMR experiments were carried out at observation frequencies of 32.38 and 29.85 MHz, respectively. Chemical shifts are given in ppm and are referred to external references: 85% H_3PO_4 and Me_4Sn for ^{31}P and ^{119}Sn NMR, respectively. Typical data acquisitions were as follows: 2500-Hz spectral width; 35-μs pulse width; 1–3-μs pulse repetition rate with complete proton decoupling. ^{31}P NMR spectrum recording requires 20 min vs 12 h for the ^{119}Sn NMR spectrum. NMR experiments were carried out at 23°C.

RESULTS

Mössbauer experiments

The following Mössbauer parameters are used: IS: isomer shift (mm · s^{-1}) relative to the reference Sn singlet ($CaSnO_3$); QS: quadrupole splitting (mm · s^{-1}); LW: experimental line width (mm · s^{-1}); I: relative intensity of line (%).

In the absence of EHDP, the ^{119m}Sn Mössbauer spectrum of the aqueous 0.01 M tin(II) chloride solution at pH 1 recorded immediately after the preparation displays a doublet (IS = 3.55 mm · s^{-1}, QS = 1.12 mm · s^{-1}, LW = 0.98 mm · s^{-1}). The ^{119m}Sn Mössbauer spectrum of the mixed aqueous 0.1 M EHDP and 0.01 M tin(II) chloride solution at pH 6 recorded at zero time exhibits a doublet (IS = 3.30 mm · s^{-1}, QS = 1.94 mm · s^{-1}, LW = 1.13 mm · s^{-1}). In addition to the doublets, the ^{119m}Sn Mössbauer spectra of the investigated solutions both allowed to stand for 3 h at room temperature display singlets: IS = −0.21 mm · s^{-1}, LW = 1.28 mm · s^{-1}, I = 15% for the EHDP and tin(II) chloride solution; IS = −0.09 mm · s^{-1}, LW = 1.06 mm · s^{-1}, I = 18% for the tin(II) chloride solution. The ^{119m}Sn Mössbauer spectrum of the aqueous 0.01 M tin(IV) chloride solution displays a single (IS = −0.11 mm · s^{-1}, LW = 1.12 mm · s^{-1}). The ^{119m}Sn Mössbauer spectrum of the mixed aqueous 0.1 M EHDP and tin(IV) chloride solution exhibits a singlet (IS = −0.19 mm · s^{-1}, LW = 0.96 mm · s^{-1}).

NMR experiments

The following NMR parameters are used: CS: chemical shift (ppm) relative to external reference; J: spin-coupling constant (Hz); I: relative intensity of line (%).

^{31}P NMR spectra. ^{31}P NMR spectra are recorded using the double-irradiation method in order to remove the spin-coupling interaction between 31P nuclei and protons of the methyl group of EHDP.

In the absence of tin(II) chloride, the decoupled ^{31}P NMR spectrum of the aqueous 0.1 M EHDP solution at pH 6 displays a unique line centered at 19.1 ppm. The ^{31}P NMR spectrum of the mixed aqueous 0.1 M EHDP and 0.01 M tin(II) chloride solution at pH 6 recorded immediately after compound mixing again displays one line centered at 19.1 ppm. Three hours later, in addition to the singlet A (CS = 19.0 ppm, I = 88%), a line, C (CS = 16.7

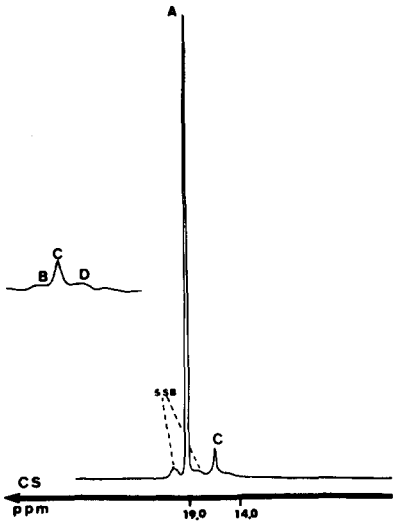

Fig. 1. ^{31}P NMR spectrum of a mixed aqueous 0.1 M EHDP and 0.01 M $SnCl_2$ solution at pH 6 and 25°C. The spectrum was recorded 3 h after mixing the two reactants. SSB represents the spinning side bands. In the left corner of the figure, scale expansion of the signal C reveals two weaker lines, B and D.

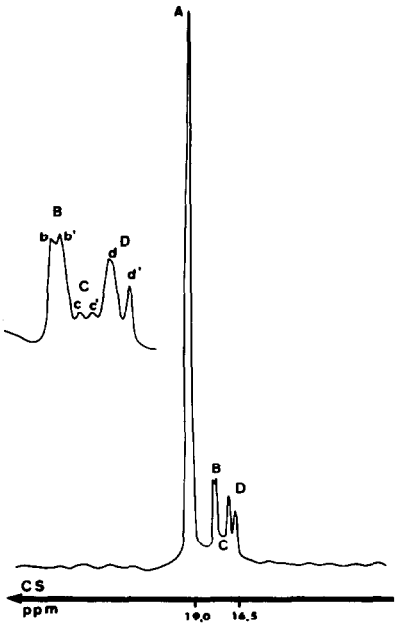

Fig. 2. ^{31}P NMR spectrum of a mixed aqueous 0.1 M EHDP and 0.01 M ^{119}Sn-enriched tin solution at pH 6 and 25°C. To the left, signal BCD is enlarged.

ppm, I = 8%), with two weaker signals, B (CS = 17.1 ppm, I = 2%) and D (CS = 16.4 ppm, I = 2%) on both sides, appears. Lines B and D are nearly symmetrical with respect to line C (J = 29 Hz) (Fig. 1). The ^{31}P NMR spectrum of the mixed aqueous 0.1 M EHDP and 0.01 M tin(IV) chloride solution at pH 6 recorded at zero time exhibits a high line A (CS = 19.0 ppm, I = 76%) and a line C (CS = 16.8 ppm, I = 15%). On both sides of line C two shoulders, B (CS = 17.1 ppm, I = 5%) and D (CS = 16.4 ppm, I = 4%), are observed and are roughly symmetrical with respect to C (J = 29 Hz). The ^{31}P NMR spectrum of the mixed aqueous 0.1 M EHDP and 0.01 M ^{119}Sn-enriched tin(II) chloride solution at pH 6 displays a main line A (CS = 19.2 ppm, I = 61%) and a group of three split lines, B–D, centered at 17.2 ppm (Fig. 2). Lines B and D are nearly symmetrical with respect to C (J is about 30 Hz). Lines B–D are greatly modified compared to that observed with natural tin. Thus, the central line C becomes the smallest and the two symmetrical signals become the highest.

^{119}Sn NMR spectra. The ^{119}Sn NMR spectrum of the mixed aqueous 0.1 M EHDP and 0.01 M ^{119}Sn-enriched tin solution at pH 6 displays five main lines, A–E (Fig. 3). Lines B, C and E are split, line A shows a shoulder on the downfield side and line D is enlarged. Lines A and E on the one hand and lines B and D on the other are roughly symmetrical with respect to line C. Each line is separated from the other by about 30 Hz.

DISCUSSION

IS (3.30 mm·s^{-1}) and QS (1.94 mm·s^{-1}) of the doublet observed in the mixed aqueous 0.1 M EHDP and 0.01 M tin(II) chloride solution was significantly different from those measured for the aqueous tin(II) chloride solution (IS = 3.55 mm·s^{-1}, QS = 1.12 mm·s^{-1}) whether Mössbauer analyses are per-

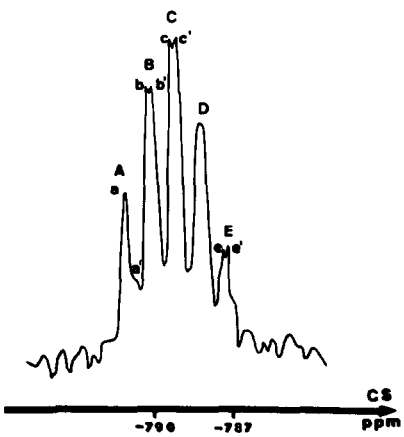

Fig. 3. ^{119}Sn NMR spectrum of a mixed aqueous 0.1 M EHDP and 0.01 M ^{119}Sn-enriched tin solution at pH 6 and 25°C.

formed on the solutions immediately after their preparation or 3 h later. Furthermore, the Mössbauer parameters of the investigated mixed aqueous EHDP and tin(II) solution are significantly different from those measured for $Sn(OH)_2$[7] (IS = 2.84 mm·s^{-1}, QS = 2.16 mm·s^{-1}). Thus, the doublet observed for the investigated mixture clearly indicates an EHDP complexation with tin. The IS value is located in the characteristic range of Sn(II).[8] Two possibilities could be suggested for the structure of the EHDP–Sn(II) complex: either Sn(II) could bridge two EHDP molecules forming a linear dimer or Sn(II) could form a ring structure with one EHDP molecule. In the same way, ^{119m}Sn Mössbauer spectroscopy performed on a mixed aqueous pyrophosphate and tin(II) chloride solution exhibited a pyrophosphate–Sn(II) complex. IS and QS values characterizing the EHDP–Sn(II) complex are significantly increased relative to those measured for the pyrophosphate–Sn(II) complex (IS = 3.19 mm·s^{-1}, QS = 1.76 mm·s^{-1}).[6] These results suggest that the ionic character of the bivalent Sn—O bonds is stronger within the EHDP–Sn(II) complex than within the pyrophosphate–Sn(II) complex.[9]

In addition to the doublets, ^{119m}Sn Mössbauer analyses performed on the EHDP and tin(II) mixture and on the tin(II) chloride solutions, both allowed to stand for 3 h at room temperature, exhibit singlets [IS = −0.21 mm·s^{-1} for the EHDP and tin(II) mixture; IS = −0.09 mm·s^{-1} for the tin(II) chloride solution], roughly identical, respectively, to singlets observed for the EHDP and tin(IV) mixture (IS = −0.19 mm·s^{-1}) and for the tin(IV) chloride solution (IS = −0.11 mm·s^{-1}). These results suggest that complexation between EHDP and tin(IV) should occur.[9]

The unique line of the ^{31}P NMR spectrum of the aqueous 0.1 M EHDP solution at pH 6 shows that the two ^{31}P nuclei of the EHDP molecule are present in the same electronic surroundings within the EHDP molecule. The ^{31}P NMR spectrum of the mixed aqueous 0.1 M EHDP and 0.01 M $SnCl_2$ solution recorded at zero time exhibits the same line and, thus, only indicates the presence of free EHDP. The appearance of three new lines, B–D, later indicates the formation of a new structure. Consequently, a reaction occurs that involves a probable EHDP complexation of EHDP with tin. The ^{31}P NMR spectrum of the mixed aqueous 0.1 M EHDP and 0.01 M $SnCl_4$ solution displays, in addition to the singlet related to free EHDP ions, three lines, B–D, with respective CSs equal to those of lines B–D reported for the EHDP and $SnCl_2$ mixture. Thus, tin included in the EHDP complex is Sn(IV). In the mixed EHDP and $SnCl_2$ solution allowed to stand for 3 h, oxidation of Sn(II) to Sn(IV) occurs. The symmetry of the group of lines B and D with respect to line C could be interpreted as a spin-coupling interaction between ^{31}P nuclei and ^{119}Sn and ^{117}Sn nuclei having a spin of $\frac{1}{2}$. This interpretation is confirmed by the change in the relative intensities of lines B–D observed for the mixed EHDP and ^{119}Sn-enriched tin solution. I_B/I_{B+C+D} and I_D/I_{B+C+D} ratios are 44 and 46% respectively and could be related to half of the ^{119}Sn isotropic enrichment (93%). Thus, the group of lines B and D originates when the coupling is present between ^{31}P and ^{119}Sn nuclei (and ^{117}Sn nuclei, too) and line C when coupling is absent (Sn nuclei having a spin of zero). On account of the high stability of the P—C—P bond in the EHDP molecule, P nuclei are expected to be associated in pairs in the complex. Thus, the presence of the B–D doublet ($J \sim 30$ Hz) is attributed to the signal of at least two equivalent ^{31}P nuclei split by one Sn nucleus. The splitting of each of the lines B–D observed for the mixed EHDP and ^{119}Sn-enriched tin solution is still unexplained. The two center peaks in the doublets have unequal separation (b–b′ and c–c′ peaks, $J = 4$ Hz; d–d′ peaks, $J = 10$ Hz). The EHDP complexation with Sn(IV) is confirmed by the ^{119}Sn NMR analysis of the EHDP and ^{119}Sn-enriched tin mixture. The quintuplet ($J \sim 30$ Hz) is attributed to the signal of one Sn nucleus having a spin of $\frac{1}{2}$ split by four equivalent P nuclei. Thus, the probable structure of the complex is $(EHDP)_2$–Sn(IV). One Sn atom and two EHDP molecules form a symmetrical spiro-structure (Fig. 4). The complexation of EHDP with tin(IV) exhibited by Mössbauer analyses is confirmed by NMR analyses. However, the splitting of lines B, C and E shown by the ^{119}Sn NMR spectrum is still unexplained (b–b′ peaks, $J = 3$ Hz; c–c′ peaks, $J = 5$ Hz; e–e′ peaks, $J = 4$ Hz). Furthermore, no NMR signal related to the presence of the EHDP–Sn(II) complex is exhibited. When the EHDP concentration is 10 times as large as the Sn(II) concentration, about 90% of the EHDP is present as the free ligand. It follows that the ^{31}P NMR spectrum of the freshly prepared EHDP and tin(II)

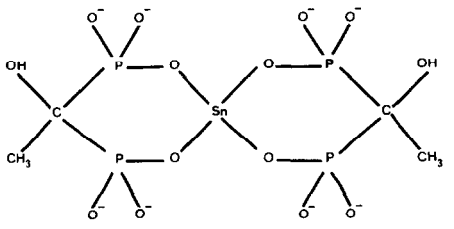

Fig. 4. Expected symmetrical spiro-structure of the $(EHDP)_2$–Sn(IV) complex consistent with ^{31}P and ^{119}Sn NMR results.

solution shows the weighted average of the signals of the free EHDP and of the EHDP–Sn(II) complex. ^{31}P NMR spectroscopy performed on mixed aqueous 0.1 M pyrophosphate and 0.01 M tin(II) chloride (or ^{119}Sn-enriched tin) solution at pH 6 displays a B–D doublet ($J = 40$ Hz),[5] for which lines B and D are not split. In agreement with ^{119m}Sn Mössbauer results, Mathieu *et al.*[5] have attributed this NMR doublet to the pyrophosphate–Sn(II) complex. However, according to the similarity of the experimental conditions used for the two NMR studies and according to the similarity of molecular structure between EHDP and pyrophosphate, the expected structure of the complex shown by Mathieu *et al.*[5] is probably (pyrophosphate)$_2$–Sn(IV). In addition to ^{31}P NMR spectroscopy performed on pyrophosphate and $SnCl_4$ mixture, ^{119}Sn NMR analysis should have avoided their earlier interpretation.

Acknowledgements—We thank Procter & Gamble Co. for providing EHDP. We are grateful to Dr Galy (Service de Radiopharmacie, Centre de Médecine Nucléaire, Lyon, France) and to Professor Marest (Institut de Physique Nucléaire, Lyon, France) for their helpful assistance.

(*Received* 12 *March* 1985; *accepted* 3 *May* 1985)

Abstract—The novel polymeric ligands, poly-$(N_4)H_2$ (I) and poly-$(N_4)H_2$ (II), in which the tetraaza macrocycle was present as an integral part of the polymer backbone, were prepared by the reaction of 5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,5,7,12-tetraene, $(N_4)H_2$, with diisocyanates [OCN-R-NCO, R = $(CH_2)_6$ (I) and $C_6H_4CH_2C_6H_4$ (II)]. These are insoluble in common organic solvents and water, suggesting that they have high molecular weights. The complexation of these polymeric ligands with copper(II) and nickel(II) in water under heterogeneous conditions showed that they can bind copper(II) selectively by complex formation with the tetraaza macrocycle. The percentage of copper(II) bound in II was found to depend on the concentration of copper(II), and the pH and ionic strength of the sample solutions. Moreover, the bound copper(II) in II could be desorbed by treatment with dilute hydrochloric acid.

Many tetraaza macrocycles and their metal complexes have been prepared and characterized.[1–4] However, the preparation and properties of polymeric ligands containing tetraaza macrocycles have been little studied so far.[5,6] In the previous work, we have found that the polymeric ligands containing 6,8,15,17-tetramethyl-dibenzo-5,9,14,18-tetraazacyclotetradecene, which are oligomers having a degree of polymerization of about 5, exhibit extraction rates of copper(II) faster than that of the corresponding monomeric ligand.[7,8] Moreover, we have described the preparation and characterization of novel tetraaza macrocycles with nitro[9] and carbamoyl[10] groups and their copper(II) and nickel(II) complexes.

In this paper, we describe the preparation of polymeric ligands containing the tetraaza macrocycle as an integral part of the polymer backbone and the complexing ability for copper(II) and nickel(II) under heterogeneous conditions.

EXPERIMENTAL

Materials

All reagents were of reagent grade. Chloroform was refluxed over P_4O_{10} and distilled. Benzene and *n*-hexane were refluxed over sodium and distilled. Other solvents were purified by common methods. Water was deionized.

Measurements

UV and visible reflectance spectra were recorded on a Hitachi 340 recording spectrophotometer attached with a Hitachi R-10A integrating sphere unit. IR spectra were recorded on a Hitachi 215 grating spectrophotometer. Atomic absorption spectra were obtained using a Nippon Jarrel Ash AA-1. The pH of a sample solution was measured with a Shibata 671 pH meter. Magnetic susceptibility was measured by the Gouy method at room temperature.

Procedure for binding and release of metal(II) ions

Binding of metal(II) ions by the polymeric ligands was carried out by using a 10-cm^3 test tube, with a stopper, which contained an aqueous solution (10 cm^3) of metal(II) acetate [copper(II) or nickel(II)] and the polymeric ligand powdered uniformly (2.0×10^{-5} unit mol). The test tube was shaken for an appropriate time, from 1 to 72 h, at room temperature by using a shaker. After shaking, the polymeric ligand was filtered off and washed with 10-cm^3 portions of water 3 times. The filtrate and

* Author to whom correspondence should be addressed.

washings were combined and diluted to 50 cm^3 with water, and the concentration of the metal(II) ion remaining in it was determined by atomic absorption spectrometry. For investigation of the effect of the ethanol content in the sample solution, filtration was carried out after shaking and the filtrate was evaporated very slowly at 80°C. The residual solution was added to dilute hydrochloric acid. The concentration of the copper(II) ion remaining in the sample solution was determined by atomic absorption spectrometry.

Release of copper(II) ion from the polymeric copper(II) complex was carried out by using a 25-cm^3 test tube, with a stopper, which contained a hydrochloric acid solution (25 cm^3) at an appropriate concentration and the copper(II) complex (25 mg, 4.46×10^{-5} unit mol). The mixture was stirred at constant revolution for an appropriate time, from 1 to 24 h. After stirring, it was filtered off and washed with 10-cm^3 portions of water several times. The filtrate and washings were combined and diluted to 100 cm^3 with water and the concentration of copper(II) ion was determined by atomic absorption spectrometry.

Preparation of poly-$(N_4)H_2$ **(I)**

To a chloroform solution (50 cm^3) of the parent tetraaza macrocycle[11] (1.0 g, 4.0 mmol) was added hexamethylene diisocyanate (0.67 g, 4.0 mmol). The mixture was stirred at room temperature for 48 h. After cooling, the resulting yellow precipitate was collected on a glass filter, washed with dry chloroform, *n*-hexane and ethanol and dried *in vacuo*. The yield was 85%. It was insoluble in water and ordinary organic solvents such as ethanol, benzene, chloroform and DMF. Found: C, 62.97; H, 9.04; N, 19.85. Calc. for $(C_{22}H_{36}N_6O_2)_n$: C, 63.42; H, 8.73; N, 20.18%. IR (in KBr disk): 3350, 1640, 1550, 1425, 1280, 1200, 1015, 820 and 760 cm^{-1}.

Preparation of poly-$(N_4)H_2$ **(II)**

To a chloroform solution (100 cm^3) of the parent macrocycle (1.0 g, 4.0 mmol) was added 4,4'-diphenylmethane diisocyanate (1.0 g, 4.0 mmol). The mixture was stirred at 30°C for 48 h. The resulting yellow precipitate was collected on a glass filter, washed with dry chloroform several times and dried *in vacuo*. The yield was 95%. It was insoluble in water and ordinary organic solvents. Found: C, 69.51; H, 6.79; N, 16.47. Calc. for $(C_{29}H_{34}N_6O_2)_n$: C, 69.84; H, 6.89; N, 16.86%. IR (in KBr disk): 3280, 1650, 1595, 1510, 1405, 1305, 1230, 810 and 750 cm^{-1}.

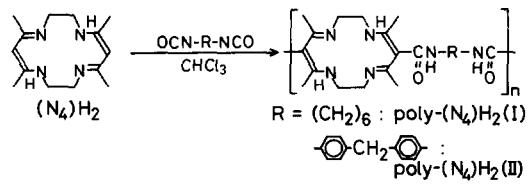

Fig. 1. Synthetic scheme for the polymeric tetraaza ligands studied.

Preparation of copper(II) complex with **II**, Cu[*poly*-(N_4)-**(II)**]

To a chloroform solution (100 cm^3) of the copper(II) complex with the parent tetraaza macrocycle (1.0 g, 3.2 mmol) was added 4,4'-diphenylmethane diisocyanate (0.8 g, 3.2 mmol). The mixture was stirred at room temperature for 48 h under a nitrogen atmosphere. The brownish green precipitate was collected on a glass filter, washed with dry benzene, chloroform and *n*-hexane, and dried *in vacuo*. The yield was 95%. Found: C, 61.85; H, 5.73; N, 14.82; Cu, 11.2 (by colorimetric determination). Calc. for $(CuC_{29}H_{32}N_6O_2)_n$: C, 62.17; H, 5.77; N, 15.00; Cu, 11.34%. IR (in KBr disk): 3250, 1640, 1590, 1405, 1310, 1235, 810 and 765 cm^{-1}. Magnetic moment (μ_{eff}) = 1.40 BM.

The preparative scheme for these polymeric ligands is shown in Fig. 1. In the reaction of the parent tetraaza macrocycle with monoisocyanates, carbamoyl derivatives substituted on the γ-carbon atoms were obtained exclusively,[10] which was confirmed by IR and ^1H NMR spectra. This is because of the high reactivity of the hydrogen atoms on them. Therefore, the present polymeric ligands may have the same unit structure as those for the carbamoyl derivatives. These polymeric ligands and the polymeric copper(II) complex were insoluble in ordinary organic solvents and water. Thus, their molecular weights could not be measured. Their poor solubilities, the analytical data and no absorption band due to isocyanate groups around 2280 cm^{-1} in the IR spectra suggest that their molecular weights are fairly high.

RESULTS AND DISCUSSION

Preliminarily, we have studied the binding abilities of the polymeric ligands for copper(II) and nickel(II) in batch systems under the following conditions: **I** (8.3 mg, 2.0×10^{-5} unit mol) and **II** (10.0 mg, 2.0×10^{-5} unit mol) were used, the concentration of aqueous solution (10 cm^3) of the metal(II) ions was 2.0×10^{-3} mol dm^{-3} (2.0×10^{-5} mol), and the pH of the sample solution was about 5.7 without using a buffer solution.

In the case of **I**, about 20% of the copper(II) was

bound after 24 h, and the percentage of bound copper(II) did not increase after additional shaking for 24 and 48 h. Moreover, the aqueous solution was wine red in color and the complex formed changed its color from brownish green to dark red, suggesting that some decomposition of the polymeric ligand occurred. This may be caused by a decrease in the pH of the aqueous phase by the complex formation. Under the same conditions binding of nickel (II) was not observed after shaking for 72 h, and thus coloration of the aqueous solution did not occur.

On the other hand, with **II** about 30% of the copper(II) was bound after shaking for 24 h and the percentage of bound copper(II) increased gradually with increasing shaking time. In this case, the polymeric complex formed was stable and its brownish color did not change after 72 h. Similarly, no binding of nickel(II) was observed after shaking for 72 h.

These results indicate that **II** is superior to **I** for application as a chelating resin selective for copper(II). Thus we studied the binding ability of the former for copper(II) in detail.

Effect of shaking time and concentration of copper(II) ion

Figure 2 shows the effects of shaking time and concentration of copper(II) ion on the percentage of copper(II) bound by **II**.

When the concentration of copper(II) ion was 2.0×10^{-3} mol dm^{-3} (equal to 1 unit mol of the polymeric ligand), the percentage of bound copper(II) reached 28% after shaking for 24 h and increased gradually with increase in shaking time. At a concentration of 2.0×10^{-4} mol dm^{-3} (0.1 unit mol of the polymeric ligand), the percentage of the bound copper(II) reached 55% after 24 h. This apparent value was larger than that at 2.0×10^{-3} mol dm^{-3}, but the amount of bound copper(II) per polymeric ligand was smaller compared to that at 2.0×10^{-3} mol dm^{-3}.

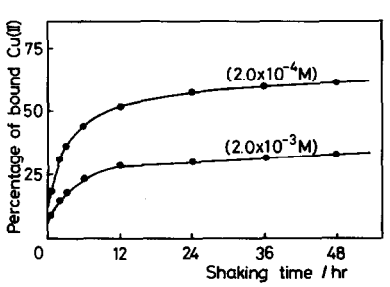

Fig. 2. Effects of shaking time and concentration of copper(II) ion on the percentage of copper(II) bound by **II**. **II**: 10 mg, copper(II) solution: 10 cm^3.

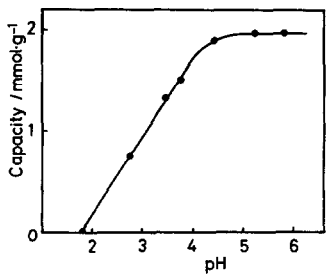

Fig. 3 Effect of pH on the binding capacity of poly-$(N_4)H_2$-(II) for the copper(II) ion. [copper(II)]: 2.0×10^{-2} mol dm^{-3}.

On the other hand, at a concentration of 2.0×10^{-2} mol dm^{-3} (10 unit mol of the polymeric ligand), the absorption equilibrium was attained within 24 h, where almost all the tetraaza macrocycles of the polymeric ligand were consumed by complex formation. The binding capacity of the polymeric ligand for copper(II) was estimated to be 2.0 mmol g^{-1}.

Effect of pH on the binding capacity

Figure 3 shows the effect of the pH of the sample solution on the binding capacity of the polymeric ligand for the copper(II) ion. The pH values were adjusted by using acetate buffer solutions (0.2 mol dm^{-3}) from 3.5 to 5.5 and by the addition of appropriate amounts of 1.0 mol dm^{-3} hydrochloric acid or sodium hydroxide below 3.5 or above 5.5, respectively.

Below pH 1.5 no copper(II) was bound by the polymeric ligand. The percentage of bound copper(II) increased linearly with increasing pH of the sample solution between 1.8 and 5.3, and was constant (2.0 mmol g^{-1}) above 5.8. This behavior agrees well with the pH effect observed in the solvent extraction of copper(II) by the corresponding monomeric ligand described in a previous paper.[10]

Effect of ionic strength

Figure 4 shows the effect of the ionic strength of the sample solution on the percentage of copper(II) bound by **II** under the following conditions: the concentration of the copper(II) ion was 2.0×10^{-3} mol dm^{-3}, shaking time was 24 h, and the pH of the sample solution was adjusted to 5.7. The ionic strength of the sample solution was varied from 0.0 to 3.0 by the addition of sodium nitrate.

The percentage of copper(II) bound by **II** increased with increasing ionic strength and approached a constant value (41%) above 1.0. The coexisting ionic salts in large amounts influence

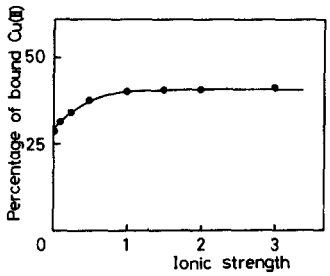

Fig. 4. Effect of ionic strength on the percentage of bound copper(II).

more or less the results for solvent extraction and adsorption on the resins: they exert a positive effect on the metal binding by desolvation around the metal ion to be captured, but spontaneously they exert a negative effect on it by weakening the interaction between the metal ion and the chelating agents. In the present system, the former process may operate effectively.

Effect of ethanol content in the sample solution

Figure 5 shows the effect of ethanol content in the sample solution on the percentage of bound copper(II). The concentration of the copper(II) ion was 2.0×10^{-3} mol dm^{-3} and ethanol content was varied from 0 to 80 vol %. Shaking time was 24 h.

The percentage of bound copper(II) after 24 h increased from 28 to 51% as ethanol content in the sample solutions increased from 0 to 80 vol %. It was noticeable at 30 vol % ethanol content. These results indicate that the complexation of the polymeric ligand with copper(II) is accelerated by the addition of ethanol.

It has already been pointed out that the addition of an appropriate organic solvent to an aqueous sample solution results in a strong retention of transition-metal ions on ion-exchange resins.[12–14] Such behavior has been ascribed to a decrease in the tendency for their hydration in a mixed solvent, in which the metal ions can interact easily with the

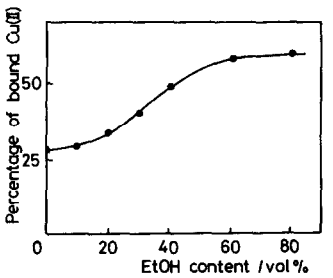

Fig. 5. Effect of ethanol content on the percentage of bound copper(II).

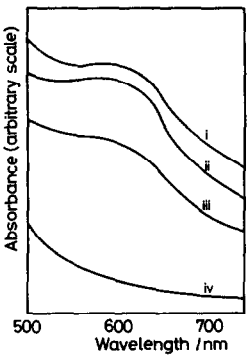

Fig. 6. Reflectance spectra: (i) Cu[poly-(N_4)-(II)], (ii) II loaded copper(II) ion (99%), (iii) II loaded copper(II) ion (30%), (iv) II.

binding sites. In the present study, a similar effect may operate and accelerate the complexation of copper(II) with tetraaza macrocycles of the polymeric ligand. Of course, other factors such as swelling of the polymeric ligand should preferably affect the increase in the percentage of bound copper(II).

Binding sites in Cu[*poly*-(N_4)-(II)]

Figure 6 shows the diffused reflectance spectra of II and its copper(II) complexes differing in the extent of their loadings; the absorption curves i–iii correspond to percentages of bound copper(II) in the polymeric ligand of 100, 99 and 30%, respectively. The first sample was Cu[poly-(N_4)-(II)] and the second and third samples were prepared by shaking the polymeric ligand with aqueous solutions of copper(II), followed by collection on a glass filter, washing thoroughly with water, and drying *in vacuo*. The polymeric ligand itself has no absorption band in the visible region. The copper(II) complex, Cu[poly-(N_4)-(II)] exhibits an absorption band centred at 600 nm, which may be assigned to ligand field transitions.[15] In fact, the absorption spectrum of the copper(II) complex with the corresponding monomeric ligand shows an absorption band at 609 nm in DMF.[10]

On the other hand, the spectra of the partially loaded polymeric complexes show an absorption band at a position similar to that of the polymeric copper(II) complex, and their intensities increase with increasing copper(II)-loaded percentage. These results suggest that the copper(II) ion is apparently bound to the tetraaza macrocycle of the polymeric ligand. Therefore, it can be said that the high selectivity of the present polymeric ligand for copper(II) results from the chelating ability of the tetraaza macrocycle itself.

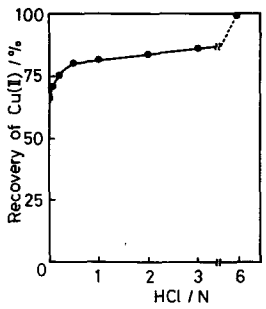

Fig. 7. Effect of concentration of hydrochloric acid on the recovery of copper(II).

Release of copper(II) from Cu[*poly*-(N_4)-**(II)**] *by hydrochloric acid*

We have examined the recovery of copper(II) bound in the polymeric ligand with hydrochloric acid, using Cu[poly-(N_4)-**(II)**]. When the polymeric complex was immersed in an acidic solution, it gradually turned from green to brownish yellow. In preliminary experiments, a constant recovery of copper(II) from the polymeric complex was obtained after stirring for 2 h with an aqueous solution of 1.0 mol dm^{-3} hydrochloric acid. Thus, this stirring time was adopted for the recovery of copper(II).

Figure 7 shows the effect of the concentration of hydrochloric acid on the recovery of copper(II). Seventy per cent of copper(II) was released with 0.1 mol dm^{-3} hydrochloric acid and the recovery of copper(II) increased to 87% when using 3.0 mol dm^{-3} hydrochloric acid. The loss of the polymeric ligand treated with 3.0 mol dm^{-3} hydrochloric acid was only 2–3%, indicating that little hydrolysis of the polymeric ligand occurred. By treating with 6.0 mol dm^{-3} hydrochloric acid, nearly 100% recovery of copper(II) was attained, but the solution turned faintly yellow and the loss of the polymeric ligand was about 13%. The polymeric ligand recovered from the polymeric copper(II) complex after release of copper(II) showed the same IR spectrum as the original polymeric ligand, indicating that the tetraaza macrocycle in the polymeric ligand was maintained after stirring in hydrochloric acid. The recovered polymeric ligand was found to be able to bind copper(II) effectively. Surprisingly, this polymeric ligand exhibits, even in concentrated hydrochloric acid, a strong resistance to hydrolysis, although imine double bonds are present in its polymer backbone. This may be caused by the hydrophobic effect of the linkage group, diphenylmethane. In fact, as described above, the polymeric ligand **I**, in which the tetraaza macrocycles are linked by a hexamethylene group, is easily hydrolysed by treatment with 1.0 mol dm^{-3} hydrochloric acid.

(*Received* 21 *March* 1985; *accepted* 3 *May* 1985)

Abstract—The synergistic extraction of Zn(II) has been studied in the PMBP–TBP system (where PMBP = 1-phenyl-3-methyl-4-benzoyl-pyrazole-5-one and TBP = tri-*n*-butyl phosphate) at various temperatures using a radiochemical technique. The thermodynamic parameters for the reactions involved support the mechanism for the synergistic extraction in which the 5-coordinate monohydrated $Zn(PMBP)_2$ chelate exchanges a water molecule for TBP.

Several solvent extraction systems show a synergistic effect in their extractability of the metal ion. Among them, the chelating agent–neutral ligand group system has been the most extensively studied.[1–8] A representative example is the system with HTTA (thenoyltrifluoroacetone) as the chelating agent and TBP (tri-*n*-butyl phosphate) or TOPO (tri-*n*-octyl phosphine oxide) as the neutral ligand.

Synergism in solvent extraction has been explained in one of the following ways. In the case where the metal ion forms a partially neutralized and coordinatively unsaturated complex with its surrounding chelating agent, the hydrophilic complex formed is not very extractable from the organic solvent. With the addition of the neutral extractant as a secondary agent, however, a new organophilic complex is formed by the substitution of hydrated water molecules from the metal ion. This newly formed adduct posess a higher distribution coefficient than that of the hydrophilic hydrated complex.[4]

There are some examples that show a notable increase in extractability with the addition of a secondary agent in spite of the fact that the complex formed is completely neutralized and coordinatively saturated. In these cases, there are two different explanations to elucidate the mechanism of the synergism. One[9–11] is that the metal ion expands its coordination number and forms a more organophilic complex by the addition of a secondary ligand. The other is the opening of one of the chelate rings, thereby introducing the secondary extractant into the primary coordination sphere of the metal ion.[12,13]

It has been known that PMBP (1-phenyl-3-methyl-4-benzoyl-pyrazole-5-one) is one of the most interesting and promising reagents for the extraction of chelate compounds.[14] In this work, we have studied the extraction of Zn(II) with PMBP and TBP to identify the mechanism of the synergistic effect.

EXPERIMENTAL

Reagents

A solution of Zn(II) tracer in 0.1 M HCl was obtained from Korea Advanced Energy Research Institute. The HCl was boiled off from the Zn(II) tracer solution by heating it and adding 0.1 M $HClO_4$ repeatedly with an IR lamp. The stock solution was prepared by diluting the resulting Zn(II) tracer with 0.1 M $HClO_4$. TBP for extraction analysis was obtained from Merck Co. and used without further purification. PMBP was synthesized according to the method reported in the literature[15] and was 3 times recrystallized in *n*-heptane solvent. Benzene was used as the organic solvent.

* Author to whom correspondence should be addressed.

Procedure

The ionic strength of the aqueous phase was adjusted to 0.1 M with $NaClO_4$. The aqueous phase was buffered with 0.1 M sodium acetate. PMBP and TBP were dissolved in benzene.

All experiments were carried out in a 40 cm^3 glass reactor jacketed to circulate water from a constant-temperature bath which was maintained at the desired temperature. Volumes (10 cm^3 each) of the organic and aqueous solutions were placed in the reactor and agitated with a magnetic stirrer for more than 1 h to assure full extractive mixing. After that the phases were sampled for analysis by an NaI scintillation counter. Each experiment was repeated more than twice under the same experimental conditions to obtain reliable data.

RESULTS AND DISCUSSION

The results for the extraction of Zn(II) from 0.1 M $NaClO_4$ by PMBP–TBP mixtures of constant total molarity 0.1 M in benzene are shown in Fig. 1. It shows that there is a synergistic effect on the extraction of Zn(II) in the PMBP–TBP system and the distribution coefficient of Zn(II) increases with increasing pH value of the aqueous phase. Using the method of continuous variation[16] the complexes present in the organic phase have been determined. Table 1 shows the extraction of Zn(II) in the various compositions of PMBP–TBP in benzene. Detailed explanations of the extraction coefficients, q_x, Q_x and Q_{AB}, are given in Ref. 16. The maximum value of Q_x appears between $x = 0.6$ and $x = 0.7$, and agrees fairly well with the theoretical value of $x = 0.67$. This indicates that the species in the organic phase are $Zn(PMBP)_2$ and $Zn(PMBP)_2TBP$ in agreement with the result[17] obtained by the equilibrium shift method.

Table 1. Extraction of Zn(II) with PMBP+TBP in benzene[a]

x(PMBP)	q_x	Q_x	Log q_{AB}
0.00	0.007	—	—
0.10	4.264	4.032	2.651
0.20	12.970	12.044	2.575
0.30	30.39	28.30	2.652
0.40	40.01	36.29	2.577
0.50	48.63	42.84	2.534
0.60	60.01	51.66	2.555
0.70	61.70	50.35	2.535
0.80	47.97	33.15	2.413
0.90	35.62	16.86	2.318
1.00	23.16	—	—

[a] $[Zn]_{tot} = 1 \times 10^{-4}$ M. $\mu = 0.1$ M $Na(H)ClO_4$. [PMBP] + [TBP] = 0.1 M. Temperature = 23°C. pH = 4.284.

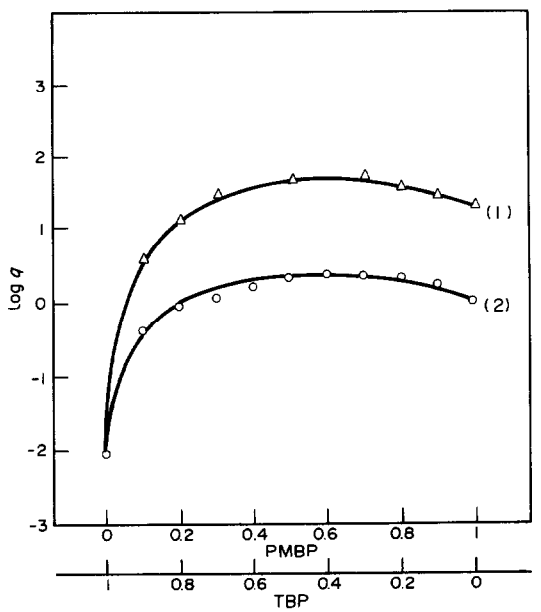

Fig. 1. Plot of log q, distribution ratio of Zn(II) vs [PMBP] (x M) and [TBP] (y M); $x + y = 0.1$ M. (1) PMBP–TBP, pH = 3.6; (2) PMBP–TBP, pH = 4.2.

The various equilibria of Zn(II) extraction by PMBP–TBP may be expressed as follows;

$$Zn^{2+}_{(aq)} + 2HPMBP_{(org)} \overset{K_1}{\rightleftharpoons} Zn(PMBP)_{2(org)} + 2H^+_{(aq)} \quad (1)$$

and

$$Zn^{2+}_{(aq)} + 2HPMBP_{(org)} + TBP_{(org)} \overset{K_2}{\rightleftharpoons} Zn(PMBP)_2TBP_{(org)} + 2H^+_{(aq)}. \quad (2)$$

In above equilibria, the equilibrium constants are:

$$K_1 = \frac{[Zn(PMBP)_2][H^+]^2}{[Zn^{2+}][HPMBP]^2} = q_o \frac{[H^+]^2}{[HPMBP]^2}$$

and

$$K_2 = \frac{[Zn(PMBP)_2TBP][H^+]^2}{[Zn^{2+}][HPMBP]^2[TBP]} = q \frac{[H^+]^2}{[HPMBP]^2[TBP]}.$$

The equilibrium for adduct formation in the organic phase is:

$$Zn(PMBP)_{2(org)} + TBP_{(org)} \overset{\beta_1}{\rightleftharpoons} Zn(PMBP)_2TBP_{(org)}, \quad (3)$$

where

$$\beta_1 = \frac{[Zn(PMBP)_2TBP]}{[Zn(PMBP)_2][TBP]} = K_2/K_1.$$

The equilibrium constants, K_1, K_2 and β_1, were determined at different temperatures. The enthalpy changes for reactions (1) and (2) were obtained through Gibbs–Helmholtz plots of the equilibrium constants against the reciprocal of the temperature. The values of enthalpy changes could be used to calculate the corresponding entropy changes. Figures 2 and 3 are Gibbs–Helmholtz plots for PMBP and PMBP–TBP systems, respectively. It was possible to calculate thermodynamic parameters for reaction (3) from the data for reactions (1) and (2). The results obtained at 23°C are given in Table 2. The errors estimated are less than 5% for ΔG and 10% for ΔS and ΔH.

There have been several suggestions for the structure of β-diketone complexes of Zn(II) and coordination numbers of 4, 5 and 6 are known.[18] An NMR study has shown that the hydration number of the Zn(II) ion in aqueous solution is 4.[19] Nash and Choppin[9] have proposed a mechanism for the synergistic extraction of Zn(II) in the TTA–TBP system, in which the increase in the coordination number of Zn(II) from 4 to 5 is caused by adduct formation with TBP. However, the thermodynamic parameters in Table 2 seem to indicate that the coordination number of the Zn(II) ion increases in the β-diketone complex formation of the hydrated Zn(II) ion in the PMBP–TBP system, i.e.:

$$[Zn(H_2O)_4]^{2+}_{(aq)} + 2HPMBP_{(org)} \rightleftharpoons Zn(PMBP)_2(H_2O)_{(org)} + 3H_2O_{(aq)} + 2H^+_{(aq)}. \quad (4)$$

Monohydrated bis(β-diketonato)Zn(II) complexes are also known.[20]

As Nash and Choppin[9] did, we could use similarly the argument that ΔH has only a unitary component and the cratic part of the entropy change is 7.9 Δn cal deg^{-1} where Δn is the change in the number of species. Assuming that the entropy change due to the hydrogen ion liberated in this buffer solution is nil, the cratic entropy change for reaction (4) is 7.9 cal deg^{-1}, since $n = 1$. If the chelation entropy for the formation of $Zn(PMBP)_2$ is approximately the same as that of $Zn(acac)_2$ (-17 cal deg^{-1}), as assumed for Zn(TTA),[9] the net entropy change for reaction (4)

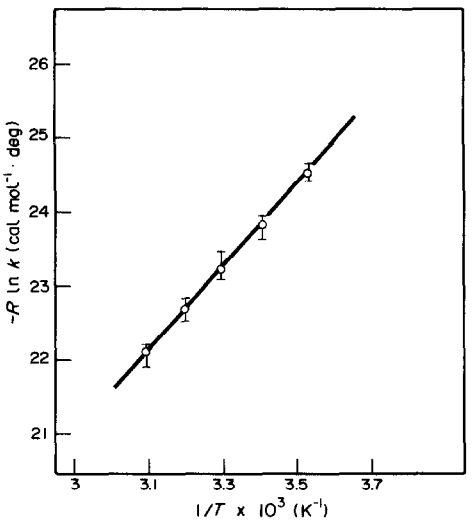

Fig. 2. Gibbs–Helmholtz plot for extraction of Zn(II) from 0.1 M $NaClO_4$ by PMBP in benzene.

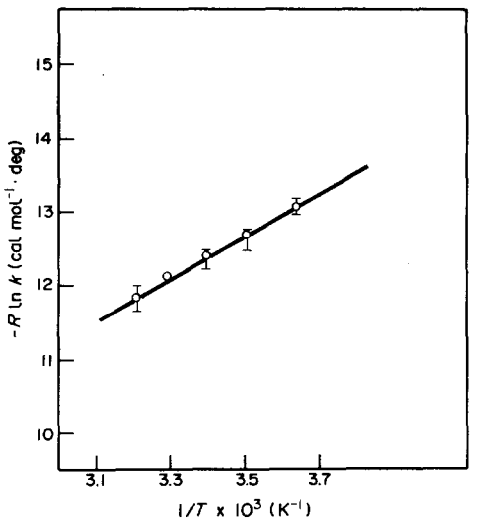

Fig. 3. Gibbs–Helmholtz plot for extraction of Zn(II) from 0.1 M $NaClO_4$ by PMBP–TBP mixtures in benzene.

Table 2. Thermodynamic values for reaction of Zn(II) with PMBP, and PMBP + TBP

Species	log K_1	log K_2	ΔG (kcal mol^{-1})	ΔH (kcal mol^{-1})	ΔS (cal deg^{-1} mol^{-1})
$Zn(PMBP)_2$	−5.203	—	+7.05	+5.51	−5.21
$Zn(PMBP)_2TBP$	—	−3.05	+4.13	+2.78	−4.51
	log β_1				
$Zn(PMBP)_2TBP$	+2.15		−2.92	−2.71	+0.70

would be -9 cal deg^{-1} mol^{-1}. The entropy change for this process was obtained experimentally to be -5.21 cal deg^{-1} mol^{-1}. This discrepancy may be due to the vibrational entropy of the PMBP ligand which is rather loosely bound in this five-coordinate as Nash and Choppin suggested for the TTA ligand.[9]

In the formation reaction of the mixed-ligand complex of Zn(II) with PMBP and TBP:

$$[Zn(H_2O)_4]^{2+}_{(aq)} + 2HPMBP_{(org)} + TBP_{(org)} \rightleftharpoons Zn(PMBP)_2TBP_{(org)} + 4H_2O_{(aq)} + 2H^+_{(aq)} \quad (5)$$

the net entropy change would be again -9 cal deg^{-1} mol^{-1}. The experimental value is about 4.5 cal deg^{-1} mol^{-1} larger, which would also be the vibrational entropy of rather loosely bound PMBP ligands.

From the above arguments, the reaction mechanism for the adduct formation of the $Zn(PMBP)_2$ chelate with TBP is deduced as follows:

$$\begin{array}{l} PMBP\text{-}Zn\text{-}PMBP_{(org)} + TBP_{(org)} \\ \quad | \\ \quad H_2O \end{array} \rightleftharpoons \begin{array}{l} PMBP\text{-}Zn\text{-}PMBP_{(org)} + H_2O. \\ \quad | \\ \quad TBP \end{array} \quad (6)$$

The rather small change in enthalpy, -2.71 kcal mol^{-1} for reaction (6) indicates the substitution of H_2O in the complex by TBP. The negligible value of the entropy change for this adduct formation, $+0.7$ cal deg^{-1} mol^{-1}, also supports this mechanism.

Abstract—The variation of magnetic moment with temperature displayed by *cis*-$[Mo(OPr^i)_2(bipy)_2]$ shows that the complex exists in an equilibrium between singlet and triplet spin states, with the singlet lying lower in energy by 158 cm^{-1}. The magnetic data can be fitted to a Bleaney–Bowers equation with values of 1.96 for g and 2×10^{-4} cgs units for the second-order susceptibility N_α. The IR, resonance Raman and electronic absorption spectra together with electrochemical data establish that the spin-state equilibrium is principally metal-centred, arising from a splitting of the t_{2g}-orbitals, though there is substantial Mo d to bipy π^* bonding.

High-spin–low-spin equilibria occur in many transition-element complexes.[1] In most cases the metal ion has between four and seven d-electrons and the ligand field is near the so-called "crossover" point between the spin-free and spin-paired configurations for the stereochemistry involved, usually in the O_h point group. There are a few exceptions. A spin-state equilibrium occurs[2] in the d^8-configuration in the nickel(II) complex $[Ni(TAAB)X_2] \cdot H_2O$ (X = Cl or Br) of the macrocyclic tetradentate ligand TAAB derived from the self-condensation of 2-aminobenzaldehyde. The strong tetragonal ligand field of TAAB gives the complex D_{4h}- rather than O_h-symmetry and a singlet–triplet spin equilibrium can occur. On the other hand the singlet–triplet equilibrium in $[Ti(\eta^5\text{-}C_5H_5)_2(bipy)]$ was ascribed[3] to the diamagnetic molecule having a low-lying excited state in which one unpaired electron is located on the $Ti(C_5H_5)_2$ unit and the other is in a π^*-orbital of the bipy ligand.

All these examples occur in complexes of first-row transition elements. This paper reports the first observation of spin-state isomerism for a heavy transition element, in the complex *cis*-$[Mo(OPr^i)_2(bipy)_2]$, whose preparation we have already reported.[4] The weak and unquantified high-temperature paramagnetism found[5] for a ruthenium tris(α-diimine) complex which is diamagnetic at room temperature was suggested to be due to spin-state isomerism or some other effect, but this has not been verified by susceptibility studies over a range of temperatures. The only previous report of spin-state isomerism in the d^4-configuration is for a manganese(III) complex of a salen-type Schiff base,[6] but in another example[7] there seems to be a sharp change from an ^5E_g- to a $^3T_{2g}$-state at 40–50 K rather than an equilibrium.

There have been very few magnetic studies of mononuclear molybdenum(II) complexes over a range of temperature. Although the d^4-configuration can give rise to a spin quintet, this is unknown for molybdenum(II), and would not be expected in a complex such as ours, which contains two bipy groups, normally considered as strong ligands. A spin triplet occurs[8] in $[Mo(diars)_2X_2]$ [diars = bis-1,2-(dimethylarsino)benzene; X = Cl, Br or I]; for these complexes the magnetic moments are about 2.85 μ_B at room temperature, falling slightly as the temperature is lowered, in keeping with the occurrence of just a little spin–orbit coupling in these low-symmetry complexes. Other monomeric

† Authors to whom correspondence should be addressed.

molybdenum(II) complexes are diamagnetic, and many are seven-coordinate to achieve the 18-electron configuration.

EXPERIMENTAL

Standard procedures for the manipulation of air-sensitive materials were employed. All solvents were dried and deoxygenated prior to use.

IR spectra were obtained from Nujol mulls between KBr plates using a Perkin–Elmer 283 spectrophotometer. UV–visible spectra were recorded on a Hitachi 330 spectrophotometer using toluene as solvent. Magnetic measurements were obtained by the Faraday technique as described previously.[9]

The electrochemical measurements were made with a PAR 173 potentiostat, a PAR 175 programmer and a Houston 2000 XY recorder. The cyclic voltammetry was carried out in a one-compartment cell, while the coulometry used a three-compartment cell. The auxiliary electrode was of platinum gauze, the working electrode was either platinum wire or gauze and the reference electrode was 0.01 F $AgNO_3$ (CH_3CN)/Ag wire. Acetonitrile solutions were used with 0.1 M tetra-*n*-butylammonium hexafluorophosphate as the supporting electrolyte, using ferrocene as the internal standard.[10]

Preparation of cis[$Mo(OPr^i)_2(bipy)_2$]

To a stirred solution of [$Mo_2(OPr^i)_6$][11] (1.0 g, 1.84 mmol) in hexane (30 cm^3) was added 2,2′-bipy (0.6 g, 3.8 mmol). The initially yellow solution immediately changed to an intense purple. The solution was stirred for 1 h and allowed to stand overnight ($\simeq$ 12 h). Black crystals of [$Mo(OPr^i)_2(bipy)_2$] were collected by filtration and dried *in vacuo*. Yield 0.56 g, 60%. The compound may be recrystallised by addition of hexane to a solution in toluene. Found: C, 59.15; H, 5.68; N, 10.74. $C_{26}H_{30}MoN_4O_2$ requires C, 59.31; H, 5.74; N, 10.65%. IR data: 1583m, 1518m, 1304s, 1254m, 1158m, 1123s, 1023w, 991s, 973s, 954s, 839w, 741s, 735vs, 720s, 601m, 487w and 424w.

RESULTS AND DISCUSSION

Magnetic properties

The variations of the magnetic susceptibility and moment of *cis*-[$Mo(OPr^i)_2(bipy)_2$] with temperature are given in Table 1. The variation of moment with temperature is shown in Fig. 1. The error in the values of magnetic moment is ± 0.06 μ_B, which is higher than is often found in magnetochemical studies. This reflects the near cancellation of the paramagnetism of the complex by the diamagnetism of the ligands and the sample holder.

Table 1. Magnetic properties of *cis*-[$Mo(OPr^i)_2(bipy)_2$]

T (K)	10^3 χ_M (cgs)	μ (μ_B)
91	1.50	1.04
110	2.02	1.33
130	2.05	1.46
149	2.02	1.55
169	2.04	1.66
189	1.94	1.71
208	1.86	1.76
226	1.79	1.80
245	1.72	1.84
265	1.72	1.91
285	1.59	1.90
305	1.57	1.96

The magnetic behaviour is quite unlike that of the other Mo(II) complexes described in the introduction. The results are most easily explained by postulating a singlet–triplet spin-state equilibrium. The full curve in Fig. 1 represents the calculated variation of magnetic moment with temperature using the usual Bleaney–Bowers treatment[12] with values of $g = 1.96$, $J = -79 \pm 5$ cm^{-1} and $N_\alpha =$

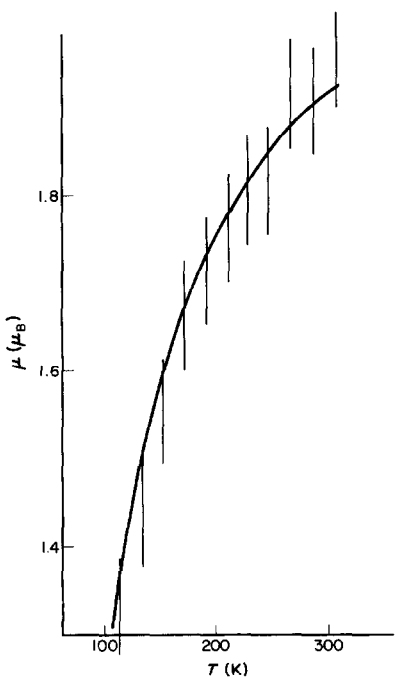

Fig. 1. Variation of magnetic moment (μ_B) of *cis*-[$Mo(OPr^i)_2(bipy)_2$] with temperature (K).

2×10^{-4} cgs units. The calculation assumed a spin-only value for the magnetic moment of the triplet state, which we think is reasonable in view of the low symmetry of the complex. The agreement with the experimental values is seen to be satisfactory.

The mol fractions of singlet and triplet spins at each temperature were also calculated to obtain the singlet–triplet equilibrium constants. An Arrhenius' plot of these gives a good straight line from which ΔH for the equilibrium was calculated as 145 ± 15 cm^{-1}. This compares favourably with the value of 158 ± 10 cm^{-1} ($= -2J$) for the singlet–triplet energy separation in the Bleaney–Bowers treatment.

Bleaney and Bowers[12] pioneered their method to interpret the behaviour of the antiferromagnetic dimer $[Cu_2(H_2O)_2(O_2CMe)_4]$, not a spin-state equilibrium in a mononuclear complex. However, their system is similar to ours in that there is a singlet ground state below a thermally accessible triplet state. This is not a common situation in spin-state isomerism; reduction in temperature usually gives a gradual or abrupt change in ground state from high spin to low spin, often accompanied by significant changes in molecular dimensions. As the evidence below shows, we believe our spin equilibrium arises from thermal population of two closely spaced orbitals which are essentially σ-nonbonding. We therefore do not expect much variation in molecular structure with temperature and conclude that there is virtually a constant energy difference between the spin states.

An alternative explanation, that the temperature dependence of the magnetic moment arises from spin–orbit coupling in a $^3T_{1g}$ ground state, can be excluded because our data do not fit any of the many combinations of parameters which describe[13] such a process.

IR and Raman spectra

The IR spectra of various metal–bipy complexes have been extensively studied, especially those with metal atoms in unusually low oxidation states where complexes of the type M^{n+}(bipy) might better be described as $M^{(n+1)+}$(bipy)$^-$, i.e. the bipy ligand is reduced.[14] On the basis of characteristic IR bands it was proposed[14] that complexes could be divided into three categories where the bipy ligands were in a normal, reduced or intermediate (partly reduced) state. The complexes with "normal" bipy ligands exhibited a strong band in the 1600–1610-cm^{-1} region and no bands in the 1500–1600- or 950–100-cm^{-1} regions. Complexes containing "reduced" bipy ligands did not have a band above 1600 cm^{-1}, but exhibited several strong bands in the 1490–1575-cm^{-1} region and a strong band in the 900–1000-cm^{-1} region. Complexes with "intermediate" bipy ligands exhibited bands in all three regions.

$[Mo(OPr^i)_2(bipy)_2]$ exhibits medium bands at 1583 and 1518 cm^{-1}, nothing above 1600 cm^{-1}, and three strong bands at 991, 972 and 954 cm^{-1}. It should be noted that O–C stretches in metal alkoxides typically occur in the 900–1000-cm^{-1} region.[15] Thus if two of the latter bands arise from O–C stretching modes, this still leaves one band assignable to a bipy mode. The IR data are therefore most consistent with a "reduced" bipy ligand on these criteria.

The resonance Raman (RR) spectrum of $[Mo(OPr^i)_2(bipy)_2]$ has previously been reported.[4] The seven A_1 framework stretches of the bipy ligand show RR enhancement and the frequencies of these modes shift to a lower energy as the electron density in the bipy π^*-orbitals is increased, either through reduction or metal $d \rightarrow$ bipy π^* back-bonding.[16] The RR frequencies of $[Mo(OPr^i)_2(bipy)_2]$ lie roughly halfway between the frequencies for a "normal" bipy ligand, such as in $[Ru(bipy)_2Cl_2]$ or $[Ru(bipy)_2(NH_3)_2]^{2+}$ and that of a fully reduced bipy as in Li^+bipy^-.[16] It was concluded that the bipy ligands in *cis*-$[Mo(OPr^i)_2(bipy)_2]$ have approximately 0.5 ε in their π^*-orbitals, i.e. they are partly but not fully reduced.

UV–visible data

The electronic absorption spectrum of *cis*-$[Mo(OPr^i)_2(bipy)_2]$ exhibits the following strong bands {[λ_{max} (nm)] [ε (M^{-1} cm^{-1})]}: 940sh, 745 (7800), 550 (17,000), 438 (5200), 380sh ($\simeq$ 6000) and 305 (27,000). No absorptions with $\varepsilon > 40$ M^{-1} cm^{-1} were found between 1300 and 2200 nm. This spectrum is not very similar to that of Na^+bipy^-: 850 (1900), 550 (4300), 380 (17,000).[17] For complexes where the $M^{(n+1)+}bipy^-$ formulation seems appropriate, spectra similar to that of Na^+bipy^- are often found.[18] The most distinguishing feature is that for "normal" bipy the intense $\pi \rightarrow \pi^*$ transition occurs[19] at $\lambda_{max} \simeq 300$ nm ($\varepsilon \simeq 15{,}000$ M^{-1} cm^{-1}) where for $bipy^-$ this transition moves to lower energy, $\lambda_{max} \simeq 380$ nm.[17] Therefore it seems more appropriate to refer to the present complex as

$$[Mo(OPr^i)_2(bipy)_2]$$

rather than

$$[Mo(IV)(OPr^i)_2(bipy^-)_2]$$

or

$$[Mo(III)(OPr^i)_2(bipy)(bipy^-)].$$

The observed transitions are then most readily assigned as metal d to bipy π^* charge-transfer

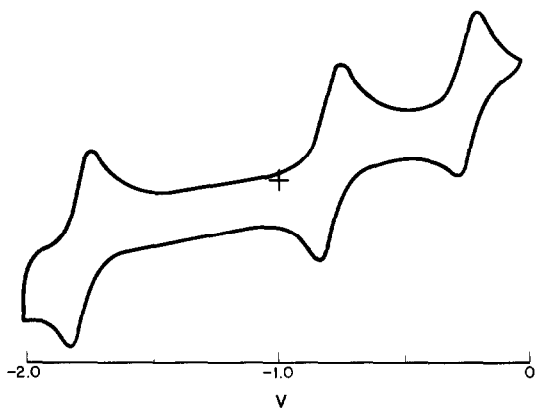

Fig. 2. Steady-state cyclic voltammogram of *cis*-[Mo(OPr^i)$_2$(bipy)$_2$]. Applied voltage is vs the SCE.

transitions. Their low energy can be ascribed to the great ease of oxidation of the metal (*vide infra*). The energy separation between the two lowest energy bands (745 and 550 nm) of $\simeq 5000\ cm^{-1}$ is typical for the separation of MLCT transitions to the lowest and second lowest π^*-orbitals of bipy.[19] The third transition (438 nm) is presumably MLCT to the third lowest π^*-orbital.

Electrochemistry

The electrochemical properties of the complex were examined in acetonitrile solutions (Fig. 2). Two oxidative couples were observed at −0.80 and −0.25 V vs the saturated calomel electrode (SCE). The anodic and cathodic peak currents of both couples were the same. Without compensation for internal resistance (ir), peak-to-peak separations of 70–80 mV were observed while separations of 60–65 mV were observed with ir compensation. Both couples are thereby implied to be reversible one-electron transfer processes. Oxidative coulometry at −0.5 V verified that the first first couple was indeed a one-electron process. A reversible reduction process was observed to occur at −1.80 V, and it also appears to be a one-electron couple.

The two oxidative couples can be assigned as Mo-centred since they do not occur at sufficiently negative potentials to be assigned as a bipy$^-$ → bipy + ε^- oxidation. Data for a wide variety of complexes have shown that bipy-based reductions occur at −1.2 V vs SCE.[20] Since the first oxidative couple occurs at a 0.3 V more positive potential than this, it can be assigned as predominantly metal-based, though substantial metal d → bipy π^* interactions are implied. Therefore the electrochemistry also supports the formulation as a neutral molecule, [Mo(II)(OPr^i)$_2$(bipy)$_2$], rather than a molybdenum(III) or (IV) species. The negative potentials for both oxidative couples show that the Mo centre is exceedingly electron-rich.

Molecular structure of cis-[Mo(OPr^i)$_2$(bipy)$_2$]

The crystal and molecular structures have previously been reported,[4] where it was emphasised that the C–C and C–N distances within the bipy ligands were substantially different from those normally seen in metal–bipy complexes. Similar distortions within the bipy ligands have subsequently been reported in the compound [Fe(η^6-toluene)(bipy)],[21] and this type of distortion has been demonstrated to result from the addition of substantial electron density to the lowest π^*-orbital of bipy.[22]

What is of particular interest in the present work is the orientation of the alkoxide ligands. This is shown in the stereoviews in Fig. 3. Assuming that the oxygen atoms are sp^2-hybridised (Mo–O–C angle is 130 ±2°), then the oxygen-filled p-orbitals lie roughly in the same plane such that they both (one on each O atom) will interact with the same Mo atomic orbital. The O–Mo–O angle of 105.3(1)° and the Mo–O distances (1.94 and 1.93 Å) are both consistent with some oxygen–Mo π-bond.[23]

Qualitative MO description

Two limiting situations may be invoked to account for the observed singlet–triplet spin-state

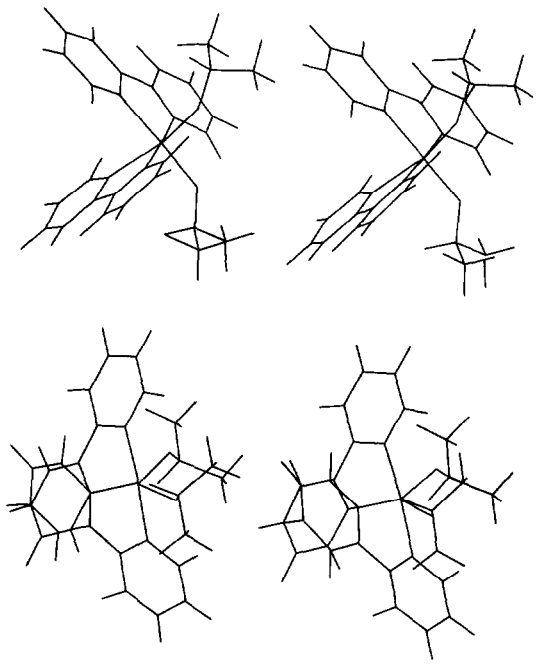

Fig. 3. Stereoviews of *cis*-[Mo(OPr^i)$_2$(bipy)$_2$] which emphasise the orientation of the alkoxide ligands.

equilibrium. (1) The electrons involved are in metal-centred orbitals and the spin equilibrium is between the configurations arising from t_{2g}^4. (2) The equilibrium is of a charge-transfer nature, Mo(II)(bipy)(singlet) $\rightleftharpoons$ Mo(III)(bipy)$^-$(triplet), similar to that previously found[3] for $[Cp_2Ti(bipy)]$. The observed electrochemical data and electronic spectrum argue against the presence of a fully reduced bipy ligand, bipy$^-$. It should be noted that these measurements were made at room temperature where the singlet : triplet ratio should be roughly 40 : 60, so that the presence of the bipy$^-$ species should be readily detectable. Although the IR data suggest the ligands belong to the "reduced" category, the more quantitative RR data showed them to be "reduced" by only $\simeq 0.5\,e$ each. The vibrational data may readily be accomodated by mixing of Mo *d*- and bipy π^*-orbitals, i.e. strong Mo *d* to bipy back-bonding. We therefore turn to a spin equilibrium involving the t_{2g}^4-configuration as a starting point for an understanding of this molecule.

The development of a simple molecular orbital scheme, based on the coordinate scheme shown in Fig. 4, can rationalise the observed results. In this axis system the t_{2g}-orbitals are d_{xz}, d_{xy} and $d_{z^2-y^2}$, which transform as *b*, *a* and *a* respectively in the C_2 point group.

First we turn to the metal–alkoxide interactions, since it is known that π-donor ligands can cause a "two below one" splitting of the t_{2g}-orbitals to give a diamagnetic d^4-configuration in an octahedral complex.[24] Both alkoxide ligands are oriented so that their filled $O(p\pi)$ orbitals essentially lie in the *yz* plane. In this situation the Mo $d_{z^2-y^2}$-orbital interacts with the oxygen *p*-orbitals. Formation of one RO–Mo π-bonding, one non-bonding (RO-centred) and one antibonding interaction may be anticipated. As noted previously the relatively short

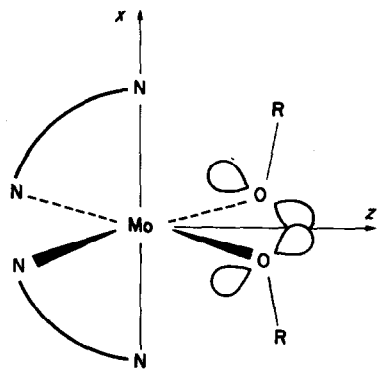

Fig. 4. Coordinate system for *cis*-$[Mo(OPr^i)_2(bipy)_2]$. The *z*-axis coincides with the C_2-axis of the molecule. The drawn $O(p\pi)$ orbitals essentially lie in the *yz* plane.

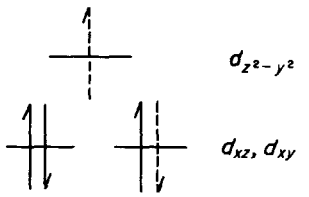

Fig. 5. Proposed orbital-ordering scheme. The dashed arrows indicate the two possible locations of the fourth metal electron for the singlet–triplet equilibrium.

Mo–O distances and enlarged (> 90°) O–Mo–O angle are all consistent with this picture. This leads to the orbital splitting shown in Fig. 5 wherein the $d_{z^2-y^2}$-orbital lies above the d_{xz}- and d_{yz}-orbitals, which are roughly equal in energy. It is also noteworthy that enlarging the O–Mo–O angle from 90° is predicted[25] to cause a further destabilisation of the Mo $d_{z^2-y^2}$-orbital as a result of a partial rehybridisation towards the alkoxide ligands which enhances π interaction. The singlet ground state corresponds to the $(d_{xy}, d_{xz})^4$ configuration, and the triplet excited state to $(d_{xy}, d_{xz})^3(d_{z^2-y^2})^1$.

Now the interactions with the bipy π^*-orbitals are considered. The lowest-energy π^*-orbital has the same phase at each N atom, i.e. it is antisymmetric with respect to rotation about the bipy C_2-axis.[3,16,21] The two combinations of these give MOs of *a*- and *b*-symmetry. Angular overlap considerations show that these have roughly equal overlaps with the $d_{xz}(b)$ and $d_{xy}(a)$ orbitals, though their overlaps with the $d_{z^2-y^2}(a)$ orbital is roughly twice as great. Thus the metal $d \rightarrow$ bipy π^* interactions should stabilise the $d_{z^2-y^2}$-orbital relative to the d_{xz}- and d_{xy}-orbitals, which is opposite to the effect of the RO ligands.

Which effect dominates? We feel the ordering with the $d_{z^2-y^2}$-orbital highest in energy is correct for the following reasons. (1) The orientation of the alkoxides implies that the $d_{z^2-y^2}$ is singled out for oxygen *p* interactions. (2) Alkoxides are strong π-donors whereas bipy ligands are relatively weak π-acceptors. The alkoxide interaction should thus be dominant. (3) If the $d_{z^2-y^2}$-orbital was beneath the d_{xy}- and d_{xz}-orbitals, then the energy splitting between the d_{xz}- and d_{xy}-orbitals would have to be responsible for the spin singlet–triplet equilibrium. There is no reason to believe that these orbitals should be split by an energy separation comparable to the pairing energy. However, the opposing influences of RO π-donor and bipy π^*-acceptor ligands could well result in the energy separation between the $d_{z^2-y^2}$ and (d_{xz}, d_{xy}) orbitals being sufficiently small (i.e. comparable to the spin-pairing energy) that the singlet–triplet spin-state equilibrium occurs.

A direct way of measuring the splitting of the t_{2g}-orbitals is to locate the $d\pi \rightarrow d\pi$ transitions. For example, many diamagnetic octahedral d^4 complexes have an absorption band in the region 500–700 nm with $\varepsilon \simeq 60$–$600\ M^{-1}\ cm^{-1}$, which has been assigned to the lowest energy $d\pi \rightarrow d\pi$ transition.[26] Unfortunately, for *cis*-$[Mo(OPr^i)_2(bipy)_2]$ this region of the spectrum is completely obscured by the strong MLCT transitions. Since no transitions with $\varepsilon > 40\ M^{-1}\ cm^{-1}$ are observed between 1300 and 2200 nm it is presumed that the energy separation is at least greater than $6000\ cm^{-1}$.

Concluding remarks

Normally, monomeric Mo(II) compounds are stabilised by strong π-acceptor ligands (CO, CNR etc.) or, when surrounded by hard or "classical"-type ligands (Cl^-, O_2CR^- etc.), are found with accompanying M–M bonds.[27] *Cis*-$[Mo(OPr^i)_2(bipy)_2]$ is unusual in being one of only a few octahedral Mo(II) complexes containing both π-donor and π-acceptor ligands.[25,26,28] It is unique, at least for the moment, in providing an example of a singlet–triplet spin-state equilibrium for a non-first-row transition element. The electrochemical data and electronic spectrum reliably establish the origin of the spin-state equilibrium to be metal centred while the IR and RR spectra and structural data provide evidence for extensive Mo *d* to bipy π^* back-bonding. This work emphasises the gradation of bipy reduction by back-bonding (analogous to the bond order reduction of C≡O) and the need to draw upon several techniques to establish a reasonable bonding description for low-valent metal–bipy complexes.

(*Received* 11 *March* 1985; *accepted* 10 *May* 1985)

Abstract—Cluster bond enthalpies, E_L(B—B), and orders, $\bar{n}$(B—B), for the structurally characterised *closo* anions, $B_nH_n^{2-}$ ($n = 6$ and 8–12), have been estimated using the logarithmic length–enthalpy and enthalpy–order relationships E_L(B—B) (kJ mol^{-1}) = 1.766×10^{11} [L(B—B)]$^{-4.0}$ and E_L(B—B) (kJ mol^{-1}) = $318.8[\bar{n}$(B—B)]$^{0.697}$, respectively. In a parallel study, the molecular-orbital bond index CNDO-based calculation method has been used to give B—B and B—H bond indices, I(B—B) and I(B—H), from which bond index based bond enthalpies, E_I, have been calculated using the relationships E_I(B—B) = $297.9I$(B—B) and E_I(B—H) = $374.8I$(B—H) (enthalpies in kJ mol^{-1}; lengths in pm). From these, total skeletal bond enthalpies $\sum E$(B—B), and total bond enthalpies, $\sum E$(B—B) + $\sum E$(B—H), have been calculated. Although calculated values of E_L and $\sum E_L$ generally exceed those of E_I and $\sum E_I$ by some 8% and calculated values of I generally exceed those of $\bar{n}$ by a greater amount, the trends in these parameters for the series of $B_nH_n^{2-}$ anions are very similar, showing the greater efficiency with which the $n + 1$ skeletal electron pairs are used as n increases. However, the two approaches differ in that, whereas the $\sum E_I$ values suggest that the anions are all of comparable stability, the $\sum E_L$ values clearly show $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ to be more stable than $B_8H_8^{2-}$, $B_9H_9^{2-}$ and $B_{11}H_{11}^{2-}$. The interatomic distances in $B_7H_7^{2-}$ and in the unknown $B_5H_5^{2-}$ are estimated and used to assess their relative stabilities. The E_L values suggest that $B_7H_7^{2-}$ is of comparable stability to $B_8H_8^{2-}$ etc., but show $B_5H_5^{2-}$ as relatively unstable. The E_I values suggest that both of these anions should be relatively stable members of the series of *closo* anions.

In an earlier note,[1] we explored the assignment of bond length based bond enthalpies, E_L, to the skeletal bonds of the *closo* borane anions, $B_nH_n^{2-}$ ($n = 6$, 8, 9, 10 or 12) (Fig. 1), as a means of estimating their relative stabilities and electron distributions. Laurie and Perkins[2] subsequently used bond index based bond enthalpies, E_I, for the same purpose for the species $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$. Here, we elaborate and extend these arguments to ascertain the extent of agreement between the two methods, and to include $B_{11}H_{11}^{2-}$ (a derivative of which, $B_{11}H_{10}SMe_2^-$, has been structurally characterised[3]

since the earlier work) and $B_7H_7^{2-}$ (for which we have estimated the interatomic distances). We also discuss briefly the probable interatomic distances and possible stability of the unknown species $B_5H_5^{2-}$.

Methods used to calculate E_L *and* E_I

The method of calculating *bond enthalpies from bond lengths* that we have used[1,4,5] employs relationships of the form $E_L(X—Y) = A[L(X—Y)]^{x-}$ to calculate bond enthalpies, E_L kJ mol^{-1}, of bonds of length L pm, where A and x are constants for the particular atom pair X—Y involved, their values being determined by fitting $\sum E_L(X—Y)$ to gas-phase atomisation enthalpies calculated from published values of ΔH_f^o for suitable molecules. The equations $E_L(B—B)$ (kJ mol^{-1}) $= 1.766 \times 10^{11}[L(B—B)]^{-4.0}$ and $E_L(B—H)$ (kJ mol^{-1}) $= 4.476 \times 10^{11}[L(B—H)]^{-4.4}$ were found[5] to give a good fit to published structural[6] and thermochemical[7] data for the *nido* and *arachno* boranes B_4H_{10}, B_5H_9, B_5H_{11}, B_6H_{10} and $B_{10}H_{14}$, using values of 560 and 218 kJ mol^{-1} for ΔH_f^o for gaseous boron and hydrogen atoms respectively. Both bridging and terminal B—H bonds were included, as were directly-bonded and hydrogen-bridged interactions, but longer-range interactions were assumed to be negligible.

These equations afforded values for $E_L(B—B)$ of 219 and 178 kJ mol^{-1} for the skeletal bonds in $B_6H_6^{2-}$ (length 168.6 pm)[8] and $B_{12}H_{12}^{2-}$ (length 177.5 pm)[9] respectively. Since the $n+1$ skeletal electron pairs in these two highly symmetrical anions can be assumed to be divided evenly between their $3n-6$ edges, these edges formally have bond orders, $\bar{n}$, of 7/12 and 13/30 respectively. This leads to the bond enthalpy–bond order relationship $E_L(B—B) = 318.8[\bar{n}(B—B)]^{0.697}$, whence a single bond between two boron atoms has a bond enthalpy of 318.8 kJ mol^{-1} and a length of 153.4 pm.

The *bond index method*[10–12] employs a CNDO–SCF calculation of molecular electronic structure, including all valence electrons and all possible orbital interactions, to obtain an electron density matrix. From this, bond indices, I, can be calculated and have been used to estimate E_I for numerous bonds, specifically for those in boranes[2] by means of the equations $E_I(B—B) = 297.9I(B—B)$ and $E_I(B—H) = 374.8I(B—H)$ (which gave a good fit to the published thermochemical data for B_4H_{10} and B_5H_9).[2] Since bond indices should correspond closely to bond orders for relatively non-polar bonds, these equations afford bond enthalpy terms, E_I, of 297.9 and 374.8 kJ mol^{-1} for single B—B and B—H bonds respectively.

The important differences between the bond length and bond index approaches to bond enthalpies are that the former assumes that the only bonding interactions of significance are those in the immediate coordination sphere of the atoms concerned, and relates their strength to their length, irrespective of the connectivities of the atoms concerned, whereas the latter relates bond enthalpies to a parameter (bond index) that is a measure of the electron density between the nuclei concerned, which may vary with atom connectivities as well as with internuclear distances, and includes all pair-wise interactions, whether involving first coordination sphere atoms or those further away, a factor which may be of importance when dealing with cluster compounds, for which neglect of cross-polyhedral interactions may not be justified.

RESULTS AND DISCUSSION

Closo *anions* $B_nH_n^{2-}$ *of known structure* (n = 6,[8] 8,[13] 9,[14] 10,[15] 11[3] *and* 12[9])

Table 1 lists the interatomic distances (L pm) for the various types of polyhedron edge in the *closo* borane anions, $B_nH_n^{2-}$ (n = 6 and 8–12), classified according to the skeletal atom connectivities, k and k', of the two boron atoms they link (k is the number of polyhedron edges that meet at the vertex occupied by the atom concerned). Table 1 also lists calculated bond indices, I, bond orders, $\bar{n}$, and bond enthalpies, E_I and E_L. Separate entries are made in cases where there are nonequivalent edges of a given connectivity—for example, for the two types of edge linking atoms of connectivities 4 and 5 in $B_8H_8^{2-}$, and for the two types of edge linking atoms of connectivities 5 and 5 in $B_9H_9^{2-}$. Average values are given in Table 2.

One structural feature of these *closo* anions $B_nH_n^{2-}$ is quite pronounced. Polyhedron edge lengths increase quite markedly with the connectivities of the atoms they link within a particular polyhedron. Clearly, the more atoms a particular boron atom

bonds to, the weaker and so longer those bonds will be, since that atom's share of the $n+1$ skeletal bonding electrons has to be divided between more two-centre links. This structural trend is reflected in the trends in the calculated I, $\bar{n}$ and bond enthalpies, whether E_I or E_L. Although E_L exceeds E_I by some 8% on average, both E_L and E_I show the same general trends, with but few exceptions which are not considered to be significant in view of the variable quality of the structural data and the approximations inherent in our approach.

Another perhaps less recognised structural feature worth noting is the manner in which bonds of a particular connectivity type tend to get progressively *shorter* as n increases, the reverse of the trend that might have been expected as the number of skeletal electrons available per boron atom, $(n+1)/n$, or per polyhedron edge, $(n+1)/(3n-6)$ *decreases* as n increases. For example, bonds linking atoms of connectivity 4 have length 168.6 pm in $B_6H_6^{2-}$,[8] and 155.9 pm in $B_8H_8^{2-}$.[13] For bonds linking atoms of connectivities 4 and 5, average lengths are 174.3 pm ($B_8H_8^{2-}$),[13] 170.8 ppm ($B_9H_9^{2-}$),[14] 167.8 pm ($B_{10}H_{10}^{2-}$)[15] and 169.4 pm ($B_{11}H_{10}SMe_2$).[3] A similar trend is apparent in edges linking atoms of connectivity 5, which have average lengths 192.6, 186.0, 181.0, 178.8 and 177.5 pm for $n = 8$,[13] 9,[14] 10,[15] 11[3] and 12[9], respectively. These trends are believed to reflect more effective use of the skeletal bonding electrons as n increases.

Table 2. Mean bond distances, L^a, indices, I, orders, $\bar{n}$, and enthalpies, E_L and E_I, classified according to the skeletal connectivities, k, of the linked atoms for $B_nH_n^{2-}$ species

k, k'	L	I	$\bar{n}$	E_L	E_I
4, 4	166.8	0.716	0.630	230	213
4, 5	171.0	0.644	0.540	207	192

[a] Data relate only to structurally characterised species, with $n = 6, 8, 9, 10, 11$ or 12.

The large discrepancy between the calculated I and $\bar{n}$ (Table 1) for the longer bonds in these polyhedra should not go unremarked, and may have its origin in two factors. On the one hand our method of calculating bond orders from bond enthalpies is crucially dependent on the interatomic distances in $B_6H_6^{2-}$[8] and $B_{12}H_{12}^{2-}$,[9] errors in which will necessarily be multiplied manifold in the considerable extrapolation involved. On the other hand,

Table 3. Total B—B bond indices, $\sum I$, and bond orders, $\sum \bar{n}$, compared with number of skeletal electron pairs for $B_nH_n^{2-}$

it is apparent that the bond indices calculated for these clusters when summed ($\sum I$) exceed the numbers of skeletal electron pairs available (Table 3). Although for simple molecules like hydrocarbons, calculated I correspond closely to $\bar{n}$,[10] the greater efficiency with which these polyhedral clusters use their relatively few skeletal electron pairs is believed to account for the difference between $\sum I$ and $n+1$ shown in column 5 of Table 3. In contrast, the total skeletal $\bar{n}$ for these clusters, $\sum \bar{n}$, listed in the penultimate column of Table 3, are, anyway, normalized against the number of skeletal bond pairs available in the cases of $B_6H_6^{2-}$ and $B_{12}H_{12}^{2-}$, and show only slight departures from the numbers of skeletal electron pairs, the extent of departure [$\sum \bar{n}-(n+1)$, listed in the final column of Table 3] reflecting the stability of $B_{10}H_{10}^{2-}$ and relative instability of $B_8H_8^{2-}$, $B_9H_9^{2-}$ and $B_{11}H_{11}^{2-}$, in keeping with their known chemistry.[6] The total I, $\sum I$, appear to vary with n or $n+1$ in a regular manner that gives no hint that $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ are more stable clusters than the other *closo* anions (which tend to disproportionate to generate these three species).

The second and third columns in Table 3 incidentally give a clear indication of the relative unimportance of the cross-polyhedral interactions in these clusters [$\sum I$(B---B), column 3] when compared with the nearest neighbour interactions [$\sum I$(B—B), column 2], in that the former represent only some 1–2% of the $\sum I$. This result, being in accord with most other treatments of these clusters which suggest that most of the skeletal electron density is close to the pseudo-spherical surfaces on which the boron atoms lie,[6] strengthens our view, made in an earlier paper,[16] that the approach developed by Fuller and Kepert,[17] in which cross-polyhedral interactions are assigned comparable energies to nearest neighbour interactions, grossly exaggerates the role of the former.

The trends apparent in the data in Table 3 are also discernible in the data in Table 4, which lists the total skeletal bond enthalpies, $\sum E_L$ and $\sum E_I$ (column 2), and the average skeletal bond enthalpy per boron atom (column 3), per electron pair (column 4) and per polyhedron edge (last column). Peaks of stability are indicated for $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ by the values of $\sum E_L$, whether expressed per boron atom, electron pair or polyhedron edge, whereas the bond index data show this to a much lesser extent, suggesting greater stability for $B_6H_6^{2-}$ than for the remainder, which all appear to be of comparable stability. This is shown in Fig. 2, which plots $\sum E/n$ and $\sum E/(n+1)$ against n. One respect in which both approaches concur is shown by the final column of Table 4, i.e. that the average enthalpy per polyhedron edge bond shows a decline after $B_6H_6^{2-}$, as the number of edges ($3n-6$) increases with n at too great a rate to be compensated by the greater efficiency with which the dwindling numbers of skeletal electrons per BH unit, $(2n+2)/n$, are used.

Puzzled that I(B—B) and the bond enthalpies derived therefrom did not show the relative stabilities of $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$, and instabilities of $B_8H_8^{2-}$, $B_9H_9^{2-}$ and $B_{11}H_{11}^{2-}$, we summed I(B—H) for the whole series of anions, calculated $\sum E_I$(B—H) for each, and hence the total bond enthalpy, $\sum E_I$(B—B)+$\sum E_I$(B—H) for each anion. The data are given in Table 5. When expressed as a total bond enthalpy per boron atom, [$\sum E_I$(B—B)+$\sum E_I$(B—H)]/n (last column of Table 5), some hint of a marginally greater stability in the cases of $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ is apparent.

The anions $B_7H_7^{2-}$ *and* $B_5H_5^{2-}$

Although *closo* carboranes, $C_2B_{n-2}H_n$, with n ranging from 5 to 12 have long been known and structurally characterised, the related series of isoelectronic anions, $B_nH_n^{2-}$, lacks a pentanuclear

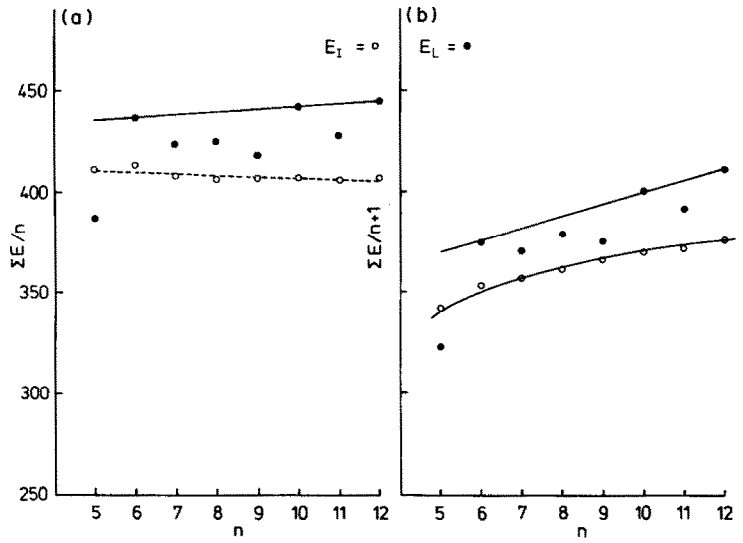

Fig. 2. (a) Average skeletal bond enthalpies (kJ mol^{-1}) per boron atom, $\sum E(B—B)/n$, plotted against the number of boron atoms, n, for $B_nH_n^{2-}$ anions. (b) Average skeletal bond enthalpies (kJ mol^{-1}) per skeletal electron pair, $\sum E(B—B)/(n+1)$, plotted against the number of boron atoms, n, for $B_nH_n^{2-}$ anions.

species $B_5H_5^{2-}$, and $B_7H_7^{2-}$, though believed on the basis of NMR solution studies[18] to be pentagonal bipyramidal, has not yet been the subject of X-ray crystallographic study. The probable interatomic distances in this anion were estimated as follows.

(i) The two distinct types of edge, which may be labelled equatorial and axial, connect atoms of connectivity 4 (equatorial) or 4 and 5 (axial). Tables 1 and 2 and our earlier discussion suggest that, for $B_7H_7^{2-}$, these will have lengths of 162 and 178 pm respectively.

(ii) For the regular polyhedral anions $B_6H_6^{2-}$[8] and $B_{12}H_{12}^{2-}$,[9] all the boron atoms are equivalent and so lie on spherical surfaces. This is not true for anions $B_nH_n^{2-}$ with n = 8–11, whose atoms of connectivity 4 lie on a sphere of radius *ca* 15% greater than that on which the atoms of connectivity 5 lie. If the same were true for $B_7H_7^{2-}$, edge lengths of *ca* 158 pm (equatorial) and 183 pm (axial) would be expected.

(iii) Comparison of anions $B_nH_n^{2-}$ with isoelectronic carboranes,[6,19] $C_2B_{n-2}H_n$, shows that the B—C distances in the latter are *ca* 8 pm shorter than B—B distances for comparable polyhedral edges in the former. From the structure of $C_2B_5H_7$,[20] we infer B—B bond distances of 163 pm (equatorial) and 179 pm (axial) for $B_7H_7^{2-}$.

Since these last figures were in good agreement with those obtained by method (i), and were obtained by comparison with a closely related compound, we decided to use them in our calculation of enthalpies

Table 4. Total skeletal bond enthalpies, $\sum E_L(B—B)$ and $\sum E_I(B—B)$, for species $B_nH_n^{2-}$, and average enthalpies per boron atom, per skeletal electron pair, and per B—B link (kJ mol^{-1} throughout)

by the bond length and bond index methods. As a check, we also carried out molecular-orbital *I* (MOBI) calculations on four variations of this geometry, (a) expanded, (b) contracted, (c) compressed and (d) elongated on the five-fold axis; these changes resulted in edge length changes of 2–5 pm but gave no significant increase in bond index or enthalpy values, and therefore in stability.

Values of I, $\bar{n}$ and bond enthalpies calculated for the suggested structure have been included in Tables 1, 3, 4 and 5, and Fig. 2 without previous comment. Inspection of the data show that the known slight instability of $B_7H_7^{2-}$ to disproportionation into $B_6H_6^{2-}$ and $B_8H_8^{2-}$ is consistent with the figures obtained.

For the as yet unknown $B_5H_5^{2-}$, analogy with the known D_{3h} structure of 1,5-$C_2B_3H_5$[21] suggests axial bond lengths of 164 pm and equatorial bond lengths of 183 pm. Calculation of bond enthalpies using these interatomic distances affords the data given in Tables 1, 3 and 4. The values of E_L obtained suggest that, although the two-centre links in $B_5H_5^{2-}$ would be of comparable strength to those in $B_6H_6^{2-}$, the former would supply far less bond enthalpy per boron atom than the latter (Table 4), and so be expected to be far less stable. This may indeed be the reason why it has not yet been isolated. However, the enthalpies calculated by the I method present a different picture, that such a structure would generate a skeletal bond enthalpy per boron atom (column 3 of Table 4, figure in parentheses) very similar to that of $B_6H_6^{2-}$, and indeed greater than that of the higher borane anions. This is the only system for which there is major disagreement between the stabilities indicated by E_L and E_I.

Skeletal electron distribution

In our earlier discussion[1] of the bond length based bond enthalpies of selected borane anions, we argued that, comparing atoms of different connectivities within a particular anion, because the total enthalpy of the four bonds to a skeletal boron atom of connectivity 4 generally exceeded the total enthalpy of the five bonds to an atom with $k = 5$, one could infer that the former type of atom had a greater share of the skeletal electron density. An advantage of the MOBI method is that it calculates the charges on the various types of skeletal atom, allowing this feature to be checked directly. The charges on the boron atoms in the structures considered here were as follows: −0.254 a.u. for the two boron atoms with $k = 3$ in $B_5H_5^{2-}$; −0.146 a.u. averaged over the 25 atoms with $k = 4$ in the anions $B_5H_5^{2-}$–$B_{11}H_{11}^{2-}$; −0.027 a.u. for the 40 atoms with $k = 5$ in the anions $B_7H_7^{2-}$–$B_{12}H_{12}^{2-}$, and +0.094 a.u. for the unique atom with $k = 6$ in $B_{11}H_{11}^{2-}$. These charges substantiate in full the conclusions drawn from other treatments, and are intelligible in valence bond terms in that, if each boron atom is to participate in three skeletal bonds, whether two- or three-centre, then a progressively higher proportion of these will need to be three-centre bonds as the connectivity k increases. Since three-centre bonds shift charge away from skeletal atoms to a greater extent than two-centre bonds, then the lower electron density associated with the more highly coordinated skeletal atoms is readily understood.[22]

CONCLUSIONS

In this paper, we have used known structural data where available, and estimated interatomic distances otherwise, to calculate bond enthalpies for the series of *closo* borane anions, $B_nH_n^{2-}$ (n = 5–12). Using enthalpy data calculated from bond lengths using the empirical relationship E_L(B—B) = 1.766 × $10^{11}[L(\text{B—B})]^{-4.0}$ we find $B_6H_6^{2-}$, $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ to be of relatively high stability, and $B_5H_5^{2-}$ to be of particularly low stability compared to the

remainder. However, data calculated from bond indices suggest that all of these borane anions are of comparable stability, the variations with n being minor. Both approaches suggest that the higher anions use their skeletal electron pairs to progressively greater effect as n increases, though because of the rate at which the number of two-centre links $(3n-6)$ in these polyhedral clusters increases with n, the average enthalpy per two-centre link tends to decrease (with exceptions in the case of the E_L figures) as n increases. Cross-polyhedral bonding interactions, neglected in the bond length based method, are shown by the I calculations to be negligibly small in these clusters, accounting for at most *ca* 2.5% of the total bond enthalpy. The I calculations also show that the charges on the skeletal boron atoms become progressively less negative/more positive as the skeletal connectivity of those atoms increases.

HAFNIUM(IV)–NITRILOTRIACETATE AND HAFNIUM(IV)–FLUORIDE COMPLEXES INVESTIGATED USING AN ION-SELECTIVE ELECTRODE

NICHOLAS E. IVORY and DAVID R. WILLIAMS*
Department of Applied Chemistry, University of Wales Institute of Science and Technology, PO Box 13, Cardiff CF1 3XF, U.K.

(*Received* 25 *April* 1985; *accepted* 10 *May* 1985)

Abstract—Models of plutonium solution chemistry *in vivo* require formation constants which are difficult to obtain but hafnium(IV) is biochemically similar to plutonium(IV) *in vivo*. This paper reports the use of fluoride as a competing ligand to suppress metal ion hydrolysis and formation constants, determined using a fluoride ion-selective electrode, for the following systems—fluoride–H^+, fluoride–hafnium(IV) and nitrilotriacetate–hafnium(IV) at 37°C, I = 150 mmol dm^{-3} sodium chloride.

Since the introduction of nuclear fission in the late 1930s, the element causing most public concern is undoubtedly plutonium, as it occurs in both weapons and energy production.[1,2] Many attempts have been made, and are still in progress, to determine the biochemistry of this man-made element.[2,3] A deeper understanding of the mechanisms of transport, tissue deposition, toxicity and excretion of complexes of plutonium would greatly assist toxicologists and clinicians. Hopefully, such an approach might lead to a range of therapeuticals that could be used to treat plutonium-intoxicated patients.[2]

The chemistry of plutonium has been widely reviewed.[3–7] The metal is unique in that it can exist simultaneously in all four of its oxidation states, (III), (IV), (V) and (VI). However, under physiological conditions it usually occurs as plutonium(IV). The human body is 70% water by weight and, when considering the biochemistry of plutonium, it is predominantly that of hydrolysis, polymerization and complex formation. The solubility product of plutonium(IV) hydroxide is of the order of 10^{-56} mol^5 dm^{-15} and so investigations into the sites of physiological attack of plutonium(IV) *in vivo* must, of necessity, have the plutonium firmly complexed in order to maintain it in solution. The ligand of choice is usually a polycarboxylic acid, such as nitrilotriacetate(NTA).

Various studies[8,9] concerning the physiological distribution of plutonium(IV) species predominating *in vivo* agree with our previous broad classification of metal distribution[2] into inert species, labile protein and low-molecular-weight complexes. The so-called inert plutonium species includes insoluble deposits of fluorides, hydroxides, oxides, and other polymeric aggregates in addition to protein complexes with ferritin and haemosiderin.[10–12] The second fraction is transferrin-bound and this β-globulin is responsible for transporting plutonium through the bloodstream.[13,14] Finally, there is some evidence that the third fraction, the low-molecular-weight complexes, is mainly plutonium citrate.[15] When soluble plutonium complexes are introduced into man, they initially complex with the iron transport protein transferrin and with citrate which carries the plutonium to the liver and bone marrow where it becomes associated with ferritin and haemosiderin.[12]

Clearly, any studies of this biochemistry and of competing complexes chosen to adapt such deposition mechanisms into excretion pathways, must be subject to the problems associated with the toxicity and radioactivity of the plutonium. Fortunately, Taylor *et al.*[16] have discovered that radiohafnium, when introduced into rats or hamsters, follows similar metabolic pathways to those for plutonium. In particular, it collects in the same target organs as plutonium(IV). Retention

times of hafnium and plutonium in the plasma and in the liver are similar and the radiohafnium becomes bound to the iron transport protein transferrin in plasma and in liver cytosol in both the rat and the hamster. Indeed, these experiments using radiohafnium suggest that non-radioactive hafnium would be a good "surrogate" metal for studying the complexing of plutonium *in vivo*.

Chemically, plutonium and hafnium have many similarities which include relatively small sizes of the solvated ions, high charge densities, and a propensity towards hydrolysis and hydrolytic polymerization.[17,18] Even though hafnium does not display plutonium's range of valency states, it does have the important valence of 4 which is the physiologically-important state for plutonium *in vivo*. Thus, we use hafnium(IV) solutions as models of plutonium complexing with ligands of biological interest. These solutions can be used in the open laboratory without the necessity for radiation protection.

When plutonium model studies using hafnium are undertaken in animals, for example, the binding of hafnium to transferrin,[19] it is necessary to use a powerful ligand such as the NTA anion in order to keep the hafnium in solution and to permit it to transfer to transferrin binding. Thus, the main aim of this research is to produce formation constants for hafnium–NTA complexing under physiological conditions of 37°C and 150 mmol dm^{-3} sodium chloride appropriate to blood plasma.

EXPERIMENTAL

Our standard glass electrode–calomel electrode potentiometric approach proved inapplicable to the hafnium–NTA–proton system because metal–ligand binding was too powerful.[20] Rather, we found that it was necessary to introduce a competing ligand in order to moderate the hafnium ion's avidity for NTA. We chose fluoride as a second ligand capable of competing with the hydroxide ion for hafnium on the basis of speciation plots generated using literature values for the hafnium hydroxy species[21] and hafnium fluoride species.[22] In the absence of fluoride, hydroxy species are prevalent even at pH values below 1, whereas, in the presence of 30 mmol dm^{-3} fluoride, such hydrolysis can be suppressed right up to pH 6. As the fluoride ion-selective electrode has been used for two decades,[23] we decided to use this as an analytical tool rather than the glass electrode which is attacked by hydrofluoric acid, the silica in the glass being converted into fluorosilicic acid. This would have resulted in inaccurate readings from the glass electrode.[24,25]

The fluoride ion-selective electrode was supplied by Orion Research Inc., and was of classical design employing a lanthanium fluoride membrane doped with 0.05 mol % europium fluoride and a filling solution of 1 mol dm^{-3} potassium fluoride solution saturated with potassium chloride and sodium chloride.[26] This design of electrode is fairly free of interference effects other than those caused by the hydroxide, citrate and some other carboxylate ions. These were not found to be a problem in our studies as fairly low concentrations were used.

The electrode was calibrated using a range of concentrations of standard fluoride solution with a constant ionic background strength of 150 mmol dm^{-3} sodium chloride. Nernstian behaviour to within a 0.1-mV drift over 1 h was found. Any variation from reproducibility with time arising because of pitting or coating of the membrane, was easily polished off using a fine polishing powder.[27] The emf readings between this electrode and a calomel reference electrode was used as input for our standard potentiometric least-squares programmes.

Protonation of fluoride was measured using the fluoride ion-selective electrode and a calomel reference electrode. The titration data produced was fed into a modified version of MINIQUAD,[28,29] which considered the fluoride ion as equivalent to the acid in conventional acid-based titrations. The value for monoprotonated fluoride, HF, is in good agreement with the results from other works,[30–37] but the species HF_2^- [38] and H_2F^+ [39,40] in addition to H_2F_2,[22] were not found in this study. Our values and the appropriate statistics are shown in Table 1.

The hafnium fluoride interaction was quantified likewise and is reported in Table 1. Formation constants for the three higher complexes of 4:1, 5:1 and 6:1 fluoride:hafnium (the 410, 510 and 610 species, respectively) were apparently measurable but the 100, 210 and 310 species were not detectable because this would have involved fluoride concentrations below the detection limit of the electrode. (approximately 10^{-6} mol dm^{-3} F^-). However, constants for the lower species were taken from the literature[22] and these have been determined by solvent extraction and by the iron redox electrode approach to potentiometry. We had some difficulty establishing the existence of the 510 species and the value reported is that obtained using the Bjerrum's $Z_{1/2}$ method. The speciation plot in Fig. 1 shows a preponderance of 410 and 610 species and very low levels of the 510 intermediate. The values obtained from the MINIQUAD assessment for the 410 and 610 species are in reasonable agreement with those reported by other workers.[21,22,41,42]

Bearing in mind that we used the fluoride electrode in preference to the glass electrode, it is interesting to

Table 1. Log formation constants at 37°C and I = 150 mmol dm^{-3} sodium chloride for the following systems: (a) fluoride (p)–proton (r), (b) hafnium (q)–fluoride (p) and (c) hafnium (q)–nitrilotriacetate (p)

	Species								
	p	q	r	log β_{pqr}	Standard deviation	Sum of squares	R factor	No. of data points	No. of titrations
(a)	1	0	1	3.003	0.0011	9.9×10^{-7}	6.3×10^{-3}	325	8
(b)	(MINIQUAD)								
	4	1	0	30.158	0.8009				
	5	1	0	Negative	—	3.32×10^{-5}	1.53×10^{-2}	386	8
	6	1	0	40.481	0.3879				
(b)	(ESTA2)								
	4	1	0	24.533	0.0246				
	6	1	0	32.926	0.0260	—	2.08×10^{-2}	386	8
(c)	1	1	0	17.30	0.175		1.57×10^{-2}	268	7

note that the statistics found with the former method are not as good as those expected from the latter, the standard deviations being approximately an order of magnitude greater and the sum of the squares being two orders of magnitude larger than those for comparable glass electrode work. We must remember, however, that the glass electrode would not have worked in the presence of fluoride. The R factor obtained by both methods is of comparable magnitude and this value, along with the superimposability of the experimentally and theoretically produced formation curves, gives us confidence that these complexes are real and that the formation constant values are reliable. The data were also fed into the ESTA2 optimization program (see Table 1).[43,44] It is noteworthy that ESTA2 also failed to detect the existence of the 510 species.

Hafnium–NTA interaction

The literature values for this system suggest that the log β is approximately 20,[45,46] a magnitude beyond simple potentiometric determination. However, by using fluoride as a competing ligand, we were able to quantify the system in terms of a constant. A good competing ligand ought not to form mixed-ligand complexes with the metal and ligand under study and fluoride fitted this description. Additionally, it suppressed the hydrolysis of hafnium during the titrations, as mentioned previously. Experimentally, we titrated an acid solution of hafnium into mixtures of solutions of the trisodium salt of NTA and sodium fluoride. The double-ligand system was analyzable by the ESTA2 program and the results are shown in Table 1, the species detected being the 110 species. The log formation constant agrees reasonably well with values suggested from ion exchange methods.[47,48] Then *et al.*[49] have suggested that a second NTA ligand may be complexed as an eight-fold coordinated hafnium(IV) ion in a dodecahedral structure but this *bis* complex was not detected by our studies. Figure 2 shows the speciation for a

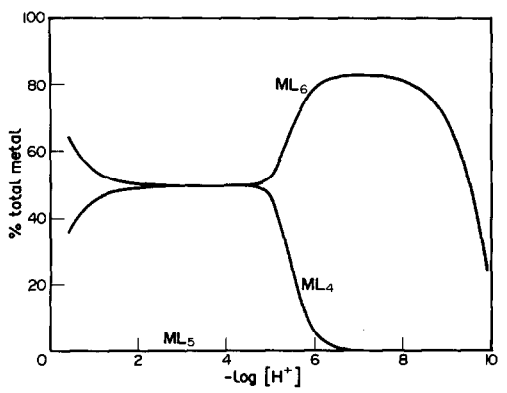

Fig. 1. Speciation plots of HfF_4, HfF_5^- and HfF_6^{2-} concentrations, pH = 0–10, calculated using the formation constants in Table 1. M = Hf(IV).

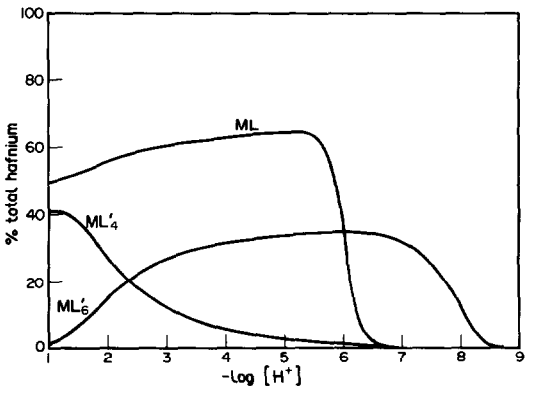

Fig. 2. Speciation plots of HfF_4, HfF_6^{2-} and $HfNTA^+$ complexes, pH 0–9, calculated using the formation constants in Table 1 for a typical fluoride and NTA competing-ligand titration. F^- = L′ and NTA^{3-} = L.

typical hafnium–NTA–fluoride system at various pHs.

CONCLUSIONS

It appears that fluoride ion-selective electrodes are a useful means of studying complexing between hafnium(IV) as a surrogate metal ion for plutonium(IV) in solution and they also permit computational studies to yield formation constants for hafnium with powerful ligands such as NTA. Furthermore, the presence of fluoride has successfully suppressed hydrolysis in this work. The fluoride electrode performed well at all times and the statistics produced for the formation constants are within an order of magnitude as good as those that could be expected from a non-glass-attacking ligand system studied using glass electrode potentiometry.

PHOTOREDOX CHEMISTRY OF NITROSYLPENTACYANOFERRATE(II) IN METHANOLIC MEDIUM

GRAŻYNA STOCHEL and ZOFIA STASICKA*
Department of Inorganic Chemistry, Jagiellonian University, 30-060 Kraków, Poland

(*Received* 8 *February* 1985; *accepted* 10 *May* 1985)

Abstract—The solvent complexes $[Fe(CN)_5(CH_3OH]^{2-}$ and $[Fe(CN)_5CH_3O]^{3-}$ were found to be the main products of the photochemical reaction of nitrosylpentacyanoferrate(II) in MeOH at room temperature. Some minor production of iron(I) species was also detected. Quantum yields are dependent on the radiation energy. Prolonged irradiation leads to the generation of Prussian blue.

Photochemistry of the $[Fe(CN)_5NO]^{2-}$ complex in aqueous solution has attracted the interest of chemists for many years.[1–3] In contrast, the photochemical behaviour in non-aqueous solvents has received much less attention[4] up to recently, when two ESR studies have been published.[5,6] These papers, however, concern mainly the photolysis of glasses that could proceed through a different mechanism than that in the liquid state.

The most important difference consists in the production of $[Fe(III)(CN)_5L]^{n-}$ complexes that was found to proceed in liquid non-aqueous solvents[7–9] and was never observed in glasses.[5,6]

The aim of this work was to provide more detailed data on the photolysis of nitrosylpentacyanoferrate(II) in methanolic solution to establish the reaction mechanism in the liquid phase.

RESULTS

A methanolic solution of $[Fe(CN)_5NO]^{2-}$ is thermally stable at least for several days irrespective of atmosphere. Its spectrum resembles that of an aqueous solution with a bathochromic shift of the maxima. The spectrum (Fig. 1) shows three moderately weak bands at 18.9 ($\varepsilon = 9.3$), 24.8 ($\varepsilon = 25.1$) and $\sim 30 \times 10^3$ cm^{-1} ($\varepsilon \sim 55$) and three more intense bands at 36.6 ($\varepsilon = 1080$), ~ 42.6 ($\varepsilon \sim 2500$) and $\sim 47.7 \times 10^3$ cm^{-1} ($\varepsilon \sim 10{,}800$).

As in aqueous solutions,[10] radiation from the first band (I in Fig. 1) was also found to be inactive in methanolic medium. Radiation from more energetic bands (II–V) was photochemically active leading to the generation of three relatively stable products and one short lived species. The type of products was found to be independent of the radiation energy; only the quantum yield values were higher within the IV and V than in the II and III bands (Fig. 1, Table 1).

The main product of the photochemical reaction of nitrosylpentacyanoferrate(II) in methanolic solution appeared to be the iron(III) complex of formula $[Fe(CN)_5CH_3OH]^{2-}$ (Fig. 2), whereas in the presence of alkalis ($c \geqslant 10^{-4}$ M) its deprotonated form, $[Fe(CN)_5OCH_3]^{3-}$ was also generated. At higher alkali concentration ($c \sim 10^{-2}$ M) the only detected iron(III) complex was the alkoxo one (Fig. 3).†

The spectra of these complexes were also recorded upon flashing and no transient species were detected within the resolution time of our apparatus. Only in diluted deaerated solutions ($c \lesssim 10^{-5}$ M) did a diffuse transient absorption appear at $\tilde{\nu} > 32 \times 10^3$ cm^{-1} that decayed within microseconds without any definite influence on the absorption at lower wave numbers. This behaviour is similar to that found in aqueous solution,[2] although in methanolic medium the spectrum is shifted bathochromically. In both cases, the nature of the species is unknown but tentatively we assign this absorption to an unstable solvated form of the released NO ligand.

ESR detection has shown that, besides the iron(III) complexes, some iron(I) species are also generated photochemically in the methanolic solution. The ESR signals, $g_{av} = 2.026$ and $A(^{14}N) = 15.0$ G,

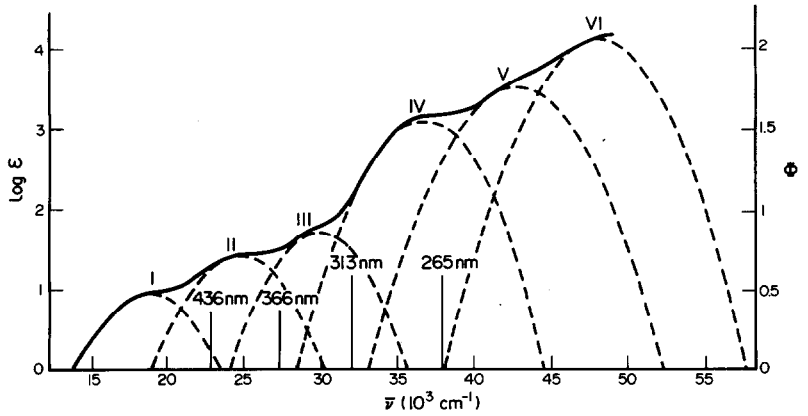

Fig. 1. Spectrum of the $[Fe(CN)_5(NO)]^{2-}$ complex in MeOH and quantum yields of $[Fe(CN)_5(CH_3OH)]^{2-}$ production. The broken lines represent the Gaussian analysis of the experimental curve made by a least-square procedure.[9]

recorded at room temperature, are consistent with those found earlier for the blue $[Fe(I)(CN)_4(NO)]^{2-}$ complex.[11,12]

Quantum yields of the Fe(I) complex formation could be only roughly assessed but doubtless they are about two orders lower than those of the iron(III) production (Table 1).

Prolonged irradiation (for minutes) of the $[Fe(CN)_5NO]^{2-}$ in methanol has led to generation of a blue precipitate that was analyzed by ESR and IR spectroscopy. In the ESR spectrum only one very broad line and no traces of the signal characteristic of $[Fe(CN)_4(NO)]^{2-}$ were detected. The IR spectrum showed a strong band due to a CN^- stretch at 2070 cm^{-1} and two weaker bands at 500 and 590 cm^{-1}. All of these features fit Prussian blue[13,14] and lead to the conclusion that prolonged irradiation of nitrosylpentacyanoferrate(II) in MeOH proceeds similarly to that in aqueous solution.[1]

Prussian blue precipitation was preceded by an increase in absorption and the appearance of a new strong band within $15.5–16.5 \times 10^3$ cm^{-1} (Fig. 4), that disappeared upon precipitation.

Both the shape and the intensity of the spectrum were affected by many factors leading to the conclusion that the absorption was due to different polymeric Fe(II)–Fe(III) precursors of Prussian blue.

Both flash and continuous-illumination experiments have shown that the Prussian blue precursors are generated in a secondary thermal reaction at the expense of the $[Fe(CN)_5(CH_3OH)]^{2-}$ complex, but the process is strongly photoaccelerated (Fig. 4).

In contrast to the iron(III) production (Table 1), the yields of $[Fe(CN)_4(NO)]^{2-}$ and the Prussian

Table 1. Photoredox quantum yields of $[Fe(CN)_5(NO)]^{2-}$ in MeOH

λ (nm)	$[Fe(III)(CN)_5(CH_3OH)]^{2-}$		$[Fe(III)(CN)_5(CH_3O)]^{3-}$		$[Fe(I)(CN)_4(NO)]^{2-}$
	N_2	O_2	N_2	O_2	N_2
265	0.61	0.62	0.54	0.54	—
313	0.63	0.61	0.50	0.53	6×10^{-3}
366	0.38	0.38	0.29	0.28	4×10^{-3}
436	0.37	0.38	0.30	0.29	4×10^{-3}

blue precursors were affected by oxygen: the former was decreased, whereas the latter was slightly increased in the presence of oxygen.

DISCUSSION

In the earlier photochemical study of the $[Fe(CN)_5NO]^{2-}$ complex in non-aqueous solvents, such as *N,N*-dimethylformamide (DMF), acetylacetone, benzaldehyde, *p*-nitrobenzaldehyde and dimethylaniline, photoreduction

$$[Fe(CN)_5(NO)]^{2-} \xrightarrow[S]{h\nu} [Fe(I)(CN)_5(NO)]^{3-} + {}^{\cdot}S^{+} \quad (1)$$

was the only process detected by EPR and UV–VIS spectroscopy.[4] This reaction was also reported to proceed as the major route in MeOH, DMF or hexamethylphosphoramide glasses.[6] On annealing, the release of one CN^- ligand

$$[Fe(CN)_5(NO)]^{3-} \rightarrow [Fe(I)(CN)_4(NO)]^{2-} + CN^- \quad (2)$$

and production of the pentacoordinated iron(I) species was detected.[6]

Our results have shown that, in methanolic liquid phases, the $[Fe(CN)_4(NO)]^{2-}$ ion is also photogenerated, but its yield is at least two orders lower than that for the photooxidation path (Table 1). The main mode detected in this medium may be summarized as follows:

$$[Fe(CN)_5(NO)]^{2-} \xrightarrow{h\nu} {}^{*}\{[Fe(CN)_5(NO)]^{2-}\} \begin{cases} \xrightarrow{CH_3OH} [Fe(III)(CN)_5(CH_3OH)]^{2-} + NO \\ \xrightarrow{CH_3O^-} [Fe(III)(CN)_5(CH_3O)]^{3-} + NO \end{cases} \quad (3)$$

The pathway is consistent with that reported earlier[2,10] for aqueous solutions. Moreover, this mode was found to be the major one in the photochemistry of nitrosylpentacyanoferrate(II) in some other solvents, such as ethylene glycol, DMF and dimethylsulphoxide.[9] In fact, the $[Fe(III)(CN)_5L]^{2-}$ complexes (where L = solvent molecule) were observed to be generated in all the liquid phases studied by us so far.[8] The lack of iron(III) complexes in the glassy phases[5,6] may be the result of the cage effect.

In the earlier liquid-phase study[4] the generation of iron(III) complexes was not detected due to analyzing the prolonged irradiated solutions, where

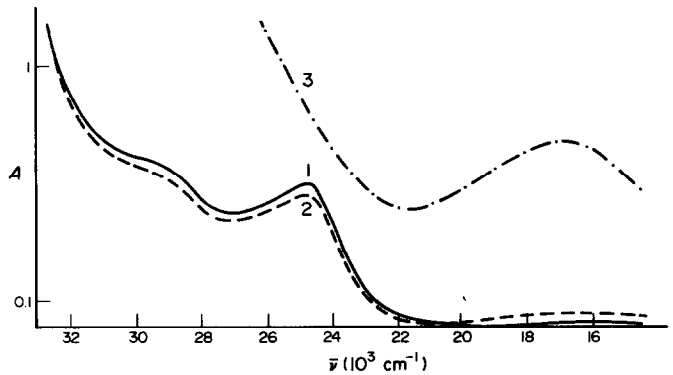

Fig. 4. Spectral changes due to secondary processes in the mixture of $[Fe(CN)_5(CH_3OH)]^{2-}$ ($c = 5\times10^{-4}$ M) and $[Fe(CN)_5(NO)]^{2-}$ ($c = 1.5\times10^{-3}$ M) (curve 1) upon thermal procedure (20 h, curve 2) and after 2 min of irradiation (curve 3).

a strong absorption of the Prussian blue precursors overlaps that of the $[Fe(CN)_5L]^{2-}$ complexes (Fig. 4). Moreover, absorption of the blue polymers occurs almost exactly within the same spectral region as that of the $[Fe(CN)_4NO]^{2-}$ complex[15] ($\tilde{\nu}_{max} = 16.5 \times 10^3$ cm^{-1}), which could lead to overestimation of the iron(I) yield.

The Fe(II)–Fe(III) polymers must be generated from the $[Fe(CN)_5(CH_3OH)]^{2-}$ complex in reaction with a Fe(II) species. When polymerization proceeds in a secondary thermal way the increase in absorption at $15.5–16.5 \times 10^3$ cm^{-1} is accompanied by decrease in absorption characteristic of the $[Fe(CN)_5(CH_3OH)]^{2-}$ complex (Fig. 4). Considerable acceleration of the reaction by light suggests that the iron(II) species is generated photochemically from the $[Fe(CN)_5NO]^{2-}$ or $[Fe(CN)_5(CH_3OH)]^{2-}$ ion.

The former would correspond to the ligand field route reported for an aqueous solution,[2] whereas the latter would be in agreement with the photoreduction of the $[Fe(CN)_5(H_2O)]^{2-}$ complex observed earlier by Moggi *et al.*[16]

The increase in the polymer concentration in the presence of oxygen also suggests that the iron(II) species may also be generated by oxygen oxidation of the $[Fe(CN)_4(NO)]^{2-}$ ion.

EXPERIMENTAL

Materials

Anhydrous sodium nitrosylpentacyanoferrate(II), $Na_2[Fe(CN)_5NO]$ was prepared by repeated recrystallization of a commercial dihydrate from aqueous solution in the dark and drying a pulverized sample at 440 K up to a constant weight. Alkalis were purified from carbonates, methanol of reagent grade was dried when it was necessary, and other chemicals were the best available commercial reagents used without further purification.

Apparatus and procedure

A high-pressure (HBO 200, Narva, G.D.R.) or a medium-pressure (ASH 400) mercury lamp was used for continuous irradiation of solutions placed in a thermostatted rectangular quartz cell ($d = 0.5$, 1.0 and 2.0 cm). Irradiations were performed at 295 ± 0.5 K with a continuous flow of nitrogen or oxygen. In some experiments cut-off filters (Schott, Jena, G.D.R.) were used to separate wave numbers: $\tilde{\nu} < 30 \times 10^3$ cm^{-1} (BG 9, 2 mm), $\tilde{\nu} < 23 \times 10^3$ cm^{-1} (OG 11, 2 mm), $\tilde{\nu} < 18 \times 10^3$ cm^{-1} (OG 2, 2 mm) and $28 \times 10^3 < \tilde{\nu} < 44 \times 10^3$ cm^{-1} (UG 5, 2 mm + 2 cm layer of saturated $NiSO_4$).

For quantum yield measurements glass filters (Schott), were used to isolate 436-, 366- and 313-nm wavelengths and an interference filter (KIF 265, C. Zeiss, Jena, G.D.R.) for 265-nm isolation. 10^{-1}–10^{-3} M solutions of $[Fe(CN)_5(NO)]^{2-}$ in MeOH or in MeOH containing additionally 10^{-2} M NaOH were irradiated up to less than 10% conversion. The light intensity was measured using trisoxalatoferrate(III) actinometry.[17] The reaction progress was followed spectrally by means of a Specord UV–VIS spectrophotometer (C. Zeiss). Flash photolysis apparatus was as described elsewhere;[2] its resolution time was not shorter than 20 μs.

ESR spectra were recorded using an ESR-220 (G.D.R.) spectrophotometer. DPPH and Mn^{2+} in MgO were used for g factor determination and magnetic field calibration. $CuSO_4$ in methanolic solution was used as a spin number standard.

SYNTHESIS AND CHARACTERIZATION OF NICKEL(II) COMPLEXES WITH POTENTIALLY PENTADENTATE MACROCYCLIC LIGANDS HAVING N_3O_2 DONOR SET

KIKUO MIYOKAWA,*† HIDENORI HIRASHIMA and ISAO MASUDA

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01, Japan

(*Received* 17 *December* 1984; *accepted* 10 *May* 1985)

Abstract—Nickel(II) complexes of N_3O_2 donor macrocycles incorporating 17- to 19-membered macrocyclic rings have been prepared. Physical measurements indicate that the complexes are of the type Ni(macrocycle)$X_2 \cdot nH_2O$ (X = Cl, Br, I, NCS or NO_3; $n = 0, \frac{1}{2}$ or 1). The macrocycles behave as a tetradentate ligand when X = NCS and as a pentadentate ligand when X = I. The coordinating behavior of the macrocycles has been found to depend on the coordinating abilities of the coexisting anions.

In contrast to the metal ion chemistry of macrocyclic ligands incorporating all ether oxygen or all nitrogen donor atoms, the chemistry of mixed oxygen–nitrogen donor macrocycles has received less attention.[1] Lindoy *et al.* have extensively investigated synthetic, kinetic, thermodynamic and structural aspects of the interaction of macrocycles of type **I** in Fig. 1 with cobalt(II), nickel(II) and copper(II).[2–5] Recently they have investigated the interaction of copper(II) with N_3O_2 donor macrocycles of type **II**, and reported that $[CuL^2(H_2O)(ClO_4)_2] \cdot H_2O$ has a pseudo square planar coordination geometry with the coordination sphere consisting of three nitrogen atoms of the macrocycle together with an oxygen from water.[6] Such macrocycles containing an N_3O_2 donor set, however, have a potentially pentadentate property. In this study, nickel(II) complexes with 17-, 18- and 19-membered macrocycles, L^1, L^2 and L^3,‡ were isolated and the coordinating behavior of the macrocycles was investigated.

EXPERIMENTAL

The preparation of macrocycles L^1 and L^2 has been described in the literature.[6] The new macrocycle, L^3, was prepared as follows: 3,3′-diaminopropylamine (6.55 g) in methanol (20 cm^3) was added slowly to a stirred boiling solution of 1,4-bis(2′-formylphenyl)-1,4-dioxabutane[7] (13.5 g) in methanol (500 cm^3). The solution was then filtered and allowed to cool. Sodium tetrahydroborate (8.0 g) was added slowly and the volume was then reduced to 150 cm^3. Water (400 cm^3) was added and an oil separated, which was extracted with chloroform (3×100 cm^3). The chloroform extract was dried over anhydrous sodium sulfate and evaporated to 50 cm^3 and to it was added diethylether (200 cm^3). The solution was cooled below 0°C to yield a white solid. Yield 15%. The product was recrystallized from a chloroform–diethylether mixture. Found: C, 71.2; H, 8.2; N, 11.3. Calc. for $C_{22}H_{31}N_3O_2$: C, 71.5; H, 8.2; N, 11.3%.

The nickel(II) complexes were prepared in the following manner: nickel(II) salt (2 mmol) in methanol (20 cm^3) was slowly added to a stirred boiling ethanol or butanol solution (50 cm^3) of the ligand (2 mmol). While boiling, the solution separated blue or green crystals which were collected on a filter and washed with methanol and then diethylether and finally dried in an oven at 100°C.

Conductance measurements were performed by using Toa conduct meter CM-15A with a Toa

RESULTS AND DISCUSSION

Reaction of L^1, L^2 and L^3 with the appropriate nickel(II) salts has led to the isolation of the green or blue complexes listed in Table 1. The elemental analyses indicate the formation of complexes with a nickel : ligand ratio of 1 : 1. All complexes have room-temperature magnetic moments in the range expected for nickel(II) with $S = 1$; these values are close to $\mu_{eff} = 3.1$–$3.3\ \mu_B$ for the nickel(II) complexes with macrocycles of type I.[2] These complexes have been reported to have an octahedral coordination geometry around the nickel atom.[2,5] The reflectance spectra exhibit two peaks in the visible region with maxima around 16 and 25×10^3 cm^{-1}; respective peaks are ascribed to the $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ and the $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transitions of nickel(II) ion in an octahedral crystal field.[9] The magnetic and spectral characteristics indicate an octahedral coordination geometry for the present complexes. The IR spectra of the thiocyanato complexes show a single ν(CN) band around 2070 cm^{-1} which is in the expected range for N-bonded coordination.[10]

The conductivities in nitromethane of NiL^1I_2 and NiL^2I_2 are 75.9 and 76.3 Ω^{-1} cm^2 mol^{-1}, which fall in the range 75–95 Ω^{-1} cm^2 mol^{-1} reported for 1 : 1 electrolytes in nitromethane;[11] the macrocycles behave as pentadentate ligands in these complexes. On the other hand, $NiL^2(NCS)_2$, $NiL^3(NCS)_2$ and NiL^3Cl_2 are non-electrolytes and the macrocycles behave as tetradentate ligands. These facts seem to indicate that the coordinating behavior of the macrocycles depends on the nature of the coexisting anions. This differs from the coordinating behavior of the macrocycles of type I, which behave as tetradentate ligands in the Ni(II) complexes regardless of the sort of coexisting anions.[2] The spectrochemical series of the anions is

$$NCS > NO_3 > Cl > Br > I,$$

and the coordinating abilities of the anions are considered to decrease in this order.[12] The complexes with the isothiocyanate anion with the highest coordinating ability are non-electrolytes and the macrocycles are tetradentate, while the complexes of the iodide anion with the lowest coordinating ability are 1 : 1 electrolytes and the macrocycles are pentadentate. Other complexes which show intermediary conductivities between non- and 1 : 1 electrolytes are considered as a mixture of non- and 1 : 1 electrolytes since the nitromethane is such a weak coordinating solvent that the ionization of the complexes hardly occurred when the complexes were dissolved in this solvent.

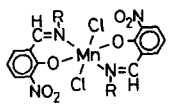
REACTION OF DICHLOROMANGANESE(IV) SCHIFF-BASE COMPLEXES WITH WATER AS A MODEL FOR WATER OXIDATION IN PHOTOSYSTEM II

MANABU FUJIWARA, TAKAYUKI MATSUSHITA* and TOSHIYUKI SHONO*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565, Japan

(*Received* 16 *April* 1985; *accepted* 10 *May* 1985)



Abstract—The dichloromanganese(IV) Schiff-base complexes Mn(*N*-R-3-NO_2 sal)$_2Cl_2$ (R = *n*-C_3H_7, *n*-C_4H_9, *n*-C_6H_{13}, *n*-C_8H_{17}, *n*-$C_{12}H_{25}$ and $CH_2C_6H_5$) have been prepared and characterized by magnetic susceptibilities, electronic spectra and cyclic voltammograms. All the manganese(IV) complexes are found to react with water to liberate molecular oxygen (O_2). The maximal liberation of O_2 is observed at neutral pH. The following reaction scheme is proposed:

$$2Mn(IV)(L)_2Cl_2 + 2H_2O \rightarrow 2Mn(II)(L)_2 + O_2 + 4H^+ + 4Cl^-.$$

Manganese-containing proteins are believed to play an important role in the photosynthetic oxygen-evolving process from water by green algae and green plants.[1–3] Although much effort has been made to clarify their function,[4–7] the oxidation states of the manganese ions in the proteins, their structures, and the mechanism for water oxidation remain to be established.

Previously, we have reported the preparation and characterization of a series of novel dichloromanganese(IV) Schiff-base complexes.[8–10] Moreover, we have preliminarily shown that the manganese(IV) complex dichlorobis(*N*-propyl-3-nitrosalicylideneaminato)manganese(IV) reacts with water to liberate molecular oxygen (O_2).[11]

In this paper we describe the preparation and characterization of a series of dichloromanganese(IV) complexes with bidentate Schiff-base ligands derived from 3-nitrosalicylaldehyde and various monoamines (Fig. 1). All the manganese(IV) complexes are found to react with water to liberate O_2.

Fig. 1. Manganese(IV) Schiff-base complexes studied.

EXPERIMENTAL

Materials

All reagents were of reagent grade. Methanol was refluxed over magnesium ribbon and distilled. Dichloromethane was refluxed over $CaCl_2$ and distilled. 2-Propanol was refluxed over CaO and distilled. Other solvents were purified by the usual methods.

Measurements

UV and visible absorption spectra were obtained from a Hitachi 340 recording spectrophotometer. IR spectra were recorded on a Hitachi EPI-215 and a Hitachi EPI-L grating spectrophotometer for the 4000–650- and 700–250-cm^{-1} regions, respectively. Mass spectra were measured with a Hitachi RMU-6E spectrometer. Magnetic susceptibilities were measured by the Gouy method at room temperature. Cyclic voltammograms were measured with a Yanaco P-8 polarograph connected with a Yanaco P8-PT potentiostat as described elsewhere.[10] Liberated O_2 in solution was determined by an EIL model 8012-1 oxygen electrode connected with a Yanaco PH 7-1913 voltmeter.

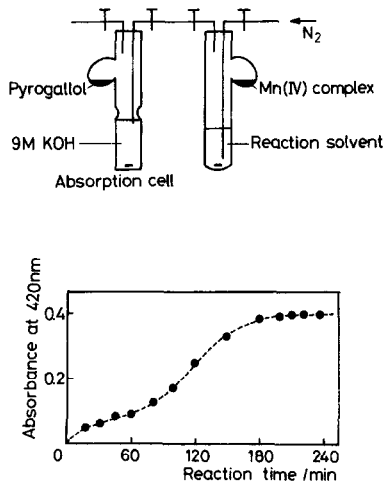

Fig. 2. Apparatus for spectrometric measurement, method 1, and changes in absorbance of pyrogallol solution in the reaction of Mn(IV)(*N*-Pr-3-NO_2 sal)$_2Cl_2$ (200 mg) with water (2 cm^3).

Procedure for detection and determination of liberated O_2

In the present work, the following two methods were employed to detect and determine O_2 liberated during the reaction of manganese(IV) complexes with water.

Method 1 is based on absorption spectrophotometry using an alkaline pyrogallol solution.[12] The apparatus is shown in Fig. 2. A reaction solvent [CH_3CN (8 cm^3)–H_2O (2 cm^3)] and a 9 M KOH solution placed in the apparatus were kept completely under a nitrogen atmosphere during all measurements. After nitrogen gas was passed through the reaction system for 1 h, pyrogallol (200 mg) was added to the alkaline solution and dissolved. The solution remained colorless and then the reaction system was sealed. A manganese(IV) complex was added to the reaction solvent, and its mixture was stirred vigorously at room temperature. Its color changed from deep green to yellowish brown, and the pyrogallol solution was colored gradually to dark brown. The color development of the pyrogallol solution was monitored by a spectrophotometer at 420 nm (Fig. 2).

Method 2 is based on the measurement of dissolved oxygen by an oxygen electrode. Dissolved oxygen in a reaction solvent [2-propanol (5 cm^3)–H_2O (20 cm^3)] was previously determined by the oxygen electrode at 10°C. After a manganese(IV) complex (10 mg) was added to the reaction solvent, the reaction system was sealed. Liberated O_2 was determined by the oxygen electrode as an increase in voltage while stirring the mixed solution at a constant revolution.

Preparation of bidentate Schiff-base ligands

3-Nitrosalicyladehyde was prepared by the method described in the literature.[13] The Schiff-base ligands were prepared by the condensation of 3-nitrosalicylaldehyde with various monoamines, R-NH_2 (R = Pr, Bu, Hx, Oct, Dod and Bz) (see Fig. 1) in tetrahydrofuran. They were recrystallized from appropriate organic solvents such as ethanol and ether. The yields were 65–85%.

Preparation of chloromanganese(III) Schiff-base complexes, Mn(N-R-3-NO_2 sal)$_2$Cl

A Schiff-base ligand [*N*-R-3-NO_2 salH (0.02 mol)], manganese(III) acetate dihydrate (0.01 mol) and lithium chloride (0.015 mol) were dissolved in a mixed solvent of methanol (100 cm^3) and dichloromethane (100 cm^3) and refluxed for 1 h. The mixture was evaporated under reduced pressure to give a dark brown solid. Upon recrystallization from a mixed solvent of dichloromethane and ether, the manganese(III) Schiff-base complex was obtained, washed with 2-propanol, and dried *in vacuo*. The yields were 70–80%. These complexes are soluble in dichloromethane, chloroform and 2-propanol, but insoluble in ether and water.

Preparation of dichloromanganese(IV) Schiff-base complexes, Mn(N-R-3-NO_2 sal)$_2Cl_2$

Mn(III)(*N*-R-3-NO_2 sal)$_2$Cl (2.0 mmol) was dissolved in 2-propanol (100 cm^3). A 2-propanol solution of hydrogen chloride (1.5-molar-fold excess over the complex) was added dropwise to the solution of the complex with stirring at room temperature. The mixture changed its color from brown to deep green immediately with a deep green precipitate. After stirring for 30 min, the resulting precipitate was collected on a glass filter, washed with 2-propanol and then ether, and dried *in vacuo*. Further purification was not carried out. The yields were 25–40%. These manganese(IV) complexes are soluble in dichloromethane, chloroform and acetonitrile, and slightly soluble in methanol and ethanol, but insoluble in ether and water. Their analytical data are given in Table 1.

RESULTS AND DISCUSSION

Electronic absorption spectra

Figure 3 shows the electronic absorption spectra of Mn(II)(*N*-Pr-3-NO_2 sal)$_2$(H_2O)$_2$, Mn(III)(*N*-Pr-3-NO_2 sal)$_2$Cl and Mn(IV)(*N*-Pr-3-NO_2 sal)$_2Cl_2$ measured in acetonitrile. The spectrum of the

manganese(III) complex possesses three absorption bands in the visible region at 16,100, 22,700 and 29,200 cm^{-1}. These bands can be assigned to the transitions due to $d_{xy} \rightarrow d_{x^2-y^2}$, $d_{xy} \rightarrow \pi^*$ (azomethine) involving d_{yz}, $d_{xz} \rightarrow d_{x^2-y^2}$, and d_{yz}, $d_{xz} \rightarrow \pi^*$ (azomethine) from lower energies.[8] Similarly, the spectrum of the manganese(IV) complex possesses three absorption bands, which are shifted to higher energies compared with those of the manganese(III) complex. The characteristic band for the manganese(IV) complex observed at 17,200 cm^{-1} may be assigned to the charge-transfer transition between manganese and chloride ions from its high intensity (log $\varepsilon = 3.4$).[8] The absorption bands due to *d–d* transitions for the manganese(IV) complex may be obscured by this intense band, so that the higher-energy bands cannot be assigned certainly, which may be associated with the charge-transfer transitions due to Mn($d\pi$) → π^* (azomethine). On the other hand, the spectrum of the manganese(II) complex has no absorption band in the region lower than 20,000 cm^{-1} and shows two absorption bands around 25,000 and 28,000 cm^{-1}. These results indicate that the oxidation states of the central manganese ions of the complexes can be easily discriminated from their electronic absorption spectra.

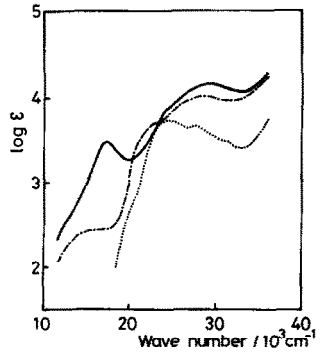

Fig. 3. Electronic spectra in CH_3CN. (——) Mn(IV)(*N*-Pr-3-NO_2 sal)$_2Cl_2$, (–·–·–) Mn(III)(*N*-Pr-3-NO_2 sal)$_2$Cl, and (·····) Mn(II) (*N*-Pr-3-NO_2 sal)$_2(H_2O)_2$.

The electronic spectra of the manganese(III) complexes with other alkyl groups are quite similar to that of Mn(III) (*N*-Pr-3-NO_2 sal)$_2$Cl, and those of the manganese(IV) complexes with other alkyl groups also possess absorption bands similar to those of Mn(IV)(*N*-Pr-3-NO_2 sal)$_2Cl_2$. The positions of the lowest-energy bands for the manganese(III) and manganese(IV) complexes are summarized in Table 2, together with their intensities. The band position of Mn(IV)(*N*-Pr-3-NO_2 sal)$_2Cl_2$ is blue-shifted about 900 cm^{-1} compared to that of Mn(IV)(*N*-Pr sal)$_2Cl_2$ obtained in a previous work.[8] This may be caused by the introduction of electron-withdrawing nitro groups on the aromatic rings.

Magnetic properties

The magnetic moments of the manganese(III) and manganese(IV) complexes determined at room temperature are summarized in Table 2. The magnetic moments of the manganese(III) complexes fall within the range 4.85–4.98 BM with the exception of Mn(III)(*N*-Bz-3-NO_2 sal)$_2$Cl. These values are consistent with the manganese(III) complexes adopting a d^4 high-spin electron configuration. The relatively low value (4.24 BM) observed for Mn(III)(*N*-Bz-3-NO_2 sal)$_2$Cl may be caused by magnetic exchange interaction due to the formation of a binuclear structure in the solid state like Mn(III)(*N*-Bz sal)$_2$Cl.[9] Further investigation on this complex was not made in this work.

On the other hand, the magnetic moments of the manganese(IV) complexes fall within the range 3.88–4.02 BM. These values are consistent with the manganese(IV) complexes adopting a d^3 high-spin electron configuration.

IR spectra

The IR spectra of the manganese(IV) complexes are almost the same as those of the corresponding manganese(III) complexes in the 4000–500-cm^{-1}

Table 2. Magnetic moments, absorption maxima and reduction potentials of the manganese(III) and manganese(IV) complexes, Mn(III)(*N*-R-3-NO_2 sal)$_2$Cl and Mn(IV)(*N*-R-3-NO_2 sal)$_2Cl_2$

region. However, in the 500–250-cm^{-1} region, the IR spectra of the manganese(III) and manganese(IV) complexes differ markedly, especially in the region sensitive to the vibration of ν(Mn—Cl). The manganese(III) complexes have weak absorption bands around 310 cm^{-1}, whereas the manganese(IV) complexes have one very sharp and strong absorption band around 350 cm^{-1} assignable to ν(Mn—Cl). The band positions listed in Table 2 are not affected so much by the alkyl groups of the Schiff-base ligands. These results indicate that all the manganese(IV) complexes adopt an octahedral configuration in which two chloride ions occupy a *trans* position about the central manganese ion as shown in Fig. 1.

Electrochemical properties

The current–potential curves of the manganese(IV) complexes measured in acetonitrile exhibit two-step cathodic waves around +1.0 and +0.25 V (vs SCE), which can be assigned to the reductions from Mn(IV) to Mn(III) and from Mn(III) to Mn(II) of the complex, respectively. The reduction potentials for the manganese(IV) complexes are given in Table 2, together with those for the manganese(III) complexes. The potentials for both reductions are not affected much by the alkyl groups of the Schiff-base ligands. These results are consistent with those obtained in the absorption spectra as described above.

It is noteworthy that the manganese(IV) complexes with *N*-alkyl-3-nitrosalicylideneamines have much more positive reduction potentials than those of the manganese(IV) complexes with *N*-alkylsalicylideneamines.[9] This is because the nitro group is one of the strongest electron-withdrawing substituents. Also, the manganese(IV) complexes with 5-nitro analogues have reduction potentials as high as the manganese(IV) complexes with 3-nitro analogues.[10] Such electrochemical properties are considered to be very important with regard to the effective generation of O_2 by oxidative decomposition of water.

Reactivity of the manganese(IV) complexes with water

All the manganese(IV) complexes investigated here are found to react with water based on their color changes from deep green to yellowish brown. These imply that the manganese(IV) species may be reduced to the manganese(III) or manganese(II) species. Thus, we have estimated the reactivity of the manganese(IV) complexes with water by measuring the absorption spectral changes of their acetonitrile solutions (5 cm^3, 2.5×10^{-4} M) caused by addition of water (0.1 cm^3). Figure 4 shows the time courses of the relative intensity of the absorbances at the maximal band positions near 17,000 cm^{-1} which are characteristic for the manganese(IV) species. It can be seen that the reactivity is affected by the alkyl groups of the complexes: the reaction with water is retarded in the order of *n*-C_3H_7 ≪ *n*-C_8H_{17} < *n*-$C_{12}H_{25}$). These results indicate that the long-chain alkyl groups such as *n*-C_8H_{17} and *n*-$C_{12}H_{25}$ can protect the central manganese(IV) ion from attack by

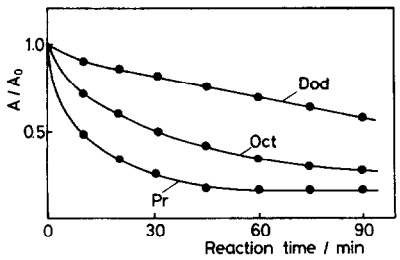

Fig. 4. Decreases in absorbance at λ_{max} after addition of water to acetonitrile solutions of Mn(IV)(*N*-R-3-NO_2 sal)$_2Cl_2$.

water molecules. This may arise from hydrophobicity of these groups. In other words, the reactivity of the manganese(IV) complexes with water can be controlled by the choice of alkyl groups.

Effect of pH of reaction media on quantities of liberated O_2

We have found that the pH values of reaction media decrease in the course of the reaction of the manganese(IV) complexes with water when without buffer solutions. Thus, the pH effect of reaction media on the quantity of liberated O_2 was examined by the use of Mn(IV)(*N*-Pr-3-NO_2 sal)$_2Cl_2$. The pH values were adjusted with 0.2 M acetate or 0.06 M phosphate buffer solutions. Figure 5(A) and (B) show the results obtained by methods 1 and 2, respectively. In both cases, the maximal liberation of O_2 was observed in the neutral pH region. This result is particularly interesting in connection with the photosynthetic oxygen evolution by green plants. The decrease in the liberated O_2 in acidic media may result from some decomposition of the manganese(IV) complex by hydrogen ions. On the other hand, the decrease in alkaline media cannot be explained clearly. However, it is supposed that the manganese(IV) complex may form Mn(IV)–OH species which further react with hydroxide ions to give relatively stable Mn(IV)=O species, which are not confirmed in this work.

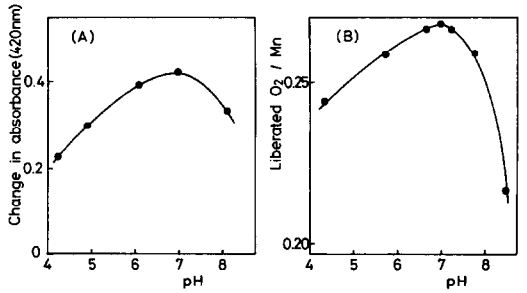

Fig. 5. Effect of pH on quantity of liberated O_2. (A) Method 1, and (B) method 2.

Table 3. Quantities of molecular oxygen (O_2) liberated during reaction of manganese(IV) complex (20 mg) with water in a mixed solvent of water (20 cm^3) and 2-propanol (5 cm^3) which was adjusted to pH = 7.0 with a phosphate buffer

Complex R	O_2 liberated/Mn
Pr	0.27
Bu	0.25
Hx	0.14
Oct	0.20
Dod	0.12
Bz	0.17

Oxygen liberation by various manganese(IV) complexes

Table 3 shows the quantities of O_2 liberated by the reactions of the manganese(IV) complexes with water at pH 7.0, which were determined by method 2. These values are presented as mol of liberated O_2 per mol of manganese(IV) complex. Among these complexes, Mn(IV)(*N*-Pr-3-NO_2 sal)$_2Cl_2$ exhibits the highest value and Mn(IV)(*N*-Dod-3-NO_2 sal)$_2Cl_2$ the lowest one. These results can be correlated with the reduction potentials and the reactivities of the manganese(IV) complexes as described above. Therefore, it can be said that the quantity of liberated O_2 depends on the oxidizing power of the manganese(IV) complexes.

Identification of reaction products of manganese(IV) complex with water

The acetonitrile or 2-propanol solution of Mn(IV)(*N*-Pr-3-NO_2 sal)$_2Cl_2$ changed its color from deep green to yellowish brown on the addition of water. This solution was evaporated under reduced pressure to yield a yellow solid, which was washed with water and dried *in vacuo*. The analytical data for this reaction product are consistent with the formula Mn(*N*-Pr-3-NO_2 sal)$_2(H_2O)_2$. Its magnetic moment determined at room temperature is 5.95 BM, indicating that the oxidation state of manganese ion in the reaction product is +II. The electronic spectrum of the product in acetonitrile is identical to that of Mn(II)(*N*-Pr-3-NO_2 sal)$_2(H_2O)_2$, which was prepared from manganese(II) acetate tetrahydrate and *N*-propyl-3-nitrosalicylideneamine. From these results, it is concluded that the manganese(IV) complexes are reduced to their corresponding manganese(II) complexes by reaction with water.

We now propose that the reaction of the manganese(IV) complexes with water proceeds

according to the following equation:

$$2Mn(IV)(L)_2Cl_2 + 2H_2O \rightarrow 2Mn(II)(L)_2 + O_2 + 4H^+ + 4Cl^-, \quad (1)$$

where L denotes the monoanion of *N*-alkyl-3-nitrosalicylideneamines. The concentration of chloride ions liberated into the reaction solvent was determined by a titration method using a silver nitrate solution. The value obtained was almost equal to that calculated from eqn (1). Moreover, the concentration of hydrogen ions liberated into the reaction solvent, when the reaction was carried out in a medium without buffer solution, was determined by measuring the decrease in the pH value. The value obtained from the pH drop was nearly equal to that calculated from eqn (1).

In order to prove that the liberated O_2 originated from water, isotopic labeled water, $H_2{}^{18}O$ (20.3 atom %), was used for the reaction solvent. Before reaction, the system and a solvent, 2-propanol (4 cm^3) and $H_2{}^{18}O$ (1 cm^3), were degassed under vacuum, and the manganese(IV) complex Mn(IV)(*N*-Pr-3-NO_2 sal)$_2Cl_2$ (10 mg) was added to it. After the reaction was complete, the generated gaseous components in the reaction system were analyzed by a mass spectrometer. The mass spectrum thus obtained shows relatively weak peaks at $m/z = 36$ and 34, in addition to an intense peak at $m/z = 32$. The former peaks can be assigned to ^{18}O–^{18}O and ^{16}O–^{18}O, respectively. Although quantitative determination of these species could not be made in this work, it is concluded that the liberated O_2 originated from the water.

INTERACTION OF SOLVATED ELECTRONS WITH AN Mo(V) OXALATE COMPLEX IN A WATER–ETHYLENE GLYCOL SYSTEM

J. O. DZIĘGIELEWSKI

Department of Inorganic and Radiation Chemistry, Institute of Chemistry, Silesian University, Katowice, Szkolna 9 Street, Poland

(*Received* 1 *February* 1985; *accepted* 10 *May* 1985)

Abstract—The reactivity of metal ions towards e_s^- was studied to identify the stable and unstable reaction products by spectroscopic analysis of the observed absorption bands. The crystal field parameters Dq(2600 cm^{-1}), Ds(−5300 cm^{-1}) and $D\tau$(900 cm^{-1}) were determined from absorption spectra and the energy terms of the Mo(V) oxalate complex were calculated as functions of the crystal field parameters. On these grounds, the absorption bands at 22,200 and 26,670 cm^{-1} of an irradiated frozen solution of the Mo(V) complex were designated as the *d–d* transition of the "hot" Mo(IV) ion and charge transfer from π^*-orbital of $C_2O_4^{3-}$, toward the antibonding molecular orbital, respectively. The electronic structure of the "hot" Mo(IV) ion was determined as $(d_{xy})^1(d_{xz}, d_{yz})^1$. The decay of the "hot ion" results in a change in the fundamental level, i.e. (d_{xz}, d_{yz}).[2] Therefore, the ligand remains in the coordination sphere as proved by ^{13}C NMR studies (signal at 165.2 ppm) as well as an absorption band at 35,100 cm^{-1} ($n \rightarrow \pi^*$ transition in the $C_2O_4^{2-}$ ion). On the grounds of the spectrophotometric and NMR investigations the structure of the oxalate complex of Mo(IV) $\{[Mo_2O_2(C_2O_4)_2(OH_2)_4]\}$ was proposed. The rate constant of the reaction of e_s^- with $[Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-}$ ions was determined as 2.6×10^9 dm^3 mol^{-1} s^{-1}.

The reactivity of a considerable number of complexes towards solvated electrons and radicals has been determined by the method of pulse radiolysis. A comprehensive set of experimental data can be found.[1] Many studies have been aimed at the identification of unstable radiolysis products of the reactions of e_s^- with complexes.[2–6] Only a few authors have analysed the spectroscopic absorption bands or ESR signals of the reaction products.[6–8]

Such an analysis enables a more precise identification of the unstable radiolysis products and the determination of the relation between the observed radiation–chemical processes and such fundamental properties of the irradiated complex as its symmetry, the covalency of the coordination bond, the electronic configuration and the spin state of the central ion. From this point of view, the d^1-electron Mo(V) complex seems to be an interesting subject.

Earlier studies of oxalate complexes[9,10] brought to light differences in the reactivity of those compounds towards electrons, the reactivity depending on the type of central ion. The present study was aimed at the determination of the reactivity of an oxalate complex of Mo(V) towards e_s^- and the identification of the unstable and stable reaction products by spectroscopic analysis of the observed absorption bands. The water–ethylene glycol system was considered suitable for this purpose.

EXPERIMENTAL

The complex $(NH_4)_2[Mo_2O_4(C_2O_4)_2(OH_2)_2]$ was obtained according to Mitchell.[11] An alternative structure of this compound is given in Fig. 1(a).[11,12]

A solution of ethylene glycol of analytical grade in triply distilled water (mol ratio 1 : 3) was prepared for investigations at room temperature, while one with a mol ratio of 1 : 2 was prepared for investigations at liquid-nitrogen temperature.

The solutions of $[Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-}$ were prepared by dissolving a corresponding amount of the Mo(V) complex prepared as above in the solvent saturated with the appropriate gas for 15 min and

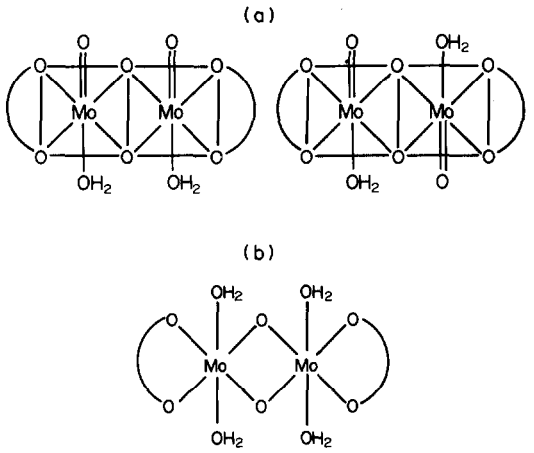

Fig. 1. Equivalent structures of the

$$[Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-}$$

ion (a) and the proposed structure of the Mo(IV) oxalate complex (b).

irradiated in the cobalt source "Issliedowatiel" with a dose rate of 2.4×10^{16} eV cm^{-3} s^{-1}.

The amount of compound modified by the radiation was determined from the intensity decrease in the 32,800-cm^{-1} band using a Beckman 5240 spectrophotometer. The low-temperature measurements were carried out in a cryostat by irradiating glassy matrices at 77 K and recording the absorption bands as functions of temperature.

The dose was determined with a Fricke's dosimeter and converted to the electron density of the water–ethylene glycol system.

The number of oxalate groups in the irradiated complex was monitored by ^{13}C NMR signals, applying external calibration by means of HMDSO.

The changes in the paramagnetic susceptibility resulting from irradiation of the oxalate Mo(V) complex in solution was determined by the ^1H NMR method described by Evans.[13,14]

Because of the low effective magnetic moment of the binuclear Mo(V) complex,[11,15] the concentration of the solution used for the measurements was 0.9 mol dm^{-3}. The variations in the magnetic susceptibility were determined from the ^1H NMR signal shift of acetone inserted into the solution after irradiation. For the NMR measurements an FT-80A multinuclear spectrometer was used.

RESULTS AND DISCUSSION

Absorption spectra of the

$$[Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-}$$

ion are presented in Table 1. The bands given in Table 1 were found for solutions of the oxalate complexes of Mo(V).[11] From the data given in Table 1, the crystal field parameters were determined: $Dq = 2600$ cm^{-1}, $Ds = -5300$ cm^{-1} and $D\tau = 900$ cm^{-1}. Assuming a C_{4v}-symmetry, the term energies of Mo(V) were calculated as functions of the crystal field parameters according to Ref. 16:

$$^2B_2 = (-4Dq + 2Ds - D\tau),$$

$$^2E = (-4Dq - Ds + D\tau),$$

$$^2B_1 = (6Dq + 2Ds - D\tau),$$

$$^2A_1 = (6Dq - 2Ds - 6D\tau).$$

The relative positions of the terms as well as the charge-transfer transitions are shown in Fig. 2.

The absorption bands resulting from irradiation of the Mo(V) complex in the frozen water–ethylene glycol system saturated with Ar are shown in Fig. 3 (line 1). Those bands do not practically appear in solutions saturated with N_2O.

As indicated by Fig. 3 (line 1), the irradiated matrix shows a very intense band at 26,670 cm^{-1} appearing

Table 1. Band positions, molar extinction coefficients and assignments

Band position (cm^{-1})	Molar extinction coefficient (dm^3 mol^{-1} cm^{-1})	Band assignment[11]
20,400	1	$(d_{xy})^1 \rightarrow (d_{xz}, d_{yz})^1$
26,000	170	$(d_{xy})^1 \rightarrow (d_{x^2-y^2})^1$
32,800	3520	$\pi \rightarrow (d_{xz}, d_{yz})$
		$\pi(C_2O_4^{2-}) \rightarrow (d_{xy})^a$
38,900	3520	$\pi \rightarrow (d_{x^2-y^2})$
		$\pi(O) \rightarrow (d_{xz}, d_{yz})^a$

[a] Corrected by the author of this paper with regard to the symmetry elements.

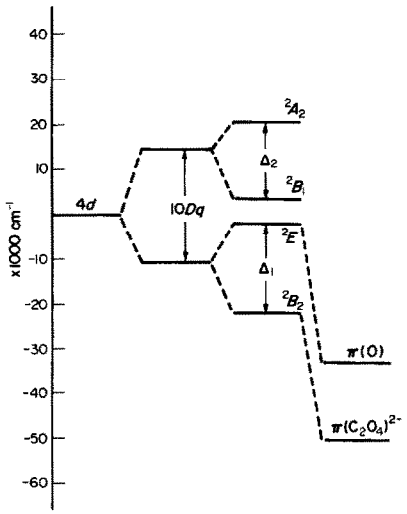

Fig. 2. Relative energies of the Mo(V) terms and the charge-transfer energies in the $[Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-}$ ion.

at 77 K and a band of low intensity at 22,200 cm^{-1} appearing at 173 K, both vanishing at about 210 K. The intense band cannot be attributed to a *d–d* inner-ligand transition because of its intensity and position. It is rather of the charge-transfer type, i.e. due to electron transfer from the π^*-orbital of $C_2O_4^{3-}$ ion, resulting from the electron capture by the oxalate ligand, toward the antibonding molecular orbital.[17,18] The disappearance of that high-energy state is connected with the transfer of electrons to the d_{xz}- or d_{yz}-orbitals of the central ion. The 22,200-cm^{-1} band may be attributed to the *d–d* transition because of its low intensity and position. The energy of this transition corresponds to the energy level difference of the terms $^2A_1 - {}^2E$. It may therefore be concluded that the trapping of an electron by Mo(V) results in the creation of the hot Mo(IV) ion with the following electronic structure, $(d_{xy})^1(d_{xz}, d_{yz})^1$. The vanishing of the 22,200-cm^{-1} transition is due to the transition of Mo(IV) from the excited to the ground state.

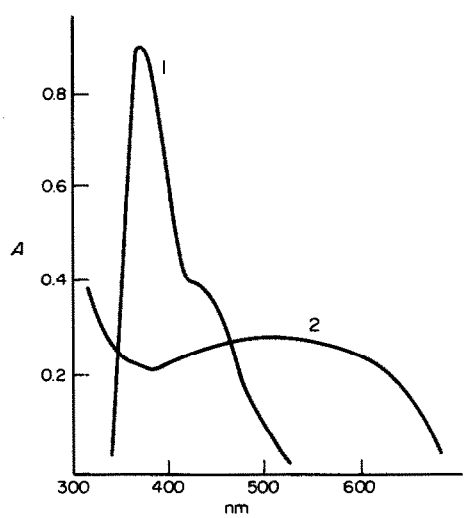

Fig. 3. Absorption bands arising after irradiation of the oxalate complex of Mo(V) at 175 K: $c = 10^{-2}$ mol dm^{-3} in the water–ethylene glycol system (2:1), dose = 7.8 kGy (line 1) and the differential spectrum of irradiated

$(NH_4)_2[Mo_2O_4(C_2O_4)_2(OH_2)_2]$

(dose = 1.9×10^{21} eV cm^{-3}) in the water–ethylene glycol system at room temperature. Solution (c = 1 mol dm^{-3}) saturated with Ar. Thickness of the absorption cell, d = 5 cm (line 2).

The reduction of Mo(V) to Mo(IV) is confirmed by the difference spectrum of the irradiated solution from the non-irradiated solution at room temperature shown in Fig. 3 (line 2). The single broad band of low intensity located at about 14,700 cm^{-1} may be attributed merely to a *d–d* transition. For Mo(IV) a band is indeed observed in the *d–d*-transition region.[19]

The distinctly lower Mo(IV) band compared to that of the crystal field of Mo(V) indicates a change in the ligand field of the reduced central ion. The variations occurring in the coordination sphere of the central ion are shown in Figs 4 and 5. From Fig. 4 it appears that the irradiation of $[Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-}$ results in a decrease in the intensity of the 32,800-cm^{-1} band and in the appearance of a new band at 38,900 cm^{-1}. The difference spectrum shown in Fig. 5 indicates that the irradiated compound also shows an additional band at about 35,100 cm^{-1}. The position of this band was determined by interpolation. The intensity decrease in the 32,800-cm^{-1} band is usually attributed to the decrease in the ligand or, at least, to its removal from the coordination sphere of the central ion.

Such an interpretation is at variance with the appearance of the new band at about 35,100 cm^{-1}, which indicates the presence of $C_2O_4^{2-}$ in the coordination sphere of Mo(IV).

As expected, the 35,100-cm^{-1} band is due to an inner transition within the $C_2O_4^{2-}$ ion.[11] In the oxalate complex of Mo(V), that band is not observed because of its low intensity and overlapping with the 32,800-cm^{-1} band. Taking into account the intensity and position of the 35,100-cm^{-1} band, it may be attributed, according to Ref. 20, to the $n \rightarrow \pi^*$ transition in the $C_2O_4^{2-}$ ion. The presence of $C_2O_4^{2-}$ ions in the coordination sphere of Mo(IV) is confirmed by the ^{13}C NMR signal of the irradiated solution at 165.2 ppm. The intensity and position of this signal are the same as for the non-irradiated solution of Mo(V).

The decrease in the intensity of the 32,800-cm^{-1}

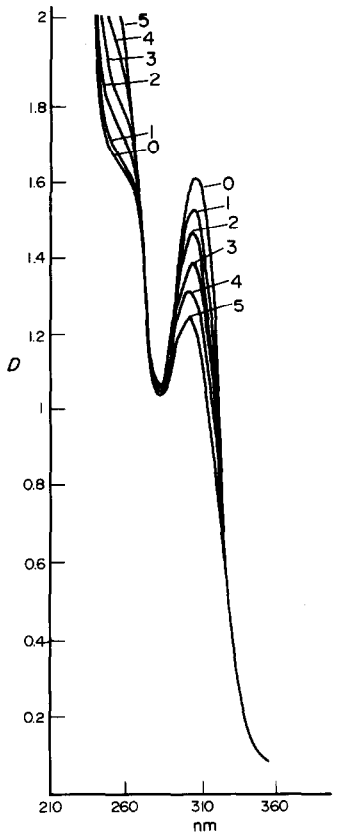

Fig. 4. Variations in the absorption spectrum (shortwave region) caused by the irradiation of the solution of

$$[Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-}$$

saturated with Ar (at room temperature) in the water–ethylene glycol system, $c = 5 \times 10^{-4}$ mol dm^{-3}, $d = 1$ cm. (0) non-irradiated solution, (1) 3.72×10^{18} eV cm^{-3}, (2) 8.68×10^{18} eV cm^{-3}, (3) 13.64×10^{18} eV cm^{-3}, (4) 15.60×10^{18} eV cm^{-3}, (5) 21.28×10^{18} eV cm^{-3}.

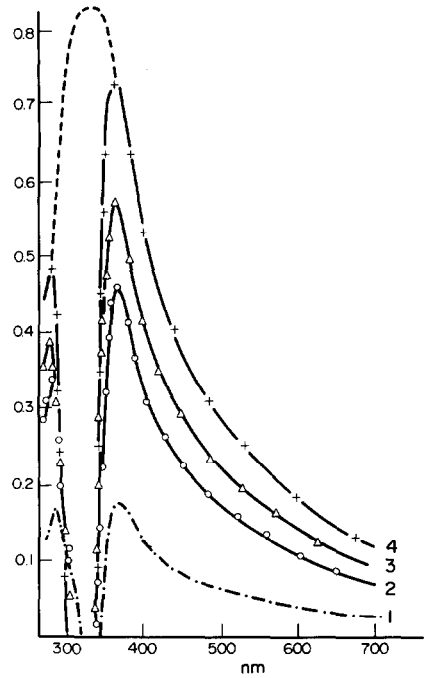

Fig. 5. Differential spectrum of the irradiated 10^{-2} mol dm^{-3} $[Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-}$ solution saturated with Ar in the water–ethylene glycol system, $c = 10^{-2}$ mol dm^{-3}, $d = 1$ cm (at room temperature): (1) 1.49×10^{20} eV cm^{-3}, (2) 2.98×10^{20} eV cm^{-3}, (3) 4.46×10^{20} eV cm^{-3}, (4) 5.95×10^{20} eV cm^{-3}.

band may, therefore, be due only to the change in the magnitude and symmetry of the crystal field around the reduced central ion. A decrease in the Dq parameter is indicated by the position of the band of the reduced Mo complex. The Dq decrease to 1470 cm^{-1} and the change in the crystal field symmetry are most probably caused by the vanishing of the Mo=O bond. The oxalate complex of Mo(IV) may, therefore, be depicted as in Fig. 1b. The presence of oxygen bridges in the Mo(IV) complex is corroborated by the weak paramagnetic properties of the irradiated solution.

The paramagnetic shift of the acetone signal is identified for both the non-irradiated and irradiated solutions and equals about 4 Hz in relation to the position of the signal of $(CH_3)_2C{=}O$ without the Mo complex. An oxalate complex of Mo(IV) with a similar structure was obtained by Wajda and Bezak,[21,22] who have also proved its weak paramagnetic properties. Thus, assuming a D_{4h}-symmetry for the Mo(IV) complex, the broad band shown in Fig. 3 can be attributed to the transitions $^3E_g \rightarrow {}^3B_{2g}$ and $^3E_g \rightarrow {}^3A_{1g}$.

The variation in the energy levels of the Mo(IV) orbitals in comparison with those of the Mo(V) orbitals explains the transfer band shift ($\pi C_2O_4^{2-} \rightarrow d_{xy}$) towards a higher frequency. In the irradiated compound, this band is shifted to 38,900 cm^{-1} (Fig. 3). The weak paramagnetism of the irradiated solution shown above confirms the fundamental term ^3E_g of Mo(IV). If there was no change in the position of the terms, the fundamental term of Mo(IV) would be $^1B_{2g}$ and the Mo(IV) complex would be diamagnetic.

The charge transfer $\pi(O) \rightarrow d_{xz}, d_{yz}$ is not observed in the irradiated solution, which indicates the vanishing of the Mo=O bond.

The quantity of the reduced Mo(V) complex was determined from the intensity decrease in the 32,800-cm^{-1} band. The quantity of reduced complex molecules depends non-linearly on the dose. The radiation yields from the conversion of the Mo(V) complex are listed in Table 2.

The yields for the solutions saturated with Ar,

higher than those for the solutions saturated with N_2O (Table 2), indicate interactions of the complex with e_s^-. The $[Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-}$ ions are most likely also reduced by hydrogen atoms produced during the radiolysis of glycol.[23] The OH radicals are not able to interact with the Mo(V) complex because of their high reactivity toward glycol.[24] From the results obtained we are led to assume the following mechanism for the radiolysis:

$$S \rightsquigarrow e_s^-, S^+, H, OH, R, \tag{1}$$

$$e_s^- + [Mo_2O_4(C_2O_4)_2(OH_2)_2]^{2-} \xrightarrow{\Sigma k_1} \begin{cases} \xrightarrow{k_1} Mo(IV)^* \\ \xrightarrow{k_1'} Mo_2O_4L_2(OH_2)_2]^{2-} \end{cases} \tag{2a}$$

$$\left[\begin{array}{l} O \\ \| \\ Mo(V)\!<\!L^- \\ | \\ OH_2 \end{array}\right]^- + 2H^+ \rightarrow \left[\begin{array}{l} OH_2 \\ | \\ Mo(IV)\!<\!L \\ | \\ OH_2 \end{array}\right]^{o}, \tag{2b}$$

$$N_2O + e_s^- \xrightarrow{H_2O} N_2 + OH + OH^-, \tag{3}$$

$$e_s^- + HOCH_2{-}CH_2OH \xrightarrow{k_3} HOCH_2{-}CH_2O^- + H, \tag{4}$$

$$(H), OH + HOCH_2{-}CH_2OH \rightarrow (H_2), H_2O + HOCH_2{-}\dot{C}HOH, \tag{5}$$

$$2HOCH{-}CH_2OH \rightarrow \begin{array}{l} HOCH{-}CH_2OH \\ | \\ HOCH{-}CH_2OH \end{array} \tag{6}$$

where S, R and L mean solvent, radical and ligand ($C_2O_4^{2-}$), respectively.

Applying the approximation of the steady state to reactions (2)–(4), the following relationship was derived:

$$\frac{1}{G_{[Mo(IV)]_{Ar}} - G_{[Mo(IV)]_{N_2O}}} = \frac{1}{G_{e_s^-}} + \frac{k_3[C_2H_6O_2]}{G_{e_s^-}[Mo(V)]\,\Sigma k_1}.$$

For $G_{[Mo(IV)]_{Ar}} - G_{[Mo(IV)]_{N_2O}}$ see Table 2. Figure 6 shows

$$\frac{1}{G_{[Mo(IV)]_{Ar}} - G_{[Mo(IV)]_{N_2O}}}$$

as a function of

$$\frac{1}{[Mo(V)]}.$$

From Fig. 6 the values $G_{e_s^-} = 0.74$ and

$$\frac{k_3[C_2H_6O_2]}{G_{e_s^-}\,\Sigma k_1} = 2.09 \times 10^{-3}$$

were found. Thus:

$$\frac{k_3}{k_1} = 1.73 \times 10^{-4},$$

assuming $k_3 = 4.5 \times 10^5$ dm^3 mol^{-1} s^{-1},[25] $k_1 = 2.6 \times 10^9$ dm^3 mol^{-1} s^{-1}.

The results obtained lead to the conclusion that the oxalate complex of Cr(III) of O_h-symmetry (lack of Jahn–Teller distortion for d^3) can react with e_s^- in a similar manner, i.e. forming the $C_2O_4^{3-}$ ion and reducing the central ion to Cr(II). However, due to the symmetry the transfer of e_s^- from $C_2O_4^{3-}$ to OM $\sigma_d^*(e_g)$ is forbidden. On the other hand, the transfer of e_s^- from $C_2O_4^{3-}$ to $\pi d(t_{2g})$ orbitals is symmetry-allowed but impossible because of the position of the oxalate ion in the spectrochemical series, which means that the ligand does not favour a $(t_{2g})^n$ low-spin configuration. Hence, the e_s^- interaction with ligand should lead to intermediate decomposition of the oxalate complex of Cr(III). The central ion reduction should decrease the oxalate σ $Cr(IV)\!<\!O_4C_2$ bond strength (e_g is an acceptor orbital) which can lead to the decomposition of Cr(III) oxalate. It may be predicted that the oxalate complex of Cr(III) of higher symmetry will be more reactive compared to the oxalate of Mo(V) of lower symmetry.

The rate constants of the reaction of e_{aq}^- with

Cr(III) oxalates determined by pulse radiolysis[9] are higher than k_1 and equal about 1.3×10^{10} dm^3 mol^{-1} s^{-1}. The lower value of Σk_1 for complex reactions seems to be comprehensible. In the light of our results, the higher symmetry (O_h) of the oxalate complexes of Cr(III) can also contribute to the increase in the probability of the decomposition of those complexes. The decomposition of the Cr(III) oxalates was proved experimentally.[9,10] The spin state of Cr(III) in oxalate complexes is $\frac{3}{2}$. In Cr(II) oxalate the spin state for the weak $C_2O_4^{2-}$ ligands should be 2 instead of 1.[26,27] According to our expectation the oxalate complex of Cr(III) has decomposed as a result of the reaction with e_s^-. The oxalate complex when undergoing an internal rearrangement (of the d-orbitals of the central ion) caused by the ligand field does not decompose if the resulting configuration (d_{xz}, d_{yz}) of d-electrons does not weaken the Mo$\langle$ O_4C_2 bond. The difference in the behaviour of the Mo(V) and Cr(III) compounds towards e_s^- is caused by differences in the electronic configuration of the central ions and in the symmetry of the oxalate complexes. Similarly, as was shown in a previous paper,[28] a different behaviour of the Mo(O) and Mo(IV) complexes with π-acceptor ligands, including lowering the complex symmetry from O_h to C_{4v}, was observed when they interact with e_s^-.

COMPLEX FORMATION BETWEEN SILVER AND IODIDE IONS IN DIMETHYLSULPHOXIDE

F. GAIZER

Department of Inorganic and Analytical Chemistry, A. József University, Szeged, P.O. Box 440, Hungary

(*Received* 25 *April* 1985; *accepted* 22 *May* 1985)

Abstract—The interaction of silver and iodide ions in dimethylsulphoxide (DMSO) at 21–25°C has been investigated by spectrophotometry and potentiometric measurements over a wide concentration range. The stability constants of the complexes AgI, $Ag_6I_8^{2-}$, $Ag_5I_7^{2-}$, $Ag_4I_6^{2-}$, $Ag_2I_4^{2-}$, AgI_2^- and AgI_3^{2-} have been determined by systematic computer evaluation of the results. The IR spectrum shows that in the isolated compound $CdAg_6I_8 \cdot 8DMSO$ the DMSO is coordinated through oxygen.

In a previous paper[1] we presented the results of investigations on complex formation between silver and iodide ions in DMSO. On the basis of a systematic computer evaluation of measurements at constant silver concentrations in the range T_{Ag} = 0.5–7.5 mM, we presumed the formation of species (6, 8), (1, 2) and (1, 3).* Since the fit was not considered satisfactory and systematic deviations were observed as a function of silver concentration, we felt it necessary to perform further experiments differently planned and to supplement the potentiometric measurements with additional ones. The present paper gives an account of these investigations.

EXPERIMENTAL

Chemicals

Silver nitrate and potassium iodide were of analytical grade. Potassium nitrate was prepared from potassium hydrogen carbonate with nitric acid and was twice recrystallized. DMSO was twice distilled in vacuum.

Potentiometric measurements

A silver electrode was used as the measuring electrode and an Ag/AgCl electrode as the reference electrode.[2] During the titrations, potassium iodide solution was titrated with silver nitrate solution at 21 ± 0.5°C. Both solutions were adjusted to 0.5 M ionic strength with potassium nitrate. The solution concentration of silver was checked via the known iodide ion concentration by the Gran method, after the break appearing at I/Ag = 1 in the titration curves. The E^o value of the measuring cell was calculated from the measured points at I/Ag < 1, via the Nernst equation. The reference electrode was in contact with the reaction mixture through 0.5 mol dm^{-3} KNO_3 solution separated by sintered glass. The electromotive force of the cell was measured with an accuracy of 0.1 mV with an ORION 701/A potentiometer.

The joint evaluation of 136 experimental points from seven independent series of measurements was performed by the least-squares computer program published previously.[3]

The program calculated with the Nernst factor for the given temperature and the E^o values of the individual titration curves. The log β values yielding the minimum error square sum of the deviations between the measured and calculated emf were calculated by applying unit weighting factors. The standard deviation values given in the tables are $\sigma(\text{mV}) = \sqrt{\sum \Delta h^2/(\text{NMP} - \text{NP} - 1)}$, where NMP is the number of measured points and NP the number of parameters to be refined.

The *spectrophotometric measurements* revealed that the spectra of solutions with compositions $T_I/T_{Ag} < 1.8$ exhibit a maximum at 298 nm and a minimum at 282 nm. In the presence of an iodide ion excess, the spectrum is gradually transformed into a

* The complex Ag_qI_p is denoted by (q, p).

rising but not characteristic one, and after about $T_I/T_{Ag} = 2.4$ no further changes can be observed. Due to the strong interaction between iodide and silver ions, reliable stability constants could not be calculated from the spectrophotometric mole ratio curve.

Preparative work

A white solid complex with the composition $CdAg_6I_8 \cdot 8DMSO$ could be prepared; this precipitated from a concentrated solution of the components at 80°C (0.36 M CdI_2 + 2.13 M AgI + 8 cm^3 DMSO). The percentage analysis data (calculated values in parentheses) are as follows: Cd, 5.0 (4.68); Ag, 26.3 (26.96); I, 42.6 (42.3); DMSO (as difference), 26.3 (26.04).

Thermal examinations

Heating-stage microscopy showed that the crystals melted at 97–98°C and new crystal needles appeared before the old ones had disappeared. On further increasing the temperature, the crystals gradually decomposed and the substance became amorphous. In the course of the derivatographic studies, an endothermic peak appeared at 90°C in the DTA curve, which can be explained by the melting of the complex. Another endothermic peak appeared at 130°C, but this cannot be interpreted reliably and visual observation gives no reason for it. The endothermic peak appearing above 200°C alike in the DTA, DTG and TG curves is due to the cracking of DMSO. There are no signs of the stepwise removal of the solvent molecules.

The IR spectrum of the compound in KBr pellets revealed the S=O valence vibration of DMSO at 1000 cm^{-1}, which is definite proof of the coordination of the solvent molecules via oxygen. In the event of coordination via sulphur, the absorbance line should be at 1100 cm^{-1}.[4] The structural character of the spectrum in the range 1020–1050 cm^{-1} leads to the supposition of the presence also of crystal DMSO.

RESULTS AND EVALUATION OF POTENTIOMETRIC MEASUREMENTS

The potentiometric titration curves are presented in Fig. 1. Two breaks can be observed in the curves. The second one appears at I/Ag = 1, corresponding to the transformation of all the iodide ions into AgI. The first break, at the beginning of precipitation of AgI, is concentration-dependent. As can be seen in Fig. 2, in a solution containing about 2 mM silver it appears at I/Ag = 1.44, and in the presence of about

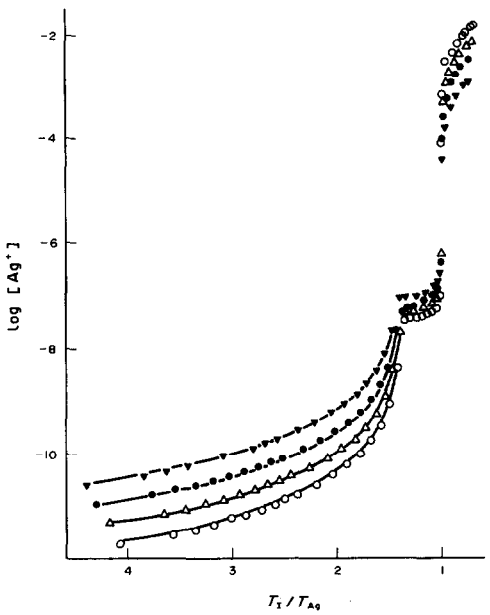

Fig. 1. Potentiometric titration of iodide ions with silver ions in DMSO. Initial iodide concentrations in mol dm^{-3}: (●) 0.00517, (+) and (▽) 0.0127, (▲) 0.0243 and (○) 0.048. The solid curves are those calculated using the constants of column 1 in Table 2.

30 mM silver at I/Ag = 1.36. Independent solubility measurements showed that in 1 mol dm^{-3} silver nitrate solution I/Ag = 1.32 ± 0.01.

Due to the complexity of the system, evaluation of the results of potentiometric measurements was carried out in several steps, different point groups being chosen. When the range I/Ag > 2 was evaluated it was found that complexes (1, 2) and (1, 3) and any polynuclear complexes with stoichiometry I/Ag < 2 were not sufficient to obtain a satisfactory fit. Evaluation with the normalized curves also excluded this supposition. We therefore attempted the introduction of polymers of the species (1, 2), $Ag_2I_4^{2-}$ giving the best fit. Inclusion of species (2, 4) besides (1, 2) reduced the standard deviation to almost two-thirds.

For substantiation of the composition of the potential polynuclear complex, systematic refinements were performed with the measured points in the range I/Ag > 1.7. The results are listed in Table 1. The formation of bi- and trinuclear species could definitely be excluded.

Extending the evaluation for the whole range freee of precipitate (I/Ag = 1.42–5), on the basis of stoichiometry the complex (4, 6) should have also been excluded as dominant species. However, refinements were made with the inclusion of the (4, 6) complex, too. Moreover, the (1, 1) complex was introduced in all evaluations on the assumption that, if its supposition is unnecessary, it will be eliminated through the decrease of its stability constant during the refinement cycles. The final results of this evaluation are presented in Table 2.

DISCUSSION

The potentiometric measurements in the range I/Ag > 2 revealed that this range could be described satisfactorily only by supposing the presence of the species $Ag_2I_4^{2-}$ besides AgI_2^-. The distribution curves in Fig. 3 show that this complex is formed in considerable amount. The presence of AgI_3^{2-} could not be substantiated, but our previous measurements,[1] where I/Ag reached 30–40, gave a reliable value for its stability constant and its formation reached about 40%. Our previous potentiometric measurements on silver bromide system[5] revealed only the predominant formation of $AgBr_2^-$ and $AgBr_3^-$ with log β values of 11.14 ± 0.04 and 12.02 ± 0.1, respectively.

To substantiate the complex(es) with I/Ag < 2, we considered the results of our liquid X-ray measurements[6] in solutions containing about 1 M silver. The differential radial distribution curves obtained (Fig. 4) did not substantiate the presence of complex(es) containing more than six silver atoms; nevertheless, curve A (I/Ag = 1.5) could be described by the supposition of $Ag_4I_6^{2}$, curve B (I/Ag = 2) by that of $Ag_4I_6^{2-}$ and a predominance of $Ag_2I_4^{2-}$, and curve C (I/Ag = 2.67) by that of $Ag_2I_4^{2-}$ and a small amount of AgI_3^{2-}. Sedimentation studies[7] did not point to the formation of species of large molecular weight either.

The data in Table 1 suggest that the supposition of species (5, 7) alone resulted in a satisfactory fit.

Table 2. Results of least-squares refinements using points in the range I/Ag = 1.42–5 (the probable errors in the last digits of the parameters are given in parentheses)

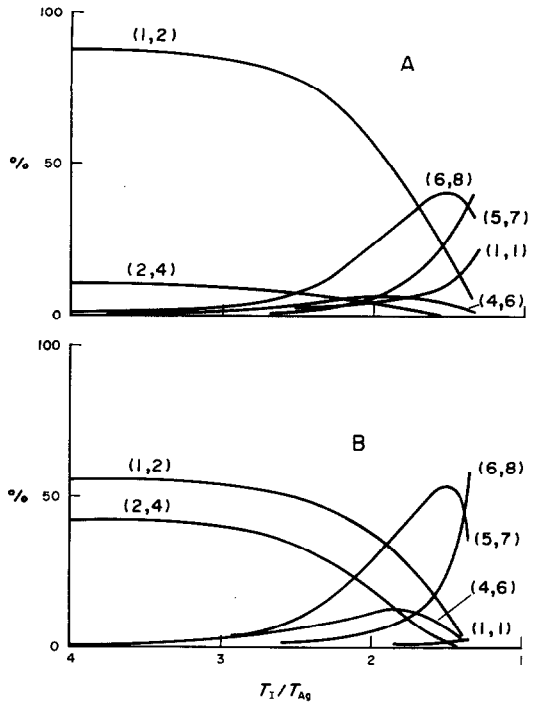

Fig. 3. Percentage distribution of silver in the individual complexes with the constants of column 4 in Table 2. T_{Ag} in mol dm^{-3}; (A) 0.001, and (B) 0.01.

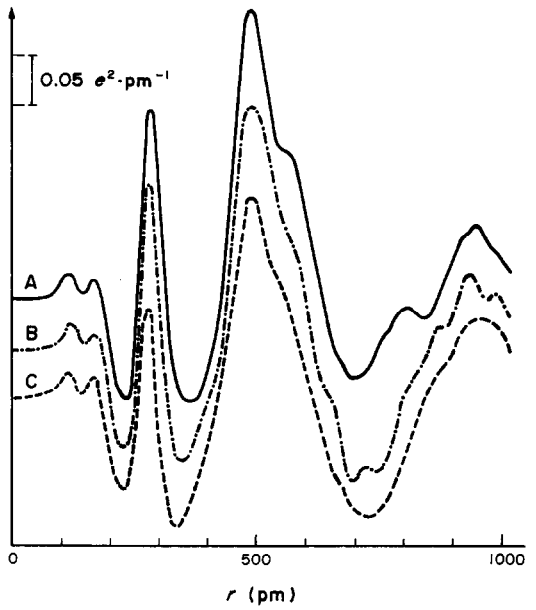

Fig. 4. Differential radial distribution curves. Compositions of solutions in mol dm^{-3}, in the sequence T_{Ag}, T_I and T_{DMSO}: (A) 1.0, 1.5 and 13.2; (B) 1.0, 2.0 and 12.9; and (C) 0.75, 2.0 and 13.0.

However with species (6, 8) as well, the fit improved and the assumption of the species (1, 1) led to a quite sufficient fit. In the course of the refinements, the (1, 1) complex was not eliminated by the program.

The inclusion of the species (1, 1) is disputable, but the concentration-dependence of the precipitation of AgI suggests that in these solutions the dissociation equilibrium of a soluble complex, e.g. $Ag_6I_8^{2-}$, should be considered:

$$Ag_6I_8^{2-} \rightleftarrows Ag_5I_7^{2-} + AgI;$$

$$K_D = [Ag_5I_7^{2-}] \times [AgI]/[Ag_6I_8^{2-}].$$

From the above expression the equilibrium concentration of AgI in solution is:

$$[AgI] = K_D \times \beta_{6,8} \times \beta_{5,7}^{-1} \times [Ag^+] \times [I^-]$$

$$= \beta_{1,1} \times [Ag^+] \times [I^-],$$

i.e. species (1, 1) can be included and K_D can be calculated.

Considering the above aspects, the stability constants obtained from the model (1, 1), (6, 8), (5, 7), (2, 4) and (1, 2) are substantiated in principle. The standard deviations of the measured and calculated values are shown in Table 2, while the calculated emf values are indicated in Fig. 1 with continuous lines. The fit is satisfactory, especially if one considers the measuring conditions, but the individual curves exhibit small systematic deviations. After the permissible and realistic correction of the E^o values for the individual titration curves by 0.5–2 mV these deviations disappeared and the fit can be considered fairly good. As can be seen from Table 2, evaluations were also performed with species (4, 6). The deviation then obtained proved a little better.

According to the models in Table 2, the previous measurements[1] have been re-evaluated. The fit obtained for 100 experimental points from five independent measurements at 25°C is satisfactory with the "rough" experimental data, too. Elimination of the systematic deviations through the E^o corrections resulted in a better fit than expected.

Evaluating our liquid X-ray measurements, we assumed the structure shown in Fig. 5 for the species (4, 6)[6] in a solution with I/Ag = 1.5. It is very likely that further AgI is bound to the two I′ and I″ atoms in the complex, and first $Ag_5I_7^{2-}$ is formed, then $Ag_6I_8^{2-}$. The formation of $Ag_2I_4^{2-}$ on the action of excess iodide ions can be explained if we assume splitting of the Ag--I--Ag bridges in (4, 6).

As a final conclusion of the present and previous

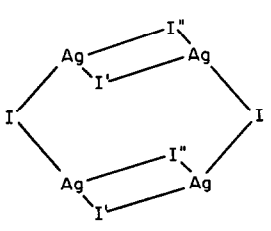

Fig. 5. Proposed structure of the species $Ag_4I_6^{2-}$.

studies, we do not consider the presence of $Ag_3I_4^-$ [8] and $Ag_2I_3^-$ [9] to be substantiated.

Acknowledgements—I express my gratitude to Mrs Mária Palotai for her valuable help in carrying out the experiments and to Dr Gy. Liptay for the thermal examinations.

FOUR- AND FIVE-COORDINATE PALLADIUM(II) COMPLEXES CONTAINING 1,10-PHENANTHROLINE AND ITS 2,9-DIMETHYL DERIVATIVE

SHINSAKU YAMAZAKI*
Chemistry Laboratory, Gakuen College Kochi, Kochi 780, Japan

(*Received* 2 *January* 1985; *accepted after revision* 22 *May* 1985)

Abstract—A series of potentially five-coordinate Pd(II) complexes, $[Pd(PMe_2Ph)_3(2,9\text{-}R_2\text{-}phen)][BF_4]_2$ (R = H or Me; phen = 1,10-phenanthroline), $[PdCl(PPh_3)_2(2,9\text{-}R_2\text{-}phen)]X$ (R = H or Me) and $[PdCl(2,9\text{-}Me_2\text{-}phen)_2]PF_6$ have been obtained from reactions of $[Pd(PMe_2Ph)_4][BF_4]_2$ and $[PdCl(PPh_3)_3]X$ (X = BF_4 or PF_6) with potentially bidentate phen and its 2,9-dimethyl derivative, respectively. By ^1H and $^{31}P\{^1H\}$FT NMR and electronic spectroscopy, these Pd(II) complexes have been characterized. Formally a three-coordinate complex of Pd(II), $[Pd(PR_2Ph)_3]BF_4$ (R = Et or Ph) has also been prepared by treating $[PdCl(PPh_3)_3]BF_4$ and $PdCl_2(PEt_2Ph)_3$ with $AgBF_4$.

Many studies concerning ligand substitution and isomerization of d^8 transition-metal complexes have been directed to monodentate phosphine ligands, especially to PMe_3 and $P(OMe)_3$. In some of these studies five-coordinate intermediates have been isolated and their crystal structures have been determined.[1–13] The systematic kinetics for MX_2L_3 [M = Ni,[1,2] X = CN, Cl or Br, L = PMe_3 or $P(OMe)_3$; M = Pd, Pt,[10] X = Cl, Br or I, L = PMe_3; M = Pt,[11] L = 1-R-3,4-dimethylphosphole, X = Cl, Br or I] have been established by ^{31}P NMR spectroscopy. However, five-coordinate Pd(II) complexes stabilized only by neutral ligands, especially by bulky PPh_3, are elusive. In addition, there have been only a few examples of five-coordinate Pd(II) complexes[5] containing potentially bidentate 1,10-phenanthroline (phen) or its 2,9-dimethyl derivative (2,9-Me_2-phen), and their solution behaviours have not been determined unambiguously compared with those of the corresponding Pt(II) complexes.[9]

The ligand substitution reactions of

$$[Pd(PPh_3)_4]X_2$$

(X = BF_4 or PF_6),[14] $[PdCl(PPh_3)_3]X$[15] and $[Pd(PMe_2Ph)_4][BF_4]_2$ may be expected to proceed comparatively readily due to the presence of bulky phosphines and the low coordination abilities of the anions. Several potentially five-coordinate Pd(II) complexes containing phen or 2,9-Me_2-phen have been prepared from these precursors.

In the five-coordinate Pt(II) complexes of phen so far isolated, it has been found that the crystal structures are mostly distorted square pyramid with elongation of the apical M—N bond length,[5,9] while no dissociation of the phen takes place in solution as evidenced by the observance of a ^{195}Pt satellite. Therefore, it seems that the apical M—N distance of the square-pyramid complex crystallographically determined is not the main factor in dominating its solution behaviour.

In this paper, the preparation and characterisation of potentially five-coordinate Pd(II) complexes are described. Some of the complexes that have been obtained have shown spectra sufficiently explicit to elucidate their dynamic structures. However, firm evidence by low-temperature NMR measurement, to freeze the dynamic motions of the complexes, has not been obtained on account of insufficient solubility. The preparation of the formally three-coordinate complexes of Pd(II), $[Pd(PR_2Ph)_3][BF_4]_2$ (R = Et or Ph), is also described.

EXPERIMENTAL

All the solvents were purified before use by distillation over $CaCl_2$ (CH_2Cl_2 or acetone) or Na (benzene or diethyl ether). Elemental analyses were performed by the Microanalytical Centre, Department of Pharmaceutical Science, Kyoto University. Spectrometers used for NMR studies are; ^1H NMR, JEOL-100; ^{13}C NMR, Hitachi R-900 (22.6 MHz); $^{31}P\{^1H\}$ NMR, JEOL FX-90Q (36.25 MHz) and FX-200 (100.14 MHz), whose measure-

ments were performed by the Applied Research Centre of NM, JEOL Ltd (Akishima). Electroconductivities were measured by a Denki Kagaku Keiki AO-6 instrument in dried acetone. Electronic spectra were obtained in a Hitachi 200-20 spectrometer. All reactions were carried out in air except for the preparation of $[Pd(PPh_3)_4]X_2$ (X = BF_4 or PF_6)[14] which was carried out *in vacuo* or under nitrogen. PMe_2Ph and PEt_2Ph were prepared by the literature procedure.[16]

Chlorotris(triphenylphosphine)palladium(II) complexes, $[PdCl(PPh_3)_3]X \cdot (CH_3)_2CO$ (X = BF_4[15] *or* PF_6)

$[Pd(PPh_3)_4][PF_6]_2 \cdot (CH_3)_2CO$ (0.3 g) was suspended in 30 cm^3 of acetone, and 0.2 g of *t*-BuCl in 3 cm^3 CH_2Cl_2 was added to the solution with vigorous stirring. The suspension dissolved in an hour, and a small amount of a canary yellow solid precipitated. After being stirred overnight, the solution was filtered and the filtrate was reduced in volume to about 10 cm^3 under reduced pressure. Addition of diethyl ether to the solution gave a yellow solid, which was recrystallized from acetone containing roughly an equimolar quantity of PPh_3 to give pale yellow needles of an acetone solvate (0.13 g, 57%). Found: C, 59.8; H, 4.5; Cl, 3.0. Calc. for the empirical formula: C, 60.48; H, 4.54; Cl, 3.14%. IR (Nujol mull): ν(CO) (acetone of solvation), 1707 cm^{-1} (vs). Conductance (in acetone): Λ_M 117 $\Omega^{-1} \cdot cm^2 \cdot mol^{-1}$. The BF_4^- salt was prepared analogously as an acetone or CH_2Cl_2 solvate (98%). Found: C, 60.8; H, 4.5. Calc. for the empirical formula: C, 60.12; H, 4.61%. IR (Nujol mull): ν(CO) (acetone of solvation), 1709 cm^{-1} (vs). ^1H NMR [in $(CD_3)_2SO$]: δ_{CH_2} (CH_2Cl_2 of solvation), 5.75 ppm (s). Conductance (acetone): Λ_M 144 $\Omega^{-1} \cdot cm^2 \cdot mol^{-1}$. The $^{31}P\{^1H\}$ NMR spectra ($CDCl_3$) show the AB_2 spin system at 32.52 (triplet, 1P) and 29.76 (doublet, 2P) ppm relative to 85% H_3PO_4 at 0.00: $J_{P,P}$ = 15.65 Hz.

Tetrakis(dimethylphenylphosphine)palladium(II) tetrafluoroborate, $[Pd(PMe_2Ph)_4][BF_4]_2$

$[Pd(PPh_3)_4][BF_4]_2 \cdot (CH_3)_2CO$ (2.0 g) was suspended in 30 cm^3 of acetone, and an acetone solution of PMe_2Ph (1.1 g) was added to the solution. The yellow mixture gradually dissolved to a pale orange homogeneous solution. The solvent was then removed under reduced pressure, giving an orange oil, which was washed with diethyl ether several times to remove liberated PPh_3 and residual PMe_2Ph. The oil was crystallized from methanol–diethyl ether to give pale yellow crystals (0.8 g, 65%). Found: C, 46.6; H, 5.1; P, 14.1. Calc. for the empirical formula: C, 46.16; H, 5.33; P, 14.88%. Conductance (acetone): Λ_M 224 $\Omega^{-1} \cdot cm^2 \cdot mol^{-1}$. $^{31}P\{^1H\}$ NMR [$(CD_3)_2CO$]: δ_P −5.96 ppm (s).

Tris(dimethylphenylphosphine)(1,10 - phenanthroline) palladium(II) tetrafluoroborate, $[Pd(PMe_2Ph_3(phen)][BF_4]_2$

$[Pd(PMe_2Ph)_4][BF_4]_2$ (0.27 g) was dissolved in acetone (25 cm^3) (partial suspension), and 0.14 g of phen monohydrate (phen · H_2O) was added to the suspension. The yellow mixture gradually dissolved, turning pale yellow, and a small amount of white solid precipitated. After 30 min, the solution was filtered and the solvent was removed under reduced pressure to give a yellow oil. The oil product was washed with 25 ml of diethyl ether to remove liberated PMe_2Ph and dissolved into 5 cm^3 of methanol. The solution was then dropped into 100 cm^3 of *n*-hexane with vigorous stirring, when a yellow crystalline solid was formed. The product was recrystallized from acetone–ethanol (0.13 g, 82%). Found: C, 49.2; H, 4.8; N, 3.1. Calc. for the empirical formula: C, 49.43; H, 4.73; N, 3.20%.

The corresponding 2,9-Me_2-phen complex, $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-phen})][BF_4]_2$ was prepared analogously (54%). Found: C, 50.0; H, 5.2; N, 3.1. Calc. for the empirical formula: C, 50.56; H, 5.03; N, 3.10%.

Chlorobis(2,9 - dimethyl - 1,10 - phenanthroline)palladium(II) hexafluorophosphate, $[PdCl(2,9\text{-}Me_2Ph)_2]PF_6$

$[PdCl(PPh_3)_3]PF_6 \cdot (CH_3)_2CO$ (0.3 g) was dissolved in 3-pentanone (30 cm^3), and 0.085 g of 2,9-Me_2-phen · $\frac{1}{2}H_2O$ was added to the solution. The yellow mixture slowly became homogeneous and turned orange, giving a small amount of yellow solid. The solution was then filtered, and the filtrate was warmed at 100°C for a few minutes to give brown crystals in insoluble in 3-pentanone (0.06 g, 26%). Found: C, 48.6; H, 3.8; N, 7.5. Calc. for $[PdCl(2,9\text{-}Me_2\text{-phen})_2]PF_6 \cdot \frac{1}{3}(C_2H_5)_2CO$: C, 48.67; H, 3.76; N, 7.65%. IR (Nujol mull): ν(CO) (3-pentanone of solvation), 1710 cm^{-1} (s). ^1H NMR [in $(CD_3)_2SO$]: δ_{Me} (3-pentanone) 0.93 ppm (t); δ_{CH_2} (3-pentanone) 2.40 ppm (q); $J_{H,H'}$ = 7 Hz.

Bis(1,10 - phenanthroline)(triphenylphosphine)palladium(II) tetrafluoroborate, $[Pd(PPh_3)(phen)_2][BF_4]_2 \cdot (CH_3)_2CO$

The preparation of this complex and the PF_6^- salt have been described previously.[14]

Chlorobis(triphenylphosphine)(1,10 - phenantholine) palladium(II) tetrafluoroborate, $[PdCl(PPh_3)_2(phen)]BF_4 \cdot (CH_3)_2CO$

$[PdCl(PPh_3)_3]BF_4 \cdot (CH_3)_2CO$ (0.2 g) was suspended in acetone (20 cm^3), and 0.05 g of $phen \cdot H_2O$ was added to the mixture. The suspension gradually dissolved, turning orange. After 30 min, the solution was reduced in volume to about 5 cm^3 under reduced pressure, and addition of diethylether to the solution gave orange crystals of an acetone solvate (91%). Found: C, 61.5; H, 4.2; H, 2.6; Cl, 3.6. Calc. for the empirical formula: C, 61.77; H, 4.47; N, 2.82; Cl, 3.58%. IR (Nujol mull): ν(CO) (acetone of solvation), 1706 cm^{-1} (s). The PF_6^- salt was prepared analogously as orange crystals (96%). Found: C, 58.4; H, 3.8; N, 2.7; Cl, 3.3. Calc. for the empirical formula: C, 58.13; H, 3.86; N, 2.82; Cl, 3.58%.

Chloro(triphenylphosphine)(trimethylphosphite)(1,10-phenanthroline)palladium(II) tetrafluoroborate, $[PdCl(P(OMe)_3)(PPh_3)(phen)]BF_4$

$[PdCl(PPh_3)_2(phen)]BF_4 \cdot (CH_3)_2CO$ (0.19 g) was dissolved in 20 cm^3 of acetone, and 0.036 g of $P(OMe)_3$ was added to the solution. The orange solution turned pale yellow in a few minutes. The solution was then reduced in volume to 10 cm^3 under reduced pressure, and addition of diethyl ether to the solution gave yellow crystals (0.13 g, 84%). Found: C, 49.6; H, 3.9; N, 3.7. Calc. for the empirical formula: C, 49.84; H, 4.06; N, 3.52%.

Chlorobis(trimethylphosphite)(1,10 - phenanthroline) palladium(II) tetrafluoroborate, $[PdCl(P(OMe)_3)_2(phen)]BF_4$

$[PdCl(PPh_3)_2(phen)]BF_4 \cdot (CH_3)_2CO$ was suspended in 20 cm^3 of acetone containing 0.06 g of PPh_3, and to the solution 0.1 g of $P(OMe)_3$ was added with vigorous stirring, when the orange solution turned off white via pale yellow. The solution was then reduced in volume to about 5 cm^3 under reduced pressure. Addition of diethyl ether to the solution gave a white solid. Recrystallization from ethanol and ether gave off white crystals (0.8 g, 38%). Found: C, 33.6; H, 3.9; N, 4.5. Calc. for the empirical formula: C, 32.90; H, 3.99; N, 4.26%.

Chloro(1,10 - phenanthroline)(triphenylphosphine) palladium(II) hexafluorophosphate, $[PdCl(PPh_3)(phen)]PF_6$

0.3 g of $[PdCl(PPh_3)_3]PF_6 \cdot (CH_3)_2$ CO was suspended in 20 cm^3 of 3-pentanone and an acetone solution of $phen \cdot H_2O$ (0.08 g) was added to the suspension. The mixture slowly dissolved and a yellow solid gradually precipitated. The yellow powder obtained was then filtered and washed with acetone and diethyl ether (0.13 g, 66%). Found: C, 49.1; H, 3.3; N, 3.8. Calc. for the empirical formula: C, 49.40; H, 3.18; N, 3.84%.

Chlorobis(triphenylphosphine)(2,9 - dimethyl - 1,10 - phenanthroline)palladium(II) tetrafluoroborate, $[PdCl(PPh_3)_2(2,9\text{-}Me_2\text{-}phen)]BF_4 \cdot (CH_3)_2CO$

This complex was prepared by an analogous procedure to the corresponding 1,10-phen complex. Recrystallization from warm ethanol–acetone gave an orange crystal of an acetone solvate. Found: C, 62.5; H, 4.8; N, 2.8. Calc. for the empirical formula: C, 62.43; H, 4.75; N, 2.75%. IR (Nujol mol): ν(CO) (acetone of solvation), 1713 cm^{-1} (s). Yield 94%. The PF_6^- salt was prepared analogously (64%). Found: C, 59.3; H, 4.8; N, 2.4. Calc. for the empirical formula: C, 59.06; H, 4.49; N, 2.60%. IR (acetone of solvation): ν(CO) (acetone of solvation), 1709 cm^{-1}.

Tris(triphenylphosphine)palladium(II) tetrafluoroborate, $[Pd(PPh_3)_3][BF_4]_2$

$[PdCl(PPh_3)_3][BF_4] \cdot (CH_3)_2CO$ was dissolved in 30 cm^3 of CH_2Cl_2, and an acetone solution of $AgBF_4$ (0.14 g) was added to the solution. The yellow solution on addition of $AgBF_4$ turned canary yellow and AgCl precipitated. The solution was filtered after an hour and the filtrate was reduced in volume to about 10 cm^3 under reduced pressure. Addition of diethyl ether to the solution gave a canary yellow powder, which was recrystallized from CH_2Cl_2–diethyl ether giving canary yellow crystals (0.4 g, 56%). Found: C, 55.9; H, 4.0. Calc. for $[Pd(PPh_3)_3][BF_4]_2 \cdot \frac{3}{2}(CH_2Cl_2)$: C, 55.81; H, 4.05%. Conductance (acetone): Λ_M 234 $\Omega^{-1} \cdot cm^2 \cdot mol^{-1}$. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 38.94 (1P) and 37.86 (2P) ppm. The structure of this complex is uncertain, but may resemble $[Rh(PPh_3)_3]BF_4$.

Tris(diethylphenylphosphine)palladium(II) tetrafluoroborate, $[Pd(PEt_2Ph)_3][BF_4]_2$

$PdCl_2(PEt_2Ph)_2$ (2 g) was suspended in 50 cm^3 of acetone, and 0.66 g of PEt_2Ph was added to the suspension as the yellow mixture dissolved to the deep orange of $PdCl_2(PEt_2Ph)_3$.[8] An acetone solution of $AgBF_4$ (1.57 g) was then added to the solution, when AgCl precipitated. After 10 min, a white precipitate AgCl was filtered, and the solvent was removed under reduced pressure to give a dark

yellow oil. The oil was dissolved in methanol (15 cm^3), and the solution was dropped into diethyl ether (150 cm^3) with vigorous stirring, giving a yellow solid. The product was recrystallized from CH_2Cl_2–diethyl ether to give deep yellow crystals (1.51 g, 43%). Found: C, 41.8; H, 5.4; P, 10.5. Calc. for $[Pd(PEt_2Ph)_3][BF_4]_2 \cdot \frac{3}{2}(CH_2Cl_2)$: C, 41.75; H, 5.34; P, 10.26%. Conductance (acetone): Λ_M 186 $\Omega^{-1} \cdot cm^2 \cdot mol^{-1}$. $^{31}P\{^1H\}$ NMR [$(CD_3)_2CO$)] of this complex shows three resonances at 36.30 (1P, broad singlet), 32.41 (1P, doublet) and 27.78 (1P, doublet) ppm with a formal $J_{P,P}$ of the latter two of 13.7 Hz ^{19}F NMR [$(CD_3)_2CO$]: δ −149.4 ppm (relative to $CFCl_3$ at 0.00). Further details about this complex are now under investigation.

Bis(diethylphenylphosphine)(1,10 - phenanthroline) palladium(II) tetrafluoroborate, $[Pd(PEt_2Ph)_2(phen)][BF_4]_2$

The deep yellow solution of

$$[Pd(PEt_2Ph)_3][BF_4]_2$$

[amount of the precursor, $PdCl_2(PEt_2Ph)_2$, 1.58 g], in acetone was bubbled through with CO for 30 min, while it turned orange. The solution was then added to phen·H_2O (0.62 g) to give grey crystals of $[Pd(phen)_2][BF_4]_2$. The solution was filtered and the solvent of the filtrate was removed under reduced pressure to give a deep green oil. The oil product was dissolved in ethanol, partially giving black Pd metal. After separation of the solid, addition of ethyl ether to the solution gave deep yellow prisms. Found: C, 48.4; H, 5.1; N, 3.3. Calc. for the empirical formula: C, 48.49; H, 4.83; N, 3.53%. Conductivity (acetone): Λ_M 294 $\Omega^{-1} \cdot cm^2 \cdot mol^{-1}$. $^{31}P\{^1H\}$ NMR [$(CD_3)_2CO$]: δ 33.00 ppm (s).

RESULTS AND DISCUSSION

$^{31}P\{^1H\}$ and ^1H NMR and conductivity data of $[Pd(PMe_2Ph)_3(2,9\text{-}R_2\text{-phen})][BF_4]_2$ (R = H or Me) are shown in Fig. 1 and Table 1. The ^{31}P NMR spectrum of the phen complex explicitly shows the typical AB_2 spin system: the ^{31}P doublet appears at a higher field than the ^{31}P triplet with $J_{P,P}$ = 22.79 Hz. In contrast, for the 2,9-Me_2-phen complex the relative positions are reversed and its ^{31}P–^{31}P coupling constant (20.34 Hz) is close to that of the phen complex.

In the five-coordinate Pd(II) and Pt(II) complexes so far studied, $PdX_2(PMe_3)_3$ (X = Br or I),[10] $[M(P(OMe)_3)_5]^{2+}$ (M = Pd or Pt)[1] and PtX_2L_3 (X = Cl, Br and I; L = 1-R-3,4-dimethylphosphole),[11]

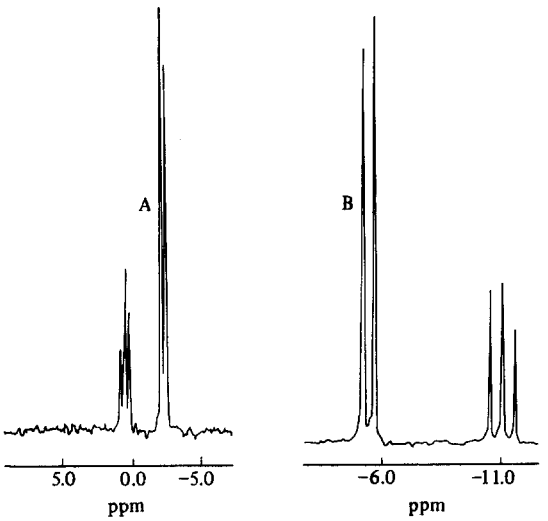

Fig. 1. ^{31}P NMR of: (A) $[Pd(PMe_2Ph)_3(phen)][BF_4]_2$, and (B) $[Pd[PMe_2Ph)_3(2,9\text{-}Me_2\text{-phen})][BF_4]_2$ in $(CD_3)_2CO$.

axial phosphines or phosphites always appear at a higher field than equatorial ones, whereas, in the corresponding Ni(II) complexes, $NiX_2(PMe_3)_3$ (X = CN or Br)[2] and $[Ni\{P(OMe)_3\}_5]^{2+}$,[1] the relative shifts are reversed. On the other hand, in the tetragonal pyramidal $PdCl_2(PMe_3)_3$[10] with one chloride atom in the axial position, the ^{31}P doublet appears at a higher field than the ^{31}P triplet with a larger $J_{P,P}$ than those of the corresponding bromide and iodide complexes.

These estimations for the previous works may be referred to the present case. The NMR spectrum of $[Pd(PMe_2Ph)_3(2,9\text{-}R_2\text{-phen})][BF_4]_2$ (R = H or Me) accordingly fits two idealized structures with one trigonal bipyramid (**A** or **C**) and one tetragonal pyramid (**B** or **D**) as shown in Fig. 2.

^1H NMR of $[Pd(PMe_2Ph)_3(2,9\text{-}Me_2\text{-phen})][BF_4]_2$ shows an equivalency of the two nitrogen atoms of the *N*-heterocyclic ligand, which corresponds to either fluxional motion of the ligand or a symmetrical environment around its halves. In addition, relatively large ^1H NMR downfield shifts for 2,9- and 3,8-protons of the *N*-heterocyclic ligand upon coordination have been observed: 0.84 and 0.45 ppm for the phen complex and 0.95 and 0.47 ppm for the 2,9-Me_2-phen complex, respectively. The coupling pattern of 3,4(7,8)-protons in the 2,9-Me_2-phen complex turns out to be an AB quartet $[J_{A,B}/(\delta_A - \delta_B) = 0.2]$. These downfield shifts for the corresponding protons of the *N*-heterocyclic ligand upon coordination are due to paramagnetic anisotropy of the metal.[17] It should also be noticed that in a seldom ion pair complex, $[Pd(PEt_2Ph)_2(phen)][BF_4]_2$, such a coordination shift of the phen has not been obtained but, rather, a higher field shift, particularly for its 2,9-protons.

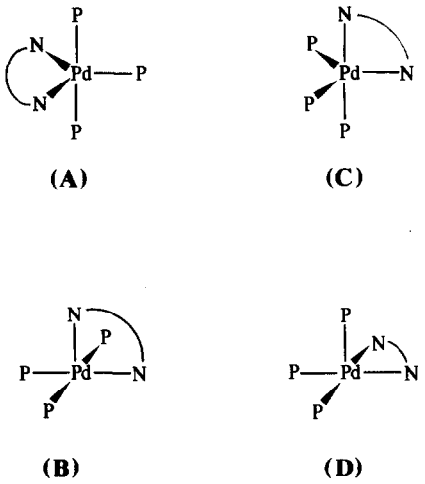

Fig. 2. Possible structures of $[Pd(PMe_2Ph)_3(2,9\text{-}R_2\text{-phen})][BF_4]_2$.

Some physical properties of $[PdCl(PPh_3)_2(2,9\text{-}R_2\text{-phen})]X$ (R = H or Me; X = BF_4 or PF_6) are given in Table 2.

The conductivity data of the complexes evidently indicate that dissociation of Cl or association of the anion does not occur in acetone solution.

^{31}P NMR spectral data of the complexes show a single resonance, which is consistent with an equivalency of the two PPh_3 ligands. ^1H NMR spectra of them also show an equivalency of the two nitrogen atoms of the *N*-heterocyclic ligand. These NMR data indicate either symmetrical environments around both the phosphines and the halves of the *N*-heterocyclic ligand or a rapid dynamic motion which may average the respective nuclei equivalently. Low-temperature NMR data could not be obtained on account of the insufficient solubility of the complexes. Any fluxional motion of $[PdCl(PPh_3)_2(2,9\text{-}Me_2\text{-phen})]X$ (X = BF_4 or PF_6), however it might occur, will be expected to be considerably restricted because of the steric crowdedness of the ligand compared to the corresponding phen complex.

The visible spectrum of $[PdCl(PPh_3)_2(phen)]PF_6$ is shown in Fig. 3, together with those of square-planar complexes, $[PdCl(PPh_3)(phen)]PF_6$ and $[Pd(PEt_2Ph)_2(phen)][BF_4]_2$. The spectrum of $[PdCl(PPh_3)_2(phen)]PF_6$ (quite analogous to that of the BF_4^- salt) with two electronic transitions at 355 and 338 nm unexpectedly shows a marked resemblance to those of the square-planar complexes, the absorptions of which may be concerned with charge-transfer bands (M → L or L → M)[8] possibly combined with a $d \rightarrow d$ transition.[18] Any characteristic absorption bands previously found for five-coordinate Pt(II) and Pd(II)[19] complexes have not been observed in the longer-wavelength region for the present case, and the $d \rightarrow d$ transition has not been resolved.

Direct evidence of the solution structure of $[PdCl(PPh_3)_2(phen)]PF_6$ has been minor. However, the electronic spectral data of the complex seem indicative that the geometry in solution is likely close to a square-planar conformation in which one nitrogen atom of the phen might be approaching to the coordination sphere from the fifth or sixth apical site of the coordination plane. The fluxional motion of the complex is accordingly explained as a rapid oscillation of the phen as observed in Pd(dmp)(2,9-Me_2-phen)(NO_3) (dmp = *N*,*N*-dimethylbenzylamine).[20]

On the other hand, the visible spectrum of $[PdCl(PPh_3)_2(2,9\text{-}Me_2\text{-phen})]PF_6$ is, as expected, different from that of the corresponding phen complex and it shows a broad and intensive electronic transition at 360 nm which is most probably caused by five coordination.

$[PdCl(PPh_3)_2(phen)]PF_6$ did not convert to $[PdCl(PPh_3)(phen)]PF_6$ but was recovered whether it had been warmed in acetone or in ethanol solution. The reaction of $[PdCl(PPh_3)_2(phen)]BF_4$ with $P(OMe)_3$ proceeds via a successive displacement of PPh_3 by $P(OMe)_3$ to give

$$[PdCl\{P(OMe)_3\}(PPh_3)(phen)]BF_4$$

and

$$[PdCl\{P(OMe)_3\}_2(phen)]BF_4.$$

The ^1H NMR spectra of both phosphite complexes similarly show an equivalency between the two nitrogen atoms of the phen. The ^1H NMR of the bis-phosphite complex shows two doublets due to Me-protons of the $P(OMe)_3$ ligand, which is consistent with two mutually *cis*-$P(OMe)_3$. The ^1H NMR coordination shifts for 2,9-protons of the phen have been obtained in these cases; 0.60 ppm for the bis-phosphite complex and 0.53 ppm for the mono-phosphite complex.

The visible spectral data for the phosphite complexes are shown in Table 3, together with the other complexes that I have obtained. The spectra of the phosphite complexes, analogously to the bis-phosphine complex, resemble considerably those of the square-planar complexes. Consequently, the solution structure of the bis-phosphite complex, in analogy with the bis-phosphine complex, is likely tetragonal pyramid, possibly approaching a square-planar conformation in which the two $P(OMe)_3$ are *cis*. The solution structure of the mono-phosphite complex (pale yellow) may be analogous to the bis-phosphite complex, while an enantiomer of this complex is uncertain.

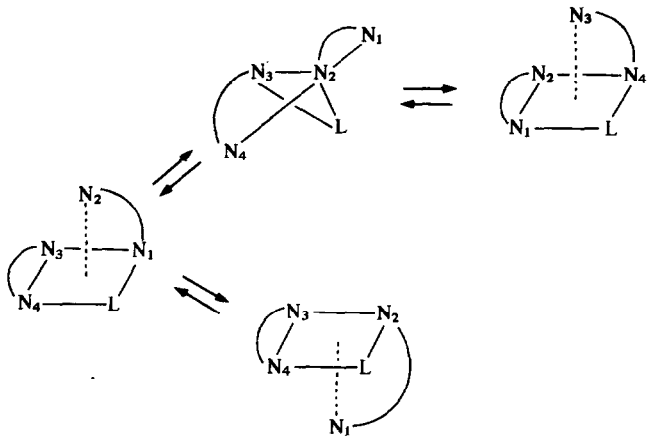
$L_1 = L_3 = PPh_3$; $L_2 = Cl$
$L_2 = L_3 = P(OMe)_3$; $L_1 = Cl$
$L_2 = PPh_3$; $L_3 = P(OMe)_3$; $L_1 = Cl$

The ^1H NMR of $[Pd(PPh_3)(phen)_2][PF_6]_2$ and $[PdCl(2,9\text{-}Me_2\text{-}phen)_2]PF_6$ show that all four nitrogen atoms of the two *N*-heterocyclic ligands are equivalent, which corresponds to fluxional motion.

For $[Pd(PPh_3)(phen)_2][PF_6]_2$, there are ^1H NMR signals broadening below $-50°C$ and even at $-100°C$ no sharp limiting spectrum could be obtained, while, on addition of free phen to $[Pd(PPh_3)(phen)_2][PF_6]_2$ at room temperature, signal broadening is observed with a pattern similar to that obtained at lower temperatures and no separate signals could be obtained. These ^1H NMR spectral data of $[Pd(PPh_3)(phen)_2][PF_6]_2$ may suggest that inter- or intramolecular exchange of phen readily occurs.

An intramolecular ligand rearrangement system of this type of five-coordinate complexes has so far been proposed in which the fluxional motion of $[Pt(CN)(phen)_2]NO_3$ has been explained by pseudorotation with a trigonal-bipyramid transition state, while that of



$[M(hfac)_2\{P(o\text{-tolyl})_3\}]$ (M = Pd or Pt; hfac = 1,1,1,5,5,5-hexafluoroacetylacetone)[21]

has been best rationalized by two rapid equilibria of twist motion and concurrent oscillation. For both cases, the mechanism of the fluxional motions has noticeably been proposed not to be dissociative, since the ^{195}Pt satellite has been observed.

The fluxional motion of the present complexes is sufficiently explained by two synchronous rearrangement systems as proposed for $[Pd(hfac)_2\{P(o\text{-tolyl})_3\}]$: one is a rapid oscillation of the apical phen which may result to average its two nitrogen atoms and the other is a twist motion of the square pyramid which may average the environments between the two *N*-heterocyclic ligands equivalently as shown in Scheme 1. The visible spectral data of $[Pd(PPh_3)(phen)_2][PF_6]_2$ and $[PdCl(2,9\text{-}Me_2\text{-}phen)_2]PF_6$ similarly show three absorption maxima, two of which are at 338–360 nm, with a resemblance to those of square-planar complexes, and the latter at 400–430 nm is now comparable with the characteristic absorptions of $PdX_2(PMe_2Ph)_3$ (X = Cl or Br)[8] at 410–444 nm. It is roughly indicated from these spectral data that the solution structure of $[PdY(2,9\text{-}R_2\text{-}phen)_2][PF_6]_{1\text{ or }2}$ (Y = PPh_3 or Cl; R = H or Me) is tetragonal pyramid with one nitrogen atom of the phen possibly at the

X-RAY PHOTOELECTRON SPECTROSCOPIC AND MAGNETIC SUSCEPTIBILITY STUDY OF *CIS*-BIS ETHYLENEDIAMINOALKYLAMINO NITRITO COBALT(III) NITRATE

S. SRIVASTAVA
Coordination Group, C.S.M.C.R.I., Bhavnagar-364002, India

(*Received* 6 *March* 1985; *accepted after revision* 22 *May* 1985)

Abstract—X-ray photoelectron spectra of *cis*-$[Co(en)_2(RNH_2)(NO_2)](NO_3)_2$ complexes, where R = CH_2CHCH_2, CH_3, *n*-C_2H_5, *n*-C_4H_9, *n*-C_5H_{11} and C_6H_{13} have been recorded on a VG scientific ESCA-3MK II electron spectrometer to study the relative covalent bonding between the metal ion and the alkylamine group (RNH_2) and to study the degree of π-back bonding from metal to ligand nitrite. The magnetic susceptibility of all these complexes was also measured by the Faraday method at room temperature.

Since the advent of electron spectroscopy for chemical analysis (ESCA)[1,2] there has been considerable interest in studying transition-metal complexes using this technique.

Jolly *et al.*[3] studied the *trans*-$[Co(en)_2(NO_2)_2]NO_3$ complex and reported three peaks corresponding to the three different nitrogen environments. The complexes chosen for the present study contain a nitrogen atom in four different electronic environments. Such systems are being reported for first time. Moreover, the basicity of the substituent amine is likely to affect the energies of the nitrogen–metal bonds and also π-back bonding from the metal to the nitrite ligand. The present communication covers the above-mentioned cases.

EXPERIMENTAL

Preparation of complexes

Trans - dichloro - *bis* - (ethylenediamine)cobalt(III) chloride, *trans*-$[Co(en)_2Cl_2]Cl$, was prepared by the reported procedure.[4] It was converted to *cis*-chloro(alkylamine)-*bis*-(ethylenediamine)cobalt(III) chloride, *cis*-$[Co(en)_2RNH_2Cl]Cl$ and finally to the nitrate, *cis*-$[Co(en)_2RNH_2Cl]NO_3$, by the following general procedure.[5]

11.5 g of *trans*-$[Co(en)_2Cl_2]Cl$ in 5 cm^3 water was triturated with an equimolar amount of alkylamine. Ethanol was added to the deep red solution to precipitate the complex. The precipitate was dissolved in a small amount of water, cooled to 0°C and a few drops of conc. HCl was added. The product was washed with ethanol and ether and crystallised twice from a very dilute aqueous solution of HCl. The conversion to nitrate was carried out by dissolving the chloride complex in a small amount of water, and adding conc. HNO_3. On cooling to 0°C, fine red crystals of the nitrate separated out, which were washed with methanol and ether, and dried.

It was then converted to *cis*-nitro(alkylamine)-*bis*-(ethylenediamine)nitrate:

$$cis\text{-}[Co(en)_2RNH_2NO_2](NO_3)_2$$

by the following procedure:

7.4 g of the above product was dissolved in water and 1.4 g $NaNO_2$ was added. On trituration for 15 min an orange–red product was formed. It was filtered, washed with methanol and ether, and was recrystallised twice from water (50°C) containing a few drops of HNO_3. The estimation of cobalt and the nitro group conformed to the formula $[Co(en)_2(RNH_2)(NO_2)](NO_3)_2$. All the compounds in this show fairly similar physical and spectral characteristics.

The red complexes show two absorption bands at ~370 and ~445 nm with molar absorptivities of ~330 and 120 l mol^{-1} cm^{-1} respectively.

Recording of spectra

The X-ray photoelectron spectra (XPS) were recorded on a VG Scientific ESCA-3MK II electron

spectrometer. The Mg-K_α X-ray line (1253.6 eV) was used for photoelectron excitation.

The Cu($2p_{3/2}$) (Eb 932.8 ± 0.2) and Au($4f_{7/2}$) (Eb 83.3 ± 0.1) lines were used to calibrate the instrument and Ag($3d_{5/2}$) (Eb 368.2) was used for cross-checking.[6]

All spectra were recorded using the same spectrometer parameters of 50 eV pass energy and 4 mm slit width. The reduced full width at half maximum for Au($4f_{7/2}$) (Eb 84.0 eV) level under these conditions was 1.2 eV.

The powdered sample was mixed with high-purity silver powder to reduce the charging effect. A thin layer of such a sample was pressed on a gold metal gauze which was welded to a nickel sample holder. The Ag($3d_{5/2}$) level (Eb 368.2 eV) obtained from this sample was sharp and did not show any observable shift. Thus the charging of the samples, if at all present, was negligible.[7] The spectra were recorded in triplicate in the region of interest. In most cases the binding energies were reproducible within ± 0.1 eV. The usual least-squares fitting procedure of determining peak position, line widths and area was used.

Measurement of magnetic susceptibility

Magnetic susceptibility was measured by the Faraday method using a Cahn Magnetic susceptibility system. $Hg[Co(CNS)_4]$ was used as a standard for calibration.[8]

RESULTS AND DISCUSSION

The measured $Co2p_{1/2}$ and $Co2p_{1/2}$ binding energies in *cis*-$[Co(en)_2(RNH_2)(NO_2)](NO_3)_2$ are listed in Table 1 (Fig. 1). It may be seen that $Co2p_{1/2,3/2}$ binding energies are maximum for C_1 and minimum for C_6 when R is an alkyl group (CH_2CHCH_2 does not fall in this sequence). Using Siegbahn *et al.*s generalization[1,2] one may therefore conclude that the maximum effective positive charge on the cobalt ion is for C_1 and minimum in the case of C_6. The decreasing order of effective positive charge in these complexes is $C_1 > C_2 > C_4 > C_5 > C_6$. It is clear that the electron-donating ability of the RNH_2 group increases with increasing number of carbon atoms in "R". It is also clear that the presence of a double bond in R(CH_2CHCH_2) decreases its electron-donating capability. These XPS data may also be taken to suggest that bond between cobalt ion and RNH_2 is more covalent in C_6 and least in C_1. The decreasing order of covalent character in these complexes is $C_1 < C_2 < C_4 < C_5 < C_6$. In the case of $CH_2CHCH_2NH_2$ the presence of a double bond makes it even lower than C_1.

[a] Full width at half maximum is given in parentheses.

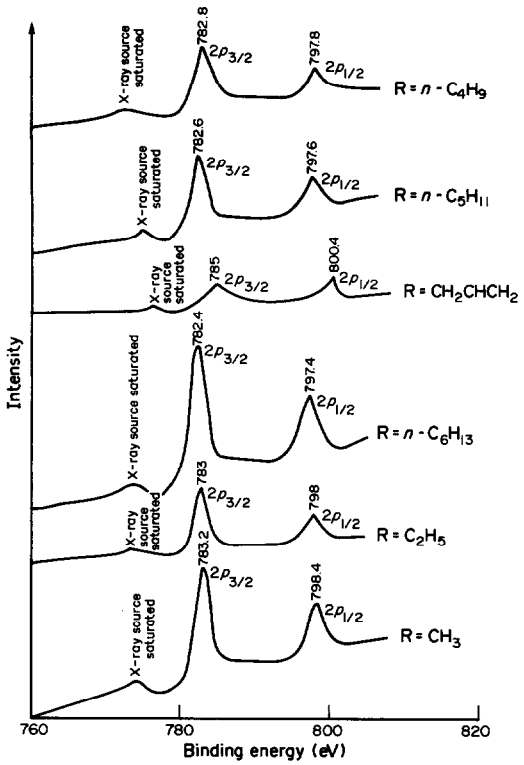

Fig. 1. $Co2p_{3/2}$ and $Co2p_{1/2}$ photoelectron peaks in *cis*-$[Co(en)_2RNH_2NO_2](NO_3)_2$.

Our magnetic susceptibility measurements (Table 1) show that all these complexes are diamagnetic.

Jolly *et al.*[3] found three N1*s* peaks for three nitrogen environments which are placed in different chemical environments in *trans*-$[Co(en)_2(NO_2)_2]NO_3$ complex at 401, 404 and 406.5 eV for ethylenediamine, nitrite and the nitro group respectively. In our study of N1*s* spectra of *cis*-$[Co(en)_2(RNH_2)(NO_2)](NO_3)_2$ complexes the nitrogen of ethylenediamine and the RNH_2 group coincide and give only three peaks with intensity ratio 5 : 1 : 2 (as shown in Fig. 2 for a few complexes). In the study of the N1*s* of the nitrite group, we observed the maximum binding energy value for C_1 and the minimum value for C_6 (see Table 1). From these XPS data we can conclude that π-back bonding from a filled metal ion orbital to a vacant antibonding ligand (NO_2) orbital is least for C_1 and increases towards C_6. The increasing order of π-back bonding in these complexes is $C_1 < C_2 \leqslant C_4 < C_5 < C_6$. When R is CH_2CHCH_2 the back bonding is minimal even lower than in the case of C_1. Thus one may conclude that, as the electron transfer from RNH_2 to the metal ion increases, the electron transfer from the metal ion to nitrogen (NO_2) through π-back bonding also increases.

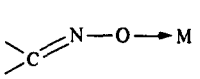
TRANSITION-METAL CHEMISTRY OF OXIME-CONTAINING LIGANDS—XXVII. FIVE- AND SIX-COORDINATE COMPLEXES OF IRON(II) AND IRON(III) WITH 2,6-DIACETYLPYRIDINE DIOXIME

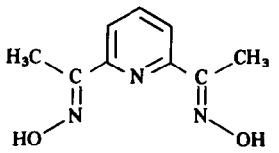
MADAN MOHAN* and MUNESH KUMAR
Department of Chemistry, N.R.E.C. College, Khurja-203 131 (U.P.), India



(*Received* 20 *June* 1984; *accepted after revision* 22 *May* 1985)

Abstract—Iron(II) and iron(III) complexes of 2,6-diacetylpyridine dioxime (H_2dapd) have been prepared and their electronic and structural properties investigated. The $[Fe(H_2dapd)X_2]$ (X = Cl, Br or I) are essentially monomeric five-coordinate complexes, whereas the $[Fe(H_2dapd)X_2]$ (X = NCS or NCSe) are polymeric, anion-bridged, six-coordinate complexes. The $[Fe(H_2dapd)_2](ClO_4)_2$ is a high-spin, distorted six-coordinate complex. The $[Fe_2(Hdapd)_2X_4]$ (Hdapd = anion of H_2dapd, X = Cl, Br, I, NCS or NCSe) are dimeric, high-spin, anion bridged, five-coordinate complexes, whereas $[Fe_2(Hdapd)_2O(NO_3)_2]$ is a dimeric, low-spin, oxygen-bridged five-coordinate complex. Intermolecular antiferromagnetic exchange interactions are present in these binuclear iron(III) complexes, where the exchange parameter varies from -9.7 to -7.0 cm^{-1} in $[Fe_2(Hdapd)_2X_4]$ complexes and is -102.0 cm^{-1} for the $[Fe_2(Hdapd)_2O(NO_3)_2]$ complex. The complexes exhibit asymmetric quadrupole-split doublets in their ^{57}Fe Mössbauer spectra. The asymmetries are found to be temperature-dependent with a relatively symmetric doublet seen at low temperatures.

Oximes are well known for their high coordinating abilities and versatile behaviour,[1] but much remains to be learned about the types of structures that are formed as well as the factors that dictate structure. In general, the oxime function coordinates to metal ions in four ways:



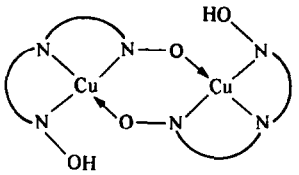
1 2 3

4

Coordination modes 1 and 3 are quite common among metal complexes but it should be noted that the oxime function is a poor donor unless it is part of a chelate ring.

2,6-Diacetylpyridine dioxime, H_2dapd (5), which possesses structural features in common with both the 2,2′,2″-terpyridyl (terpy) and the dimethylglyoxime ligand, is a particularly interesting chelating oxime ligand. H_2dapd was first investigated by Hanania *et al.*[2] who studied its Fe(II) complex in solution. They observed[2] that the pK_a for

H_2dapd



5

the ligand dropped markedly upon coordination, an effect that was attributed to resonance stabilization of anionic oxime conjugate base (=N—Ō). Following Hartkamp's report[3] that aqueous Ni(II) solutions of H_2dapd are oxidised by air, Baucum and Drago[4] isolated several complexes, including $[Ni(H_2dapd)_2](ClO_4)_2$, $Na_2[Ni(dapd)_2]$ and the oxidised complex, $[Ni(dapd)_2]$, believed to contain Ni(IV). It is argued[4] that the higher oxidation state of

* Author to whom correspondence should be addressed.

nickel is favoured by localized accumulation of negative charges on donor atoms and by the formation of strong metal–ligand σ-bonds. Subsequently Sproul and Stucky reported[5] the X-ray crystal structure of $[Ni(dapd)_2]$ and found that the ligand is a planar NNN donor chelating agent and that considerable strain is developed in the $dapd^{2-}$ moiety when it coordinates to nickel.

Recently Nicholson *et al.*[6] isolated the monomeric five-coordinate complex $[Cu(H_2dapd)Cl_2]$ which is remarkably acidic in aqueous solutions (the pK for proton dissociation being 2.8 ± 0.1 in H_2O at 25.1°C). The second proton is not removed by aqueous base. Deprotonation of $[Cu(H_2dapd)Cl_2]$ in alcoholic solution afforded the dimeric dication $[Cu(Hdapd)]_2^{2+}$, isolated as the chloride or tetrafluoroborate. In the dimer the copper centers are highly coupled and the fourth coordination position is occupied by an O^- donor derived from a deprotonated =N—OH group to give a bridged chromophore of type **6**.[7] The dimer structure is readily ruptured by coordinating solvents.

6

Because of these interesting properties, we have extended the previous work to several other metal ions. In this paper the synthesis and electronic and structural properties of Fe(II) and Fe(III) complexes with H_2dapd are reported.

EXPERIMENTAL

Materials

H_2dapd was prepared from 2,6-diacetylpyridine (Aldrich Chemical Co.) according to the method of Baucom and Drago.[4] The authenticity of the compound was established on the basis of elemental analysis (Table 1) and IR spectra. The anhydrous iron(II) halides, ferrous sulphate, potassium thiocyanate and selenocyanate, and other solvents were of reagent grade chemicals.

Dihalogeno - mono(2,6 - diacetylpyridine dioxime) iron(II), $[Fe(H_2dapd)X_2]$ (X = Cl, Br *or* I). A solution of ferrous halide (0.02 mol) in 50 cm^3 of anhydrous methanol was prepared and kept under an N_2 gas atmosphere. A solution of ligand (0.02 mol) in 50 cm^3 of anhydrous methanol was prepared by heating under reflux while bubbling a rapid stream of N_2 through the solution. The metal salt solution was then added very slowly under an N_2 gas atmosphere to the ligand solution. A red colour was developed immediately and a precipitate was formed within minutes. The mixture was allowed to stand for 30 min under N_2 and then heated to boil and filtered hot via suction through a sintered glass under N_2. The red crystalline solid was dried over P_4O_{10} *in vacuo*.

Bis(2,6-diacetylpyridine dioxime)iron(II) perchlorate, $[Fe(H_2dapd)_2](ClO_4)_2$. A hot solution of $FeSO_4 \cdot 7H_2O$ (0.02 mol) in 20 cm^3 of methanol was

[a] H_2dapd, 2,6-diacetylpyridine dioxime ($C_9H_{11}N_3O_2$); Hdapd, anion of 2,6-diacetylpyridine dioxime ($C_9H_{10}N_3O_2$).
[b] Anion.
[c] Se.

added dropwise with constant stirring to a boiled solution of 5 (0.045 mol) in 20 cm^3 of methanol. A deep red solution was formed. Aqueous saturated solution of sodium perchlorate was added and the pH of the solution mixture was adjusted to *ca* 7.0 by adding a few drops of sodium hydroxide. The solution mixture was then heated under reflux for about 1 h. On cooling a dark red crystalline solid was formed which was filtered, washed with water, methanol and diethylether and dried over P_4O_{10} *in vacuo*.

Dihalogeno-di-μ-halogeno-di-hydrogen bis(2,6-diacetylpuridine dioxime)diiron(III),

$$[Fe_2(Hdapd)_2X_4] \ (X = Cl, Br \text{ or } I).$$

A solution of $FeSO_4 \cdot 7H_2O$ (0.01 mol) in 25 cm^3 of water was prepared by gently heating and added to a solution of **5** (0.015 mol) in 25 cm^3 of 1 : 1 acetone–18 M aqueous NH_3. To this solution, an excess of $(NH_4)_2S_2O_8$ in a minimum amount of water was added and the solution was mixed thoroughly until all traces of the red colour had disappeared leaving a blue–green solution. The solution was cooled in an ice-bath and 8–10 cm^3 of a saturated aqueous solution of NaCl, NaBr or NaI was added to effect precipitation. The dark red crystalline solid was filtered, washed with water and dried *in vacuo* over P_4O_{10}. The entire preparation was carried out in the dark to minimize the possibility of reduction.

Dithiocyanato-di-μ-thiocyanato and diseleno-cyanato-di-μ-selenocyanato-hydrogen bis(2,6-diacetyl-pyridine dioxime)diiron(III),

$$[Fe_2(Hdapd)_2X_4] \ (X = NCS \text{ or } NCSe).$$

A suspension of $[Fe_2(Hdapd)_2Cl_4]$ (0.01 mol) in 25 cm^3 of methanol was refluxed with an excess of solid KSCN or KSeCN (0.025 mol) for about 1 h. The dark red crystalline solid formed was filtered, washed with methanol and diethylether and dried *in vacuo* over P_4O_{10}.

Dinitrato-mono-μ-oxo-dihydrogen bis(2,6-diacetyl-pyridine dioxime)diiron(III),

$$[Fe_2(Hdapd)_2O(NO_3)_2].$$

The dark red crystalline solid,

$$[Fe_2(Hdapd)_2O(NO_3)_2],$$

was prepared by the similar procedure given above except that $NaNO_3$ was used to cause precipitation.

Analytical methods and physical measurements

Iron was determined[8] by EDTA titrimetry using Eriochrome Black T as an indicator after destroying the organic part first with aqua regia and then with conc. H_2SO_4. Halides were estimated by Volhard's method[9] and nitrate was determined[9] as its nitrone salt. The $[SCN]^-$ and $[SeCN]^-$ ions were estimated[9] as silver thiocyanate and selenium metal, respectively. Carbon, hydrogen and nitrogen were determined microanalytically at CDRI, Lucknow, India, and the data are given in Table 1.

Conductance measurements were made on a Toshniwal conductivity bridge type CL01/01. Magnetic measurements were made on a standard Gouy balance calibrated with $HgCo(NCS)_4$[10] from room temperature down to 78 K (Table 2). Diamagnetic corrections were applied using Pascal's constants.[11]

Diffuse reflectance spectra were recorded on a Cary-14 spectrophotometer equipped with a reflectance accessory, using MgO as the reference. The IR spectra of H_2dapd and its complexes were recorded in the 4000–200 cm^{-1} range on a Perkin–Elmer 337 spectrophotometer in CsI and far-IR spectra in the 400–100 cm^{-1} range were recorded on a Fourier spectrophotometer (FS-30).

^{57}Fe Mössbauer spectra were obtained on polycrystalline samples by using a constant-acceleration Mössbauer spectrometer which was calibrated with natural α-iron foil. The source was $^{57}Co(Pd)$ and was at room temperature for all experiments. The low-temperature results were measured in a vacuum cryostat with a sample holder which protected the sample from the cryostat vacuum. The Mössbauer results were determined by inspection with an accuracy of ± 0.01 mm s^{-1}.

RESULTS AND DISCUSSION

The interaction of iron(II) salts with H_2dapd in a 1 : 1 ratio in methanol afforded complexes of general formula $[Fe(H_2dapd)X_2]$ (X = Cl, Br, I, NCS or NCSe). Rapid isolation of these complexes was necessary to preserve the 1:1 (metal:ligand) stoichiometry. Longer reaction times, even with less than an equivalent amount of the ligand being present, result in the formation of $[Fe(H_2dapd)_2]X_2$ or products whose analyses suggested mixtures of 1 : 1 and 1 : 2 adducts. This type of rearrangement to a bis-ligand complex was previously observed for 1 : 1 terpyridyl complexes.[12] The bis-ligand complex $[Fe(H_2dapd)_2](ClO_4)_2$ was isolated by refluxing a solution of $FeSO_4 \cdot 7H_2O$ with H_2dapd in methanol, followed by the addition of a saturated solution of $NaClO_4$. The pH of the solution was maintained at *ca* 7.

Attempts to isolate pure iron(III)–H_2dapd complexes by direct addition of the ligand to iron(III) salts were unsuccessful and resulted in rapid

reduction and formation of products whose analyses indicated mixtures of 1 : 1 and 1 : 2 iron(II) adducts. This is similar to the behaviour of terpyridyl which, upon direct reaction with iron(III) salts, results in the formation of bis-ligand iron(II) complexes.[13] Oxidation of $[Fe(terpy)_2]^{2+}$ followed by saturation of the solution with weakly reducing anions, Cl^-, ClO_4^- or NO_3^-, gave an iron(III)–terpy complex which is of a different nature in each case.[13] We applied this method to isolate iron(III)–H_2dapd complexes. It is interesting to note that the halide afforded binuclear red complexes of type $[Fe_2(Hdapd)_2X_4]$ (X = Cl, Br or I) and the nitrate a dark red binuclear oxo-complex of type $[Fe_2(Hdapd)O(NO_3)_2]$. Several attempts were made to isolate a bis-ligand iron(III) complex with perchlorate but failed. The $[Fe_2(Hdapd)_2X_4]$ (X = NCS or NCSe) were obtained by refluxing $[Fe_2(Hdapd)_2Cl_4]$ in methanol with an excess of KSCN or KSeCN.

All the complexes are quite stable at room temperature and do not show any sign of their decomposition after a long period of standing. They are insoluble in water and non-polar solvents and, except for iron(II) thiocyanato and selenocyanato, and iron(III) complexes, are soluble in polar solvents. The molar conductivities of $[Fe(H_2dapd)X_2]$ (X = Cl, Br or I) at 10^{-3} M in methanol are in the range expected for non-electrolytes while for the $[Fe(H_2dapd)_2](ClO_4)_2$ complex 1 : 2 electrolytes.[14]

Magnetic susceptibility results

The μ_{eff} values for iron(II) and iron(III) complexes have been measured as a function of temperature and are detailed in Table 2. The magnetic moments of $[Fe(H_2dapd)X_2]$ (X = Cl, Br or I) complexes are almost independent of temperature, ranging from 5.26–5.23 μ_B at *ca* 298 K to 5.06–5.02 μ_B at 78 K. These values are consistently lower than that of six-coordinate complexes ($\mu_{eff} = 5.50\ \mu_B$)[15] and are consistent with those reported for five-coordinate iron(II) complexes.[16] The presence of axial ligands in the five-coordination sphere would generate a great splitting of the $^5T_2$ state (of O_h origin), thereby reducing the orbital contribution to μ_{eff}. The magnitude and slight temperature dependence (*ca* 3% or less) of the magnetic moments strongly suggest a tetragonally distorted octahedral geometry for

$$[Fe(H_2dapd)X_2]\ (X = NCS^-\ \text{or}\ NCSe^-)$$

and

$$[Fe(H_2dapd)_2](ClO_4)_2$$

complexes.[17]

Compounds

$$[Fe_2(Hdapd)_2Cl_4],\ [Fe_2(Hdapd)_2Br_4],$$

$$[Fe_2(Hdapd)_2I_4],\ [Fe_2(Hdapd)_2(NCS)_4],$$

$$[Fe_2(Hdapd)_2(NCSe)_4]$$

and

$$[Fe_2(Hdapd)_2O(NO_3)_2]$$

have effective magnetic moments of 5.27, 5.30, 5.20, 5.08, 5.07 and 1.80 μ_B, respectively at *ca* 298 K. As the sample temperature is lowered, these μ_{eff} values decrease to 3.65, 3.80, 3.57, 3.26, 3.22 and 0.51 μ_B, respectively, at 78 K. Plots of the magnetic data for these complexes are illustrated in Fig. 1. This behaviour is a reflection of an intermolecular antiferromagnetic exchange interaction between the two $S = \frac{5}{2}$ ions in each of the six binuclear compounds.[18] Such an exchange interaction between two $S = \frac{5}{2}$ ions can be largely accounted for with an isotropic exchange spin Hamiltonian of the form $\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2$, where S_i is the spin operator on each of the two metal centers and J is the

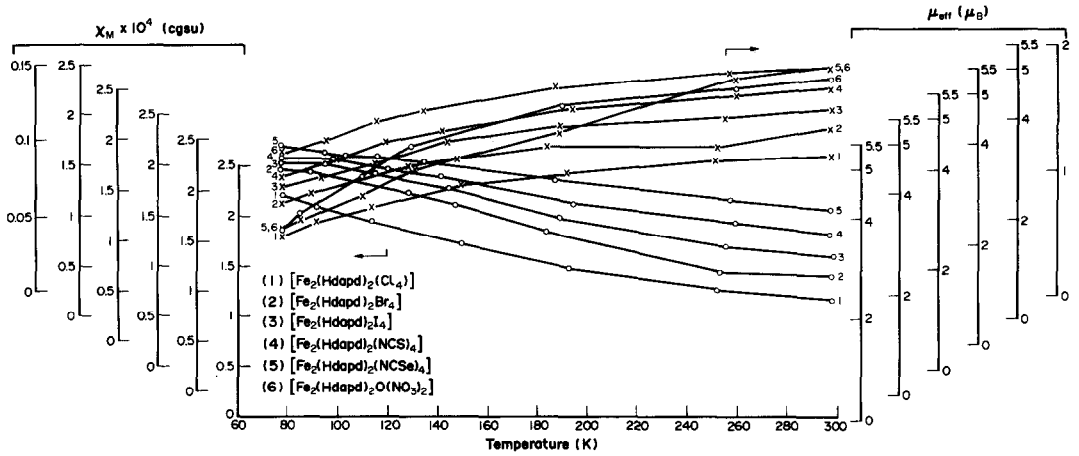

Fig. 1. Corrected molar paramagnetic susceptibility (χ_M in cgsu per mol of binuclear complex) and effective magnetic moment per mol of iron(III) ion (μ_{eff}/Fe) vs temperature curves for: (1) $[Fe_2(Hdapd)_2Cl_4]$, (2) $[Fe_2(Hdapd)_2Br_4]$, (3) $[Fe_2(Hdapd)_2I_4]$, (4) $[Fe_2(Hdapd)_2(NCS)_4]$, (5) $[Fe_2(Hdapd)_2(NCSe)_4]$, and (6) $[Fe_2(Hdapd)_2O(NO_3)_2]$. The solid lines result from the fitting of the data to theoretical equations.[19]

exchange parameter, which is a gauge of the magnitude of the interaction. An exchange-coupled, $S_1 = S_2 = \frac{5}{2}$, complex has electronic states with a total spin of $S' = 5$, 4, 3, 2, 1 and 0. It is the characteristic of such an interacting ferric dimer that, even for a weak interaction, the variation in Boltzmann distribution over the S' states as a function of temperature is gradual and has an effect even at high temperatures. Thus, even a weak antiferromagnetic exchange interaction can influence the μ_{eff} values at *ca* 298 K and this could partially explain why the observed values are below the spin-only value of 5.9 μ_B.

The variable-temperature magnetic susceptibility data for iron(III) complexes were fitted to the theoretical equations[19] to give

$$J = -7.4\ \{[Fe_2(Hdapd)_2Cl_4]\},$$
$$-7.0\ \{[Fe_2(Hdapd)_2Br_4]\},$$
$$-8.2\ \{[Fe_2(Hdapd)_2I_4]\},$$
$$-9.5\ \{[Fe_2(Hdapd)_2(NCS)_4]\},$$
$$-9.7\ \{[Fe_2(Hdapd)_2(NCSe)_4]\}$$

and

$$-102.0\ cm^{-1}\ \{[Fe_2(Hdapd)_2O(NO_3)_2]\}$$

and $g = 2.0$. The theoretical fits to both the μ_{eff} and χ_M vs temperature curves are indicated in Fig. 1 as solid lines. It can be seen that the fits are reasonable, which verifies the suggestion that there is an antiferomagnetic exchange interaction present in each of the binuclear complexes. It is interesting to note here that the J value for $[Fe_2(Hdapd)_2X_4]$ (X = Cl, Br, I, NCS or NCSe) is in the range of -7.0 to -9.5 cm^{-1} and for $[Fe_2(Hdapd)_2O(NO_3)_2]$ is -102.0 cm^{-1}. The magnitude of the latter interaction is very close to those found for μ-oxo-bridged iron(III) dimers.[13] Thus, the antiferromagnetic interaction is a reflection of the details of the electronic structure of bridged species and does not depend simply on metal–metal distance.

Mössbauer effect spectral data

^{57}Fe Mössbauer spectra of iron(II) complexes have been studied at room temperature and 78 K and the spectral parameters are listed in Table 3. The chemical isomer shift values, δ, relative to natural iron foil, which are sensitive to both the oxidation state and the spin-state of iron, are in agreement with the structural assignments made on the basis of magnetic, electronic and IR results (*vide infra*) for iron(II) complexes.[17,20,21] The small reduction in the chemical isomer shift in the $[Fe(H_2dapd)X_2]$ (X = NCS or NCSe) complexes as compared with reported nitrogen-containing octahedral iron(II) complexes[17] is believed to be due to the lower total electronegativity of the coordinated atoms. The lower sulphur electronegativity results in a higher *s*-electron density in the vicinity of the iron nucleus and, consequently, in a smaller chemical isomer shift in $[Fe(H_2dapd)X_2]$ (X = NCS or NCSe) complexes.

For $[Fe(H_2dapd)X_2]$ (X = Cl, Br or I), $[Fe(H_2dapd)X_2]$ (X = NCS or NCSe) and $[Fe(H_2dapd)_2](ClO_4)_2$ complexes characterization

[c] Room temperature.

as five- and six-coordinate high-spin iron(II) derivatives is confirmed by the ΔE_Q values. These are in the ranges 3.85–3.88 and 2.60–2.64 mm s^{-1} at room temperature and 3.98–4.00 and 2.90–3.02 mm s^{-1} at 78 K which are characteristic of five- and six-coordinate high-spin iron(II), as demonstrated for a broad series of related complexes.[17,20,21] The large ΔE_Q values for the $[Fe(H_2dapd)X_2]$ (X = Cl, Br or I) complexes are most probably caused by large contributions of like sign from both the non-spherical electron density and the ligand field dissymmetry. The contribution to ΔE_Q from the nonspherical d-electron distribution will depend upon the nature of the ground state. Under a tetragonal distortion $^5T_2$-state (of O_h-symmetry) is split into $^5B_2$- and ^5E-states. The magnitude of contributions to ΔE_Q from a $3d$ electron in either a $^5B_2$ or a ^5E ground state are equal, but the electric field gradients associated with these two states are of opposite signs. The results of magnetically perturbed Mössbauer spectrum of a five-coordinate complex imply that the ground state is $^5B_2$ contrary to the ordering of the one-electron d-orbitals expected from crystal field theory for both the square pyramidal and the trigonal bipyramidal geometries.[22] From this result it is assumed that the ground state in $[Fe(H_2dapd)X_2]$ (X = Cl, Br or I) complexes is $^5B_2$.

The slightly large ΔE_Q values for $[Fe(H_2dapd)X_2]$ (X = NCS or NCSe) complexes are assumed to be caused by the larger ligand field dissymmetry which results in a larger electric field gradient. This ligand field dissymmetry may be a direct result of the lower total electronegativity of the coordinated atoms which comprise the coordination sphere of the complexes.

^{57}Fe Mössbauer spectra were obtained for all six iron(III) complexes; the spectral parameters are reported in Table 4. The spectra of $[Fe_2(Hdapd)_2Cl_4]$ and $[Fe_2(Hdapd)_2O(NO_3)_2]$ at 298, 78 and 4.2 K are illustrated in Figs 2 and 3, respectively. Essentially identical spectra to $[Fe_2(Hdapd)_2Cl_4]$ were observed for the remaining iron(III) complexes. The δ values are of the magnitude observed for high-spin binuclear five-coordinate iron(III) complexes and show, as expected, a slight increase with decreasing temperature.[23] These δ are surprisingly constant and do not significantly change with change in anion in $[Fe_2(Hdapd)_2X_4]$ complexes, indicating that varying electron-withdrawing effects of different anions have little effect upon the s-electron density at the surface of the iron nucleus. The magnitude of the quadrupole splitting ΔE_Q is also that which is observed for high-spin five-coordinate iron(III) complexes.[23]

The interesting aspect of the Mössbauer spectra of iron(III) complexes is the asymmetry observed in the intensity of the quadrupole-split lines. This asymmetry is apparent in Figs 2 and 3. The asymmetric quadrupole-split doublets may be explained in many ways. Partial orientation of sample crystallites in the sample container, as observed[24] for $Fe_2(CO)_9$, is one possible explanation. Because asymmetry was decreased with decreasing temperature, this explanation is not applicable.

Goldanski *et al.*[25] and Karyagin[26] suggested that anisotropy of the recoil-free fraction of the ^{57}Fe center should produce asymmetry in the $\frac{3}{2} \leftarrow \frac{1}{2}$ doublet, if a site distortion from octahedral geometry is present. The Goldanski–Karyagin effect leads to a change of relative peak areas of the two components of a doublet as a function of temperature while the

line widths remain unchanged. This second explanation also does not appear to applicable, because the best fit of the spectral data is obtained when the areas of the high- and low-velocity peaks of one doublet are set equal. The best fit is illustrated in Figs 2 and 3 as solid lines.

The asymmetry of quadrupole-split doublet and broadening of lines in a Mössbauer spectrum may be attributed to paramagnetic relaxation of the Fe(III) ion. It has been shown[27] that such asymmetry is possible when the spin-relaxation rate is of the same magnitude as the Larmor precessional frequency of the Mössbauer nucleus in the internal hyperfine field generated by unpaired electron spins. For an exchange-interacting iron(III) dimer at 4.2 K, most of the molecules are in the diamagnetic $S' = 0$ state; there is no hyperfine field and the doublet is symmetric. At higher temperatures, other dimer states, where $S' \neq 0$, become populated and slow relaxation of the spins results a magnetic hyperfine broadening and an asymmetric doublet. That is why $[Fe(salen)Cl]_2$ [salen = *N*,*N*′-ethylene bis(salicylideneiminato)] ($J = -7.5\ cm^{-1}$)[28] gives a symmetric quadrupole-split doublet[29] at *ca* 6 K, whereas that for $[Fe(salen)]_2O$ ($J = -95\ cm^{-1}$)[30] is at 80 K.[31] Buckley *et al.*[32] have shown that the interactions in these types of molecules are intermolecular in nature. Hence, it appears that the asymmetric doublets and temperature dependence of asymmetry in our compounds is most likely due to the intermolecular spin–spin relaxation. In this regard, it is important to note that $[Fe_2(Hdapd)_2X_4]$ exhibit symmetric quadrupole-split doublets at 4.2 K whereas those for $[Fe_2(Hdapd)_2O(NO_3)_2]$ is at 78 K.

Electronic spectral results

The diffuse reflectance spectra of $[Fe(H_2dapd)X_2]$ (X = Cl, Br or I) exhibit two broad bands at *ca* 5.0 and *ca* 11.0 kK at room temperature. These two absorption bands are assigned[16] to the $^5A_1$- and $^5B_1$-states derived from the splitting of the ^5E spectroscopic term in the tetragonal ligand field. On the other hand, the spectra of $[Fe(H_2dapd)X_2]$ (X = NCS or NCSe) exhibit two well-resolved bands at *ca* 7.2 and 13.2 kK at room temperature. These spectral bands are assigned[33] to the $^5B_{1g}$- and $^5A_{1g}$-states which are components of the ^5E_g excited state in O_h-symmetry. It is apparent that in halogeno-iron(II) complexes the splitting of the ^5E excited state is of the order of *ca* 6 kK, while the separation of the $^5B_{1g}$- and $^5A_{1g}$-states in thiocyanato- and selenocyanato-iron(II) complexes is of the order of *ca* 3 kK. This indicates a much more highly distorted ligand field in the former complexes than in the latter and is certainly consistent with the two structure types of these complexes.

The diffuse reflectance spectrum of $[Fe(H_2dapd)_2](ClO_4)_2$ exhibits two bands at 8.7 and 11.2 kK at room temperature. These spectral bands are characteristic of distorted octahedral iron(II) and are assigned[34] to components of the $^5T_{2g} \rightarrow {}^5E_g$. The splitting of this band may be due to a pronounced reduction in the ligand field symmetry caused by the greater steric requirements of the two ligand molecules. The intense band observed at 18.5 kK in the spectrum is assigned to a charge-transfer band [$^1{2_g}$(Fe) → $\pi^*(H_2dapd)$].

The iron(III) complexes reported herein are dark red, as is common for iron(III) compounds of oxime-containing ligands. This colour is usually ascribed to the presence of one or more low-lying charge-transfer absorption bands. Because of these very intense bands, one does not usually observe *d–d* transitions in the visible spectra of such compounds. This unfortunate situation is found in the present iron(III) complexes and the positions and intensities of the spectral bands are affected little by the anions. A low-intensity band is however observed at *ca* 11.0 kK in $[Fe_2(Hdapd)_2X_4]$ (X = Cl, Br, I, NCS or NCSe) and $[Fe_2(Hdapd)_2O(NO_3)_2]$ complexes which can be assigned to a ligand field transition. A similar absorption has also been observed in the electronic spectrum of other five-coordinate iron(III) complexes.[13] Although the absorption observed at *ca* 11,000 cm^{-1} cannot be assigned properly, it appears to be a common feature of five-coordinate iron(III) complexes.[13,35]

IR spectral data

H_2dapd exhibits multiple bands between 3350 and 3000 cm^{-1} which are assigned[36] to the intermolecular H-bonded ν(OH) of the NOH groups. The $[Fe(H_2dapd)X_2]$ and $[Fe(H_2dapd)_2](ClO_4)_2$ complexes exhibit sharp bands at 3470–3460, 3370–3360, 3200–3150, 3050–3000 and 2840–2820 cm^{-1} which are assigned[36] to the free ν(OH), H-bonded ν(OH), ν(C—H), coupled ν(OH) and ν(C=N) (overtone), respectively. In $[Fe_2(Hdapd)_2X_4]$ and $[Fe_2(Hdapd)_2O(NO_3)_2]$ complexes, strong bands observed at 3510–3500, 3440–3430, 3110–3100, 3040–3000 and 2840–2830 cm^{-1} are assigned[36] to the free ν(OH), H-bonded ν(OH), ν(C—H) and ν(C=N) (overtone) modes of ligand molecules, respectively. None of these iron(III) complexes exhibit any band in the region 3400–3200 cm^{-1}, indicating ionization of one of the NOH groups of H_2dapd.

The free ligand H_2dapd exhibits ν(C=N)(acyclic) and ν(N—O) vibrations at 1560 and 970 cm^{-1},

respectively. In $[Fe(H_2dapd)X_2]$ and

$$[Fe(H_2dapd)_2](ClO_4)_2$$

complexes the ν(C=N)(acyclic) and ν(N—O) vibrations shift towards the higher-frequency side and appear at *ca* 1600 and *ca* 1050 cm^{-1}, respectively. The shift of bands towards the high-frequency side is an indication of the coordination of the nitrogen atom of the neutral oxime group,

$$\rangle C{=}N{-}OH,$$

to iron(II) ion.[36] In $[Fe_2(Hdapd)_2X_4]$ and

$$[Fe_2(Hdapd)_2O(NO_3)_2]$$

complexes the ν(C=N)(acyclic) is shifted towards the low-frequency side and is obscured by pyridine band-I stretching vibration. The ν(N—O) also appears at a lower frequency (*ca* 1010 cm^{-1}). This situation is certainly consistent with the heterolysis of one of the NOH group in H_2dapd and the coordination through the nitrogen of the

$$\rangle C{=}N{-}O$$

group to the iron(III) ion. The coordination of the pyridine nitrogen atom to iron (II) and iron(III) is indicated by the shifting and splitting of ring vibrations as is usually observed for pyridine coordination.[17]

The presence of bridging thiocyanato and selenocyanato groups in $[Fe(H_2dapd)X_2]$ (X = NCS or NCSe) is indicated[37] by the presence of almost equal intensity splitting ν_1 [ν(C—N stretch)] at 2110s and 2070s cm^{-1}, whereas the ν_1 bands at 2130s, 2090s and 2030m cm^{-1} suggest[38] the presence of both terminal and bridging thiocyanato and selenocyanato groups in $[Fe_2(Hdapd)_2X_4]$ complexes. The ν_2 [δ(NCS) or δ(NCSe) bending], and ν_3 [ν(C—S) or ν(C—Se) stretch] are obscured by ligand absorption bands. The appearance of bands at 1310m and 1450s cm^{-1} indicates[39] the monodentate coordination of nitrato groups in $[Fe_2(Hdapd)_2O(NO_3)_2]$ complex.

In the far-IR spectrum the $[Fe(H_2dapd)Cl_2]$ exhibits[16] bands at 288s [ν_{sym}(Fe-Cl)], 265m [ν_{asym}(Fe-Cl)], 250s [ν(Fe-py)], 236w [δ(Fe-Cl)] and 220m {ν[Fe-N(oxime)]} cm^{-1}, whereas the $[Fe(H_2dapd)Br_2]$ exhibits bands at 250w [ν(Fe-py)], 235s [ν_{sym}(Fe-Br)], 220m {ν[Fe-N(oxime)]}, 208s [ν_{asym}(Fe-Br)] and 196m [δ(Fe-Br)] cm^{-1}. No band in the spectrum of the $[Fe(H_2dapd)I_2]$ complex can be assigned to ν(Fe-I) vibration though such an absorption is expected near 200 cm^{-1}. The bands which appeared at 250s and 220m cm^{-1} are assigned to ν[Fe-N(py)] and ν[Fe-N(oxime)], respectively. The $[Fe(H_2dapd)X_2]$ (X = NCS or NCSe) complexes exhibit bands at *ca* 260s [ν(Fe-NCS) or ν(Fe-NCSe)], 220s {ν[Fe-N(oxime)]}, 208m {ν[Fe-N(py)]}, 185s [ν(Fe-SCN) or ν(Fe-SeCN)] and *ca* 160s [ν(Fe-NCS-Fe) or ν(Fe-NCSe-Fe)] cm^{-1}, again confirming the presence of bridging thiocyanato and selenocyanato groups in these complexes.[37] The ν[Fe-N(py)] and ν[Fe-N(oxime)] in the $[Fe(H_2dapd)_2](ClO_4)_2$ complex are observed at 250s and 220s cm^{-1}, respectively.

In the $[Fe_2(Hdapd)_2Cl_4]$ complex the bands are observed at 295s {ν[Fe-$Cl_{(terminal)}$]}, 250s {ν[Fe-N(py)]}, 240m {ν[Fe-$Cl_{(bridging)}$]}, and 220s {ν[Fe-N(oxime)]} cm^{-1}, whereas the spectrum of the $[Fe_2(Hdapd)_2Br_4]$ complex exhibits bands at 250s {ν[Fe-N(py)]}, 230s {ν[Fe-$Br_{(terminal)}$]}, 218 m {ν[Fe-N(oxime)]} and 185m {ν[Fe-$Br_{(bridging)}$]} cm^{-1}, respectively. The ratio of ν[Fe-$Cl_{(bridging)}$] to ν[Fe-$Cl_{(terminal)}$] and ν[Fe-$Br_{(bridging)}$] to ν[Fe-$Br_{(terminal)}$] is *ca* 0.80 and agrees well with the ratio observed in similar complexes.[16] In the $[Fe_2(H_2dapd)_2I_4]$ complex, the bands due to ν(Fe-I) vibrations are, as usual, weaker and in consequence less readily distinguishable from ligand vibrations, but the bands at 245m and 218w cm^{-1} are assigned to ν[Fe-N(py)] and ν[Fe-N(oxime)], respectively. The $[Fe_2(Hdapd)_2X_4]$ (X = NCS or NCSe) complexes exhibit bands at *ca* 280s, 270m, *ca* 245s, 220s and 186w cm^{-1}, which are assigned to ν[Fe-N(NCS or NCSe)$_{(terminal)}$], ν[Fe-N(NCS or NCSe)$_{(bridging)}$], ν[Fe-N(py)], ν[Fe-N(oxime)] and ν[Fe-S or Se(SCN or SeCN)$_{(bridging)}$], respectively. The bands observed at 245s and 220s cm^{-1} are assigned to ν[Fe-N(py)] and ν[Fe-N(oxime)] vibrations, respectively, in the $[Fe_2(Hdapd)_2O(NO_3)_2]$ complex. A sharp broad band at 845 cm^{-1} is assigned to ν(Fe-O-Fe) vibration.[13,40]

NITROSATION OF ALKENES BY NITRIC OXIDE: CRYSTAL STRUCTURES OF BIS-(1-NITROSO-2-NITRO-CYCLOHEXANE) AND BIS-(1-NITROSO-2-NITRO-1-PHENYLETHANE)

KWOK W. CHIU,* PAUL D. SAVAGE, GEOFFREY WILKINSON† and DAVID J. WILLIAMS†

(*Received* 27 *March* 1985; *accepted* 22 *May* 1985)

Abstract—The reaction of nitric oxide with alkenes has been studied. Crystal structures have been established by X-ray diffraction studies for bis-(1-nitroso-2-nitro-cyclohexane) and bis-(1-nitroso-2-nitro-1-phenylethane).

In a recent communication[1] it was reported that in certain solvents, e.g. dimethylformamide, styrene and nitric oxide in the presence of the cobaloxime, $[Co(DMGH)_2(py)Cl]$ (DMGH = monoanion of dimethylglyoxime, py = pyridine) and BH_4^- gave acetophenoneoxime in a slow catalytic reaction.

We had previously attempted an alkene nitrosation reaction analogous to hydroformylation [$CO + H_2$ + alkene + $RhH(CO)(PPh_3)_3$], namely that of $NO + H_2$ + alkene + $RuH(NO)(PPh_3)_3$. However, it was quickly apparent that: (a) the presence of the ruthenium complexes (or other similar metal species) did not affect the reaction pathway, and (b) no hydrogen was absorbed. Nitric oxide reacted with the alkene within an hour only at a pressure of 5 atm or above and yielded the well-known ψ-nitrosites (together with more complex unidentified materials). From cyclohexene and styrene we obtained the ψ-nitrosites[2] whose structures have been confirmed by X-ray crystallography (see below).

Such ψ-nitrosites commonly have been made by the interaction of alkenes with dinitrogen trioxide.[2,3] As pointed out by Brown[4] in his study of the reaction of nitric oxide with isobutylene, it was stated by N. V. Sidgwick as late as 1949 that pure nitric oxide did not react with olefins. However, pseudonitrites had already been obtained from cyclohexene and other olefins from nitric oxide (purity not specified) in 1944.[5]

Reactions of NO with fluoro-olefins were also established,[6] where it was assumed, like Brown,[4] that a trace of nitrogen dioxide is required as the initiator, either as an impurity or from traces of dioxygen. We have used purified nitric oxide at approximately 7 atm pressure. The exothermic reactions (carried out at 10°C) are much faster than those previously observed at 1 atm, although slower than when nitric oxide (which contains some NO_2) was used directly from the cylinder. We therefore suggest that the reaction involves the well-known[7] disproportionation

$$3NO = N_2O + NO_2,$$

although this reaction was studied at pressures much higher (200 atm) than those used here. As a product of the reaction we should expect to find N_2O rather than N_2,[4,5] and indeed we have confirmed (mass spectrometry) that the residual gas after complete absorption of nitric oxide by cyclohexene is only N_2O. The result is that the reaction with "pure NO" is tantamount to the reaction with dinitrogen trioxide or "nitrous fumes" as used in the older work. The initial rate of uptake of NO (% atm) by cyclohexene was measured semi-quantitatively at four temperatures between −10 and +22°C. An Arrhenius' plot gave a respectable straight line from which an activation energy (E_a) (=45.5 kJ mol^{-1}) was obtained. We assume that this is for the disproportionation reaction.

We have also studied the cobaloxime system[1] but were unable to reproduce the reported results. Styrene and NO in the presence of $NaBH_4$ or $[Co(DMGH)_2(py)Cl]$ in diethyl ether yield bis-(1-nitroso-2-nitro-1-phenylethane). Although reac-

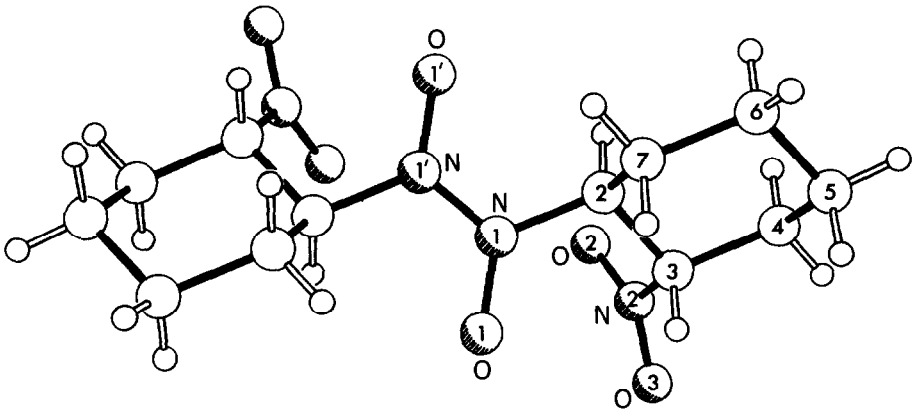

Fig. 1. Molecular structure of **1** giving the crystallographic numbering scheme. Selected torsion angles (°): N(1')N(1)C(2)H(2), −38; N(1')N(1)C(2)C(7), 81; C(2)C(3)N(2)O(2), 32.

tions involving alkenes, NO and cobalt nitrosyl complexes have been reported to yield species with C—N bonds[8] which may then be reduced by $LiAlH_4$ to amines, these reactions involved NO at 1 atm. In view of the present studies it seems unlikely that reactions with alkenes carried out under higher pressures of NO in order to achieve faster stoichiometric or catalytic reactions will prove useful, as competitive formation of ψ-nitrosites is likely to occur at a much faster rate.

CRYSTALLOGRAPHIC STUDIES

Figure 1 shows a perspective view of the molecule of the pseudonitrosite from cyclohexene (**1**) and bond lengths and angles are given in Tables 1 and 2. There is a crystallographic 2-fold axis passing through the centre of the N=N bond and normal to the plane of the *trans*-nitroso groups. The ONNO and CNNC torsion angles are 180.0(2) and 178.9(2)°, respectively, the latter angle reflecting a small out-of-plane distortion (0.004 Å) at the nitrogen atom. In nitrosocyclohexane[9] both the ONNO and CNNC torsion angles are 180° (there is a crystallographic centre of symmetry at the centre of the N=N bond); there is however a small rotation (0.7°) of the ONNO fragment with respect to that of the CNNC producing a 0.005 Å out-of-plane distortion at the nitrogen atom. The N=N, N=O and C—N bond lengths in **1** are all, within statistical significance, the same as those in nitrosocyclohexane.[9] These N=N and N—O bond distances are typical for a dimeric nitroso compound.[10] Clearly the addition of the *p*-nitro groups in **1** in no way significantly perturbs the geometry of the nitroso groups.

The bond lengths and valence angles for the compound from styrene (**2**) are given in Tables 3 and 4, while Fig. 2 shows a perspective view of the molecule. There is a crystallographic centre of symmetry at the centre of the N=N bond producing CNNC and ONNO torsion angles of 180°. The rotation about the N=N bond of the CNNC unit with respect to the ONNO (0.2°) and the consequent out-of-plane distortion at the nitrogen atom (0.002 Å) are both very small and probably not significant. The N=N, N—O and C—N bond lengths do not differ significantly from those of **1**.

Both **1** and **2** represent, in each case, one of three possible *trans* isomeric forms. **1** is chiral, though the presence of a glide plane in the crystal structure produces equal numbers of (*R*,*R*) and (*S*,*S*) molecules. For **2**, however, the crystal structure

reveals only the *meso* form. Clearly in both instances there is the possibility that the other *trans* and *cis* isomers were formed in the chemical reaction. In both cases the alternative configurational or conformational geometries would change the crystal packing and probably also the crystal morphology. However, in neither case was there any noticeable inhomogeneity in the crystalline samples. We do not discount, however, the possibility that different crystalline isomers may have also been present.

In this respect it may be noted that the ^{1}H NMR spectrum of bis-(1-nitroso-2-nitro-1-phenylethane) (**2**) showed two distinct sets of peaks. These can be assigned to the (*R,S*) and the (*R,R*) and (*S,S*) stereoisomers. Due to the different chemical environments of the ethyl protons the spectrum exhibits an ABC character. As expected, 12 lines are observed in all, each proton signal being split into a doublet of doublets.

Handpicking of the crystal mass allowed separation of the clear *meso* (*R,S*) form and the opaque (*R,R* + *S,S*) form, whose conformation was confirmed by NMR (see Experimental and diagram **1**).

(1)

EXPERIMENTAL

Microanalysis was carried out by Imperial College Laboratories. Molecular weights were determined cryoscopically in benzene; m.ps are

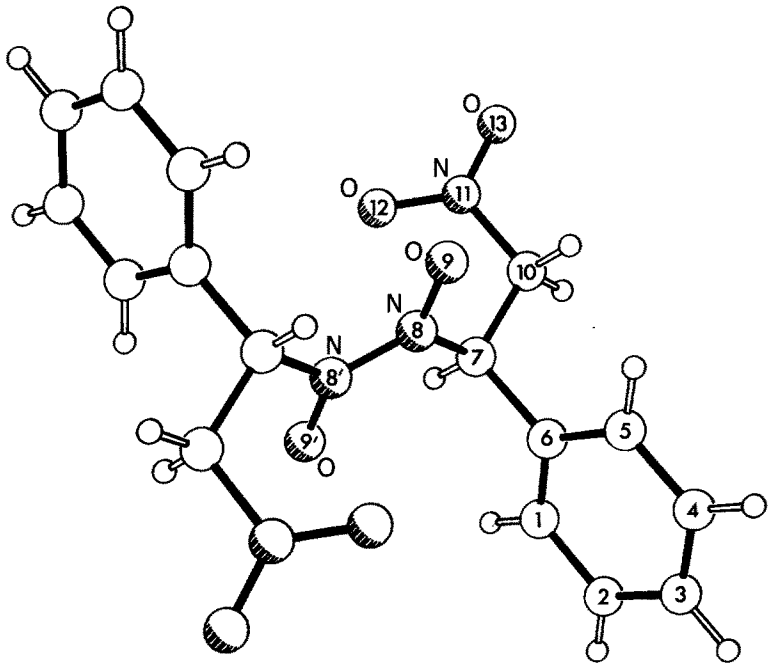

Fig. 2. Molecular structure of **2** giving the crystallographic numbering scheme. Selected torsion angles (°): N(8')N(8)C(7)H(7), 28; N(8')N(8)C(7)C(6), −91; N(8)C(7)C(6)C(5), −61; N(8)C(7)C(10)N(11), −62; C(7)C(10)N(11)O(12), −4.

uncorrected. All operations were carried out under nitrogen or in a vacuum. Solvents were dried over sodium–benzophenone and distilled before use. Alkenes were passed through alumina and distilled from sodium under reduced pressure. Nitric oxide (British Oxygen Co. cylinders, 0.35% NO_2) was passed through a steel cylinder packed with powdered sodium hydroxide, and then through a copper spiral coil at −78°C.

Spectrometers

NMR: JEOL FX 90Q and Bruker WM 250. Data are given in δ ppm referenced to Me_4Si (^1H) and d^6-acetone (^{13}C). IR: Perkin–Elmer 683, spectra (cm^{-1}) in Nujol mulls referenced to polystyrene. Mass spectra were obtained on a VG 7070 spectrometer.

Bis-(1-nitroso-2-nitro-cyclohexane) (**1**)

A typical reaction procedure is as follows. Cyclohexene (3 cm^3, 0.03 mol) in a 90-cm^3 pressure bottle was pressurized with nitric oxide (100 psi). The white solid formed after 1 h was collected, washed with diethylether, and recrystallised from dichloromethane and diethylether. Yield 3.4 g, 36% based on alkene. M.p. 136°C. [Analysis of $C_{12}H_{20}N_4O_6$: C, 45.6 (45.6); H, 6.4 (6.5); N, 17.7 (17.6)%. *M* 342 (320).] ^1H NMR ($CDCl_3$): 1.1–2.8 (16H), 4.80–5.18 (multiplet of six, 2H), 5.34–5.78 (multiplet of six, 2H). IR: 1556s, 1410sh, 1266, 1216s, 1133 and 910 cm^{-1}.

Bis-(1-nitroso-2-nitro-1-phenylethane) (**2**)

As above except that crystals were obtained from dichloromethane after 2 days at −20°C. Yield 2.9 g, 27% based on styrene. M.p. 108.4°C. [Analysis of $C_{16}H_{16}N_4O_6$: C, 53.1 (53.3); H, 4.4(4.5); N, 15.4 (15.5)%. *M* 340(360).] Two distinct types of crystals were separated manually. NMR: (a) clear (*R,S*). ^1H (C_6D_6): 3.29, d of d, (2H), H^b, J_{AB} = 16 Hz, J_{BC} = 11.4 Hz; 4.82, d of d, (2H), H^a; 6.57, d of d, (2H), H^c, J_{AC} = 2.9 Hz; 7.0–7.16, (10H), Ph. (b) Opaque crystals, (*R,R*) and (*S,S*) forms. ^1H: 3.21, d of d, (2H), H^b, J_{AB} = 14.9 Hz; 3.79, d of d, (2H), H^a, J_{AC} = 3.6 Hz; 6.06, d of d, (2H), H^c, J_{BC} = 10.1 Hz; 6.9–7.09, (10H), Ph. ^{13}C–{^1H} (d^6-acetone): 139.5s (CH_2NO_2); 138.7s (*C*HPhNO); 132.7s (*para* ring C); 131.6s (quaternary C); 130.3s (*meta* ring C); 130.1s (*ortho* ring C). IR: 1568s, 1502, 1415, 1267, 1210s and 984 cm^{-1}.

Bis-(1-nitroso-2-nitro-norbornane)

As for **2** but using norbornylene (2 g) and ether (5 cm^3) as solvent in pressure bottle. Yield 2.5 g, 34%. M.p. 118.4°C. [Analysis: C, 49.7 (49.4); H, 5.9 (5.9);

N, 16.3(16.5)%.] Mass spectrum (130°C, 70 eV): *m/z*: 170 ($\frac{1}{2}M^+$, 8%); 140 ($\frac{1}{2}M^+ - NO$, 86%); 124 ($\frac{1}{2}M^+ - NO_2$, 89%); 96 ($\frac{1}{2}M^+ - NO_2 - C_2H_4$, 56%), 94 ($C_7H_{10}$, 51%). IR: 1545s, 1410, 1370sh, 1330, 1305, 1265, 1240s, 1190, 1050, 890 and 780 cm^{-1}.

X-RAY STRUCTURAL ANALYSES OF 1 AND 2

Crystal data

(**1**) $C_{12}H_{20}N_4O_6$, monoclinic, $a = 14.438(2)$, $b = 12.382(1)$, $c = 11.706(2)$ Å, $\beta = 131.38(1)°$, $U = 1570$ Å^3, space group $C2/c$, $Z = 4$, $M = 316.3$, $D_c = 1.34$ g cm^{-3}. (**2**) $C_{16}H_{16}N_4O_6$, triclinic, $a = 5.494(3)$, $b = 8.742(8)$, $c = 9.507(4)$ Å, $\alpha = 70.20(6)$, $\beta = 78.28(4)$, $\gamma = 89.60(6)°$, $U = 420$ Å^3, space group $P\bar{1}$, $Z = 1$, $M = 360.3$, $D_c = 1.43$ g cm^{-3}.

Measurements

Refined unit cell parameters were obtained by centering 16 (**1**) and 12 (**2**) reflections on a Nicolet R3m diffractometer. 971 and 1029 independent observed reflections [$|F_o| > 3\sigma(|F_o|)$] were measured for **1** and **2** respectively. The data were corrected for Lorentz and polarisation factors; no absorption corrections were performed.

Both structures were solved by direct methods and the non-hydrogen atoms refined anisotropically. All hydrogen atoms were placed at idealised positions (C—H = 0.96 Å), assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$, and allowed to ride on their parent carbons. Refinement was by block-cascade, full-matrix least-squares to $R = 0.038$, $R_w = 0.048$ [$w^{-1} = \sigma^2(F) + 0.0003F^2$] for **1** and $R = 0.053$, $R_w = 0.063$ [$w^{-1} = \sigma^2(F) + 0.0005F^2$] for **2**. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[11]

Final atomic coordinates for both compounds, including those of the hydrogen atoms, and thermal parameters have been deposited with the Editor as supplementary data.*

Acknowledgements—We thank the SERC for support (K.W.C.) and for provision of the diffractometer. We also thank Mr R. Jones for his assistance with the X-ray analyses.

Abstract—Reaction of $Pt(PPh_3)_3$ with $S_4N_4H_4$ gives *cis*-$Pt(S_2N_2)(PPh_3)_2$ (**1**) in 45% yield. **1** was characterised by IR, ^{31}P NMR and X-ray crystallography as the tetrachloroform solvate (**2**), which crystallises in the monoclinic system, space group $P2_1$ with $a = 14.635(7)$ Å, $b = 12.758(4)$ Å, $c = 15.405(8)$ Å, $\beta = 117.77(3)°$. The $S_2N_2^{2-}$ ligand coordinates in a bidentate fashion with Pt—N = 2.018(14) Å, Pt—S = 2.288(5) Å and contains two short [1.546(16) and 1.567(19) Å] and one long [1.682(16) Å] S—N bond.

The preparation of transition-metal complexes containing simple sulphur–nitrogen ligands is currently an area of interest both from the point of view of establishing new structural types and as a result of the unusual electrical properties of polymeric sulphur nitride, $(SN)_x$. Reactions between higher oxidation state transition-metal halides/complexes and tetrasulphurtetranitride, S_4N_4, or, more recently, S_7NH have been reported by us,[1,2] whilst Dehnicke and co-workers have studied reactions of $S_3N_3Cl_3$ with group V and VI metal halides.[3,4] Although there are examples of reactions between $S_3N_3Cl_3$ and low oxidation state metal–phosphine complexes[5] very few reactions between metal(0) complexes and S_4N_4 or $S_4N_4H_4$ have been reported. Bhattacharyya *et al.* have carried out some work on reactions between $Pt(PPh_3)_4$ and $S_4N_4/S_4N_4H_4$. In their first paper[6] they claimed the preparation of $Pt(S_2N_2H_2)(PPh_3)_2$ and $Pt(S_2N_2)(PPh_3)_2$ (**1**) on the basis of microanalytical data and UV–Vis spectroscopy. More recently[7,8] they have changed the formulation of the disulphurdiimide complex to $Pt(OSNH)_2(PPh_3)_2$ as a result of X-ray crystallographic studies, although, in a later paper,[9] they again postulated the existence of a complex containing an $S_2N_2H_2$ ligand.

As part of a wider study of the interactions between sulphur–nitrogen species and transition-metal centres we are investigating the usefulness of Pt(0) complexes in the synthesis of metalla-sulphur–nitrogen complexes and clusters and we have recently been successful[10] in the reaction of $Pt(C_2H_4)(PPh_3)_2$ with $(Me_3Si)_2N_2S$ to form $Pt(NSNSiMe_3)_2(PPh_3)_2$. Here we report on our studies on the reaction between $S_4N_4H_4$, $Pt(PPh_3)_3$ and $Pt(PPh_3)_4$, together with the X-ray crystal structure of the major product from these reactions, **1**. We also report NMR studies of the reaction between S_4N_4 and the above Pt(0) phosphines.

EXPERIMENTAL

All chemicals were of reagent grade. K_2PtCl_4 was from Johnson–Matthey Chemicals. Solvents were dried before use; hexane and toluene were distilled from sodium–benzophenone, dichloromethane was distilled from calcium hydride, and acetone was dried over 4 Å molecular sieves. $^{31}P-\{^1H\}$ NMR spectra were recorded on a JEOL FX90Q F.T. NMR spectrometer and are referred to external 85% H_3PO_4, and IR spectra were recorded as KBr discs on a Perkin–Elmer 683 spectrophotometer. Elemental analyses were performed by the microanalytical department of the chemistry department of Imperial College.

Tetrasulphurtetraimide, tetrasulphurtetranitride, $Pt(PPh_3)_4$, $Pt(PPh_3)_3$ and $Pt(C_2H_4)(PPh_3)_2$ were prepared as described in the literature.[11–14]

Preparation of $Pt(S_2N_2)(PPh_3)_2$ (1)

Tetrasulphurtetraimide (0.019 g, 1.0 mmol) in acetone (5 cm^3) was treated with tris(triphenylphosphine)platinum (0.1 g, 0.1 mmol) in toluene (5 cm^3). The reaction mixture was stirred for 1.5 h whereupon hexane (*ca* 30 cm^3) was added to precipitate the crude product which was dried *in vacuo*, extracted with cold toluene and reprecipitated with hexane to give a fine yellow powder (yield 36 mg, 45%). Found: C, 52.3; H, 3.9; N, 3.6. Calc. for $C_{36}H_{30}N_2P_2S_2Pt$: C, 53.26; H, 3.72; N, 3.45%. $^{31}P-\{^1H\}$ ($CDCl_3$): $\delta = 23.57$ [*d*, $^2J(^{31}P-^{31}P)$ 22 Hz, $^1J(^{31}P-^{195}Pt)$ 2827 Hz]; $\delta = 11.42$ (d, ^2J 22 Hz, ^1J 2994 Hz). IR (KBr disc): 1045(s) [ν(NS)], 610(sh, m) [ν(NS)], 445(w) [ν(PtN)], 360(m) [δ(NS)] and 352(sh) [ν(PtS)]. Crystals suitable for X-ray crystallography were obtained by slow diffusion of hexane into a chloroform solution of **1**.

X-ray structural analysis of $Pt(S_2N_2)(PPh_3)_2 \cdot 4CHCl_3$ (2)

Crystal data. $C_{36}H_{30}N_2P_2PtS_2 \cdot 4CHCl_3$, yellow plates, monoclinic, $a = 14.635(7)$ Å, $b = 12.758(4)$ Å, $c = 15.405(8)$ Å, $\beta = 117.77(3)°$, $U = 2545$ Å^3, space group $P2_1$, $Z = 2$, $M = 1289.3$, $D_c = 1.68$ g cm^{-3}, μ(Cu-K_α) = 128 cm^{-1}.

Measurements. Crystal dimensions $0.29 \times 0.34 \times 0.12$ mm. Refined unit cell parameters were obtained by centering 14 reflections on a Nicolet R3m diffractometer, 3603 independent reflections ($\theta \leqslant 58°$) were measured with Cu-K_α radiation (graphite monochromator) using the ω-scan measuring routine. Of these 3423 had $|F_o| > 3\sigma(|F_o|)$ and were considered to be observed. Lorentz polarisation and an empirical absorption correction based upon 360 azimuthal measurements (maximum and minimum transmission factors 0.95 and 0.15) were applied.

Structure analysis. The structure was solved by the heavy-atom method. The positions of the platinum and one of the phosphorus atoms were determined from a Patterson map. The positions of the remaining atoms were found from a succession of ΔF maps which also revealed the presence of four solvent chloroform molecules. The non-hydrogen atoms were refined anisotropically. The hydrogen atom positions were idealised (C—H = 0.96 Å) assigned isotropic thermal parameters [U(H) = $1.2U_{eq}$(C)] and allowed to ride on their parent carbon atoms.

Refinement was by block cascade full-matrix least squares to $R = 0.052$, $R_w = 0.054$ [$w^{-1} = \sigma^2(F) + 0.0014F^2$]. The polarity of the structure was established by an R factor test. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[15] Scattering factors were taken from the *International Tables for X-ray Crystallography*.[16]

Final atomic coordinates, including those of the hydrogen atoms, and thermal parameters have been deposited with the Editor as supplementary data.*

RESULTS AND DISCUSSION

Reaction of tetrasulphurtetraimide with tris(triphenylphosphine)platinum(0) proceeds at room temperature to give **1** as a pale yellow solid, in good (45%) yield. **1** was characterised by microanalysis, IR and NMR and its structure [as the tetrachloroform solvate (**2**)] determined by X-ray crystallography.

The IR spectrum of **1** shows the expected absorptions due to triphenylphosphine together with bands due to ν(NS) at 1045 and 610 cm^{-1} and δ(NS) at 360 cm^{-1}; the ν(PtN) and ν(PtS) vibrations (445 and 352 cm^{-1}) are assigned by analogy with previous work[17] on $M(S_2N_2H)_2$ complexes.

The $^{31}P-\{^1H\}$ NMR of **1** is an **AX** spectrum with satellites due to $^{31}P-^{195}Pt$ couplings. The $^2J(^{31}P-^{31}P)$ coupling constant (22 Hz) and the $^1J(^{31}P-^{195}Pt)$ couplings (2827 and 2994 Hz) are as expected for a Pt(II) compound with *cis* phosphine ligands. It is possible to assign the individual phosphorus resonances since the larger ^1J coupling is expected to be associated with the shorter Pt—P bond,[18] i.e. P(2) *trans* to nitrogen, $\delta = 11.42$. The chemical shift of P(2) in **1** is very close to that observed[10] for the phosphorus nuclei in $Pt(NSNSiMe_3)_2(PPh_3)_2$ ($\delta = 11.76$ ppm) consistent with the triphenylphosphine groups in these two compounds being in similar environments, i.e. both having phosphines *trans* to sulphur diimide groups.

The crystal structure of **2** (Fig. 1 and Table 1) reveals planar coordination of the platinum by two

cis-triphenylphosphine groups and a bidentate $S_2N_2^{2-}$ ligand, with a maximum deviation from the least-square plane comprising Pt, P(1), and P(2) and the S_2N_2 ring of 0.049 Å. The PtS_2N_2 plane is even closer to planar with a maximum deviation of 0.008 Å. As is often the case steric effects open up the PPtP angle [98.4(1)°] whilst the NPtS angle is slightly less than 90 at 87.6(5)°. The Pt—P distances [2.317(4) and 2.263(4) Å] are normal for a Pt(II) complex, the slight difference in the two bond lengths being attributable to the differences in π-acceptor and σ-donor ability of the sulphur and nitrogen atoms. The S—N distances in the $S_2N_2^{2-}$ ligand are unequal with two short [1.546(16) and 1.567(19) Å] and one long [1.681(16) Å] bond as is the case for previous examples of complexes containing this ligand[19–21] and its protonated analogue.[22,23] The longer S—N distance indicates a bond order of close to one whilst the two shorter distances are reasonable for double bonds in the sulphur di-imide (N_2S) like part of the ring. The bond angles within the PtS_2N_2 ring correspond well with previous studies[19–22] with N(1), S(1) and N(2) having ring angles of close to 116° and Pt—S(2)—N(2) being 104.0(7)°. These angles are consistent with the description of the ring as being made up of a delocalised N_2S group with S(2) being sp^3-hybridised. Complete delocalisation of the six π-electrons formally present is thus not apparent.

The formation of **1** from the reaction described above is somewhat surprising in the light of the reports[8] that treatment of $Pt(PPh_3)_4$ with $S_4N_4H_4$ gives $Pt(OSNH)_2(PPh_3)_2$ (**3**) in 94% yield. We have carried out the reaction, as reported here, several times, both under N_2 and in air and always observed (by ^{31}P NMR) the formation of **1** as the only platinum phosphine. Reaction under N_2 was found to be preferable to avoid sulphate impurities (from IR) but **1**, once obtained, is not air-sensitive and so does not appear to be the source of **3**. Attempts to prepare **3** by the published route[6] have, in our hands, been unsuccessful. The crude toluene solution from the published reaction contains approximately (by ^{31}P NMR) 10% Ph_3PS, 30% Ph_3PO, 20% Ph_3P and 40% **1**. We suspect that the formation of **3** may have come about as a result of the presence of catalytic quantities of impurities in previous workers' reactions.

Other routes to **1** have also been studied. Reaction of $Pt(PPh_3)_4$ with S_4N_4 has been reported as giving rise to **1** as a brown solid in 73% yield. Since **1** is yellow the previously reported product[6] obviously contained impurities and our ^{31}P NMR studies indicate several other compounds with **1** (*ca* 25%) when we repeated the published procedure. Reaction of $Pt(O_2)(PPh_3)_2$, $Pt(C_2H_4)(PPh_3)_2$ or $Pt(PPh_3)_3$ with S_4N_4 all give **1** (*ca* 20% by ^{31}P NMR) together with other platinum phosphines which we hope to report on later.

The mechanism of formation of **1** is not clear; however, it is interesting to note that reactions of the S_3N^- anion with metal halides result in the formation of compounds containing $S_2N_2H^-$ ligands.[24] It seems possible that the currently unknown $S_2N_2^{2-}$ anion is involved as an intermediate in many of the solution equilibria of sulphur imides.

Acknowledgements—We are grateful to Johnson–Matthey Chemicals for loans of precious metals and to Dr C. P. Warrens for useful discussions on ^{31}P NMR.

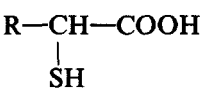
A POTENTIOMETRIC STUDY ON THE COMPLEX EQUILIBRIA BETWEEN NICKEL(II) AND 2-MERCAPTO-2-PHENYLACETIC ACID



ENRIC CASASSAS,* MONTSERRAT FILELLA, ALVARO IZQUIERDO, DOLORS PRAT and ROSA RODRÍGUEZ

Departament de Química Analítica, Universitat de Barcelona, 08028 Barcelona, Spain

(*Received* 29 *April* 1985; *accepted* 26 *May* 1985)

Abstract—Complex formation between nickel(II) and 2-mercapto-2-phenylacetic acid (H_2MPA) has been studied at 25°C and 1 mol dm^{-3} ClO_4^- in 50% (v/v) ethanol–water using glass electrode potentiometry. The emf data obtained have been analyzed using the ESTA programs. Protonation constants for the ligand and formation constants for the complexes $Ni_3(MPA)_4^{2-}$, $Ni_2(MPA)_3^{2-}$ and $Ni(MPA)_2^{2-}$ are reported.

2-Mercaptoacids are compounds with the general structure

which act as complexing agents for metal ions. They have many applications in analytical chemistry and they are also of interest in relation to various biological systems.

Nickel(II) is one of the metal ions whose complexation by 2-mercaptoacids has been most widely studied. After an initial investigation of the complex formation between nickel(II) and mercaptoacetic acid (R = H),[1] where only the existence of mononuclear complexes was found, Leussing *et al.*[2] established that polynuclear complexes of the type $M[ML_2]_n^{2-2n}$ were commonly formed in this system. The main species were $M_4L_6^{4-}$ and ML_2^{2-}. The same system has been studied by Perrin and Sayce,[3] who also found that $M_4L_6^{4-}$ and ML_2^{2-} were the major species but that $M_3L_4^{2-}$, $M_2L_3^{2-}$, MLH^+ and ML_3^{4-} did occur simultaneously. These results were largely confirmed in a subsequent study by De Brabander *et al.*,[4] although these authors could not find any evidence for the formation of $M_2L_3^{2-}$, MLH^+ and ML_3^{4-}.

Fewer studies have been conducted on the complexation of nickel(II) with 2-mercaptopropanoic acid (R = CH_3). However, De Brabander *et al.*[5] have reported that only $M_3L_4^{2-}$ and ML_2^{2-} are formed; they attributed the lack of formation of the complex $M_4L_6^{4-}$ to the steric hindrance caused by the 2-methyl group.

As has already been pointed out by Perrin and Sayce,[3] many published values of formation constants for the nickel(II) complexes of these ligands must be considered unreliable because they have been calculated on the assumption that the monomeric species are the only ones formed.

No studies on the complexation of 2-mercapto-2-phenylacetic acid (R = Ph) with metal ions appear in the literature. This is probably because it is not commercially available and it is not soluble in water. In order to compare the influence of an arylic substituent on the complexing ability of 2-mercaptoacids with nickel(II) we undertook the study of the system between nickel(II) and 2-mercapto-2-phenylacetic acid.

EXPERIMENTAL

Materials

2-Mercapto-2-phenylacetic acid was prepared by the action of potassium *O*-ethyldithiocarbonate on 2-bromo-2-phenylacetic acid.[6] The product obtained, a yellow oil which crystallizes rapidly, was hydrolyzed with concentrated ammonium hydroxide.[7] The crude product is again an oil which only crystallizes gradually. By recrystallization from petroleum ether 40–60°C, 2-mercapto-2-phenylacetic acid is obtained as white crystals (m.p. 60–61°C). *Analysis.* Found: C, 57.0; H, 4.8; S, 18.9.

* Author to whom correspondence should be addressed.

Calc. for $C_8H_8O_2S$: C, 57.1; H, 4.8; S, 19.1%. Its purity was tested periodically by iodometric titrations.[8] Although the compound was found to be quite stable, a freshly prepared solution was used for each titration.

A standard stock solution of nickel was prepared as its perchlorate salt (K&K) and standardized gravimetrically as bis(dimethylglyoximato)nickel for metal concentration[9] and by Gran plots for hydrogen ion concentration.[10]

Sodium hydroxide solution was prepared frequently from sodium hydroxide pellets (Merck) and standardized by titration against standard grade potassium hydrogen phtalate (Merck).

To maintain ionic strength, all solutions were made up to a perchlorate concentration of 1 mol dm^{-3} by the addition of sodium perchlorate prepared as described in Ref. 11.

All solutions were prepared using deionized double distilled water boiled and cooled under nitrogen and absolute ethanol (Merck), so that all solutions were 50% (v/v) ethanol–water.

High-grade nitrogen (S.E.O.) was passed through a vanadate solution,[12] concentrated sodium hydroxide, sulphuric acid and ionic background thermostatted at 25°C. A purified nitrogen atmosphere was maintained in the vessel during the titrations and all solutions were thoroughly flushed with nitrogen before use.

Method

Protonation constants for the ligand and formation constants for the nickel complexes were determined by potentiometric titrations in a double walled vessel, thermostatted at 25.0±0.05°C by circulating water. The free hydrogen ion concentration was measured using Radiometer PHM 84 Research pH Meter equipped with a wide-range glass electrode (Radiometer G202B) and a silver–silver chloride electrode prepared as described by Brown.[13] The following cell, which includes a Wilhelm bridge,[14] was employed:

Ag, AgCl(s)	10 mmol dm^{-3} NaCl 990 mmol dm^{-3} $NaClO_4$ [50% (v/v) ethanol–water]	1 mol dm^{-3} $NaClO_4$ [50% (v/v) ethanol–water]	TS	glass electrode.

The electrode system was calibrated in terms of hydrogen ion concentration by performing strong acid vs strong base titrations.[15]

Experimental solutions containing ligand, metal (when appropriate) and perchloric acid were titrated, the hydrogen ion concentration being varied by adding sodium hydroxide. Total metal ion concentrations were kept constant by adding, after each addition of sodium hydroxide, an equal volume of metal ion solution with a concentration twice that of the total metal ion in the cell.

Protonation curves for the ligand were obtained at a variety of different ligand concentrations and, similarly, the metal complex formation curves were obtained at different ligand:metal ratios and for different ligand and metal concentrations.

The number of the titration points, the compositions of the starting solutions and the $-\log [H]$ ranges used in the calculations are shown in Table 1. The upper limits of the reactants were largely determined by the insolubility of the ligand or by the formation of metal complex precipitates. The upper limits of the $-\log [H]$ ranges were determined by a sudden drop in the rate at which equilibrium was attained, as evidenced by a slow drift in the potentiometric readings.

Data treatment

In evaluating the equilibrium constants, metal M^{2+}, ligand L^{2-} [i.e. deprotonated 2-mercapto-2-phenylacetic acid (MPA)] and H^+ were chosen as components. The general three-component equilibrium can be written as:

$$pM + qL + rH \rightleftharpoons M_pL_qH_r. \quad (1)$$

The overall formation constants are defined as:

$$\beta_{pqr} = \frac{[M_pL_qH_r]}{[M]^p[L]^q[H]^r}, \quad (2)$$

where the square brackets indicate the concentration of the free-metal, ligand and hydrogen ions. Charges are omitted for simplicity.

The initial model, initial estimates of the values of the formation constants and the final selection of species were obtained as described in Ref. 16.

Formation constant refinement was performed using the ESTA[17] optimization module with a weighted least-squares objective function based on emf residuals:

$$U = \frac{\sum_n w(\text{emf}^o - \text{emf}^c)^2}{N - n_p}, \quad (3)$$

where N = total number of experimental titration points and n_p = total number of optimized parameters. The weight at each titration point was

Table 1. Summary of the titration data used for calculating formation constants: number of titration points, initial concentrations of nickel (C_{Ni}) and ligand (C_{MPA}), and rough $-\log$ [H] ranges (concentrations expressed in mol dm^{-3})

based on standard deviations in titre of 0.001 cm^3 and in emf of 0.05 mV. The sum of squares of residuals is based on total electrode ion concentrations.

All calculations were performed on a VAX 11/780 computer at UWIST (Cardiff, U.K.).

RESULTS AND DISCUSSION

2-Mercapto-2-phenylacetate shows two protonation constants (Table 2), that can be assigned to the carboxylate and thiol group. The values found are quite similar to those reported for mercaptoacetic and 2-mercaptopropanoic acids[18] as might be expected from the inductive, electrostatic and mesomeric effects that usually modify protonation constant values.

An analysis of the formation curves (Fig. 1) and the deprotonation curves (Fig. 2) clearly suggests the presence of polynuclear complex species in the Ni^{2+}–MPA–H$^+$ system. The formation of polynuclear species is favoured by the tendency of ligands

Table 2. Formation constants determined in this study at 25°C and I = 1 mol dm^{-3} ClO_4^- [50% (v/v) ethanol–water]

	pqr	$\log \beta_{pqr}$	U	Sum of squares of residuals	No. of data points	No. of titrations
H$^+$	011	10.366 ± 0.001	521.5	3.365E-06	498	9
	012	14.420 ± 0.002				
Ni^{2+}	340	40.437 ± 0.013	131.7	3.892E-06	615	15
	230	28.819 ± 0.008				
	120	16.717 ± 0.003

containing a mercapto group to form complexes with sulphur bridges between two or more metal ions as well as by the ability of metal ions containing filled or almost filled *d*-electron shells to form bonds with the vacant 3*d* orbitals of the sulphur atom.

The best model was found to contain the species 340, 230 and 120. The lack of formation of the 460 complex, reported for mercaptoacetic acid, is probably caused by steric hindrance due to the presence of bulky phenyl group in the molecule. The complexes 340 and 230 would probably have the same structure as the corresponding complexes for mercaptoacetic acid proposed by Leussing *et al.*[2]

Table 3 contains some literature values of formation constants of nickel complexes of related 2-mercaptoacids. The comparison of those values with

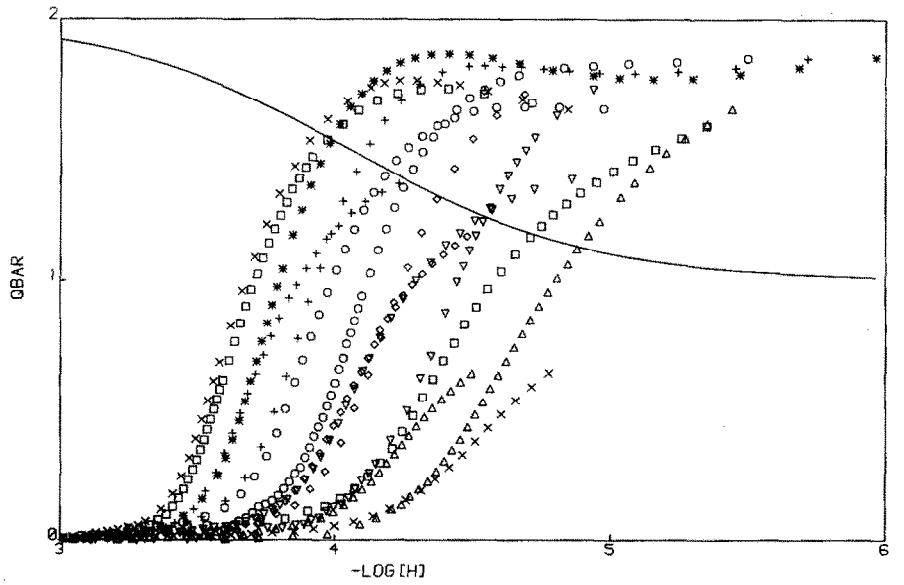

Fig. 2. Ni^{2+}–MPA–H^{+} experimental deprotonation curves. The different symbols have the same meaning as in Fig. 1. A plot of $\bar{n}$ vs $-\log[H]$ appears as a solid line.

STRUCTURE OF A DIRUTHENIUM(II,III) COMPLEX WITH BENZAMIDATO BRIDGING LIGANDS

AKHIL R. CHAKRAVARTY and F. ALBERT COTTON*
Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 4 *April* 1985; *accepted* 28 *May* 1985)

Abstract—The compound $Ru_2Cl(C_6H_5CONH)_4$ has now been obtained in crystalline form and the crystal and molecular structure determined by X-ray methods. The crystals are triclinic, $P\bar{1}$, with the following unit cell dimensions: $a = 11.666(4)$ Å, $b = 12.721(4)$ Å; $c = 10.754(6)$ Å, $\alpha = 90.62(4)°$; $\beta = 111.10(5)°$; $\gamma = 83.21(2)°$; $V = 1478(2)$ Å^3; $Z = 2$. The $[Ru_2(C_6H_5CONH)_4]^+$ ions are linked by Cl^- ions into infinite, zigzag chains with Ru—Cl—Ru angles of 116.2(1)° and a mean Ru—Cl distance of 2.592(3) Å. The benzamidato ligands are arranged in a cisoid 2:2 fashion about the Ru_2^{5+} units, in which the average Ru—Ru distance is 2.293(2) Å.

Recent reports[1,2] from this laboratory on the reactivity of amidato-bridged diruthenium(II,III) complexes towards triarylphosphines have shown that $P(Ar)_3$ when reacted with $Ru_2Cl(ArCONH)_4$ undergoes a metal assisted P—C bond cleavage leading to transfer of an aryl group from $P(Ar)_3$ to Ru, thus giving an edge-sharing bioctahedral diruthenium(III,III) species,

$$Ru_2(Ar)_2(ArCONH)_2[Ar_2POC(Ar)N]_2.$$

Transfer of a *p*-tolyl group from $P(p\text{-tol})_3$ onto the metal reveals[2] the fact that there is indeed a simple migration of a C—P bond from P to Ru, rather than an orthometallated intermediate, or other more complex process.

Discussions of the reaction processes, as presented in our earlier reports,[1,2] were based on the assumption that the arrangement of ligands in tetra-amidato species are of the cisoid 2:2 type as observed[3] in $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot MeOH$. However, this assumption was unproven for $Ru_2Cl(PhCONH)_4$ since earlier attempts to prepare single crystals of this compound had been unsuccessful.

Recently, in an investigation of the generality of the migratory processes we attempted to react diphenylphosphinobutane (dppb) with $Ru_2Cl(PhCONH)_4$ following procedures similar to those described in our previous reports.[1,2] It was found that dppb is unreactive towards $Ru_2Cl(PhCONH)_4$, but from the reaction mixture we were able to isolate a homogeneous crystalline mass of $Ru_2Cl(PhCONH)_4 \cdot MeOH$. We report here the results of structural investigations on this compound.

The structure which has been obtained by X-ray crystallography† is shown in Fig. 1. The asymmetric unit consists of two half dimers linked by a Cl atom, and one methanol molecule as solvent of crystallization. The dinuclear units,

$$[Ru_2(PhCONH)_4]^+,$$

form infinite zigzag chains through Cl bridges. Similar sorts of arrangements are known to occur among tetracarboxylates[4–8] and in

$$Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot MeOH.^3$$

† The triclinic crystals belong to the space group $P\bar{1}$. Cell dimensions: $a = 11.666(4)$ Å, $b = 12.721(4)$ Å, $c = 10.754(6)$ Å, $\alpha = 90.62(4)°$, $\beta = 111.10(5)°$, $\gamma = 83.21(2)°$, $V = 1478(2)$ Å^3, $Z = 2$, $d_c = 1.616$ g cm^{-3}, μ(Mo-K_α) = 11.33 cm^{-1}. Instrument: Enraf–Nonius CAD-4; radiation: Mo-K_α ($\lambda = 0.71073$ Å); scan method = ω–2θ; total data = 5172 in the range $4° < 2\theta < 50°$ with 2406 having $F_o^2 > 3\sigma(F_o^2)$; residuals: $R_1 = 0.062$ ($R_2 = 0.069$); quality-of-fit = 1.55; largest shift/esd = 0.06. Empirical absorption corrections were made. No decay of the crystal was seen during 68.7 h exposure time. Complete tables of structure factors, anisotropic thermal parameters and complete lists of bond distances and angles (22 pp.) have been deposited with the Editor at Queen Mary College. Positional parameters and isotropic thermal parameters have been forwarded to the Director, Cambridge Crystallographic Data Centre.

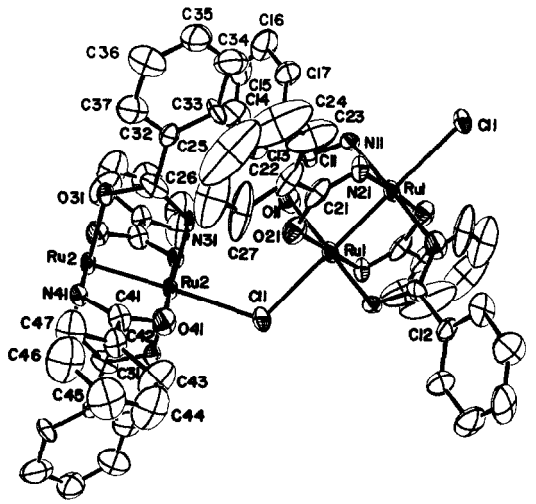

Fig. 1. An ORTEP drawing of the complex in $Ru_2Cl(PhCONH)_4 \cdot MeOH$ with atom-labelling scheme. Selected bond lengths and bond angles are: Ru(1)—Ru(1), 2.295(2), Ru(2)—Ru(2), 2.290(2), Ru(1)—Cl(1), 2.572(3), Ru(2)—Cl(1), 2.612(3), Ru(1)—O(11), 2.049(8), Ru(1)—O(21), 2.018(9), Ru(1)—N(11), 2.034(9), Ru(1)—N(21), 2.006(10), Ru(2)—O(31), 2.042(7), Ru(2)—O(41), 2.043(9), Ru(2)—N(31), 2.001(9), Ru(2)—N(41), 2.058(9) Å; Ru(1)—Cl(1)—Ru(2), 116.2(1), av. Ru(1)—Ru(1)—O, 89.9(3), av. Ru(1)—Ru(1)—N, 89.4(3), av. Ru(2)—Ru(2)—O, 90.6(3), av. Ru(2)—Ru(2)—N, 89.4(3)°. The C(1)—O(1) distance in MeOH is 1.36(3) Å.

The average Ru—Ru distance in $Ru_2Cl(PhCONH)_4$ is 2.293(2) Å and each ruthenium center has an $RuClN_2O_2$ coordination sphere where the Ru—Ru—Cl angles are essentially linear. The formal oxidation state of Ru is +2.5 and the Ru—Ru bond order is 2.5. The Ru—Cl—Ru bridge angle is 116.2(1)°. The average Ru—N, Ru—O and Ru—Cl distances are 2.025(9), 2.038(8) and 2.592(3) Å, respectively. The axial Ru—Cl distance is similar to those in other diruthenium(II,III) complexes[3–10] having axial coordination at both metal atoms, but considerably longer than the Ru—Cl distances in polar[9–13] diruthenium(II,III) species. Physicochemical studies reported[1] on $Ru_2Cl(PhCONH)_4$ and other amidato species[14,15] show that the Ru—Cl bonds are weak and can be easily cleaved by strongly polar solvents like Me_2SO. The reaction between $Ru_2Cl(PhCONH)_4$ and PPh_3 in Me_2SO–MeOH mixture is known[1] to give $Ru_2(Ph)_2(PhCONH)_2[Ph_2POC(Ph)N]_2$. Our proposed mechanism in an earlier report[2] suggested that the arrangement of bridging ligands in $Ru_2Cl(PhCONH)_4$ should be of the cisoid 2:2 type. The structure of this compound confirms that assumption and thus supports the proposed[2] mechanism.

Acknowledgements—We are grateful to the National Science Foundation for support and to Dr W. Schwotzer for his help in solving the structure.

SYNTHESIS AND CHARACTERIZATION OF NEW COMPLEXES BETWEEN SODIUM MONOALKYL BENZENEAZOPHOSPHONATES AND DIBENZO-18-CROWN-6

LJ. TUŠEK-BOŽIĆ* and D. SEVDIĆ

Department of Physical Chemistry, Institute Rudjer Bošković, Zagreb, Yugoslavia

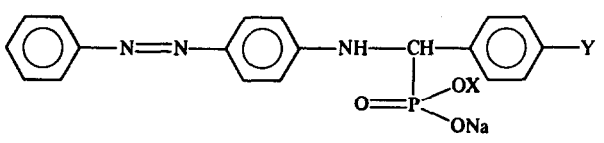
(*Received* 1 *May* 1985; *accepted* 26 *May* 1985)

Abstract—A new series of crystalline complexes of sodium monoethyl ester and sodium monobutyl ester of [α-(4-benzeneazoanilino)-*N*-benzyl]phosphonic acid, [α-(4-benzeneazoanilino)-*N*-4-hydroxybenzyl]phosphonic acid and [α-(4-benzeneazoanilino)-*N*-4-methoxybenzyl]phosphonic acid with dibenzo-18-crown-6 have been synthesized. The complexes obtained were identified and characterized by elemental and thermogravimetric analysis, conductivity measurements and UV, IR and ^{1}H NMR spectra. The molecular structure and the electronic configuration of the anion are important factors in a salt–ligand system with influence on ease of solubilization, charge separation and the formation of crystalline complex in alcoholic and acetonitrile solutions.

Macrocyclic polyethers as polydentate ligands of flexible conformation can form complexes with alkali and other metal salts providing increased salt solubility and increased anion reactivity in aprotic organic solvents.[1,2] In recent years macrocyclic polyethers and their complexes have therefore been extensively employed in studies of mediated ion transport, solute separations, and anion-activated catalysis.[3,4] Besides the complexes with simple salts of inorganic acids, great interest has developed in obtaining information on macrocyclic polyether complexes with salts of organic anions. The chelating organic anions mostly used were those obtained by the deprotonation of nitrophenols and hydroxy-, nitro- or aminobenzoic acids.[5–9]

In continuation of our systematic study of the macrocyclic polyether complexes with various alkali metal salts,[9–11] this paper describes for the first time the preparation and the properties of complexes with sodium salts of some benzeneazophosphonates (NaA_1–NaA_6). The various factors, including the dimensions of the polyether hole and the metal cation, size and charge density of anion as well as solvent used, have been found to play a fundamental role on the formation of the salt complexes.

EXPERIMENTAL



Materials

The preparation of the sodium salt of the monoethyl ester and the sodium salt of the monobutyl ester of [α-(4-benzeneazoanilino)-*N*-benzyl] phosphonic acid (NaA_1 and NaA_2), [α-(4-benzeneazoanilino) - *N* - 4 - hydroxybenzyl]phosphonic acid (NaA_3 and NaA_4) and [α-(4-benzeneazoanilino) - *N* - 4 - methoxybenzyl]phosphonic acid (NaA_5 and NaA_6) has been described earlier.[12,13] Sodium salts were purified by repeated recrystallization from absolute ethanol and dried by heating to about 50°C under high vacuum.

Dibenzo-18-crown-6 (DBC) (the trivial name for 6,7,9,10,17,18,20,21 - octahydrodibenzo[b,k] [1,4,7,10,13,16]hexaoxacyclooctadecin) prepared as previously described[14] was recrystallized twice from acetone.

The purification of methanol[15] and acetonitrile[16] was carried out by published methods in order to obtain solvents suitable for conductance measurements.

n-Bu	OMe	NaA_6

Preparation of complexes

An equimolar amount of macrocyclic polyether and sodium salt of monoalkyl ester of benzeneazophosphonic acids was dissolved in ethanol or acetonitrile and refluxed for 2–6 h with vigorous stirring. The clear hot solution was filtered and the solvent was slowly evaporated at room temperature. Complexes of sodium monoethyl esters were gradually formed by removal of solvent. The crystalline precipitate was filtered off, washed with cold reaction solvent and dried. The filtrate was again subjected to evaporation in order to achieve further crystallization of the complex. Complexes of sodium monobutyl esters were isolated after the whole of the solvent was driven off. The homogeneity of the crystals was ascertained under the microscope. The majority of the complexes obtained were hygroscopic compounds as were the free sodium salts.[12,13] After drying under high vacuum for several hours at room temperature the complexes of sodium salts of methoxy-substituted benzeneazophosphonates became anhydrous, while the others were obtained as monohydrated complexes.

We tried to prepare all complexes in methanol, ethanol and acetonitrile solutions. Complexes of sodium salts of hydroxy-substituted benzeneazophosphonates were isolated only from ethanol, while all the other complexes were precipitated from acetonitrile solutions. It was shown that free macrocyclic polyether gradually precipitated from methanolic solutions, and no complex could be isolated.

Physical measurements and analyses

Melting points were recorded using hot-stage (0–360°C) microscopy and are uncorrected. UV spectra were obtained in methanolic solutions with a Perkin–Elmer 124 spectrophotometer. IR spectra were recorded on KBr pellets and Nujol mulls using a Perkin–Elmer 580 B spectrophotometer in the region 4000–200 cm^{-1}. NMR spectra were determined on JEOL FX90Q Fourier transform NMR spectrometer in deuterochloroform solutions with tetramethylsilane as the internal standard using a sweep width of 1200 Hz. Thermogravimetric measurements were performed with a Cahn RG electromicro balance applying a heating rate of 2° min^{-1} in an atmosphere of static air.

Conductivity measurements were performed in methanol and acetonitrile using a Tacussel conductivity bridge, type CD 7A. The solutions were thermostatted at 25 ± 0.02°C by a double water bath and stirred by means of a magnetic stirrer. The procedure of measuring and calculation of equivalent conductance at infinite dilution and ion-pair dissociation constants of free sodium salts and their complexes was the same as described previously.[17] The conductance data were analysed by the Fuoss–Onsager theory in the usual form, through an iterative machine calculation procedure using the expanded form of the Fuoss–Hsia conductance equation.

Elemental analyses were performed in the Microanalytical Laboratory of the Rudjer Bošković Institute.

RESULTS AND DISCUSSION

The complexes isolated between sodium monoalkyl benzeneazophosphonates (NaA_1–NaA_6) and DBC with the analytical data and the other physical properties are listed in Table 1, the UV and IR data in Table 2, the summarized ^1H NMR spectra are shown

in Table 3, and the conductance data are given in Table 4.

DBC forms 1 : 1 complexes with sodium salts. The sodium ion (ionic diameter 1.94 Å) easily fits into the hole of the 18-membered polyether ring (2.6–3.2 Å diameter),[18] and the anion and water molecules are able to interact with it from the vacant axial directions. The low melting points of the complexes as against the high melting points of the corresponding sodium salts (above 220°C), indicate that the charge of the sodium ion in the complexes is extensively delocalized. On the other hand some degree of charge-transfer between the cation and anion can take place, increasing the stability of the complex.

The great similarity in the properties and the spectral data of all the sodium salt complexes indicates that metal–polyether interactions are essentially the same. Differences which are observed in their preparation can be attributed partially to the different solubility of sodium salts in the solvent of reaction. Sodium salts of monobutyl esters are more soluble than the corresponding monoethyl esters, as are also the sodium methoxy-substituted benzeneazophosphonates compared to those of non-substituted or hydroxy-substituted analogues,

Table 3. ^{1}H NMR data of the salt complexes

[b] Salts NaA_1–NaA_4 are too insoluble for measurement.

respectively. Although all the salts form complexes with DBC in alcoholic solutions, they cannot be isolated always in the solid state. The uncomplexed polyether precipitates when the solution is concentrated. Generally, it was shown that the failures to isolate the metal salt complexes can be attributed either to the strong M^+A^- ion association as a consequence of which M^+ fails to cause necessary polarization of the polyether molecule, to the high lattice energy of the salt, or to the strong hydrogen bonding between the cation or anion and the synthesis media.

UV spectra

DBC has, in methanol, a characteristic absorption maximum at 274 nm (log ε 3.72).[14] Complexing with a cation brings about distinctive changes in this band. When salts themselves do not absorb too strongly in the region of 270–290 nm, a hypsochromic shift, variations in absorbance or the appearance of a second peak to the longer wavelength side of the major peak can be attributed to complex formation.[1] In the spectra of complexes of sodium monoalkyl benzeneazophosphonates a slight hypsochromic shift, and in some cases a new peak not clearly separated from the main one, is evident. Interaction between polyether and the sodium salt can take place in alcoholic solution even when it was not possible to isolate the complex in a crystalline form.[9]

Sodium salts give an absorption maximum at 397 nm (log ε 4.45) which corresponds to conjugation of the azo group with aromatic rings (π–π^* transition). It remains unchanged upon complex formation, suggesting non-coordinated ionic monoakyl benzeneazophosphonato groups.

IR spectra

IR spectra of macrocyclic polyether complexes with sodium monoalkyl benzeneazophosphonates are very complex and a complete assignment of the absorption bands is not possible. Only the frequencies associated with the characteristic functional groups are presented in Table 2. Generally, significant differences between the spectra of macrocyclic polyether and its complexes may be noticed in the region 1250–900 cm^{-1} where bands arising from various modes of vibration of ether and methylene groups are present.[9] In every case the spectrum of the solid complex distinctly differed from that of the physical mixture of the constituents.

Since all the sodium salts alone give a series of complex bands between 1250 and 1165 cm^{-1}, characteristic of asymmetric stretching of the ionised PO_2^- group,[13,19] it is not possible to determine the exact position of the ν_{as}(Ar—O—CH_2) bands in their complexes (free polyether exhibits these bands at 1256 and 1230 cm^{-1}). The complexes are characterized by the very intense bands near 1250 and 1220 cm^{-1}, respectively. The ν_{as}(CH_2—O—CH_2) band, present in the polyether at 1130 cm^{-1}, upon complexing is slightly shifted to lower energy. Considerable differences are observed in the 1000–900-cm^{-1} region which contains bands attributed to wagging, twisting and rocking modes of vibration of the methylene groups. DBC shows two bands arising from these vibrations at 997 and 932 cm^{-1}. In the spectra of its complexes they are missing, and a rather intense band appears around 950 cm^{-1}. Less restriction on the coupling of these vibrational modes in the complexes is probably due to some bonding between the oxygen atoms of the polyether ring and the metal cation.

All the salt complexes which contain water have one peak at about 3600 cm^{-1}, indicating metal-coordinated water. A water molecule in the complex is considered metal-coordinated if relatively sharp absorption bands appear over 3400 cm^{-1}, especially above 3500 cm^{-1}, but anion-bonded if the latter is missing and the broad peaks or humps appear around and below 3400 cm^{-1}.[6]

^{1}H NMR spectra

The ^{1}H NMR spectrum of DBC in $CDCl_3$ has two multiplets at about δ 4.11 ppm for methylene protons of the polyether ring, and a singlet at δ 6.92 ppm due to the aromatic protons.[14] The ether multiplet is typical of what is observed for a XCH_2CH_2Y fragment undergoing rapid rotamer conversion.[20] In the complexes the polyether ring protons show

only one singlet at about δ 4.06 ppm. The slight broadening observed is a reflection of the slower dissociation rate for the ion-pair complexes in the solvent system. The overlapping of the polyether aromatic protons by the signals of the anion aromatic protons results in an unresolved multiplet. Comparison of the spectra of sodium monoalkyl benzeneazophosphonates with the spectra of their polyether complexes indicates some chemical shift differences for the anion protons. In the complexes of sodium salts of monoethyl esters a triplet (J = 8 Hz) for the CH_3 part of the $POCH_2CH_3$ group is shifted slightly upfield by 10 cps. The absorption of the methylene protons of the ethoxy group is complex. In addition to the coupling between the CH_2 and CH_3 protons, there is a spin–spin splitting of the CH_2 protons by the phosphorus. Butyl derivatives give too complex spectra to allow analysis. The proton of the benzylic CH group usually appears as a doublet of doublets, because of the spin–spin interaction with the phosphorus (J = 22 Hz) and with the NH proton (J = 8 Hz).[13,21] D_2O exchange eliminates the smaller splitting and retains the larger one. In the *p*-hydroxy substituted derivatives the doublet observed is broad and blurred. Shaking with D_2O produces a sharp doublet. The NH proton is found as a broad singlet (δ 5–6 ppm), while the phenolic OH group is hidden by the aromatic protons.

Conductivity measurements

The conductance of sodium monoalkyl benzeneazophosphonates and their complexes with DBC was investigated in methanol and acetonitrile at 25°C. The values of the equivalent conductance at infinite dilution (Λ_o) and the ion-pair dissociation constants (K_D) of the complexes are compared with those obtained for the free sodium salts, and the results are summarized in Table 4.

It was shown that the sodium salts and their complexes are completely dissociated in a methanolic solution. With all complexes the difference Λ_o(NaA) − Λ_o(NaA · DBC) is substantial, implying that the average cross-section of the complexed sodium ion is larger than that of the solvated one. Some additional interaction of the complex cation with solvent molecules, which becomes possible after the anion is removed, causes a further decrease in the mobility of the cation complex. The gradation in Λ_o values of the complexes reflects the increase in their bulkiness.

Sodium monoalkyl benzeneazophosphonates are slightly soluble in acetonitrile at room temperature, and only for the *p*-methoxy-substituted derivatives could the conductance measurements be performed. Our studies indicate very small K_D values for free salts and their macrocyclic polyether complexes. The low symmetry of monoalkyl benzeneazophosphonato anions with sites of charge localization may account for the increased association observed in these compounds. A similar behaviour was found in acetonitrile solutions for picrate complexes of some macrocyclic polyethers.[17] The fact that the total drop in the equivalent conductance for the complexes is remarkably smaller in acetonitrile than in methanol, can be explained by the weaker solvation and the great ion-pair association in acetonitrile solutions.

The results of the present investigation corroborate the results obtained in the recently published conductometric studies of the complexes of various alkali metal salts with macrocyclic polyethers in methanol[11,22] and acetonitrile.[17,23]

The conduction process is not only conditioned by the size of the complexes which are formed, but also by competitive interactions with the cation caused by the solvent and the macrocyclic polyether. The anion in a salt–ligand system is important for the ease of solubilization and the resulting charge separation in solution. Applications involving phase-transfer catalysis often restrict variables to a choice of ligand, cation and its counterion.

PREPARATION AND STUDY OF SILVER MALEONITRILEDITHIOLATE COMPLEXES

F. ESTEVAN, P. LAHUERTA* and I. SOLANA

Departamento de Química Inorgánica, Facultad de Químicas, Universidad de Valencia, Burjasot, Valencia, Spain

(*Received* 15 *May* 1985; *accepted* 26 *May* 1985)

Abstract—This paper reports the reaction of $Ag_2(mnt)$ and $[(NEt_4)Ag(mnt)]$ (mnt^{2-} = maleonitriledithiolate) with PPh_3 and 1,2-bis(diphenylphosphino)ethane. In the first case, compounds of formulation $[Ag_2(mnt)(PPh_3)_4]$ and $[(NEt_4)Ag(mnt)(PPh_3)_2]$ were isolated. ^{31}P NMR and conductivity measurements suggest that the complex $[Ag_2(mnt)(PPh_3)_4]$ has an ionic structure in solution, $[Ag(PPh_3)_2]^+[Ag(mnt)(PPh_3)_2]^-$, with an anion–cation interaction via a sulfur atom from the mnt ligand.

The transition-metal complexes with 1,2-dithiolene ligands have attracted considerable interest over the last decades because of their special properties, like the ability to undergo reversible oxidation–reduction processes. This produces series of structurally similar molecules apparently differing in the formal oxidation state for the metal.[1,2]

Many complexes with the ligand 1,2-maleonitrile dithiolate (mnt^{2-}) are known,[3] but only a few references are found in the literature for silver mnt^{2-} complexes.[4,5]

The preparation of $Ag_2(mnt)$ by reacting $AgNO_3$ with $Na_2(mnt)$ in water–chloroform,[4] has been reported previously but without describing any reactivity. The same compound has been prepared by an indirect reaction from $[(NEt_4)Cu(mnt)_2]$.[6] A related complex of stoichiometry $[Ag_2(mnt)(PPh_3)_4]$ has been briefly described by Caffery and Coucouvanis[5] through reaction of $Na_2Ni(mnt)_2$ with $Ag(PPh_3)_2Cl$.

We report in this paper the preparation of complexes of Ag(I) with mnt^{2-} and their reactivity with PPh_3 and diphosphines, as well as some ^{31}P NMR data on some of the most representative compounds.

EXPERIMENTAL

$Na_2(mnt)$ was recrystallized by dissolving it in ethanol–isopropanol (1 : 1) and precipitating it with diethyl ether. It is unstable and decomposes even in an inert atmosphere. The solvents were deoxygenated prior to use. All the reactions were carried out in an inert atmosphere using the Schlenck technique.

Preparation of the compounds

$Ag_2(mnt)$ (I). This compound was prepared by a modified version of the previously described method.[4]

A solution of $AgNO_3$ (459 mg, 2.7 mmol) in water (10 cm^3) was added to a solution of $Na_2(mnt)$ (168 mg, 0.9 mmol) in acetone (50 cm^3). The precipitation was completed in 10 min. The precipitate was filtered, washed with acetone–water (5 : 1) and then with acetone. The compound was dried *in vacuo* over P_4O_{10}. (Found: C, 13.4; N, 7.8. $C_4Ag_2N_2S_2$ requires: C, 13.5; N, 7.5%.) Melting point 170°C (decomposes).

$(NEt_4)Ag(mnt)$ (II). A solution of $AgNO_3$ (155 mg, 0.9 mmol) in water (8 cm^3) was added to a solution of $Na_2(mnt)$ (166 mg, 0.9 mmol) in acetone (60 cm^3). Then a solution of $NEt_4Cl \cdot H_2O$ (164 mg, 0.9 mmol) in water (6 cm^3) was added. The solvent was evaporated under reduced pressure until the volume was approximately 20 cm^3, precipitating a red–orange compound which was filtered, washed with water and dried *in vacuo* over P_4O_{10}. (Found: C, 38.4; H, 6.0; N, 10.0. $C_{12}H_{20}AgN_3S_2$ requires: C, 38.1; H, 5.3; N, 11.1%.) Melting point 160°C (decomposes).

$Ag_2(mnt)(PPh_3)_4$ (III). PPh_3 (223 mg, 0.85 mmol) was added slowly to a suspension of $Ag_2(mnt)$ (61 mg,

* Author to whom correspondence should be addressed.

0.17 mmol) in DMF (15 cm^3). The silver compound was dissolved giving a yellow solution from which yellow crystals separated by standing at room temperature. The crystals were filtered, washed with diethyl ether and dried *in vacuo*. The compound can be recrystallized from CH_2Cl_2–acetone. (Found: C, 64.4; H, 4.4; N, 2.0. $C_{76}H_{60}Ag_2N_2P_4S_2$ requires: C, 65.0; H, 4.3; N, 2.0%.) Melting point 185°C.

Other solvents, like acetone, CH_2Cl_2 or $CHCl_3$, can be used for this preparation, but the best-quality crystals are obtained from DMF.

The same compound is obtained by direct reaction of stoichiometric amounts of $Na_2(mnt)$, $AgNO_3$ and PPh_3 in the solvents previously mentioned.

When 1,2-bis(diphenylphosphino)ethane (dppe) (181 mg, 0.45 mmol) was used in the previous procedure, a compound of stoichiometry $[Ag_2(mnt)(dppe)_2]$ was obtained. (Found: C, 58.7; H, 4.4; N, 2.2. $C_{56}H_{48}Ag_2N_2P_4S_2$ requires: C, 58.3; H, 4.2; N, 2.4%.) Melting point 148°C.

$NEt_4Ag(mnt)(PPh_3)_2$ (**IV**). PPh_3 (81 mg, 0.3 mmol) was added to a suspension of $(NEt_4)Ag(mnt)$ (58 mg, 0.15 mmol) in acetone (10 cm^3). The mixture was stirred until a yellow solution was formed. The solvent was removed under reduced pressure and diethyl ether was added. The yellow precipitate was filtered, washed with diethyl ether and dried *in vacuo*. (Found: C, 64.1; H, 4.2; N, 5.3. $C_{48}H_{50}AgN_3P_2S_2$ requires: C, 63.9; H, 4.6; N, 5.5%.) Melting point 194°C.

The same compound was obtained by direct reaction of stoichiometric amounts of $Na_2(mnt)$, $Ag(PPh_3)_2NO_3$ and $NEt_4Cl \cdot H_2O$ in the same solvent.

When dppe (60 mg, 0.15 mmol) was used in the previous procedure a yellow compound of stoichiometry $[(NEt_4)Ag(mnt)(dppe)]$ was obtained. (Found: C, 58.4. $C_{38}H_{44}AgN_3P_2S_2$ requires: C, 58.7%.) Melting point 158°C.

RESULTS AND DISCUSSION

I was obtained by reacting $Na_2(mnt)$ with $AgNO_3$ in acetone–water. The insolubility of **I** in all the common solvents suggests a polymeric nature. Its amorphous structure was confirmed by X-ray diffraction.

This product reacts with basic phosphines or diphosphines in almost any solvent. No reaction was observed with more π-acid P-donating ligands like $P(OMe)_3$ or $P(OPh)_3$, or with N-donating ligands. The resulting compounds can only be isolated in the crystalline state when PPh_3 or dppe are used.

The product of the reaction of **I** with PPh_3 gives an analysis of **III**. It behaves as a 1:1 electrolyte in acetone, but the values of molar conductivity in this solvent are low. The representation of $(\Lambda_0 - \Lambda)$ vs $\sqrt{c}$ according to Feltham and Hayter[7] is a straight line with a slope similar to the 1:1 electrolytes. An increase in the molar conductivity is observed by addition of an excess of PPh_3 to the solution of compound **III** in acetone.

The reaction of **II** with PPh_3 yields a yellow compound (**IV**). This compound behaves as a 1:1 electrolyte in acetone.

The ^{31}P NMR spectrum of **III** in CD_2Cl_2 at room temperature shows a broad signal at $\delta = 7.0$ ppm (reference $\delta = 0$ for 85% H_3PO_4 in D_2O). When some PPh_3 was added to the sample, the signal shifted towards a higher field.

This result indicates the existence of a fast dissociative process for the phosphine ligand, already reported for other silver–phosphine complexes.[8]

The low-temperature spectrum (−96°C) shows eight signals corresponding to two doublets of doublets centered at $\delta_1 = 6.0$ ppm and $\delta_2 = 4.6$ ppm, indicating the presence of two different silver moieties in solution with different values of ^1J(Ag—P) coupling constants.

Muetterties and Alegranti[9] have established a direct relationship between the *s* character in the Ag—P bond and the values of ^1J(Ag—P) valid for several silver–phosphine complexes. According to these values we can fix the signal at 4.6 ppm [$^1J(^{107}Ag—P) = 223$ Hz] to the phosphine ligands bonded to a tetracoordinated silver atom, and the signal at 6.0 ppm [$^1J(^{107}Ag—P) = 309$ Hz] to phosphine bonded to a tricoordinated silver atom.

The ratio $^1J(^{109}Ag—P)$: $^1J(^{107}Ag—P)$ is equal to 1.15, approximating the theoretical value (1.149).[10]

The ^{31}P NMR spectrum of compound **IV** at −96°C shows two doublets centered at $\delta = 4.6$ ppm with $^1J(^{107}Ag—P) = 223$ Hz. This coupling constant value is in good agreement with that calculated for tetracoordinated silver atoms. The δ (ppm) and $^1J(^{107}Ag—P)$ values are identical to the signals observed for compound **III**.

These spectroscopic results indicate that the tetracoordinated anionic species

$$[Ag(mnt)(PPh_3)_2]^-$$

is present in solution in compounds **III** and **IV**.

The conductivity values for compounds **III** and **IV** indicate the existence of an ionic equilibrium at room temperature as follows:

$$[Ag_2(mnt)(PPh_3)_4] \rightarrow [Ag(PPh_3)_2]^+ + [Ag(mnt)(PPh_3)_2]^-,$$

$$[(NEt_4)Ag(mnt)(PPh_3)_2] \rightarrow [NEt_4]^+ + [Ag(mnt)(PPh_3)_2]^-.$$

Table 1. ^{31}P NMR parameters for the complexes

	$^1J(^{107}Ag—P)$ (Hz)	$^1J(^{109}Ag—P)$ (Hz)
$[Ag_2(mnt)(PPh_3)_4]$	309 223	354 257
$[(NEt_4)Ag(mnt)(PPh_3)_2]$	223	258
$[Ag\{P(C_7H_7)_3\}_4PF_6]$[a]	224	
$[Ag\{P(C_7H_7)_3\}_3PF_6]$[a]	321	
$[Ag\{P(C_7H_7)_3\}_2PF_6]$[a]	496	

[a] Values obtained from Ref. 9.

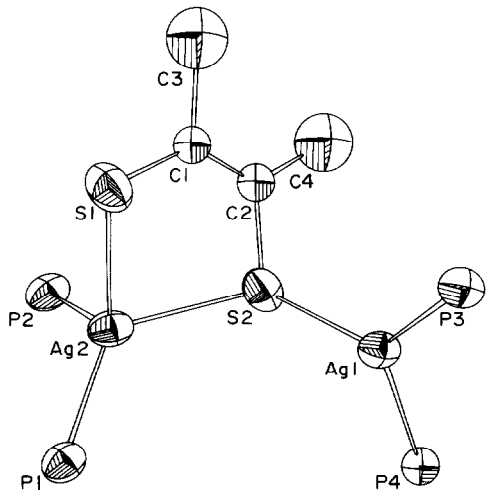

Fig. 1.

The low value of $^1J(^{107}Ag—P)$ observed at −96°C for the second signal in the spectrum of compound **III** is more consistent with the existence of an sp^2 hybridisation in the cationic silver species, indicating the existence at this temperature of an anion–cation interaction via S—Ag bonds. This result is in accordance with the low values for molar conductivity found for this compound and with the increase in molar conductivity by addition of PPh_3 to a solution of compound **III** in acetone.

An S—Ag interaction is observed in the molecular structure of **III** in the solid state[11] (see Fig. 1).

A similar interaction is found in the complex $[Ag(PPh_3)_2]_2[Ni(mnt)_2]$.[12]

The ^{31}P NMR spectra of compounds

$[Ag_2(mnt)(dppe)_2]$

and

$[(NEt_4)Ag(mnt)(dppe)]$

at low temperature are more complex than for compounds **III** and **IV**, suggesting the existence of more equilibria in solution.

Acknowledgement—We thank Mrs B. Ulbrich for technical assistance in the preparation of the ligand.

VARIABLE-TEMPERATURE FOURIER TRANSFORM IR AS A PROBE OF INTERMOLECULAR FORCES: APPLICATION TO ORGANOTIN COMPOUNDS

R. H. HERBER

Department of Chemistry, Rutgers, The State University of New Jersey, New Brunswick, NJ 08903, U.S.A.

(*Received* 21 *February* 1985; *accepted after revision* 29 *May* 1985)

Abstract—The medium and strong IR absorptions of a number of organometallic complexes of Sn(IV) have been studied as a function of temperature over the range $78 \leqslant T \leqslant 300$ K and $4800 \geqslant \omega \geqslant 400$ cm^{-1}, using variable-temperature Fourier transform IR techniques. The positions of the IR bands are essentially temperature-independent (± 1 cm^{-1}) for $(C_6H_5)_4Sn$ and $(C_6H_5)_3SnCl$, which are aggregates of monomeric units in the solid state, whereas the IR bands of $(CH_3)_2SnF_2$, $(CH_3)_3SnF$ and $(CH_3)_2SnCl_2$, which form polymeric network solids, are observed to have appreciable frequency shifts with temperature. In particular, for the organotin polymers, both $\nu_{as}(SnC_2)$ and $\nu_s(SnC_2)$ shift to lower frequency as the temperature is raised, whereas the symmetric and antisymmetric CH modes shift in the opposite direction. A plausible origin for these temperature-dependent frequency shifts is suggested.

Modern techniques of Fourier transform IR (FTIR) spectroscopy have provided the experimentalist with a powerful new tool for the study of vibrations of molecular systems. Among the major strengths of this methodology is the digitization of the spectral data (intensity and band profile) and reference of the wavelength scale to a laser-locked frequency standard which permits the determination of absorption band positions with high accuracy and with replicability from spectrum to spectrum.

Because the IR power deposition[1] on the sample in an FTIR spectrometer is of the order of two magnitudes smaller than it is in a typical dispersive IR spectrometer, it has become possible to carry out vibrational spectroscopic studies over the cryogenic-temperature range (4.2–300 K) using relatively simple cooling techniques, and to gather such IR data conveniently and rapidly. This method of variable-temperature Fourier transform IR (VTFTIR) spectroscopy has opened up a new area of investigation of the temperature dependence of IR absorptions, and in particular of the study of the effect of inter-molecular forces on the band positions of IR active modes in solids. At the present time, there are very few data in the literature concerning the temperature dependence of IR modes in solids and what kind of information can potentially be extracted from such measurements.

SOME FUNDAMENTALS

In the following discussion a very simple phenomenological approach will be used to account in a qualitative manner for the temperature dependence of the IR band line positions in monomeric and polymeric covalent solids.[2] As a starting point we consider the relationship between the frequency, ν, of a vibration in a diatomic molecule, and the force constant, K, arising from the chemical bonding interaction between the two atoms; that is:

$$\nu = \frac{1}{2\pi}\left(\frac{K}{\mu}\right)^{1/2}, \tag{1}$$

where μ is the reduced mass of the diatomic system. K, in turn, is given by the second derivative of the interatomic potential and coordinate:

$$K = \left(\frac{\partial^2 V}{\partial q^2}\right) \tag{2}$$

and is thus related to the shape of the potential energy surface in the vicinity of the two quantized vibrational levels involved in the spectroscopically detected transition. For a diatomic molecule in the gas phase, the potential energy surface for a given set of vibrational states is insensitive to temperature, and hence the energy difference between the two

states will be temperature-insensitive. By extension, in covalent solids with small or negligible intermolecular forces, the frequency of a given vibrational transition will be temperature-insensitive, since the shape of the potential energy surface does not change significantly with temperature. The cubic expansion coefficient for such solids reflects the increase in vibrational amplitudes as the temperature is raised, but such effects do not change significantly the frequency of the transition between a given set of vibrational states, nor—to a first approximation—the equilibrium internuclear distances and electron densities at a given lattice site in the solid.

When intermolecular forces are not negligible, as in polymeric compounds, or where there are significant hydrogen bonding forces between adjacent molecules, the temperature dependence of K becomes significant, and hence some (or all) of the spectroscopically active transitions will show a non-negligible temperature dependence. If one considers a linear polymer of the form ... ABAB ..., the cubic expansion (thermal) of the solid will influence the internuclear distances of all the atoms in the chain, and hence the shape of the potential energy surface and the overlap of the electronic (molecular) wave functions which obtain in the condensed matter matrix. In the presence of such intermolecular forces, $V = V(T)$, and hence $K = K(T)$, so that $\nu = \nu(T)$. A similar situation is expected to arise in solids in which the monomer units are tied together by strong intermolecular interactions in two and three dimensions, since, in principle, the cubic expansion of such solids should result in a change in the electron density at each atomic lattice point.

In this connection, two points need to be kept in mind: the IR-active modes considered (experimentally) in the discussion below are—in general—not fundamental normal modes, but involve a variety of combination modes in which several motional symmetries may be coupled to give rise to the absorption being measured. Secondly, it is likely that thermal expansion—and the concomitant change in K in molecular solids—will result in both positive and negative shifts in IR band positions, and in some instances, mutual cancellation of opposing effects may, in fact, result in a temperature invariance of *some* of the bands observed in the spectra. Thus it is appropriate to consider *all* of the IR-active modes which can be observed in such solids.

It is the purpose of the present study to demonstrate that $\nu(T)$ reflects the presence (or absence) of strong intermolecular interactions in solids, and to suggest the utility of such temperature dependencies of vibrational mode frequencies in the study of polymer interaction in solids.

EXPERIMENTAL

All of the compounds examined in the present study were obtained commercially,[3] and purified by recrystallization [e.g. $(C_6H_5)_3SnCl$ from hexane and $(C_6H_5)_4Sn$ from 1,1,2-trichloroethane] as necessary. Dimethyltindichloride was resublimed twice at ~ 1 torr and 50–60°C prior to use. Pellets were prepared by pulverizing the subject compound with spectroscopic grade KBr in a plastic ball mill ("wiggle bug") arrangement and pressing the resultant powders at 20,000 lb in^{-2} in an evacuated die, using a concentration of 0.5–1% by weight.

These pellets were clamped into an Invar cell (chosen because of the exceptionally low thermal expansion coefficient of this material to prevent breakage of the sample pellet on thermal cycling) which in turn was mounted on the copper cold finger of a Heli-tran cryostat[4] whose temperature was monitored via thermocouples attached to the copper block adjacent to the sample space. The thermal lag between the temperature registered by the thermocouple and that of the KBr disc was determined experimentally, using the well-defined first-order phase transitions in adamantane,[5] NH_4Br[6] and benzil.[7] This thermal lag was determined to be less than 0.5° in the range $78 \leqslant T \leqslant 300$ K.[8]

IR spectral data were obtained using a nitrogen purged IBM 32 FTIR spectrometer. In a typical scan, the sample was allowed to reach thermal equilibrium (usually 15–20 min, although ancillary data suggested that a steady-state value was reached in less than 5 min under the prevailing conditions), after which time 100 interferometer scans were co-added and ratioed to a background obtained with a comparable KBr blank in the sample compartment. The peak positions of the relevant (medium- or strong-intensity) IR bands were determined using the IBM IR software in the manual (cursor) mode or by using the PEAKPICK software. Replicate scans, using different samples, and acquired several days apart, showed that line positions of a given band at a given temperature were reproducible within an error of ± 0.5 cm^{-1} or less at a resolution of 2 cm^{-1}.

RESULTS AND DISCUSSION

Tetraphenyltin(IV)

The crystal structure of this molecule has been reported by Chieh and Trotter[9] who concluded that the solid is composed of discrete molecular units, despite the fact that it has a relatively high melting point (229°C) and exhibits an observable ^{119}Sn

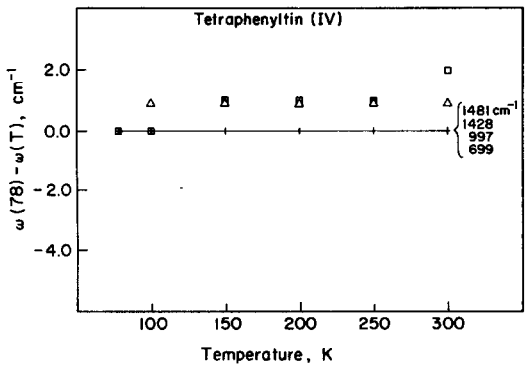

Fig. 1. Temperature dependence of the most prominent mid-range IR modes of tetraphenyltin(IV). The shift is taken with respect to the band position observed at 78 K. The horizontal axis indicates the sample temperature in K. The crosses pertain to four temperature-invariant modes at 699, 997, 1428 and 1481 cm^{-1}.

Mössbauer resonance at room temperature.* The effect of temperature change on the angle of rotation of the molecule about the $\bar{4}$ axis, the z-axis of the crystal, is not known, especially in a KBr matrix. Nonetheless, for the purposes of the present discussion this compound is taken to be representative of a covalent solid with negligible intermolecular forces. The vibrational spectrum shows nine medium or strong IR active bands in the range $400 \leqslant \omega \leqslant 1600$ cm^{-1}. The temperature dependence of the band positions is summarized graphically in Fig. 1, from which it is noted that the maximum frequency shift, $\Delta\omega$, defined by:

$$\Delta\omega(T) = \omega(78\text{ K}) - \omega(T),$$

is 2 cm^{-1} for the y'-mode, identified either as the symmetric Sn—C stretch[10] or an out-of-plane ring bending mode.[11,12] For all of the other bands, over the entire temperature range, the band position is either temperature-invariant or within the experimental uncertainty cited above. This temperature invariance of the band positions over a 200° temperature interval is taken to be characteristic of covalent monomeric solids. With two exceptions, the observed band positions are in good agreement with the data cited in the literature. The CH out-of-plane bending mode (ν_{11b}, ν_{10b}) reported[13] as a strong absorption at 710 cm^{-1} is observed in the present study at 699 cm^{-1}, while the comparable mode (ν_4) reported earlier[13] at 745, and 736 cm^{-1},[14] is seen at 731 cm^{-1} in the present work.

Triphenyltin(IV) chloride

Although there has been some speculation in the literature concerning the possible penta-coordination of the metal atom in this molecule at low temperature,[15,16] detailed variable-temperature ^{119m}Sn Mössbauer effect studies[17] in the range $4.2 \leqslant T \leqslant 300$ K have failed to support a transition from the tetracoordination at room temperature which can be inferred from the crystallographic data of Bokii *et al.*[18] and the IR data of Kriegsmann and Geissler,[10] and which argues against the presence of bridging chlorine ligands at room temperature. The temperature independence of the IR modes of this solid support this conclusion, since none of the nine medium- or strong-intensity bands reported by Kriegsmann and Geissler[10] and Griffiths and Derwish[13] show a temperature dependence outside the resolution limit of the present study. The temperature dependence of $\Delta\omega$ for the nine modes observed in the frequency range $400 \leqslant \omega \leqslant 1600$ cm^{-1} are summarized graphically in Fig. 2. The combination band $\nu_5{}^1$ at 1156 cm^{-1}, which involves the Sn—C asymmetric stretch, and the weak band ν_5 at 1064 cm^{-1}, which involves the Sn—C symmetric stretch [reported at 1156 and 1072 cm^{-1}, respectively, in tetraphenyltin(IV) by Randle and Whiffen[19]] are apparently completely temperature-invariant under the conditions of the present study.

Dimethyltin(IV) difluoride

In contrast to the two monomeric solids considered above, this compound is a well-characterized polymeric material in which fluorine bridges join adjacent six-coordinate metal centers in an infinite lattice. A detailed X-ray diffraction structural study has been reported by Schlemper and

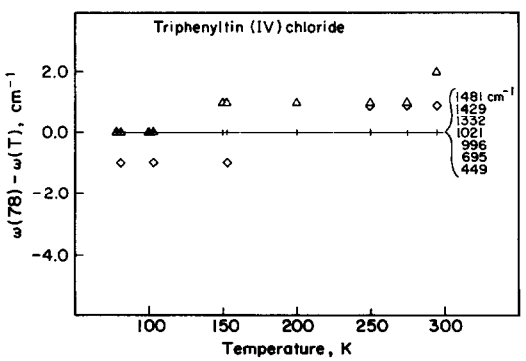

Fig. 2. Temperature dependence of the most prominent IR modes of triphenyltin(IV) chloride. The crosses pertain to seven temperature invariant modes at 449, 695, 996, 1021, 1332, 1429 and 1481 cm^{-1}. For axes, see caption to Fig. 1.

* It has been pointed out by one of the reviewers that "... a convincing case can be made that this material acts as a 'virtual polymer', even though the closest carbon–carbon approach is 3.54 Å—a van der Waals' interaction".

Hamilton[20] and the IR spectrum has been examined by Hobbs and Tobias[21] and Goldstein and Unsworth,[22] *inter alia*. The latter authors have also reported the IR spectrum of $(CH_3)_2SnF_2$ at ~120 K and note a 1-cm^{-1} shift in the symmetric SnC_2 stretch over their temperature range. The rotational barrier of the methyl group is calculated to be ~1 kJ mol^{-1} at 296 K. Hobbs and Tobias[21] have carried out a complete normal coordinate analysis of this compound, making the assumption that the constituent moieties are $(CH_3)_2Sn^{2+}$ cations and F^- anions, and make use of a Urey–Bradley force field equation to calculate K_{C-H} (4.63 ± 0.02 mdyne $Å^{-1}$), K_{C-Sn} (1.53 ± 0.06 mdyne $Å^{-1}$) and K_{Sn-F} (0.99 ± 0.04 mdyne $Å^{-1}$).

The temperature dependence of the IR band positions for this compound are summarized in Fig. 3, from which it is seen that there are gradual and significant shifts in the line positions of all of the medium and strong bands observed in the spectrum. In particular, both the symmetric and asymmetric SnC_2 stretches (526 and 599 cm^{-1} at 295 K, respectively) show a similar decrease in frequency with an increase in temperature, and this is also comparable to the symmetric $\delta(CH_3)$ mode at 1206 cm^{-1}. On the other hand the CH_3Sn rocking mode at 780 cm^{-1} and both the symmetric and asymmetric methyl group CH stretches at 2930 and 3015 cm^{-1} show a similar frequency increase over the same temperature interval.

Of the seven assigned modes in the interval $3100 \geq \omega \geq 400$ cm^{-1}, with the exception of the weak band at 1408 cm^{-1} assigned to the asymmetric bending mode of the methyl group, all show a temperature dependence of the line position to be expected if the electron density at *each* atomic lattice

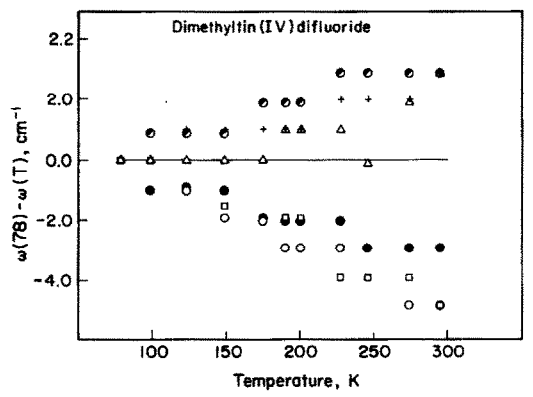

Fig. 3. Temperature dependence of the most prominent IR modes of dimethyltin(IV) difluoride. The following symbols are used: (○) $\rho(CH_3Sn)$, (□) $\nu_{as}(CH_3)$, (●) $\nu_s(CH_3)$, (+) $\delta_s(CH_3)$, (△) $\nu_s(SnC_2)$, and (◑) $\nu_{as}(SnC_2)$. For axes, see caption to Fig. 1.

point is influenced by the thermal expansion of the solid as the temperature is increased. In contrast to the observations noted for the two monomeric aryl tin compounds, none of the significant IR absorptions remain temperature-invariant. To ensure that the temperature-dependent frequency shifts observed in the IR spectra of $(CH_3)_2SnF_2$ are not matrix-dependent, a replicate set of experiments was carried out, using TlBr as a dispersant, instead of KBr, since the heavier bromide crystallizes in the CsCl structure, while KBr has the NaCl structure. However, using TlBr as above, the results are completely identical (within experimental error) to those observed using the KBr matrix samples—both $\nu_s(SnC_2)$ and $\nu_{as}(SnC_2)$ move to lower frequencies as T is increased, whereas $\nu_s(CH_3)$, $\nu_{as}(CH_3)$ and $\rho(CH_3Sn)$ all move to higher frequencies. These results confirm the assumption that the temperature-dependent frequency shifts observed in this polymeric solid reflect the electron distribution in the molecule rather than being an artifact of the dispersing medium, although the possibility of halogen exchange within the matrix is not directly addressed by this procedure.

Trimethyltin(IV) flouride

The structure of this polymeric solid was determined by Clark *et al.*[23] and discussed in detail in the review by Ho and Zuckerman.[16] A fundamental disorder of the fluorine atoms and the F—Sn—F chains in the crystal at room temperature prevents the structure of trimethyltin fluoride from being solved to the usual R factors.[23] The solid is composed of non-planar $(CH_3)_3Sn$ units bridged by fluorine atoms to give rise to a zig-zag chain with non-linear Sn—F—Sn units. IR assignments for this compound have been reported by Kriegsmann and Pischtschan[24] and Yasuda.[25] The presence of strong inter-monomer unit forces is inferred both from the optical and chemical properties of this material, as well as from the observation by Licht *et al.*[26] of a 239-cm^{-1} shift of the Sn—F vibration in going from the polymeric solid- (349 cm^{-1}) to the gas-phase monomer (588 cm^{-1}), which may be ascribed to a change from five to four coordination around the metal atom.

The temperature dependence of the four prominent modes in the $1600 \geq \omega \geq 400$ cm^{-1} range is summarized in Fig. 4. The symmetric SnC_3 mode at 619 cm^{-1} is too weak in the IR spectrum to be used in the present analysis, although the non-planar $Sn(CH_3)_3$ configuration should make this band (which is observed as a strong absorption at ~520 cm^{-1} in the Raman spectrum) extractable from the spectra. As noted from Fig. 4 the three CH_3

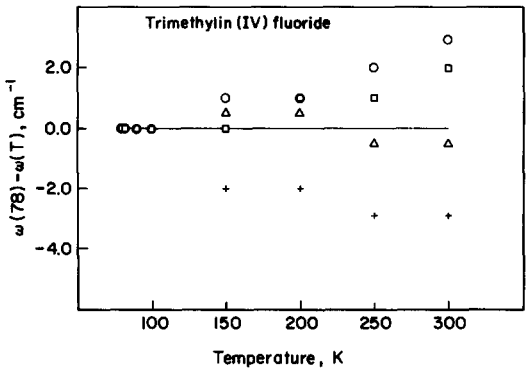

Fig. 4. Temperature dependence of the most prominent IR modes of trimethyltin(IV) fluoride. The following symbols are used: (△) $\rho(CH_3)$, (+) $\rho(CH_3)$, (□) $\nu_{as}(SnC_3)$, and (○) $\delta_s(CH_3)$. For axes, see caption to Fig. 1.

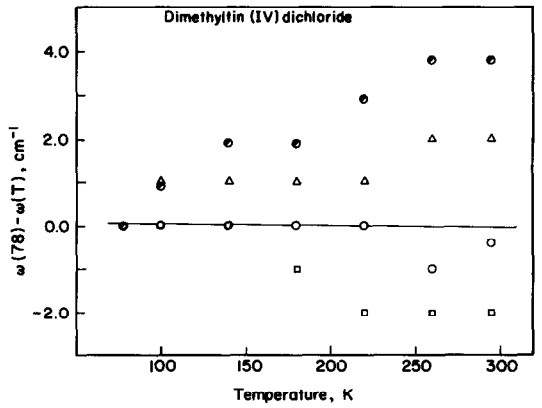

Fig. 5. Temperature dependence of the most prominent IR modes of dimethyltin(IV) dichloride. The following symbols are used: (○) $\nu_{as}(CH_3)$, $\delta_s(CH_3)$ and $\rho(CH_3)$, (◑) $\nu_{as}(SnC_2)$, (△) $\nu_s(SnC_2)$, and (□) $\delta_{as}(CH_3)$.

modes at 782, 1189 and 1210 cm^{-1}, as well as the asymmetric SnC_3 stretch show a progressive shift as the temperature is raised from 78 to 300 K. As in the case of the two-dimensionally polymeric $(CH_3)_2SnF_2$, the one-dimensionally polymeric $(CH_3)_3SnF$ shows the temperature-dependent IR band shifts discussed above. For these solids with one or more strong intermolecular bonding interactions, the present data suggest a small but real change in the electron density around the central metal atom as thermal expansion effects a change in the internuclear distance of the atoms involved in this bonding mode.

Dimethyltin(IV) dichloride

The structure of this solid has been discussed by Davies *et al.*[27] who were able to show that adjacent $(CH_3)_2Sn$ units are bridged by four chlorine atoms, two of which have Sn—Cl distances of 2.40 Å and the other two (in an approximately *trans* position) of 3.54 Å. The C—Sn—C bond angle is found to be 123.5° so that the local environment around the metal atom is that of a symmetry strongly distorted away from tetrahedral. Such large distortions from ideal T_d-geometry—even in the absence of bridging interactions of the chloride ligands—appear to be more common than has been assumed, but are usually associated with sterically demanding (i.e. bulky) organic moieties attached to the metal atom. As Baxter *et al.*[28] have recently pointed out in connection with their structural study of bis(biphenylyl-2) tin(IV) dichloride, compression of the Cl—Sn—Cl bond angle to 99.71°, and expansion of the C—Sn—C bond angle to 130.8°, can be traced to steric demands of the organic group rather than to any involvement of the halogen atom in bridging behavior. Such steric demands are, however, minimal in $(CH_3)_2SnCl_2$. The absence of an inversion center at the metal atom leads to the ready observation of both $\nu_{as}(Sn—C_2)$ and $\nu_{as}(Sn—C_2)$ at 566 and 516 cm^{-1}, respectively, as sharp intense bands in the IR spectrum. The most prominent band in the spectrum is a broad intense band at 799 cm^{-1} assigned by Edgell and Ward[29] to a CH_3 rocking mode. Other IR assignments for this compound have been reported by Taimsalu and Wood[30] and Okawara *et al.*[31] The only mode which is too weak to be used in the present analysis is the $\nu_s(CH_3)$ band at ~2925 cm^{-1}, although this band has been reported[29] to be of strong intensity in the IR spectrum of the liquid.

The temperature dependence of the six most prominent IR active bands of $(CH_3)_2SnCl_2$ is shown in Fig. 5. Of these, $\nu_{as}(CH_3)$, $\delta_s(CH_3)$ and $\rho(CH_3)$ at 3013, 1201 and 799 cm^{-1}, respectively, are essentially temperature-independent over the range $78 \leqslant T \leqslant 300$ K, while the mode at 566 cm^{-1}, due to the asymmetric SnC_2 stretch, shows the most pronounced variation with temperature, being red shifted by 3.8 cm^{-1} between 78 K and room temperature. In addition, both the $\delta_{as}(CH_3)$ mode at 1404 cm^{-1} and the symmetric SnC_2 stretch at 516 cm^{-1} show a small temperature dependence, as expected from the polymeric structure of this compound.

CONCLUSIONS

In the present study of the IR spectra of a number of organotin(IV) compounds, it has been observed that, for those solids which are comprised of non-interacting monomeric molecular entities, the location of the most prominent absorption bands is essentially temperature-independent over the range

$79 \leqslant T \leqslant 300$ K within an experimental resolution limit of $\sim \pm 1$ cm^{-1}. In contrast, the spectra of associated solids which form one- or two-dimensional polymeric structures, all of the prominent absorption bands show temperature-dependent frequency shifts. On the basis of currently available data it is inferred that these frequency shifts originate from bond distance changes resulting from thermal expansion of the solid. These changes in the internuclear distances of some of the bonded atom pairs in the structure result in principle—by virtue of electron-following effects—in a change in the electron density in all of the bonding overlaps in the molecule.

The magnitudes of the effects observed in the present study are not large enough to answer the question of whether the temperature dependence of $\Delta\nu$, as defined above, is a linear function of temperature (as implied in the figures) or not. This question, as well as development of a more detailed theoretical treatment of the observed effects, is currently under study in these laboratories. Notwithstanding the paucity of the present results, it is clear that the experimental demonstration of temperature-dependent IR band positions has provided the spectroscopist with a new, sensitive and powerful tool for the study of intermolecular associations in covalent solids.

Acknowledgements—I am indebted to my colleagues, Professors K. Krogh-Jespersen and L. Goodman, for stimulating discussions of this problem. This research has been made possible by a grant from the National Science Foundation (DMR 810 2940) which also provided support for the acquisition of the FTIR Spectrometer.

CYANATO-COPPER(II) COMPLEXES WITH ORGANIC LIGANDS—XXIV.* DIISOCYANATO-BIS(3,5-DIMETHYLPYRAZOLE)COPPER(II)—THE CYANATE MEMBER OF THE COLIGAND ISOMER PAIR FROM THE Cu(II)–NCO^-–3,5-DIMETHYLPYRAZOLE SYSTEM

Department of Inorganic Chemistry, Slovak Technical University, 812 37 Bratislava, Czechoslovakia; and ‡Institute of Chemistry, Wrocław University, 50 383 Wrocław, Poland

(*Received* 18 *December* 1984; *accepted* 4 *June* 1985)

Abstract—The title compound was prepared, and found to be isomeric with the known bis(1-carbamoyl-3,5-dimethylpyrazolato)copper(II). Its IR, far-IR, electronic and ESR spectra were recorded and its magnetic susceptibilities down to 4.2 K were measured. A five-coordinate binuclear or polymeric chain structure is assumed with *N*-bridging as well as terminal NCO groups. The ESR spectrum shows zero-field splitting in the triplet state. The temperature-dependent magnetic behaviour is characteristic of an intramolecular ferromagnet. The exchange parameters were determined on the basis of a dimeric model and three various linear-chain models, and the fits were compared.

In 1979 we reported[2] the crystal and molecular structures of α-bis(1-carbamoyl-3,5-dimethylpyrazolato)copper(II), $Cu(dmpz \cdot NCO)_2$ (dmpz = 3,5-dimethylpyrazole), and the physical properties of this compound, as well as of its isomeric (β) form. The anionic chelate ligands in these complexes were formed by nucleophilic addition between dmpz and NCO in the Cu(II) coordination sphere. The isomeric cyanato complex, $Cu(NCO)_2(dmpz)_2$, which should form with $Cu(dmpz \cdot NCO)_2$ a pair of coligand isomers,[3] was not isolated at that time. However, in the course of further attempts we succeeded in preparing this complex. Therefore we report the preparation of $Cu(NCO)_2(dmpz)_2$ and its characterization by chemical analysis, spectroscopy and magnetochemistry. We used indirect structural methods, as we had not been able to obtain single crystals suitable for X-ray study.

EXPERIMENTAL

Preparation

A solution of 12.5 mmol of $Cu(NO_3)_2 \cdot 3H_2O$ in 10 cm^3 of water, cooled in a refrigerator, was mixed with a cooled solution of 26.5 mmol of KOCN in 10 cm^3 of water. The mixture was poured into a cooled solution of 23.7 mmol of dmpz in a mixture of 25 cm^3 of water and 15 cm^3 of methanol. From the resulting solution a green suspension has been separated, which changed into a blue, crystalline substance. This was washed with ice-cold water, dried in a desiccator with KOH, and put in a refrigerator. Found: C, 42.2; H, 4.7; N, 24.6; Cu, 18.8. Calc. for $C_{12}H_{16}N_6O_2Cu$: C, 42.4; H, 4.75; N, 24.7; Cu, 18.7%.

Physical measurements

Magnetic susceptibilities have been measured in the range of 4.2–300 K using a Faraday balance, calibrated using $HgCo(NCS)_4$.[4] Magnetic susceptibilities calculated per Cu(II) were corrected for diamagnetism of -180×10^{-6} cm^3 mol^{-1} and for temperature-independent paramagnetism of 60×10^{-6} cm^3 mol^{-1} to obtain χ_M^{corr} values. The effective magnetic moments, μ_{eff}, in Bohr magnetons, μ_B,§ were calculated from the formula $\mu_{eff} = 2.83(\chi_M^{corr}T)^{1/2}$. The exchange parameter, J, was obtained by fitting the susceptibility data to the respective theoretical model on an Odra 1204 computer. The spectroscopic splitting factor, g_{av}, obtained from the ESR spectrum, was used as a constant in the fitting process. The minimization of

the sum, defined as $ERR = \sum_{i=1}^{n} [\chi_M(calc.)_i - \chi_M(expt)_i]^2$, was the criterion used to determine the best fit.

The ESR spectrum was recorded using a JES-ME-3X spectrometer. The magnetic field was calibrated with Mn^{2+} ion doped in MgO ($\Delta H_{3-4} = 86.9$ G*).

The IR (3800–400 cm^{-1}),[5] far-IR (400–50 cm^{-1})[6] and electronic spectrum (4.0–0.4 μm^{-1})[7] were obtained as described in the cited papers.

The results of the physical measurements are listed in Tables 1–3.

RESULTS AND DISCUSSION

General

The analytical results of $Cu(NCO)_2(dmpz)_2$ are satisfactory for a chemical individual. The IR spectrum shows that the majority of the bands belonging to free dmpz[8] can be identified in the complex. Some of these bands, however, are perceptibly shifted, apparently as a consequence of coordination and possibly also the hydrogen bonding of dmpz (see IR section).

The blue compound $Cu(NCO)_2(dmpz)_2$ is sufficiently stable only in the cool. At ambient temperature it is gradually converted to a gray and finally a gray–black product. It is interesting that $Cu(NCO)_2(dmpz)_2$ does not change to the already investigated[2] α- or β-form of $Cu(dmpz \cdot NCO)_2$.

IR spectrum

The IR spectrum of $Cu(NCO)_2(dmpz)_2$ was compared with that of free dmpz published by Zecchina *et al.*[8] as well as of $CuCl_2(dmpz)_2$ and, thus, the bands of cyanate vibrations were picked out. These bands are indicative of the cyanate groups coordinated through nitrogens.[9] There are six absorptions between *ca* 670 and 590 cm^{-1}, which can be assigned only to the δ(NCO) mode. Such an extensive splitting indicates N-bridged NCO groups[9] and with respect to the number of bands, even two kinds of NCO groups (bridged and terminal) can be supposed.[10] The two well-separated bands in the region of 2200 cm^{-1} belonging to the ν_{as}(NCO) mode are consistent with the latter assumption.

For the NH stretching vibration two bands were found separated by ≈ 130 cm^{-1}, that of the higher frequency being shifted with respect to the band of free dmpz (in CCl_4 solution)[8] lower by ≈ 145 cm^{-1}. These facts suggest the occurrence of two NH···OCN hydrogen bonds of unequal strength formed from one structure unit. The behaviour of the NH deformation is still stranger, apparently involving four absorptions between *ca* 1190 and 1140 cm^{-1}.

The IR spectrum of the gray sample formed by the aging of blue $Cu(NCO)_2(dmpz)_2$ contains also bands characteristic of the species with chelate ligands of the carbamoylpyrazolate type.[2,3] In this substance apparently a fraction of the original ligands underwent a linking into the dmpz·NCO ligand system. Since all the cyanate bands remain present (somewhere with an additional splitting), probably only the terminal NCO groups are involved in the nucleophilic addition, the bridging ones being substantially unchanged.

Electronic spectrum

The electronic spectrum shows a broad ligand field band with the maximum at 1.56 μm^{-1} and a pronounced shoulder at about 1.28 μm^{-1}. Such a band accords with a planar nitrogen environment of Cu(II), being completed in one axial position by the

[a] Some values selected from among 60 experimental points are presented.

bridging cyanate nitrogen to a tetragonal pyramid.[11] In such a case the presence of bridging as well as of terminal NCO groups, indicated by the IR spectrum, is understandable and a binuclear (A) or polymeric chain (B) structure may be postulated (Fig. 1).

Far-IR spectrum

An approximate symmetry around Cu(II) in the proposed coordination environment is C_{2v}. Based on this local symmetry, we can expect 11 IR-active skeletal modes, five A_1 + three B_1 + three B_2. From those, two A_1 + two B_1 species are Cu—N(dmpz) as well as two in-plane Cu—NCO stretchings, and one B_2 species is the out-of-plane Cu—NCO stretching. The remaining species, three A_1 + one B_1 + two B_2, are Cu—N deformations.

An inspection of Table 2 reveals that three strong bands appear in the region allowable for stretchings involving the equatorial donors, viz. at 354, 295 and 258 cm^{-1}. We assign the first band to the in-plane Cu—NCO stretch[9] and the two bands below 300 cm^{-1} to the Cu—N(dmpz) stretch.[12] Thus, there is only a single in-plane Cu—NCO stretching band, but the relevant two modes may be accidentally degenerate or close to each other in energy.

The assignment of the lower-frequency bands is less warranted. By analogy with the region of the Cu—OCN stretches for the Cu(II) cyanate having long axial Cu—OCN bonding[6] we suppose that the medium band near 80 cm^{-1} might belong to the out-of-plane Cu—NCO stretch. Further bands occurring below 200 cm^{-1} are probably Cu—N deformations or torsions[13] and the $\approx$60 cm^{-1} band might also be a lattice vibration.

ESR spectrum

The ESR spectrum of $Cu(NCO)_2(dmpz)_2$ measured at two temperatures is presented in Fig. 2.

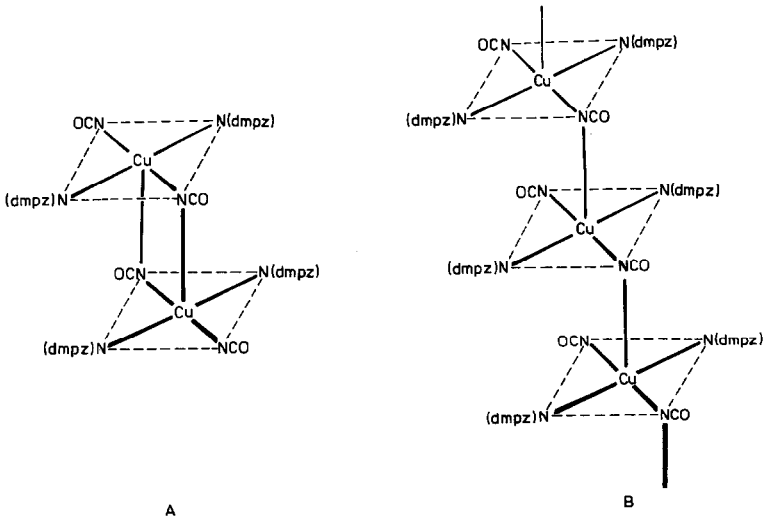

Fig. 1. Possible structure variants for $Cu(NCO)_2(dmpz)_2$.

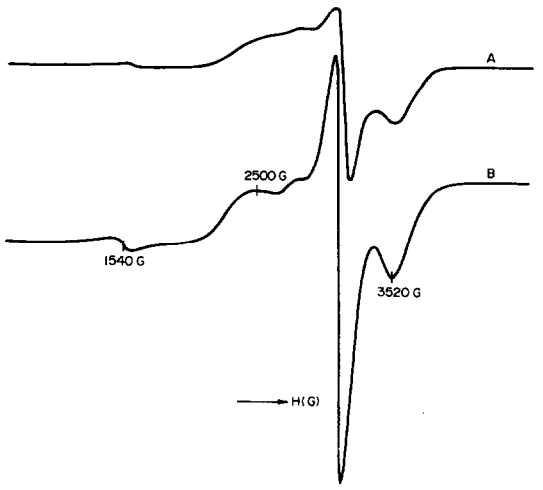

Fig. 2. ESR spectrum of $Cu(NCO)_2(dmpz)_2$ at 293 (A) and 193 K (B).

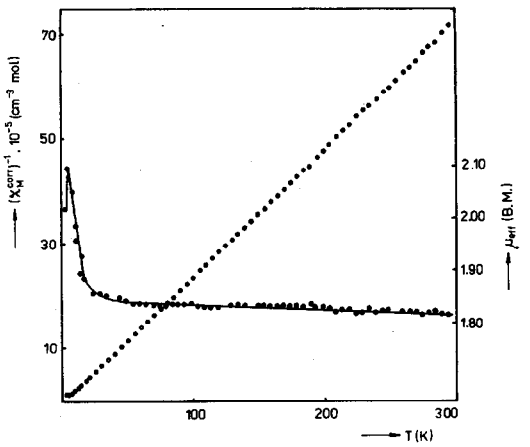

Fig. 3. Temperature dependence of inverse molar susceptibility (○) and magnetic moment (●) for $Cu(NCO)_2(dmpz)_2$.

At 293 K the spectrum consists of a very broad line spreading over ≈1600 G, with bulges at low and high fields. An improved resolution appears at 193 K when the spectrum shows distinct evidence of triplet state transitions.[14] Therefore, it has been interpreted on the basis of the usual spin Hamiltonian for $S = 1$. The bands at 2500 and 3520 G can be assigned to the low- and high-field parallel $\Delta M_S = 1$ transitions and this assignment leads to the values of $g_{\parallel} = 2.206$ and $D = 0.0526$ cm^{-1} (D = zero-field splitting parameter). In this calculation it was assumed that the orthorhombic splitting, E, is zero.

Since $h\nu > D$ ($h\nu$ is the microwave quantum of 0.310 cm^{-1}), the forbidden $\Delta M_S = 2$ transition was observed, viz. at 1540 G (see Fig. 2). From this resonance field position, H_{min}, and from the use of the following equation:[15]

$$g_{av} = \frac{(\omega_o^2 - \frac{4}{3}D^2)^{1/2}}{H_{min}},$$

where $\omega_o = h\nu$, a value of $g_{av} = 2.115$ is calculated.

The value of $g_{\perp}$ can now be obtained using the formula $g_{av} = \frac{1}{3}(2g_{\perp} + g_{\parallel})$; this value amounts to 2.070. Thus, the positions of the perpendicular $\Delta M_S = 1$ resonances would be predicted at *ca* 3410 and 3470 G, where they are superimposed by the high-field parallel absorption. The strong line centered at 3130 G cannot be reliably identified, but it might originate in monomeric paramagnetic impurities contaminating our compound.

Magnetic susceptibilities

The temperature dependence of the inverse molar magnetic susceptibility (Fig. 3) exhibits a Curie–Weiss behaviour over practically the whole temperature range of the measurements, with deviations only beginning to appear at the lowest temperatures. A least-squares analysis of the $(\chi_M^{corr})^{-1}$ vs T function with use of the Curie–Weiss law yields Curie–Weiss constant values for three temperature ranges (Table 4). In the region of 25–295 K, completely beyond the area of deviations, the C value is practically unchanged, but the θ value is somewhat higher.

The variation of the magnetic moment with temperature (Fig. 3) is characteristic of an intramolecular ferromagnet. With decreasing temperature the magnetic moment increases from 1.81 B.M. at room temperature to the maximum value of 2.10 B.M. at 5 K. Below this temperature, the decrease of μ_{eff} (2.03 B.M. at 4.2 K) was observed, probably due to the intermolecular antiferromagnetic interaction between the molecular units.

For the dimer (Fig. 1A) the magnetic susceptibility data were least-squares fitted to the Bleaney–Bowers equation[16] to give a J of $+3.23$ cm^{-1}.

For the polymeric system (Fig. 1B) the fitting was accomplished by the use of three different models for exchange coupling: the Heisenberg model for ferromagnetically coupled $S = \frac{1}{2}$ centres,[17] the Ising

Table 4. Parameters from the Curie–Weiss law

Temperature range (K)	C (cm^3 K mol^{-1})	θ (K)
4.2–295	0.413	1.89
6–295	0.413	1.97
25–295	0.412	2.26

Table 5. Estimated exchange parameters

Model	J (cm^{-1})	ERR $\times 10^4$
Binuclear Bleaney–Bowers	+3.23	0.817
Heisenberg model for ferromagnetically coupled $S = \frac{1}{2}$ ions	+0.93	1.53
Ising model for isolated regular chain	+0.80	1.83
One-dimensional zero-field Heisenberg model ($N+1$ spins)	+0.80	1.82

model for an isolated regular chain,[18] and the one-dimensional zero-field Heisenberg model ($N+1$ spins).[19] The exchange parameter values determined on the basis of these models (Table 5) are around +0.9 cm^{-1} and are much lower than those calculated from the binuclear model.

A comparison of the magnetic data fits for the two possible structures of the complex indicates that the binuclear model describes the susceptibility data more accurately than the linear chain models do, but this difference is not definitive.

The exchange coupling is realized most likely by a σ-orbital mechanism[20] using the orbitals of the bridging cyanate nitrogens for electron transfer and intraatomic direct exchange.

Conclusions

The compound $Cu(NCO)_2(dmpz)_2$, forming with $Cu(dmpz \cdot NCO)_2$ previously studied[2] a coligand isomer pair, shows in the family of $Cu(NCO)_2L_2$ complexes[9] a unique structure, as well as spectroscopic and magnetic properties. Its five-coordinate dimeric or polymeric chain structure with half of the NCO groups N-bridging the Cu(II) atoms has consequences in ferromagnetic exchange coupling and zero-field splitting in the triplet ground state. These interesting features are surely caused by the dmpz ligand and its structural properties, which also demonstrate the relatively difficult formation of the complex.

THE CHEMISTRY OF ISOMERS OF ICOSABORANE(26): CRYSTAL AND MOLECULAR STRUCTURE OF 1,2′-BI(*NIDO*-DECABORANYL)

SIMON A. BARRETT, NORMAN N. GREENWOOD,* JOHN D. KENNEDY and MARK THORNTON-PETT

Department of Inorganic and Structural Chemistry, University of Leeds, Leeds LS2 9JT, U.K.

(*Received* 8 *May* 1985; *accepted* 7 *June* 1985)

Abstract—The crystal and molecular structure of 1,2′-(*nido*-$B_{10}H_{13}$)$_2$ has been determined by single-crystal X-ray diffraction analysis, thus confirming the results of an earlier characterisation of this species by multi-element multiple-resonance NMR spectroscopy. Crystals were monoclinic, space group $P2_1/n$ with $a = 1099.7(2)$, $b = 1144.6(3)$, $c = 1409.4(3)$ pm, $\beta = 111.80(1)°$; final R factors were $R = 0.0467$ and $R_\omega = 0.0557$ for 3491 observed reflections. The intercluster boron–boron *conjuncto* linkage is 169.6(4) pm, and there appears to be a slight lengthening of intracluster boron–boron distances associated with the two atoms in the *conjuncto* linkage.

Since its initial characterization as an impurity in technical-grade *nido*-decaborane,[1] a number of routes have been used for the synthesis of icosaborane(26),[2–4] so that it is now the largest neutral binary borane that can be reliably synthesized (though in small yield).[5] Its constitution is that of bi(*nido*-decaboranyl), $[B_{10}H_{13}]_2$, and 11 distinct geometrical isomers are possible.[4] Of these the (1,2′), (1,5′), (2,2′), (2,5′), (2,6′), (5,5′) and (6,6′) isomers have been separated and structurally identified by NMR spectroscopy,[4,6] and the (1,5′), (2,2′) and (2,6′) isomers characterized by single-crystal X-ray diffraction analysis.[3,7,8] We now report the results of single-crystal X-ray diffraction analysis of 1,2′-bi(*nido*-decaboranyl), which has previously been characterized only by NMR spectroscopy. It was prepared by the photolysis of *nido*-decaborane in cyclohexane solution.

EXPERIMENTAL

$B_{10}H_{14}$ was photolysed in cyclohexane solution under N_2 as described previously.[2,4,8] After removal of the solvent (rotary evaporator, $T \leqslant ca$ 70°C), the unreacted decaborane was sublimed off under reduced pressure (*ca* 70°C/<1 mmHg, *ca* 95% recovery). The residue was taken up in CH_2Cl_2, filtered through silica, evaporated to dryness under reduced pressure, dissolved in CH_2Cl_2–hexane (1:10), and subjected to chromatographic separation using a Perkin–Elmer Series 2 HPLC chromatograph with a 16 × 250 mm Knauer preparative column packed with Si60 7 μm silica and 10% CH_2Cl_2 in AnalaR light petroleum (40–60°C) as eluting medium, flow-rate 20 cm^3 min^{-1}. Eluted components were detected by changes in the UV absorption of the eluted fluid at 315 nm. Best separations were obtained using aliquots of *ca* 25 mg reaction product in *ca* 1 cm^3 of solvent, and repeated injections were required to gather sufficient pure product for further work. Under these conditions traces of residual decaborane had a retention time of *ca* 4 min, and 2,2′-($B_{10}H_{13}$)$_2$ and 1,2′-($B_{10}H_{13}$)$_2$ were readily separable as pure products with retention times of *ca* 6.7 and 7.4 min respectively; the other $B_{20}H_{26}$ isomers present did not mutually separate. Removal of the solvent from the 1,2′-($B_{10}H_{13}$)$_2$ fraction, followed by recrystallization from CH_2Cl_2–hexane (50:50) at 4°C gave crystals suitable for single-crystal X-ray diffraction analysis.

CRYSTALLOGRAPHIC STUDIES

Unit cell and intensity data were obtained using a Syntex $P2_1$ diffractometer operating in the ω–2θ scan mode and using graphite monochromatized Mo-K_α radiation ($\lambda = 71.069$ pm) following a procedure described elsewhere in detail.[9]

* Author to whom correspondence should be addressed.

Crystal data

$B_{20}H_{26}$, $M = 242.41$, monoclinic, $a = 1099.7(2)$, $b = 1144.6(3)$, $c = 1409.4(3)$ pm, $\beta = 110.80(1)°$, $U = 1.659$ nm^3, space group $P2_1/n$ (= $P2_1/c$, No. 14), $Z = 4$, $D_c = 0.97$ g cm^{-3}, μ(Mo-K_α) = 0.18 cm^{-1}, $F(000) = 504$, $T = 290$ K. Scan speeds 2.0–29.3° min^{-1}, $4.0 < 2\theta < 45.0°$, scans running from 1° below $K_{\alpha 1}$ to 1° above $K_{\alpha 2}$. 4372 data were collected, and 3491 were considered observed [$I > 2\sigma(I)$].

Structure solution and refinement

The structure was solved by direct methods using the SHELXS program system[10] and refined by full-matrix least-squares using the SHELX76 program system.[11] All boron atoms were assigned anisotropic thermal parameters. All hydrogen atoms were located experimentally and were freely refined with individual isotropic thermal parameters. The weighting scheme $\omega = 1/[\sigma^2(F_o) + 0.00045(F_o)^2]$ was used at the end of refinement to give acceptable agreement analyses. Final R values were $R = 0.0467$ and $R_\omega = 0.0557$ (285 parameters).

RESULTS AND DISCUSSION

The molecular structure of the compound is shown in Fig. 1. Interatomic distances are given in Table 1 and selected angles about atoms B(1) and B(2′) are in Table 2. (Tables of atomic coordinates and other crystallographic data have been deposited with the Editor.*) The structure is clearly 1,2′-$(B_{10}H_{13})_2$, consistent with earlier conclusions based upon multi-element multiple-resonance NMR spectroscopy.[4] The molecule conforms approximately to an idealized mirror-plane symmetry; the twist-angle about the intercluster B(1)—B(2′) bond [as defined by planes passing through: (a) B(2′)B(4′)B(9′)B(6′), and (b) B(1)B(3) and the mid-points of B(5)B(10) and B(7)B(8)] being *ca* 5.4°. It should be noted that in solution there is free rotation about this bond, giving time-averaged mirror-plane symmetry in terms of interpretation of NMR properties.[4]

The intercluster B(1)—B(2′) bond distance of 169.6(4) pm is very close to those determined for the (1,5′), (2,2′) and (2,6′) isomers, which have values of 169.8(2),[3] 169.2(3)[7,8] and 167.9(3)[8] pm respectively. These values are similar to other interboron two-electron two-centre σ-bonds, e.g. 169.3(9) pm in $(\overline{NMeCH_2CH_2NMeB}\text{-})_2$[12] and 171.1(6) pm in $(\overline{OCMe_2CMe_2OB}\text{-})_2$.[13] The values within the $(B_{10}H_{13})_2$ isomers themselves show a small but probably significant variation, which may well reflect differences in boron electron character available for *exo*-polyhedral bonding at the various *nido*-decaboranyl cluster sites. This should also be manifested in the intercluster boron–boron ^{11}B NMR spin–spin coupling constant $^1J(^{11}B\text{–}^{11}B)$, which will be strongly dependent, *inter alia*, on the boron electron *s*-character available for bonding.[14] For 1,2′-$(B_{10}H_{13})_2$ this coupling constant takes a value of *ca* 105 Hz,[4] but comparative data are not available for the other isomers. In the related series of *conjuncto*-bi(*nido*-pentaboranyl) compounds, $(B_5H_8)_2$, however, the corresponding values of $^1J(^{11}B\text{–}^{11}B)$ vary by the large factor of almost 2 among the (1,1′), (1,2′) and (2,2′) isomers, indicating a considerable variation in *exo*-polyhedral bond character among these three intercluster linkages.[15] In these $(B_5H_8)_2$ compounds, however, only one intercluster boron–boron distance is available, that for the (1,1′) isomer at 174(6) pm,[16] but the estimated standard deviation on this is too large for meaningful comparison with the $(B_{10}H_{13})_2$ species.

* They have also been deposited with the Cambridge Crystallographic Data Centre.

B(2')—B(1)—B(5)	117.7(2)	B(1)—B(2')—B(6')	118.1(2)
B(2')—B(1)—B(10)	118.2(2)	B(1)—B(2')—B(7')	124.4(2)

The individual clusters themselves have very similar geometries to the individual *nido*-decaboranyl clusters of the other isomers examined by X-ray diffraction analysis,[3,7,8] and also to the cluster geometry of *nido*-decaborane itself.[17] In particular the characteristically long open-face distances B(5)B(10), B(7)B(8), B(5')B(10') and B(7')B(8') of 195.3(4)–197.6(4) pm are readily apparent. Compared to otherwise equivalent distances in the molecule, there appears to be a lengthening of about 1–3 pm in the intracluster B—B distances associated with the B(1) and B(2') atoms in the intercluster linkage. This again is also characteristic of the other isomers examined, and may be indicative of an increased electron demand for the intercluster B—B bond formation vs bond formation of an *exo*-terminal B—H bond.

Acknowledgements—We thank the SERC for support, and Yvonne Cheek for some assistance in the initial stages of this project.

NEW NICKEL(II) CHLORIDE–MORPHOLINE COMPLEXES

JOSÉ PALAZÓN, JOSÉ GÁLVEZ, GABRIEL GARCÍA and GREGORIO LÓPEZ*

Department of Inorganic Chemistry, University of Murcia, Murcia, Spain

(*Received* 15 *January* 1985; *accepted after revision* 10 *June* 1985)

Abstract—The compounds $[NiCl_2(Morph)_3(H_2O)_2]$ and $[NiCl_2(Morph)_3]$ have been prepared by treating $NiCl_2 \cdot 6H_2O$ with morpholine (Morph) in the presence of 2,2-dimethoxypropane or 2,2-dimethoxypropane–ethanol, respectively. The thermal treatment of both compounds leads to the formation of $[NiCl_2(Morph)_2]$ and $[NiCl_2(Morph)]$. The thermal study also includes the determination of reaction enthalpies and kinetic parameters such as activation energies and reaction orders. Magnetic and spectral data can be interpreted assuming a pseudo-octahedral environment around the nickel atom.

Two recent articles have been published on the preparation[1] and thermal behaviour[2] of some adducts of morpholine (Morph) with nickel salts. The thermal treatment of some of these complexes has been shown to be a useful method for the preparation of intermediates which cannot be isolated directly by reaction of the nickel salts with Morph.[2]

As a continuation of our study on nickel(II)–Morph complexes, we have investigated the $NiCl_2$–Morph system. The compounds $[NiCl_2(Morph)_3]$ and $[NiCl_2(Morph)_3(H_2O)_2]$ have been prepared and the thermal treatment of both compounds has led to the isolation of the new adducts $[NiCl_2(Morph)_2]$ and $[NiCl_2(Morph)]$.

EXPERIMENTAL

Materials and methods

Morph, 2,2-dimethoxypropane and nickel(II) chloride were commercial products and used as such. Diethyl ether was distilled over sodium in the presence of benzophenone and ethyl alcohol was dried with calcium oxide and distilled over magnesium.

The C, H and N analyses were performed with a Perkin–Elmer 240 C microanalyzer. Nickel was determined by titration with EDTA.[3]

IR spectra were recorded in the 4000–250 cm^{-1} range on a Perkin–Elmer 457 spectrophotometer as Nujol mulls. The diffuse reflectance spectra were recorded in Nujol mulls on a Beckman DK-2A spectrophotometer; the mulls were smeared between two glass plates on filter paper and run against a reference consisting of similar plates containing Nujol only. Thermal decomposition studies were carried out on a Netzsch STA-429 thermobalance. The thermograms were recorded with a heating rate of 5°C min^{-1}, but those used for the determination of reaction orders and activation energies were recorded with a heating rate of 2°C min^{-1} in order to achieve greater accuracy. Magnetic susceptibilities were measured at 20°C by the Faraday method using a Cahn RG 2102 electrobalance and a Systron Conner 6001 electromagnet calibrated with $Co[Hg(SCN)_4]$.[4]

Preparation of the complexes

$[NiCl_2(Morph)_3]$. A solution of $NiCl_2 \cdot 6H_2O$ (0.9 g, 3.8 mmol) in ethanol–2,2-dimethoxypropane (15 and 5 cm^3, respectively) was refluxed for 45 min. After cooling, Morph (8 cm^3) was added and the colour of the solution changed from yellow to green. On stirring, a yellow solid precipitated from the solution which was filtered off under nitrogen, washed with diethyl ether and dried *in vacuo*. Yield = 84%. The compound is hygroscopic and was kept in a P_4O_{10} desiccator.

IR (cm^{-1}): 3240m, 3200s, 1325m, 1310s, 1295m, 1265s, 1245s, 1200m, 1185s, 1165m, 1110vs, 1095vs, 1050s, 1035vs, 1025vs, 890vs, 870vs, 835m, 820m, 645m, 635m, 435w and 415w.

$[NiCl_2(Morph)_3(H_2O)_2]$. A suspension of $NiCl_2 \cdot 6H_2O$ (0.82 g, 3.4 mmol) in 2,2-dimethoxypropane (10 cm^3) was refluxed for 45 min. After

Table 1. Colours and analytical data of nickel compounds

Compound	Colour	Analyses (%) [found (calc.)]			
		Ni	C	H	N
$[NiCl_2(Morph)_3(H_2O)_2]$	Pale green	13.9 (13.8)	33.2 (33.7)	6.9 (7.3)	9.9 (9.8)
$[NiCl_2(Morph)_3]$	Yellow	15.3 (15.0)	36.9 (36.9)	7.0 (6.9)	11.2 (10.7)
$[NiCl_2(Morph)_2]$	Pale yellow		31.7 (31.6)	6.1 (5.9)	9.0 (9.2)
$[NiCl_2(Morph)]$	Brown		22.1 (22.1)	4.2 (4.1)	7.0 (6.5)

cooling, Morph was added (8 cm^3) and the yellow solid turned green. The solid was filtered off under nitrogen, washed with diethyl ether and dried *in vacuo*. Yield = 94%. The compound was kept in a P_4O_{10} desiccator.

IR (cm^{-1}): 3300s(br), 3200s, 1325m, 1315m, 1310m, 1260s, 1250s, 1200sh, 1190m, 1180m, 1120sh, 1115s, 1100vs, 1055s, 1040s, 1030vs, 895s, 880vs, 850m, 640m, 610w, 445w, 415w and 280w.

$[NiCl_2(Morph)_2]$ *and* $[NiCl_2(Morph)]$. Both compounds were obtained by heating either $[NiCl_2(Morph)_3]$ or $[NiCl_2(Morph)_3(H_2O)_2]$ as described below.

IR $[NiCl_2(Morph)_2]$ (cm^{-1}): 3200s, 1310s, 1305s, 1250s, 1205s, 1190s, 1110s, 1095s, 1060s, 1030s, 895s, 880vs, 835w, 825w, 640m and 445w.

IR $[NiCl_2(Morph)]$ (cm^{-1}): 3200s, 1315m, 1305m, 1255sh, 1250s, 1200s, 1115vs, 1085s, 1065s, 1030s, 1015m, 895s, 885vs, 830w, 645m, 445w.

RESULTS AND DISCUSSION

Partial or complete elimination of the H_2O molecules from $NiCl_2 \cdot 6H_2O$ is accomplished by the use of the dehydrating agent 2,2-dimethoxypropane,[5] which is hydrolyzed according to eqn (1):

$$CH_3C(OCH_3)_2CH_3 + H_2O \rightarrow CH_3COCH_3 + 2CH_3OH. \quad (1)$$

The presence of Morph in the reaction medium determines the formation of either

$$[NiCl_2(Morph)_3(H_2O)_2]$$

or

$$[NiCl_2(Morph)_3],$$

depending on whether 2,2-dimethoxypropane is used alone or together with ethanol, respectively. The analytical data of both compounds (Table 1) fit quite well the respective stoichiometries.

Figures 1 and 2 illustrate simultaneous TG and DTA curves for $[NiCl_2(Morph)_3]$ and $[NiCl_2(Morph)_3(H_2O)_2]$. The results of TG and DTA are summarized in Table 2.

Under an N_2 atmosphere $[NiCl_2(Morph)_3]$ is stable up to 140°C and then decomposes through three stages discernible in the TG curve within the

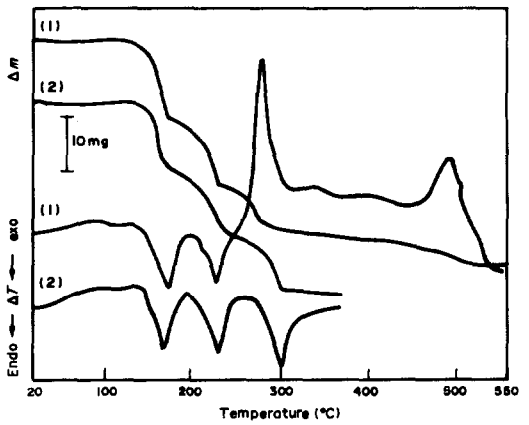

Fig. 1. Simultaneous TG and DTA curves for thermal decomposition of $[NiCl_2(Morph)_3]$ in: (1) air, 60.0 mg; and (2) N_2, 55.6 mg.

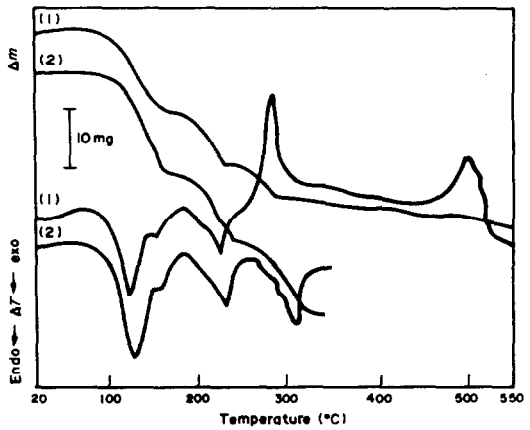

Fig. 2. Simultaneous TG and DTA curves for thermal decomposition of $[NiCl_2(Morph)_3(H_2O)_2]$ in: (1) air, 49.4 mg; and (2) N_2, 62.8 mg.

Table 2. Data on thermal decomposition of nickel complexes in N_2

Decomposition reaction	Weight loss[a] (%)	Temperature range [°C (TG)]	DTA peaks	ΔH (kJ mol^{-1})	Activation energy (kJ mol^{-1})	Reaction order	Mechanism suggested[b]
(1) $[NiCl_2(Morph)_3](s) \rightarrow [NiCl_2(Morph)_2](s) + Morph(g)$	23.8 (22.3)	140–175	170	53.32	214.6[c] 225.7[d]	1	F_1
(2) $[NiCl_2(Morph)_2](s) \rightarrow [NiCl_2(Morph)](s) + Morph(g)$	21.5 (22.3)	175–233	230	56.43	134.6[c] 137.9[d]	0.5	R_2
(3) $[NiCl_2(Morph)](s) \rightarrow NiCl_2(s) + Morph(g)$	21.0 (22.3)	233–305	300	66.68	163.1[c] 167.2[d]	0.5	R_2
(4) $[NiCl_2(Morph)_3(H_2O)_2](s) \rightarrow [NiCl_2(Morph)_2](s) + Morph\ (g) + 2H_2O(g)$	29.5 (28.8)	90–162	130	165.67	—	—	—

[a] Calculated values are given in parentheses.
[b] See Ref. 9.
[c] Coats–Redfern method.
[d] Satava method.

temperature ranges 140–175, 175–233 and 233–305°C. The stages lead to the formation of $[NiCl_2(Morph)_2]$, $[NiCl_2(Morph)]$ and $NiCl_2$, respectively. The transformations are endothermic with DTA peaks at 170, 230 and 300°C. The behaviour under an air atmosphere is the same as in N_2 up to 233°C but above this temperature $[NiCl_2(Morph)]$ decomposes through two exothermic stages (in the 233–280 and 280–540°C ranges; DTA peaks at 278 and 540°C). The difference between experimental (24.32%) and theoretical (22.3%) weight losses may be attributed to partial transformation of $NiCl_2$ into NiO.[6]

$[NiCl_2(Morph)_3(H_2O)_2]$ gives $[NiCl_2(Morph)_2]$ in two overlapped stages, between 90 and 162°C (in nitrogen), or 90 and 155°C (in air). Once $[NiCl_2(Morph)_2]$ is formed, the thermal behaviour is identical with that observed for the same intermediate from $[NiCl_2(Morph)_3]$.

Reaction enthalpies are collected in Table 2. They have been derived from the DTA curves as described in Ref. 2. As expected, enthalpy values increase as the Morph content decreases across the series

$$[NiCl_2(Morph)_3] \rightarrow [NiCl_2(Morph)_2] \rightarrow [NiCl_2(Morph)] \rightarrow NiCl_2.$$

This result is in agreement with our previous observations[2] and the study of Van Dam *et al.*[7] on complexes of nickel halides with imidazole. The rather high value of ΔH for the reaction

$$[NiCl_2(Morph)_3(H_2O)_2](s) \rightarrow [NiCl_2(Morph)_2](s) + (Morph)(g) + 2H_2O(g)$$

is roughly the sum of the ΔHs for the liberation of one Morph molecule and two water molecules (according to Ref. 7 a value of 60 kJ mol^{-1} H_2O may be assumed).

Activation energies and reaction orders for the processes (1)–(3) have been evaluated by the Coats–Redfern method,[8] and, furthermore, activation energies and reaction mechanisms have been determined by the Satava[9] method (Table 2). According to Ref. 9, process (1) should be controlled by a random nucleation mechanism and processes (2) and (3) by a phase boundary reaction with cylindrical symmetry.

The room-temperature magnetic moments (Table 3) are typical for the paramagnetic d^8-species. Electronic spectra (Table 3) are all compatible with a pseudo-octahedral geometry for the nickel compounds.[10] Two or three bands are observed, which can be assigned to the transitions from the ground state $^3A_{2g}(F)$ to the excited states $^3T_{2g}(F)$, $^3T_{1g}(F)$ and $^3T_{1g}(P)$; moreover, the frequencies of maxima are quite similar to those observed for related nickel

Table 3. Magnetic moments and electronic spectra of nickel compounds

Compound	μ_{eff} (BM)	Electronic bands (cm^{-1})
$[NiCl_2(Morph)_3(H_2O)_2]$	3.48	8695, 14,925
$[NiCl_2(Morph)_3]$	3.46	14,085, 22,470
$[NiCl_2(Morph)_2]$	3.57	8200, 13,425, 22,370
$[NiCl_2(Morph)]$	3.05	7550, 13,245, 21,280

amine halocomplexes in which a distorted octahedral configuration has been proposed.[10]

The IR spectra of the nickel compounds show that coordination of Morph to nickel is through the nitrogen atom, since in all cases a drop of $\sim 100\,cm^{-1}$ is observed for the N—H stretching frequency (Table 4). The fundamentals ν_{13} and ν_{14}, which in free Morph have the largest contributions from the C—N and C—O stretches,[11] appear in the spectra of $[NiCl_2(Morph)_3(H_2O)_2]$, $[NiCl_2(Morph)_3]$ and $[NiCl_2(Morph)_2]$ as single bands. However, the presence of two bands at 1030 and 1015 cm^{-1} (see Table 4) in the spectrum of $[NiCl_2(Morph)]$ could be indicative of a nickel–oxygen interaction, i.e. of bidentate Morph. On this basis, and assuming an octahedral environment about the nickel atom, the polymeric structures

$$[NiCl_{4/2}(Morph)_2]$$

and

$$[NiCl_{4/2}(Morph)_{2/2}]$$

may be proposed for

$$[NiCl_2(Morph)_2]$$

and

$$[NiCl_2(Morph)],$$

respectively.

From previous results and those reported herein, it is now possible to compare $[NiCl_2(Morph)_3]$ with $[NiBr_2(Morph)_3]$. Whereas the enthalpy change in the process

$$[NiX_2(Morph)_3](s) \xrightarrow{\Delta} [NiX_2(Morph)_2](s) + (Morph)(g)$$

is nearly the same for both compounds,[2] the structures of the resulting halocomplexes are different. In $[NiCl_2(Morph)_2]$ the nickel atom is in an octahedral environment, but in the deep blue $[NiBr_2(Morph)_2]$ the stereochemistry around the metal atom was shown to be tetrahedral.[1] This difference is attributed to the different size of the halogen. A similar reason may be adduced for the fact that nickel iodide forms the adduct $[NiI_2(Morph)_4]$,[1] in contrast to the above-mentioned halides where the highest adduct is $[NiX_2(Morph)_3]$.

(*Received* 7 *June* 1984; *accepted after revision* 10 *June* 1985)

Abstract—Palladium(II) malonato complexes with heterocyclic ligands have been synthesized and characterized by spectroscopic and biological studies. The compounds are of the general formula $Pd(mal)(L)_n$, where mal = malonato; and L = *N*-methylimidazole, *N*-ethylimidazole, *N*-propylimidazole and 2-methylbenzoxazole for $n = 2$; L = benzoxazole and ethylenediamine for $n = 1$. Our results have shown that the four $Pd(mal)(L)_2$ derivatives are soluble in water and are monomeric square planar. The two Pd(mal)(L) derivatives have poor solubility in water: the benzoxazole compound is dimeric square planar with bridging bidentate ligands, while the ethylenediamine derivative is monomeric square planar with a chelating ligand.

In previous studies[1] we prepared and studied the palladium(II) oxalato complexes with some heterocyclic ligands. The oxalato compounds are soluble in water and important in biological systems, but they present a relatively high toxicity.

Because malonate complexes have a good biological activity but a lower toxicity than oxalate derivatives, for the present paper we prepared the malonato complexes with the heterocyclic ligands *N*-methylimidazole (*N*-MeIm), *N*-ethylimidazole (*N*-EtIm), *N*-propylimidazole (*N*-PropIm), benzoxazole (Benzox), 2-methylbenzoxazole (2-MeBenzox) and ethylendiamine (en), in order to establish the stereochemistry of the compounds and to compare their biological effects with respect to the oxalato compounds.

EXPERIMENTAL

N-MeIm, en and 2-MeBenzox purum were supplied by Fluka, Benzox purum by EGA-Chemie, and *N*-EtIm and *N*-PropIm were kindly presented by BASF.

Palladium(II) malonate was prepared mixing the aqueous solution of potassium tetrachloro palladate(II) and potassium malonate in a 1:1 ratio at room temperature, and then heated in a water bath.

Pd(mal) was purified by washing with ethyl alcohol and dried over P_4O_{10}.

All the complexes were prepared by refluxing

* Author to whom correspondence should be addressed.

Pd(mal) with the ligand in excess for about 48 h. The compounds were washed in petroleum ether and dried over P_4O_{10}.

Analyses

The percentage values of carbon, hydrogen and nitrogen were determined with a Perkin–Elmer 240 elemental analyzer.

IR spectra

The IR spectra were recorded in the 4000–200-cm^{-1} range on a Perkin–Elmer 325 spectrophotometer with CsI discs in a Nujol mull.

Electronic spectra

The reflectance spectra were recorded on a Varian Cary 219 spectrophotometer in the range 40,000–10,000 cm^{-1}.

Biological activity

The method of extraction of the sarcoplasmatic reticulum containing Ca, Mg-dependent ATP-ase was performed according to a previous paper.[2] Inhibitory activity of the complexes towards the substrate in aqueous solution was obtained by determining the number of the SH groups by means of amperometric titrations.[2] When the complexes were insoluble in water we proceeded as follows: the complexes were dissolved in $CHCl_3$ or in C_2H_5OH and, after the solvent had completely evaporated and a thin film had formed, ATP-ase in aqueous solution was added, in order to evaluate the inhibitory activity of the complexes.

RESULTS AND DISCUSSION

The isolated complexes are reported in Table 1 together with analytical data and other physical properties.

The compounds are of two types: Pd(mal)$(L)_2$, where L = *N*-MeIm, *N*-EtIm, *N*-PropIm and 2-MeBenzox; and Pd(mal)L where L = Benzox and en.

All the complexes are powder-like, diamagnetic and non-conductors. The Pd(mal)$(L)_2$ derivatives are soluble in water and in the usual solvents, while the Pd(mal)L derivatives have a poor solubility in water and a good solubility in EtOH, $CHCl_3$ and DMF.

The IR spectra of the ligands in the 4000–400-cm^{-1} range are interpreted on the basis of previously reported data.[3,4]

In Table 2 the principal IR bands of the complexes in the 4000–200 cm^{-1} range are reported.

The medium absorption band within the 3440–3380-cm^{-1} range for ν(OH), and that within the 1650–1630-cm^{-1} range for δ(HOH), are present in all the complexes which lose water completely at 110°C before decomposing. From a detailed analysis of the IR spectra we have found that the rocking, twisting and wagging modes, ascribable to coordinated water according to Nakamoto,[5] are absent. However, the above bands are absent in Pd(mal)(Benzox), since it does not contain water molecules.

The IR spectra of the complexes are more difficult to interpret and the ν_{sym}(COO) and ν_{asym}(COO) are often ambiguously assigned as can be seen in the literature.[6,7] On our part, we have decided to follow a recent article[8] by O'Brien, where the (COO) vibrations are attributed differently, as regards the oxalate complexes.

In fact, in the IR spectra the vibrations present in the 1630–1580- and 1575–1540-cm^{-1} ranges are assigned to ν_{sym}(COO), and the vibrations in the 1450–1402- and 1370–1340-cm^{-1} ranges to ν_{asym}(COO). These values are in agreement with the fact that the carboxyl groups are unidentate and therefore that the bridging malonato groups[8] are absent.

K_2(mal)	1570–1550 sh	1370 s			

[a] Stetching vibration of the malonate.
[b] Stretching vibration of the heterocyclic ligand.

In the far-IR region a stretching band appears at 585–465 cm^{-1}, and it is attributed to ν(Pd—O), due to the coordinated malonato group.

The Pd(mal)$(L)_2 \cdot 2H_2O$ derivatives, where L = *N*-MeIm, *N*-EtIm or *N*-PropIm, show two bands in the 248–228-cm^{-1} range, due to ν(Pd—N) for the square-planar stereochemistry[9] in a *cis* configuration.

In the Pd(mal)(2-MeBenzox)$_2 \cdot 2H_2O$ derivate, we observe a band at 304 cm^{-1}, due to the metal–oxygen vibrations; therefore we may say that the ligand is oxygen-bonded.[10]

Pd(mal)(Benzox) is a dimeric square-planar compound.

In fact the absorption band at 325 cm^{-1}, due to ν(Pd—O), and the band at 241 cm^{-1}, due to (Pd—N), confirm that Benzox acts as a bridging bidentate ligand.[9,10] Pd(mal)(en)$\cdot H_2O$ shows a band at 565 cm^{-1} assigned to ν(Pd—N) according to literature data.[11]

In Table 3 the reflectance electronic spectra and the Δ_1 values are reported.

In the solid state these spectra are indicative of a square-planar geometry.[12] The band in the 28,170–25,640-cm^{-1} range was assigned to the $^1A_{1g} \rightarrow {}^1B_{1g}$ transition. In the UV region, the strong absorption vibrations in the 37,740–29,410-cm^{-1} range are due to charge-transfer transitions mal → Pd and L → Pd.

By assuming a value of $F_2 = 10F_4 = 600$ cm^{-1} for the Slater–Condon interelectronic repulsion parameters,[12] we were able to derive the value $\Delta_1 = \nu_1 + 3.5F_2$ from the first spin-allowed *d–d* transition. The values lie in the 30,270–27,740-cm^{-1} range.

Biological activity

Inhibitory activity towards the Ca, Mg-dependent ATP-ase was obtained only with some of the Pd(mal)$(L)_n$ complexes, since the others were reduced in solution.

We have compared the results of these palladium malonate complexes with respect to the analogous oxalato complexes.[1]

The inhibitory effect of Pd(mal)(*N*-EtIm)$_2 \cdot 2H_2O$ is twice as great as that of Pd(ox)(*N*-EtIm)$_2$. The malonate anion is more basic than the oxalate, so the *N*-EtIm is less strongly bonded to the Pd(II) ion and is easier to substitute with the thiol groups of the enzyme.

The Pd(mal)(Benzox) have 12% inhibitory activity, which value is smaller than that of the *cis*-Pd(Benzox)$_2$Br$_2$ derivative,[4] because in the former

Table 3. Electronic reflectance spectra

Compound	Bands (cm^{-1})	Δ_1
Pd(mal)(*N*-MeIm)$_2 \cdot 2H_2O$	37,740, 33,330, 26,670, 25,640	27,740
Pd(mal)(*N*-EtIm)$_2 \cdot 2H_2O$	37,740, 30,770, 33,330, 27,300	29,400

Pd(mal)(en)$\cdot H_2O$	37,450, 33,330, 29,410, 28,170	30,270

Table 4. Inhibitory activity of some malonato complexes with respect to the analogous oxalato

Compound	% (±2)[a] at 10^{-4} M	Solvent
Pd(mal)(*N*-EtIm)$_2 \cdot 2H_2O$	46	Water
Pd(ox)(*N*-EtIm)$_2$	23	Water
Pd(mal)(Benzox)	12	$CHCl_3$
cis-Pd(Benzox)$_2Br_2$	16	$CHCl_3$
Pd(mal)(en)$\cdot H_2O$	0	C_2H_5OH
Pd(ox)(en)	0	C_2H_5OH

[a] % is the percentage of the inhibitory activity.

the bridging ligand with weaker bonds is more easily replaced by the S^- of the ATP-ase mash.

In Pd(mal)(en)$\cdot H_2O$, as in Pd(ox)(en), this effect is zero, because the en is a strong chelating agent and it is difficult to substitute one or two positions with the thiol group(s) of the enzyme.

As far as regards the inhibitory mechanism, the irreversible interaction of the enzyme on the complexes occurs with the sulphur anion of the SH groups of the ATP-ase, which replaces the ligands in the square-planar complexes.

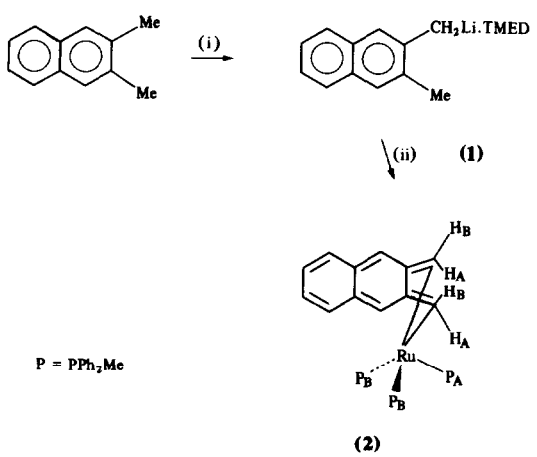
COMMUNICATION

A 2,3-NAPHTHOQUINODIMETHANE COMPLEX OF RUTHENIUM

WILLIAM FAULKNER, DAVID S. BARRATT, DOMENICO C. CUPERTINO and DAVID J. COLE-HAMILTON*
School of Chemistry, University of Liverpool, P.O. Box 147, Liverpool L69 3BX, U.K.

(*Received* 24 *May* 1985; *accepted* 26 *May* 1985)

Abstract—Treatment of 2,3-dimethylnaphthalene with BuLi·TMED (TMED = tetramethylethylenediamine) gives 2-lithiomethyl-3-methyl-naphthalene·TMED, which in turn reacts with $[RuCl_2(PMePh_2)_4]$ to give the 2,3-naphthoquinodimethane complex.



The stabilisation of otherwise unstable organic compounds by coordination to transition elements is an area of particular interest, especially if the organic moiety can be released and undergo subsequent reactions.

A number of reports has recently appeared[1–6] on the stabilisation of *o*-quinodimethane (*o*-xylylene), which is an important intermediate in the synthesis of a range of organic products.[7] Most of these syntheses involve deprotonation[2,4] (or oxidation)[6] of coordinated hexamethylbenzene complexes or reactions of *o*-bis(bromomethyl)benzene derivatives.[1,3] Since these types of precursor are not always readily available for more complex aromatic systems, complexes of more elaborate analogues of *o*-quinodimethane have not been prepared.

In contrast, we have reported[5] that *o*-quinodimethane complexes of ruthenium can be obtained directly from *o*-xylene by deprotonation with BuLi·TMED (TMED = tetramethylethylenediamine) and reaction of the resulting lithium salt with, for example, $[RuCl_2(PMe_3)_4]$. Since *o*-dimethylaromatic compounds are often readily available, this reaction should be of more general applicability. We now report the preparation of a 2,3-naphthoquinodimethane complex by this method.

Reaction of 2,3-dimethylnaphthalene with BuLi·TMED in light petroleum affords a red oil, presumed to be **1** (see Scheme 1). Reaction of excess of this oil with $[RuCl_2(PMePh_2)_4]$ in diethylether affords a red solution from which **2** can be crystallised in 70% yield. Although large crystals of **2** can be obtained, they are soft and do not diffract X-rays, the identification of **2** as the 2,3-naphthoquinodimethane complex therefore relies on spectroscopic data.

Table 1 shows a comparison of certain features of the ^1H and ^{31}P NMR spectra of **2** and the related η^4-*o*-quinodimethane complex, $[Ru(CH_2C_6H_4CH_2)(PMePh_2)_3]$ (**3**).[5] The similarity between the spectra of the two complexes confirms the η^4-binding of the 2,3-naphthoquinodimethane complexes, in particular the high field shift of the H_A protons is indica-

Scheme 1. Preparation of **2** from 2,3-dimethylnaphthalene, BuLi and $[RuCl_2(PMePh_2)_4]$. (i) BuLi, TMED, petroleum, 25°C, 6 h. (ii) $[RuCl_2(PMePh_2)_4]$, Et_2O, 25°C, 48 h.

[d] $J_{P_BH}+J_{P_BH'}$.

tive of a butadiene-like coordination.[5] Furthermore, the very low value of $J_{P_AP_B}$ rules out the alternative structure involving a five-coordinate complex of a substituted ruthenacyclopentene, but similar low values of $J_{P_AP_B}$ have been noted for a range of complexes of the general form [Ru(diene)P_2L] (P = PPh_3, L = PPh_3[8] or styrene,[9] diene = buta-1,3-diene or hexa-1,3-diene; P = L = PMe_2-Ph, $PMePh_2$, PMe_3 or PEt_3, diene = *o*-quinodimethane[5]).

The red colour of **2** is somewhat surprising since 18e complexes of ruthenium(0) or (II) are generally yellow, whilst 16e complexes are red.[10] However, the red colour of **2** arises from an absorption in the visible spectrum at 510 nm (ε = 2410), which is close to the position of the major absorption of matrix isolated 2,3-naphthoquinodimethane (541 nm), which is also reported to be red.[11]

The isolation of this 2,3-naphthoqinodimethane complex is somewhat surprising since η^4-binding leads to localisation of the bonding in the aromatic system.[5] Assuming that this occurs in the naphthoquinodimethane complex, a much larger resonance energy will be lost (resonance energies for benzene and naphthalene are 164 and 315 kJ mol^{-1}, respectively). This demonstrates the very high affinity of ruthenium for diene-like coordination.

Acknowledgements—We thank the SERC for a fellowship (D.S.B.) and studentship (D.C.C.) and Johnson–Matthey Ltd for loans of ruthenium. D.J.C.-H. is the Sir Edward Frankland Fellow of the Royal Society of Chemistry, 1984–1985.

(*Received* 1 *March* 1985; *accepted* 4 *June* 1985)

Abstract—The sulphite radical anion, $SO_3^{\dot{-}}$, was generated from the redox reactions between the bisulphite ion, HSO_3^-, and transition-metal ions such as VO_2^+, CrO_4^{2-} and MnO_4^-, as well as the reaction of Ce^{4+} with HSO_3^-. The formation of the $SO_3^{\dot{-}}$ radical was determined by ESR spectroscopy coupled with a rapid-mixing flow technique.

It is well known that the rapid-mixing flow technique coupled with ESR is very useful in detecting short-lived radicals having lifetimes longer than a few milliseconds. By using this technique we have reported in previous papers that the sulphite radical anion, $SO_3^{\dot{-}}$, which is generated from a Ce^{4+}–$NaHSO_3$ system in acidic aqueous solutions[1] can add to compounds having C=C,[2,3] C≡C[4] and C=S[5] bonds to give the corresponding secondary radicals. Also, in alkaline aqueous solutions at pH 9, the same radical species, $SO_3^{\dot{-}}$, which is obtained from a Ti^{3+}(ethylenediaminetetraacetic acid)–H_2O_2–Na_2SO_3 system,[6] can add to uracil derivatives having a C=S bond.[7]

Since the $SO_3^{\dot{-}}$ radical is generated by the redox reaction between Ce^{4+} and the bisulphite ion,[1] HSO_3^-, we have further examined the reactions of many kind of metal ions having the redox ability and HSO_3^- in acidic aqueous solutions by the use of an ESR method coupled with the rapid-mixing flow technique to detect the $SO_3^{\dot{-}}$ radical.

We report these results in this paper.

EXPERIMENTAL

The ESR measurements were carried out on a JEOL-PE-lX ESR spectrometer (X-band) with 100-kHz field modulation in conjunction with a JEOL mixing chamber. This apparatus enabled us to detect radicals having lifetimes of 5–100 ms. The ESR parameters were calibrated by comparison with an aqueous solution of Fremy's salt ($g = 2.0055$, $a^N = 1.30$ mT)[8] kept in a capillary tube attached to the sample. The concentrations of the spins were approximated to the peak-to-peak height of a given signal.

To detect the formation of the $SO_3^{\dot{-}}$ radical, the following metal salts were used without further purification: $CuSO_4 \cdot 5H_2O$ (Wako), $Fe_2(SO_4)_3 \cdot nH_2O$ (Wako), NH_4VO_3 (Wako), $K_2Cr_2O_7$ (Wako), $KMnO_4$ (Wako) and $Ce(NO_4)_4 \cdot 2(NH_4NO_3)$ (Wako). Sodium bisulphite ($NaHSO_3$) was obtained from Wako and used without further purification.

Two solutions were prepared, containing: (a) 0.01 M metal ions acidified to pH 2 with sulphuric acid, and (b) 0.1 M $NaHSO_3$. Details of the experimental procedure have been reported previously.[9]

* Author to whom correspondence should be addressed.

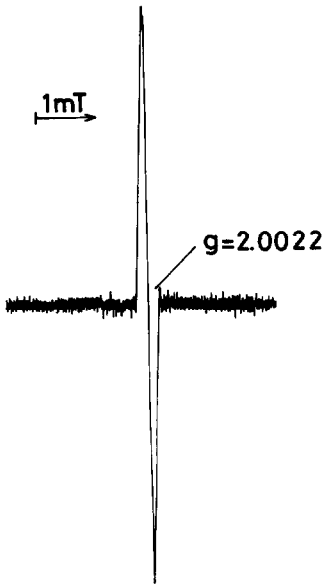

Fig. 1. ESR spectrum observed during the reaction of VO_2^+ with HSO_3^- in an acidic aqueous solution (pH 2) at room temperature.

RESULTS AND DISCUSSION

When two solutions [(a) (metal ion is Ce^{4+}) and (b)] were mixed in the cavity of the ESR spectrometer, a singlet line was observed, as expected ($g = 2.0022$), which has been assigned by us to the $SO_3^{\dot{-}}$ radical.[1] The same singlet signal was observed upon mixing HSO_3^- with the following metal ions: VO_2^+, CrO_4^{2-} and MnO_4^-. Figure 1 shows the ESR spectrum of the $SO_3^{\dot{-}}$ radical observed during the reaction of VO_2^+ with HSO_3^-. However, the signal intensity of the $SO_3^{\dot{-}}$ radical obtained from a VO_2^+–, CrO_4^{2-}– or MnO_4^-–$NaHSO_3$ system is smaller than that obtained from Ce^{4+}. No ESR signal could be observed during the reaction of Cu^{2+} or Fe^{3+} with HSO_3^-.

These results are summarized in Table 1, along with the reduction potentials of metal ions used here.[10]

In view of the strong one-electron oxidizing capability of Ce^{4+}, the $SO_3^{\dot{-}}$ radical must be formed according to reaction (1):

$$HSO_3^- + Ce^{4+} \rightarrow SO_3^{\dot{-}} + H^+ + Ce^{3+}. \quad (1)$$

Table 1. Abilities of metal ions to oxidize HSO_3^- and their reduction potentials

Metal ion	Valence change	Generation of $SO_3^{\dot{-}}$	Reduction potential (V)
Cu^{2+}	$Cu^{2+} \rightarrow Cu^+$	No	0.153
Fe^{3+}	$Fe^{3+} \rightarrow Fe^{2+}$	No	0.77
VO_2^+	$VO_2^+ \rightarrow VO^{2+}$	Yes	1.00
CrO_4^-	$Cr^{6+} \rightarrow Cr^{3+}$	Yes	1.36
MnO_4^-	$Mn^{7+} \rightarrow Mn^{2+}$	Yes	1.52
Ce^{4+}	$Ce^{4+} \rightarrow Ce^{3+}$	Yes	1.61

On using VO_2^+, the same reaction as shown in eqn (1) may occur to give the $SO_3^{\dot{-}}$ radical. Although, when CrO_4^{2-} or MnO_4^- is used, the stoichiometry of the reaction is not clear, these ion can oxidize HSO_3^- to yield the $SO_3^{\dot{-}}$ radical.

From Table 1, it is reasonable to consider that, because of the low reduction potentials of Fe^{3+} or Cu^{2+}, these ions cannot oxidize HSO_3^- and so no ESR signal could be observed.

In conclusion, the formation of the $SO_3^{\dot{-}}$ radical is dependent on the reduction potentials of the oxidizing metal ions.

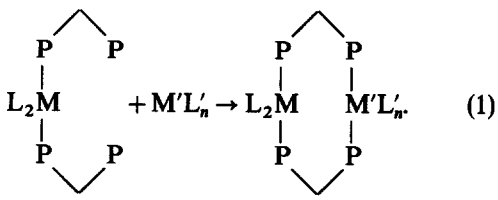
SYNTHESIS, ^{31}P AND ^{199}Hg NMR SPECTROSCOPY OF THE CATIONIC HETERODIMETALLACYCLE $[HgAg\{\mu\text{-}[BIS(DIPHENYLPHOSPHINO)METHANE]\}_2]^{3+}$

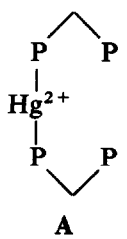
MARIA LUSSER and PAUL PERINGER*



Institut für Anorganische und Analytische Chemie der Universität Innsbruck, Innrain 52a, A-6020 Innsbruck, Austria

(*Received* 20 *May* 1985; *accepted* 11 *June* 1985)

Abstract—The complex $[Hg(\eta^1\text{-dppm})_2](O_3SCF_3)_2$ [dppm = bis(diphenylphosphino) methane] reacts with AgO_3SCF_3 to give the new eight-membered ring compound $[HgAg(\mu\text{-dppm})_2](O_3SCF_3)_3$ (**1**) in high yield. **1** is also formed in a redistribution reaction of the respective homobimetallic mercury and silver rings, and was characterized by ^{31}P and ^{199}Hg NMR spectroscopy. The magnitude of the coupling constant $J(^{199}Hg, ^{107}Ag)$ amounts to 60 Hz.



Bis(diphenylphosphino)methane (dppm) is an excellent ligand for grouping two metal centres in close proximity in complexes of the form of eight-membered rings $[M_2(\mu\text{-dppm})_2]$.[1] The synthetic methods suited to the formation of homonuclear complexes are not generally adaptable for the generation of heterobimetallic compounds.

Shaw *et al.*[2] recently described a systematic high-yield synthesis for heterobimetallic compounds involving M = Pt or Pd [eqn (1)]:

(1)

We found very recently that $[Hg(dppm)_2](O_3SCF_3)_2$ adopted structure **A**,[3]

A

which was expected to have a corresponding synthetic potential for heterobimetallic eight-membered metallacycles involving mercury.

EXPERIMENTAL

Chemical analyses were obtained on a Heraeus EA-415, and NMR spectra were recorded on a multinuclear Bruker WP-80 spectrometer operating in the FT mode. The chemical shifts are referred to 85% H_3PO_4 or aqueous $Hg(ClO_4)_2$ (2 mmol HgO cm^{-3} 60% $HClO_4$), and positive shifts are to high frequency of the reference. Coupling constants are in Hz. The program PANIC on a Bruker Aspect 2000 computer was used for the simulation of the spectra and for the refinement of the parameters by iteration.

Preparation of bis[sulfinylbis[methane]]silverbis[μ-methylenebis[diphenylphosphine]-P : P']bis[sulfinylbis[methane]] mercury(3+)tris[trifluoromethanesulfonate] (**1**)

0.125 mmol $[Hg_2(\mu\text{-dppm})_2](O_3SCF_3)_4$[4] {prepared *in situ* from 242 mg (0.25 mmol) $[Hg(Me_2SO)_6](O_3SCF_3)_2$ and 96 mg (0.25 mmol) dppm} in 1 cm^3 CH_2Cl_2 and 160 mg (0.125 mmol) $[Ag_2(\mu\text{-dppm})_2](O_3SCF_3)_2$ in 1 cm^3 CH_2Cl_2 are mixed together and concentrated to *ca* 1 cm^3. The product crystallizes upon standing overnight as

* Author to whom correspondence should be addressed.

colorless air-stable crystals in 70% yield. M.p. 220°C (dec.).

Found: C, 40.0; H, 3.7. Calc. for

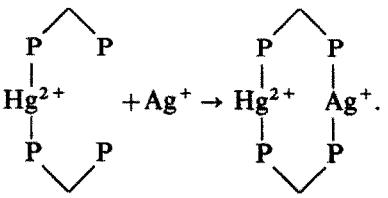
$C_{61}H_{68}AgF_9HgO_{13}P_4S_7$: C, 39.9; H, 3.7%.

The complex is sparingly soluble in CH_2Cl_2, MeOH or acetone, and readily soluble in Me_2SO or DMF.

1 is also obtained from equivalent amounts $[Hg(\eta^1\text{-dppm})_2](O_3SCF_3)_2$[3] {prepared *in situ* from $[Hg(Me_2SO)_6](O_3SCF_3)$ and two equivalents dppm} and AgO_3SCF_3 in CH_2Cl_2, followed by a similar work-up procedure.

Preparation of bis[μ-methylene[diphenylphosphine]-P:P']disilver(2+)bis[trifluoromethanesulfonate]

96 mg (0.25 mmol) dppm and 64 mg (0.25 mmol) AgO_3SCF_3 are mixed together in 1 cm^3 of MeOH and stirred for 10 min. The product crystallizes upon evaporation of the solvent *in vacuo* in the form of colorless crystals in almost quantitative yield. M.p. 110–118°C.

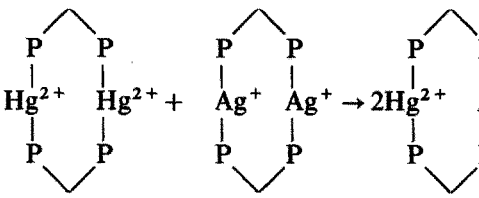


Found: C, 48.1; H, 3.3. Calc. for

$C_{52}H_{44}Ag_2F_6O_6P_4S_2$: C, 48.7; H, 3.5%.

Corresponding carboxylato and tetrafluoroborato complexes were obtained by Van der Ploeg and Van Koten.[5]

RESULTS AND DISCUSSION



The reaction of $[Hg(\eta^1\text{-dppm})_2](O_3SCF_3)_2$ and AgO_3SCF_3 leads to the heterobimetallacyclic compound **1** according to eqn (2):

(2)

1

This compound is also accessible from the respective homobimetallic mercury and silver rings [eqn (3)]:

(3)

Remarkably, the redistribution equilibrium positions are far on the side of the heterobimetallic compound **1**, as evidenced by the absence of signals of the homobimetallic species in the ^{31}P NMR spectrum. The redistribution proceeds within 20 min at ambient temperature in methanol solution. The product was isolated in the form of colorless air-stable crystals in almost quantitative yield as Me_2SO solvate.

The mixed Ag–Hg–dppm complex has been characterized by $^{31}P\{^1H\}$ and $^{199}Hg\{^1H\}$ NMR spectroscopy.

The $^{31}P\{^1H\}$ NMR spectrum of **1** recorded in DMF at 253 K as shown in Fig. 1 is a superposition of the four NMR relevant isotopomers

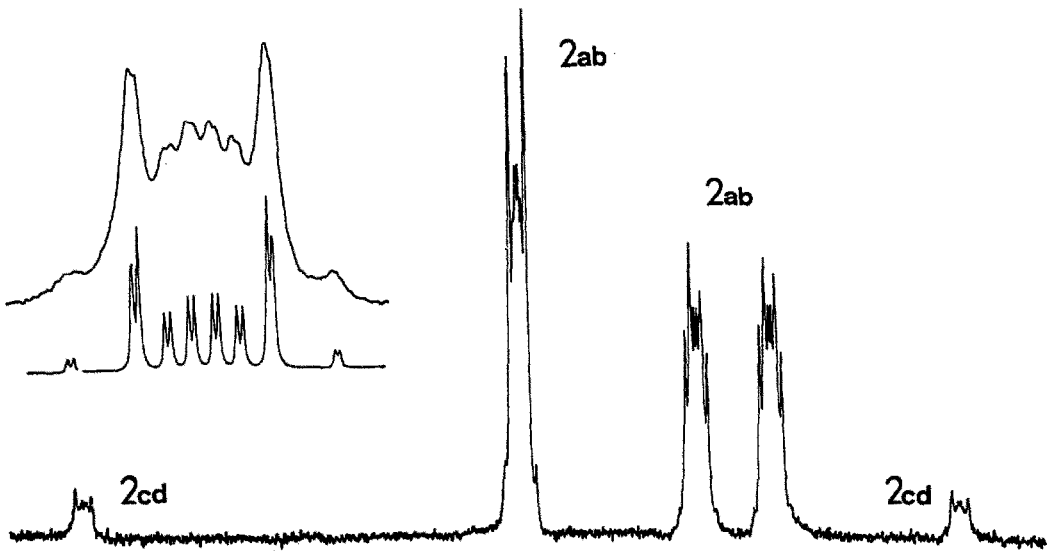


Fig. 1. $^{31}P\{^1H\}$ NMR spectrum of **1** in DMF at 253 K. The part of the phosphorus atoms coordinated to mercury is enlarged together with the corresponding computer-simulated pattern (the parameters are shown in Table 1).

Table 1. NMR parameters[a]

	$[AgHg(dppm)_2]^{3+}$	$[Ag_2(dppm)_2]^{2+}$	$[Hg_2(dppm)_2]^{4+}$ [b]
$\delta(^{31}P)Hg$	26.1	—	36.8
$\delta(^{31}P)Ag$	−0.9	4.8	—
$\delta(^{199}Hg)$	1358	—	1361
$^1J(^{199}Hg, ^{31}P)$	5899	—	5675
$^3J(^{199}Hg, ^{31}P)$	19	—	147
$^1J(^{107}Ag, ^{31}P)$	470	482	—
$^3J(^{107}Ag, ^{31}P)$	4	4	—
$^2J(^{31}PC^{31}P)$	111	160	32
$J(M, M)$	60	—	959
T (K)	253	233	—

[a] Ambient temperature unless otherwise stated; solvent is DMF.
[b] Taken from Ref. 4.

$[Hg^{107}Ag(dppm)_2]$ (**2a**, 43.09%), $[Hg^{109}Ag(dppm)_2]$ (**2b**, 40.07%), $[^{199}Hg^{107}Ag(dppm)_2]$ (**2c**, 8.73%) and $[^{199}Hg^{109}Ag(dppm)_2]$ (**2d**, 8.11%). The high-frequency part of the spectrum of **2a** and **b** (Fig. 1) originates from the phosphorus atoms bound to mercury, whereas the low-frequency part is attributed to the phosphorus atoms bound to silver in keeping with greater coordination chemical shifts of tertiary phosphines usually observed for mercury complexes compared with that of silver.[6] The part of the phosphorus atoms coordinated to mercury is enlarged together with the corresponding computer-simulated pattern. The parameters, refined by iteration, are shown in Table 1 together with the data of the homobimetallic mercury and silver rings. Major differences between data of the homo- and heterometallic rings, e.g. $\delta(^{31}P)$, $^3J(^{199}Hg, ^{31}P)$ and $^2J(^{31}PC^{31}P)$, may be caused by different geometries of the rings. The form of the patterns turned out to be rather insensitive to the value of the couplings $^2J(^{31}PHg^{31}P)$ and $^2J(^{31}PAg^{31}P)$.

The coupling between the ^{199}Hg and ^{107}Ag nuclei amounts to 60 Hz compared with a value of 900 Hz for $J(^{199}Hg, ^{199}Hg)$ in the homobimetallic mercury ring.[4]

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry, 8th Edition. Sn—Organic Compounds, Part 11, Trimethyltin- and Triethyltin–Oxygen Compounds. H. Schumann and I. Schumann, Springer, Berlin, 1985, ISBN 3-540-93501-0, x + 292 pp., DM995.

In this eleventh volume of their Herculean effort, the Schumanns deal with the mononuclear trimethyl- and triethyltin–oxygen compounds, Me_3SnOX and Et_3SnOX, covering the literature up to the end of 1982. Much of the space is devoted to the hydroxides, alkoxides and carboxylates, but the derivatives of the oxyacids of sulphur, nitrogen, phosphorus and so on, are included.

The presentation follows that with which has been established in the previous volumes.

The book begins with a list (43 pp.) of general references, and ends with a formula index (20 pp.). The text is nowadays wholly in English. Much of the material is presented in tabular form, and molecular structures obtained by X-ray diffraction are reproduced. For example, more than 7 pp. and 111 references are devoted to the description of triethyltin hydroxide. Eleven references are given to various preparations, and contradictory reports of the melting point and boiling point are discussed. Physical properties such as the chromatographic behaviour, and the IR and Mössbauer spectra are given; the reactions are presented mainly in tabular form, and there is more than a page on its biological properties and industrial applications.

This volume carries the stamp of authority which characterises this series by the Schumanns; all organotin chemists will want to have access to it.

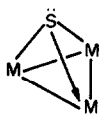
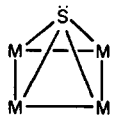
I. INTRODUCTION



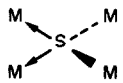
The class of low-valent polynuclear metal complexes that contain metal–metal bonds are known as cluster compounds. These compounds have attracted a great deal of attention with the idea they might serve as models for metal surfaces and heterogeneous catalysts.[1–3] More recently, interest has been focused on the chemical properties that may make them distinct from both heterogeneous and mononuclear metal homogeneous catalysts.[4]

A major problem in the use of cluster compounds as catalysts is their tendency to undergo degradative fragmentation when subjected to forcing reaction conditions. In an effort to prevent this a number of workers have chosen to employ bridging ligands.[5,6] The bridging ligands are usually derived from elements of the main groups and may be suitably modified with alkenyl and aryl substituents (e.g. NR, PR, PR_2, As, AsR, AsR_2, S, SR etc.). In this report attention will be focused on compounds that contain the bridging sulfido ligand and the transition element osmium.



In cluster complexes containing three metal atoms, the sulfido ligand invariably serves as a triple bridge, **1**.[6] It contains a lone pair of electrons and, when viewed as an uncharged ligand, it serves as a four-electron donor. Thus, within the framework of the valence-bond description one of the three M—S bonds would be viewed as a two-electron S to M donor bond. It is not a requirement that the M_3 group contain three M—M bonds and there are many documented examples where triply bridging sulfido ligands span M_3 units which have two or less metal–metal bonds.[6]

In the presence of four metal atoms the sulfido ligand frequently serves as a quadruply bridging ligand, **2** or **3**. If all the metal atoms lie on the same side of a plane that passes through the sulfido ligand, it is regarded as a four-electron donor and it contains a lone pair of electrons (**2**).* Interestingly, the ligand then has only three orbitals for use in bonding to the four metal atoms. Although the bonding is difficult to describe in terms of valence-bond theory, it fits naturally into the framework of the delocalized bonding scheme of the polyhedral skeletal electron pair (PSEP) theory. In most, if not all cases, the structural type **2** contains an M_4 cluster with four metal–metal bonds.

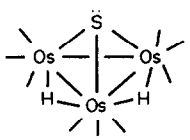


* There may be one exception to this definition. This occurs in the complex $[HPtOs_3(CO)_8(\mu_4\text{-}S)(\mu_3\text{-}S)(PPh_2C_6H_4)]_2$ which is described later in this section.

1

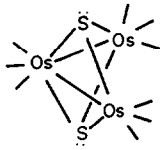
2

3



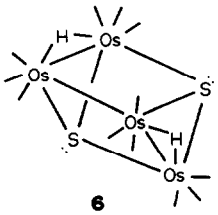
The structural type **3** contains four metal atoms arranged in a tetrahedral or distorted tetrahedral array about a centralized sulfido ligand. This sulfido ligand, viewed as an uncharged atom, serves as a six-electron donor and two of the four M—S bonds can be viewed as donor–acceptor bonds. There are no examples of type **3** sulfido ligands in the presence of six metal–metal bonds. The sulfido ligand appears to be very flexible and able to adapt to conditions imposed upon it by the arrangements of the metal atoms. For example, in the presence of M—M bonding, M—S—M bond angles as low as 65–75° are common. In the absence of M—M bonding these angles may range from 125 to 140°.[9] A compound which imposes an unprecedented degree of distortion upon a quadruply bridging sulfido ligand is $[HPtOs_3(CO)_8(\mu_4\text{-}S)(\mu_3\text{-}S)(PPh_2C_6H_4)]_2$.[7] The heavy-atom framework of the structure of this molecule is shown in Fig. 1. The quadruply bridging sulfido ligands, S_1 and S_2, are believed to serve as six-electron donors of type **3**. However, due to the highly strained polycyclic network of M_nS rings, all the metal atoms are drawn to one side of a plane which passes through the sulfido ligand. Similar highly strained geometries have been observed for carbon atoms in certain polycyclic hydrocarbon compounds, and these geometries have been described as "inverted" tetrahedral.[10]

II. SYNTHESES AND STRUCTURES



1. *Reagents and reactions*

Although a number of sulfur-containing compounds have been used in the synthesis of sulfido-transition-metal cluster compounds,[6] surprisingly few of these have been used for the synthesis of sulfido osmium carbonyl clusters.



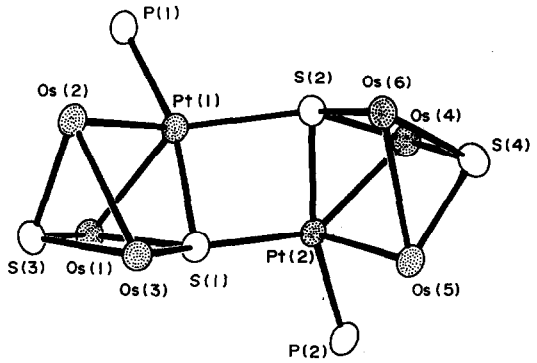
Hydrogen sulfide (H_2S) would seem to be an ideal source of sulfide, but it has not yet been used with wide success. H_2S does react with $Os_3(CO)_{12}$ at 125°C to form the cluster $Os_3(\mu\text{-}H)_2(\mu_3\text{-}S)(CO)_9$ (**4**) in nearly quantitative yields.[11] Both hydrogen atoms are transferred from the sulfur atom to the metal atoms where they bridge adjacent metal–metal bonds. The sulfido ligand serves as a triple bridge.

4

5

6

The reaction of $Os_3(CO)_{12}$ with elemental sulfur at 125°C yields compound **4** plus the compounds $Os_3(\mu_3\text{-}S)_2(CO)_9$ (**5**) and $Os_4(\mu\text{-}H)_2(\mu_3\text{-}S)_2(CO)_{12}$ (**6**).[12] Compound **5** and the selenium homologue of **6** have been characterized crystallographically. Compound **5** contains triply bridging sulfido ligands on each side of an open triangular cluster of three metal atoms.[13] The Os_4S_2 framework of **6** has the shape of a trigonal prism with only three osmium–osmium bonds, two of which contain bridging hydride ligands.[12] At temperatures greater than 200°C, the reaction yields the higher-nuclearity sulfido osmium carbonyl clusters, $Os_5(\mu_4\text{-}S)(CO)_{15}$ (**7**), $Os_7(\mu_4\text{-}S)_2(CO)_{20}$ (**8**) and $Os_{10}(\mu_4\text{-}S)_2(CO)_{23}$ (**9**).[14] These have been characterized structurally by X-ray diffraction methods. ORTEP diagrams of **7** and **8** are shown in Figs 2 and 3, respectively. Compound **7** consists of a square pyramid of five osmium atoms with a quadruply bridging sulfido ligand spanning the square base.[15] Compound **8** consists of an Os_5S_2 cluster core in the shape of a pentagonal bipyramid and has two $Os(CO)_4$ units bridging adjacent apical–equatorial edges of the cluster.[16] To date, compound **9** is the highest-nuclearity sulfido osmium carbonyl cluster that has been characterized. Its structure has been described as two square pyramids fused to two trigonal bipyramids that have one Os—Os edge in common.[14] Quadruply bridging sulfido



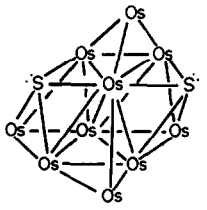


Fig. 1. An ORTEP drawing of the heavy-atom structure for the compound $[HPtOs_3(CO)_8(\mu_4\text{-}S)(\mu_3\text{-}S)(PPh_2C_6H_4)]_2$ showing the inverted tetrahedral geometry of the sulfido ligands S(1) and S(2). Pt(1)–S(1)–Os(1) = 68.3(2)°, Pt(1)–S(1)–Os(3) = 102.86(2)°, Os(1)–S(1)–Os(3) = 97.8(2)°, Pt(1)–S(1)–Pt(2) = 85.0(2), Pt(2)–S(1)–Os(1) = 116.2(2)°, Pt(2)–S(1)–Os(3) = 145.3(3)°, Pt(2)–S(2)–Os(4) = 67.3(2)°, Pt(2)–S(2)–Os(6) = 101.2(2)°, Os(4)–S(2)–Os(6) = 97.6(2)°, Pt(2)–S(2)–Pt(1) = 83.8(2)°, Pt(1)–S(2)–Os(4) = 135.0(3)°, Pt(1)–S(2)–Os(6) = 122.2(2)°.

ligands span the square bases of the two square pyramidal units.

9

Carbon disulfide (CS_2) reacts with $Os_3(CO)_{12}$ to form the compound $Os_3(\mu_3\text{-}S)_2(CO)_8(CS)$ (**10**) which is structurally analogous to **5** but contains a terminally coordinated thiocarbonyl ligand in place of one of the carbonyl ligands.[17] CS_2 reacts with the lightly-stabilized cluster $Os_3(\mu\text{-}H)_2(\mu_3\text{-}S)(CO)_8(NCMe)$ to form the compound $Os_3(\mu\text{-}H)_2(\mu_3\text{-}S)_2(CO)_8(CS)$ (**11**).[18] Compound **11** is an open cluster with two triply bridging sulfido ligands, a bridging hydride ligand across

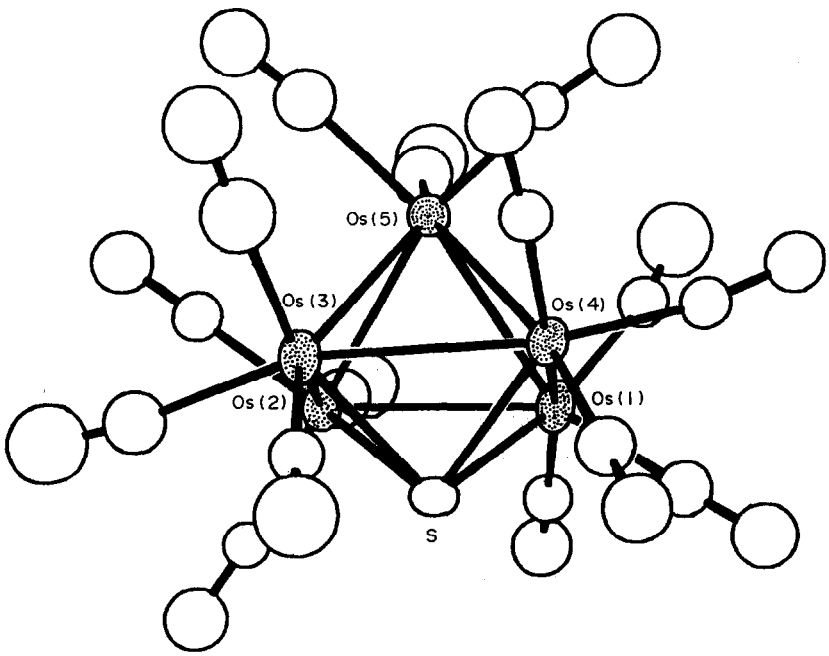

Fig. 2. An ORTEP diagram of $Os_5(\mu_4\text{-}S)(CO)_{15}$ (**7**) showing 50% probability thermal ellipsoids.

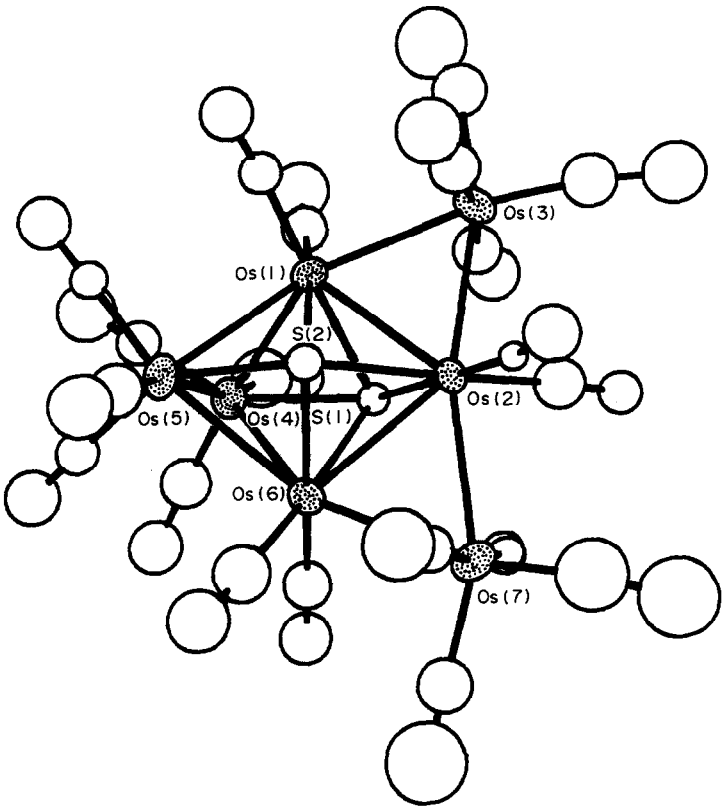

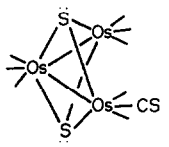

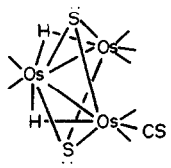

Fig. 3. An ORTEP diagram of $Os_7(\mu_4\text{-}S)_2(CO)_{20}$ (**8**) showing 50% probability thermal ellipsoids.

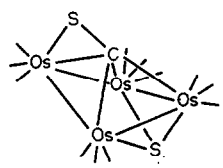
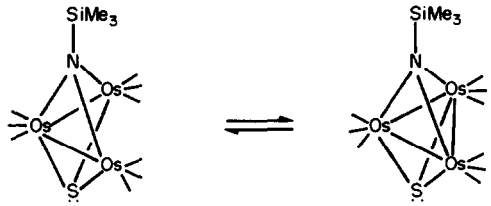


each of the two metal–metal bonds and one linear terminal thiocarbonyl ligand. The reaction of $Os_6(CO)_{18}$ with CS_2 at 165°C under CO pressure yields compounds **5**, **10** and the new compound $Os_4(\mu_3\text{-}S)(\mu_4\text{-}CS)(CO)_{12}$ (**12**) in 8% yield.[19] The structure of **12** consists of four osmium atoms arranged in the form of a puckered square. Three of the osmium atoms are bridged by a triply bridging sulfido ligand. The thiocarbonyl ligand serves as a quadruple bridge with the carbon atom bonded to all four osmium atoms and the sulfur bonded to only one. The C—S bond length, 1.757(18) Å, is slightly shorter than a C—S single bond length (i.e. 1.81 Å).

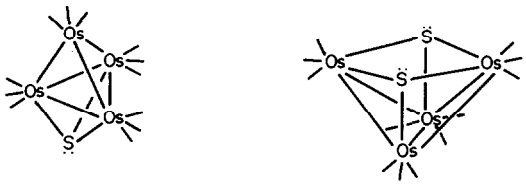
10



11

12

Süss-Fink *et al.*[20] have reported that the sulfurdimide, $Me_3SiN{=}S{=}NSiMe_3$, reacts with $Os_3(CO)_{12}$ at 125°C to give the compound $Os_3(\mu_3\text{-}S)(\mu_3\text{-}NSiMe_3)(CO)_9$ (**13**) in 13% yield. The crystal structure analysis of **13** reveals an open triangular structure similar to that of **5** but it contains a triply bridging amido ligand, Me_3SiN, and one triply bridging sulfido ligand. The temperature-dependent ^{13}C NMR spectrum of **13** in solution reveals the reversible formation of a second species at high temperature in which all the carbonyl ligands are either equivalent or are rapidly averaged. This was interpreted in terms of an isomeric species, **14**, which contains three metal–metal bonds. Although the structure **14** could explain the spectral observations, it should be pointed out that this structure does not adhere to currently accepted cluster bonding theories. Thus, until further evidence is presented it should be regarded as tentative.



13 14

Of all the routes to sulfido osmium carbonyl clusters, perhaps the most productive, are those which involve the desulfurization of organosulfur ligands. For example, the arylthiolatotriosmium-decarbonylhydride clusters readily eliminate arene when heated to 150°C to yield a variety of sulfido osmium carbonyl clusters [i.e. eqn (1)]:[21]

$$\underset{\mathbf{15}}{Os_3(\mu\text{-H})(\mu\text{-SPh})(CO)_{10}} \xrightarrow[-C_6H_6]{150^\circ C} \underset{\mathbf{5}}{Os_3(\mu_3\text{-S})_2(CO)_9} + \underset{\mathbf{16}}{Os_4(\mu_3\text{-S})(CO)_{12}}$$

$$+ \underset{\mathbf{17}}{Os_4(\mu_3\text{-S})_2(CO)_{12}} + \underset{\mathbf{7}}{Os_5(\mu_4\text{-S})(CO)_{15}} + \underset{\mathbf{18}}{Os_6(\mu_4\text{-S})(\mu_3\text{-S})(CO)_{16}} + \underset{\mathbf{8}}{Os_7(\mu_4\text{-S})_2(CO)_{20}}. \quad (1)$$

The yields of the various products are very sensitive to the reaction conditions. For example, when pyrolyzed in the absence of solvent at temperatures greater than 200°C, only compounds **5**, **16**, **7** and **8** are obtained.[16] When pyrolyzed at 160°C under 100 bar CO pressure, only compound **5** plus three equivalents of $Os(CO)_5$ is obtained.[15] Compounds **16**–**18** have been characterized by X-ray diffraction methods. Compound **16** consists of a tetrahedral cluster of four osmium atoms with a triply bridging sulfido ligand on one of the Os_3 faces.[22] Compound **17** consists of a "butterfly" tetrahedral cluster of

16 17

four osmium atoms with triply bridging sulfido ligands across the two open triangular faces.[21] The structures and bonding of **16** and **17** will be described further in Section III. An ORTEP diagram of compound **18** is shown in Fig. 4.[21] The molecule consists of a square pyramid of five osmium atoms with a quadruply bridging sulfido ligand spanning the square base and an $Os(CO)_3$ group and a triply

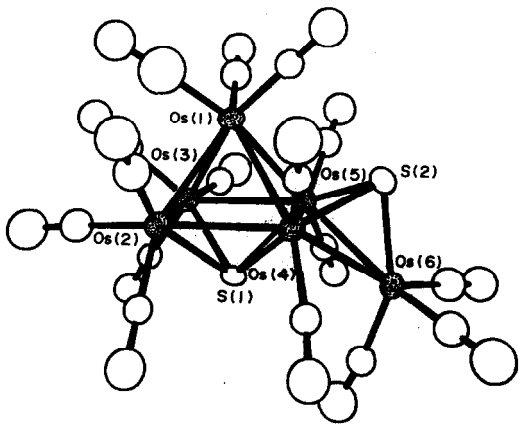


Fig. 4. An ORTEP diagram of $Os_6(\mu_4\text{-S})(\mu_3\text{-S})(CO)_{16}$ (**18**) showing 50% probability thermal ellipsoids.

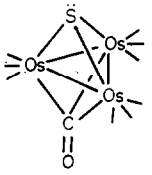

bridging sulfido ligand bridging an edge of the square base. The independent syntheses of compounds **7**, **8** and **16–18**, as well as related compounds suggest mechanisms for their formation. These are described in Section II.2(a).

When irradiated under a rapid purge of CO, compound **15** loses benzene and yields the compound $Os_3(\mu_3\text{-}S)(\mu_3\text{-}CO)(CO)_9$ (**19**) [eqn (2)]:[23]

$$Os_3(\mu\text{-}H)(\mu\text{-}SPh)(CO)_{10} \xrightarrow[-C_6H_6]{h\nu/CO} Os_3(\mu_3\text{-}S)(\mu_3\text{-}CO)(CO)_9. \quad (2)$$

19

Compound **19** consists of a triangular cluster of three osmium atoms with a triply bridging sulfido ligand one side of the Os_3 plane and a triply bridging carbonyl ligand on the other side.

19

Thermal degradation of the benzylthiolato cluster, $Os_3(\mu\text{-}H)(\mu\text{-}SBz)(CO)_{10}$ (**20**) occurs apparently by two competing mechanisms.[24] One which is analogous to that found for **15** results in the elimination of toluene and the formation of compounds **5**, **16** and **8**. The other mechanism results in formation of dibenzyl and the two isomeric hexaosmium dihydro clusters $Os_6(\mu\text{-}H)_2(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_{17}$ (**21** and **22**). ORTEP diagrams of **21** and **22** are shown in Figs 5 and 6. The red isomer **21** contains a quadruply bridging sulfido ligand of type **3** while the green isomer **22** contains a quadruply bridging sulfido ligand of type **2** and an extended planar array of six osmium atoms. The formation of dibenzyl and dihydrido hexaosmium species suggests a radical mechanism involving an initial homolysis of the sulfur–carbon bond in **20**.

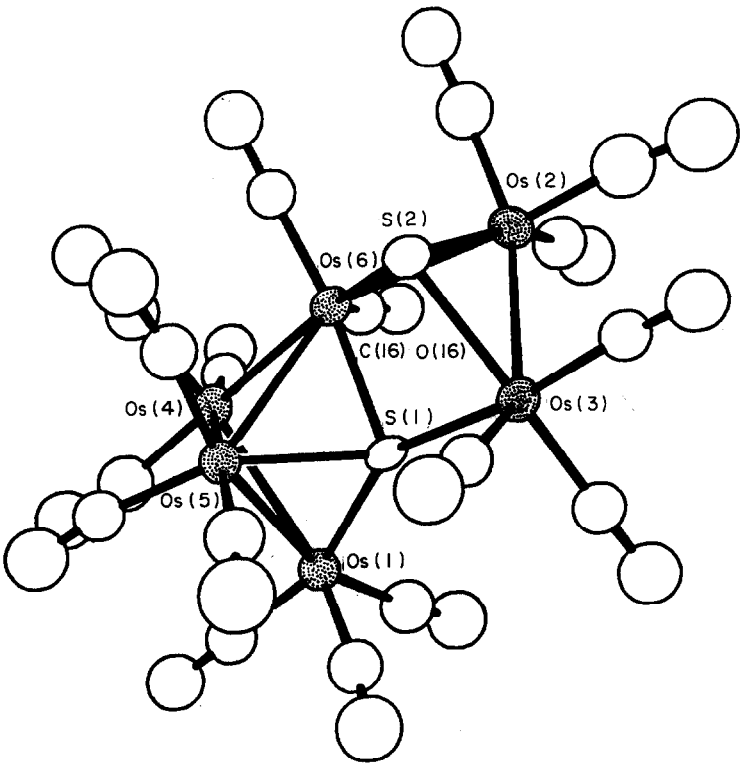

Fig. 5. An ORTEP diagram of the red isomer of $Os_6(\mu\text{-}H)_2(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_{17}$ (**21**) showing the quadruply bridging sulfido ligand S(1) of type **3**.

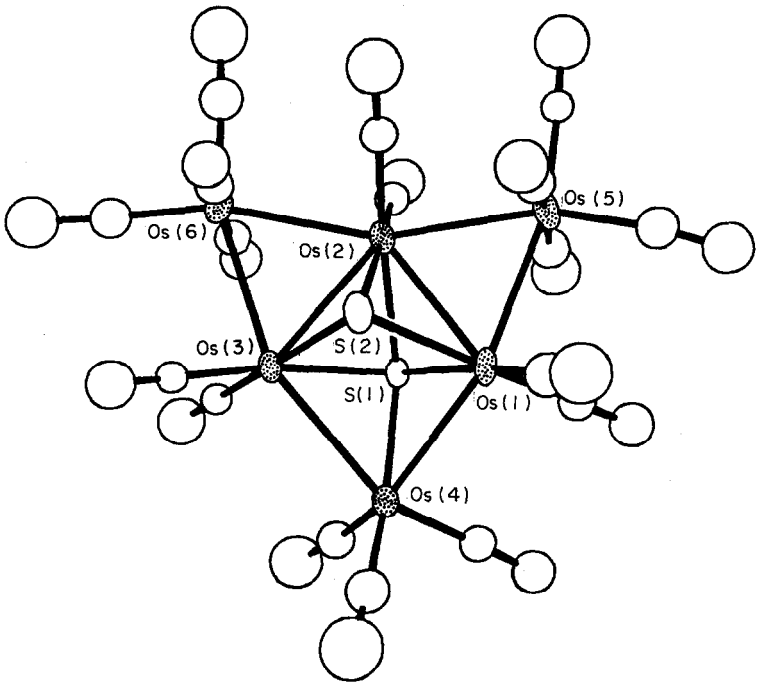

Fig. 6. An ORTEP diagram of the green isomer of $Os_6(\mu\text{-}H)_2(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_{17}$ (**22**) showing the quadruply bridging sulfido ligand S(1) of type **2**.

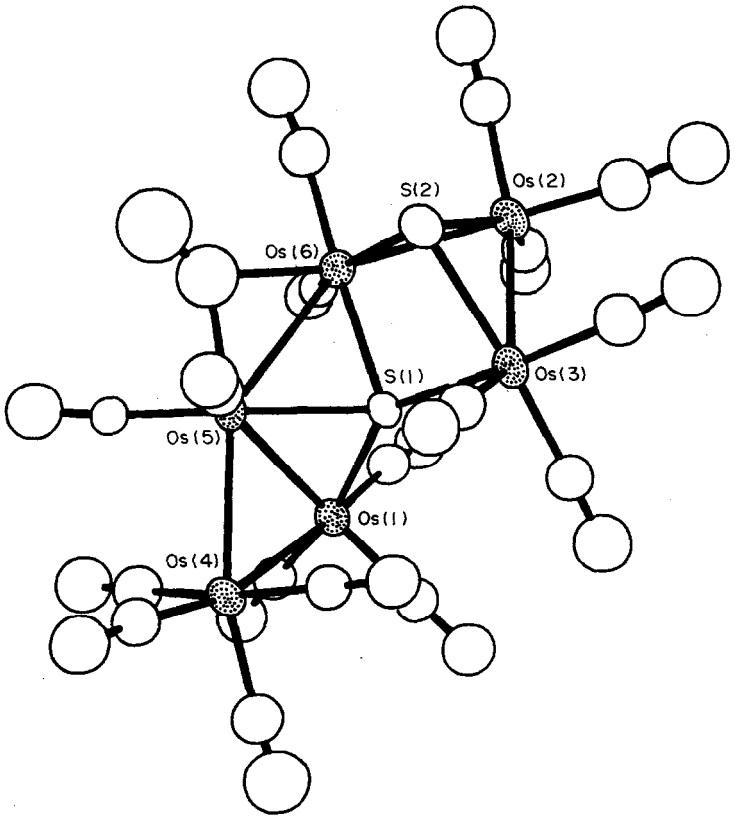

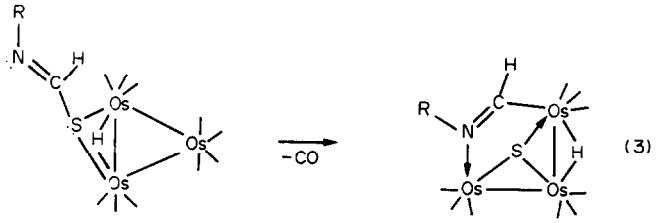

Fig. 7. An ORTEP diagram of $Os_6(\mu\text{-}H)_2(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_{18}$ (**23**) which is a precursor to $Os_6(\mu\text{-}H)_2(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_{17}$ (**21**).

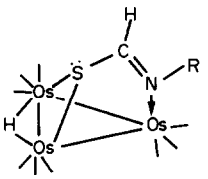
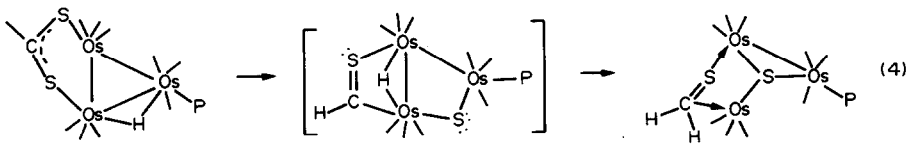


The principal product formed when compound **20** is irradiated at 25°C is the compound $Os_6(\mu\text{-}H)_2(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_{18}$ (**23**). An ORTEP diagram of **23** is shown in Fig. 7. It is similar to **21**, and was shown to be a precursor to **21** by its thermal decarbonylation.

Thioformamido and dithioformato ligands can serve as precursors for sulfido ligands [eqns (3)[25] and (4)[26]]:

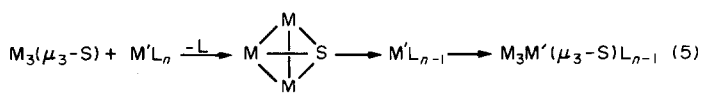


(3)

24 **25**

26

(4)



27 **A** **28**

The desulfurization of the thioformamido complex in **24** was found to proceed via a decarbonylated intermediate **26** which was isolated and shown to contain a triply bridging thioformamido ligand. Structural analyses of **24** and **26** showed that the C—S bond length was significantly longer than the C—S bond length of thioformamido ligands in complexes where the sulfur atom was not in a bridging position. Thus, it was inferred that *the bridging environment induced a weakening of the* C—S *bond and this facilitated the bond cleavage.* In ligand-splitting reactions such as these both fragments of the ligand usually remain coordinated to the cluster.

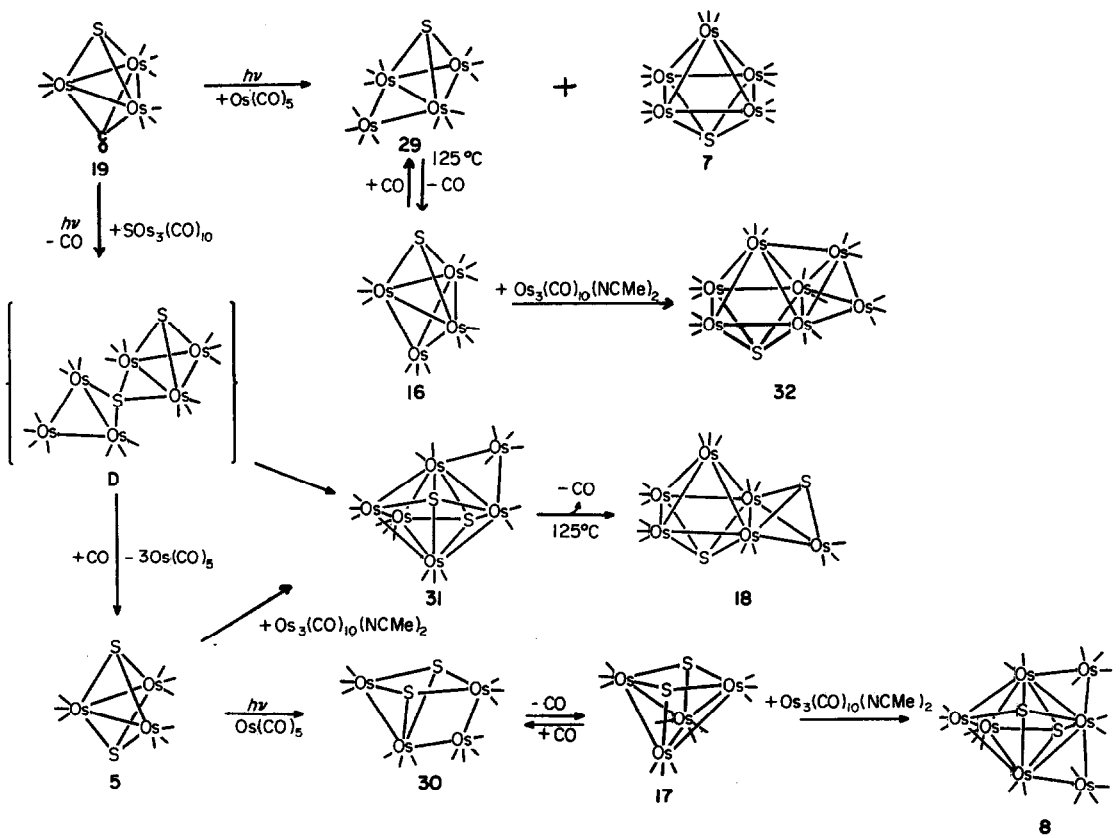
The desulfurization of the dithioformato ligand in **27** probably proceeds via an intermediate species such as **A** containing a thioformyl ligand, but this was not observed. The species **28** which contains a bridging thioformaldehyde ligand was isolated. This could be formed by a reductive elimination of C—H from the proposed intermediate.

2. *Cluster condensation reactions*

(a) *Homonuclear clusters.* The triply bridging sulfido ligand with its lone pair of electrons would seem to be an ideal species for use in cluster size-expansion reactions. By using the lone pair of electrons to form coordinative interactions to electron-deficient metal groupings, the sulfido ligand could facilitate the entry of metal-containing units into the cluster [eqn (5)]:

(5)

B **C**



The paucity of isolated intermediates such as **B** suggests that these species are less stable than their rearrangement products **C**.

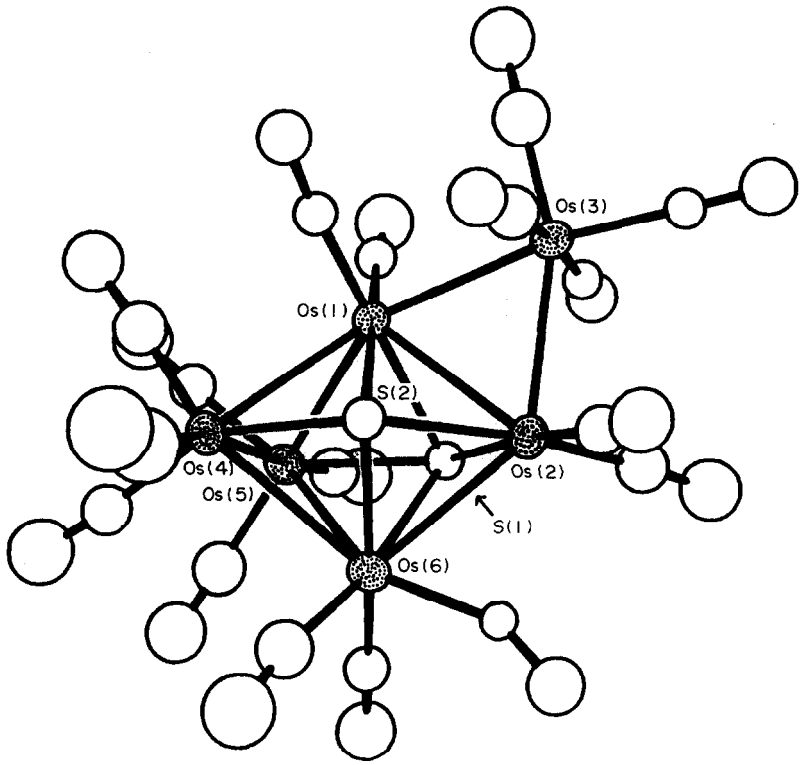
The low-nuclearity sulfido clusters **5** and **19** have served as starting points for these aggregation or *condensation* reactions. Osmium pentacarbonyl which is readily decarbonylated to the reactive intermediate $Os(CO)_4$ when irradiated has been used as a source of monoosmium fragments. The lightly stabilized complex $Os_3(CO)_{10}(NCMe)_2$ has been found to serve as a reagent for the addition of triosmium groupings. By using this methodology most of the cluster complexes synthesized in low yields in the pyrolysis reactions described in Section II.1 have now been made in much higher yields. In addition, a number of new complexes that were not observed in the pyrolysis reactions have been isolated. Some of these can be converted into the pyrolysis products and thus suggest mechanisms for their formation.

The irradiation of solutions of **19** and $Os(CO)_5$ has resulted in the formation of the higher-nuclearity clusters, **29** and **7** in 40 and 3% yields, respectively (see Scheme 1). The structure of **29** consists of a nearly planar butterfly cluster of four osmium atoms with a triply bridging sulfido ligand on one triangular face.[15] When heated to 125°C, **29** loses 1 mol of CO and condenses to **16** quantitatively.

When solutions of **5** and $Os(CO)_5$ are irradiated the compound $Os_4(\mu_3\text{-}S)_2(CO)_{13}$ (**30**) is formed in 40% yield[16] (see Scheme 1). The structure **30** consists of a planar group of four osmium atoms connected by three Os—Os bonds.[27] Triply bridging sulfido ligands are symmetrically disposed about the Os_4 plane. When heated to 68°C, **30** loses 1 mol of CO quantitatively and the cluster closes to form **17**.

The reaction of **5** with $Os_3(CO)_{10}(NCMe)_2$ yields the new hexaosmium cluster $Os_6(\mu_4\text{-}S)_2(CO)_{17}$ (**31**) in 29% yield.[28] The structure of **31** is shown in Fig. 8. The molecule is very similar to **8** and contains an Os_5S_2 cluster in the form of a pentagonal bipyramid but has only one $Os(CO)_4$ group bridging an apical–equatorial edge.[28] This compound was also prepared in good yield by the UV irradiation of **19** in an inert solvent. The condensation of 2 mol of **19** via the unobserved intermediate **D** is shown in Scheme 1. An intermediate such as **D** is probably also traversed in the formation of **5** as observed in the pyrolysis of **15** under CO pressure.[15] When heated to 125°C compound **31** quantitatively loses 1 mol of CO to yield **18**. The CO ligand that is lost probably comes from th CO-rich bridging $Os(CO)_4$ grouping. A rearrangement that would readily produce condensation of **31** to **18** is shown in Scheme 2.[28]

Scheme 1.



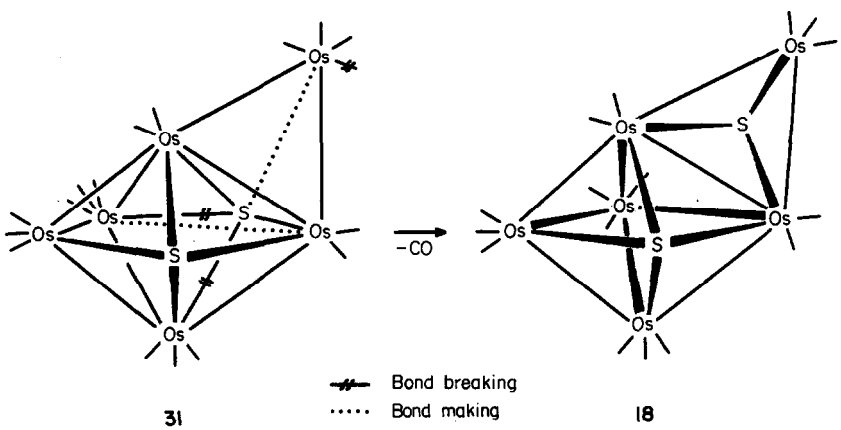


Fig. 8. An ORTEP diagram of $Os_6(\mu_4\text{-}S)_2(CO)_{17}$ (**31**) which is a precursor to $Os_6(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_{16}$ (**18**).

The reaction of **16** with $Os_3(CO)_{10}(NCMe)_2$ in refluxing octane yields the highly condensed heptanuclear cluster $Os_7(\mu_4\text{-}S)(CO)_{19}$ (**32**) in 23% yield.[22] No intermediates have been isolated. The structure of **32** is shown in Fig. 9. The structure is best described as a fused combination of a square pyramid of five osmium atoms and a trigonal bipyramid of five osmium atoms with one triangular face [Os(1)–Os(2)–Os(4)] in common. The base of the square pyramid is spanned by a quadruply bridging sulfido ligand of type **2**.

The addition of $Os_3(CO)_{10}(NCMe)_2$ to **17** leads to the formation of **8** in 16% yield.[16] Curiously, it was found that compound **8** could not be prepared by the irradiation of solutions of **31** and $Os(CO)_5$.

It has been found that $Os_3(CO)_{10}(NCMe)_2$ will add to **19** to form the sequence of products $Os_6(\mu_3\text{-}S)(CO)_{19}$ (**33**) and $Os_6(\mu_4\text{-}S)(CO)_{17}$ (**34**). Compound **33** is converted into **34** in 23% yield at

Scheme 2.

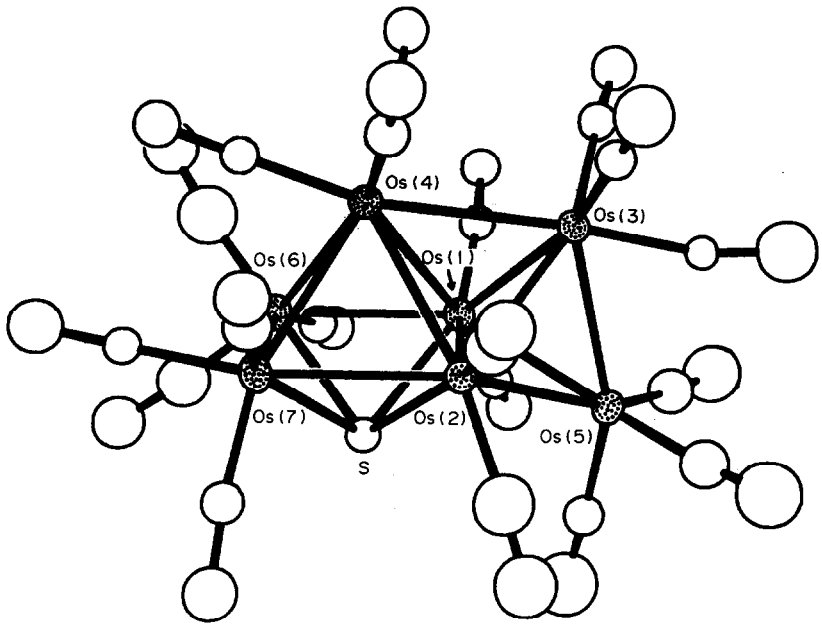

Fig. 9. An ORTEP diagram of the fused cluster $Os_7(\mu_4\text{-}S)(CO)_{19}$ (**32**) showing 50% probability thermal ellipsoids.

110°C.[29] The molecular structure of **33** is shown in Fig. 10. The molecule consists of a butterfly tetrahedral cluster of four osmium atoms with a triply bridging sulfido ligand across one of the open triangular faces. $Os(CO)_4$ groupings bridge the two edges of that same open triangular face. The structure of **34** is shown in Fig. 11. This molecule consists of a square pyramid of five osmium atoms with a quadruply bridging sulfido ligand over the square base and a capping $Os(CO)_3$ group on one of the triangular faces. The transformation of **33** into **34** involves the loss of 2 mol of CO. A proposed rearrangement which involves the loss of one CO from each of the bridging $Os(CO)_4$ units is shown in Scheme 3.

When irradiated under a rapid purge with nitrogen, compound **5** undergoes a self-condensation and forms the green dimer $[Os_3(\mu_3\text{-}S)_2(CO)_8]_2$ (**35**). Compound **35** has a most unusual structure which is shown in Fig. 12. The central portion of the molecule consists of a butterfly tetrahedron of four osmium atoms [Os(1)–Os(2)–Os(3)–Os(4)] with a dihedral angle of 136°. Exterior $Os(CO)_3$ groups are attached to the hinge atoms Os(1) and Os(2). Pairs of triply bridging sulfido ligands bridge opposite edges of the butterfly tetrahedron and extended to the exterior $Os(CO)_3$ groups. The formation of **35**

Scheme 4.

can be viewed as a back-to-back coupling of two $Os_3(\mu_3\text{-}S)_2(CO)_8$ units derived from **5** by the loss of one CO ligand from the central osmium atom (see Scheme 4).

The self-condensation of compound **25** provides an interesting sequence of products that reveals in great detail the importance of the bridging sulfido ligand to the cluster growth process. When heated to 125°C compound **25** is decarbonylated and yields a mixture of several hexaosmium compounds.[30] Of particular importance are the compounds of formula $Os_6(\mu\text{-}H)_2(\mu_4\text{-}S)(\mu_3\text{-}S)(\mu\text{-}HC{=}NR)_2(CO)_{17}$ (**36**) and $Os_6(\mu\text{-}H)_2(\mu_4\text{-}S)(\mu_3\text{-}S)(\mu\text{-}HC{=}NR)_2(CO)_{16}$ (**37**) (R=C_6H_5 and *p*-C_6H_5F). The former exists in two separable isomeric forms. The latter exists in three separable isomeric forms. Compounds **36** can be converted into **37** by further heating at 125°C. An ORTEP diagram of one of the isomers of **36** is shown in Fig. 13. The molecule consists of two open triosmium clusters linked by a quadruply bridging sulfido ligand of type **3**. The Os(1)–Os(2)–Os(3) grouping contains 10 CO ligands which is one more than it contained in the form **25**. The Os(4)–Os(5)–Os(6) grouping contains only seven CO ligands. It is not known if the CO ligand acquired by the Os(1)–Os(2)–Os(3) group was transferred intramolecularly or intermolecularly from the Os(4)–Os(5)–Os(6) group. The most important feature of the molecule is the quadruply bridging sulfido ligand S(1) which has brought the two triosmium groups into an

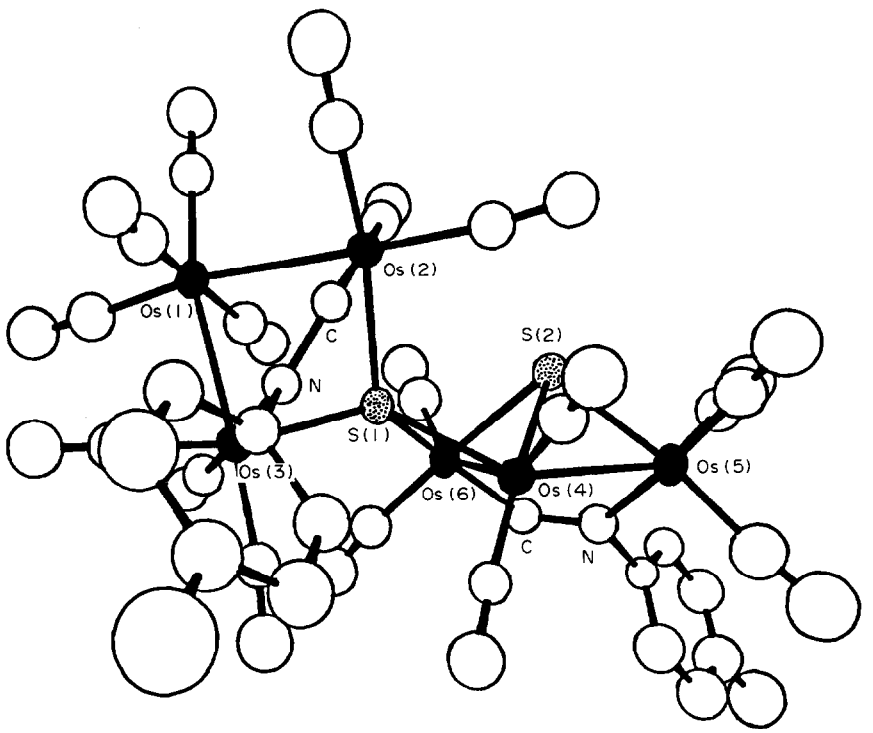

Fig. 13. An ORTEP diagram of one of the isomers of $Os_6(\mu\text{-}H)_2(\mu_4\text{-}S)(\mu_3\text{-}S)(\mu\text{-}HC{=}NC_6H_4F)_2(CO)_{17}$ (**36**). The metal atoms are blackened completely.

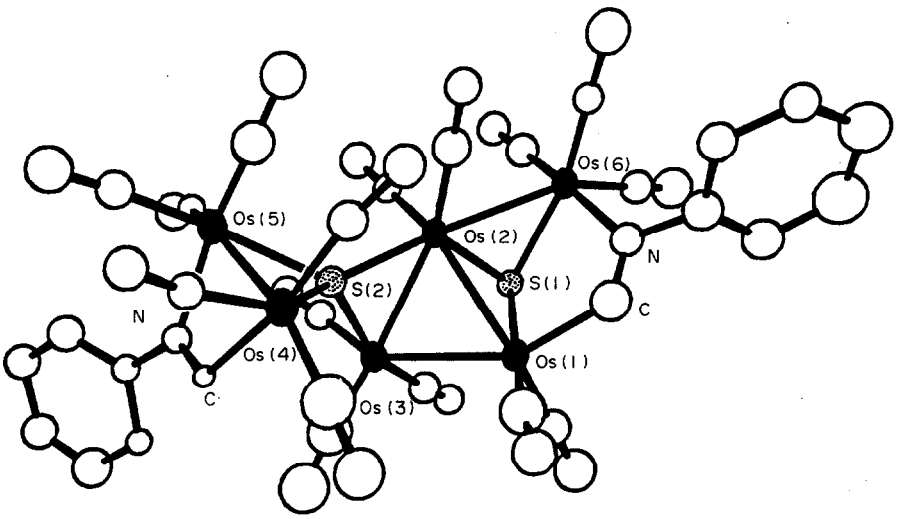

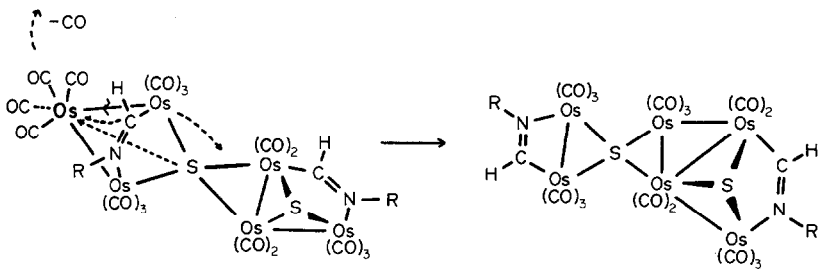

Fig. 14. An ORTEP diagram of one of the isomers of $Os_6(\mu\text{-}H)_2(\mu\text{-}HC{=}NC_6H_5)_2(CO)_{16}$ (**37**). The metal atoms are blackened completely.

inseparable relationship. No metal–metal bonds were made and none were broken in the conversion of **25** into **36**.

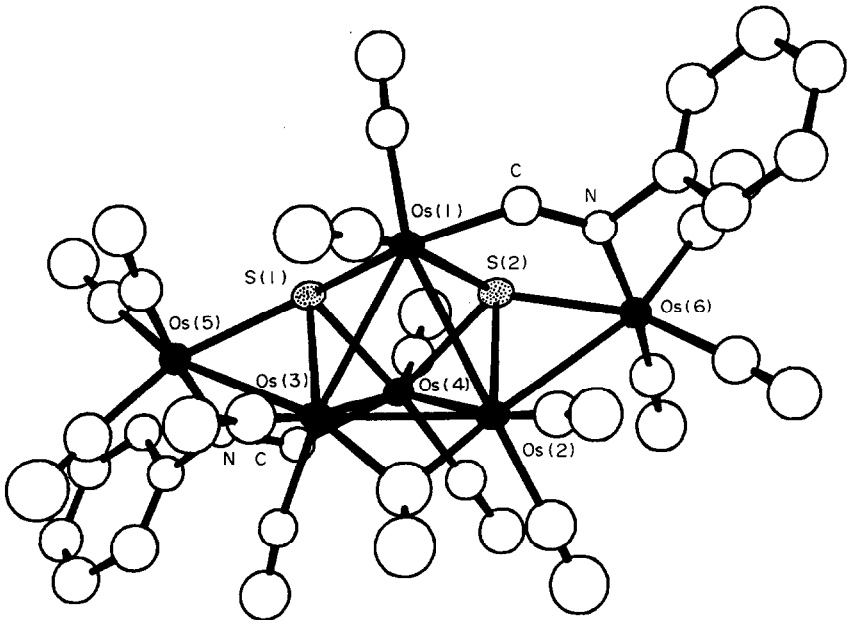
An ORTEP diagram of **37** is shown in Fig. 14. This molecule consists of groups of four and two osmium atoms. A quadruply bridging sulfido ligand S(2) joins these two groups. The formation of **37** from **36** has occurred by the transfer of one osmium atom from one group of three metal atoms to the other group of three. In this transformation there is a loss of one CO ligand and a net increase by one in the number of metal–metal bonds. The transformation of **36** into **37** must have involved several steps. A mechanism that shows the essential atomic and ligand shifts is shown in Scheme 5.

When heated to 150°C, compound **37** loses another CO ligand plus an equivalent of H_2 and forms the compound $Os_6(\mu_4\text{-}S)_2(\mu\text{-}HC{=}NR)_2(CO)_{15}$ (**38**). An ORTEP diagram of the molecular structure of **38** is shown in Fig. 15. This molecule consists of a butterfly tetrahedron of four osmium atoms with external $Os(CO)_3$ groups attached to each of the "hinge" atoms of the butterfly tetrahedron. Quadruply bridging sulfido ligands bridge the open triangular faces of the butterfly tetrahedron and extend to the external $Os(CO)_3$ groups. These sulfido ligands are highly strained and conform to the definition of "inverted" tetrahedra (see Section I). There is a bridging carbonyl ligand across the Os(2)–Os(3) hinge bond. A transformation that shows the rearrangements implicit in the conversion of **37** into **38** is given in Scheme 6. The most important feature is that the condensation process has progressed further and at this stage a new cluster grouping (the butterfly tetrahedron) that is quite distinct from the two original triosmium units has assembled and has become a focal point of the molecule.

(b) *Mixed-metal clusters.* Some efforts have been made to investigate the potential for the synthesis of mixed-metal cluster compounds by adding groupings with transition elements other than osmium to

36 **37**

Scheme 5.



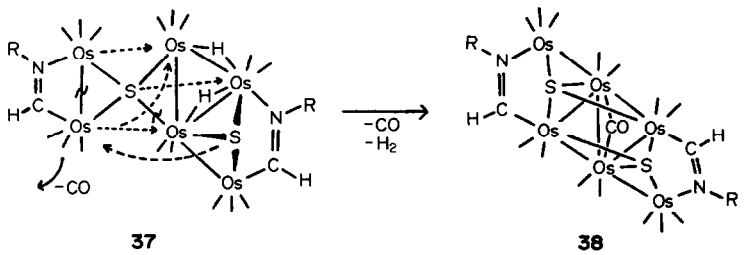


Fig. 15. An ORTEP diagram of $Os_6(\mu_4\text{-}S)_2(\mu\text{-}HC{=}NC_6H_5)_2(CO)_{15}$ (**38**). The metal atoms are blackened completely.

the sulfido osmium clusters described above. These preliminary studies have been quite successful. The groupings that have received the most attention are platinum phosphine species and tungsten carbonyl complexes. Platinum phosphine complexes are labile and usually add to the sulfido osmium clusters smoothly at room temperature. The tungsten carbonyl complexes are less reactive and usually require application of UV irradiation to initiate the reactions. The reactions of mononuclear metal species with the clusters results usually in the addition of only one metal unit.

The reactions of **19** with $Pt(PMe_2Ph)_4$ yields four tetranuclear products. These are $PtOs_3(\mu_3\text{-}S)(CO)_{10}(PMe_2Ph)_2$ (**39**), $PtOs_3(\mu_3\text{-}S)(CO)_9(PMe_2Ph)_3$ (**40**), $PtOs_3(\mu_3\text{-}S)(CO)_9(PMe_2Ph)_2$ (**41**) and $PtOs_3(\mu_3\text{-}S)(CO)_8(PMe_2Ph)_3$ (**42**).[31] The last two can be prepared from the first two, in order, by thermal decarbonylation. An ORTEP diagram of **39** is shown in Fig. 16. The molecule consists of a planar butterfly tetrahedron (dihedral angle = 177°) of three osmium and one platinum atoms. The platinum atom contains only two phosphine ligands and the sulfido ligand bridges a $PtOs_2$ triangular group instead of an Os_3 group as it did in **19**. Compound **40** is structurally analogous but contains an $Os(CO)_3(PMe_2Ph)$ group instead of the $Os(CO)_4$ group in **39**.[31] Of the two decarbonylation products, only compound **42** has been characterized structurally.[31] An ORTEP diagram of **42** is shown in Fig. 17. This molecule consists of a closed tetrahedral cluster of three osmium and one platinum atoms, but in this case the sulfido ligand bridges an Os_3 triangle. Compound **41** is believed to be structurally analogous to **42**. A mechanism that accounts for the formation of this sequence of products is shown in Scheme 7. It is believed that an interaction of the sulfido ligand

37 **38**

Scheme 6.

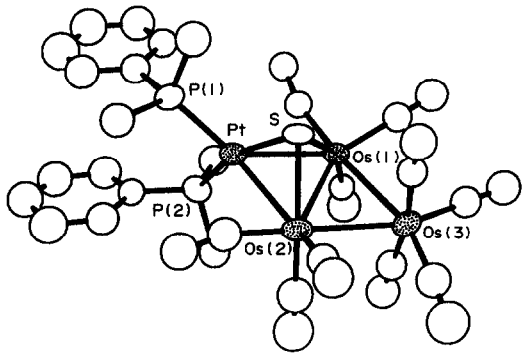

Fig. 16. An ORTEP diagram of $PtOs_3(\mu_3\text{-}S)(CO)_{10}(PMe_2Ph)_2$ (**39**) showing 50% probability thermal ellipsoids.

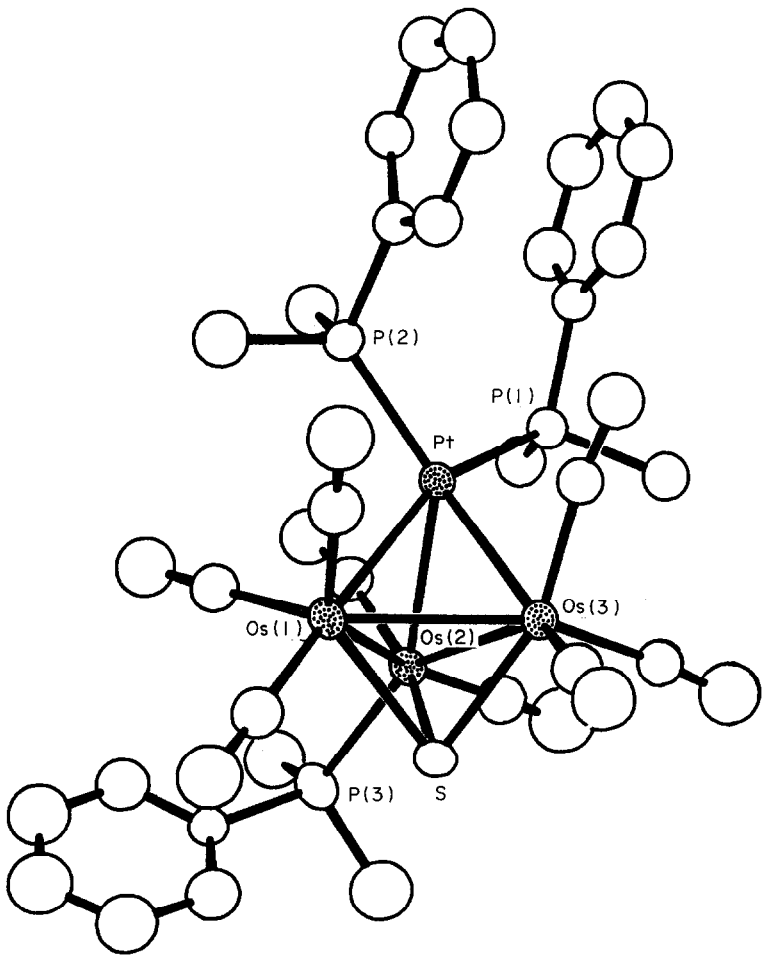
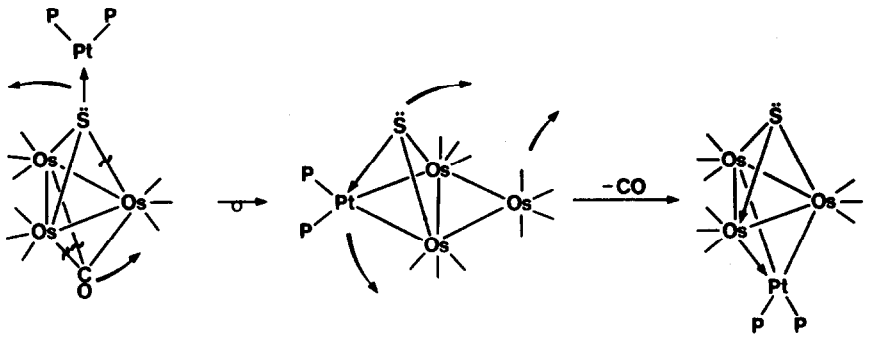
with the platinum moiety is an important first step in the reaction. It should be noted that the facile synthesis of the mixed-metal clusters **39–42** contrasts sharply with similar reactions in which no sulfido ligands are present. For example, the reaction of $Os_3(CO)_{12}$ with $Pt(PR_3)_4$ yields only phosphine-substituted derivatives of $Os_3(CO)_{12}$.[32]

The irradiation of solutions of **19** and $W(CO)_5(PMe_2Ph)$ in hexane solvent leads to formation of the





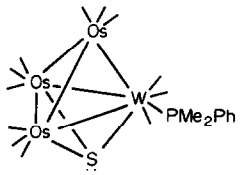


Fig. 17. An ORTEP diagram of $PtOs_3(\mu_3\text{-}S)(CO)_8(PMe_2Ph)_3$ (**42**) showing 50% probability thermal ellipsoids. Os(1)–Pt = 2.853(1) Å, Os(2)–Pt = 2.740(1) Å, Os(3)–Pt = 2.766(1) Å, Os(1)–Os(2) = 2.816(1) Å, Os(1)–Os(3) = 2.770(1) Å, Os(2)–Os(3) = 3.064(1) Å.

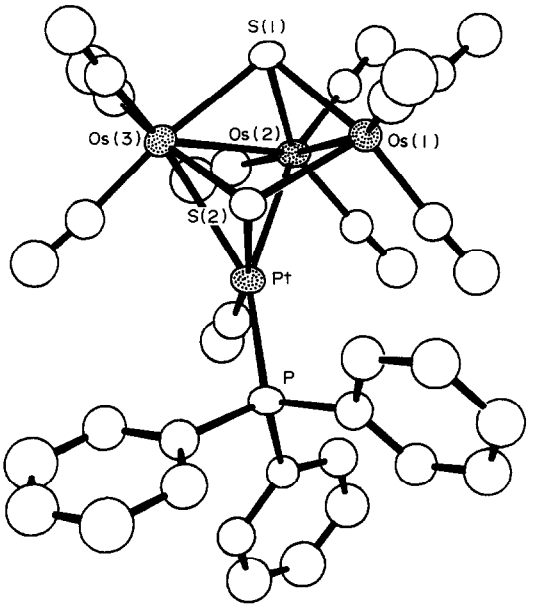
Scheme 7.

mixed tungsten–osmium cluster $Os_3W(\mu_3\text{-}S)(CO)_{11}(PMe_2Ph)_2$ (**43**) in 27% yield. The molecule consists of a closed tetrahedral cluster with the sulfido ligand bridging an Os_2W triangular face.[33] The mechanism of formation of **43** has not been established yet.

43

Compound **5** reacts with $Pt(PPh_3)_2C_2H_4$ to give two tetranuclear products $PtOs_3(\mu_3\text{-}S)_2(CO)_9(PPh_3)L$ (**44**) (L = CO) and **45** (L = PPh_3) and a PPh_3 substitution product of **5**. Compound **44** has acquired one CO ligand, and its yield is significantly increased when the reaction is performed under a CO atmosphere. The structure of **44** is shown in Fig. 18. The molecule contains four metal–metal bonds. Three of these exist in a triangular $PtOs_2$ group. The fourth links an $Os(CO)_3$ group to



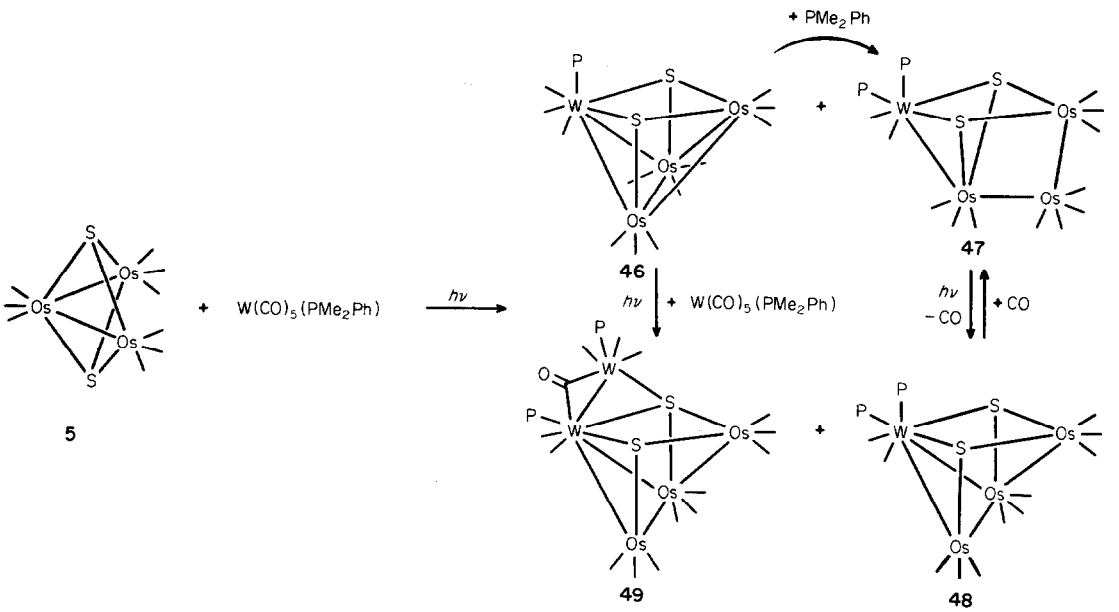


Fig. 18. An ORTEP diagram of $PtOs_3(\mu_3\text{-}S)_2(CO)_{10}(PPh_3)$ (**44**) showing 50% probability thermal ellipsoids. Os(1)–Os(2) = 2.826(1) Å, Os(2)–Os(3) = 2.990(1) Å, Pt–Os(2) = 2.858(1) Å, Pt–Os(3) = 2.905(1) Å, Os(1)...Os(3) = 3.585(1) Å, Os(1)...Pt = 3.401(1) Å.

the triangular group at one of the osmium atoms. The distance of this external osmium atom to the platinum atom is 3.401(1) Å, which seems to be too long for a significant bonding interaction. The $PtOs_2$ group contains triply bridging sulfido ligands that bridge a Pt—Os and the Os—Os edges and extend to the third osmium atom. The compound appears to have been formed by the insertion of a Pt-containing group into two adjacent Os—S bonds of **5**. Compound **45** has a similar structure. Unlike compound **17** (see below) compounds **44** and **45** are electron-precise [i.e. all the metal atoms obey the effective atomic number (EAN) rule].

When irradiated in the presence of $W(CO)_5PMe_2Ph$, compound **5** yields four new products: $Os_3W(\mu_3\text{-}S)_2(CO)_{12}(PMe_2Ph)$ (**46**), $Os_3W(\mu_3\text{-}S)_2(CO)_{12}(PMe_2Ph)_2$ (**47**), $Os_3W(\mu_3\text{-}S)_2(CO)_{11}(PMe_2Ph)_2$ (**48**) and $Os_3W_2(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_{14}(PMe_2Ph)_2$ (**49**).[34] The structures and relationships between these molecules are shown schematically in Scheme 8. Compound **46** has a butterfly tetrahedral cluster of four metal atoms with triply bridging sulfido ligands on the two open triangular faces. It is structurally analogous to the homonuclear compound **17**. Compound **47** consists of a planar cluster of four metal atoms with triply bridging sulfido ligands on opposite sides of the Os_3W plane. Compound **47** can be made from **46** by adding one equivalent of PMe_2Ph. Compound **48** is isoelectronic with **46** but it adopts a structure similar to **44** and **45**, consisting of triangular group of three metal atoms with an external $Os(CO)_3$ group linked to the triangle by one metal–metal bond and the bridging sulfido ligands. Compound **48** can be made independently by the irradiation-induced decarbonylation of **47**. The pentanuclear Os_3W_2 compound **49** contains an Os_3W cluster analogous to **48** but has a $W(CO)_4(PMe_2Ph)$ group bridging a W—S edge of the cluster. Compound **49** can be made by the irradiation-induced addition of a $W(CO)_4(PMe_2Ph)$ moiety to **46**.

In all of the tungsten–osmium complexes there are bonds between the tungsten atoms and the sulfido ligands. As discussed earlier [cf. eqn (5)], it is believed that preliminary metal–sulfur interactions may be important to the condensation process. The photo-induced reaction of $W(CO)_6$ with **5** yields the product $Os_3(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_9[W(CO)_5]$ (**50**), which shows such an interaction in its most fundamental form.[35] The structure of **50** is shown in Fig. 19. Most simply, the molecule contains a $W(CO)_5$ group attached to one of the triply bridging sulfido ligands of a molecule of **5**. The connection involves a simple donor–acceptor bond formed by donation of the lone pair of electrons on the sulfido ligand into an empty orbital on the tungsten atom.

Scheme 8.

III. BONDING AND UNUSUAL REACTIVITY

The nature of the metal–metal bonding in polynuclear metal complexes is still not well understood. Localized 2*c*–2*e* bonding and application of the EAN rule works well for small clusters (i.e. four metal

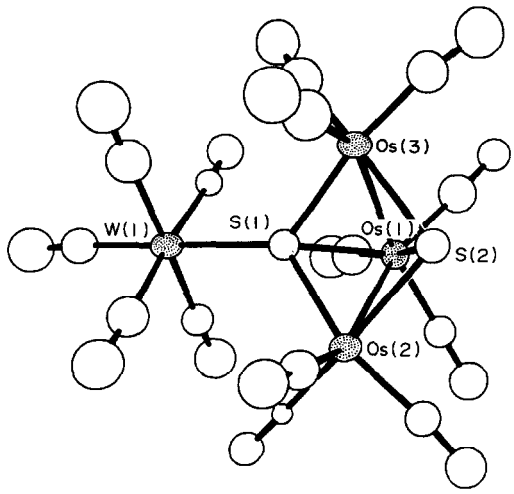

Fig. 19. An ORTEP diagram of $Os_3(\mu_4\text{-}S)(\mu_3\text{-}S)(CO)_9[W(CO)_5]$ (**50**) showing 50% probability thermal ellipsoids.

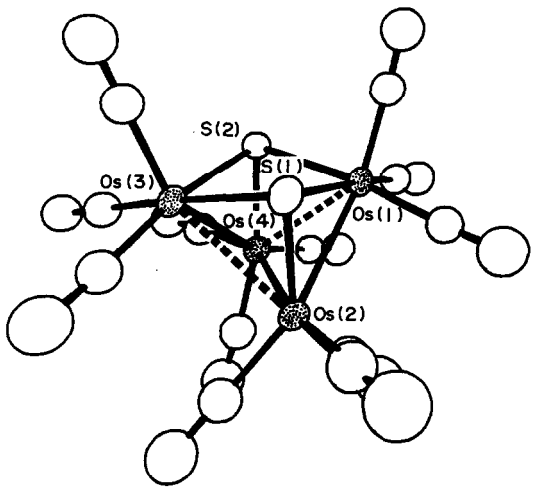
atoms or less) while the PSEP theory,[36] which employs a delocalized bonding, works better for the larger clusters (i.e. five atoms or more). Recently, Teo has described the topological electron counting theory which incorporates the essential features of both the EAN and the PSEP theories.[37] It should be pointed out, however, that in many cases the EAN rule and the PSEP theory predict the same connectivities for the metal atoms in both the large and small clusters.

1. M_4S_2 *clusters*

Recent studies have revealed a small number of tetranuclear clusters that conform to the PSEP theory but show unusually high reactivities.[27,38] In reactions they convert to products that obey the EAN rule. One of these clusters is the sulfido osmium cluster $Os_4(\mu_3\text{-}S)_2(CO)_{12}$ (**17**).[27] An ORTEP diagram of **17** is shown in Fig. 20. The molecule consists of a butterfly tetrahedron of four metal atoms and has sulfido ligands bridging the two open triangular faces. There are five osmium–osmium distances that are short enough (less than 3.10 Å) to imply significant bonding interactions. Each metal



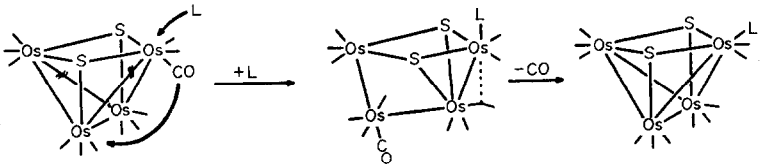


Fig. 20. An ORTEP diagram of $Os_4(\mu_3\text{-}S)_2(CO)_{12}$ (**17**) showing 50% probability thermal ellipsoids. Os(1)–Os(2) = 2.914(1) Å, Os(1)–Os(4) = 3.091(1) Å, Os(2)–Os(4) = 2.935(1) Å, Os(2)–Os(3) = 3.002(1) Å, Os(3)–Os(4) = 2.940(1) Å, Os(1)...Os(3) = 3.551(1) Å.

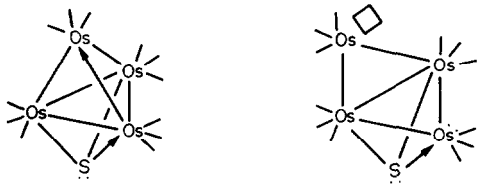
atom contains three carbonyl ligands and, if the sulfido ligands serve as four-electron donors, then the cluster contains 64 valence electrons. This is two in excess of the requirements of the EAN rule. For this reason we have chosen to describe the molecules as *electron-rich*. If the molecule simply eliminated one metal–metal bond, then all the metal atoms could be made to adhere to the EAN rule. Curiously enough, the isoelectronic compounds **44**, **45** and **47** do have only four metal–metal bonds, but **46** has five. The reason for this is not clear, but steric effects could be important. Intuitively, it seems that compound **47** is more sterically crowded than **46** and this could mitigate against the formation of the fifth bond. The structures of **17** and **46** are, however, in accord with the PSEP theory. According to the PSEP theory $Os(CO)_3$ groups contribute two electrons to cluster bonding and triply bridging sulfido ligands contribute four. There are thus 16 or 8 pairs of cluster valence electrons present in **17**. The PSEP theory predicts a cluster shape based on a polyhedron with seven vertices. This is the pentagonal bipyramid. The structure of **17** can be regarded as a pentagonal bipyramid with one vertex missing (i.e. a *nido*-pentagonal bipyramid). Thus, the observed structure with five metal–metal bonds is the expected one. However, upon close examination of the metal–metal bonding, it is observed that two of the metal–metal bonds, indicated by the dashed connections in Fig. 20, are significantly longer (greater than 3.00 Å) than the other metal–metal bonds in **17** and also the metal–metal distances in $Os_3(CO)_{12}$ [2.877(3) Å]. The latter might best be regarded as Os—Os single bonds. It has not been established if these bond lengthenings are a result of incomplete delocalization or are caused by distortions in the ligand structure.

Studies were undertaken to try to establish if compounds **17** and **46**, which show similar distortions, might exhibit any unusual reactivity. These studies showed the compounds to be remarkably reactive and most surprisingly, toward the addition of Lewis donors, L. For example, compound **17** adds 1 mol of CO at room temperature under 1 bar pressure to form compound **30**.[27] The addition of phosphines and isocyanides proceeds similarly to yield the derivatives $Os_4(\mu_3\text{-}S)_2(CO)_{12}L$ (**51**) (L = PMe_2Ph) and (**52**) (L = $CNBu^t$).[39] The structures of **51** and **52** (see Scheme 9) show that a shift of a carbonyl ligand between the metal atoms must have occurred since each molecule contains an $Os(CO)_4$ group. Also since phosphine ligands do not engage in intramolecular shifts, it implies that the site of addition was one of the "wing-tip" metal atoms of the cluster of **17**. Compounds **30**, **51** and **52** each contain only three metal–metal bonds. They are thus "electron-precise" and all the metal atoms obey the EAN rule. The formation of these compounds can be achieved most easily by cleaving the two elongated bonds in **17**, transferring one CO ligand between a pair of metal atoms, and shifting the attachment of one of the bonds of one of the sulfido ligands to a different metal atom. The reason for the nucleophilic addition at the wing-tip metal atom in **17** could be steric. The wing-tip metal atoms are less crowded being only 6-coordinate while the hinge atoms are 7-coordinate. Compounds **51** and **52** lose CO when heated to form substitution derivatives of **17**. Compound **46** reacts similarly to **17**, but the electron-precise analogs, especially **44** and **45**, are considerably less reactive and undergo cluster degradation when subjected to forcing conditions. Surprisingly, none of these compounds will add alkenes or alkynes.

Another interesting and important reaction is the addition of hydrogen to **17**.[40] The reaction requires a temperature of 100°C and cluster degradation due to further reaction occurs but the initial product is compound **6**. The mechanism of the reaction is not known, but it involves the addition of 1 mol of H_2 and the cleavage of the two elongated metal–metal bonds in **17**. The end product of the reaction is $H_2Os_3(\mu_3\text{-}S)(CO)_9$.



Scheme 9.

2. M_4S *clusters*

The archetypical molecule of this series is compound **16** which is a 60-electron cluster that consists of a closed tetrahedral cluster of metal atoms with a triply bridging sulfido ligand on one triangular face.

The molecule is electron-precise and all the metal atoms obey the EAN rule, but careful consideration reveals a feature about the bonding that could be important to its reactivity. Specifically, one of the metal–metal bonds to the unique osmium atom can be viewed as a heteropolar (donor–acceptor) bond.[41] In addition, since the sulfido ligand is a four-electron donor, one of the Os—S bonds can be

16 16A

regarded similarly. Of course, in its resonance stabilized state all the metal–metal bonds to the unique osmium atom and all the metal–sulfur bonds will be chemically equivalent. However, the notion of the heteropolar bond suggests something about its potential reactivity that may distinguish it from the homopolar bond. Namely, one of these bonds can be opened **16A** without producing a charge separation and a ligand can be added to the vacant site on the unique metal atom. In compound **16** reactions of this type are remarkably facile.[42] For example, **16** adds 1 mol of CO at room temperature under 1 bar pressure to form compound **29**. The reaction is quantitative and complete in approximately 3 h. A similar reaction occurs with phosphines and even with amines, and with amines the reaction is complete in a matter of seconds. These additions are also reversible.

Compound **16** activates hydrogen, and this reaction proceeds albeit slowly even at room temperature/1 bar pressure. The product is $Os_4(\mu\text{-}H)_2(\mu_3\text{-}S)(CO)_{12}$ (**53**) and the ORTEP diagram of structure of **53** is shown in Fig. 21. The molecule consists of a butterfly tetrahedral cluster with the sulfido ligand bridging one of the open triangular faces. The hydride ligands were not located in the structural analysis, but the two metal–metal bonds opposite the sulfido ligand are elongated and this suggests that each may contain one bridging hydride ligand. The formation of **53** has involved the cleavage of one of the homopolar sulfur-bridged metal–metal bonds in **16** and not the "heteropolar" bond. This may be related to the fact that the addition of hydrogen *results* in a homolytic cleavage of the H_2 molecule.

The reaction of **16** with alkynes is especially interesting, but to date only reactions with terminal alkynes have been investigated.[43] The reaction of **16** with PhC≡CH yields two noninterconvertible products. These have been identified as $Os_4(\mu_3\text{-}S)[\mu_4\text{-}C{=}C(H)Ph](CO)_{12}$ (**54**) and $Os_4[\mu_4\text{-}SC(Ph)CH](CO)_{12}$ (**55**). The structure of **54** is shown in Fig. 22. The molecule consists of a puckered rhombus of four osmium atoms connected by four metal–metal bonds. A sulfido ligand bridges three of the metal atoms while a phenylvinylidene ligand bridges all four metal atoms on the opposite side of the

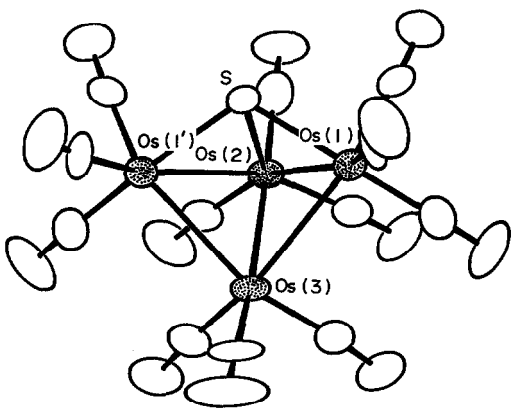


Fig. 21. An ORTEP diagram of $Os_4(\mu\text{-}H)_2(\mu_3\text{-}S)(CO)_{12}$ (**53**). The molecule contains a crystallographic plane of symmetry passing through the atoms S, Os(2) and Os(3). Os(1)–Os(2) = 2.8149(6) Å, Os(1)–Os(3) = 2.9699(9) Å, Os(2)–Os(3) = 2.8578(10) Å, Os(1)...Os(1') = 3.9295(9) Å.

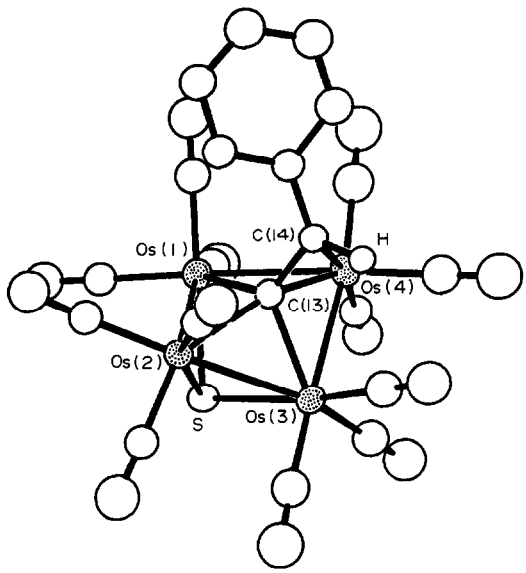

Fig. 22. An ORTEP diagram of $Os_4(\mu_3\text{-}S)[\mu_4\text{-}C{=}C(H)Ph](CO)_{12}$ (**54**) showing 50% thermal ellipsoids. Os(1)–Os(2) = 2.850(1) Å, Os(1)–Os(4) = 2.859(1) Å, Os(2)–Os(3) = 2.787(1) Å, Os(3)–Os(4) = 2.866(1) Å, C(13)–C(14) = 1.446(16) Å.

rhombus. The formation of the vinylidene has obviously occurred by a 1,2-shift of the acetylenic hydrogen atom. These rearrangements have been observed previously in a number of cases in reactions of metal complexes with terminal alkynes.[44] The structure of **55** is shown in Fig. 23. The molecule consists of a butterfly tetrahedral cluster of four metal atoms with a quadruply bridging S—CPh=CH thiolato ligand. The sulfur atom of this unusual ligand bridges two osmium atoms while the alkenyl group is σ,π-bonded to the other two. The ligand was formed by the formation of a carbon–sulfur bond between the phenyl-substituted carbon of the alkyne and the sulfido ligand and a cleavage of one osmium–sulfur and one osmium–osmium bond in the cluster. Curiously, the hydrogen shift that occurred in the formation of **54** did not occur in the formation of **55**. Although the mechanism of this hydrogen shift is not yet known, it is tempting to speculate that the absence of a hydrogen shift in the formation of **55** may somehow be related to the formation of the bonding interaction between the

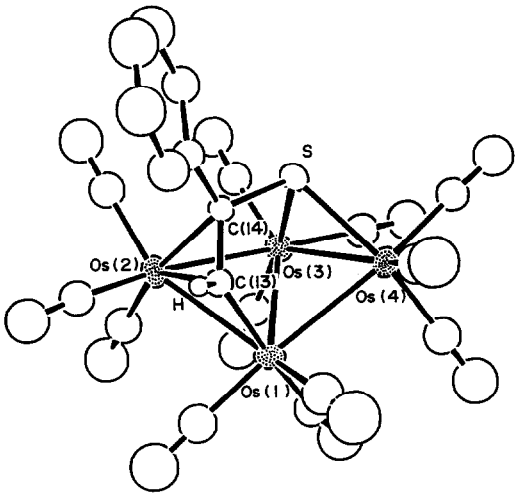

Fig. 23. An ORTEP diagram of $Os_4[\mu_4\text{-}SC(Ph){=}CH](CO)_{12}$ (**55**) showing 50% probability thermal ellipsoids. Os(1)–Os(2) = 2.7840(7) Å, Os(1)–Os(3) = 2.8490(7) Å, Os(1)–Os(4) = 2.8442(7) Å, Os(2)–Os(3) = 2.8132(7) Å, Os(3)–Os(4) = 2.764(1) Å, S–C(14) = 1.817(11) Å, C(13)–C(14) = 1.400(15) Å.

alkyne and the sulfido ligand. Such effects might also occur in the sulfur-inhibited reactions of certain heterogeneous transition metal catalysts. In fact a variety of sulfur–ligand interactions similar to those found in **55** could be responsible for and explain a range of the sulfur-poisoning effects that exist for heterogeneous catalysts.[45,46]

(*Received* 29 *March* 1985; *accepted* 10 *June* 1985)

Abstract—The reaction of 2-(1-methyl-2-piperidinyl)ethanethiol with sodium tetrachloropalladate(II) at pH = 8 yields a yellow precipitate of formula $[Pd_2(C_8H_{16}NS)_2Cl_2]$ which crystallized in the orthorhombic space group *Pcab* with $a = 22.050(4)$ Å, $b = 14.644(3)$ Å, $c = 13.834(3)$ Å, $V = 4467(3)$ Å^3, and $Z = 8$. The organic ligands chelate to one Pd atom through the S and N atoms and bridges to another Pd atom through the S atom to form a dimer in which each molecule of the organic ligand has the same chirality. IR, UV–Vis and ^{1}H NMR spectra are presented for this compound.

The study of complexes with aliphatic γ-mercaptoamines has been undertaken in our Department and several results have been published elsewhere.[1–4] 3-Amino-1-propanethiol has been revealed as a chelating agent while *N*,*N*-dimethyl-3-amino-1-propanethiol behaves as a unidentate ligand with first-row transition metals, and as a bidentate one with second-row transition metals. In order to investigate the influence of substituents on the nitrogen atom upon the coordination through this atom we have studied the ligand 2-(1-methyl-2-piperidinyl)ethanethiol. This ligand resembles *N*,*N*-dimethyl-3-amino-1-propanethiol but with a crowded substituent around the nitrogen atom and the possibility of optical isomerism.

EXPERIMENTAL

To a solution of 0.150 g of ligand (0.964 mmol) in 5 cm^3 of a water–methanol mixture [8 : 2 (v/v)] 0.284 g of $Na_2(PdCl_4)$ (0.964 mmol) in 5 cm^3 of water were slowly added with stirring. The precipitate that formed was allowed to redissolve and the resulting yellow solution was treated with dilute NaOH to pH = 8. The solid that precipitated was stirred for 15 min, filtered, washed with a water–methanol mixture [8 : 2 (v/v)] several times and dried *in vacuo* over silica gel. The dry product was recrystallized by slow diffusion of ether into a dichloromethane solution of the complex. Elemental analyses agreed with a stoichiometry of $PdC_8H_{16}NSCl$. Found : C, 32.1 ; H, 5.2 ; N, 4.7. Calc. for $[Pd_2(C_8H_{16}NS)_2Cl_2]$: C, 32.0 ; H, 5.37; N, 4.67%. Elemental analyses were performed on a Perkin–Elmer 240 elemental analyzer.

The electronic spectrum of the complex was analyzed by the fourth-derivative method[5] and the following bands were found : 23.2 (sh), 27.5 (sh), 35.5, 43.9 (sh) and 45.7 kK. The first two can be assigned to *d*–*d* transitions but they are strongly overlapped with charge-transfer bands.

IR spectra were recorded on a Beckman IR-20 A

* Author to whom correspondence should be addressed.

spectrophotometer as KBr (4000–600 cm^{-1}) or polyethylene (600–250 cm^{-1}) pellets. UV–Vis spectrum was recorded on a Shimadzu 240 spectrophotometer in dichloromethane solution.

The IR spectrum of the complex shows two bands at 2927 and 2857 cm^{-1} instead of the four bands at 2930, 2850, 2780, and 2705 cm^{-1} in the ligand. The bands at 2780 and 2705 cm^{-1} in the latter have been assigned to the ν(C—H) vibrations of a methyl group when bonded to a nitrogen atom having a lone electron pair on it[6] and disappear upon coordination. The bands at 475, 322 and 278 cm^{-1} have been assigned to ν(Pd—N), ν(Pd—S) and ν(Pd—Cl) respectively according to reported data.[7]

The ^{1}H NMR spectrum was recorded on a Varian XL-200 spectrometer in $CDCl_3$ solution.

In the ^{1}H NMR spectrum the signal assigned in the ligand to the methyl group shifts to lower fields (δ = 2.75 and 2.26 in the ligand), and the signal assigned to the proton bonded to the sulphur atom disappears. These facts revealed a bidentate behaviour of the ligand in the complex.

The above-mentioned results were confirmed by X-ray diffraction methods. An orange prism (0.1 × 0.1 × 0.2 mm) was selected and mounted on a Philips PW-1100 four-circle diffractometer. The unit cell parameters were determined from the automatic centering of 25 reflections ($4 \leqslant \theta \leqslant 9°$) and refining the cell parameters by least squares. Intensities were collected with Mo-K_α radiation and the ω scan mode. A summary of the main crystal data are shown in Table 1. Lorentz polarization, but not absorption, corrections were made.

The palladium atoms were located from a Patterson synthesis while the remaining non-hydrogen atoms were located with the DIRDIF system.[8] The structure was isotropically and anisotropically refined by full-matrix least-squares method using the SHELX 76 computer program.[9] The function minimized was $\sum w\|F_o|-|F_c\|^2$, where $w = [\sigma^2(F_o)+0.0108|F_o|^2]^{-1}$: f, f' and f'' were taken from the *International Tables of X-ray Crystallography*.[10] Hydrogen atoms were refined with an overall isotropic temperature coefficients from computed positions. The final R value was 0.068 (R_w = 0.091) for all observed reflections. Atomic coordinates, thermal parameters and lists of F_o and F_c values have been deposited as supplementary material with the Editor. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

DISCUSSION

Figure 1 is a perspective view of the molecule showing the atom numbering. Hydrogen atoms have been omitted for clarity. Table 2 lists the principal intramolecular distances and angles. The structure consists of discrete molecules linked by Van der Waals' forces. Each palladium atom is linked to two sulphur atoms, a nitrogen atom and a chlorine atom in a nearly planar fashion [largest deviation of atom from mean plane is −0.079(4) Å for Pd(1) and −0.084(4) for Pd(2), respectively]. The ring formed by Pd and S atoms is hinged Å dihedral angle between S,Pd,S planes (θ) = 142.8(1)°] with a *syn–endo* conformation. The Pd—S distance is shorter than the sum of their covalent radii (2.36 Å according to

Pauling[11]) and also shorter than others reported in the literature.[12] The S—S distance is shorter than the sum of the Van der Waals' radii (3.70 Å), suggesting the existence of weak interactions between the two sulphur atoms according to Fackler.[12(f)] The six-membered chelate rings have chair conformation as well as the piperidine rings. Both piperidine rings lie on the same side of the coordination planes of the palladium atoms. In each molecule only one of the optical isomers of the ligand is found. The centre of inversion relates four molecules of the *R*,*R* isomer with the other four of the *S*,*S* isomer.

The structure of the molecule as a whole resembles that of af-dichloro-bd,ec-bis[μ-(*N*,*N*-dimethyl-3-amino - 1 - propanethiolato) - *S*,*N*,μ - S]dipalladium(II). A comparison of the salient dimensions of the molecules is presented in Table 3. The major observation is that $[Pd_2(C_5H_{12}NS)_2Cl_2]$ more

closely approximates to the square planar symmetry, probably owing to the presence of a piperidine ring in $[Pd_2(C_8H_{16}NS)_2Cl_2]$. The opening of the Pd—S—Pd angles makes shorter the S—S distance in the former, but also in the latter this is shorter than the sum of the Van der Waals' radii. The dihedral angle is larger in $[Pd_2(C_5H_{12}NS)_2Cl_2]$ but the disorder observed in this molecule may account for this feature.

CATALYTIC ACTIVITY OF ETHYLENE-BRIDGED AMINOACID–COPPER(II) COMPLEXES FOR THE DISMUTATION OF SUPEROXIDE

B. M. KATZ and V. I. STENBERG*

Department of Chemistry, University of North Dakota, Grand Forks, ND 58202, U.S.A.

(*Received* 2 *February* 1985; *accepted after revision* 10 *June* 1985)

Abstract—Copper complexes of bridged ethylene derivatives of the aminoacids leucine, isoleucine, valine, alanine, glycine and 2-methylalanine showed marked differences in their ability to quench superoxide. Leucine, alanine and 2-methylalanine ethylene-bridged copper complexes displayed the highest activity, the glycine complex was the least active, and valine had low and isoleucine intermediate activities. A study of differences in speciation, chelation, electronic and steric factors with the aid of molecular models led to a tentative hypothesis that the methyl groups of isoleucine and valine, when distorted toward tetrahedral, are able to block the axial site of copper from binding to superoxide. The glycine-bridged copper complex is believed to form a dimer at the axial copper site which completely blocks the attachment of superoxide.

Copper is an essential trace element required by several enzymes of the body. One of these is superoxide dismutase which has the function of inhibiting the superoxide anion (O_2^-). The production of the latter has been associated with oxygen toxicity.[1] The active site of the enzyme is copper and the mechanism of catalytic activity of copper towards superoxide appears to involve open-coordination positions of copper for reaction with superoxide.[2]

Kinetic studies of superoxide dismutation by copper histidine,[3] *o*-phenanthroline[4] and an ESR study of copper salicylate[5] indicate that superoxide initially binds to the axial copper site. When the open-coordination site of copper is bound by a polypeptide nitrogen, the activity of the metal complex is markedly reduced.[6] Aminoacid–copper complexes were found to exhibit a wide range of activities with superoxide, but mechanistic studies to elucidate structure–activity relationships were not done.[7]

The objectives of this study were to synthesize various substituted ethylenediaminediacetic acid complexes and examine their ability to react with the superoxide ion. The ethylene bridge is for the purpose of attaining compounds that possess enhanced chelation properties compared to the unbridged amino acids.[8] In catabolism, the organic ligand is expected to yield the corresponding ketoacids and ethylenediamine by transamination. The ethylenediamine ligands are derivatives of the aliphatic aminoacids: valine, isoleucine, leucine, alanine, 2-methylalanine and glycine.

EXPERIMENTAL

Aminoacids and ethylenediamine-*N*,*N*′-diacetic acid were supplied by Sigma Chemical Co., Eastman Co. and Fisher Scientific Co. NMR spectra were recorded on a Varian EM 390 spectrometer. The aminoacid derivatives were dissolved in NaOD. The internal standard was 3-(trimethylsilyl)-1-propanesulfonic acid, sodium salt hydrate.

General procedure for the preparation of ethylene derivatives of aminoacids

The appropriate aminoacid (0.1 mol) was dissolved in 100 cm^3 of water containing 0.1 mol NaOH and 0.05 mol sodium carbonate. To this solution was added 0.05 mol ethylene bromide in 100 cm^3 95% ethanol. The solution was heated for approximately 3 h under reflux or until a homogeneous solution was attained. This solution was cooled and acidified to pH 3 with 6 M HCl. The resultant precipitate was filtered, washed with

* Author to whom correspondence should be addressed.

distilled, deionized water and 95% ethanol. The aminoacid derivatives were air-dried. Solutions that did not precipitate with acid were concentrated until a precipitate formed. The compounds were purified by dissolving in aqueous solution, pH 10, and reprecipitating by adding HCl to pH 3.

D,L-leucine–ethylene. Yield 18.3%, m.p. (°C) 237–239 decomposed (d), molecular weight (MW) 288.22. Found: C, 58.2; H, 9.4; N, 9.4. Calc. for $C_{14}H_{28}O_4N_2$: C, 58.3; H, 9.7; N, 9.7%. NMR spectra: δ 0.9 (*d*, 6, $J = 2$ Hz) $(CH_3)_2CH$; 1.4 (*m*, 3) CH_2CH; 2.6 (*s*, 2) CH_2CH_2; 3.1 (*t*, 1, $J = 4$ Hz) $CHCOO^-$.

D,L-isoleucine–ethylene. Yield 21%, m.p. (°C) 260–262 d, MW 288.22. Found: C, 58.3; H, 10.0; N, 9.8. Calc. for $C_{14}H_{28}O_4N_2$: C, 58.3; H, 9.7; N, 9.7. NMR: δ 0.08 (*t*, 6) CH_3CH_2, CH_3CH; 1.1 (*m*, 2) CH_2CH; 1.5 (*m*, 1) CH_2CH; 2.5 (*s*, 2) CH_2CH_2; 2.8 (*d*, *d*, 1, $J = 3$ Hz, 6 Hz) $CHCOO^-$.

L-valine–ethylene. M.p. (°C) 301–302 d, reported 270–310 d.[9] NMR: δ 0.9 (*d*, *d*, 6, $J = 1$ Hz), $(CH_3)_2CH$; 1.8 (*m*, 1, $J = 4$ Hz) $CHCH_2$; 2.7 (*s*, 2) CH_2CH_2; 2.9 (*d*, 1, $J = 6$ Hz) $CHCOO^-$.

D,L-alanine–ethylene. M.p. (°C) 260–262 d, reported 264–266.[10] NMR: δ 1.4 (*d*, 3, $J = 4.5$ Hz), CH_3CH; 2.9 (*s*, 2) CH_2CH_2; 3.3 (*q*, 1, $J = 5$ Hz) $CHCOO^-$. The method of Schlesinger[11] was used for the preparation of 2-methylalanine.

Test solutions

Solutions for superoxide-quenching assays, ESR and photometric studies were prepared by weighing an appropriate amount of the ligand to obtain 1×10^{-2} M aminoacid–ethylene derivatives. A 10^{-2} M solution of $Cu(NO_3)_2$ was also prepared. Dilutions of 1×10^{-3} and 1×10^{-4} M copper complexes were attained by mixing equal volumes of the 1×10^{-2} M solution of the ligand and 1×10^{-2} M solution of the copper ion and diluting with a pH-7.6 aqueous buffer. Only a metal : ligand ratio of 1 : 1 was prepared.

Superoxide assays

KO_2 method.[12] To a series of test tubes were added 3.0 cm^3 buffer solution followed by 0.05, 0.1, 0.3 and 0.5 cm^3 of 1×10^{-4} M solution of the compound to be tested and brought to the same volume with 0.45, 0.4, 0.2 and 0 cm^3 of distilled deionized water. The final concentration varies from 1×10^{-6} to 1×10^{-5} M. To each tube was then added 0.1 cm^3 of a nitroblue tetrazolium (NBT) solution (4 mg cm^{-3}) in dimethylsulfoxide (DMSO) (Aldrich Gold Label), 0.1 cm^3 of a solution containing 20 mg KO_2 with 0.1056 g/10 cm^3 18-crown-6 (Aldrich) in DMSO. The tubes were shaken thoroughly after the addition of each reagent. The absorbance was read immediately at 540 mμ using a Bausch & Lomb Spectronic 20. All readings were taken against a blank containing everything except the potassium superoxide solution. A standard curve of increasing concentrations of KO_2 with absorbance gave a straight line with a correlation coefficient of 0.999. Three repetitive assays for one concentration were conducted for most of the test compounds in order to assure reproducibility. The average error did not exceed 5%.

β-Nicotinamide–adeninedinucleotide (NADH) method.[13] The assay was identical to the KO_2 method except for the following. After the addition of the NBT solution, 0.1 cm^3 phenazine methosulfate (PMS, 10 mg/100 cm^3 in buffer) was added. The reaction was then started by the addition of 0.3 cm^3 of NADH (1.5 mM in buffer) solution. The NADH solutions were made fresh before each assay. After standing in the dark for 10 min the readings were taken as described above. Preweighed vials purchased from Sigma Chemical Co. were the source of NADH. The results of three successive determinations with NADH from the same vial did not vary over 1%. The phosphate buffer was prepared by mixing 4.24 cm^3 of solution A (22.6 g $NaH_2PO_4 \cdot H_2O$ in 1 l) and 45.75 cm^3 of solution B (71.7 g $Na_2HPO_4 \cdot 12H_2O$ in 1 l) and diluting to 200 cm^3. Distilled, deionized water was used for all preparations and assays.

Potentiometric and spectrophotometric measurements

Potentiometric titrations were performed on the valine–, leucine– and isoleucine–copper complexes with metal : ligand ratio of 1 : 1, 10^{-2} M concentration, 25°C and 0.1 M KNO_3.[14] The dissociation constants were calculated from the inflection points. With the copper complexes of valine, leucine and isoleucine ethylene-bridged compounds, dissolution does not occur until a slightly basic pH is reached. Rapid back-titration with HCl provided a means for titration to an acid pH before bulk precipitation occurred. The values obtained with the back-titration were used in the calculations. Titration of copper with the basic ligands for determination of stability constants were done as outlined for nickel glycine.[14] The calculation of association constants was adapted to a dibasic acid system as described by Courtney *et al.*[15]

Equations (1)–(5) were assumed for the calculation of the dissociation constants where $[L^{2-}]$ is the concentration of completely deprotonated ligand, $[LH^-]$ is the concentration of monopronated ligand, $[LH_2]$ is the concentration of protonated

ligand, and α_L^{2-} is the fraction of the deprotonated ligand:

$$LH_2 \rightleftarrows LH^- + H^+, \quad (1)$$

$$LH^- \rightleftarrows L^{2-} + H^+, \quad (2)$$

$$k_1 = \frac{[LH^-][H^+]}{[LH_2]}, \quad (3)$$

$$k_2 = \frac{[L^{2-}][H+]}{[LH^-]}, \quad (4)$$

$$\alpha_L^{2-} = \frac{k_1 k_2}{[H^+]^2 + k_1[H^+] + k_1 k_2}. \quad (5)$$

The calculation of the metal–ligand speciation was done using eqns (6)–(8), where $[L^{2-}] = L_T \times \alpha_L^{2-}$, $[L_T]$ is the original concentration and K_1 and K_2 are the association constants of metal and ligand:

$$\beta_{Cu^{2+}} = \frac{1}{1 + K_2[L^{2-}] + K_1 K_2[L^{2-}]^2},$$

fraction of free Cu^{2+}; (6)

$$\beta_{CuLH^+} = \frac{K_1[L^{2-}]}{1 + K_1[L^{2-}] + K_1 K_2[L^{2-}]^2},$$

fraction of $CuHL^+$; (7)

$$\beta_{CuL} = \frac{K_1 K_2[L^{2-}]^2}{1 + K_1[L^{2-}] + K_1 K_2[L^{2-}]^2},$$

fraction of CuL. (8)

Calculations for speciation were made for a ligand concentration of 1×10^{-5} M similar to that for the superoxide-quenching assays. Calculations made for the alanine- and glycine-bridged copper complexes from the constants given by Chaberek and Martell[16] indicate that both compounds contained less than 0.1% of the free Cu(II). Calculations of metal–ligand association constants followed the procedure of Courtney *et al.*[15] for dibasic acids. All absorbance measurements were made with a Beckman 25 recording spectrophotometer at a pH of 7.6.

ESR spectroscopy

Copper complexes in aqueous solution buffered at pH 7 and ambient temperature were taken in capillaries with the concentration of the metal and ligand each at 10^{-3} M. Superoxide was prepared immediately before use as described above. Ratios of 1:1, 1:2, 1:4, 1:6 and 1:8 (metal complex : superoxide) were prepared. Measurements were taken on a Model ER-420 JOEL X band ESR spectrometer.

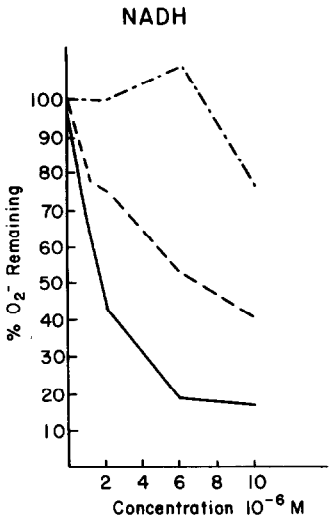

Fig. 1. The quenching of superoxide by the copper complexes using the NADH assay. (——) Ethylene–dileucine, (– – –) ethylene–di-isoleucine, and (–·–) ethylene–divaline.

RESULTS

The rates of reaction of the complexes with superoxide ion *in vitro* were leucine ≅ alanine ≅ 2-methylalanine > isoleucine > valine ≫ glycine (cf. Figs 1–4). The ligands without copper had no reactivity with the superoxide anion. Copper(II) ion in the absence of the synthesized aminoacid ligands quenched superoxide at rates comparable to that of the leucine complex. The activity to quench the superoxide ion was examined at four different

concentrations of the copper complexes. Although the reactivity order of the copper complexes were the same for the two independent assays, the potassium superoxide assay sensitivity decreased markedly at higher concentrations of the complexes.

The results in Figs 5–7 indicate the speciation is the same for the three different copper complexes. The main species in the region of pH 7–8 for the valine–, leucine– and isoleucine–ethylene–copper complexes ia a copper complex with a net plus one charge. The titration curves of the ethylene-bridged amino acids (unprocessed data for Figs 5–7) shows two inflection points.

Table 1. The UV and visible spectra of substituted ethylenediaminediacetic acid–copper complexes in aqueous solution

Copper–ethylene complex	Visible λ_{max} (nm)	Visible ε_{max}	UV λ_{max} (nm)	UV ε_{max}
Valine	635–665	39	254	4465
Isoleucine	630–665	31	250	4135
Leucine	640–665	27	250	3750
Alanine	660–700	30	250	4000
Glycine	600–615	16	nd[a]	
2-Methylalanine	580–620	19	—[b]	

[a] Not detected.
[b] Not determined.

The visible and UV spectra from aqueous solutions of the bridged aminoacid–copper complexes were determined in order to observe possible differences in configuration. The λ_{max} and ε_{max} are summarized in Table 1. The visible region of the spectra consists of broad absorption bands for all complexes. They are very close in energy but differ in intensity. The latter increase in the series: leucine– < isoleucine– < valine–copper complexes. The λ_{max} for the copper–alanine complex was slightly higher than the other copper complexes in the series. In the UV region of the spectra, very intense peaks at low concentrations were observed at the 250-nm region for all complexes but the glycine–copper complex. This peak was absent with copper(II) and the ligands without copper.

The ESR spectra of the copper–aminoacid bridged complexes were obtained in the presence and absence of superoxide. All complexes except the glycine had four hyperfine peaks. The glycine one had seven peaks. Figure 8 shows the spectra of alanine–, glycine–, isoleucine– and leucine–copper complexes before superoxide was added. The spectrum of the copper–alanine complex was poorly resolved compared to the other copper complexes. After the first addition of superoxide anion, another type of spectra occurs which represents a paramagnetic species but differs from the spectrum without superoxide by an increase in hyperfine structure. This occurs before further reduction to a species where all absorption bands disappear with further addition of superoxide.

The spectra for the copper–valine complex before and after addition of two increments of superoxide is illustrated in Fig. 9. The copper–valine complex prior to superoxide addition did not have a pronounced hyperfine structure compared to the leucine one (Figs 8 and 9).

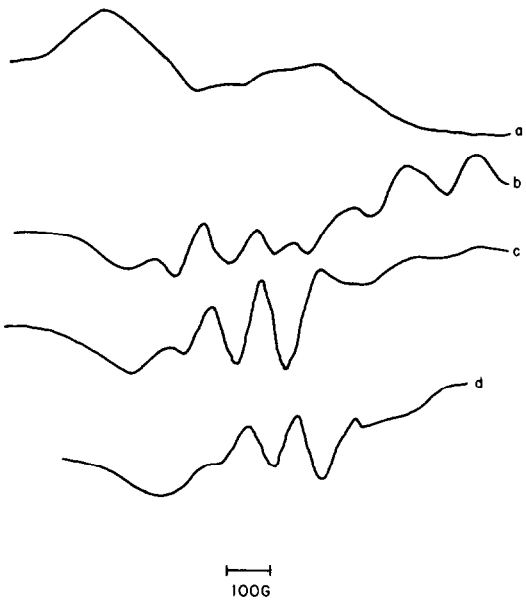

Fig. 8. ESR spectra of ambient aqueous solutions of copper(II) complexes. (a) Ethylene–*N*,*N*′-dialanine, (b) ethylene–diglycine; (c) ethylene–*N*,*N*′-di-isoleucine, and (d) ethylene–dileucine.

DISCUSSION

The substituted ethylenediaminediacetic acid–copper complexes formed from leucine, alanine and 2-methylalanine display the highest rate of reactivity with the superoxide ion of the derivatives synthesized (Figs 1–4). The copper–glycine derivative did not show any activity. In these complexes, the presence of the copper ion is essential to the complexes in order for them to react with the superoxide anion. A superoxide intermediate is believed to account for observations in kinetic studies of superoxide reacting with copper complexes.[4,17] The site proposed for superoxide attachment is the axial site of Cu(II), and the mechanism of the interaction is represented by eqns (9)–(11):

$$Cu(II) + O_2^- \rightleftharpoons Cu(II)O_2^-, \quad (9)$$

$$Cu(II)O_2^- \rightleftharpoons Cu(I)O_2, \quad (10)$$

$$Cu(I)O_2 \rightleftharpoons Cu(I) + O_2. \quad (11)$$

$Cu(II)O_2$ and $Cu(I)O_2$ are the oxygen adducts.

The ESR spectra of solutions in which these complexes are reacted with various concentrations of the superoxide anion give evidence for the initial bonding of the anion with the copper(II) cation and its subsequent reduction to copper(I). The buffered, aqueous, ambient-temperature ESR spectra of all copper complexes show an initial increase in the hyperfine structure of copper with increasing

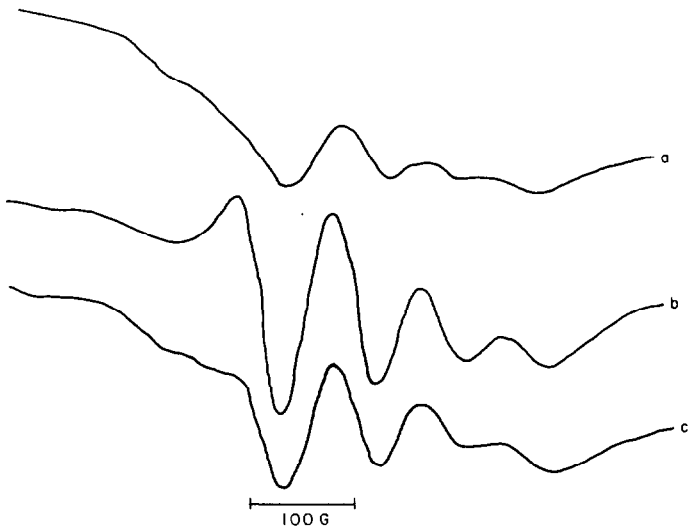

Fig. 9. ESR spectra of ambient aqueous solutions of ethylene–*N,N'*-divaline with increments of superoxide. (a) No equivalent superoxide, (b) one equivalent superoxide, and (c) three equivalents of superoxide.

increments of superoxide followed by loss of the hyperfine structure as reduction to Cu(I) occurs. As an example, the ESR spectra of the valine derivative copper(II) complex interaction with three different concentrations of superoxide are given in Fig. 9. In a study of copper salicylate, DeAlvare *et al.*[5] previously interpreted such spectra as superoxide complexing to copper with subsequent reduction.

All five complexes examined herein have two nitrogen atoms complexed with the copper(II) ion. Agarwal and Perrin[18] have shown that the number of nitrogen atoms bound to copper can be distinguished by the visible spectra. If an absorption occurs below 600 nm, the copper ion is bound to three nitrogen atoms, but above 600 nm to two nitrogen atoms. The compounds in the present study all have absorption maxima above 600 nm (Table 1).

The intense peaks in the UV spectra of the copper complexes are charge-transfer bands of the N—Cu—N bonds as verified by their absence in the spectra of copper(II) solutions and the ligands without copper. By comparison with the bis(diamine)copper complexes, the bands are assigned to a σ–σ^* (R_1N–Cu–NR_2) transition.[19] Only the glycine complex does not show the charge-transfer band. This indicates it has a different structure from the other four aminoacid complexes.

Since the concentration of copper is identical for all the complexes, the data of Figs 1–4 demonstrate that the copper ligand nature influences the rate of reaction with the superoxide anion. The coordination number of the copper ion does not change within the series: isoleucine, leucine, and valine ethylene-bridged copper complexes. The speciation curves illustrated in Figs 5–7, calculated from the experimentally derived association constants for these three complexes, are virtually identical. Consequently, the diverse reactivities of these three complexes towards the superoxide ion are caused by factors other than speciation.

Steric hindrance to the approach of the superoxide ion to the copper(II) is believed to account for the decreased reactivity of the valine- and isoleucine-bridged derivatives. Both have branching of the hydrocarbon chain at C-3, whereas the most reactive three complexes do not. Hence there is steric hindrance in close proximity to the active site. The 2-methylalanine-bridged complex ability to quench superoxide approximates that of the leucine complex in spite of the extra methyl group at C-2. Therefore, the important steric interactions appear to be at C-3. By using conformational analysis, Raos and Simeon[20] presented evidence that a methyl group which extends over copper reduces hydration of the axial copper site. This, together with the known tendency of copper complexes to distort toward tetrahedral, provides the possibility of the two C-3 alkyl groups of isoleucine and valine to extend over the axial site of copper to block this site and lessen its catalytic activity.[21–26] This was examined with the aid of molecular models. The C-3 alkyl groups of the isoleucine and valine complexes are unlikely to extend over copper in a square planar conformation. However, with an incease in distortion toward tetrahedral, these alkyl groups can readily be positioned over the copper(II).

There is evidence for tetrahedral distortion among the six ethylenediamineacetic acid complexes of

copper studied herein. Red shifts and intensity enhancements of *d–d* electronic absorption bands accompany changes from square planar toward tetrahedral geometry.[21] The λ_{max} of the aminoacid bridged complexes (Table 1) have broad bands and are close in energy, but the intensities increase markedly from leucine- to valine-bridged copper complexes. With the exception of alanine, the degree of tetrahedral distortion roughly corresponds to the extent of superoxide quenching by these complexes. It appears that both the presence of two alkyl blocking groups at C-3 and tetrahedral distortion are necessary and act synergistically to block the axial site of copper(II) to superoxide.

Bereman *et al.*[27] concluded that tetrahedral distortion is the single most important dominating factor which changes $E_{1/2}$ for their copper complexes and ESR parameters which reflect the degree of tetrahedral distortion varied linearly with $E_{1/2}$.[27] Yokoi and Addison[28] also showed that ESR parameters varied linearly with $E_{1/2}$. It is therefore probable that the reduction potential varies in the series studied here. However, it appears that the resultant potential is a function of the structure which determines the availability of the axial copper site for the redox reaction with superoxide.

The lack of activity of the copper glycine-bridged complex is attributed to formation of a dimer on the axial copper site. The complex is the smallest of the series, and small copper compounds have been found to dimerize.[29] In an analogous study of copper–aminoacid complexes, only with glycine did a third group add to the axial site of copper.[30] Although dimeric copper compounds are antiferromagnetically coupled, resulting in an absence of an ESR spectra,[31] the ESR of the copper–glycine–ethylene complex had seven peaks, indicating a weaker interaction of two copper nuclei (cf. Fig. 8). Although it was recognized that dimerization had occurred from a frozen ESR spectra of a 1 : 1 copper-bridged glycine complex, the nature of the structure was not forwarded.[32] The significance of seven lines for a copper dimer was attributed to out-of-plane interactions for the *N,N'*-ethylene-bis(salicyldeneiminato) copper complex.[33] Based on the ESR spectrum and the absence of a charge-transfer band which indicates a change of symmetry (Table 1), a tentative structure is proposed (Fig. 10). The axial copper site in this structure is occupied by another bridged glycine so that it is inaccessible to superoxide, resulting in deactivation of the catalytic activity of copper to quench superoxide.

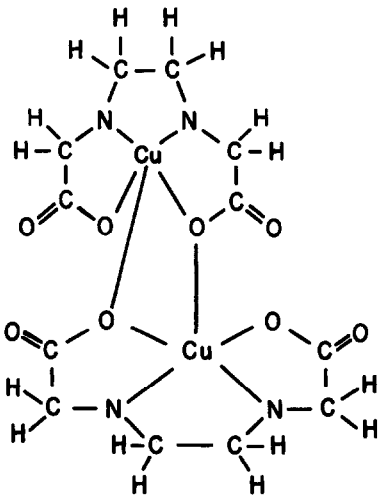

Fig. 10. Proposed structure for Cu(II)–ethylene–diglycine.

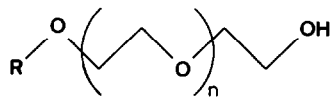
NONIONIC SURFACTANTS AS LIGANDS FOR THE COMPLEXATION OF ALKALI AND ALKALINE-EARTH CATIONS IN METHANOL

HANS-JÜRGEN BUSCHMANN

Universität-GH Siegen, Physikalische Chemie, Postfach 101240, D-5900 Siegen, F.R.G.



(*Received* 15 *May* 1985; *accepted* 10 *June* 1985)

Abstract—The stability constants and thermodynamic values of complex formation of nonionic surfactants with alkali and alkaline-earth cations were determined by calorimetric titration in methanol. The purity of the ligands examined was checked by calorimetric end point titration. This method gives good results only if 1:1 complexes are formed. For the smallest ligands a ligand:cation ratio of x:1 is found. In contrast the surfactant with the longest oligoethylene glycol chain forms 1:x complexes. With increasing number of donor atoms the reaction enthalpies become more negative but the stability constants do not change very much due to compensating changes in entropies. Compared with the monocyclic ligand 18-crown-6 it is possible to obtain higher values of the reaction enthalpies and the high stability constants for crown complexes are caused mainly by favourable entropic factors.

The complexing properties of oxygen-containing noncyclic ligands have not hitherto been much investigated because they are not able to compete with crown ethers[1] and cryptands.[2] Only in a few cases were the complex stabilities of noncyclic polyethers determined for comparison with the cyclic analogues.[3] Favretto[4] reported data for the complexation of alkali metal ions with polyoxyethylene glycol derivatives in methanol where the number of ether atoms varies from 4 to 11. Stability constants and thermodynamic values for the reaction of alkali and alkaline-earth cation with short-chain glycols and glymes have also been published.[5] The publications mentioned above show that, with increasing chain length, the stability of the formed complexes is enhanced. So far no measurements have been performed to answer the question whether it is possible or not to obtain stability constants with linear polyethers of the same order of magnitude as for crown ethers. The synthesis and purification of well-defined long-chain polyethers is rather difficult and this is probably the main reason why no data for complex formation are available. We found that the purity of some nonionic surfactants was high enough to use them as noncyclic ligands for the complexation of mono- and bivalent cations in methanol. The complexing properties of these ligands were examined by calorimetric titrations.

EXPERIMENTAL

All ligands examined (see Fig. 1) are commercially available samples and were used without further purification. Only 2,5,8,11,14-pentaoxapentadecanol (PEGM, Janssen) was distilled *in vacuo* prior to use. The names of the nonionic surfactants, with abbreviations, are given in Fig. 1. All are registered trade marks so the letter B stands for Brij (ICI Americas Inc.) and I for Igepal (GAF Corp.).

JCO-720	749.00	884
JCO-890	1982.50	1254

The salts $NaNO_3$ (Merck), KNO_3 (Merck), $RbNO_3$ (Ventron), CsF (Ventron), $Ca(NO_3)_2$ (BDH), $Sr(NO_3)_2$ (Merck) and $Ba(ClO_4)_2$ (Merck) were anhydrous and of the highest purity commercial available. All solutions were prepared by dissolving the dried salt in anhydrous methanol (Merck, H_2O content less than 0.01%).

All calorimetric titrations were performed using a Tronac calorimeter (Modell 450). The purity of all ligands was checked by calorimetric end-point titrations. The values of Table 1 were estimated by titrating a solution of $Ba(ClO_4)_2$ ($1.0–1.5 \times 10^{-3}$ N). A typical thermogram is given in Fig. 2. No sharp end-point of the titration is found. To test the accuracy of this method the molecular weight (MW) of Kryptofix-5 (Merck, MW = 448.52) which also gives no well-defined end point at the titration with cations was estimated. A value of 448.8 ± 0.1 was found.

To measure thermograms for the calculation of stability constants and reaction enthalpies a ligand solution (0.08 N) was titrated to a solution of a metal ion (5×10^{-3} N). A typical thermogram is given in Fig. 3. After correction for all nonchemical heat effects the heat produced during the reaction is related to the reaction enthalpy by:

$$Q_t = \Delta H \cdot \Delta n_t. \quad (1)$$

The number of mols of complex formed at the time t, Δn_t, is a function of the stability constant. The reactions observed can be described by the following equation:

$$M^{n+} + L \rightleftharpoons ML^{n+}, \quad K = \frac{[ML^{n+}]}{[M^+][L]}. \quad (2)$$

An iterative procedure was used to calculate stability constants and reaction enthalpies from the thermograms.[6] The temperature increase during the titration is very small so the stability constant is not affected.

RESULTS AND DISCUSSION

The calorimetric end-point titration gives information about the composition of the complex (see Table 1). If the measured MW of the ligand is higher than expected a complex of composition ML_x^{n+} is formed. A 1:1 complex is present in the case when given and estimated MW are nearly identical. If the MW calculated from the end-point is smaller than the theoretical value the ratio of ligand to cation changes to M_xL^{xn+}. This happens with ICO-890 and no effort was made to calculate any data from the

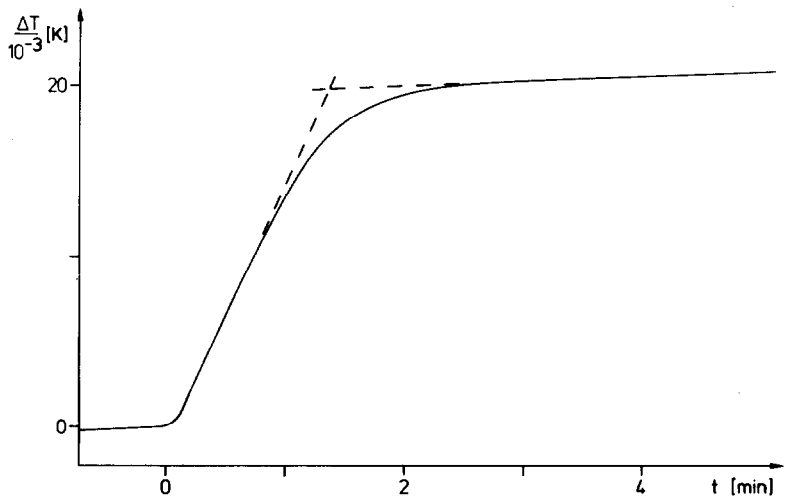

Fig. 2. Thermogram for the evaluation of the molecular weight. At time $t = 0$ the addition of a solution of B99 to a solution of $Ba(ClO_4)$ (1.5×10^{-3} M) starts.

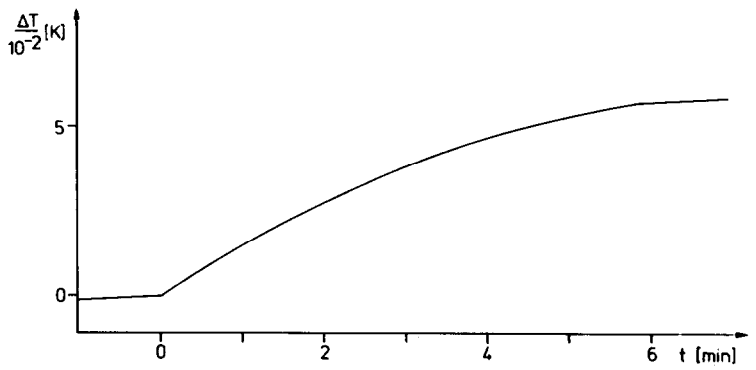

Fig. 3. Thermogram for the titration of K^+ with B99. The titration starts at $t = 0$ and ends at $t = 6$ min.

thermogram. This problem will be treated in more detail in another publication.[7]

All measured values for the 1:1 complexes of PEGM and nonionic surfactants with alkali and alkaline-earth cations are given in Table 2. The complexation behaviour of PEGM is very similar to that of PG. These ligands and PEG possess the same numbers of oxygen atoms as 18-crown-6 and they are

able to surround Na^+, K^+, Rb^+, Ca^{2+} and Sr^{2+}. The bulky methyl groups hinder the complex formation more than the small protons of the OH groups do. This is reflected in the values of the reaction entropies. On the other hand the higher dipole moment of the hydroxyl end-groups compared with the ether groups leads to a stronger repulsion of the opposing parts of the ligand. Thus, the reaction enthalpies of the complex formation with PEG are lowered. These factors do not influence the reaction with the biggest cations, Cs^+ and Ba^{2+}. The ligands are too small to wrap around the cations and the different end-groups are not able to reach each other. Therefore reaction enthalpies and entropies for the complexation of Cs^+ by PEG, PEGM and PG are very similar. The same situation is found for the reactions of Ba^{2+}.

Although the number of oxygen atoms is only reduced by one the nonionic surfactant B30 shows a behaviour quite different from PEGM. The values of the reaction enthalpies for the complexation of alkali and alkaline-earth cations by B30 are much smaller compared to PEGM. This indicates that the number of donor atoms participating in the reaction is small. On the other hand the reactions of B30 are favored by the reaction entropies. The long nonpolar chain of B30 possibly produces a conformation of the uncomplexed ligand which facilitates complex formation. A similar behaviour was found for the reactions of a ligand with the same number of oxygen atoms containing chinoline end-groups.[5]

With increasing number of donor atoms the nonpolar chain becomes unimportant for the complexation. Reaction enthalpies and entropies for ICO-720 and PEGM are nearly identical. The same is found for the reactions of B58 and B99. B35, the ligand with the longest oligoethylene glycol chain which forms 1 : 1 complexes, acts nearly like the smaller ligands. Generally with increasing number of donor atoms in the nonionic surfactants the reaction enthalpies with all cations favor the complex formation. In contrast the reaction entropies become more negative with chain length. As a result the stability constants for all complexes do not increase. Log K reaches a very similar value for all cations examined.

It is not surprising that no selectivity for cations is found as in the case of crown ethers. The ligands are so flexible as to get optimal interactions with the different cations. The reaction enthalpies of the noncyclic ligands reach much higher values than 18-crown-6 (see Table 2). The monocyclic ligand is not able to surround the complexed cation completely. Some solvent molecules are still coordinated to the cation. Only steric requirements are responsible for the low stability constants of the noncyclic ligands examined. Crown ethers already possess an ordered conformation with a fixed position of the donor atoms. This leads to less negative values of the reaction entropy.

In water an interesting effect is possible. The nonionic surfactants are able to form micelles with a more regular conformation compared to the monomeric form of the molecules. Therefore these micelles should act as ligands and form complex ions. Further investigations are in progress and the results will be reported later.

SPECTROPHOTOMETRIC AND POTENTIOMETRIC STUDY OF THE COBALT(II)–THIOCYANATE SYSTEM IN AQUEOUS MEDIUM

NINA COICHEV FERREIRA VELLOSO, EDUARDO ALMEIDA NEVES* and IVANO G. R. GUTZ

Instituto de Química da Universidade de São Paulo, Caixa Postal 20.780—CEP 01498, São Paulo—SP, Brasil

(*Received* 18 *March* 1985; *accepted* 19 *June* 1985)

Abstract—The cobalt(II)–thiocyanate system was spectrophotometrically studied at 2.0 M ionic strength ($NaClO_4$) and 25°C. The following formation constants were obtained: $\beta_1 = 6.9\ M^{-1}$, $\beta_2 = 28.9\ M^{-2}$, $\beta_3 = 12.1\ M^{-3}$ and $\beta_4 = 1.30\ M^{-4}$. Three wavelengths were considered, 515, 590 and 615 nm, and the molar absorptivities of each species were calculated. Linear relationships were obtained for $\bar{\varepsilon}$ vs $\bar{n}$ and α_i. There is strong evidence that the tetrahedral $[Co(SCN)_4]^{2-}$ is virtually the only species absorbing at 590 and 615 nm. An indirect potentiometric method led to comparable equilibrium constants. The cadmium(II)–thiocyanate formation constants used in the indirect method, under the same conditions, were found to be $\beta_1 = 21.51 \pm 0.09\ M^{-1}$, $\beta_2 = 123 \pm 1\ M^{-2}$, $\beta_3 = 130 \pm 3\ M^{-3}$ and $\beta_4 = 173 \pm 1.2\ M^{-4}$, in good agreement with earlier literature data.

The cobalt(II)–thiocyanate reaction is an old analytical test[1] known as Vogel's reaction. The bluish colour obtained, enhanced in acetone medium, is well accepted as being caused by the formation of the tetrahedral $[Co(SCN)_4]^{2-}$ species.[2–8]

In spite of theoretical and practical concerns about this reaction, the equilibrium studies in aqueous medium are incomplete, most of them referring only to the $[Co(SCN)]^+$ species, and showing inconsistencies. There are very few equilibrium data referring to the stepwise complexes up to four thiocyanate ligands.[9,10]

This paper reports a spectrophotometric study of this system by the corresponding solutions method,[11] with the main purpose of obtaining the overall stepwise formation constants of this system in aqueous medium of 2.0 M ionic strength, at 25°C. An indirect potentiometric method, using an indicator cadmium(II)–thiocyanate system, provided comparable results in a fairly limited ligand concentration range.

EXPERIMENTAL

All spectrophotometric measurements were carried out with a Zeiss DMR 10 instrument with the cell compartment thermostatted at 25.0±0.1°C. A recorder was used to obtain the full spectra. It was substituted by a digital voltmeter with $4\frac{1}{2}$ digits for the precise measurement of the absorbance (±0.002) at fixed wavelengths. Cells with 1.000-cm pathlength were normally used. However, with highly absorbing solutions, a calibrated 0.1000-cm pathlength pair of cells was used. The wavelengths of 515, 590 and 615 nm were conveniently selected for the determination of the stability constants. Three series of solutions with 0.01000, 0.05000 and 0.1000 M cobalt(II) were measured at several thiocyanate concentrations, all of them with the ionic strength adjusted to 2.0 M with sodium perchlorate.

The potentiometric measurements were performed with a hanging cadmium amalgam drop electrode using the same experimental arrangement as previously described.[12] The precision was ±0.02 mV.

The cadmium(II)–thiocyanate system was accurately studied to be used as an indicator for the cobalt(II)–thiocyanate system. The working solutions for potential measurements were prepared by adding increasing volumes of 1.700 M sodium thiocyanate with 0.1000 M cobalt(II) perchlorate, 1.000 mM cadmium perchlorate and 1.000 mM perchloric acid to 10.00 ml of a similar solution in which sodium perchlorate changes the thiocyanate, at 25.0±0.1°C.

* Author to whom correspondence should be addressed.

Data of the cadmium(II)–thiocyanate system were analysed with a previously described programme[13–15] on an HP-9825 desk-top computer. The same computer was used in the other calculations described in this paper.

Chemicals were of A.R. or C.P. specifications from Merck, Carlo–Erba and Baker.

Cobalt(II) perchlorate was prepared by treatment of 1 M perchloric acid with excess cobalt(II) carbonate for 2 days, at room temperature. The filtered solution was boiled. Perchloric acid was added to a pH of 2. Standardization was performed by electrogravimetry.[16]

Sodium thiocyanate was potentiometrically titrated with silver nitrate.

Sodium perchlorate solution was gravimetrically standardized by slow evaporation of 3.00 ml and heating in an oven at 120°C.

RESULTS AND DISCUSSION

Spectrophotometric determination of the equilibrium constants

Figure 1 shows the spectra for a wide ligand concentration range, at 2.0 M constant ionic strength. $\bar{\varepsilon}$ is the average molar absorptivity at a given wavelength and free ligand concentration:

$$\bar{\varepsilon} = \frac{A}{C_{Co} \cdot b}, \tag{1}$$

where A is the absorbance of the solution with C_{Co} (M), the analytical concentration of cobalt(II), and b is the pathlength (cm).

It can be seen that the band at 615 nm begins to be defined only above 0.6 M thiocyanate. Conversely the band at 515 nm begins to develop even at low thiocyanate concentrations. Thus it is more appropriate for equilibrium studies at smaller ligand concentrations. Measurements were taken at these two wavelengths and also at the minimum at 590 nm.

The data obtained at the two absorption peaks can be seen in Figs 2 and 3, and were used to calculate the average ligand number, $\bar{n}$, and the free ligand concentration, [SCN^-]. This is possible because the corresponding solutions, with the same $\bar{\varepsilon}$, have the same $\bar{n}$ and [SCN^-]. The three C_{SCN^-} collected for each group of corresponding solutions in Figs 2 and 3, plotted vs C_{Co}, yield a straight line with the free ligand concentration as the intercept and $\bar{n}$ as the

Spectra for the cobalt(II)–thiocyanate system. b = 1.000 cm, C_{Co} = 0.05000 M, T = 25.0°C, and C_{SCN^-} = (a) zero, (b) 0.05000 M, (c) 0.1000 M, (d) 0.2000 M, (e) 0.3000 M, (f) 0.4000 M, (g) 0.5000 M, (h) 0.6000 M, (i) 0.7000 M, (j) 0.8000 M, (l) 1.000 M, (m) 1.200 M, (n) 1.400 M, and (o) 1.600 M.

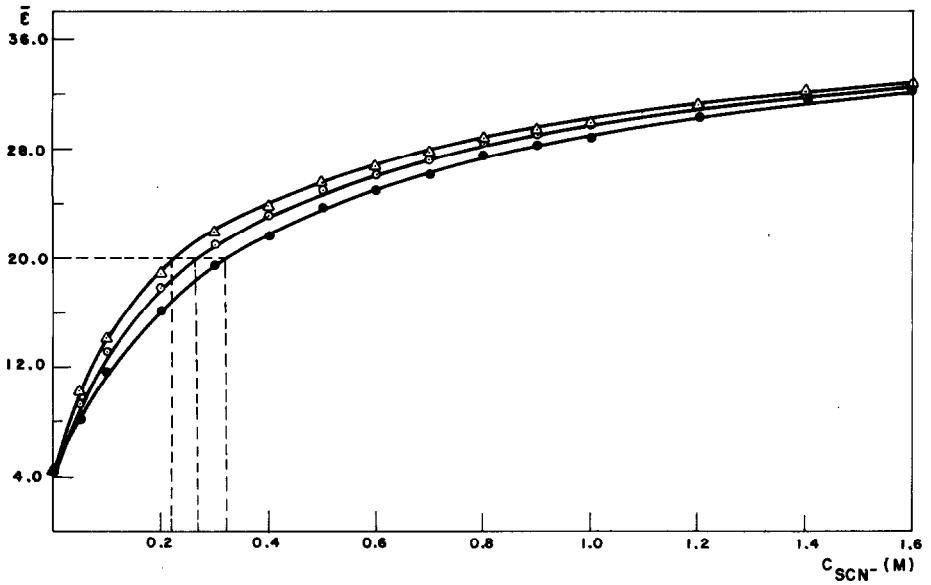

Fig. 2. Calculated curves traced from the experimental data, with: $\beta_1 = 6.9\ M^{-1}$, $\beta_2 = 28.9\ M^{-2}$, $\beta_3 = 12.1\,M^{-3}$ and $\beta_4 = 1.3\,M^{-4}$. $\lambda = 515$ nm. $C_{Co} = (\triangle)0.01000$ M, $(\bigcirc)0.05000$ M, and $(\bullet)0.1000$ M. An example of three corresponding solutions is indicated by the dashed lines.

slope:[17]

$$C_{SCN^-} = [SCN^-] + \bar{n} \cdot C_{Co}. \qquad (2)$$

The resulting formation curve is presented in Fig. 4, which contains data for the three wavelengths. The average curve was found by smoothing the experimental data by least-squares fitting of moving polynomials.

The data at 515 nm become inconsistent above 0.4 M thiocyanate and were rejected. The contributions of the data at 590 and 615 nm become more significant in this region of the formation curve.

Integration of the $\bar{n}$ vs log $[SCN^-]$ curve leads to the well-known Fronaeus[18] function:

$$F_0(SCN) = 1 + \sum_{i=1}^{N} \beta_i [SCN^-]^i. \qquad (3)$$

The analysis of subsidiary functions[18] (Fig. 5) indicates the existence of four stepwise complexes. The following overall constants were obtained

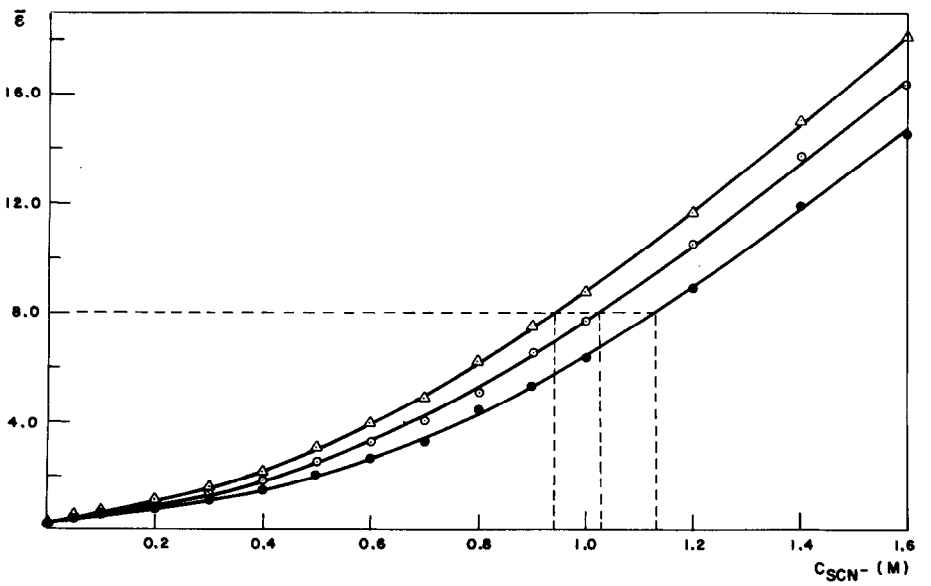

Fig. 3. Calculated curves traced from the experimental data. Same conditions as in Fig. 2. $\lambda = 615$ nm.

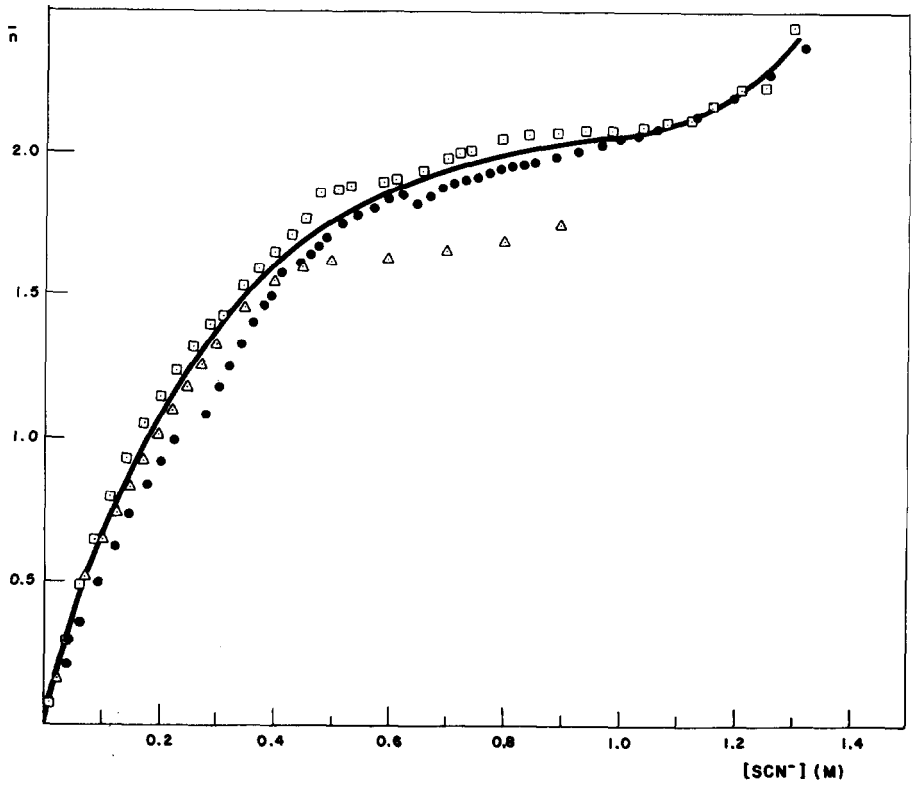

Fig. 4. Medium curve traced on basis of the data obtained from measurements at: (△) 515 (□) 590, and (●) 615 nm.

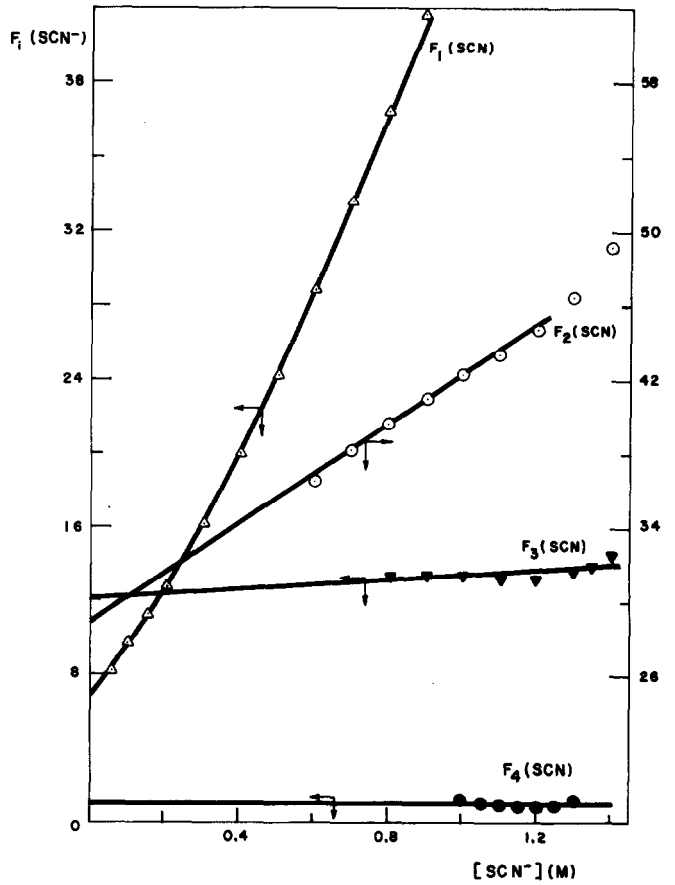

Fig. 5. Graphical extrapolation of the F_i data to obtain β_i.

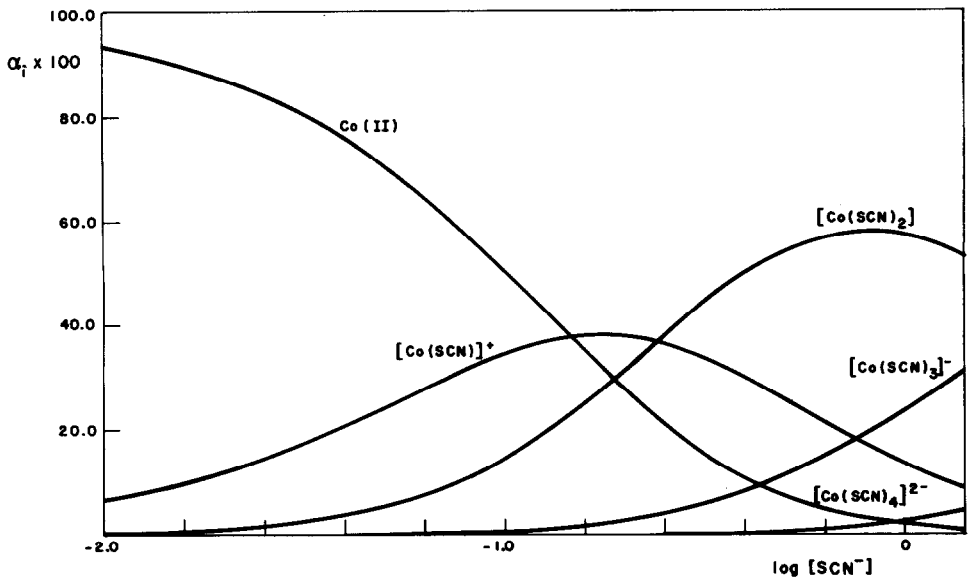

Fig. 6. Distribution diagram for the cobalt(II)–thiocyanate system. Ionic strength 2.0 M ($NaClO_4$) and $T = 25°C$.

by a previously described weighted least-squares procedure:[15] $\beta_1 = 6.9\ M^{-1}$, $\beta_2 = 28.9\ M^{-2}$, $\beta_3 = 12.1\ M^{-3}$ and $\beta_4 = 1.30\ M^{-4}$.

It can be inferred that the complexes are weak and that it is difficult to introduce more than two ligands, as can be seen in a distribution diagram (Fig. 6).

Dependence of $\bar{\varepsilon}$ on equilibrium data: evolution of ε_i

Interesting information was obtained from plots of $\bar{\varepsilon}$ vs equilibrium data calculated from the formation constants. A linear relationship is found at 515 nm (but not at 590 and 615 nm) for $\bar{\varepsilon}$ vs the calculated $\bar{n}$ (spectrophotometric constants) (from 0.4 to 2.4), corresponding to a wide ligand range (Fig. 7). This suggests a regular increase in the individual molar absorptivity of each complex as the number of ligands attached increases. On this basis the extrapolation of $\bar{\varepsilon}$ to $\bar{n} = 4$ leads to the estimation of ε_4, referred to $[Co(SCN)_4]^{2-}$. This also means that all species absorb at this wavelength whether tetrahedral or not.

At 590 and 615 nm a linear plot is observed for $\bar{\varepsilon}$ vs α_4 (see Fig. 8) with an intercept at a low value in the ordinate axis. This indicates that only the highly symmetrical tetrahedral fourth species absorbs. The contribution of the lower members of the series is very small. The limit of $\bar{\varepsilon}$ for α_4 tending to 1 is ε_4, which can be obtained by linear extrapolation.

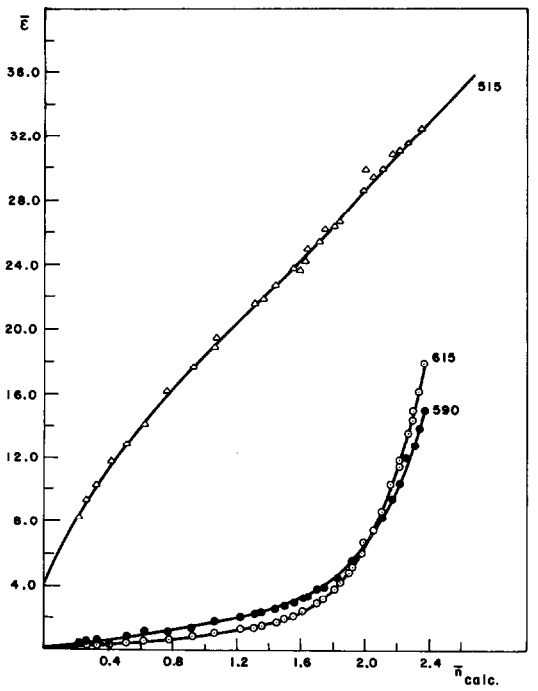

Fig. 7. Variation of $\bar{\varepsilon}$ with $\bar{n}$ at 515, 590 and 615 nm.

The following equation relates $\bar{\varepsilon}$ with the molar absorptivities and the corresponding β_i formation constants:[17]

$$\bar{\varepsilon} = \frac{\varepsilon_0 + \varepsilon_1\beta_1[SCN^-] + \varepsilon_2\beta_2[SCN^-]^2 + \varepsilon_3\beta_3[SCN^-]^3 + \varepsilon_4\beta_4[SCN^-]^4}{1 + \beta_1[SCN^-] + \beta_2[SCN^-]^2 + \beta_3[SCN^-]^3 + \beta_4[SCN^-]^4}. \quad (4)$$

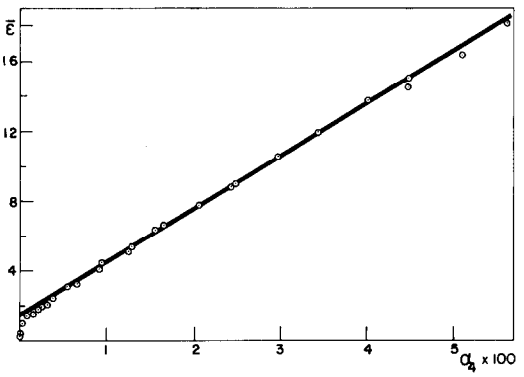

Fig. 8. Verification of the linearity of $\bar{\varepsilon}$ vs α_4 at 615 nm.

Combination with eqn (3) gives:

$$\bar{\varepsilon}\cdot F_0(SCN) = \varepsilon_0+\varepsilon_1\beta_1[SCN^-] +\varepsilon_2\beta_2[SCN^-]^2+\varepsilon_3\beta_3[SCN^-]^3 +\varepsilon_4\beta_4[SCN^-]^4. \quad (5)$$

The number of unknowns is decreased from nine to five by introducing the previously determined formation constants. In addition, ε_0 is found by direct measurement in uncomplexed medium and ε_4 from linear extrapolation. A simpler system of simultaneous equations can be used for calculation of ε_1, ε_2 and ε_3:

$$\phi_0 = \bar{\varepsilon}F_0(SCN)-\varepsilon_0-\varepsilon_4\beta_4[SCN^-]^4 \quad (6A)$$

$$= \varepsilon_1\beta_1[SCN^-]+\varepsilon_2\beta_2[SCN^-]^2 +\varepsilon_3\beta_3[SCN^-]^3 \quad (6B)$$

and

$$\phi_1 = \frac{\phi_0}{[SCN^-]} = \varepsilon_1\beta_1+\varepsilon_2\beta_2[SCN^-] +\varepsilon_3\beta_3[SCN^-]^2. \quad (7)$$

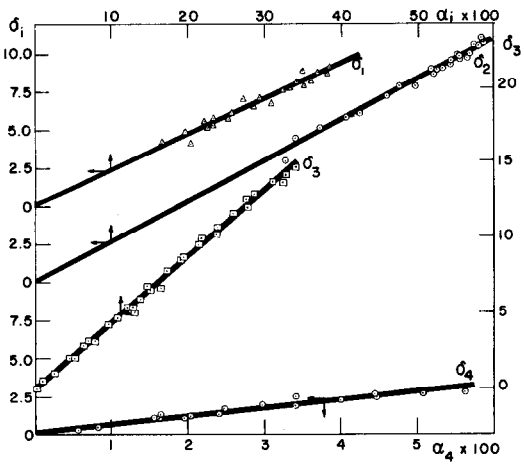

Fig. 9. Verification of the linearity of δ_i [eqn (10)] vs α_i at 515 nm.

Simultaneous equations were taken for ϕ_1 vs $[SCN^-]$. As the magnitude of ϕ_1 terms changes markedly with the concentration of the ligand, a weighting factor:

$$\omega_j = \frac{1}{\bar{\varepsilon}_j} \quad (8)$$

was used in order to place all $\bar{\varepsilon}$ data to a same magnitude. The reason of that is the adjustment of the magnitude of the relative error of absorbance measurements to a same level, in order to provide a consistent system of simultaneous equations. This kind of procedure has been successfully used with other experimental data of equilibrium studies.[15,19]

Table 1 presents the molar absorptivities of the individual species at the three wavelengths, as found from a combination of strategies.

At 515 nm, a verification of the compatibility of the β_i and ε_i values with the experimental $\bar{\varepsilon}$ data was obtained by considering the isolated contribution of each species. At a determined free ligand concentration:

$$\bar{\varepsilon} = \sum_{i=0}^{4} \varepsilon_i\cdot\alpha_i. \quad (9)$$

The contribution of the first species is:

$$\delta_1 = \bar{\varepsilon}-(\varepsilon_0\alpha_0+\varepsilon_2\alpha_2+\varepsilon_3\alpha_3+\varepsilon_4\alpha_4) = \varepsilon_1\cdot\alpha_1. \quad (10)$$

As expected, the plot of δ_1 as a function of the α_1 calculated for each datum point can be fitted by a straight line with zero intercept and slope ε_1. The same agreement was observed for ε_2, ε_3 and ε_4 (Fig. 9).

The ε_1–ε_4 values at 515 nm have a linear relationship to the number of ligands, but ε_0 is too low to be fitted in this series. The behavior at 590 and 615 nm suggests (see Figs 7 and 8) that the fourth species is virtually tetrahedral with a fairly high molar absorptivity. Very little of this complex is present in the equilibrium in the explored concentration range but its molar absorptivity is fairly high at 590 and 615 nm, compared to the other ε_i. A situation of ambiguity exists with regard to the other lower species. They can be octahedral with a very low molar absorptivity, or the observed data are averages of highly absorbing tetrahedral complexes, but present in a very low concentration, in equilibrium with the octahedral ones, which do not absorb at 590 and 615 nm.

The use of the determined paramaters (ε_i and β_i) in eqn (4) for the several thiocyanate concentrations led to the calculated $\bar{\varepsilon}$ for the three cobalt(II) concentrations used in the measurements. The comparison between calculated and experimental $\bar{\varepsilon}$ data led to relative standard deviations of 1.8% at 515 nm, 1.9% at 590 nm and 2.6% at 615 nm.

It should be pointed out that the assumption of a

Table 1. Molar absorptivities calculated at the three wavelengths, with $\beta_1 = 6.9\ M^{-1}$, $\beta_2 = 28.9\ M^{-2}$, $\beta_3 = 12.1\ M^{-3}$ and $\beta_4 = 1.3\ M^{-4}$

system with only three stepwise complexes led to a very inconsistent fit between calculated and experimental measurements.

Indirect potentiometric determination of the equilibrium constants

Another set of constants was obtained by an indirect method.[14] Firstly the formation constants of cadmium(II)–thiocyanate were redetermined under very reliable conditions with a cadmium amalgam electrode, leading to the following values: $\beta_1 = 21.51 \pm 0.09\ M^{-1}$, $\beta_2 = 123 \pm 1\ M^{-2}$; $\beta_3 = 130 \pm 3\ M^{-3}$ and $\beta_4 = 173 \pm 1\ M^{-4}$, in good agreement with published data.[20]

Substituting these constants in eqn (3) and remembering that the change in the potential of the amalgam electrode is related to $F_0(SCN)$, at 25°C, by:

$$\Delta E = \frac{-0.05916}{2} \log F_0(SCN), \qquad (11)$$

and that the free ligand concentration must satisfy the equilibria involving both metal ions, it is possible to calculate $[SCN^-]$ in the presence of added cobalt(II). The calculation of $[SCN^-]$ and the $\bar{n}$ of the cobalt(II) complexes was done with an appropriate computer programme. The smoothed curve in the range 0–2.2 for $\bar{n}$ was integrated and analysed by the same procedure as used for the spectrophotometric data. The stability constants obtained are $\beta_1 = 11.0\ M^{-1}$, $\beta_2 = 22.0\ M^{-2}$, $\beta_3 = 11.2\ M^{-3}$ and $\beta_4 = 1.63\ M^{-4}$.

Table 2. Values of stability constants obtained by different authors for the Co(II)–SCN^- system

[a] Extraction with methyl isobutyl ketone.

The formation curve is very close to that obtained from spectrophotometric data up to $\bar{n} = 0.9$. A speculative explanation for the disagreement after this point is an interaction of the anionic $[Cd(SCN)_3]^-$ and $[Cd(SCN)_4]^{2-}$ with $Co(SCN)_2$ to form binuclear species at higher thiocyanate concentration. This point deserves further investigation.

The potentiometric method provides more accurate equilibrium data when the free metal cation is directly measurable. In the cobalt(II)–thiocyanate system an indirect potentiometric method was used. The spectrophotometric $\bar{n}$ data are probably more reliable because they come from a direct method. In fact the linear plot involving experimental $\bar{\varepsilon}$ data vs calculated $\bar{n}$ looks more consistent when β_i values from a spectrophotometric origin are considered in calculations.

Table 2 is a survey of several equilibrium constants determined by a variety of methods and background electrolytes.

There is a reasonable agreement in the β_1 values, situated in the range from 7 to 11 in the majority of cases. Only one study with the estimation of four stepwise equilibrium constants was found for an aqueous medium, but obtained by a solvent extraction method,[10] with severe disagreement with the present results for β_2, β_3 and β_4. Only the first constant falls in the previously mentioned range, certainly because it was separately determined by a spectrophotometric method.[10] However, the solvent extraction method can be much more critical for such a complex study, because the distribution function can be affected by other factors such as the change in the activity of extracted species in the organic phase with a wide range of ligand concentration in the aqueous phase.

THE PAIRING PRINCIPLE IN TENSOR SURFACE HARMONIC THEORY: ELECTRON COUNTS OF LARGE *CLOSO* BORANES

P. W. FOWLER*

Department of Theoretical Chemistry, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

(*Received* 8 *May* 1985; *accepted* 19 *June* 1985)

Abstract—Tetratomic tetrahedral main-group clusters have four or six (but not five) skeletal pairs, an exception to the $(n+1)$ rule for *closo* clusters. A general group-theoretical criterion, based on the pairing principle in Stone's tensor surface harmonic (TSH) theory, is presented for symmetry-induced departures from the $(n+1)$ rule. A count of $(n+2)$ or n skeletal pairs is *forced by symmetry* for: (i) T- or T_d-clusters with an odd number of sets of four equivalent cage atoms, and (ii) C_m or C_{mv} ($m \geqslant 3$) clusters with an odd number of cage atoms on the C_m-axis. Three such cases, B_nH_n or $B_nH_n^{4-}$, are found among the hypothetical supraicosahedral *closo* boranes proposed by Brown and Lipscomb (n = 16, 19 or 22). Extended Hückel calculations show that the TSH pattern applies to the whole series of *closo* boranes ($n \leqslant 24$). Charges of +4, −8 and −2 are discussed for a very large $B_{32}H_{32}^{q}$ cluster.

Polyhedral boranes have a special significance in the theory of cluster compounds, because they give the simplest example of the link between molecular structure and electron count.[1] The *closo* series $B_nH_n^{2-}$ consists of molecules that are deltahedral in shape (for $5 \leqslant n \leqslant 12$), and held together by $(n+1)$ skeletal electron pairs. If we regard linear $B_2H_2^{2-}$ and triangular $B_3H_3^{2-}$ as trivally deltahedral, the only exception to the $(n+1)$ rule is the tetrahedral cluster which needs either four (represented in B_4Cl_4) or six skeletal pairs, but not five. The MO diagram for B_4H_4 has a nonbonding doubly degenerate level, as a well-understood consequence of T_d-symmetry, and we may regard the $n = 4$ tetrahedron as an "*intrinsic*" exception to the $(n+1)$ rule.

A second class of departures from the $(n+1)$ rule is found for boron halides, B_nCl_n (e.g. $n = 8$ or 9), where clusters which are geometrically *closo* are held together by only n skeletal pairs.[2] These electron counts are rationalised by noting that the $(n+1)$th skeletal pair would occupy a nondegenerate, not very bonding MO for these clusters, and supposing that the cluster geometry is not sensitive to loss of this pair.[2] It is also possible that back-donation from the *exo* halides may be a significant factor in the stabilisation of B_nX_n relative to $B_nX_n^{2-}$.[3] Insofar as the electron count is determined by numerical values of the MO energies, we may regard these exceptions to the $(n+1)$ rule as "*accidental*" in contrast to the tetrahedral case.

Related to the *closo* boranes are the *nido* (formally $B_nH_n^{4-}$) and *arachno* (formally $B_nH_n^{6-}$) compounds with skeletons corresponding to the *closo* polyhedra minus one and two vertices, respectively.

There have been various attempts to explain these regularities and to derive the electron-counting rules from first principles.[4–6] One, which is based on a simple assumption that borane skeletons are roughly spherical clusters of B atoms, was put forward by Stone.[7] This is the tensor surface harmonic (TSH) theory. It accounts for the $(n+1)$ rule for *closo* boranes and the special stability of the deltahedral shapes. When combined with point group symmetry arguments, it explains the electron counts of tetrahedral clusters. In an extended Hückel (EH) formulation of TSH[8] the derived MO energies can be used to rationalise the "accidental" departures from the $(n+1)$ rule for B_nX_n.

Although the experimental series of *closo* boranes ends at $n = 12$, there is interest in the possibility that supra-icosahedral clusters may be stable. Brown and Lipscomb[9] invented plausible structures for the hypothetical 13- to 24-atom clusters, and speculated on clusters of even higher nuclearity such as the 32-boron omnicapped dodecahedron. The proposed structures were deltahedral, very roughly spherical

* Present address: Department of Chemistry, University of Exeter, Stocker Road, Exeter EX4 4QD, U.K.

in overall shape, with bond lengths estimated from known molecules. Approximate PRDDO calculations on these structures[10] verified the appropriateness of the -2 charge for all but three clusters. For $n = 16$, 19 or 22 it was found, "surprisingly", that the *neutral* molecule had a closed shell. It is shown in the present work how Stone's TSH theory can be used to predict, without calculation, that precisely these three clusters have an "*intrinsic*" departure from the $(n+1)$ rule.

In this paper we present an analysis of "*intrinsic*" exceptions to the $(n+1)$ rule and establish a general criterion for their existence based on the pairing principle in TSH theory. Energy level diagrams for the whole series $B_nH_n^q$ $(13 \leqslant n \leqslant 24)$ are obtained by EH calculation and found to conform to the TSH pattern. *Nido* structures are also studied. Finally, EH energy levels are calculated for $B_{32}H_{32}^q$ and it is found that the HOMO–LUMO gap predicts a charge of $+4$ or -8 on this deltahedral cluster.

AN OUTLINE OF TSH THEORY

Stone's theory of clusters starts from a very simple picture and uses the power of angular momentum and group theory to give a general analysis of cluster bonding. The polyhedral boranes $B_nH_n^q$ consist, to a first approximation, of a set of B atoms distributed on the surface of a sphere, each participating in an *exo* radial BH bond. After subtraction of localised BH bonds, the basis left for skeletal bonding consists of an inward-pointing (σ) hybrid and two tangential (π) orbitals on each boron. In TSH we construct a set of approximate molecular orbitals from the solution of a model problem—the free electron on a sphere.[7]

The analytical solutions to the model problem are known; they are the scalar spherical harmonics (σ), the even (π) and odd ($\bar{\pi}$) vector surface harmonics, and higher functions not needed here. In common with other free-electron MO models, TSH uses the analytical forms to set the coefficients of the basis functions in the MOs. Thus the amplitude of the spherical harmonic at the boron vertex gives the contribution of the σ-hybrid on that atom to a σ MO of the cluster. Similarly, π and $\bar{\pi}$ MOs are formed from atomic tangential p-functions, weighted according to the vector surface harmonics. For the infinite, spherical cluster there are three infinite series of MOs (S^σ, P^σ, D^σ, ... L^σ ...; P^π, D^π, ... L^π...; $\bar{P}^\pi$, $\bar{D}^\pi$,... $\bar{L}^\pi$...) but for a finite cluster we count only the first n independent functions of the σ, π and $\bar{\pi}$ type, respectively.[7] In spherical symmetry both L^σ and L^π belong to the same representation of the spherical group, Γ_g^L (for even L) or Γ_u^L (for odd L). Thus, even within the spherical model, they can mix. In contrast, the $\bar{\pi}$-orbitals $\bar{L}^\pi$ have Γ_u^L-symmetry (for even L) or Γ_g^L-symmetry (for odd L) and cannot mix with σ- or π-orbitals within the TSH model.

The lowest MO, S^σ, consists of an in-phase combination of σ-hybrids on all atoms and is always bonding. More detailed reasoning[7] shows that σ–π interaction of the remaining σ-orbitals and their equisymmetric π counterparts produces n bonding and n antibonding orbitals for a deltahedral cluster. The $\bar{\pi}$-orbitals are intrinsically antibonding; thus the total number of skeletal bonding MOs is $(n+1)$ in agreement with Wade's rules.

The detailed order of orbital energies is also predicted rather well by a TSH calculation with σ–π interaction,[8] even though the MOs are based on such a simple model. As in other situations where free-electron models work well, e.g. conjugated hydrocarbons, the energy order in clusters is determined by the nodal pattern of the orbitals rather than their detailed form. TSH uses MOs with the correct nodal characteristics, though derived from a different Schrödinger equation, and therefore achieves the correct ordering. This is also the reason for the success of semiempirical schemes like EH[11] or MNDO[12] in predicting electron counts and orbital patterns.

THE PAIRING PRINCIPLE IN TSH THEORY

Although the π and $\bar{\pi}$ MOs are of different spherical symmetries, there is a pairing principle or one-to-one correspondence between them.[7] A component of a π-set L^π is converted to a component of the $\bar{\pi}$-set $\bar{L}^\pi$ by the "parity operation"—a twist of each p-orbital in the cluster through 90°, all in the same clockwise or counterclockwise sense. A second application of the operation recovers the original π-orbital but with all signs reversed (Fig. 1). Stone has shown how every bonding overlap is converted to antibonding by the parity operation, and vice versa. Thus in the absence of σ–π interaction, there would be a mirror relationship between π (bonding) orbital energies and $\bar{\pi}$ (antibonding) energies. Even after σ–π interaction an approximate mirror relationship persists near the bonding/antibonding frontier.[8]

In terms of representations, the symmetry of an L^π-set is converted to that of the $\bar{L}^\pi$-set by multiplication by the odd-parity, pseudoscalar representation:

$$\left.\begin{aligned} \Gamma(L^\pi) &= \Gamma(\bar{L}^\pi) \times \Gamma_u^o, \\ \Gamma_u^o \times \Gamma(L^\pi) &= \Gamma(\bar{L}^\pi). \end{aligned}\right\} \qquad (1)$$

Γ_u^o is a one-dimensional representation with character $+1$ under proper operations and -1 under improper ones. Its effect here is to switch g and

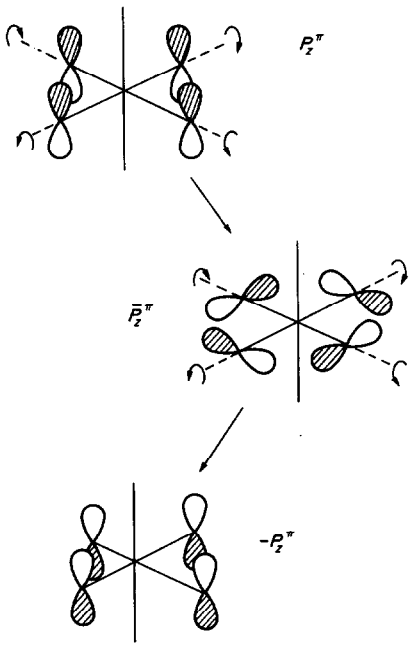

Fig. 1. Effect of the parity operation on P_z^π-orbitals of an octahedral cluster. Each atomic p-orbital is rotated by 90° about the line joining the vertex to the centre of the cluster.

u labels. A formal proof that the parity operator itself transforms as Γ_u^o is given by Ceulemans.[13]

The labels σ, π and $\bar{\pi}$ apply to infinite spherical clusters. In finite clusters the MOs are labelled by their point group representations, which follow from the splittings of the $(2L+1)$-degenerate sets of harmonics on descent in symmetry. A detailed discussion of the relation between fragment and cluster orbitals is given in Ref. 13. Table 1 shows how the harmonics transform in the point groups O_h, T_d, C_{3v} and D_3. Notice that because O_h retains the inversion symmetry g/u, the mixing of orbitals L^π and $\bar{L}^\pi$ is still forbidden. In finite groups the parity operation still interconverts π and $\bar{\pi}$ and eqn (1) applies to the symmetries in the point group, e.g. in O_h:

$$\Gamma(P^\pi) = T_{1u}, \quad \Gamma_u^o = A_{1u}, \quad \Gamma(\bar{P}^\pi) = T_{1g} = A_{1u} \times T_{1u}.$$

If we define representations as *conjugate* when they are related by the parity operation, i.e. Γ_A and Γ_B are conjugate when:

$$\Gamma_A = \Gamma_B \times \Gamma_u^o, \quad \Gamma_B = \Gamma_A \times \Gamma_u^o,$$

then the L^π and $\bar{L}^\pi$ representations are always conjugate. In the spherical group R_{3h}, Γ_A and Γ_B are distinct. However, for the finite point groups there are three possibilities (illustrated by Table 1).

(i) Γ_A is always distinct from its conjugate Γ_B, e.g. in O_h Γ_A and Γ_B are of opposite parity since $\Gamma_u^o = A_{1u}$, so $\Gamma_A \neq \Gamma_B$. Groups of this type include C_i, C_s, C_{2v}, $D_{(2n+1)d}$, C_{nh}, $S_{(4n-2)}$, D_{nh}, T_h, O_h, I_h and R_{3h}, and contain the inversion and/or a σ_h mirror plane.

(ii) Γ_A is always *self-conjugate*, e.g. in D_3 Γ_u^o is A_1, so $\Gamma_A = \Gamma_B \times A_1 = \Gamma_B$. Groups of this type describe optically active molecules, e.g. C_n, D_n, T, O and I. In these groups $\Gamma(L^\pi) = \Gamma(\bar{L}^\pi)$ with two exceptions (see below).

(iii) Some Γ_A are self-conjugate and some are not, e.g. in T_d Γ_u^o is A_2 and thus E is self-conjugate ($E \times A_2 = E$), whereas T_1 and T_2 are conjugate to each other ($T_1 \times A_2 = T_2$). The self-conjugate representations are those with zero character under all improper operations, and must be doubly degenerate. Groups of this type are C_{nv} ($n \geqslant 3$), S_{4n}, D_{2nd} and T_d.

These considerations become relevant to the theory of bonding in clusters when we remember that TSH assigns essentially bonding character to L^π-orbitals (really to L^σ–L^π combinations) and essentially antibonding character to $\bar{L}^\pi$.[7] The total representation of all tangential p-orbitals, $\Gamma_{\pi+\bar{\pi}}$ splits into two distinct subshells for cases (i) and (ii).[13] In case (ii) it is particularly easy to assign π and $\bar{\pi}$ just by counting half of each symmetry species in π and half in $\bar{\pi}$. It is when the molecule belongs to a group of

Table 1. Symmetries of the spherical harmonics in some finite point groups

	O_h	T_d	C_{3v}	D_3
S^σ	A_{1g}	A_1	A_1	A_1

D^σ, D^π	E_g+T_{2g}	$E+T_2$	A_1+2E	A_1+2E
F^σ, F^π	$A_{2u}+T_{1u}+T_{2u}$	$A_1+T_1+T_2$	$2A_1+A_2+2E$	A_1+2A_2+2E
G^σ, G^π	$A_{1g}+E_g+T_{1g}+T_{2g}$	$A_1+E+T_1+T_2$	$2A_1+A_2+3E$	$2A_1+A_2+3E$
Γ_u^o	A_{1u}	A_2	A_2	A_1
$\bar{P}^\pi$	T_{1g}	T_1	A_2+E	A_2+E
$\bar{D}^\pi$	E_u+T_{2u}	$E+T_1$	A_2+2E	A_1+2E
$\bar{F}^\pi$	$A_{2g}+T_{1g}+T_{2g}$	$A_2+T_1+T_2$	A_1+2A_2+2E	A_1+2A_2+2E
$\bar{G}^\pi$	$A_{1u}+E_u+T_{1u}+T_{2u}$	$A_2+E+T_1+T_2$	A_1+2A_2+3E	$2A_1+A_2+3E$

type (iii) that things are more interesting. If the representation $\Gamma_{\pi+\bar{\pi}}$ contains an *odd* number of a self-conjugate E-type symmetry species, the cluster is *forced* by symmetry *to show a non-Wade electron count.*

To see why this is, consider the example of the tetrahedral cluster.[7] The four σ-orbitals transform as $A_1 + T_2$ ($= S^\sigma + P^\sigma$). The eight tangential p-orbitals transform as $E + T_1 + T_2$. From Table 1 we can assign T_2 to P^π and T_1 to $\bar{P}^\pi$, which leaves the E pair. If one component of the pair is π, then the other must be $\bar{\pi}$ since E is self-conjugate, but the two components are degenerate and so the pair must be *nonbonding.* Thus TSH and symmetry arguments lead to the correct picture of the bonding–bonding orbitals and a nonbonding level that may contain zero or four electrons for a closed shell. Intermediate occupations would give rise to Jahn–Teller distortion and loss of tetrahedral symmetry. The departure from the $(n+1)$ rule is an "intrinsic" consequence of the cluster symmetry.

We can generalise this reasoning: If the total $(\pi + \bar{\pi})$ representation contains an *odd* number $(2m+1)$ of a self-conjugate species, then, when we have assigned m to π and m to $\bar{\pi}$ there is left a pair of $(\pi, \bar{\pi})$ character that must be nonbonding. An electron count of n or $(n+2)$ but not $(n+1)$ skeletal pairs is then predicted.

Stone and Alderton[7] used this argument to deduce the electron count for *nido* boranes, supposing that the nonbonding doubly degenerate frontier orbital is stabilised by protonation and therefore occupied, to give the $B_nH_n^{4-}$ electron count. Removal of a vertex from a *closo* cluster in high-symmetry cases, is often accompanied by descent in symmetry from our case (i) to case (iii) and the appearance of self-conjugate representations, e.g. E in C_{4v} and T_d and E_1 and E_2 in C_{5v}:

$$\underset{O_h}{B_6H_6^{2-}} \xrightarrow[-\text{vertex}]{} \underset{C_{4v}}{B_5H_5^{4-}},$$

$$\underset{D_{3h}}{B_5H_5^{2-}} \xrightarrow[-\text{axial vertex}]{} \underset{T_d}{B_4H_4^{4-}},$$

$$\underset{I_h}{B_{12}H_{12}^{2-}} \xrightarrow[-\text{vertex}]{} \underset{C_{5v}}{B_{11}H_{11}^{4-}}.$$

The pairing principle is also useful in explaining the bonding in electron-precise polyhedral hydrocarbons, C_nH_n, which have three-connected skeletons. TSH calculations reproduce the correct total of $3n/2$[8] skeletal pairs. Mingos and Johnson[14] show how this is related to the weakly bonding character of $(n/2-1)$ L^π MOs, and thus by the pairing principle an equal number of weakly antibonding $\bar{L}^\pi$ MOs exist. In these polyhedra the π–$\bar{\pi}$ pairs are not exactly degenerate, but if we suppose $(n/2-1)$ $\bar{\pi}$ MOs are occupied the correct electron count is found. ETSH calculations[8] confirm that the extra π–$\bar{\pi}$ pairs are all bonding for C_nH_n clusters.

APPLICATION TO LARGE *CLOSO* BORANES

The ideas in the previous section were applied to the list of preferred structures for *closo* $B_nH_n^q$ $(13 \leqslant n \leqslant 24)$ postulated by Brown and Lipscomb.[9] Table 2 lists the point groups of the polyhedra; the structures themselves are illustrated in Ref. 9. They divide neatly into four each of cases (i), (ii) and (iii). Thus four structures are optically active and four others are candidates for non-Wade electron counts.

In order to apply the pairing principle we need to find the symmetry of the basis atomic orbitals. The representation of the σ-hybrids, Γ_σ, is easily found: for any operation it has the character χ_σ, equal to the number of atoms unshifted by that operation. Γ_σ is also called the positional or permutational representation. A very neat way of deriving the representation of the remaining $2n$ tangential p-orbitals, $\Gamma_{\pi+\bar{\pi}}$, has been described recently.[15] If Γ_{xyz} is the vector representation, i.e. the symmetry of the translations (x, y, z), then the symmetry of the tangential orbitals is derived from Γ_σ by:

$$\Gamma_{\pi+\bar{\pi}} = \Gamma_\sigma \times \Gamma_{xyz} - \Gamma_\sigma.$$

Another way to find $\Gamma_{\pi+\bar{\pi}}$ is to note that the full basis $n(\sigma+\pi+\bar{\pi})$ transforms as the set of vibrational, rotational and translational displacements of the skeleton:

$$\Gamma_\sigma + \Gamma_{\pi+\bar{\pi}} = \Gamma_{\text{vib}} + \Gamma_{\text{rot}} + \Gamma_{xyz}.$$

Standard tables for Γ_{vib} are available for many point groups.[16]

In Table 3 are shown the MO symmetries for the optically active clusters in the series. As pointed out in the previous section, the representation of the tangential orbitals contains an even number of each symmetry present when the molecule is optically active and is easily assigned to π- and $\bar{\pi}$-subspaces.

Table 2. Symmetry groups of the hypothetical *closo* clusters $(13 \leqslant n \leqslant 24)$

n	Group	n	Group	n	Group
13	C_{2v}	17	C_{2v}	21	D_3
14	D_{6d}	18	D_3	22	T_d
15	D_{3h}	19	C_{3v}	23	D_3
16	T_d	20	D_{6h}	24	T

Table 3. Representations of the skeletal MOs of optically active structures

n	Group	Γ_σ	$\Gamma_{\pi+\bar{\pi}}$
18	D_3	$3A_1+3A_2+6E$	$6A_1+6A_2+12E$
21	D_3	$4A_1+3A_2+7E$	$6A_1+8A_2+14E$
23	D_3	$5A_1+4A_2+7E$	$6A_1+8A_2+16E$
24	T	$2A+2E+6T$	$4A+4E+12T$

For example, for $n = 21$:

$$\Gamma_\pi = 3A_1+4A_2+7E,$$

$$\Gamma_{\bar{\pi}} = 3A_1+4A_2+7E,$$

and the occupied MOs span $\Gamma_\pi+A_1$, i.e. $(n+1)$ skeletal pairs. The more interesting case is shown in Table 4. Groups D_{6d}, T_d and C_{3v} contain a single self-conjugate representation (E_3, E and E, respectively). For $n = 14$ the tangential representation contains $2E_3$, which may be assigned separately to F^π and $\bar{F}^\pi$, giving a TSH picture of $(n+1)$ occupied orbitals

$$(S^\sigma)^2(P^{\sigma/\pi})^6(D^{\sigma/\pi})^{10}(F^{\sigma/\pi})^{12}$$

in this cluster. However for each of $n = 16$, 19 and 22 there is an *odd* number of E representations in $\Gamma_{\pi+\bar{\pi}}$ and consequently a nonbonding E pair is predicted. Inspection of Table 1 shows that one component of the pair is G^π, the other $\bar{G}^\pi$, where the corresponding pair for the $n = 4$ tetrahedron is $D^\pi/\bar{D}^\pi$. Thus, of the proposed *closo* structures, those for $n = 16$, 19 and 22 have closed shells as neutral (or 4−) systems. This purely group theoretical use of the pairing principle gives results in agreement with the PRDDO calculations of Bicerano *et al.*[10]

It might be supposed that *all* T_d-clusters would show an odd number of E MOs. That this is not true can be seen from the Brester table of Γ_{vib} for T_d molecules.[16] From it we can deduce that the number of E pairs in $\Gamma_{\pi+\bar{\pi}}$ is $(4m+2m_d+m_3)$, where the cluster has m sets of 24, m_d sets of 12 and m_3 sets of four equivalent atoms. Thus the non-Wade electron count occurs only if m_3 is odd; in all cases so far encountered $m_3 = 1$ but it is possible to envisage larger T_d-clusters with atoms at the four vertices *and* over the centroids of the four faces of a tetrahedron, giving $m_3 = 2$ and obeying the $(n+1)$ rule.

The tables[16] also show that for C_{nv}-clusters the $(\pi+\bar{\pi})$ representation contains an odd number of the self-conjugate representation if there is an odd number of cage atoms on the n-fold axis. However it can be shown that, for the remaining point groups of type (iii), i.e. D_{2nd} and S_{4n}, that the $(\pi+\bar{\pi})$ representation *never* contains an odd number of the self-conjugate E species. Thus we can state the group-theoretical criterion for symmetry-induced departures from the $(n+1)$ electron count. A count of $(n+2)$ or n, but not $(n+1)$ skeletal pairs is predicted for geometrically *closo* clusters in just two cases:

(i) T- or T_d-clusters with an odd number of sets of four equivalent cage atoms,

(ii) C_m or C_{mv} $(m \geqslant 3)$ clusters with an odd number of cage atoms on the C_m-axis.

In order to check these qualitative considerations, and to see how well TSH describes bonding in these large clusters, EH calculations[17] were performed for the full set of *closo* structures. The Cartesian coordinates were generated by a symmetry-adapted iterative procedure, using the B—B bond lengths from Ref. 9. All BH bonds were taken to be radial and of length 1.19 Å. Figure 2 shows the resulting orbital energies, grouped in $L^{\sigma/\pi}$ shells using the TSH classification. As was found for the smaller *closo* boranes,[8] the energies occur in quite well-defined bands corresponding to different L values. Some crossing of F and D, and F and G bands occurs, but the general picture is as one would predict from TSH theory. The three non-Wade clusters are found to have a doubly degenerate level within 0.15 eV of the nonbonding energy. In Fig. 2 the lowest virtual and the highest occupied MOs conform to the mirror pattern about the nonbonding energy. The terminal BH bonds also follow a set of L^σ bands, giving an approximate order:

$$S^\sigma(\text{skel}) < P^\sigma \ldots G^\sigma(\text{BH}) < P^{\sigma/\pi} \ldots G^{\sigma/\pi}(\text{skel}),$$

though there is strong mixing of terminal and skeletal P, and to a smaller extent of D.

For comparison, Fig. 3 shows the equivalent energy bands for $2 \leqslant n \leqslant 12$ *closo* boranes. These

n	Group	Γ_σ	$\Gamma_{\pi+\bar{\pi}}$
14	D_{6d}	$2A_1+2B_2+E_1+E_2+E_3+E_4+E_5$	$A_1+A_2+B_1+B_2+3E_1+2E_2+2E_3+2E_4+3E_5$
16	T_d	$2A_1+E+T_1+3T_2$	$A_1+A_2+3E+4T_1+4T_2$
19	C_{3v}	$6A_1+A_2+6E$	$6A_1+6A_2+13E$
22	T_d	$3A_1+2E+T_1+4T_2$	$A_1+A_2+3E+6T_1+6T_2$

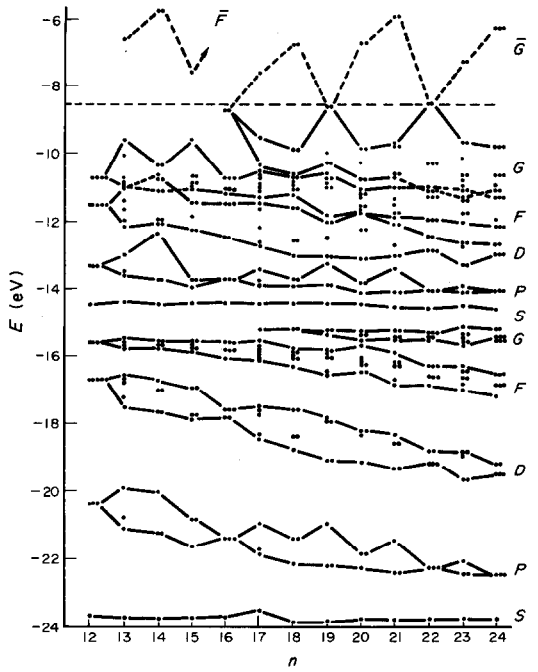

Fig. 2. Orbital energies of the supraicosahedral *closo* boranes calculated by the EH method.

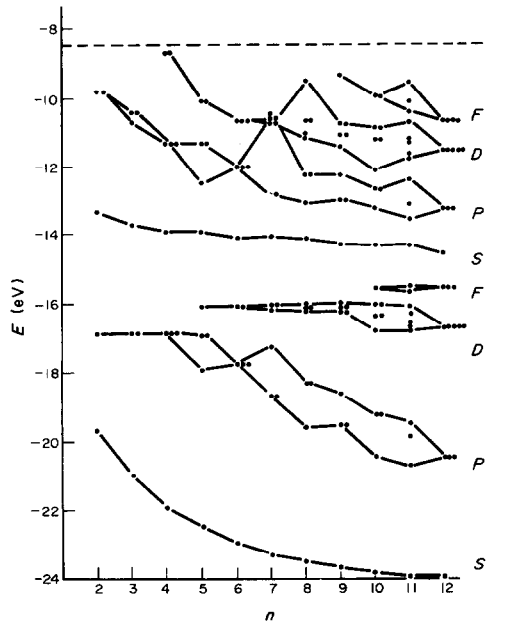
calculations[8] used equilateral deltahedra with r(BB) = 1.70 Å and therefore there is some mismatch of energies between Figs 2 and 3. Figure 2 includes the icosahedral $B_{12}H_{12}^{2-}$ levels for r(BB) = 1.77 Å. It can be seen that the qualitative features of the TSH description apply for the whole range of clusters $2 \leqslant n \leqslant 24$, confirming Brown and Lipscomb's suggestion as very plausible guesses for supra-icosahedral *closo* boranes.

For $n > 13$ the clusters all have 12 boron atoms of coordination number 6 (including the terminal H) and $(n-12)$ of coordination number 7. EH calculations on all possible *nido* structures obtained by abstracting a vertex from the *closo* clusters showed, as expected, that removal of the HCV was always favoured. This is consistent with the TSH explanation[7] that the open face of a *nido* cluster is analogous to a conjugated ring system and the frontier orbital is more stable for larger rings, i.e. for removal of the HCV. The favoured *nido* structures formally derived from those *closo* clusters obeying the $(n+1)$ rule have a $B_nH_n^{4-}$ electron count. Removal of a vertex from the $n = 16, 19$ or 22 clusters leads to (-2) or (-6) species.

Returning to the distinction made in the introduction between "*intrinsic*" and "*accidental*" depatures from the $(n+1)$ electron count, it appears from Fig. 2 that clusters with 13, 15 and 17 boron atoms *might* retain their *closo* structures with only n skeletal pairs as B_nCl_n because they have nondegenerate orbitals near the nonbonding line.

The simple calculations described here do not, of course, rule out other structures as the most stable arrangements of large groups of boron atoms. Bicerano *et al.*[10] were able to find low-symmetry structures for $n = 16$, 19 and 22 obeying the $(n+1)$ electron count. The only clusters of more than 12 boron atoms known so far contain more open arrangements of subicosahedral fragments.[18]

Finally, some deltahedra of even higher nuclearity have been proposed as possible borane structures.[10,18] One example is $B_{32}H_{32}^{q}$, the omnicapped I_h dodecahedron (I). It has 20 seven-coordinate borons on a dodecahedron, capped by an icosahedral array of 12 six-coordinate borons. The structure is deltahedral but what charge would it carry? The basic I_h dodecahedron is an electron-precise structure, adopted by $C_{20}H_{20}$, and has 30



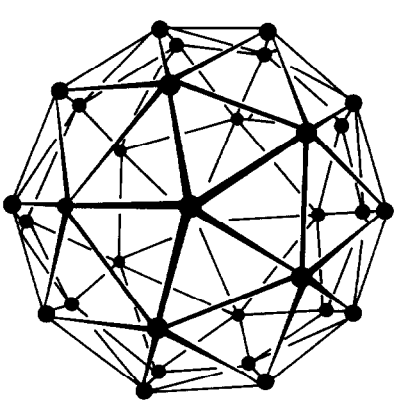


Fig. 3. Orbital energies of the small *closo* boranes calculated for equilateral deltahedra by the EH method.

I

Table 5. Symmetries of the spherical harmonics in the icosahedral group I_h

	σ, π	$\bar{\pi}$
S	A_g	
P	T_{1u}	T_{1g}
D	H_g	H_u
F	$T_{2u}+G_u$	$T_{2g}+G_g$
G	G_g+H_g	G_u+H_u
H	$T_{1u}+T_{2u}+H_u$	$T_{1g}+T_{2g}+H_g$

skeletal pairs in MOs spanning:

$$\Gamma_{30} = A_g+T_{1u}+T_{2u}+G_g+G_u+2H_g+H_u.$$

An icosahedral set of capping BH units has frontier orbitals spanning:

$$\Gamma_{cap} = A_g+T_{1g}+2T_{1u}+T_{2u}+G_g+G_u+2H_g+H_u,$$

so the 30 skeletal pairs will be stabilised by capping but also some new MOs will appear. Γ_{cap} contains T_{1g}, not present in Γ_{30}, that may be stabilised by interaction with an antibonding orbital of the dodecahedron, and in addition Γ_{cap} has one more T_{1u} set than Γ_{30}. Inspection of Table 5 shows that a weakly-bonding T_{1g} set would come from $\bar{H}^{\pi}$, paired to a T_{1u} set in H^{π}. Thus symmetry predicts a maximum count of 36 skeletal pairs, $B_{32}H_{32}^{8-}$.

Figure 4 shows EH orbital energies calculated with an expanded version of Ref. 17 for $B_{20}H_{20}$, $(BH)_{12}$ and $B_{32}H_{32}^{q}$. Lying ~2.5 V above the $B_{32}H_{32}^{4+}$ ($\equiv C_{20}H_{20}$) closed shell is a $(T_{1g}+T_{1u})$ set separated by only 0.12 eV and with a centre of gravity bonding by 0.06 eV. A gap of 7.2 eV separates these from the antibonding orbitals. Thus the most likely charges on $B_{32}H_{32}$, according to EH theory, would be +4 or −8 rather than the conventional *closo* count. However it is possible that the T_{1g} and T_{1u} orbital energies may split in a more sophisticated calculation, i.e. one that includes electron–electron repulsions, and that the −2 electron count would be restored, albeit with a low-lying unoccupied set of 3 MOs.

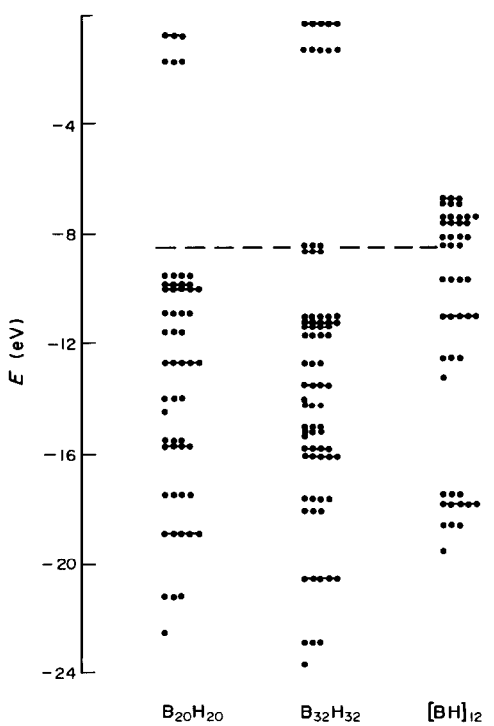

Fig. 4. Orbital energy diagrams for the capping of a pentagonal dodecahedron by 12 BH units, calculated by the EH method. g levels (●—●); u levels (● ●). All nondegenerate levels shown are A_g.

Acknowledgements—I would like to thank A. J. Stone and A. Ceulemans for useful comments on this work.

(*Received* 19 *April* 1985; *accepted* 19 *June* 1985)

Abstract—Some Pd(II) and Pt(II) halide complexes with 2-bromo- and 2-chloro-1,3,4-thiadiazoles have been prepared and characterized by electronic, NMR, Raman and IR spectroscopy, and by thermogravimetric analysis and conductivity measurements. All of the complexes appear to have square-planar stereochemistry with MN_2X_2 (X = Cl or Br) chromophores. Two of them are present in the *cis* configuration while for all the others unambiguous *trans* configurations are observed.

As a part of a series of investigations on the behaviour of heterocyclic ligands showing interesting biological[1,2] and pharmaceutical[3] properties, with some transition-metal ions, we have considered the 1,3,4-thiadiazole ring, which is the main framework of a very important class of diuretic drugs, the sulphonamide inhibitors of the zinc metallo-enzyme carbonic anhydrase.[4]

In this paper we have taken into account the coordination behaviour of 2-chloro-1,3,4-thiadiazole (ctz) and 2-bromo-1,3,4-thiadiazole (btz) with Pd(II) and Pt(II).

We have already theoretically investigated the nucleophilic ability of the nitrogen and sulphur atoms in the ring.[5] It was pointed out that the sulphur atom has the lowest chance of coordination, whereas the N(4) atom has the greatest chance, as the halogen atom X hinders the nitrogen in the 3-position.

EXPERIMENTAL

Preparation of the complexes

Two methods of preparation have been followed:

(a) PtL_2Br_2 (L = ctz or btz). One millimole of solid $PtBr_2$ and 2.3 mmol of solid L were mixed and heated at 80°C in 5 cm^3 of DMF solution for 5 min. The yellow precipitate was filtered and washed with EtOH and dried.

(b) PdL_2X_2 and PtL_2Cl_2 (M = Pd or Pt, X = Cl or Br). One millimole of MX_4^- was solubilized in a minimum amount of water and then MeOH was added, avoiding any insolubilization. To the above solution, 2.3 mmol of L dissolved in the same mixture solution (water–MeOH) were added. The precipitate obtained was washed with MeOH and dried.

Analysis

Carbon, nitrogen, sulphur and hydrogen were determined using a Carlo–Erba 1106 analyser.

The electrical conductances of the complexes were measured in DMF. The IR spectra were recorded with a Perkin–Elmer 180 spectrophotometer as KBr disks or Nujol mulls on polyethylene. The electronic spectra were recorded with a Shimadzu MPS 50L spectrometer either in DMF or in the solid state.

NMR measurements of the ligand btz (0.06 M in DMF-d_7) and of the $Pt(btz)_2Cl_2$ complex (0.06 M in DMF-d_7) were registered at 293 and 350 K on a Varian XL-200 spectrometer. The external reference for ^{195}Pt is related to the signal of the $PtCl_4^{2-}$ ion in a 0.036 M solution of K_2PtCl_4 in D_2O. The aquospecies $PtCl_3(D_2O)^-$ signal is 437 ppm at a lower field than $PtCl_4^{2-}$, in good agreement with other authors.[6]

Thermal gravimetric analysis (t.g. and d.t.g.) were made in air on a Mettler TG50 thermobalance equipped with a Mettler TC10 TA processor; a scan rate of 10° min^{-1} was used.

RESULTS AND DISCUSSION

The new compounds prepared in the present investigation are listed in Table 1. Analytical data agree very well with the formula ML_2X_2.

The molar conductances in DMF are in the 20–30 Ω^{-1} mol^{-1} cm^2 range in 10^{-3} M, indicating the nonelectrolytic nature of the compounds. This is consistent with the stoichiometry assumed for the complexes on the basis of analytical data.

All the compound are diamagnetic, as would be expected for planar coordination around the Pd(II) and Pt(II) ions in the complexes.

Electronic spectra

The relative pale colour of the derivatives indicate that 2-X-1,3,4-thiadiazoles have low ligand field strength in forming the complexes in which the *d–d* bands can easily be found.

Two ligand field bands at *ca* 24.5 and 31.0 and 26.5 and 35.0 kK in solution or in the solid state, for Pd(II) and Pt(II) respectively, are detected. Considering a square-planar configuration they can be assigned to $^1A_{1g} \rightarrow {}^1B_{1g}$ and $^1A_{1g} \rightarrow {}^1E_g$ transitions, respectively (Table 2). A strong charge-transfer band has been found at *ca* 38.0 kK in all the complexes. The crystal field stabilization energies for Pd(II) and Pt(II) complexes obtained from the relation: $E(\nu) = \Delta_1 - 35F_4$[7] [$F = 60$ cm^{-1} for both Pd(II) and Pt(II)] are summarized in Table 2. For the Pd(II) complexes the Δ_1 values are close in value to those of PdN_2Cl_2 and PdN_2Br_2 chromophores.[8] In the case of Pt(II) the observed values are somewhat lower than those of the PtN_2X_2 (X = Cl or Br) chromophores,[7] probably due to a stronger interaction of the X atoms than the N atoms with respect to the metal ion.

IR and Raman spectra

In the 2-X-1,3,4-thiadiazoles (X = Cl or Br) the halogen atom lower the symmetry of the ring molecule, a decoupling of the C=N stretching vibration and a large modification of the ring spectra are expected.

Because of the rigidity of the penta-atomic ring containing the three potentially coordinating atoms, the IR bands of the ligands arising from the vibration of several atoms of the ring cannot be related to definite bonds and supply direct and unambiguous informations on the coordination of the ligand molecules. Only the strong and well-isolated band at 650 cm^{-1} for ctz and at 642 cm^{-1} for btz can be easily identified in the complexes without any possibility of confusion with other neighbouring bands. Its frequency lies in the range characteristic for C—S stretching frequencies (750–570 cm^{-1}) and may be attributed principally to ν(CS) vibrations. An effective increase of about 10–20 cm^{-1} to higher frequencies for all the complexes is attributable to the shift produced by the coordination of the ligands to the metal ions.

Table 1. Analytical and other physical properties for the Pd(II) and Pt(II) complexes

Compound	Colour	Found (calc.) (%)				Λ_M^a

[a] Solid state.
[b] DMF solution.
[c] Ligand field splitting energy.

The bands at *ca* 350 and 240 cm^{-1} in the IR spectra are halogen-sensitive and hence attributable to the M—Cl and M—Br stretching vibration modes. Also those at *ca* 300 and 200 cm^{-1} for Pd(II) derivatives and at 210 cm^{-1} for Pt(II) derivatives in the Raman spectra are attributable to the same modes. The general lack of coincidence between IR and Raman spectra suggests a centrosymmetric structure in all the complexes with the exception of PtL_2Cl_2. A *trans*-square-planar symmetry can be proposed in agreement with the principal features included in Table 3.

In the PtL_2Cl_2 complexes four almost coincident bands in the far-IR and Raman spectra, two of them attributable to ν(Pt—Cl) (the values are some cm^{-1} higher than those found in the literature[9]), and the others to ν(Pt—N) are observed. For these last complexes a *cis*-configuration can be formulated.

The steric hindrance of the two ligands and two halogens atoms seems to be always critical in the Pd(II) complexes, while in the case of Pt(II) complexes the steric hindrance will be critical passing from chlorine to bromine. In conclusion the IR and Raman spectra are not particularly useful, in this case, for a precise identification of the ligand nitrogen atom involved in the coordination; moreover the band shifts found cannot be correlated either to the monodentate or the bidentate behaviour of the hetero-ring.

NMR spectra

The only complex suitable for structural investigations by NMR spectroscopy is $Pt(btz)_2Cl_2$.

This complex exhibits, just like the btz ligand, a good solubility and stability in DMF.

All NMR data are consistent with the hypothesis that the ligand is *N*-bonded to the Pt(II) atom, and in particular through the N_4 atom of the 1,3,4-thiadiazole ring. In fact the ^1H spectrum of $Pt(btz)_2Cl_2$ shows a downfield shift for the ligand proton: δ_H (free ligand) = 8.04 ppm and δ_H $Pt(btz)_2Cl_2$ = 9.85 ppm, and a Pt–H coupling constant of 25.5 Hz. This coupling constant is in agreement with other $^3J_{Pt-H}$ values found for system containing the Pt—N=C—H fragment.[9]

Table 3.

Compound	Structure	Point group	Active zone	Tension M—X	Tension M—L
cis	Square plane	C_{2v}	IR	A_1, B_2	A_1, B_2
			Raman	A_1, B_2	A_1, B_2
trans	Square plane	D_{2h}	IR	B_{3v}	B_{2v}
			Raman	A_g	A_g

The ^{13}C spectrum shows a different deshielding of the two carbon atoms:

	δ_{C_2} (ppm)	δ_{C_5} (ppm)
Free ligand	140.78	158.90
$Pt(btz)_2Cl_2$	143.33	165.82
$\Delta\delta$ (ppm)	+2.55	+6.92

At first sight the carbon nearest to the coordination centre should be the most sensitive, so the most important changes in δ value generally affect the C nucleus directly bonded to the N atom coordinated to the metal ion.

The $\{^1H\}$–^{195}Pt spectrum performed at 298 K exhibits an unresolved broad signal ($\Delta\nu_{1/2} \cong 400$ Hz) at −335 ppm (the minus sign means upfield with respect to the external reference). The large ^{195}Pt linewidth in the complex due to spin–spin interactions with ^{14}N quadrupolar nuclei suggests a Pt—N bond; the spectrum recorded at 350 K shows a fine structure, a typical multiplet (quintet) clearly attributable to Pt—^{14}N coupling ($^1J_{Pt-^{14}N} = 230 \pm 5$ Hz). In addition, a chemical shift variation ($\Delta\delta_{Pt} = +14$ ppm) due to the increased temperature is visible according with other authors.[10]

Thermal behaviour of the complexes

The t.g. studies of the compounds show that all the present compounds start decomposing at *ca* 160–200°C, in a first step, losing a great part of the ligand atoms. In a second step the halogens and the remaining part of the ligand are lost. All the compounds attain constant weight at *ca* 600–800°C.

The dark-grey residue in each complex has been characterised as Pd(II) oxide or platinum metal sponge.

Acknowledgements—We thank the M.P.I. for the financial support (60%), Mr. Gianni Goldoni for the elemental analyses and the Centro Strumenti of the University of Modena for IR, Raman and NMR spectra.

REDUCTIVE ISOMERIZATION OF ICOSAHEDRAL METALLOCARBABORANES

TIMOTHY P. HANUSA and LEE J. TODD*

Department of Chemistry, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 19 *April* 1985; *accepted* 26 *June* 1985)

Abstract—When reduced over a sodium amalgam, a variety of icosahedral metallocarbaboranes are found to isomerize under mild experimental conditions. Complexes containing second-row transition metals (Ru and Rh) rearrange rapidly at room temperature, but even cobaltacarbaboranes will isomerize in refluxing 1,2-dimethoxyethane (85°C) or diethylene glycol dimethyl ether (162°C). The direction of rearrangement is that found in straight thermally-induced isomerizations.

Thermal polyhedral rearrangements of *closo* borane anions[1] and isoelectronic carbaborane,[2] and metallocarborane species[3–5] have been known for some time. Depending upon the experimental conditions involved, the skeletal rearrangements induced in a given compound may give one or several isomeric products.

We wish to report our initial findings concerning a rather low temperature reductive isomerization procedure which gives rearranged products in the thermally-expected order. Reductive polyhderal isomerization may offer access to selected rearrangement products under comparatively mild experimental conditions.

EXPERIMENTAL

Physical measurements

Boron (^{11}B) NMR spectra were obtained at 115.8 MHz with a Nicolet NT-360 spectrometer and were externally referenced to $BF_3 \cdot O(C_2H_5)_2$ (positive values downfield). Proton NMR spectra were recorded at 361 MHz on the Nicolet instrument and were referenced to internal Me_4Si. Melting points were determined in sealed, evacuated capillaries and are uncorrected.

Materials

All reactions were performed under an atmosphere of prepurified dinitrogen. Tetrahydrofuran (THF), 1,2-dimethoxyethane (DME) and diethylene glycol dimethyl ether (diglyme) were distilled from sodium benzophenone ketyl. (Cyclopentadienyl)diiodorhodium

$([(C_5H_5)RhI_2]_n)$,[6] 3,1,2-$(C_5H_5)CoC_2B_9H_{11}$,[7]

3,6,1,2-$[(C_5H_5)Co]_2C_2B_8H_{10}$,[7]

3,1,2-$(\eta$-$C_6H_6)RuC_2B_9H_{11}$,[8]

and $Tl[3,1,2\text{-}TlC_2B_9H_{11}]$[9] were prepared according to literature methods.

Preparation of 3,1,2-$(C_5H_5)RhC_2B_9H_{11}$

To a slurry of $[(C_5H_5)RhI_2]_n$ (0.62 g) in dry THF (50 cm^3) was added $Tl[3,1,2\text{-}TlC_2B_9H_{11}]$ (0.42 g, 0.77 mmol) while stirring. Stirring under nitrogen was continued for 24 h, after which the dark brown mixture was opened to air and silica gel (1 g, 100–200 mesh) added. After the solvent was removed *in vacuo*, the solids were transferred to a silica gel column (2 × 30 cm) packed with toluene–hexane [2:1 (v/v)]. Elution was begun with the same solvent mixture; enrichment of the eluent with toluene and finally CH_2Cl_2 produced a pale yellow band. Stripping of the solvent from the eluate yielded 3,1,2-$(C_5H_5)RhC_2B_9H_{11}$. The product was redissolved in CH_2Cl_2 and treated with decolorizing carbon. Hexane was added to the filtered solution, and slow evaporation produced apple-green plates (69 mg, 30% yield), m.p. 225–228°C (dec.). ^{11}B NMR (115.8 MHz, $CDCl_3$): δ 6.5 (d, 1, J = 145 Hz), 4.5 (d, 1, J = 151 Hz), −4.9 (d, 2, J = 156 Hz), −7.1 (d,

2, J = 144 Hz), −17.3 (d, 1, J = 158 Hz), −23.3 (d, 1, J = 170 Hz). ^{1}H NMR (361 MHz, $CDCl_3$): δ 5.90 (s, 5), 4.2 (br s, 2). Mass spectrum, m/z 302.1170 (calc. for $^{12}C_7{}^1H_{16}{}^{103}Rh^{11}B_9$; 302.1172).

Reductions: general procedures

A sodium amalgam ranging from 0.4 to 0.6% (0.24–0.41 g Na in 68 g Hg) was prepared under nitrogen and *ca* 40 cm^3 of the designated solvent were added. The metallocarbaborane (0.08–0.78 mmol) was dissolved with stirring in the liquid, and the reaction then maintained over the amalgam at room temperature (24°C in THF) or under reflux (85 and 162°C in DME and diglyme, respectively). Samples (*ca* 1 cm^3) were withdrawn at measured intervals and dioxygen bubbled through the solution for 1 min to quench the reaction. The products were then analyzed by ^{11}B and/or ^{1}H NMR spectroscopy.

RESULTS AND DISCUSSION

The four icosahedral metallocarbaboranes,

3,1,2-(η-C_6H_6)$RuC_2B_9H_{11}$,

3,1,2-$(C_5H_5)CoC_2B_9H_{11}$,

3,1,2-$(C_5H_5)RhC_2B_9H_{11}$

and 3,6,1,2-$[(C_5H_5)Co]_2C_2B_8H_{10}$, were reduced in various solvents over sodium amalgam, and then maintained over the amalgam either at room temperature or under reflux. Samples were withdrawn periodically from the reactions, oxidized and analyzed by NMR spectroscopy. The ratios of observed products at each measured time and temperature are expressed as percentage conversions in the Table. All isomerized complexes were those either known or expected from thermally-induced rearrangements (i.e. involved a migration of the carbon atoms away from each other and the metal)[3–5] but several results were obtained which are not typical of thermal isomerizations of icosahedral metallocarbaboranes at the higher temperatures reported previously. Figures 1 and 2 illustrate the structures of the starting materials and products of these isomerization processes.

Temperature

The most striking feature of the isomerizations is the temperature at which the onset of isomerization occurs; the rhodium and ruthernium complexes undergo over 90% conversion while at room temperature, and even the two cobalt species have begun to isomerize at 85°C. Such mild conditions do not normally effect the rearrangement of monocage icosahedral metallocarbaboranes;* the lowest reported temperatures for the thermal isomerization of 3,1,2-$(C_5H_5)CoC_2B_9H_{11}$ and 3,6,1,2-$[(C_5H_5)Co]_2C_2B_8H_{10}$, for example, are 380 and 340°C, respectively.[4,5]

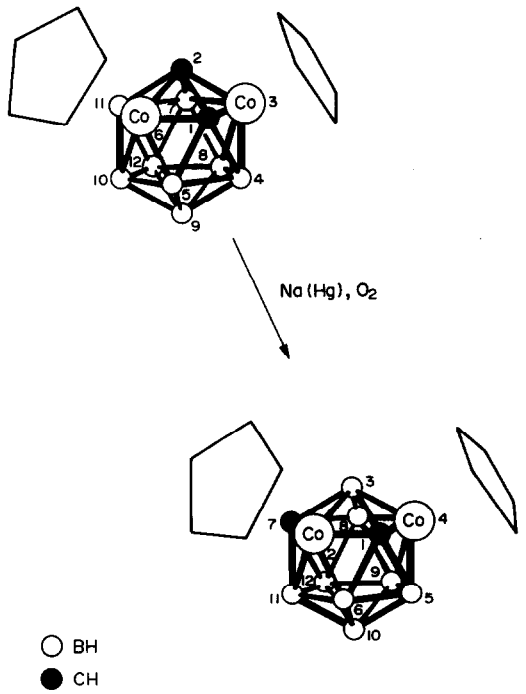

Fig. 2. Reductive isomerization of 3,6,1,2-$[(C_5H_5)Co]_2C_2B_8H_{10}$ to the 2,4,1,7 configuration.

* Several *bis*-cage complexes of the form $[(RC)_2B_9H_9]_2M^{n-}$ (R = H or CH_3; M = Ni or Pd; n = 0, 1 or 2) are known which rearrange at or below room temperature.[10]

Selectivity

The specificity of the reactions distinguishes them from the gas-phase isomerization of transition-metal metallocarbaboranes,[4] but is similar to that observed with thermal isomerizations in solution.[5] All of the reactions described here generally yielded only one isomer in addition to the starting material; the exception was $(C_5H_5)CoC_2B_9H_{11}$, for which none of the starting isomer was present after 3 h at 162°C, and instead a mixture of the 2,1,7 and 4,1,7 complexes was present. Evidently the thermodynamically-favored products are able to accumulate during the comparatively long reaction times involved. The approach to an equilibrium state of isomerized products is evident with $(C_5H_5)CoC_2B_9H_{11}$ at 85 and 162°C, as the 3,1,2:2,1,7 and 2,1,7:4,1,7 isomer ratios, respectively, eventually converge to *ca* 1:5.

Conversion of $3,6,1,2\text{-}[(C_5H_5)Co]_2C_2B_8H_{10}$

The extraordinary slowness of the isomerization of the bimetallocarbaborane differentiates it from the isoelectronic monometallic species, as only under 162°C reflux is an appreciable rate of transformation noticed. In contrast, the thermal rearrangement of $3,6,1,2\text{-}[(C_5H_5)Co]_2C_2B_8H_{10}$ requires a temperature no greater than that for $3,1,2\text{-}(C_5H_5)CoC_2B_9H_{11}$.[4,5]

Rate dependence on metal

The rapidity of isomerization of $3,1,2\text{-}(\eta\text{-}C_6H_6)RuC_2B_9H_{11}$ under reducing conditions is remarkable: in 3 h at room temperature, 50% is converted to the 2,1,7 isomer,* whereas the isoelectronic complex incorporating $(C_5H_5)Co(III)$ undergoes only a 6% change during a reaction period over 30 times as long.

In order to determine the extent to which the change in rate was due solely to the effect of the second-row transition metal (rather than the difference in the metal oxidation state or the ligand), the new metallocarbaborane, $3,1,2\text{-}(C_5H_5)RhC_2B_9H_{11}$, was synthesized from $[(C_5H_5)RhI_2]_n$ and $Tl[3,1,2\text{-}TlC_2B_9H_{11}]$ in THF, and isolated as yellow-green plates in moderate yield. Its ^{11}B NMR spectrum indicates that the molecule possesses a *closo* icosahedral geometry exactly analogous to that of its cobalt counterpart.[4] Under reducing conditions, the rhodium complex undergoes over 90% conversion in 3 h at room temperature to the 2,1,7 isomer.† Thus its rate of isomerization is well over an order of magnitude faster than the cobalt homologue under identical conditions and nearly twice as rapid as for the (π-benzene) ruthenium metallocarbaborane. Clearly, the presence of a second-row transition metal exerts a major influence on the rearrangement process.

Sodium amalgam reduction of $(C_5H_5)CoC_2B_9H_{11}$ is known to produce the $(C_5H_5)CoC_2B_9H_{11}^-$ ion,[11] and, since the ruthenium complex, and probably the rhodium species as well, are even more difficult to reduce,‡ it is likely that only one-electron reductions occur in all the cases. Some *nido* 12-atom metallocarbaboranes are known to undergo thermal rearrangement at relatively low temperature.[13] Although the resulting $27e^-$ compounds would presumably not possess the open geometry observed for 12-membered $28e^-$ *nido* metallocarbaboranes,[14] the extra electron might relax the rigidity of the polyhedron producing a more-flexible cage with a lowered E_{act} for rearrangement. If this is the case, then the enhanced overlap between the cage orbitals and those of the 4*d* relative to the 3*d* elements might promote more effective electron delocalization and hence more rapid isomerization.[15]§

Recently it was reported that *closo*-3,3-$(Ph_3P)_2$-3-H-1-C_6H_5-3,1,2-$IrC_2B_9H_{10}$ will undergo polytopal rearrangement to the 2,1,8 isomer under toluene reflux in 30 h.[16] Compounds of this type are known to undergo conversion, in an equilibrium process, to an "*exo–nido*" structure.[17,18] It may well be that the *exo–nido* intermediate provides the facile pathway for this lower-temperature polyhedral isomerization.

---

*2,1,7-$(\eta\text{-}C_6H_6)RuC_2B_9H_{11}$. ^{11}B NMR (115.8 MHz, $Me_2SO\text{-}d_6$): δ −0.9 (1, J = 126 Hz), −6.3 (2, J = 144 Hz), −11.7 (1, J = 159 Hz), −14.9 (2, J = 139 Hz), −16.0 (1, J = 130 Hz), −20.4 (2, J = 146 Hz); ^1H NMR (361 MHz, $Me_2SO\text{-}d_6$): δ 6.38 (s, 6, C_6H_6), 3.0 (br, 2, C_{cage}—H); mass spectrum, m/z 316.1230 (calc. for $^{11}B_9{}^{12}C_8{}^1H_{17}{}^{104}Ru$ = 316.1223); light yellow crystals, m.p. 310–312°C (dec.).

†2,1,7-$(C_5H_5)RhC_2B_9H_{11}$. ^{11}B NMR (115.8 MHz, $CDCl_3$): δ 3.4 (1, J = 142 Hz), −1.9 (2, J = 153 Hz), −8.2 (1, J = 164 Hz), −13.4 (3, J = 152 Hz), −18.6 (2, J = 157 Hz); ^1H NMR (361 MHz, $CDCl_3$); δ 5.89 (s, 5, C_5H_5), 3.2 (br, s, 2, C_{cage}—H); yellow needles, m.p. 220–222°C (dec.). The low-resolution mass spectrum cut off at m/z 302 corresponds to $^{12}C_6{}^{13}C_1{}^1H_{16}{}^{103}Rh{}^{11}B_9$.

‡Cyclic voltammetry of $3,1,2\text{-}(\eta\text{-}C_6H_6)RuC_2B_9H_{11}$ [THF, 0.2 M $(n\text{-}Bu)_4N^+OH^-$ as supporting electroyte, Ag–AgCl reference electrode, Pt bead working electrode, 100 μA, 200 mV sec^{-1}] indicates irreversible reduction occurs at −1.83 eV. Under identical conditions in CH_3CN, $3,1,2\text{-}(C_5H_5)CoC_2B_9H_{11}$ displays a reversible reduction wave at −1.16 eV.[12]

§A similar argument based on the "diffuseness' of 5*d* relative to 4*d* orbitals has been invoked in connection with the more rapid thermal isomerization of $(C_2B_{10}H_{12})_2Hf^{2-}$ compared to the isoelectronic $(C_2B_{10}H_{12})_2Zr^{2-}$ ion.[15]

CONCLUSIONS

Reductive polyhedral isomerization offers access to various isomers of icosahedral metallocarbaboranes under comparatively mild experimental conditions, and its full scope remains to be explored. Applied to other icosahedral and non-icosahedral systems, such isomerizations could be a valuable probe of the relative thermodynamic stabilities of metallocarbaboranes, and perhaps of the many structurally and electronically-related metal atom clusters as well.[19]

DECOMPOSITION OF SILANE ON SOLID P_4O_{10}

B. S. SURESH and D. K. PADMA*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560 012, India

(*Received* 15 *April* 1985; *accepted* 25 *June* 1985)

Abstract—Silane undergoes thermal decomposition on the surface of "phosphorus pentoxide" (P_4O_{10}) into its elements around 200–400°C. The hydrogen formed partially reduces the P_4O_{10} forming lower oxides of phosphorus and water. Elemental silicon is precipitated as reddish-brown solid, which is separated by dissolving out the phosphorus oxides. Silica and disiloxane are not formed in the reaction.

In the course of our study on the reaction of silicon compounds with "phosphorus pentoxide" (P_4O_{10}), an interesting observation was the decomposition of silane into silicon and hydrogen over a bed of P_4O_{10} held around 200–400°C, a temperature much lower than the decomposition temperature of silane in glass vessels.[1] The details of such a study are presented in this paper.

EXPERIMENTAL

Materials and methods

Silane was prepared by the standard method of reduction of SiF_4 with $LiAlH_4$.[2] P_4O_{10} (BDH) was purified by sublimation in a stream of dry oxygen.[3] IR spectra of gaseous compounds were recorded in a 10-cm cell with KBr windows and those of the solids in a KBr pellet on a Perkin–Elmer (599) spectrophotometer.

Reaction of silane with P_4O_{10}

Procedure: P_4O_{10} (1.7 g, ~6.0 mmol) and silane (~96 mg, ~3.0 mmol) were placed in an evacuated reaction vessel and heated at 200°C. After about an hour, a reddish-brown solid began to deposit on the surface of the P_4O_{10}. The heating was continued for 12 h. IR spectra of the gaseous component indicated the presence of unreacted silane. The temperature of the reaction vessel was raised to 400°C and it was heated at this temperature for 12 h. On cooling, the gaseous component indicated the absence of silane but the presence of an uncondensable gas. Mass spectral data indicated the presence of hydrogen. The solid was treated with water and slightly warmed, when a gas with a characteristic odour of phosphine was evolved which turned moist silver nitrate paper black. The aqueous solution decolourized a dilute potassium permanganate solution. The tests indicated that the solid contained lower oxides of phosphorus such as P_4O_6.[4] The bulk solid was treated with water and well stirred. Excess P_4O_{10} as well as the lower oxides of phosphorus formed were dissolved and the remaining reddish-brown solid was filtered, washed thoroughly with water and dried *in vacuo* and analysed.

This dried solid did not exhibit any IR absorption bands. It remained unchanged in both dilute hydrofluoric acid and dilute alkaline solutions indicating the absence of Si—H and Si—O bonds. When the solid was heated in an air oven it turned white. The white solid was characterised to be silica by elemental analysis and IR spectral data.

The effect of relative proportions of reactants on the nature of the products formed was studied by conducting the experiment with silane in excess (~4.0 mmol), (P_4O_{10} ~ 1.0 mmol) at 200 (12 h) or 400°C (12 h). The products were found to be the same as in the previous case. Possible products such as silica and disiloxane were not observed.

Pure silane (~96 mg, ~3.0 mmol) was heated alone in a reaction vessel between 200 and 400°C for 24 h, but no decomposition was observed.

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSIONS

The experimental results indicate that the reaction of silane with P_4O_{10} is one of decomposition, the products being an orange red solid, hydrogen and lower oxides of phosphorus. The analytical results indicate that the red solid is amorphous silicon. The fact that other expected products such as silica and disiloxane were not formed in the reaction even when the relative proportions of the reactants were changed, indicates that no other reaction has taken place other than decomposition. This is in contrast to the reported reactions of tetrahalosilanes[1] with P_4O_{10} where the reaction products are phosphoryl halides and silica.

The overall decomposition reaction could be represented as follows:

$$SiH_4 \xrightarrow{200\text{–}400^\circ C} Si + 4[H],$$

$$P_4O_{10} + 8[H] \xrightarrow{200\text{–}400^\circ C} P_4O_6 + 4H_2O.$$

An interesting aspect of the present study is that P_4O_{10} lowers the decomposition temperature of silane. Similar decomposition of silane around 200°C have been noted on silica gel or charcoal.[5] An added advantage in the present case is the easy separation of silicon formed by the addition of water.

PREPARATION AND CHARACTERIZATION OF TETRAHALODIMOLYBDENUM(II) COMPLEXES WITH ALKYL-SUBSTITUTED PYRIDINES

K. J. EWING* and S. I. SHUPACK

Department of Chemistry, Villanova University, Villanova, PA 19085, U.S.A.

(*Received* 29 *March* 1985; *accepted* 27 *June* 1985)

Abstract—The preparation and characterization of new tetrahalodimolybdenum(II) complexes with alkyl-substituted pyridines is described. IR and visible data are used to infer structural information with respect to previously prepared complexes of this type.

Many dimolybdenum complexes of the types $Mo_2X_4L_4$ and $Mo_2X_4(LL)_2$, where X = Cl or Br, L = C_5H_5N, 4-$CH_3C_5H_4N$, $P(C_4H_{10})_3$ or $P\{S(CH_3)\}_3$, and LL = bipy, dppe, arphos or dpae, have been prepared and characterized.[1–3] These complexes characteristically have two Mo—Cl stretching bands in the IR; complexes with monodentate ligands exhibit these bands[2] at 337 ± 15 and 285 ± 10 cm^{-1}, the complex α-$Mo_2Cl_4(dppe)_2$ exhibits these bands at 307 and 290 cm^{-1}, while complexes with arphos and dpae exhibit these bands[3] at 350 ± 10 and 295 ± 5 cm^{-1}. The existence of a *trans* arrangement of chlorine atoms about each molybdenum in complexes with monodentate ligands, a *cis* arrangement in the α-$Mo_2Cl_4(dppe)_2$ complex, and a unique staggered structure in complexes with arphos and dpae have been proposed from these data. The X-ray structures of $Mo_2Br_4(arphos)_2$[4] and β-$Mo_2Cl_4(dppe)_2$[5] agree with the proposed structure of each complex. The position of the δ–δ^* transition has also been shown to reflect a complex geometry.[3]

The structure of Mo_2X_4(4-methylpyridine)$_4 \cdot CHCl_3$ (X = Cl or Br) as determined by X-ray is shown in Fig. 1(a). Changes in its low-frequency IR spectrum may indicate rotation about the quadruple bond to the structure in Fig. 1(b).[6]

We report here the synthesis and characterization of the complexes $Mo_2X_4L_4$, where X = Cl or Br, and L = 3-methylpyridine (3PIC), 3,4-dimethylpyridine (34LUT), 3,5-dimethylpyridine (35LUT) and 4-*t*-butylpyridine (4TBP). These complexes were prepared to study the effect that different substituents on pyridine would have on the electronic and structural properties of the complex. A more comprehensive report will be forthcoming.

EXPERIMENTAL

All solvents and ligands were dried via literature methods and kept under dry nitrogen prior to use.[7] All reactions, filtrations and recrystallizations were also carried under a dry nitrogen atmosphere using Schlenk equipment. IR and visible spectra of Nujol mulls of the complexes were taken using the Perkin–Elmer 229 and Cary 219 spectrophotometers, respectively. NMR spectra of the complexes in $CDCl_3$ or C_6D_6 were obtained from the Varian XL-200 spectrometer in sealed tubes. Raman spectra were obtained as described elsewhere.[8]

Tricesium hydridooctachlorodimolybdate(II) and tricesium hydridooctabromodimolybdate(II) were prepared via literature methods.[2,9,10] Dimolybdenum tetraacetate was purchased from Aldrich and used without further purification. The ligands 3-picoline and 4-picoline were purchased

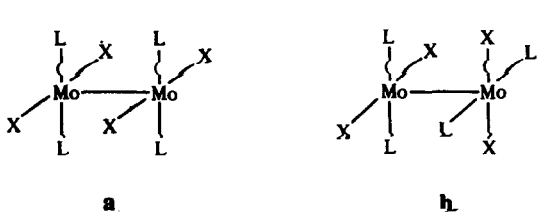

Fig. 1.

from the Eastman Kodak Co.; 3,4-lutidine, 3,5-lutidine and 4 TBP were purchased from Aldrich. The general synthesis for the complexes is similar to the synthesis of the tetrahalodimolybdenum tetrapyridine complex.[2] Microanalyses were performed by Galbraith Laboratories Inc., Knoxville, TN.

RESULTS AND DISCUSSION

The visible, IR, NMR and Raman spectra of the complexes $Mo_2X_4L_4$, where X = Cl or Br and L = py, 4PIC, 3PIC, 4TBP, 34LUT and 35LUT, are given in Table 1. Complexes with 4PIC, py, 3PIC and 34LUT have similar IR and visible spectra, with two Mo—Cl stretching bands in the ranges 320–340 and 270–280 cm^{-1}; the proposed δ–δ^* transition energy increases in the order py $\cong$ 4PIC < 3PIC $\cong$ 34LUT. This transition for the 3PIC and 34LUT complexes ranges from 585 to 725 cm^{-1} higher in energy than those of the py and 4PIC complexes. The similarity in the IR spectra of these complexes leads us to propose that the 3PIC and 34LUT complexes have the same structure as that of the 4PIC complex determined by Brencic *et al.*[6] The Raman shows a single intense band for these complexes in the vicinity of 350 cm^{-1}, indicative of the Mo≡Mo quadruple bond. Proton NMR spectra of these complexes show a downfield shift for the *ortho* protons of approximately 0.8 ppm. The deshielding of these protons is due to their close proximity to the quadruple bond.[11]

The 35LUT complex has the proposed δ–δ^* transition higher in energy than any of the other complexes; it is also the most sterically restrictive ligand. The proposed δ–δ^* transition occurs 1179 cm^{-1} higher in energy than that of the 4PIC complex, with three Mo—Cl bands in the IR. The Raman spectrum of this complex shows a very intense band at 349 cm^{-1}, indicative of the Mo≡Mo quadruple bond. The NMR spectrum of this

complex shows a downfield shift for all ligand protons. However, the *ortho* protons are not shifted as far downfield as in the 4PIC, 3PIC and 34LUT complexes. The data suggest that $Mo_2Cl_4(35LUT)_4$ has a different geometry from any of the latter complexes. Further work is necessary to be conclusive.

The complex $Mo_2Cl_4(4TBP)_4$ precipitates from a pentane–4 TBP mixture as a green powder, while precipitation from a pentane–benzene mixture yields a blue powder. The green material has the proposed δ–δ^* transition at 17,182 cm^{-1} and is the material reported on in this paper. The blue material has not been analyzed, but possesses visible and IR spectral characteristics of $Mo_2X_4L_4$ type complexes (see Table 1). When $Mo_2Br_4(4TBP)_4$ was slowly recrystallized from a benzene–pentane mixture at 0°C, a mixture of dark blue needles and dark green

cubic crystals were obtained. The analysis of these crystals gave the stoichiometry of both crystalline forms as $Mo_2Br_4(4TBP)_4$. The separated crystals gave identical IR spectra down to 200 cm^{-1}, but different visible spectra (see Table 1). This indicates that $Mo_2X_4(4TBP)_4$ (X = Cl or Br) may exist as geometric isomers similar to structures **a** and **b**. We are currently growing crystals of these complexes for X-ray analysis.

Acknowledgements—We wish to thank Drs T. Spiro and R. Czernuszewicz for their generous help in obtaining Raman spectra.

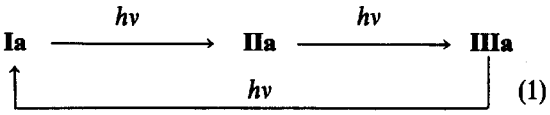
SELF-CONSISTENT-FIELD-Xα-SCATTERED-WAVE MOLECULAR ORBITAL CALCULATION OF [CpMoS(μ-S)]$_2$, A MOLECULE THAT UNDERGOES A PHOTOCHEMICALLY INDUCED ISOMERIZATION



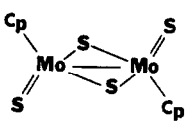
MITCHELL R. M. BRUCE, ALICE E. BRUCE and DAVID R. TYLER*

Department of Chemistry, Columbia University, New York, NY 10027, U.S.A.

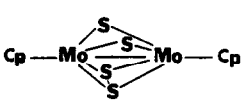
(*Received* 3 *April* 1985; *accepted* 27 *June* 1985)

Abstract—A self-consistent-field-Xα-scattered-wave molecular orbital calculation was carried out on the [CpMoS(μ-S)]$_2$ (Cp = η^5-C_5H_5) complex. The calculated results were used to rationalize the observed photochemical isomerization of the title complex to [CpMo(μ-S)][μ-S_2]. It is proposed that a terminal sulfur (S_t) → Mo charge-transfer excitation is responsible for the isomerization, which is an intramolecular redox; i.e. Mo(V) is reduced to Mo(IV) and S^{2-} is oxidized to S_2^{2-}, a result consistent with the charge-transfer character of the excitation. Specifically, the transition responsible for the isomerization is proposed to be $16b_u \rightarrow 18a_g$ ($^1A_g \rightarrow {}^1B_u$). The $18a_g$ orbital is primarily Mo in character but it is also Mo—S_t π-antibonding; cleavage of the Mo—S_t π-bond facilitates the isomerization.

As part of our continuing study[1–5] of the ligand-to-metal charge-transfer (LMCT) photochemistry of organometallic complexes, we investigated the photochemical reactivity of the [Cp*MoS(μ-S)]$_2$ [Cp* = η^5-$C_5(CH_3)_5$] and [(MeCp)MoS(μ-S)]$_2$ (MeCp = η^5-$CH_3C_5H_4$) complexes, **Ia** and **Ib**, respectively (Fig. 1).[5] When **Ia** is irradiated, isomer **IIa** forms and then isomer **IIa** undergoes a photochemical isomerization to **IIIa**. This sequence of reactions is best described by the cyclic photoisomerization process shown in eqn (1):[5]

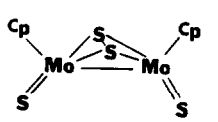


(1)



A similar photochemistry is observed for the **b** isomers.[5] In order to gain insight into the electronic structures of **Ia** and **Ib**, we carried out a self - consistent - field - Xα - scattered - wave (SCF-Xα-SW) molecular orbital calculation on [CpMoS(μ-S)]$_2$ (Cp = η^5-C_5H_5) (**Ic**). The results of the calculation are presented here and discussed in relation to the isomerization process, **I** → **II**.

EXPERIMENTAL



Calculations were carried out by the SCF-Xα-SW molecular orbital method.[6–9] Current versions of

Ia, Cp = η^5-$(CH_3)_5C_5$
Ib, Cp = η^5-$(CH_3)C_5H_4$
Ic, Cp = η^5-C_5H_5

IIa, Cp = η^5-$(CH_3)_5C_5$
IIb, Cp = η^5-$(CH_3)C_5H_4$
IIc, Cp = η^5-C_5H_5

IIIa, Cp = η^5-$(CH_3)_5C_5$
IIIb, Cp = η^5-$(CH_3)C_5H_4$
IIIc, Cp = η^5-C_5H_5

the programs were used* and they were run on the Columbia chemistry department's DEC VAX 11/780 computer. Norman's procedure for interpolation of overlapping sphere sizes was used to optimize the virial coefficient at one.[10,11]† Schwarz's α_{HF} values[12,13] were used for the atomic exchange parameters. The α values for the intersphere and outersphere regions were a weighted average of the atomic α values, where the weights are the number of valence electrons on the different neutral free atoms. A minimal basis set in partial wave expansion was used.‡ The coordinates used for **Ic** were based on the crystal structure data of Rakowski DuBois *et al.*[14]§ for **Ib** and adjusted to idealized C_{2h}-symmetry (Table 1). The coordinate axis and atomic labels used in the calculation are shown in Fig. 2. The outersphere was centered at the origin. The exact coordinates are listed in Table 2.

[b] Based on the structural data of $(\eta^5\text{-}C_5H_5)_2TiCl_2$.[4]

[c] The placement of the cyclopentadienyl ligand was estimated based on analogous Cp—Mo—Cp and Cp—Mo—S bond angles.[16–18]

[d] Idealized C—C—C angle in the cyclopentadienyl ring.

RESULTS

The SCF-Xα-SW molecular orbital calculation was performed on **Ic** rather than the analogs **Ia** and **Ib** in order to simplify the calculation.[14] This simplification is justified for two reasons. First, the initial photochemical isomerization of **I** to **II** is identical for the Cp* and MeCp complexes.[5] Second, the electronic absorption spectra for **Ia** and **Ib** are identical in the photochemically active region 400–600 nm. Because the substitution of five methyl groups on the Cp ring causes a small perturbation relative to MeCp (in terms of the photochemical reactivity and the electronic spectra), it is reasonable that the perturbation between MeCp and Cp will also be small.

The groundstate eigenvalues and symmetries of the upper occupied and lower unoccupied molecular orbitals are shown in Table 3. Of special interest to us are the charge distributions of the upper occupied and lower unoccupied molecular orbitals which are predicted to be involved in the low-energy electronic transitions. The charge distributions of these molecular orbitals can be most clearly seen by inspection of contour plots of the wave function density.

Figure 3 shows the contour plots of the wave function density for the three highest occupied molecular orbitals, $9b_g$, $16b_u$ and $17a_g$. Figure 4 shows the plots for the four lowest unoccupied molecular orbitals, $17b_u$, $10b_g$, $18a_g$ and $10a_u$. Four types of contour plots are shown: (1) the *xz*, *yz* and *xy* planes; (2) a plane parallel to the *yz* plane but containing Mo [this is labeled *yz* (Mo)]; (3) a plane that contains a Mo and a terminal S (S_t) and is perpendicular to the *xy* plane (this plane is labeled MoS_t); and (4) a plane that contains an Mo and a bridging S (S_b) and is perpendicular to the *xz* plane (this plane is labeled MoS_b).

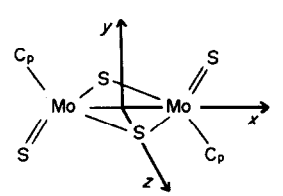

Fig. 2. Coordinate system used in the SCF-Xα-SW calculation of $[CpMoS(\mu\text{-}S)]_2$.

* The programs were received from K. H. Johnson in 1981 and converted for use on a DEC VAX 11/780 by W. H. Klemperer and M. R. M. Bruce.

† In practice, the program calculates the ratio of atomic radii and varies the percent of the calculated atomic radii while holding the ratio fixed to be used in the molecular potential. Limited computer time necessitates close but non-one virial coefficients. For **Ic** the percent value of 89% produced a virial coefficient of 1.000190 at convergence.

‡ Minimal basis set: Mo, $l = 2$; C, $l = 1$; H, $l = 1$; S, $l = 1$. For the outersphere region the value of $1 = 2$ was sufficient to generate basis function components in all representations. (The use of a minimal basis set was justified based on previous work.[4])

§ The complex with unsubstituted cyclopentadienyl ligands is suggested to be a polymer composed of dimeric units connected by sulfide or polysulfide bridges.

The contour plots show that the $9b_g$ orbital (Fig. 3) is primarily S_b in character. The contour plots of the $16b_u$ orbital (Fig. 3) show it to be a highly delocalized molecular orbital with Cp, S_t and S_b character. The $16b_u$ orbital is essentially Cp–S_t–S_b nonbonding. The $17a_g$ orbital (Fig. 3) is primarily Cp in character with a small amount of Mo character. The interaction is only slightly Cp–Mo bonding. As expected, there is a significant amount of wave function density in the planes above and below the Cp ring, parallel to the carbon skeleton. However, these planes are not shown (see Table 3).

The contour plots of the unoccupied molecular orbitals (Fig. 4) show that the $17b_u$, $10b_g$, $18a_g$ and

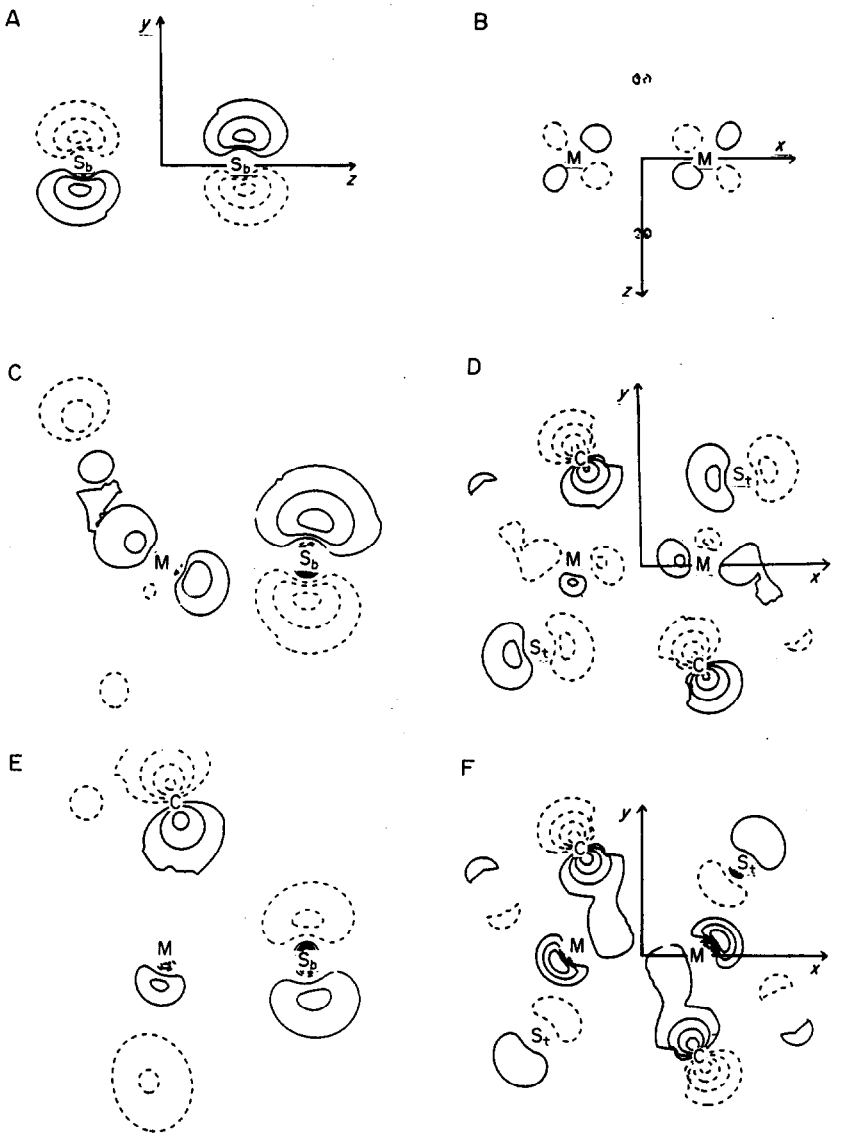

Fig. 3. Wave function contour plots for $[CpMoS(\mu\text{-}S)]_2$: (A) $9b_g$, yz plane; (B) $9b_g$, xz plane; (C) $9b_g$, MoS_b plane; (D) $16b_u$, xy plane; (E) $16b_u$, MoS_b plane; and (F) $17a_g$, xy plane. See Fig. 2 for coordinate system. Solid lines denote contours at values of 0.04–0.32 $e^{1/2}$ bohr$^{-3/2}$, while broken lines denote values of -0.04 to -0.32 $e^{1/2}$ bohr$^{-3/2}$. Those atoms that are in the plane are labeled as follows: M = molybdenum, S_b = bridging sulfur, S_t = terminal sulfur, and C = carbon.

$10a_u$ molecular orbitals are all primarily Mo in character with significant S_t content. In addition, there is some S_b character in the $17b_u$ and $10b_g$ orbitals. The Mo–S_t interaction is antibonding in all four molecular orbitals with the strongest interaction in the $17b_u$ and $18a_g$ orbitals. The Mo–S_b interactions are essentially nonbonding in these four unoccupied orbitals.

The eigenvalues can be used to predict unrelaxed transition state energies by taking the difference between occupied and unoccupied energy levels (see Table 4).* Assignments are then made by comparing the overall experimental pattern with that predicted by the SCF-Xα-SW calculation. Figure 5 compares the overall pattern of experimental optical transition energies to the calculated transition energies. Only

* Unrelaxed transition-state energies do not take into account electron–electron repulsion effects. In order to account for the effects of orbital relaxation, a relaxed transition-state procedure was developed by Slater (see Ref. 6, pp. 49–53). However, as Johnson and Slater have pointed out, close agreement between the unrelaxed and relaxed transition-state energies is expected where the perturbation to the potential energy is small when optical transitions occur between valence orbitals and empty orbitals lying immediately above (see Ref. 7, pp. 168–169, and references therein).

Table 4. Calculated and experimental[a] electronic transition energies[b] for $[CpMoS(\mu\text{-}S)]_2$

Transition	A/F[c]	Primary transition type[d]	Transition energy		
				Experimental	
			Calculated[e]	**Ia**	**Ib**

[a] Reference 5 and A. Bruce and D. Tyler, unpublished results.
[b] Energies in eV except for those in parentheses which are in nm.
[c] Symmetry allowed or forbidden.
[d] Shown only for allowed transitions. See text for discussion of how transition type assignments are made.
[e] Unrelaxed transition-state calculation.

symmetry-allowed transitions are considered. The top two lines show the experimental transition energeis for **Ia** and **Ib** respectively, and the bottom line shows the calculated transition energies for **Ic**. It is apparent that the SCF-Xα-SW calculated transition energies are red shifted with respect to the experimental values, but the pattern of the transitions (i.e. the energy spacings between the peaks) predicted by the calculation is in excellent agreement with the experimental pattern.*

The two lowest energy allowed electronic transitions are predicted to be the $17a_g \rightarrow 17b_u$ ($^1A_g \rightarrow {}^1B_u$) and $16b_u \rightarrow 10b_g$ ($^1A_g \rightarrow {}^1A_u$) transitions, respectively. When **Ia** and **Ib** are irradiated into their two low-energy absorption bands ($\lambda > 700$ nm, 1.8 eV), there is no apparent photochemistry. The next transition is predicted to be composed of the following group of transitions: $17a_g \rightarrow 10a_u$ ($^1A_g \rightarrow {}^1A_u$), $16b_u \rightarrow 18a_g$ ($^1A_g \rightarrow {}^1B_u$) and $9b_g \rightarrow 17b_u$ ($^1A_g \rightarrow {}^1A_u$). The isomerization occurs when the complexes are irradiated into this absorption band ($\lambda \approx 600$ nm, 2.1 eV).

The transitions at higher energy ($\lambda < 500$ nm, 2.5 eV) are predicted to be composed of two sets of transitions: a set of three transitions at ≈500 nm (2.5 eV), $9a_u \rightarrow 10b_g$ ($^1A_g \rightarrow {}^1B_u$), $9b_g \rightarrow 10a_u$ ($^1A_g \rightarrow {}^1B_g$) and $17a_g \rightarrow 18b_u$ ($^1A_g \rightarrow {}^1B_u$); and another set of two transitions at ≈445 nm (2.8 eV), $9a_u \rightarrow 18a_g$ ($^1A_g \rightarrow {}^1A_u$) and $16a_g \rightarrow 17b_u$ ($^1A_g \rightarrow {}^1B_u$). Isomerization also occurs when the complex is irradiated in these absorption bands.

* It should be noted that the procedure as outlined in Experimental will generate one "best" calculated answer, i.e. one that optimizes the viral coefficient at one while holding the ratio of the overlapping sphere sizes fixed. When making electronic spectral assignments, there are other approaches which can be used to fit the calculation to experiment, including the use of variable overlapping sphere sizes.

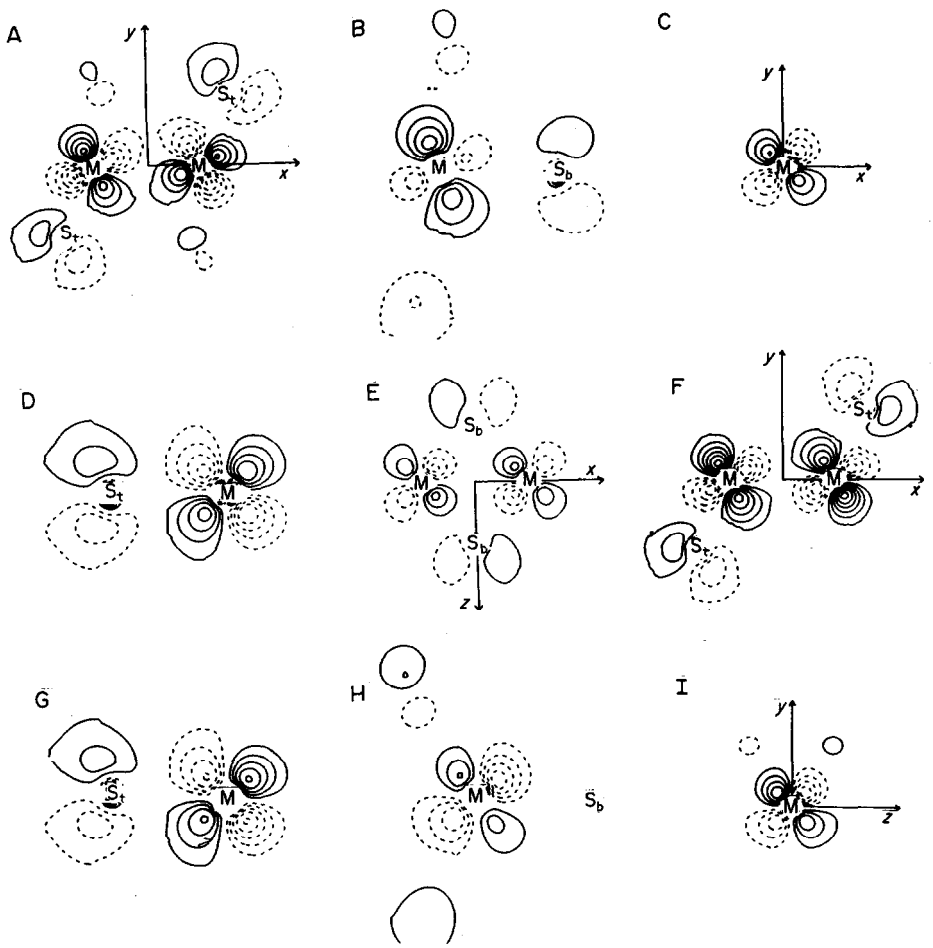

Fig. 4. Wave function contour plots for $[CpMoS(\mu\text{-}S)]_2$: (A) $17b_u$, xy plane; (B) $17b_u$, MoS_b plane; (C) $10b_g$, yz plane; (D) $10b_g$, MoS_t plane; (E) $10b_g$, xz plane; (F) $18a_g$, xy plane; (G) $10a_u$, MoS_t plane; (H) $10a_u$, MoS_b plane; and (I) $10a_u$, yz plane. See Fig. 2 for coordinate system. Solid lines denote contours at values of 0.04–0.32 $e^{1/2}$ bohr$^{-3/2}$, while broken lines denote values of -0.04 to -0.32 $e^{1/2}$ bohr$^{-3/2}$. Those atoms that are in the plane are labeled as follows: M = molybdenum, S_b = bridging sulfur, S_t = terminal sulfur, and C = carbon.

Because **Ic** is a dinuclear complex the orbitals on the two metals can interact with each other to form σ, π, and δ bonding and antibonding orbitals. The Mo–Mo interactions are indicated on the right-hand side of Table 3. Of special interest is the $16a_g$ orbital which is the Mo–Mo σ-bonding interaction, and the $19b_u$ orbital which is the antibonding interaction.

DISCUSSION

Lack of photofragmentation

When **Ic** is irradiated, there is no photofragmentation. We explain the lack of Mo–Cp cleavage by reasoning that no Mo–Cp antibonding orbitals are populated in the excited states for $\lambda > 300$ nm (see Fig. 4). Using the same logic, the Mo—S_b bonds are also not expected to be broken. However, low-energy transitions are predicted to weaken the Mo—S_t π-bond by a population of molecular orbitals which show Mo–S_t antibonding interactions. This is especially true for excitations that populate the $17b_u$ or $18a_g$ orbital. Note, however, that while cleavage of the Mo—S_t π-bond may occur, cleavage of the Mo—S_t σ-bond is very unlikely. The calculation shows that the Mo—S_t σ-bond is low in energy (≈ -10.8 eV vs -6.2 eV for the HOMO) and therefore transitions originating in the S_t–Mo σ-orbital, or terminating in the S_t–Mo σ^*-orbital (> -2.7 eV) will not occur at any of the wavelengths used in our experiments. Thus, even if the Mo—S_t π-bond breaks completely, the Mo—S_t σ-bond will remain intact and prevent fragmentation of the complex. The calculation also demonstrates why no photochemistry involving the Mo—Mo bond is observed. As the right-hand side of Table 3 shows, the $16a_g$

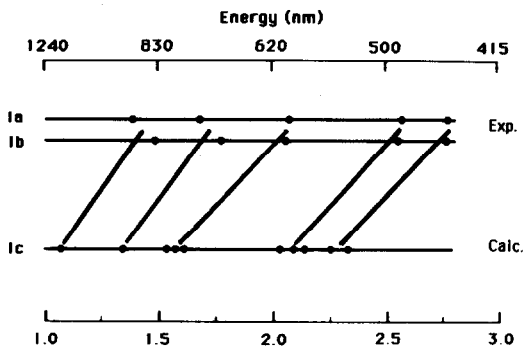

Fig. 5. SCF-Xα-SW transition state vs experimental transition energies for $[CpMoS(\mu\text{-}S)]_2$. **(Ia)** $[(\eta^5\text{-}(CH_3)_5C_5)MoS(\mu\text{-}S)]_2$, experimental transition energies;[5] **(Ib)** $[(\eta^5\text{-}(CH_3)C_5H_4)MoS(\mu\text{-}S)]_2$, experimental transition energies;[5] and **(Ic)** $[(\eta^5\text{-}C_5H_5)MoS(\mu\text{-}S)]_2$, unrelaxed SCF-Xα-SW transition state calculation. Only allowed transitions are shown.

molecular orbital is primarily Mo–Mo bonding.* Because of its low energy, it is not expected to be depopulated upon irradiation with $\lambda > 600$ nm (2.1 eV). The $19b_u$ molecular orbital which is Mo–Mo σ^* is also not involved in any low-energy excitations ($\lambda > 600$ nm). Thus, cleavage of the metal–metal bond is not expected. In conclusion, the results of the SCF-Xα-SW calculation are consistent with the experimental results with regard to the lack of photofragmentation.

Photoisomerization

Analysis of the calculations for **Ic** in conjunction with the observed photochemistry leads to the conclusion that the most significant aspect of the electronic transitions responsible for the photochemistry is the population of an Mo–S_t π^* molecular orbital. As mentioned above, the $17b_u$ and $18a_g$ orbitals show the strongest Mo–S_t π^* interaction. In order to show this interaction more clearly, the low-density contour plots for these two orbitals are shown in Fig. 6. The $17b_u$ orbital is populated in the lowest-energy transition but no photochemistry is observed by irradiating into this weak ($\varepsilon \sim 50$), low energy ($\lambda \approx 900$ nm, 1.4 eV) absorption band. The absence of photochemistry demonstrates that occupation of an Mo–S_t π^*-orbital is not sufficient to photoisomerize the complex. As explained below, the excited state must also have considerable $S_t \rightarrow$ Mo charge-transfer character. Note that the next to lowest energy transition $[16b_u \rightarrow 10b_g\ (^1A_g \rightarrow {}^1B_u)]$ is also photochemically inactive; no Mo–S_t π^*-orbital is populated in this transition.

Recall that the photochemical isomerization occurs when complex **I** is irradiated at wavelengths shorter than 600 nm. Two of the three transitions which are predicted to occur at 600 nm (≈ 50 kcal mol^{-1}) involve the $17b_u$ and $18a_g$ orbitals; these are $16b_u \rightarrow 18a_g$ and $9b_g \rightarrow 17b_u$. Each of these transitions is an LMCT transition (see Table 4), and both result in a formal reduction of the molybdenum, oxidation of the ligand (S_t in the $16b_u \rightarrow 18a_g$ and S_b in the $9b_g \rightarrow 17b_u$), and weakening of the Mo–S_t π-bond. The photoisomerization of **I** to **II** is logical when viewed as a redox process involving cleavage of the Mo–S_t π-bond. The molybdenum is reduced from oxidation state +5 to +4 and the terminal sulfides (S^{2-}) are oxidized to a disulfide (S_2^{2-}). We suggest that the $16b_u \rightarrow 18a_g$ transition is responsible for the observed photochemistry because the $16b_u$ orbital has S_t character. [The $9b_g$ orbital is assigned as primarily S_b in character (see Table 4 and Fig. 3)]. It is logical to propose that the two oxidized S_t ligands couple to form the bridging S_2^{2-} ligand. This coupling may occur by twisting the two halves of the molecule so as to bring the S_t ligands together.

Alternatively, we can speculate that the LMCT excitation initiates a coupling of the oxidized sulfido (S·) ligand on one Mo atom with the other Mo atom. The resulting $CpMo(\mu\text{-}S)_4MoCp$ complex would then rearrange to give **II**. Hoffmann *et al.*[19] used theoretical calculations in an analogous system to analyze the interconversion of doubly-bridged and quadruply-bridged structures of $Cp_2M_2(CO)_4$. They showed that the Cp—M—M angle in the doubly-bridged structure can open up to accommodate two more bridging CO ligands to form the quadruply-bridged structure with very little change in energy. The isomerization of **I** to **II** is expected to be a more facile process than the interconversion of doubly-bridged to quadruply-bridged isomers of $Cp_2M_2(CO)_4$. There is less constraint on the geometry in the sulfur-bridged structure, **II**, because the sulfur atoms need not be kept from interacting, i.e. sulfur–sulfur bonds readily form.

In summary, the SCF-Xα-SW calculation predicts that the photoisomerization of **I** to **II** is initiated by population of the Mo–S_t π^* molecular orbital. The driving force for the isomerization may be due to the redox nature of the LMCT excited state.

Acknowledgements—We thank Procter & Gamble Co. for a University Exploratory Research Grant and American Cyanamid for a fellowship to A. E. B.

* Enemark *et al.* performed extended Hückel and Fenske–Hall molecular orbital calculations on three isomers of $Mo_2S_4(dme)_2^{2-}$, one of which has the anti-Mo_2S_4 core as in complex **I**. They found that the HOMO orbital in each isomer was the Mo–Mo σ-bonding orbital.[19]

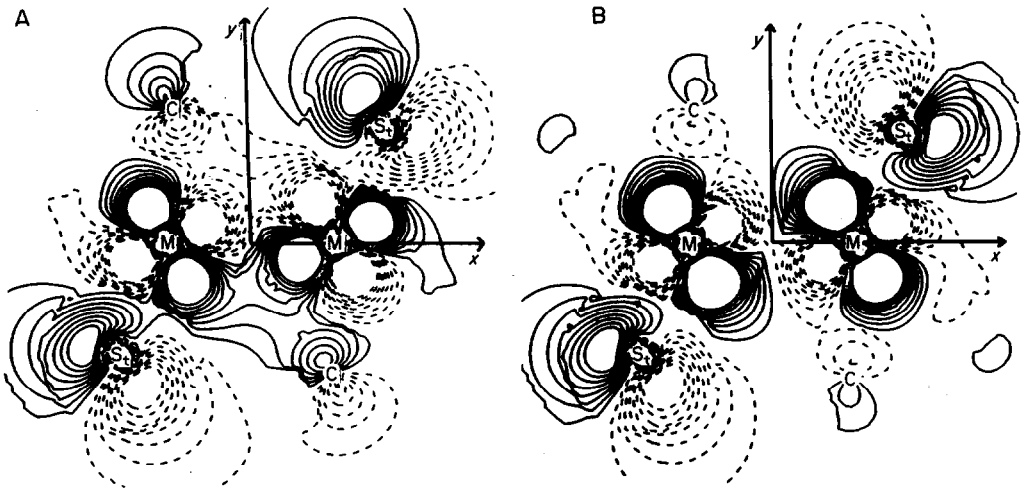

Fig. 6. Wave function contour plot for $[CpMoS(\mu\text{-}S)]_2$: (A) $17b_u$, xy plane; and (B) $18a_g$, xy plane. See Fig. 2 for coordinate system. Solid lines denote contours at values of 0.01–0.08 $e^{1/2}$ bohr$^{-3/2}$, while broken lines denote values of -0.01 to -0.08 $e^{1/2}$ bohr$^{-3/2}$. Those atoms that are in the plane are labeled as follows: M = molybdenum, S_t = terminal sulfur, and C = carbon.

SYNTHESIS AND CHARACTERIZATION OF TRIORGANOANTIMONY(V) COMPLEXES WITH BIDENTATE LIGANDS

NARENDRA K. JHA* and DHIRENDRA M. JOSHI

Department of Chemistry, Indian Institute of Technology, New Delhi 110 016, India

(*Received* 9 *July* 1984; *accepted after revision* 29 *June* 1985)

Abstract—Monochelated organoantimony(V) complexes of the type $R_3Sb(OMe)L$, where R = Me or Ph, and L is the anion of acetylacetone, 8-hydroxyquinoline, salicylaldehyde, *o*-hydroxyacetophenone or 2-hydroxy-1-naphthaldehyde have been obtained from triorganoantimony(V) dibromide and the sodium derivative of the ligands in a benzene–methanol mixture. Molecular weight determination in benzene reveals the monomeric nature of these complexes. IR and NMR data suggest that L acts as a bidentate ligand giving an octahedral environment for the antimony atom.

Triorganoantimony(V) complexes with potentially chelating organic ligands are interesting from the synthetic and structural points of view. Some such complexes have been reported in the literature containing bi- and tridentate ligands.[1–7] We have also reported such complexes containing tetradentate ligands.[8] In the complexes of the type R_3SbXL, where R = alkyl or aryl group, X = simple anion like Cl^-, Br^- or OH^-, and L = anion of bidentate ligand, the antimony atom has a choice between penta- and hexa-coordination, depending upon the monodentate or bidentate nature of the ligand L. Recently hexa-coordination of antimony has been observed in a number of complexes having a β-diketone as chelating ligand.[5] For some of the complexes a change in geometry has also been reported, e.g. $Ph_3SbCl(ox)$, ox = 8-hydroxyquinolinate ion, has a trigonal bipyramidal geometry in solution but is octahedral in the solid state.[1]

Gopinathan and coworkers, without assigning any structure, have reported replacement of both the bromine atoms of Ph_3SbBr_2 with monobasic bidentate ligands (HL).[9] Complexes formed are of the type Ph_3SbL_2. If L^- is behaving as a bidentate ligand, the coordination number of antimony in these complexes ought to be seven. Other workers have also used similar bidentate ligands but they have not been able to get Ph_3SbL_2 but found that only one X was replaced by L even though the Ph_3SbBr_2 : ligand ratio was 1 : 2.[5] It is because of these conflicting reports that we took up the present investigation. The potential bidentate ligands used in this investigation are the anions of acetylacetone (acac), 8-hydroxyquinoline (ox), salicylaldehyde (sal), *o*-hydroxyacetophenone (hap) and 2-hydroxy-1-naphthaldehyde (hna).

RESULTS AND DISCUSSION

The complexes have been prepared by the treatment of R_3SbBr_2 (R = Me or Ph) with the sodium salt of the ligand in 1 : 3 molar ratio in a dry benzene–methanol mixture:

$$R_3SbBr_2 + 2NaL \xrightarrow{\text{benzene + methanol}} R_3Sb(OMe)L + 2NaBr.$$

All the complexes are white in colour, except for the ox complexes, which are yellow. $Me_3Sb(OMe)(acac)$ was obtained as a brown coloured viscous liquid which is highly sensitive to moisture. All the complexes were recrystallised either from a benzene–hexane or a benzene–petroleum ether (b.p. 40–60°C) mixture. Physical and analytical data of the complexes prepared are given in Table 1. Molecular weight determination of the complexes soluble in benzene show that they are non-dissociating monomers in benzene.

[a] Decomposed.

IR spectra

The main IR frequencies of the ligands and their complexes are given in Table 2 with their assignment.

A broad band in the region 2800–2700 cm^{-1} in the ligands, which may be assigned to the intramolecularly hydrogen bonded OH[10] is not observed in the IR spectra of the complexes, indicating Sb—O bond formation.

The absence of a free carbonyl band at 1620 cm^{-1} and the presence of a ν(C···O) absorption band at 1565–1590 cm^{-1} in the IR spectrum of $Ph_3Sb(OMe)(acac)$ suggests that the ligand moiety is bonded to the antimony atom through the carbonyl oxygen.[2,4]

Similar shifts in the ν(C···O) are observed in the other complexes, except for those of ox (Table 2). In the IR spectrum of $Ph_3Sb(OMe)(ox)$ the presence of two bands at 1605 and 1575 cm^{-1}, in place of only one band at 1590 cm^{-1} attributed to ν(C=N)[11] in the ligand, indicates coordination of nitrogen with the antimony. This is further confirmed by the

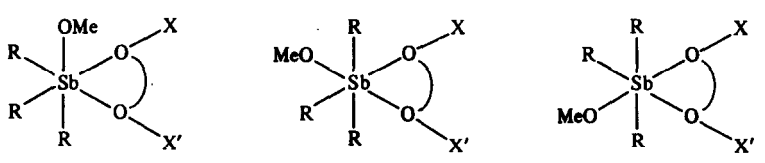
presence of a band at 270 cm^{-1} which is assigned to the ν(Sb—N).[12] A sharp band at $\sim$1070 cm^{-1} in all the complexes might be due to the Sb—OMe streching mode.[4]

A band at $\sim$400 cm^{-1} is assigned to the Sb—O stretching frequency in all the complexes.[4,13]

PMR spectra

PMR spectra of all the complexes (Table 3) recorded in $CDCl_3$ or DMSO-d_6 do not show the presence of hydroxyl protons originally present in the free ligands in the hydrogen-bonded state. This indicates the replacement of hydroxyl protons by antimony, thus confirming Sb—O bond formation.

The PMR spectrum of $Ph_3Sb(OMe)(acac)$ in $CDCl_3$ at room temperature showed a quartet (δ 7.56–7.47 ppm) due to the *ortho*-protons of three equivalent phenyl groups, a triplet (δ 7.30–7.24 ppm) due to the *meta*- and *para*-protons of the phenyl group, a sharp singlet each for methine (δ 5.21 ppm), methoxy (δ 2.14 ppm) and methyl (δ 1.80 ppm) protons. Integrated intensities due to the phenyl, methine, methoxy and methyl protons were in a 15 : 1 : 3 : 6 ratio, confirming the coordination of only one ligand moiety with the antimony atom in the complex formation.



In the PMR spectra of $R_3Sb(OMe)(sal)$ and $R_3Sb(hna)$ a downfield shift of the aldehydic proton on coordination confirms strong interaction of antimony atom with the carbonyl oxygen of the ligand ring. Such a downfield shift was also observed for the $COCH_3$ protons in $R_3Sb(OMe)(hap)$, although the shift is smaller than expected, because the protons are attached to an adjacent carbon atom in this case.

Tentatively an octahedral structure is proposed for all the complexes. Such complexes having bidentate ligands may exist in three possible configurations as shown in the Fig. 1.

For $Ph_3Sb(OMe)(acac)$ (Fig. 1; R = Ph, and X = X′ = Me; structures **ii** and **iii** are the same) only two isomers are possible. Structure **i** will give rise to single peaks due to the methyl and methine protons of the acac group whereas two peaks are expected for the methyl protons of structure **ii** or **iii**. Since only single peaks were observed, structure **i** is suggested at first sight in which the methoxy group is *trans* to a phenyl group. However, at room temperature the possibility of a configuration in which the methoxy group is *cis* to a phenyl group (structures **ii** and **iii**) cannot be ruled out completely. Since structures **ii** and **iii** will also give single peaks if the molecule has a stereochemically non-rigid configuration. An X-ray single crystal study would be required for assignment of an unambiguous structure for these molecules.

The single peak for the methyl group may also arise if the acac acts as a labile unidentate ligand, but the IR spectrum indicates that acac is bidentate.

For complexes with sal, hap and hna three

i **ii** **iii**

Fig. 1. *fac*-R (**i**), *mer*-R (**ii**), and *mer*-R (**iii**).

geometrical isomers are possible (Fig. 1, $X \neq X'$). Since singlets were observed for aldehydic protons in the complexes $R_3Sb(OMe)(sal)$ and $R_3Sb(OMe)(hna)$ and for methyl protons of the $COCH_3$ group in $R_3Sb(OMe)(hap)$ structure **i** is again suggested in the first instance in this case as well. However, structures **ii** and **iii** cannot be ruled out for the same reasons as discussed for the acac complex.

In the complex $Ph_3Sb(OMe)(ox)$ the downfield shift of the aromatic protons of the ox group to δ 8.86–6.71 is attributed to strong interaction of the metal atom with the nitrogen of the ligand ring in the complex.

The ^{13}C NMR spectra of acetylacetone (acacH) and the complex $Ph_3Sb(OMe)(acac)$ were also recorded. The ^{13}C signals of acacH agreed with those reported in the literature.[14] In acacH different signals were obtained due to $\diagdown C{=}O$ (201 ppm) and $\diagdown C{-}OH$ (190 ppm), but in the complex only one signal was obtained at 191 ppm. Similarly two signals due to the methyl groups at 30 and 22 ppm for acacH were replaced by only one signal at 28 ppm in the complex. Further a slight shift was also observed in the $-CH\diagdown$ signal of the ligand which changes from 99 to 102 ppm on complexation. Aromatic ^{13}C signals were observed from 151 to 127 ppm in the complex. A signal at 47 ppm in the complex is assigned to the methoxo carbon. The complex $Ph_3Sb(OMe)(acac)$ has also been reported by Jain *et al.*[5] Their preparative route was slightly different from ours. PMR data for the complex indicates two peaks for methine, three for methoxy and three for methyl protons. On this basis they have suggested both of the geometrical isomeric forms (*fac*-Ph and *mer*-Ph) at room temperature. In our case, however, we believe that we have obtained only the *fac*-Ph form of this complex.

EXPERIMENTAL

Ph_3SbBr_2[15] and Me_3SbBr_2[16] were prepared and purified by the methods given in the literature. Ligands and solvents were purified and dried before use. All the reactions were performed in an atmosphere of dry nitrogen.

Antimony was determined volumetrically by a reported method.[17] Carbon, hydrogen and nitrogen were analysed in semi-micro scale at CDRI, Lucknow. Molecular weights of the complexes soluble in benzene were determined cryoscopically using a Beckmann thermometer of $\pm 0.01°C$ accuracy.

IR spectra in the range 4000–400 cm^{-1} were recorded in KBr pellets using an SP-1200 spectrophotometer. The far-IR spectra of some of the complexes were recorded in the range 500–100 cm^{-1} on a Fourier transform spectrophotometer, Polytech FIR 30. NMR spectra were recorded in $CDCl_3$ solution on a JEOL JNM 100 NMR spectrometer using TMS as an internal standard.

Preparation

Methanolic solution of the sodium salt of the ligand (15 mmol in 50 cm^3) (prepared from 15 mmol each of sodium and ligand in dry methanol) was added to the benzene solution of triorganoantimony(V) dibromide (5 mmol in 50 cm^3). The mixture was refluxed for 4 h. The volume of the solvent was reduced to 50 cm^3 by distilling under reduced pressure. The sodium bromide and unreacted sodium salt of the ligand were filtered. The benzene–methanol mixture was removed from this filtrate under reduced pressure. Recrystallisation from a benzene–hexane or a benzene–petroleum ether (b.p. 40–60°C) mixture gave crystalline products. The yields of the various complexes are reported in the Table 1.

Abstract—The nature of the 8-quinolinato ligand in various forms has been examined by ^{15}N, ^{13}C and ^{119}Sn NMR spectroscopy, with evidence also from electronic spectroscopy. These forms include 8-quinolinol (HQ), 8-quinolinate, the 8-hydroxyquinolinium ion, *O*- and *N*-methyl derivatives, 8-methoxyquinoline (MeQ), the zwitterionic *N*-methylquinolinium-8-olate and the *N*-methylquinolinium ion, and the chelating ligand in organotin(IV) complexes. The ^{15}N shift from MeQ to HQ affords a measure of the intramolecular hydrogen bonding in HQ. The ^{15}N shifts and $^{2}J(^{15}N^{1}H)$ couplings afford criteria of chelation, and the *O*- and *N*-methyl compounds provide useful reference points for its assessment. Evidence for chelation is demonstrated in three groups of compounds, $[SnR_2Q_2]$ (R = Me, Et, Bu^n, Oct^n or Ph), $[SnR_3Q]$ (R = Me, Et, Bu^n or Ph) and $[SnR_2ClQ]$ (R = Me, Et, Bu^n or Oct^n), the ^{15}N and ^{119}Sn shielding increasing from the $[SnR_3Q]$ to the $[SnR_2Q_2]$ compounds.

8-Quinolinol (HQ or oxine) coordinates to a large number of metal ions. It has long been used as an analytical and sequestering agent, and as an "unnatural" chelate it is also a bactericide and fungicide.[1] The molecule is particularly versatile because of its amphoteric, tautomeric, and zwitterionic capabilities, shown in Scheme 1. It can also coordinate in monodentate or bidentate fashion. Both possibilities arise in organoderivatives of metals such as tin or antimony[2] which form strong bonds to oxygen and weaker bonds to nitrogen, and can expand their coordination sphere with electronegative substituents and with chelating ligands such as 8-quinolinol which have a small bite. Various physical methods have been used to indicate the mode of coordination, and differing results reported which may reflect the differing conditions appropriate to the method. The observed degree of chelation may decrease from the solid state, monitored by X-ray crystallography or Mössbauer or IR spectroscopy, to concentrated solutions as used to increase NMR sensitivity, and decrease further in the dilute solutions studied by UV spectroscopy, particularly if the solvent competes with the metal in bonding or hydrogen-bonding to nitrogen. Intermolecular association is found in many tin compounds but various measurements have shown the 8-quinolinates to be monomolecular in solution and in the solid state.

Nitrogen NMR spectroscopy has obvious potential[3,4] for detecting the chelation, or dynamic

Scheme 1.

equilibrium, but poses technical problems, such as quadrupolar broadening for the abundant nucleus ^{14}N, particularly for uncoordinated nitrogen (carrying a lone pair of electrons) and larger molecules. The spin-$\frac{1}{2}$ nucleus ^{15}N has a low natural abundance (0.36%) and relaxation is slow in the absence of nearby protons. Both ^{14}N and ^{15}N have relatively low NMR sensitivity, and ^{15}N has a negative magnetogyric ratio and nuclear Overhauser effect. In the absence of inexpensive routes to ^{15}N-enriched 8-quinolinol we have measured ^{15}N spectra in natural abundance in saturated solutions in a wide-bore spectrometer at 4.228 T, normally with added $[Cr(pd)_3]$ as relaxation reagent and without proton decoupling. A further problem in the NMR study of 8-quinolinates is their limited solubility in many solvents, which limited the range we could measure.

A useful criterion of chelation of 8-quinolinol is the $^2J(^{15}N^1H)$ coupling, which decreases sharply on coordination or protonation of the nitrogen, and so is diagnostic of chelation on the time-scale given by the coupling constant. On this score the organotin 8-quinolinates that we have studied appear to contain the chelating ligand whereas the organoantimony compounds[2] appear to contain the monodentate and some bidentate ligand, conclusions which we could check against the evidence from ^{13}C, ^{119}Sn and UV spectroscopy. A further criterion is the chemical shift. Protonation of aza-arenes, which removes the long-wavelength $n_N \rightarrow \pi^*$ band from the electronic spectrum, is well-known to increase the nitrogen shielding by 100 ppm or more, by removal of this low-energy paramagnetic contribution. Hydrogen-bonding acts in the same sense to a lesser degree, by stabilising the ground state relative to the excited state, the shielding increasing as the $n_N \rightarrow \pi^*$ band moves to shorter wavelengths.[3,5]

The difference in shielding from the free ligand to the complex can therefore be diagnostic of the mode of coordination. These results we found puzzling: the ^{15}N coordination shifts ($\Delta\delta$) relative to 8-quinolinol in $CDCl_3$ were only -5 to -35 ppm for di- and tri-organotin complexes of the apparently chelating ligand, and formed a continuous range with the smaller (or positive) coordination shifts in the related organoantimony complexes.[2] This raised the question of what should be taken as the "free ligand" for this purpose. In 8-quinolinol strong intramolecular hydrogen-bonding persists even in strongly hydrogen-bonding solvents or basic solvents such as DMSO,[6] and such hydrogen-bonding can be taken to model the chelation of a metal ion.

We therefore undertook ^{15}N and ^{13}C and further UV spectroscopic studies of different species in Scheme 1 in which selective methylation models the *O*- or *N*-coordination separately. This has the added interest of the comparison of the chemical shifts with the electronic absorption of the changing chromo-

phore, including the coordinated ligand, for which there is additional information from ^{119}Sn NMR and other physical methods. Whereas the electronic absorption (which also affords a criterion of chelation) is a property of the chromophore as a whole, the NMR method can monitor the changes at each atom.

RESULTS AND DISCUSSION

Metamorphoses of 8-quinolinol

Table 1 shows that the largest coupling constant, $^2J(^{15}N^1H)$, is nearly 11 Hz for pyridine or quinoline[7] and slightly smaller in 8-quinolinol. It decreases to 3 Hz or less in pyridinium or quinolinium ion[7] and was not resolved by us in the protonated, *N*-methylated or chelated forms of 8-quinolinol. The large increase in reduced two-bond coupling constant when one of the atoms carries a *cis* lone pair is general, and can be traced to the lone pair's Fermi contact contribution, which is large because of the high *s* character and small energy denominator;[8] any decrease from pyridine or quinoline to 8-quinolinol could then be linked with the internal hydrogen bonding.

The increase in ^{15}N shielding on protonation or *N*-methylation of 8-quinolinol (as measured in $CDCl_3$ solution) is somewhat smaller than for pyridine or quinoline. That the decrement can be related to the internal hydrogen bonding in 8-quinolinol is suggested by the decrease in nitrogen shielding, by 11.7 ppm, on *O*-methylation. In pyridine, for comparison, the nitrogen is shielded by 10 ppm in $CHCl_3$ and 20 ppm in aqueous solution relative to solution in CCl_4.[5] We have therefore used

[a] HQ is 8-quinolinol, MeQ is 8-methoxyquinoline, (NMe)Q is *N*-methylquinolium-8-olate (cf. Scheme 1).

[b] Spectra were run at 293 K. ^{15}N shifts are referenced to neat $CH_3^{15}NO_2$, high frequency positive, and corrected for differences in susceptiblity due to the addition of $[Cr(pd)_3]$ to promote relaxation. Digital resolution is 3 Hz in our measurements; unresolved $^{2,3}J(^{15}NH)$ coupling constants are therefore <3 Hz.

[c] Longest-wavelength bands; concentration typically 10^{-4} M.

[d] $\Delta\delta$ is the coordination shift from the free base HQ in $CDCl_3$.

[e] Insufficiently soluble.

[f] NMR.[7]

[g] In tfa.

the *O*-methylated compound as a reference for nitrogen coordination shifts in the 8-quinolinates in Table 2. We were unable to observe a signal for 8-quinolinol in water, in which the solubility is low.

The nitrogen-shielding sequence has no simple relationship with the longest wavelength of absorption given in Table 1. The $n_N \rightarrow \pi^*$ band is observable for pyridine, but for more extended π systems as in quinoline the stronger $\pi \rightarrow \pi^*$ bands move to longer wavelengths and obscure the $n_N \rightarrow \pi^*$ band.[9] With incorporation of oxygen into the delocalised system in the quinonoid forms the $\pi \rightarrow \pi^*$ bands move into the visible region, as in the 8-quinolinol zwitterion present in tautomeric equilibrium in water (Scheme 1). These bands are blue-shifted by hydrogen-bonding solvents or acids which protonate oxygen and nitrogen, so to that extent blue-shifting may correlate with increased shielding of nitrogen, and carbon adjacent to oxygen or nitrogen. Although these $\pi \rightarrow \pi^*$ excitations are magnetic dipole forbidden,[3] the LUMOs are of course related to those of $n \rightarrow \pi^*$ excitations in the same system.

Moeller[10] and Sone[11] noted that the absorption near 310 nm of 8-quinolinol in neutral solution shifted to 350–360 nm in acid or alkaline solution, and to 370–430 nm or so in chelates. The longer-wavelength absorption was therefore proposed as a criterion of chelation; according to Sone,[11] the longer the wavelength of absorption the more stable the chelate. In fact neutral aqueous solution shows a weaker band at 430 nm due to the zwitterion, and it

[m] Broad resonance.

can be isolated as the *N*-methyl derivative, *N*-methylquinolinium-8-olate [(NMe)Q], called an "anhydro-salt"[12] or "diazoxine",[13] as it is the ether-insoluble product of reaction of diazomethane with "oxine". This zwitterion is a red solid which gives violet solutions in non-polar solvents, the long-wavelength band blue-shifting with hydrogen-bonding. Our ^{15}N NMR studies with this interesting compound were limited by the low solubility in non-polar solvents. In methanol, however, the nitrogen is deshielded relative to the 8-hydroxyquinolinium ion (H_2Q^+) in aqueous acid, consistent with lowering of the excitation energies in the zwitterion. It is shielded relative to H_2Q^+ in DMSO, a rather basic solvent.

The evidence as to the nature of the 8-quinolinol ligand that is available from the ^{13}C shifts was shown by measurements on Zn(II) and Mo(VI) chelate complexes of 4-methyl-8-quinolinol (4MQ), chosen for greater solubility, and comparisons with $4MQ^-$, 4MQH and $4MQH_2^+$.[14] Our measurements in Table 2 follow these assignments, the $4MQ^-$ shifts affording an estimate of the values for Q^-, as in Table 3. The largest spread of aromatic carbon shifts, 60 ppm, is given by the zwitterion (NMe)Q and the anions, and the next largest (55 ppm) by the zinc chelate, in which the bonding to the metal is relatively ionic. In the more covalent molybdyl and tin complexes the spread is 45 ppm or less. In the tin complexes, however, the carbon bonded to oxygen (C-8) is still relatively deshielded (though 4 ppm more

[a] All values are chemical shifts in ppm, except those in parentheses which are $^{119}Sn^{13}C$ coupling constants in Hz. The C-2–C-10 series refers to the 8-quinolinol ligand and the C-1–C-4 series to the alkyl or phenyl group.

[b] DMSO solution: similar values were reported in Ref. 14.

[c] Assignments tentative as the phenyl resonances are in the same region.

[d] Reference 21.

shielded than in the zinc complex), suggesting that the oxygen is still quite negative.

Protonation, methylation and coordination of the oxygen all increase the *ipso* carbon (C-8) shielding. They deshield the *para*-carbon (C-5), as commonly observed with electron-withdrawing substituents,[14] and also C-2, *ortho* to nitrogen. Similarly, protonation or methylation of nitrogen deshields the *para*-carbon C-4, e.g. by 4–5 ppm from 8-quinolinate to (NMe)Q, cf. 2 ppm in the zinc complex, 10 ppm on methylation of pyridine,[4] and 14 ppm in the molybdyl complex. C-4 is deshielded by 3 ppm in the organohalogenotin complexes, in which bonding to tin is relatively strong, and by about 0.5 ppm in the $[SnR_2Q_2]$ complexes and $[SnPh_3Q]$, but very slightly shielded (by 1 ppm or less) in the $[SnR_3Q]$ compounds. For C-2 and C-9 (*ortho* to nitrogen) the shielding increases from 8-quinolinate to (NMe)Q, and with protonation, or coordination of the nitrogen to tin, zinc or molybdenum, cf. increases of 3 or 7 ppm on *N*-methylation or protonation of pyridine.[4]

Evidently protonation or methylation can model the coordination of oxygen or nitrogen to a metal, in its effect on the carbon shifts. It is likely therefore that *N*-methylation can distinguish the additional effects of chelation. The carbon shifts thus provide evidence of zwitterionic character in the ligand, the more ionic the complex, and of increasing strength of chelation from the $[SnR_3Q]$ to the $[SnR_2Q_2]$ and $[SnR_2ClQ]$ complexes.

The nature of the 8-quinolinato ligand in organotin(IV) complexes

Further criteria of the coordination number in solution are available in the ^{119}Sn shift and in the $^1J(^{119}Sn^{13}C)$ couplings to the organo ligands, since the tin shielding and the reduced coupling constant both increase with coordination number. They increase also with electronegative substituents, as in the chloro complexes, and with π-delocalisation, as in the phenyltin complexes.[15–22] This is evident in Table 2, which compares ^{15}N and ^{119}Sn NMR and electronic spectral measurements for $[SnR_2Q_2]$, $[SnR_3Q]$ and $[SnR_2ClQ]$ complexes. We were unable to see an ^{15}N signal for any halogeno derivative, despite many attempts using $CDCl_3$ or CD_3OD as solvent, with and without added $[Cr(pd)_3]$. The problem is not one of solubility, as the dioctyl and dibutyl complexes in particular are highly soluble. If some kind of fluxionality is responsible, there was no evidence for this in the ^{13}C spectra, though linewidths of 50–55 Hz were observed in ^{119}Sn resonance, as against *ca* 10 Hz for the $[SnR_2Q_2]$ and $[SnR_3Q]$ compounds. Little or no concentration-dependence is observed in these spectra.

^{119}Sn shifts, but not coupling constants, have been reported for most of the compounds in Table 3.[20–23] The relatively high shielding was considered to reflect six-coordination in $[SnEt_2Q_2]$,[23] cf. the X-ray crystallographic evidence of a distorted six-coordinate structure for $[SnMe_2Q_2]$, with NSnO angles of 74° in the chelate ring.[24] Typical ranges of tin shifts have been proposed[20] for coordination numbers five (−90 to −330 ppm) and six (−125 to −515 ppm) for organotin chelates in $CHCl_3$ solution, this description being applied to the $[SnR_2Q_2]$ and $[SnR_2ClQ]$ compounds and $[SnPh_3Q]$, but not $[SnR_3Q]$ with R = alkyl. According to proposed ranges of $^1J(^{119}Sn^{13}C)$ coupling constants,[19] the $[SnR_3Q]$ compounds could be four- or five-coordinate. Mössbauer work has demonstrated five-coordinate (trigonal bipyramidal) structures in the solid state for $[SnPh_3Q]$ and $[SnR_2ClQ]$ and confirms six-coordination for $[SnR_2Q_2]$ compounds.[25] Following Bent's rule[26] (and Walsh) the electronegative substituents occupy axial positions preferentially. This gives equatorial–axial chelation of 8-quinolinate in trigonal bipyramidal structures, the small equatorial–axial angle being suited to a ligand with a small bite. Dependence of the tin shifts and $^1J(^{119}Sn^{13}C)$ coupling constants on the geometry of the coordination sphere has been pointed out,[21] with lower shielding and coupling constants for equatorial–axial chelation and equatorial and axial phenyl groups in $[SnPh_3(LL')]$ compounds, compared with all phenyls equatorial. Lower shielding is observed also for ligating carbon in phenyl groups in five-coordinate compared with four-coordinate compounds.[21]

The $[SnR_2Q_2]$ and $[SnR_2ClQ]$ compounds and $[SnPh_3Q]$ may thus be characterised as chelates in $CHCl_3$ solution, with the $[SnR_3Q]$ compounds apparently marginal. They have been described as four-coordinate, on the ^{119}Sn NMR evidence.[22] If five-coordinate, a possible explanation for low tin shielding is that this is observed when tin forms part of a five-membered ring. Tin is deshielded by 50 ppm in $[SnMe_2C_4H_8]$ compared to $[SnMe_2Et_2]$,[27] and by 130 ppm in $SnMe_2Q_2]$ compared to $[SnMe_2(pd)_2]$[20] (the shielding being enhanced in a six-membered ring).[27] Comparable ^{31}P deshielding is observed in five-membered rings formed by chelating diphosphines, relative to equivalent monophosphine complexes.

On Moeller's criterion[10] all three compound types in Table 2 contain chelating 8-quinolinate, since all show the longer-wavelength absorption in several

solvents.[28] An earlier report of four-coordination in $[SnPh_3Q]$ was explained in terms of displacement of nitrogen by a polar solvent, in aqueous alcohol solution.[29] This criterion does not however exclude the presence of some monodentate ligand (depending on the absorptivity observed).

Proton NMR criteria of the denticity have been formulated. On the evidence of the H-2 shifts, the 8-quinolinato ligand was considered to be monodentate in CH_2Cl_2 solutions of $[SnR_2Q_2]$ and $[SnR_3Q]$ compounds. This proton, like C-2, is deshielded (with respect to 8-methoxyquinoline in the same solvent) when the interaction with nitrogen is strong, as in the halogeno derivatives, though shielded when it is weak. The shielding of H-4 (like C-4) decreases with increasing interaction.[6,30] Another proposed criterion is the benzene-induced shift of H-2 of the 8-quinolinate ligand. Such shifts (in benzene relative to a chloro solvent) are to lower frequency near positively charged sites, and vice versa. The 2-proton shows a large shift of this type (0.5–0.7 ppm) in the chelating or protonated ligand, compared with a small shift (0–0.3 ppm) in the free or *O*-methylated ligand. $[SnMe_3Q]$ passes this test of chelation.[31]

The last word for the present remains with the ^{15}N NMR evidence so far obtained. The singlet ^{15}N resonance observed for the $[SnR_2Q_2]$ and $[SnR_3Q]$ compounds alike is consistent with chelation, or perhaps with exchange involving a proportion of the monodentate ligand. Any such exchange, however, must be very fast, since no signs were observed in the ^{13}C or ^{119}Sn spectra, nor in the proton spectrum at 400 MHz of $[SnMe_3Q]$ at $-85°C$ in CH_2Cl_2 solution. The exchange would then be expected to average the $^2J(^{15}N^1H)$ couplings for ligating and non-ligating nitrogen as well as the nitrogen shifts.

As to the chemical shifts, few measurements on compounds containing Sn—N bonds are available for comparison. In stannylamines[32] the tin is relatively deshielded but the nitrogen highly shielded, as in other amines; in stannatranes both the tin (bound to three oxygens) and the (amino) nitrogen are highly shielded.[33]

A particularly interesting feature of Table 2 is the tendency for the ^{15}N and ^{119}Sn shielding to increase together, as might be expected with increase in strength of the tin–nitrogen bond, from $[SnR_3Q]$ to $[SnR_2Q_2]$. Interestingly, there is some red-shifting of the long-wavelength bands, from $[SnR_3Q]$ to $[SnR_2ClQ]$ and to the $[SnR_2Q_2]$ compounds. It seems reasonable to ascribe the rather low shielding of tin and nitrogen, particularly in the $[SnR_3Q]$ compounds, to the influence of low-lying π^* LUMOs for magnetically active excitations of the *p*-electrons in the bonds to the 8-quinolinato ligand.[3]

Conclusions

Selective methylation of oxygen or nitrogen in amphoteric compounds such as 8-quinoline can provide new insights as to the nature of the protonated, hydrogen-bonded or ligating compound, in conjunction with NMR spectroscopy, as earlier by the use of electronic spectroscopy. With the NMR method, we have three or more sensitive probes of the sites of interaction.

EXPERIMENTAL

8-Quinolinol was methylated by CH_2N_2 to give (NMe)Q as ether-insoluble and 8-methoxyquinoline as ether-soluble portions.[12,13] *N*-methylquinolinium hydrochloride was made by methylation of 8-quinoline with methyl iodide, followed by anion exchange. The organotin(IV) 8-quinolinates were made from the corresponding chlorides by published methods.

The ^{13}C, ^{119}Sn and ^1H spectra were measured on Bruker WH180 and WH400 and JEOL FX90Q spectrometers. The ^{15}N spectra were measured in natural abundance on 15-cm^3 samples in a Bruker WH180 spectrometer taking 25-mm tubes. The $^1J(^{119}Sn^{13}C)$ coupling constants were obtained from satellites in the ^{13}C spectra, but sensitivity was insufficient for satellites to be observed in ^{15}N resonance.

Acknowledgements—We thank Dr R. E. Lenkinski of the South Western Ontario High Field NMR Centre for high-field measurements, Mr Maurice Cooper of the Physico-Chemical Measurements Unit for ^{15}N measurements (also the S.E.R.C. for the widebore spectrometer facilities) and Dr P. J. Smith of the International Tin Research Institute for organotin(IV) chlorides. V.K.J. and B.S.S. thank the Council of Scientific and Industrial Research (New Delhi) and the Open University respectively for post-doctoral fellowships.

(*Received* 20 *May* 1985; *accepted* 10 *June* 1985)

Abstract—The extraction of Ni(II) from nitrate medium of ionic strength 2.0 mol · dm^{-3} by *n*-dodecanoic acid (HA) dissolved in toluene has been studied at 293 K. Distribution measurements of the metal ion in a wide range of pH and carboxylic acid concentration have been performed. Experimental data, treated by different graphical methods as well as numerically by the LETAGROP-DISTR program, have been explained assuming the presence in the organic phase of the species NiA_2, $NiA_2(HA)_2$, $[NiA_2(HA)_2]_2$ and $[NiA_2(HA)_2]_3$. Equilibrium constants for the different extraction reactions are given.

The extraction of metal ions by long-chain carboxylic acids has been widely investigated under a great variety of experimental conditions. Most of the early work was directed to explore industrial applications whereas less emphasis was given to equilibrium studies. Later on, many authors published detailed series of studies concerning the extraction equilibria of different metal ions with carboxylic acids, reporting the composition of the extracted species and their extraction constants.

Literature on the subject, reviewed by Fletcher and Flett,[1] Flett and Jaycock,[2] Miller[3] and Rice[4] basically agree on the existence in the organic phase of monomer–polymer equilibria between solvated metal carboxylates. In the case of Ni(II) extraction many authors agree on the existence of dimeric species, although some discrepancies concerning the solvation number of the nickel carboxylates have been found.[5–14]

In the present work the study of the extraction of Ni(II) in nitrate medium by *n*-dodecanoic acid dissolved in toluene has been undertaken as a necessary intermediate step in the interpretation of the distribution data in the system Ni(II)–LIX 63–*n*-dodecanoic acid. The object of the work was to determine the composition of the metallic extracted species as well as their extraction constants.

EXPERIMENTAL

Reagents

$Ni(NO_3)_2 \cdot 6H_2O$ (C, Erba, p.a.) was purified by recrystallization from doubly distilled water. *n*-Dodecanoic acid (Merck, p.a.) was purified twice by recrystallization from ethanol and acetone.[15] Sodium nitrate, nitric acid, sodium hydroxide and toluene (Merck, p.a.) were used as supplied.

Experimental technique

The distribution coefficient of Ni(II) was determined for several *n*-dodecanoic acid concentrations as a function of pH. Organic solutions of *n*-dodecanoic acid (HA) in the concentration range of 0.050–0.300 mol · dm^{-3} were mixed with the aqueous solutions consisted of 0.5 mmol · dm^{-3} Ni(II), 2.0 mol · dm^{-3} $NaNO_3$ and variable pH from approximately 5 to 8. The pH was measured using a

* Author to whom correspondence should be addressed.

Radiometer pHM 64 meter, fitted with a GK2322C Radiometer combined glass electrode standardized with buffer solutions of pH 4.00 and 7.00 at 293 K.

Equal volumes (10 cm^3) of organic and aqueous phases were mechanically shaken in special stoppered tubes until equilibrium was attained (less than 15 min). Nickel concentration in both phases was measured by atomic absorption spectroscopy (Perkin–Elmer 560). In order to determine the organic metal concentration, the stripping of nickel from the organic phases with 1.0 mol·dm^{-3} nitric acid was carried out.

RESULTS

Figure 1 shows the experimental results in the form log D vs pH, at several total n-dodecanoic acid concentrations. The non-linear dependence on the aqueous phase acidity seems to indicate the formation of polynuclear metallic species in the organic phase.

The extraction of Ni(II) by the carboxylic acid can be described by the following general equation:

$$j\mathrm{Ni}^{2+} + \tfrac{1}{2}(2+m)j(\mathrm{HA})_{2\,\mathrm{org}} \rightleftharpoons [\mathrm{NiA_2(HA)}_m]_{j\,\mathrm{org}} + 2j\mathrm{H}^+, \quad (1)$$

where HA represents n-dodecanoic acid, which behaves as a dimer in the organic diluent.[16]

Assuming an ideal behaviour in both phases, the stoichiometric equilibrium constant for this reaction may be written as:

$$k_{mj} = \frac{[(\mathrm{NiA_2(HA)}_m)_j]_{\mathrm{org}}[\mathrm{H}^+]^{2j}}{[\mathrm{Ni}^{2+}]^j[(\mathrm{HA})_2]_{\mathrm{org}}^{[(2+m)/2]j}}. \quad (2)$$

Considering eqn (2), the distribution coefficient of Ni(II), defined by:

$$D = C_{\mathrm{Ni,org}} \cdot C_{\mathrm{Ni,aq}}^{-1} \quad (3)$$

can be easily transformed into:

$$D = \sum_j \sum_m j k_{mj} \alpha_{\mathrm{Ni}}^{-1} [\mathrm{Ni}^{2+}]^{j-1} \times [(\mathrm{HA})_2]_{\mathrm{org}}^{[(2+m)/2]j} [\mathrm{H}^+]^{-2j}, \quad (4)$$

α_{Ni} being the side-reaction coefficient of Ni(II) in the aqueous phase due to the formation of hydroxo[17] and nitrate[18] complexes.

From eqn (4), values of the stoichiometric coefficient for the extracted species as well as their extraction constants were determined using both graphical and numerical methods.

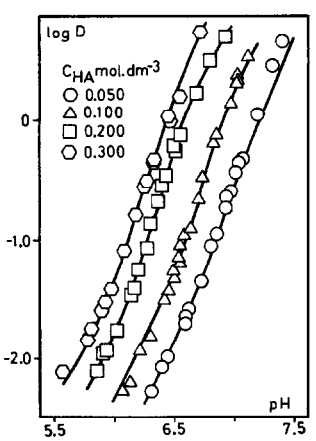

Fig. 1. Variation of the nickel distribution coefficient as a function of pH at several total n-dodecanoic acid concentrations. Continuous lines have been drawn using the proposed extraction constants.

Graphical treatment of the data

In order to estimate the degree of polymerization of the metal species extracted in the organic phase, a preliminary curve-fitting analysis assuming the formation of monomers and polymers of general composition $\mathrm{NiA_2(HA)}_x$ and $[\mathrm{NiA_2(HA)}_z]_j$, respectively, was carried out. Under this hypothesis, eqn (4) may be written as:

$$D = k_{x1}\alpha_{\mathrm{Ni}}^{-1}[(\mathrm{HA})_2]_{\mathrm{org}}^{(x+2)/2}[\mathrm{H}^+]^{-2} + jk_{zj}\alpha_{\mathrm{Ni}}^{-1} \times [\mathrm{Ni}^{2+}]^{j-1}[(\mathrm{HA})_2]_{\mathrm{org}}^{(j/2)(2+z)}[\mathrm{H}^+]^{-2j}. \quad (5)$$

Defining the new variables:

$$V = D[\mathrm{H}^+]^2\alpha_{\mathrm{Ni}}k_{x1}^{-1}[(\mathrm{HA})_2]_{\mathrm{org}}^{-(2+x)/2}, \quad (6)$$

$$W = (jk_{x1}^{-1}k_{zj}[(\mathrm{HA})_2]_{\mathrm{org}}^{-1-x/2+j(1+z/2)})^{1/(j-1)} \times [\mathrm{Ni}^{2+}][\mathrm{H}^+]^{-2}, \quad (7)$$

and the parameter:

$$i = j - 1, \quad (8)$$

eqn (5) can be rearranged to give:

$$\log V = \log (1 + W^i). \quad (9)$$

By comparison between the model functions defined by eqn (8) plotted at different i values with the experimental function $\log D + \log \alpha_{\mathrm{Ni}} - 2\mathrm{pH}$ vs $\log [\mathrm{Ni}^{2+}] + 2\mathrm{pH}$ at constant reagent concentration, values of the coefficient j were estimated. As an example of the treatment, Fig. 2 shows the fit between the experimental data at $C_{\mathrm{HA}} = 0.200$ mol·dm^{-3} with the theoretical functions. The best agreement for all the reagent concentrations was found for $i = 2$, which, according to eqn (8), indicates the extraction of a trimeric metal species, whereas the poor fit obtained for higher i values seems to exclude the formation of polymers of higher aggregation degrees.

The results of the above treatment indicate the

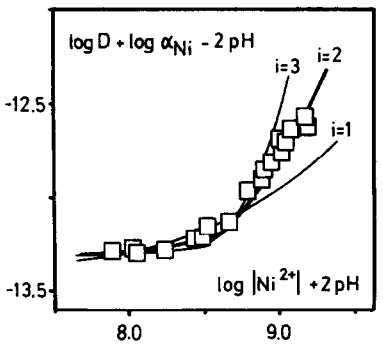

Fig. 2. Determination of the degree of polymerization of the extracted species.

predominance in organic solution of metallic monomer–trimer equilibria. Taking into account that intermediate dimer species may be also formed in the organic phase, the formation of the species $NiA_2(HA)_x$, $[NiA_2(HA)_y]_2$ and $[NiA_2(HA)_z]_3$ has been assumed.

With k_{x1}, k_{y2} and k_{z3}as the respective equilibrium constants for the above species, the nickel distribution coefficient can be written as follows:

$$D = k_{x1}\alpha_{Ni}^{-1}[(HA)_2]_{org}^{(2+x)/2}[H^+]^{-2} + 2k_{y2}\alpha_{Ni}^{-1}[Ni^{2+}][(HA)_2]_{org}^{2+y}[H^+]^{-4} + 3k_{z3}\alpha_{Ni}^{-1}[Ni^{2+}]^2[(HA)_2]_{org}^{[3(z+2)]/2}[H^+]^{-6}. \quad (10)$$

Equation (10) can be rearranged to give:

$$\frac{D\alpha_{Ni}[H^+]^2}{k_{x1}[(HA)_2]_{org}^{(2+x)/2}} = 1 + \frac{2k_{y2}[Ni^{2+}][(HA)_2]_{org}^{1+y-1/2x}}{k_{x1}[H^+]^2} + \frac{3k_{z3}[Ni^{2+}]^2[(HA)_2]_{org}^{(4+3z-x)/2}}{k_{x1}[H^+]^4}. \quad (11)$$

Defining the new normalized variables:

$$Y = \frac{D\alpha_{Ni}[H^+]^2}{k_{x1}[(HA)_2]_{org}^{(2+x)/2}}, \quad (12)$$

and

$$X = \frac{2k_{y2}[Ni^{2+}][(HA)_2]_{org}^{1+y-1/2x}}{k_{x1}[H^+]^2}, \quad (13)$$

the following family of theoretical curves is obtained:

$$Y = 1 + X + aX^2, \quad (14)$$

where a is a parameter defined by:

$$a = 3k_{z3}(4k_{y2}^2)^{-1}k_{x1}[(HA)_2]_{org}^{(3z+x)/2-2y}. \quad (15)$$

The experimental functions $\log D + \log \alpha_{Ni} - 2pH = f(\log [Ni^{2+}] + 2pH)$ and the model function $\log Y = f(\log X)$ for given values of the parameter a, will have the same shape since its variables differ only in constant values:

$$\Delta Y = \log Y - (\log D + \log \alpha_{Ni} - 2pH) = -\log k_{x1} - \tfrac{1}{2}(2+x)\log [(HA)_2]_{org}, \quad (16)$$

$$\Delta X = \log X - (\log [Ni^{2+}] + 2pH) = \log 2k_{y2}k_{x1}^{-1} + (1 + y - \tfrac{1}{2}x)\log [(HA)_2]_{org}. \quad (17)$$

Superimposing both functions by translation in the two axes, a position was found where both sets coincide, being $a = 10$ the best parameter value for all the reagent concentrations studied (Fig. 3).

In order to obtain x, y, k_{x1} and k_{y2} values, plots of ΔY and ΔX vs $\log [(HA)_2]_{org}$ were made, yielding two straight lines of slope values -2 and 2 respectively (Fig. 4). According to eqns (16) and (17), values of the stoichiometric coefficients $x = 2$ and $y = 2$ were deduced. From the intercepts of the plots on the Y-axis, values of the extraction constants $\log k_{21} = -11.52$ and $\log k_{22} = -19.10$ were determined.

Finally, according to eqn (15), the constant value of the parameter a for all the experimental curves indicates that $z = 2$ and, consequently, the extraction constant of the species $[NiA_2(HA)_2]_3$ could be determined from eqn (15), yielding $\log k_{23} = -25.55$.

Numerical treatment of the data

Computer calculations were undertaken both in order to refine the values of the extraction constants graphically obtained as well as to search for additional species which could contribute to improve the fit to the experimental data. Numerical

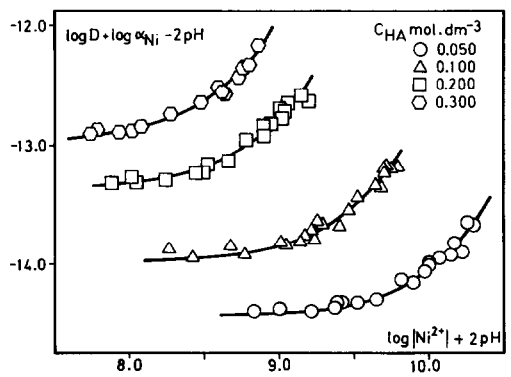

Fig. 3. Superimposition of the experimental functions $\log D + \log \alpha_{Ni} - 2pH = f(\log [Ni^{2+}] + 2pH$ and the theoreticals $\log Y = f(\log X)_a$ in the position of best fit.

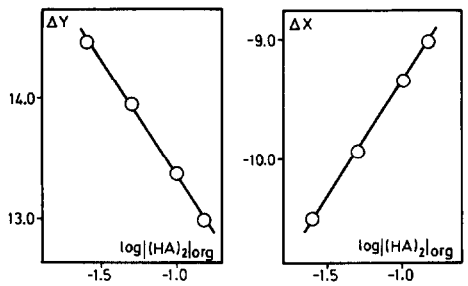

Fig. 4. Values of the differences in Y-axis (ΔY) and X-axis (ΔX) from Fig. 3 plotted as a function of log $[(HA)_2]_{org}$.

calculations were performed by using the program LETAGROP-DISTR,[19] which searches for the best set of species which would minimize the error square sum, U, defined by:

$$U = \sum_{N_p} (\log D_{calc} - \log D_{exp})^2, \qquad (18)$$

where D_{exp} represents the experimental distribution coefficient and D_{calc} the corresponding magnitude calculated by the program assuming a certain set of species and constants. N_p is the number of experimental data. For each combination of species tried the program calculates both U_o and $\sigma \log D$, the mean standard deviation defined by:

$$\sigma \log D = (U/N_p)^{1/2}. \qquad (19)$$

The results of the calculations are summarized in Table 1, and indicate that the combination of the species graphically determined, $NiA_2(HA)_2$, $[NiA_2(HA)_2]_2$ and $[NiA_2(HA)_2]_3$, as well as the monomer NiA_2, provides the best fit to the data. In Table 2 the values of the extraction constants for these species are given. The fit to the data is illustrated in Fig. 1, where the theoretical log D vs pH curves calculated with the extraction constants in Table 2 have been represented.

$[NiA_2(HA)_2]_2$	-18.96 max -18.67
$[NiA_2(HA)_2]_3$	-26.57 max -26.30

CONCLUSIONS

The results of this work, summarized in Table 2, indicate that a sequence of monomer–polymer equilibria may explain the extraction of Ni(II) in nitrate medium by *n*-dodecanoic acid dissolved in toluene. With the constants in Table 2 the mole fraction of Ni(II) in the different species has been computed as a function of the total extractant concentration and plotted in Fig. 5. From this plot it can be seen that the unsolvated monomer NiA_2 predominates in the low reagent concentration range, whereas at higher *n*-dodecanoic acid concentrations the polymerization of the solvated metal carboxylate is almost complete. This type of distribution diagram suggests that nickel extraction proceeds by a stepwise process in which the solvation of the metal carboxylate is followed by self-association reactions of the solvated monomer.

Several monomeric species ranging from NiA_2[10] to $NiA_2(HA)_4$[7] in equilibrium with the dimeric nickel carboxylate $[NiA_2(HA)_2]_2$[5–7,10,14] have been proposed for the extraction of the metal ion with different carboxylic acids in a wide range of conditions. This pattern is partially in agreement with the results obtained in our work, suggesting that the formation of the dimeric $[NiA_2(HA)_2]_2$ is

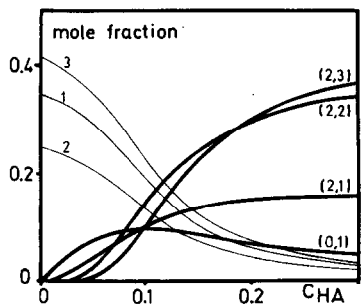

Fig. 5. Nickel distribution diagram as a function of the total *n*-dodecanoic acid concentration at pH = 7.00. Lines 1–3 represent, respectively, Ni^{2+}, $NiNO_3^+$ and $Ni(NO_3)_2$ species in the aqueous phase.

strongly favoured whereas the solvation number of the monomer seems to be highly dependent on the characteristics of the system and experimental conditions.

In addition to the monomer–dimer equilibrium, both graphical and numerical calculations support the formation in our system of trimeric species but exclude the presence of metal carboxylates with aggregation number higher than three. A monomer–dimer–trimer equilibrium of this type has been proposed by Nakasuka *et al.*[20] in a similar system involving the extraction of Cd(II) by *n*-decanoic acid dissolved in benzene.
