The activation parameters for the exchange on Zn and Cd complexes are comparable; the exchange rate is lower for the zinc compound than for CdL_4^{2+} as expected on the base of the ionic radii of the two metals (0.74 Å for Zn^{2+} and 0.97 Å for Cd^{2+}).[21] Electrostatic interactions between the ligand and the cation are certainly prevailing since there is no ligand field stabilization effect for these ions because of their complete *d*-shells. Although determined under quite different conditions, the substitution of water is reported to be equally about ten times faster on Cd^{2+} than on Zn^{2+}.[1] Steric reasons are to be considered too. The large sulphur atom produces more crowding

in the neighbourhood of the Zn^{2+} ion than of Cd^{2+}, leading to a relative destabilization of the OSC in the former case compared to the latter.

CONCLUSION

For the first time to our knowledge a complete study of the kinetics and mechanism on a cadmium complex with a neutral unidentate ligand has been realized in the work described here. Only a value of a rate constant, $k(25°C) = 1.6 \times 10^8\ s^{-1}$, had been reported for the exchange of water.[22]

Publications of zinc-complexes with this kind of ligands are equally rather rare; only two papers[4,7] report a complete study of the kinetics and mechanism of exchange reactions on this cation of biological interest. In one case, with the ligand HMPA, a purely associative mechanism was found, in the other, with tetramethylthiourea, a purely dissociative one. Our study gives evidence for the existence of a third possible exchange pathway for tetracoordinated zinc-complexes, an interchange mechanism. The greater bulkiness of thio-HMPA as compared to HMPA probably prohibits the formation of a five-coordinate intermediate necessary for an associative mechanism.

Other studies of metal perchlorates with this promising organophosphorus ligand had been planned; the hazards of explosion however, inherent in the combination of perchlorate and P=S groups suggests the choice of another anion to continue this work.

PREPARATION, CHARACTERIZATION AND CYCLIC VOLTAMMETRIC BEHAVIOUR OF DIMERIC SULPHIDOMOLYBDENUM(V) DITHIOCARBAMATE COMPLEXES

K. S. NAGARAJA and M. R. UDUPA*
Department of Chemistry, Indian Institute of Technology, Madras-600 036, India

(*Received* 2 *March* 1984; *accepted* 17 *August* 1984)

Abstract—$Mo_2S_4(R_2dtc)_2$ (R = methyl, ethyl or benzyl; R_2 = pyrrolidinyl, piperidinyl or 4-morpholinyl) have been prepared starting from ammonium tetrathiomolybdate. The IR spectra of the complexes suggested the bidentate nature of the dithiocarbamate with the disulphido bridged structure. The dimeric structure of the complexes is further confirmed by the mass spectral data. The cyclic voltammetric peak potentials for the select complexes are observed at −1.00 and −1.27 V vs SCE.

The genetic, enzymological and biophysical experiments on molybdo-enzymes show[1] that they contain two Mo atoms per molecule. Further, the recognition[2] of the importance of sulphido ligation in the molybdo-enzymes has led to study[3] of dimeric sulphidomolybdenum(V) dithiocarbamates. The electrochemical investigations of $Mo_2S_4(Et_2dtc)_2$ and $Mo_2S_4(n\text{-}Bu_2dtc)_2$ were reported[4–6] in the literature. In the present paper, we report the characterization and cyclic voltammetric studies of $Mo_2S_4(R_2dtc)_2$ (R = methyl, ethyl or benzyl; R_2 = pyrrolidinyl, piperidinyl or 4-morpholinyl) complexes, which have been prepared by following an elegant method.

EXPERIMENTAL

Materials

Laboratory grade chemicals were used as supplied. Ammonium tetrathiomolybdate and the ligands were prepared[7] using the procedure reported elsewhere. General method of preparation of di-μ-sulphidobis[sulphido(dithiocarbamato)molybdenum (V)], $Mo_2S_4(dtc)_2$. Ammonium tetrathiomolybdate (10 mmol) in water (40 cm^3) and sodium dithiocarbamate (40 mmol) in water (100 cm^3) were mixed and stirred for 0.5 h. The precipitated dark red complex was filtered, washed with water and finally with methanol and dried. Yield 70%. The elemental analyses of the complexes are given in Table 1. The complexes are found to be insoluble in water and common organic solvents, but are soluble in dimethylsulphoxide or dimethylformamide. The IR, UV–visible and mass spectra were recorded on Perkin–Elmer 257, Carl Zeiss DMR-21 and VG micro-mass 70-70 FF spectrometers respectively. The voltammetric measurements were made with a three electrode McKee–Pedersen potentiostatic circuit constructed from operational amplifiers. The working electrode was a Pt foil. A Pt wire sealed in the glass tube served as auxiliary electrode and SCE was used as the reference electrode. The reference electrode was separated from the experimental solution by means of a non-aqueous salt bridge. Sweep rates varied between 0.01–0.3 V s^{-1}. Deaeration of the solution was performed by passing purified nitrogen. All the potentials are reported w.r.t. SCE.

RESULTS AND DISCUSSION

Hitherto reported procedures[4–6] to synthesise complexes with the $Mo_2S_4^{2+}$ core described various starting compounds which were prepared with relatively great difficulty. We have employed ammonium tetrathiomolybdate which was obtained by passing hydrogen sulphide gas through an ammoniacal solution of ammonium molybdate. The complete substitution of the oxo groups in MoO_4^{2-} ion was monitored by the characteristic UV–visible spectra.

Table 1. Analytical data for $Mo_2S_4(R_2dtc)_2$ complexes

Complex	Found (calc.) (%)				
	C	H	N	S	Mo
$Mo_2S_4(Me_2dtc)_2$	13.0 (12.8)	2.3 (2.1)	4.8 (5.0)	45.4 (45.7)	34.0 (34.2)
$Mo_2S_4(Et_2dtc)_2$	19.4 (19.5)	3.3 (3.3)	4.4 (4.5)	41.7 (41.6)	31.1 (31.2)
$Mo_2S_4(pyrroldtc)_2$	19.5 (19.6)	2.6 (2.6)	4.6 (4.6)	41.8 (41.9)	31.3 (31.3)
$Mo_2S_4(pipdtc)_2$	22.3 (22.5)	2.8 (3.1)	4.4 (4.4)	39.9 (40.0)	30.1 (29.9)
$Mo_2S_4(4\text{-morphdtc})_2$	18.5 (18.6)	2.5 (2.5)	4.4 (4.3)	39.7 (39.8)	29.8 (29.8)
$Mo_2S_4(dibenzdtc)_2$	41.9 (41.7)	3.5 (3.3)	3.2 (3.2)	29.6 (29.7)	22.2 (22.1)

The complexes are found to be diamagnetic. Mo(V) has d^1 electronic configuration and is expected to be paramagnetic. However in dimeric complexes of this type $Mo_2S_4^{2+}$, the d_{xy} orbitals of the two Mo atoms are oriented to allow direct overlap across MoS_2Mo bridge and as such the bonding level of this interaction accommodates the two electrons in accordance with the diamagnetism observed. The electronic spectra of the complexes (Table 2) exhibited λ_{max} around 470 and 320 nm, which are attributed[3] to $S_t \rightarrow Mo$ charge-transfer and internal ligand $\pi \rightarrow \pi^*$ transitions respectively.

The IR spectra of the complexes showed absorptions (Table 2) around 1500 and 960 cm^{-1}, which are characteristic[8] of bidentate dithiocarbamate ligand. The higher value of $\nu_{(CN)}$ for $Mo_2S_4(Me_2dtc)_2$ is explained due to the electron releasing methyl groups attached to the nitrogen atom exerting hyperconjugation effect. The decrease in $\nu_{(CN)}$ value of $Mo_2S_4(dibenzdtc)_2$ when compared to $Mo_2S_4(Me_2dtc)_2$ is attributed to the presence of electron withdrawing phenyl rings attached to methylene groups. The bands (Table 2) observed around 540 and 525 cm^{-1} are assigned[4] to $\nu_{(Mo=S)}$ (terminal). The observation of two bands indicate that the complexes are of *syn* form, that is two terminal sulphido groups are *cis* to each other. The bands at 475 and 340 cm^{-1} are due to asymmetric and symmetric stretching vibrations of a sulphur bridged[4] MoS_2Mo group. The absorption observed in the spectra of the complexes at 380 cm^{-1} is attributed[7] to $\nu_{(Mo-S)_{dtc}}$. The 15 line mass spectrum

over 592–576 m/z (parent-32) units, of $Mo_2S_4(Et_2dtc)_2$ confirms[9] the dimeric nature.

The cyclic voltammograms of Mo_2S_4(4-morphdtc)$_2$ were recorded in dimethylsulphoxide using tetramethyl ammonium perchlorate as the supporting electrolyte. Two reversible cathodic peaks are observed at potentials −0.97, −1.27; −1.05, −1.27 and −1.07, −1.28 V vs SCE for $Mo_2S_4(Et_2dtc)_2$, Mo_2S_4(pyrroldtc)$_2$ and Mo_2S_4(4-morphdtc)$_2$ respectively with the sweep rate of 0.1 V s^{-1}. The cyclic voltammogram of $Mo_2S_4(Et_2dtc)_2$ (Fig. 1) is comparable to that reported by Schultz *et al.*[4] The cathodic peak potentials around −1.00 and −1.2 V are attributed to the successive one electron reduction. The peak current for the second wave varies with the sweep rate, which may suggest that the reduction is preceded by a chemical decomposition step. The first cathodic peak potential seems to be susceptible to the electronic effects of the coligand which is present along with Mo_2S_4 core.

PREPARATION OF MIXED ISOPROPYL/TRIMETHYLSILYL DERIVATIVES OF BORIC ACID, $(Me_3SiO)_nB(O^iPr)_{3-n}$ ($n = 1$–3), AND THEIR GC–MS SPECTRA

HIROAKI WADA, SHUNJI ARAKI, KAZUYUKI KURODA and CHUZO KATO*
Department of Applied Chemistry, Waseda University, Shinjuku-ku, Tokyo 160, Japan

(*Received* 28 *November* 1983; *accepted in revised form* 17 *August* 1984)

Abstract—Boric acid was trimethylsilylated with $Me_3SiCl/(Me_3Si)_2O$ in the presence of 2-propanol. The resulting mixture was analysed by using a combined gas chromatograph–mass spectrometer. The compounds $(Me_3SiO)_nB(O^iPr)_{3-n}$ ($n = 0$–3) were detected as products.

We have already reported[1] that by the reaction of silicate minerals such as hemimorphite with trimethylsilylating reagent containing ethylene glycol, a viscous "silicate–organic copolymer" was formed as a result of the partial esterification of unsilylated silanol groups. Therefore, it was interesting to study the possibility of preparing partially esterified trimethylsilyl derivatives of boric acid. Though there have been many reports on the preparation and properties of fully trimethylsilylated boric acid,[2–4] no investigations on the preparation of partially trimethylsilylated alkyl derivatives of boric acid have been reported.

The purpose of this study is to report the preparation and GC–MS analysis of the partially trimethylsilylated isopropyl derivatives of boric acid.

EXPERIMENTAL

Materials

Boric acid and 2-propanol were reagent grade and were used without purification.

Trimethylchlorosilane (Shin-etsu Chemicals) was washed with hydrochloric acid and was distilled before use.

Hexamethyldisiloxane was obtained by the hydrolysis of trimethylchlorosilane and was distilled once.

Preparation

5 cm^3 of trimethylchlorosilane, 5 cm^3 of hexamethyldisiloxane and 0.2 cm^3 of 2-propanol were put in a 50-cm^3 flask. The solution was stirred for 30 min. Then 0.2 g of boric acid was added to the solution. After stirring for 3 h, the solution was filtered in order to remove unreacted boric acid and concentrated by use of an aspirator.

The product obtained was a colourless liquid containing hexamethyldisiloxane.

Analysis

The mass spectra were obtained using a gas chromatograph–mass spectrometer GCMS-QP1000 (Shimadzu Seisakusho Ltd). The electron energy was 70 eV. The ion source temperature was maintained at 250°C and separator at 270°C. The GC column (length 1.5 m and inside diameter 3 mm) was packed with 5 wt.% of OV-17 on 80/100 mesh Chromosorb W.

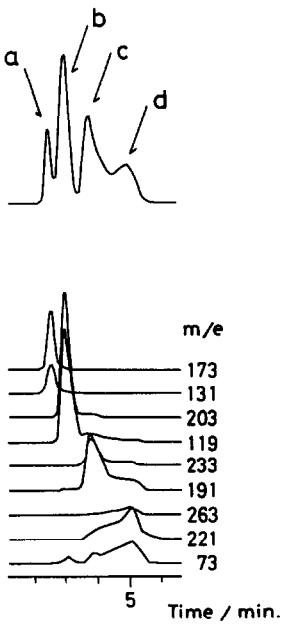
RESULTS AND DISCUSSION

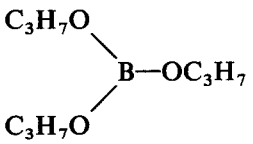
Figure 1 shows chromatographic separation of the product. Four peaks were found in TII (total ion intensity) chromatogram (upper part of the figure), though peaks c and d were not well separated. Changes of the intensity of several masses characteristic of each peak with time are shown in Fig. 1 (mass chromatogram; lower part of the figure).

The mass spectra of peaks a–d in the TII chromatogram are shown in Fig. 2(a–d). Under the present experimental conditions, boric acid would not polymerise in this low pH,[5] therefore, trialkyl borate (a), di- and monoalkyl substituted trimethylsilyl derivatives of boric acid, b and c respectively, were expected to be formed in addition to the fully silylated derivative (d).

Though no molecular ion M^+ was observed in all

* Author to whom correspondence should be addressed.





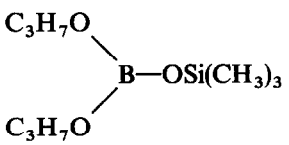


Fig. 1. TII and mass chromatograms.

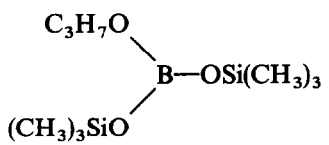
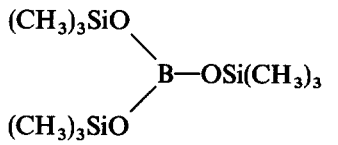


spectra, the peaks [exactly corresponding to $(M-15)^+$ (loss of a methyl group) respectively] were detected in each spectrum. The observed and calculated abundance of $(A-1)^+$, A^+ and $(A+1)^+$ ions were summarised in Table 1 by the consideration of isotopes of boron, carbon and silicon ["A" represents $(M-15)^+$ ion]. In view of these data, it could be concluded that the compounds formed were **1–4**.



1

2

3

4

In the spectra of the compounds containing trimethylsilyl group (Fig. 2b–d), the peak at *m/e* 73 (known as $(CH_3)_3Si$ group) increased with the increase in the number of the trimethylsilyl group compared to the $(M-15)^+$ ion.

In the spectrum of tris(trimethylsilyl)borate (Fig. 2d), *m/e* 221 was observed. Butts and Rainey[6] proposed that the loss of 42 mass units (263 → 221) was due to the loss of CH_3BO neutral fragment by considering the following points.

(1) A peak at *m/e* 220 was not observed. This fact clearly indicated that the ion at *m/e* 221 did not contain a boron atom.

(2) In the case of other trimethylsilylated anions such as sulphate, carbonate and oxalate, they found that, in general, the central hetero-atom is lost early in the fragmentation pattern with the rearrangement of the silyl groups.

According to our results, the peak ratio (*m/e* 221 : *m/e* 222 : *m/e* 223) was 8.6 : 1.9 : 1.0, which was in fair agreement with the calculated ratio 8.1 : 1.9 : 1.0 assuming that CH_3BO was lost from the $(M-15)^+$ ion. Moreover, in mass spectra of other trimethylsilyl derivatives, an intense peak at *m/e* 221 was frequently observed in addition to *m/e* 73 and 147.[7–9] In conclusion, *m/e* 221 could be assigned to be due to the rearrangement of trimethylsilyl groups.

Although the shift of 42 mass units was also observed in Fig. 2a (173 → 131), in Fig. 2b (203 → 161), and in Fig. 2c (233 → 191), it was not possible

Table 1. Abundance of $(A-1)^+$, A^+ and $(A+1)^+$

*Calculated on the basis of natural abundance: ^{10}B (19.7%), ^{11}B (80.3%); ^{12}C (98.892%), ^{13}C (1.108%); ^{28}Si (92.18%), ^{29}Si (4.71%), ^{30}Si (3.12%).

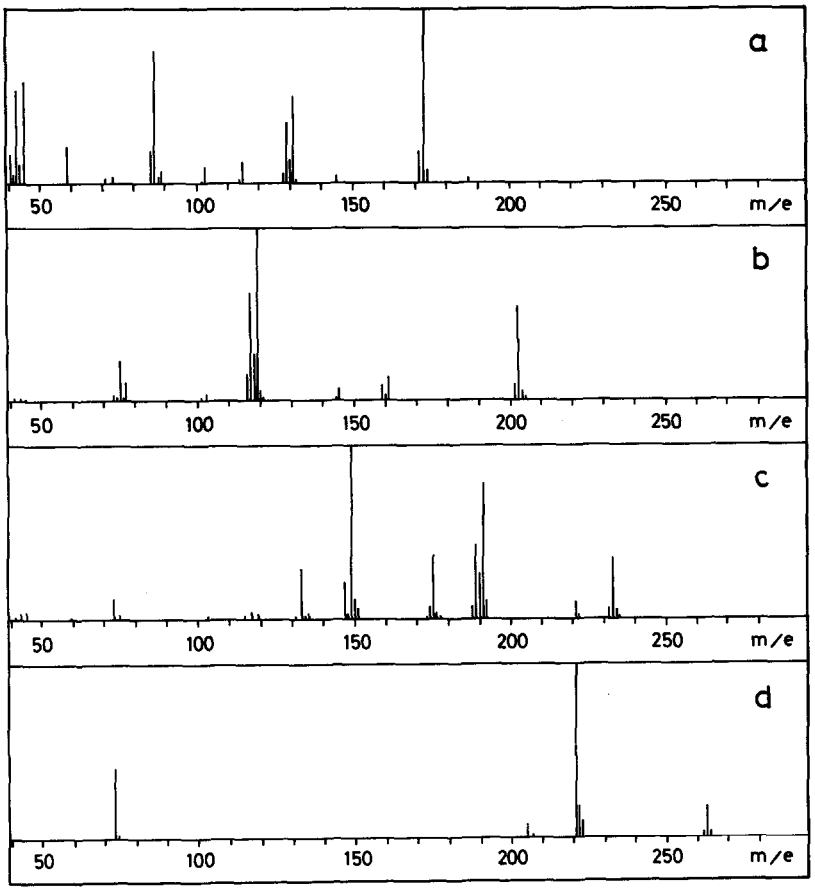

Fig. 2. Mass spectra of the compounds: (a) **1**, (b) **2**, (c) **3** and (d) **4**.

to conclude that it was actually due to the loss of CH_3BO. Namely, it could not be understood whether the peaks at *m/e* 130, 160, and 190 in Fig. 2a–c were the isotopic peaks of *m/e* 131, 161 and 191 ions and/or those of *m/e* 129, 159 and 189 ions respectively. Loss of 42 mass units from $(M-15)^+$ ion was reported by Calhoun and Masson,[10] who studied the 2-propanol/calcium silicate system. They tentatively proposed that it was due to $(M-15)^+-C_3H_6$. According to our calculation of the relative intensities of the peak at *m/e* 191, 192 and 193 in Fig. 2c, it seemed likely that the loss of 42 mass units was due to the loss of C_3H_6 rather than that of CH_3BO.

Furthermore, Calhoun and Masson[10] observed peaks corresponding to $(M-15)^+-44$, which were also shown in our spectra (*m/e* 129 in Fig. 2a, 159 in Fig. 2b, and 189 in Fig. 2c), and proposed that it was due to $(M-15)^+-C_3H_8$. However, taking into account the fragmentation patterns of other alkyl borates,[11] these peaks could also be ascribable to $(M-59)^+$ (loss of an isopropoxy group from M^+). On the basis of above data, it was unable to identify each peak of the spectra because of the complex overlapping of the peaks.

A strong peak at *m/e* 87 in Fig. 2a was ascribed to $C_3H_7OBOH^+$[11] or $O_2BOCHCH_3^+$ by the comparison of the calculated ratio (1:4.1) with the observed ratio (1:4.2) of *m/e* 86 and 87.

In Fig. 2c, peaks at *m/e* 147, 133, 131, 119, 117, 73, 45 and 43 were observed. These peaks are also found in the mass spectrum of hexamethyldisiloxane (HMD). Since HMD (b.p. *ca* 100°C) was eluted much earlier than the compound **1** on chromatogram, it was thought that these peaks were due to the formation of $(CH_3)_2Si{=}O^+{-}Si(CH_3)_3$ (*m/e* 147)[12] by the rearrangement of two trimethylsilyl groups of the compound **3**. These peaks could not be observed in Fig. 2d (spectrum of compound **4**; fully trimethylsilylated derivative). In the mass spectrum of the compound **4** reported by Butts and Rainey,[6] a very small peak at *m/e* 147 was detected. The absence of this peak in our spectrum is probably due to its much lower relative intensity than the "base peak" (*m/e* 221). Peaks other than *m/e* 147 were in good agreement with those obtained by them.

Although the difference of the reactivity of trimethylsilyl group and alkyl group was not well known, we have already reported that the compounds containing both isopropyl and trimethylsilyl groups were formed in the case of silicates.

Mono-, di- and tri-isopropyl-substituted trimethylsilyl derivatives of monomeric and dimeric silicates were formed by trimethylsilylation of olivine[13] and hemimorphite[14] respectively. It was thought that the same types of reaction occurred in boric acid and 2-propanol system, though we were not able to determine one of the reactions (trimethylsilylation and esterification) occurred first or the two processes proceeded simultaneously.

The yield of the product was so small that the amount of each compound was insufficient to be analysed by spectroscopic methods. However, it can be thought that trimethylsilylation is a promising technique for the investigation and the syntheses of organic–inorganic copolymers containing not only silicon but also boron.

SPECTROSCOPIC STUDIES OF MIXED HALOGENOTETRAPHOSPHAZENES

T. TUNDE BAMGBOYE
Department of Chemistry, University of Ilorin, Ilorin, Nigeria

(*Received* 5 *October* 1983; *accepted in revised form* 17 *August* 1984)

Abstract—Cyclotetraphosphazenes substituted non-geminally by fluorine and either chlorine or bromine have been prepared. The compounds with the general formula $P_4N_4F_{8-n}X_n$, where X = Cl or Br and $n = 2$ and 4, result from the reactions under pressure between either hydrogen chloride or bromide and dimethylaminofluorocyclotetraphosphazenes. In most cases mixture of isomers are obtained. The main structural evidence is obtained by ^{19}F NMR assisted by GLC and IR spectroscopy.

The fluorination of $P_4N_4Cl_8$ or $P_4N_4Br_8$ with potassium fluorosulphite is a stepwise process leading exclusively to geminal isomers. The alternative isomers in which the different halogen atoms occupy non-geminal positions must therefore be obtained by an indirect method as summarised by the equations:

$$P_4N_4Cl_8 + 2nHNMe_2 \rightarrow P_4N_4Cl_{8-n}(NMe_2)_n + nNMe_2H, HCl, \quad (1)$$

$$P_4N_4Cl_{8-n}(NMe_2)_n + SbF_3 \rightarrow P_4N_4F_{8-n}(NMe_2)_n + SbCl_3, \quad (2)$$

$$P_4N_4F_{8-n}(NMe_2)_n + 2nHX \rightarrow P_4N_4F_{8-n}X_n + nNMe_2H_2X. \quad (3)$$

Equation (1) is the aminolysis of $P_4N_4Cl_8$ to give the non-geminal substituted isomers, which can be fluorinated using antimony trifluoride [eqn (2)], then the resulting dimethylaminofluorotetraphosphazenes are finally treated with either HCl or HBr to give the non-geminal bromo- or cloro-fluorotetraphosphazenes [eqn (3)].

Both non-geminally[1] and geminally[2] substituted mixed halides of the trimer are well established, but only the geminally substituted chloro-fluorotetraphosphazenes have been reported.[2] We expect that the method used for non-geminally substituted trimer might give these compounds.

Attempts to prepare the non-geminal isomers of $P_4N_4F_4Cl_4$ (**VII** and **VIII**), $P_4N_4F_4Br_4$ (**VII** and **VIII**), $P_4N_4F_6Cl_2$ (**XI** and **XII**) and $P_4N_4F_6Br_2$ (**XIII** and **XIV**) (see Fig. 1) are presented.

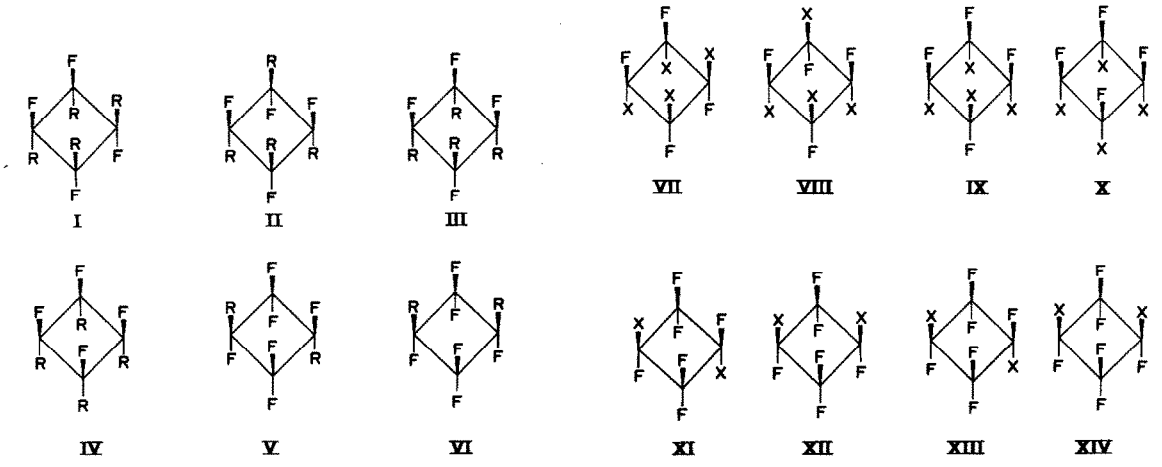

Fig. 1. R or X = NMe_2, Cl or Br in all structures.

EXPERIMENTAL

Reactions of the starting materials with either hydrogen chloride or hydrogen bromide followed the same pattern and details for one reaction with hydrogen chloride are given below. Other reactions are summarized in Table 1. All reactions were monitored by GLC. Mass spectra confirmed the stoichiometry of the compounds.

Reaction of $P_4N_4F_4(NMe_2)_4$ **(I** *and* **II)** *with hydrogen chloride*

The reaction was carried out in a Carius tube fitted with a Rotaflo Tf6/24 valve and a standard taper joint for attachment to a vacuum line. The phosphazene (0.8 g, 0.002 mol) was added to the Carius tube and degassed, after which hydrogen chloride (2.48 g, 0.069 mol) was condensed into the sample by cooling the tube in liquid nitrogen. The "Rotaflo" valve was closed and the tube surrounded by a protective wire gauze. After about 30 days the tube was cooled at −196°C and the excess hydrogen chloride removed at −45°C on a vacuum line at 0.01 mm pressure.

The remaining solid was extracted with boiling petrol (60–80°C) to separate the mixed halide from dimethylaminohydrochloride. After the removal of the solvent the product was a colourless liquid.

Examination of the material by GLC (5 ft × $\frac{3}{8}$ in. stainless steel column packed with 10% silicone gum rubber on Chromosorb W at 60°C) showed a broad asymmetric peak characteristic of two components with very similar retention times, the ratio of these was estimated as 1 : 1.2. Because of the closeness of the retention times, separation to give pure isomers by preparative GLC was not feasible.

Mass spectrometry confirmed the presence of $P_4N_4F_4^{35}Cl_4$ by the observation of a parent ion at m/z 396 with the correct isotopic distribution pattern for four chlorine atoms; completion of the reaction was also confirmed by the absence of peaks associated with amine containing mixed halides.

Instruments

A Varian-Aerograph 90 P-3 preparative gas–liquid chromatograph was used with helium carrier gas. NMR spectra were obtained with a Varian HA100 spectrometer. Fluorine resonances were obtained on 10% (w/v) solutions in carbon tetrachloride with trichlorofluoromethane as internal standard. IR spectra were obtained for either liquid film samples or solutions in carbon tetrachloride on a Perkin–Elmer 457 spectrometer. Mass spectra were obtained on an AEI MS902 double-focusing mass spectrometer. Introduction of liquid samples was through the all glass heated inlet system while for solids the direct insertion leak was used.

RESULTS AND DISCUSSION

Preparation

In the trimer, the mixed halide reactions had to be carried out at elevated temperatures;[1] but it is interesting to note here that in the tetramer series, the reactions were performed at room temperatures. This is a consequence of the known greater reactivity of the tetrameric compounds.[3]

The rate of deaminolysis was faster with hydrogen bromide than with hydrogen chloride, probably as a

Table 1. Reaction with HCl and HBr

Reactant	Product	Relative area under peak	Retention time (min)	Analytical data N (%) Found	Calc.	Reaction conditions t (°C)	Time (h)
$P_4N_4F_4(NMe_2)_4$ (I and II)	$P_4N_4F_4Cl_4$ (VII)	1.0	3.4				
	$P_4N_4F_4Cl_4$ (VIII)	1.2	3.6	13.7	14.1	60	720
$P_4N_4F_6(NMe_2)_2$ (V and VI)	$P_4N_4F_6Cl_2$ (XIV)	1.0	2.7				
	$P_4N_4F_6Cl_2$(XIII)	1.8	5.0	14.7	15.4	50	240
$P_4N_4F_4(NMe_2)_4$ (I and II)	$P_4N_4F_4Br_4$ (VII)	1.0	38.5	9.8	9.7	100	432
	$P_4N_4F_4Br_4$ (VIII)	1.1	40.2				
$P_4N_4F_6(NMe_2)_2$ (V and VI)	$P_4N_4F_6Br_2$ (XI)	1.0	31.0				
	$P_4N_4F_6Br_2$ (XII)	1.5	35.0	12.3	12.3	90	120

result of hydrogen bromide being a stronger nucleophile than hydrogen chloride.[4]

The deaminolysis of $P_4N_4F_{8-n}(NMe_2)_n$ ($n = 2$ and 4) with hydrogen halide[5] probably involved a preliminary coordination to the basic ring nitrogen atom (i.e. the nitrogen atom flanked by two amine groups).

Vibrational spectra

The IR data for the compounds are collected in Tables 2 and 3. For purposes of comparison, the vibrational spectra of the four compounds are discussed together. The vibrational spectra of $P_4N_4F_6Br_2$ and $P_4N_4F_6Cl_2$ are, as expected, very similar with major differences occurring in the 530–580 cm^{-1} region which contains bands ascribed to the PBr and PCl stretching vibrations respectively. The strongest band in the spectra of these compounds is a ring stretching mode occurring at 1360–1400 cm^{-1}. Two effects to consider here are namely (a) the fact that this mode moves to higher energy with increasing fluorine content and (b) this is a degenerate mode in $P_4N_4Cl_8$ (the chloro precursor) and with decreasing symmetries would expect (in $P_4N_4F_4X_4$, $P_4N_4F_6X_2$; X = Cl, Br compounds) the degeneracy to be raised. Other ring modes can be assigned to bands occurring at *ca* 1040, 810, 665, 425 and 415 cm^{-1}.

The remaining bands are thus due to PF_2 asymmetric in-phase and out-of-phase stretches, PF_2 symmetric in-phase and out-of-phase stretches,

Table 2. IR spectra* of compounds $P_4N_4F_4Br_4$ (VII) and $P_4N_4F_4Cl_4$ (VIII)

VII	VIII	Assignment
1360 vs	1370 vs	Ring

718 m	718 m	$\nu_s PF_2$ (o.p)
650 s	670 vs	Ring
	580 s	νPCl
530 vs		νPBr
485 m	492 m	νPF_2
415 w	425 m	Ring

* Obtained as liquid film.

PF_2 deformation and PF stretching vibrations. The bands at *ca* 965, 960 and 908 cm^{-1} can be associated with PF_2 asymmetric (in-phase and out-of-phase) vibrations. The band at *ca* 956 cm^{-1} is also due to PF stretching vibrations. The PF_2 deformations occur at *ca* 492 and 485 cm^{-1}.

Apart from differences in the region associated with PBr and PCl stretching vibrations, the IR spectra of compounds $P_4N_4F_4Br_4$ and $P_4N_4F_4Cl_4$ are indeed very similar. The bands at *ca* 565 cm^{-1} in $P_4N_4F_4Cl_4$ and at *ca* 530 cm^{-1} in $P_4N_4F_4Br_4$ are assigned to the phosphorus–halogen stretching modes.

^{19}F NMR spectra

Elemental analysis and mass spectrometry were used to confirm the stoichiometry of the compounds summarised in Fig. 1.

The complete ^{19}F NMR data for the compounds are collected in Table 4. Figure 2 shows the spectrum of compound $P_4N_4F_4Cl_4$. This consists of two doublets most probably arising from the two isomers shown to be present by GLC. Figure 1 shows the four possible non-geminal isomers for a compound with stoichiometry $P_4N_4F_4X_4$ (X = Cl, Br). For the compound $P_4N_4F_4X_4$ (X = Cl), compounds **VII**, **VIII** and **X** are likely isomers but **IX** can be eliminated as its spectrum would give three doublets.

Compounds **I** and **II** (see Fig. 1) for which X-ray structures are available[6,7] are the amino-fluoride precursors of the isomers of compound $P_4N_4F_4Cl_4$ and on this basis compounds **VII** and **VIII** are the most likely structures.

Invoking a "*cis*-effect"[8] pragmatically, chemical

$P_4N_4F_4Br_4$	−70.86		−28.88			1010
			−31.56		927	960
			−34.38			996

† δ (ppm) relative to $CFCl_3$.

shifts of two compounds could be related to their structures. In compound **VII** the two fluorine nuclei are *cis* to each other and this will show higher field shift to compound **VIII**. On this basis, compound **VII** with a shift of *ca* −39 ppm is assigned a *cis–cis–trans*-configuration while compound **VIII** with a shift of −37 ppm is assigned a *cis–trans–cis–trans*-configuration. This is also confirmed by GLC evidence which showed shorter retention time for the *cis*-isomer in contrast to the aminochlorides and aminofluorides (an observation noted by Green and Sowerby).[9]

In the ^{19}F NMR data for the compound $P_4N_4F_4Br_4$ the sigmal at −70 ppm indicates an isomer with a geminal PF_2 group. Alternatively, the compound of composition $P_4N_4F_5Br_3$ may also be present but mass spectral data did not confirm this. Therefore assignment of this structure is not unambiguous in contrast to the chloride analogue.

For the compounds $P_4N_4F_6X_2$ (X = Cl, Br), the ^{19}F NMR spectra consists basically of two doublets in the intensity ratio of 2 : 1 (see Figs 3 and 4). The two doublets indicate two types of fluorine environments namely (PF_2) and (PFCl) groupings for compound (X = Cl) and (PF_2) and (PFBr) groupings for compound (X = Br).

The possible structures compatible with the observed ^{19}F NMR spectra are explicable by a consideration of the isomers of compounds **V** and **VI** (see Fig. 1) which are starting materials to compounds $P_4N_4F_6X_2$ (X = Cl, Br). This starting material—$P_4N_4F_6(NMe_2)_2$—consisted of approximately equal amounts of two isomers thought to be 1,*trans*-5-$P_4N_4F_6(NMe_2)_2$ (**V**) and 1,*cis*-5-$P_4N_4F_6(NMe_2)_2$ (**VI**) as discussed in Ref. 10. In view of this, it is most likely that these dibromo- and chloro-compounds also have these structures.

Evidence from GLC analyses showed the presence of two isomers in each of the compounds. On this basis, the isomers with the shorter retention times could be assigned the *cis*-isomer.[10] Hence compounds **XI** with X = Cl and compound **XIII** with X = Br are assigned a 1,*trans*-5-configuration and compound **XII** with X = Cl and compound **XIV** with X = Br the 1,*cis*-5-configuration.

Acknowledgement—Thanks to Dr D. B. Sowerby of Nottingham University, for his help in going through the manuscript and most particularly for the critical discussion of the ideas expressed in certain phases of evaluation.

REACTIONS OF COORDINATED MERCAPTIDE GROUP—III. REACTIONS OF ACYL CHLORIDES ON BIS(THIOSEMICARBAZONATO) CHELATES OF NICKEL(II)

SULEKH CHANDRA
Department of Chemistry, Zakir Husain College, Ajmeri Gate, Delhi-110006, India

(*Received* 20 *March* 1984; *accepted* 17 *August* 1984)

Abstract—Reactions of acetyl chloride and benzoyl chloride have been carried out on bis(thiosemicarbazonato)nickel(II) complexes of acetone and ethylmethyl ketone thiosemicarbazones. The reactions are taking place at the coordinated mercaptide group forming thioester *in situ*. The products which are obtained during reactions are characterised by elemental analyses, magnetic, moments, IR and electronic spectral studies.

Studies on the reactions of coordinated ligands are important in view of the fact that the coordinated metal ions, influence to a very great extent, the course of many complicated reactions, occurring during the metabolic activities,[1–3] in living organisms. Reactivity of the coordinated sulphur atom towards nucleophiles is of particular significance, in this context.

Amongst the most powerful nucleophiles, the mercaptide ion is of great significance in organic chemistry[4] and its nucleophilic property is not deterred even when this mercaptide group is bound to a metal ion as is the case in the formation of coordinated thioesters by the reactions of coordinated mercaptide group with alkyl halides.[5–7]

In this paper the reactions of acyl chlorides are reported on bis(thiosemicarbazonato)nickel(II) complexes. The reactions take place on the coordinated mercaptide group forming thioester *in situ*.

EXPERIMENTAL

All chemicals used were of AnalaR grade. The reactions were carried out in pyrex glass apparatus with interchangeable joints. Extreme precautions were taken to exclude moisture throughout the experiment. The solvents were dried before use. Pyridine (Fluka) was dried over KOH followed by distillation (b.p. 115–116°C). Dimethylformamide (Fluka) was dried over anhydrous K_2CO_3 followed by distillation (b.p. 153–154°C). Acetyl chloride and benzoyl chloride were dried by simple distillation (b.p. 51–52 and 197–198°C) respectively.

Preparation of bis(thiosemicarbazonato)nickel(II) complexes

These complexes were prepared by the method reported earlier.[8]

Reactions of acyl chlorides on acetone/ethylmethyl ketone bis(thiosemicarbazonato)nickel(II)

The reactions were carried out in two ways.

Reactions on dry chelates. Dry powdered bis chelates (0.05 mol) were taken in a 100 cm^3 round bottom flask and to it CH_3COCl/C_6H_5COCl (0.1 mol) was slowly added with constant stirring. On refluxing the contents on a water bath a green compound separated out. This was filtered under reduced pressure, washed with dry ether and dried under vacuum. The compound so obtained give analyses for $NiL_2 \cdot 2RCOCl$ (Table 1).

Reactions in DMF/Py medium. Dry powdered bis chelates (0.05 mol) were suspended in 100 cm^3 of dimethylformamide or pyridine in a 250 cm^3 round bottom flask and to it CH_3COCl/C_6H_5COCl (0.1 mol) was added dropwise with constant stirring. An exothermic reaction occurs and a dirty green to green solution is obtained. On adding *n*-hexane to this solution a yellowish green compound is obtained. Extra solvent is removed by decantation. The compound is dried under vacuum. These compounds give analysis corresponding to $NiL_2 \cdot 2RCOCl \cdot 2DMF/Py$ (Table 1).

Physical measurements

Magnetic susceptibility measurements were carried out on Gouy balance using $Hg[Co(CNS)_4]$

as calibrating agent ($\chi_g = 16.44 \times 10^{-6}$ cgs units at 20°C). IR spectra of the ligand and complexes were recorded on a Perkin–Elmer 621 automatic recording spectrophotometer. Electronic spectra were recorded on a Backman DK-2 automatic recording spectrophotometer.

Analysis for carbon and hydrogen were carried out in microanalytical laboratory of Chemistry Department of Delhi University. Nitrogen in the complexes was determined by Kjeldahl's method. Nickel was determined gravimetrically as nickel dimethylglyoxime.

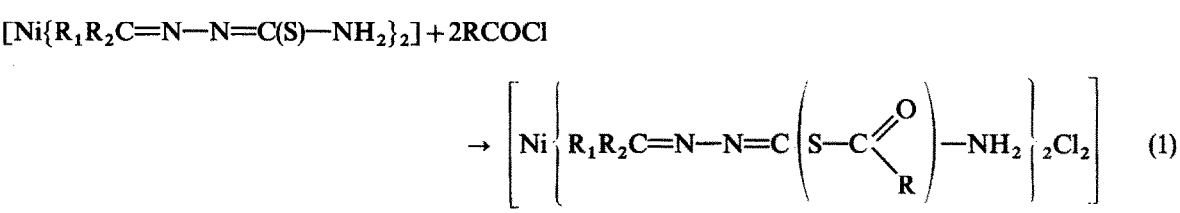
RESULTS AND DISCUSSION

Thiosemicarbazones, like thiosemicarbazide, exist predominantly in their enolic form (**b**) in alkaline solution:[9]

a **b**

In this form they react with bivalent nickel to form neutral bis chelates, NiL_2. These complexes were diamagnetic and square planar.[9] From the structure of the complex NiL_2 [Fig. 1 (**I**)] it is apparent that there are two possible sites for acylation and aroylation,

(i) the coordinated mercaptide group,
(ii) the free $-NH_2$ group.



IR spectra of these complexes excludes the possibility of acylation and aroylation at the free-NH_2 group. IR spectra of the parent complex NiL_2 [Fig. 1 (**I**)] and the complexes [Fig. 1 (**II** and **IIa**)] display sharp bands of medium intensity at 3350 and 3300 cm^{-1} which are characteristics of ν_{NH_2} stretching frequencies.[10] A third band of a comparable intensity occurs at 1610 cm^{-1} which can be attributed to the δ_{NH_2} deformation mode.[10] The appearance of these bands confirms the presence of primary amine. In contrast, a secondary amine usually exhibits a strong characteristic band in the deformation region at rather lower frequency and a single ν_{NH} stretching frequency.[11]

On the basis of these spectral observations, the electrophilic nature of the attacking acyl chlorides and the usual inability of amide nitrogen to undergo chemical reaction, it would appear that acylation and aroylation take place at the coordinated mercaptide group.

Reaction on dry bis-chelates

Dry powdered samples of ketone bis-(thiosemicarbazonato)nickel(II) dissolve with change in colour in acetyl chloride or benzoyl chloride on gentle warming. The endothermic reaction (1) takes place at the coordinated mercaptide group producing thioester *in situ*.

The axial position of the complexes are occupied by chloride ions to give six-coordinated tetragonal structure [Fig. 1 (**II**)]. These complexes show magnetic moments corresponding to two unpaired electrons (Table 2). Electronic spectra of these complexes have been recorded in Nujol mull. All these complexes display electronic spectral bands at 9000–9100, 16,000–16,400 and 23,500–24,000 cm^{-1} which may be assigned to ν_1 ($^3A_{2g} \rightarrow {}^3T_{2g}$), ν_2 [$^3A_{2g}$

$R_1 = CH_3, R_2 = CH_3$ or C_2H_5 and $R = CH_3$ or C_6H_5

$\rightarrow {}^3T_{1g}(F)$] and ν_3 [$^3A_{2g} \rightarrow {}^3T_{1g}(P)$] transitions respectively for tetragonal nickel(II) complexes.[12,13] When reactions are carried out in the presence of coordinating solvent, viz. dimethylformamide and pyridine, axial positions in the resulting complexes are occupied by the solvent molecules [reaction (2)] [Fig. 1 (**IIa**)].

These reaction products also show magnetic moments corresponding to two unpaired spins (Table 2) and exhibit electronic spectral bands at 10,000, ν_1($^3A_{2g} \rightarrow {}^3T_{2g}$), 17,000, ν_2($^3A_{2g} \rightarrow {}^3T_{1g}$) and 24,500 cm^{-1} ν_3[$^3A_{2g} \rightarrow {}^3T_{1g}(P)$] corresponding to tetragonal geometry. The transition energy of the complexes obtained in reaction (2) is higher than the complexes of reaction (1). This may be attributed to the higher ligand field of the solvent (DMF/Py) molecules than the chloro group.

$$[Ni\{R_1R_2C{=}N{-}N{=}C(S){-}NH_2\}_2] + 2RCOCl$$

$$\xrightarrow{DMF/Py} \left[Ni\left\{ R_1R_2C{=}N{-}N{=}C\left(S{-}C\begin{matrix} \overset{O}{\parallel} \\ R \end{matrix} \right){-}NH_2 \right\}(DMF/Py)_2 \right] Cl_2 \qquad (2)$$

$$R_1 = CH_3, R_2 = CH_3 \text{ or } C_2H_5 \text{ and } R = CH_3 \text{ or } C_6H_5$$

It is interesting to note that reaction (1) without solvent is endothermic while reaction (2) in coordinated solvents like dimethylformamide and pyridine is exothermic. This may be explained on the following lines. In the course of reaction (2), the solvent molecules first occupy axial positions to form a neutral pseudo-octahedral complex as shown below:

$$[Ni\{R_1R_2C{=}N{-}N{=}C(S){-}NH_2\}_2(solvent)_2]$$

These mercaptide groups in the intermediate complex would become more reactive compared to those in the parent compound, as the equatorial metal sulphur link is weakened because of axial coordination.

All these reactions products are highly sensitive to moisture. The coordinated thioester group undergoes hydrolysis [reactions (3) and (4)] to yield the corresponding acid and the coordinated thioketo group.

The reaction products are also paramagnetic and exhibit magnetic moments in the range 2.98–3.02 BM (Table 2). Electronic spectra of these complexes exhibit bands at 9600–10,000, 16,800–17,000 and 24,200–24,600 cm^{-1} (Table 2) corresponding to pseudo-octahedral geometry.

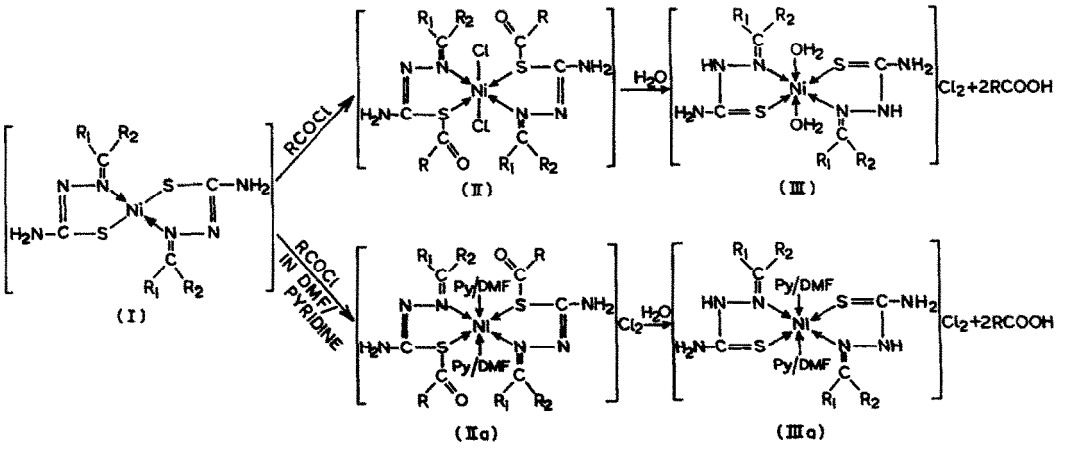
Acids which are obtained during hydrolysis reactions have been characterised by their IR and spectral studies.

$$\left[Ni\left\{ R_1R_2C{=}N{-}N{=}C\left(S{-}C\begin{matrix} \overset{O}{\parallel} \\ R \end{matrix} \right){-}NH_2 \right\}_2 Cl_2 \right] + 4H_2O$$

$$\rightarrow [Ni\{R_1R_2C{=}N{-}NH{-}C(S){-}NH_2\}_2(H_2O)_2]Cl_2 + 2RCOOH \qquad (3)$$

$$\left[Ni\left\{ R_1R_2C{=}N{-}N{=}C\left(S{-}C\begin{matrix} \overset{O}{\parallel} \\ R \end{matrix} \right){-}NH_2 \right\}_2(Py/DMF)_2 \right] Cl_2 + 2H_2O$$

$$\rightarrow [Ni\{R_1R_2C{=}N{-}NHC(S){-}NH_2\}_2(Py/DMF)_2]Cl_2 + 2RCOOH \qquad (4)$$



$$R_1 = CH_3, R_2 = CH_3 \text{ or } C_2H_5 \text{ and } R = CH_3 \text{ or } C_6H_5$$

(*Received* 9 *January* 1984; *accepted* 17 *August* 1984)

Abstract—Photoreduction of water is achieved with the system tris(2,2'-bipyridine)rhodium(III)/dextrose under UV illumination. A strong pH effect is exhibited with a maximum at pH = 1.30. Explanations are given both in terms of thermodynamics and kinetics of the involved reaction. Heterogeneous redox catalysts are tested, with best efficiency for TiO_2 supported Pt(0).

The conversion and storage of solar energy in the form of a chemical potential has aroused considerable interest, from the point of view of fundamental knowledge, and for its application in the near future. The production of clean fuels, such as hydrogen, has recently been extensively studied in systems using either homogeneous (dyes, metal complexes) or heterogeneous (semiconductor material) photosensitizers.[1,17,18]

When decomposition of water aims only at the production of hydrogen, various organic electrodonors such as substituted tertiary amines are used as reducing agents. The latter are stoichiometrically oxidized with respect to the hydrogen evolution.

The use of raw material or biological wastes like carbohydrates as a donor material, though requiring more energetic photons, should render the energy conversion aspect more promising because of a valuable recovery of otherwise worthless biochemicals.

As a continuation of earlier work on the photogeneration of hydrogen with the CdS/tertiary amines or carbohydrates systems,[2] this report describes results obtained with the tris(2,2'-bipyridine)rhodium(III)/dextrose/redox catalyst system. Dextrose (D) is chosen to represent heavier oligo- and polysaccharides and the rhodium complex is a good homogeneous UV-photosensitizer.

The effect of pH in hydrogen productivity efficiency and the action of heterogeneous redox catalysts, i.e. platinum deposited on finely dispersed supports, are particularly studied. These two factors markedly affect the overall efficiency of the process.

EXPERIMENTAL

Chemicals

The following reagents were used without further purification (unless otherwise stated) and obtained from commercial sources as indicated hereafter: $RhCl_3 \cdot 3H_2O$ (for synthesis, Merck); $CoCl_2 \cdot 6H_2O$ (pur, Merck); 2,2'-bipyridine, TiO_2, Nb_2O_5 and Al–Ni 50/50 alloy (A.R. quality grade, U.C.B.); $SrTiO_3$ (purity > 99.5%, Alfa Ventron); H_2PtCl_6 10% solution (A.R. Merck); *N*-ethylmorpholine (for synthesis, Merck); Al_2O_3–Pt 10% (purissimum, Fluka); charcoal–Pt 10% (catalyst grade, Koch–Light Laboratories); Ru sponge (spectrographic standard substance, Johnson Matthey & Co.).

Monodistilled water was used to make up the aqueous solutions (resistivity > 10^6 Ω. cm).

Procedure for the preparation of the catalysts

Catalysts 1–4: Ni–Al alloy, $H_2PtCl_{6\,aq}$, platinum on charcoal or on activated Al_2O_3 were used from commercial sources without any further preparation.

Catalyst 5: an aqueous solution (50 μl) of H_2PtCl_6 0.20 M was added to a suspension of TiO_2 (1.0 g in 5 cm^3 H_2O). The mixture was stirred in air for 24 h at

* Author to whom correspondence should be addressed.

room temperature and evaporated to dryness on the sandbath. This last operation was repeated after addition of 5 cm^3 water and mixing. The solid obtained was ground in an agate mortar and put for 24 h in an oven at 120°C. This impregnated powder was reduced for 2 h under a flow of H_2 at 200°C, allowed to cool down to 25°C for another 2 h and to stand 2 h under H_2.

Catalyst 6: same procedure as for catalyst 5 using a suspension of Nb_2O_5 (0.5 g in 2.5 cm^3 H_2O) and $SrTiO_3$ (0.5 g in 2.5 cm^3 H_2O).

Catalyst 7: same procedure as for catalyst 5 using 500 μl of aqueous H_2PtCl_6.

Catalyst 8: metallic Ru sponge was heated at 960°C in air for 42 h (conditions previously established by thermogravimetric analysis).

Catalyst 9: $SrTiO_3/RhO_x$ was prepared according to reference 5.

The percentage of metal loading for these catalysts is indicated in Table 2.

Procedure for hydrogen generation experiments

As a function of pH. Illumination experiments were conducted on a 30 cm^3 aliquot of an aqueous solution containing 25 mg tris(2,2'-bipyridine)Rh(III)chloride tetrahydrate, 270 mg dextrose (5×10^{-2} M) at adjusted pH (pH 0.00: H_2SO_4 1 M; pH 0.61: H_2SO_4 0.25 M; pH 0.77: $KHSO_4$ 2 M; pH 1.30: $KHSO_4$ 0.5 M/K_2SO_4 0.5 M; pH 2.00: $KHSO_4$ 0.24 M/K_2SO_4 0.24 M; pH 2.73: H_3PO_4 0.2 M/NaH_2PO_4 0.6 M; pH 4.36: NH_4Cl 0.5 M/NaH_2PO_4 0.5 M; pH 7.00: NaH_2PO_4 0.5 M/Na_2HPO_4 0.5 M; pH 9.23: H_3BO_3 0.2 M/KOH 0.1 M; pH 14.0 NaOH 1 M).

The round bottomed 100 cm^3 Pyrex bulb was dipped to half its height in a thermostatted water bath held at 30 ± 1°C. The solution was thoroughly stirred (750 rpm) and the upper part of the vessel illuminated as close as possible by three 125 W high pressure Hg-lamps (Philips). The solution was degassed under vacuum before irradiation so that the internal pressure reached about 20 mmHg (2.7 kPa). At the end of an experiment, the internal pressure was brought to atmospheric pressure by admission of water through a side arm fitted with a Teflon plug.

As a function of the catalysts. The redox catalysts were all tested in identical experimental conditions, i.e. 25 mg $Rh(bipy)_3Cl_3 \cdot 4H_2O$/48.5 mg 2,2'-bipyridine (1.1×10^{-2} M)/2.700 g dextrose (0.5 M)/30 cm^3 $KHSO_4$ 0.2 M (pH 1.30)/redox catalyst as stated in the Table 2.

A 100 cm^3 quartz bulb was used and its bottom thermostatted at 21 ± 1°C. The light source was provided by a 1000 W ultrahigh pressure Xe–Hg lamp (Müller Electronik-Optik, $\lambda > 260$ nm) fitted with an IR water filter (spectral transmission 200–900 nm); the light beam was focused on the solution by means of appropriate lenses.

Analysis of the gas

The residual gas contained in the flask after equilibration of pressure was collected through a septum valve and quickly injected as previously described[2] into the gas chromatograph (Porapak column at 50°C, N_2 as carrier). The VPC detector was a catharometer calibrated by means of a 99.98% pure H_2 standard. Analysis showed that the gas is mainly H_2 with some residual air and water vapour. Known volumes of gas were analyzed and total volume measured in a reversed burette in a water bath or with an appropriate syringe.

Preparation of the tris(2,2'-bipyridine)rhodium(III) trichloride complex $Rh(bipy)_3Cl_3 \cdot 4H_2O$ was made according to the reference 3. The yield was 96.5%. The water content was measured by thermogravimetric analysis.

The electronic spectrum showed maxima at 305 nm and 319 nm with absorption coefficients (ε) amounting to 45,000 and 43,500 l $mole^{-1}$ cm^{-1} respectively [lit.[4] for $Rh(bipy)_3(ClO_4)_3$ λ max (ε): 305(33,800), 318(31,600)] [lit.[3] for $Rh(bipy_3)(SO_4)_{1.5}$ λ max (ε): 305(43,800), 318(46,700)]. pH measurements were made by means of a calibrated (±0.01) pH meter fitted with a glass–calomel combined electrode (Radiometer Copenhague). Spectrofluorimetric experiments were performed with a Perkin–Elmer MPF-3 spectrofluorimeter.

RESULTS AND DISCUSSION

The proposed reaction scheme is shown in the equation sequence (1)–(4) where D stands for dextrose and bipy for 2,2'-bipyridine. It should be pointed out that the photoreaction proceeds without any relay species.

$$Rh(bipy)_3^{3+} \underset{\text{radiationless decay}}{\overset{h\nu}{\rightleftharpoons}} {}^*Rh(bipy)_3^{3+} \quad \text{(counterion: } Cl^-\text{)}, \quad (1)$$

$${}^*Rh(bipy)_3^{3+} \xrightarrow{D} \text{reduced rhodium(II) complex} + D^+, \quad (2)$$

$$\xrightarrow{D^+} Rh(bipy)_2^+ + bipy + D^{2+},$$

$$Rh(bipy)_2^+ + 2H_3O^+ \xrightarrow{bipy} Rh(bipy)_3^{3+} + 2H_2O + H_2\nearrow, \quad (3)$$

$$D^{2+} \xrightarrow{H_2O} \text{aldonic acids}. \quad (4)$$

Table 1. Photogenerated H_2 evolution rates as a function of pH in the $Rh(bipy)_3^{3+}$/dextrose/buffer systems (see Experimental for reaction conditions)

pH	Irradiation time (h)	Volume of H_2 produced (ml)	Average H_2 evolution rate ($\mu l\ h^{-1}$)*

*The quoted errors on average evolution rates are calculated as standard deviation for 10 samples at least and include the error on calibration.

and the overall reaction may be written

$$\text{Dextrose} + H_2O \xrightarrow{h\nu} \text{aldonic acid} + H_2. \quad (5)$$

Table 1 and Fig. 1 show a strong pH effect on the H_2 evolution. This may arise from several factors:

(1) A thermodynamic reason is invoked (redox potential of some occurring species of the type $Rh(bipy)_{3-n}^{x+}$ are represented in Fig. 3). The driving force of reaction (3) is modulated by the H_3O^+ concentration as E_0 $[Rh(bipy)_3^{3+}/Rh(bipy)_2^{+}]$ = −0.67 V (NHE at pH = 7)[3] and E_0 $[H_3O^+/H_2]$ = 0.00–0.059 pH) V. This explains the noncapability of reaction (3) to occur in alkaline media. Indeed, from pH = 9.23 and above a dark red-violet colour develops slowly and accumulates in solution as the reaction proceeds; at pH = 14.0 this colour is obtained within a minute; admission of air consumes this coloured species which is again formed after an air-free illumination and the cycle can be repeated several times. This air sensitive reduced complex has the spectrophotometric characteristics of $Rh(bipy)_2^{+}$ (λ max = 520 nm) and has been reported as such in voltametric experiments.[24]

(2) A kinetic hindrance for H_2 evolution caused by overvoltage (no specific redox catalyst being added because of voluntary limitation of experimental parameters in the reaction) adds to the thermodynamic conditions. This is invoked for the non-evolution of H_2 in neutral and the low level evolution in weakly acidic media.

(3) Maximum H_2 evolution occurs around pH = 1.30 and stronger acidic media (i.e. pH = 0.0) nearly make it stop. Chemical stability of the tris(2,2′-bipyridine)rhodium(III) photosensitizer may be affected by protonation of the ligand [equation (6)] and subsequent loss of the photophysical characteristics.

$$Rh(bipy)_3^{3+} \overset{H^+}{\rightleftharpoons} Rh(bipy)_3H^{4+} \overset{H^+}{\rightleftharpoons} Rh(bipy)_2^{3+} + (\text{bipy } H_2)^{2+} \overset{H^+}{\rightleftharpoons} \cdots \quad (6)$$

The unsaturated $Rh(bipy)_x^{3+}$ species then undergoes rapid aquation or addition of the chloride counterion.

In this context, the $Rh(bipy)_3^{3+}$ complex displays a similar mechanistic behaviour as during its relay role in the $Ru(bipy)_3^{2+}/Rh(bipy)_3^{3+}$/tertiary amine/bipy/redox catalyst system,[19] although UV excitation and quenching by dextrose does occur. UV sensitization has been chosen to permit difficult (i.e. endoergic) reaction to take place efficiently. This disadvantage of using UV can be lowered, if one bears in mind that the absorption bands of the rhodium complex are shifted towards visible light[21] because of modification of the ligand[3] (phenanthroline, dimethylbipyridine, ...) or change of the metal cation (iridium and osmium complexes behave similarly).[6,20]

Extensive photophysical studies of rhodium (III) complexes with polyheterocyclic nitrogen ligands[7–11] show that luminescence takes place mostly at visible wavelengths (450 nm, 485 nm, 580 nm, i.e. 2–3 eV). Thus, a shift of the absorption bands towards the visible should not considerably affect the emission energies and hence the thermodynamic and redox properties. However, preliminary spectrofluorimetric experiments with $Rh(bipy)_3Cl_3$ and dextrose rather emphasize a radiationless decay

mode (see also reference 23). The type of excitation is also important: a metal to ligand charge transfer (MLCT) promotes an effective electron transfer from a donor to an excited state.

In the present case, $Rh(phen)_3^{3+}$, which is closely related to $Rh(bipy)_3^{3+}$ from a structural point of view, exhibits dual luminescence emission, showing both a metal-centred (^{3}MC) excited state at 298 K and a ligand centred excited state (^{3}LC) in a rigid matrix at 77 K. The temperature plays a major role and its variations should yield information about the transition from one excitation mode to another, which may pass by MLCT.

Further work is required to elucidate this question. On the other hand, the use of dextrose, or its heavier derivatives, as an electron-donor is also favoured by the application potentialities of its oxidation products, aldonic acids.

Table 2 and Fig. 2 display the catalytic capability of some platinum carrying substrates for enhancing the H_2 evolution.

Some of these catalysts were highly efficient compared with an experiment where no catalyst was added.

The most active ones are the semiconductors supporting platinum metal (TiO_2, Nb_2O_5, $SrTiO_3/Pt^0$) which are known for their small overpotential for H_2 evolution in water electrolysis.[12,13] Many factors contribute to the catalytic efficiency: degree of dispersion and area of the support, electrical properties of the powder (conducting as charcoal, insulating as Al_2O_3 or semi-

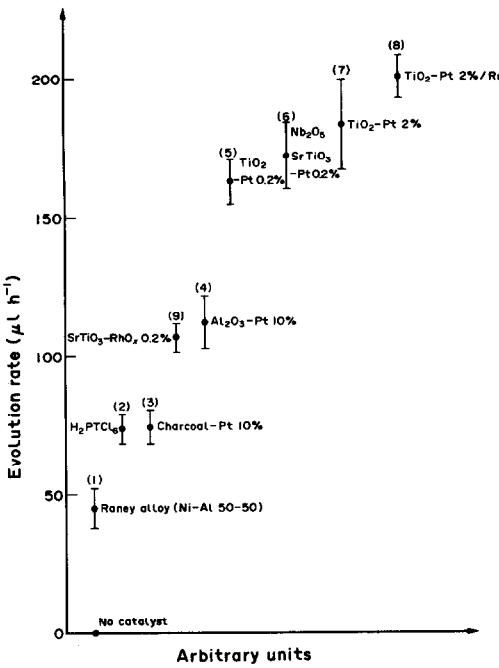

Fig. 2.

conducting) and optical properties. This latter behaviour is thought to explain the higher capability of semiconductors: these may act in a photoactive step of the reduction process by involving both band-gap excitation (i.e. generation of a chemically reactive hole–electron pair) and electron injection in the conduction band (E_0 [$Rh(bipy)_3^{3+}/Rh(bipy)_2^{+}$] $= -0.67$ V $< E_0$ (e_{CB}^- $SrTiO_3$ and Nb_2O_5) $= -0.60$ V, $< E_0$ (e_{CB}^- in TiO_2) $= -0.25$ V).[14,16] Since E (H_3O^+/H_2) $= -0.077$ V at pH = 1.30, heterogeneous efficient H_2 evolution may occur. On the other hand, surface states of the catalysts may act in a favourable way and strong metal–support interaction of low temperature reduced noble metals on TiO_2[15] is responsible for a long-term chemical stability of the deposits. Addition of RuO_2 slightly enhanced the overall efficiency, probably by oxidation catalysis. H_2PtCl_6 has a homogeneous catalytic role, as no visible colloid was detected by laser light scattering after irradiation. Ni^0–Al^0 alloys must not be considered as good catalysts: 82.5% of the Ni content was recovered in solution (as determined by dimethylglyoxime gravimetry) $Co(bipy)_3Cl_2$, tested as a potential relay, decreases the efficiency. $SrTiO_3$ loaded with rhodium oxide RhO_x showed a good activity as previously observed in water photolysis experiments.[5]

Further investigation is in progress using gamma-radiation induced preparations of finely dispersed noble metal catalyst aggregates. Catalysis experiments were conducted in the presence of free bipyridine (10^{-2} M) ($pK_A = 4.30$)[22] to avoid kinetic limitation in reaction (3), as this compound is known to have a catalytic role in the regeneration of $Rh(bipy)_3^{3+}$ from $Rh(bipy)_2^{+}$ when used as a relay.[3]

Differences in efficiency between pH and catalysis experiments result from changes of the experimental conditions [addition of bipyridine (i.e. change of pH), temperature, presence of potassium sulphate, type of vessels and lamps, etc.]. Nevertheless each type of experiment has been achieved in carefully controlled identical conditions.

The considerations in the present work permit optimistic views as to the double purpose of producing hydrogen from photoreduction of water while revalidating worthless biochemicals.

STRUCTURAL STABILITY INDEX OF HETEROPOLY- AND ISOPOLY-ANIONS—III. APPLICATION TO SITE-VACANT FRAGMENTS OF KEGGIN AND DAWSON POLYANIONS α-$[PW_{12}O_{40}]^{3-}$ AND α-$[P_2W_{18}O_{62}]^{6-}$

(*Received* 20 *March* 1984; *accepted* 17 *August* 1984)

Abstract—For some site-vacant species of Keggin and Dawson polyanions α-$[PW_{12}O_{40}]^{3-}$ and α-$[P_2W_{18}O_{62}]^{6-}$ containing hypothetical species, the structural stability indexes have been estimated. For the hypothetical species, the effect of negative charge should be also taken into account as a main factor. The electric condition has been proposed as a criterion for the existing polyanions. The site-vacant species of Keggin and Dawson polyanions, which have not been found yet, have been discussed using a combination of the structural stability and the electric condition.

In our previous papers,[1,2] the structural stabilities of a number of heteropoly- and isopoly-anions have been discussed in terms of the stability index η. The index has been estimated according to $\eta = (\Sigma B \cdot C)/A$, where A is the number of octahedral MO_6 units constituting the polyanion cage, B the number of MO_6 units constituting the closed loop and C the number of closed loops. The closed loop consists of the interpenetrating loop $-O_c-M-O_b-M-O_c-$ formed by a junction of M ion and bridging oxygens (O_b, O_c) around the polyanion cage. Site-vacant polyanions, formed by removal of some MO_6 octahedra from Keggin- and Dawson-structure polyanions $[XM_{12}O_{40}]^{n-}$ and $[X_2M_{18}O_{62}]^{n-}$ (M = Mo, W), have been used as starting materials for the preparation of other interesting heteropolyanions.[3–13] In this paper, we discuss the structural stabilities of some site-vacant Keggin and Dawson polyanions containing hypothetical species and also show that the electric charge is another important factor.

RESULTS AND DISCUSSION

The site-vacant polyanions derived from the Keggin-structure α-$[PW_{12}O_{40}]^{3-}$ ion have some isomers, which correspond to the geometrical isomers of α-$[PZ_xW_{12-x}O_{40}]^{n-}$ arising from partial substitution of a metal ion Z. They have been previously counted by Pope and Scully.[14] Using the molecular models, we have counted the number of closed loops and estimated the stability index. The formulae and structural parameters of the species with non-zero η are listed in Table 1. The numbering of the vacant sites is performed according to the method of Pope and Scully (Fig. 1).[14] The total isomers in di- and tri-vacant Keggin ions are 5 and 13, respectively. It can be readily verified that unlisted isomers such as the 1,4-vacant $[PW_{10}O_{38}]^{11-}$ ion, the 1,2,4- and 1,4,12-vacant $[PW_9O_{36}]^{13-}$ ions, the 1,2,6- and 1,3,4-vacant $[PW_9O_{35}]^{11-}$ ions, the 1,4,9-, 1,4,10- and 1,5,10-vacant $[PW_9O_{37}]^{15-}$ ions have no closed loop, or $\eta = 0$. The isolated polyanions are only monovacant $[PW_{11}O_{39}]^{7-}$ and trivacant $[PW_9O_{34}]^{9-}$ ions[15–23] and the others are unknown, or hypothetical. The 1,2,3- and 1,6,7-isomers of the trivacant $[PW_9O_{34}]^{9-}$ ion are usually designated B-α and A-α, respectively.[16] The latter is also called a half-Dawson structure polyanion.[1,2] The crystal and molecular structures of the trivacant species, $[PMo_9O_{34}H_3]^{6-}$ and $[PMo_9O_{34}H_6]^{3-}$, which are protonated forms of the 1,6,7-trivacant $[PMo_9O_{34}]^{9-}$ ion, have been determined by D'Amour and Allmann,[21] Strandberg,[22] and D'Amour.[23] Recently, the mono- and trivacant species have also been found in the aqueous solutions by base degradations of $[SiW_{12}O_{40}]^{4-}$ and $[PW_{12}O_{40}]^{3-}$ polyanions.[24,25]

* Species that conflict with the electric condition (1) in the text.

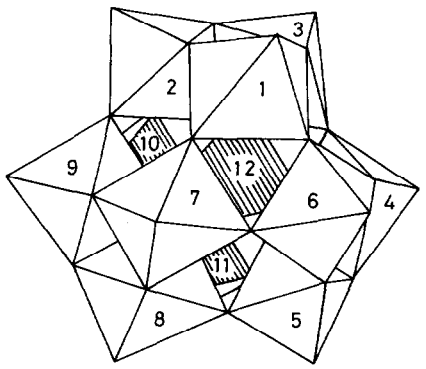

Fig. 1. Idealized α-Keggin structure polyanion and the numbering of vacant site according to Pope and Scully.[14] Tetrahedral part of the central heteroatom is omitted for clarity.

The index of structural stability has been conveniently applied only to isolated, or existing polyanions, but not to hypothetical ones. Whether such polyanions exist or not should be due to many factors other than the structural stability. The most important factor will be the effect of the negative charge of the polyanion. We therefore explored the heteropoly- and isopoly-anions of more than 250 examples which have been shown to be isolated or existing compounds, including a number of combinations of X, Z and M in the substituted polyanions $[XZ(H_2O)M_{11}O_{39}]^{n-}$ and $[X_2Z(H_2O)M_{17}O_{61}]^{n-}$ (X is a heteroatom, Z is a substituted metal ion and M is Mo or W). The following relation about the negative charge could

be deduced:

$$-4/3 \leqslant p \leqslant -1/6. \quad (1)$$

In this relation, p is $-n/A$, $-n$ is a charge of polyanion and A is the number of octahedral MO_6 units constituting the skeleton of polyanion to whom the number of $ZO_5(H_2O)$ unit in the substituted polyanions is also included. The total charge $-n$ involves the contribution from the heteroatom. The p is representative of mean electric charge per MO_6 unit. The lower limit of p is observed in the polyanions such as $[M_6O_{19}]^{8-}$ (M = Nb, Ta)[26] and $[XW_6O_{24}]^{8-}$ (X = Ni(IV), Mn(IV)),[27,28] and the upper limit in the $[PRe(VII)W_{11}O_{40}]^{2-}$ polyanion.[29] The relation (1) results in an electric condition for the isolated or existing polyanions, independently of the magnitude of the structural stability index. If the condition (1) can be applied to the polyanions in the Table 1, the following species are excluded; $[PW_9O_{36}]^{13-}$ in the trivacant ions and all of the tetravacant ($[PW_8O_{33}]^{13-}$, $[PW_8O_{34}]^{15-}$), the pentavacant ($[PW_7O_{31}]^{15-}$) and the hexavacant ($[PW_6O_{28}]^{15-}$) ions. These are asterisked in Table 1. In the remainder, the divacant ions $[PW_{10}O_{37}]^{9-}$ and $[PW_{10}O_{38}]^{11-}$ containing two geometrical isomers with non-zero η have been unknown. Even though they exist, three polyanions except the 1,11-vacant $[PW_{10}O_{38}]^{11-}$ ion are predicted to be unstable or metastable from the magnitude of the index.[1,2]

Here it should be noted that the asterisked species in Table 1 may possibly exist in the protonated forms or the modified forms by some attaching groups, whenever the electric condition is attained. The $[CH_3AsMo_6O_{21}(H_2O)_6]^{2-}$ anion previously reported by Matsumoto is an assemblage of six MoO_6 octahedra and a tetrahedral CH_3AsO_3 group, the former constituting a ring with alternate edge- and corner-sharing and the latter locating in the centre of ring.[30,31] Thus, this polyanion can be considered to be the derivative of the 1,2,3,5,8,11-hexavacant Keggin ion, or the compound possessing the similar skeleton. However, the electric condition (1) is kept, since each molybdenum atom has two terminal oxygens in the *cis* position and is coordinated by one water molecule. The structural stability is based on one closed loop passing through six MoO_6 octahedra ($\eta = 1$).

The site-vacant polyanions studied here lead to the substituted Keggin ions by filling the sites with other metal ions. Since the stability indexes of the substituted polyanions are the same as that of the Keggin ion ($\eta = 2$),[2] the structural stabilities of the site-vacant polyanions become to be more increased by filling the lacunary sites. Even though some site-vacant polyanions as precursors of substituted ions are unstable, the idea of structural stability does not preclude the presence of polyanions substituted in such lacunary sites. For instance, 1,4-substituted Keggin ions $[Ti_2W_{10}PO_{40}]^{7-}$ and $[\{CpFe(CO)_2Sn\}_2W_{10}PO_{38}]^{5-}$ have been recently prepared by Knoth and Domaille.[32] Although the 1,4-vacant polyanion $[PW_{10}O_{38}]^{11-}$ is considered to be a precursor of them, it is predicted to be unstable from the stability index ($\eta = 0$). In fact, such di-substituted polyanions have been prepared not from an isolated $[PW_{10}O_{38}]^{11-}$ compound, but from the "template" reactions of $TiCl_4$ and $CpFe(CO)_2SnCl_3$ with aqueous solutions of sodium tungstate and sodium dihydrogen phosphate under rather basic conditions.[32]

In the Dawson-structure α-$[P_2W_{18}O_{62}]^{6-}$ polyanion, many site-vacant species and their geometrical isomers can also be considered. The combination of the electric condition and the structural stability index with $\eta > 0.6$ allows the existence of limited species of them. They are listed in Table 2 together with the structural parameters. The numbering of the vacant sites is performed according to the method of Contant and Ciabrini (Fig. 2).[33] The stability index of more than 0.6 may be a criterion for many isolated polyanions.[1,2]

Only a few examples have been isolated.[33–36] Two monovacant polyanions, the so-called α_1- and α_2-forms of $[P_2W_{17}O_{61}]^{10-}$, have been well-known.[33,36] The stability index is estimated to be 1.29 for α_1-(4-vacant) form and 1.18 for α_2-(1-vacant) one. These indexes indicate both isomers will be formed in nearly equal probability or in the rather inclination to α_1-form, if the main factor that governs the metal departure from 1- and 4-positions of α-$[P_2W_{18}O_{62}]^{6-}$ is regarded as quite equivalent. However, it has been known that the partial degradation of the parent ion gives α_2-form only, and the α_1-form is produced by acidifying of the further alkaline-degraded solution of α_2-form, and then the α_1-form slowly isomerises into the α_2-form.[34] These should be attributed to the essential natures of the metals of 1- and 4-positions, but not to the structural stabilities, and should also depend strongly upon the experimental conditions.

Only one of many possible trivacant polyanions has been prepared, the vacant sites of which are suggested to be 1,2,3-positions.[4,33,34] Of the polyanions listed in Table 2, the hexavacant $[H_2P_2W_{12}O_{48}]^{12-}$ ion, which is a protonated form of the $[P_2W_{12}O_{48}]^{14-}$ ion, has been known.[33,34] The vacant sites are probably 1,4,9,10,15,16-positions. Only from the electric condition ($p = -1.5$), other unlisted hexavacant species, for instance, 1,2,3,16,17,18-vacant $[P_2W_{12}O_{50}]^{18-}$ ion is excluded, although its stability index is adequately

large, or $\eta = 1$ ($A = 12$ and $(B, C) = (6, 2)$). If the 1,2,3,16,17,18-isomer is readily protonated or modified with some attaching groups and the electric restriction is relaxed, such a form can possibly exist and may be more stable than the 1,4,9,10,15,16-isomer. Although many possible di-, tetra- and pentavacant species are listed in Table 2, none of them have been prepared.

Our approach rules out the possibility of the species with more than heptavacant species, except the half-unit of the Dawson-structure which corresponds to the enneavacant Dawson polyanion and also to the 1,6,7-isomer of the trivacant Keggin ion. This prediction may be justified from the polarographic experiments of the alkaline degradation of $[P_2W_{18}O_{62}]^{6-}$ in solution by Contant and Ciabrini.[34]

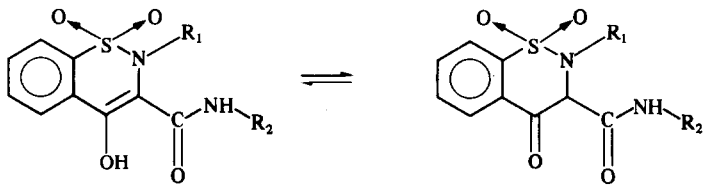
Abstract—The preparation, spectroscopic and magnetic properties are reported for complexes of iron(III), cobalt(II), nickel(II), copper(II) and zinc(II) with the anti-inflammatory drug 4-hydroxy-3-(5-methyl-3-isoxazolocarbamyl)-2-methyl-2*H*-1,2-benzothiazine-1,1-dioxide (isoxicam). In all the complexes studied the isoxicam acts as a chelate monoanionic ligand with coordination involving the enolate oxygen atom and the carbonyl oxygen atom of the amide group. The copper(II) complex appears to be square planar whereas the hydrated cobalt(II), nickel(II) and, by inference, zinc(II) complexes possess an octahedral stereochemistry involving two coordinate drug molecules. The iron(III) complex contains three coordinated chelate isoxicam ligands.

The current therapeutic approach to treating musculoskeletal diseases, such as rheumatoid arthritis, relies heavily on non-steroidal anti-inflammatory agents.[1,2] However, these drugs may cause adverse reactions such as peptic ulceration and gastrointestinal bleeding. Recently increasing interest has been shown in the therapeutic use of metallic compounds in treating connective tissue disease.[3] Copper[4,5] and gold[6,7] preparations specifically have been shown to exhibit anti-inflammatory effects. Copper complexes of a number of non-steroidal anti-inflammatory drugs have been reported to be more potent anti-inflammatory agents and less ulcerogenic than the parent anti-inflammatory drug.[8]



The work reported here is part of a comprehensive study aimed at isolating and characterising coordination compounds formed between non-steroidal anti-inflammatory drugs and transition metal ions. Non-steroidal anti-inflammatory agents may be characterised chemically as lipophilic, moderately strong organic acids. Although many such agents are arylalkanoic acids[2] current interest has focussed on a series of enolizable amides.[9] Three *N*-heterocyclic 3-carboxamides of 4-hydroxy-2-methyl-2*H*-1,2-benzothiazine-1,1-dioxide, namely sudoxicam ($R_1 = CH_3$; R_2 = 2-thiazole), piroxicam ($R_1 = CH_3$; R_2 = 2-pyridyl) and isoxicam ($R_1 = CH_3$; R_2 = 5-methyl-3-isoxazolyl) (see Fig. 1), have attracted particular attention as anti-arthritis drugs.[10,11]

This paper presents the results of an investigation of the complexes formed by isoxicam with some first row transition metal ions.

EXPERIMENTAL

Isoxicam was supplied by Warner–Lambert/Parke–Davis and was used without further purification. All metal salts used, with the exception of iron(III) chloride hexahydrate (B.D.H.), were of Analar reagent grade.

Fig. 1.

Preparation of complexes

Isoxicam (1.5 g; 1 mole equiv) was dissolved in 0.1 M sodium hydroxide (50 cm^3) by slow addition of the alkali with constant agitation and warming to $\leqslant$ 60°C. The volume of alkali was deliberately kept to a minimum to exclude excess hydroxide ions. The resulting pale yellow solution was filtered to remove excess undissolved ligand and the filtrate was added slowly with stirring to a cold solution of the metal chloride (0.5 mole equiv) in 35 cm^3 of ethanol [for Fe(III), Co(II), Ni(II) or Cu(II)) or water (Zn(II)]. The resulting precipitate of the metal complex was filtered off under vacuum, washed with cold ethanol, followed by cold ethoxyethane and dried at 80°C. All the metal complexes were obtained in high yield (> 90%) as microcrystalline powders.

Physical measurements

Carbon, hydrogen and nitrogen analyses were performed in the microanalytical laboratory of the University College of North Wales, Bangor. The diffuse reflectance spectra were determined on a Beckmann DK-2A spectrophotometer fitted with a standard reflectance accessory. IR spectra (4000–650 cm^{-1}) were recorded on a Perkin–Elmer 197 spectrophotometer in sodium dry Nujol mull using KBr plates. Room temperature magnetic measurements on powdered samples were made on a Newport Instruments Gouy balance using gouy tubes calibrated with $HgCo(CNS)_4$.

RESULTS AND DISCUSSION

The complexes were all obtained from solutions of the sodium salt of isoxicam and were precipitated with isoxicam present as a mono-anionic ligand (see Table 1). The Co(II), Ni(II), Fe(II) and Zn(II) complexes were all hydrated but the Cu(II) complex was obtained in an anhydrous state.

IR spectra

A partial assignment of the absorption bands observed for isoxicam and the metal complexes is given in Table 1. The IR spectra of the complexes are

$Zn(isox)_2 \cdot 4H_2O$	41.54	3.16	10.38	41.72	3.97	10.43

very similar to one another and to that of isoxicam itself. The ligand shows a sharp absorption band at 3290 cm^{-1} characteristic of a free O—H group. The absence of this absorption band in the anhydrous $Cu(isox)_2$ complex indicates that the isoxicam is attached to the metal as an anionic ligand via the oxygen atom of the tautomeric enol form. The intensity and broadness of the 3000–3500 cm^{-1} absorption in the remaining hydrated complexes suggests the presence of hydrogen bonded water molecules. The intensity and broadness of the bands in this region for the hydrated complexes (Table 2) is partially reduced on heating the complexes to 200°C, indicating that partial dehydration can occur at elevated temperatures.

The sharp band observed at 1633 cm^{-1} in the free ligand is assigned to the carbonyl stretch of the secondary amide group —CO—NHR_2. This is lowered to 1620 cm^{-1} in all the complexes. The N—H stretch observed in the ligand at 3165 cm^{-1} as a weak absorption is only seen in the anhydrous $Cu(isox)_2$ complex. In the hydrated complexes this vibration is obscured by the broad bands due to hydrogen bonding. The band at 1550 cm^{-1} assigned to the C=N stretching vibration and the two very strong bonds at 1350 and 1190 cm^{-1} and assigned to the asymmetric and symmetric stretching vibrations of the SO_2 group in the free ligand, appear at very similar frequencies in the complexes.

From a consideration of the IR spectra it is clear that in these complexes isoxicam acts as a mono-anionic ligand species through the enolate oxygen atom. It is probable that a second metal ligand bond is formed through the carbonyl oxygen atom of the amide group forming a six-membered chelate ring. It is also possible that the amide nitrogen atom may be involved in some of the complexes.

Diffuse-reflectance spectra (see Table 3)

Isoxicam and all the complexes exhibit an intense charge transfer band above 24,000 cm^{-1}. The reflectance spectra of $Zn(isox)_2 \cdot 4H_2O$ (d^{10}) complex and of isoxicam itself in the region 4000–24,000 cm^{-1} are quite similar, and show only a number of low intensity bands that may be considered to be IR overtones of the ligand. The reflectance spectrum of the zinc(II) complex has therefore been used as reference spectrum for the other complexes as the absorption bands due to isoxicam are slightly more intense in the zinc complex than in the free ligand.

For octahedral cobalt(II) complexes three bands are expected corresponding to the three spin-allowed transitions: $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ (ν_1); $^4T_{1g}(F)$

Table 3. Diffuse reflectance spectra and room-temperature magnetic moments*

	μ_{eff} (BM)	Absorption bands (cm^{-1})	D_q (cm^{-1})

$Ni(isox)_2 \cdot 5H_2O$	3.40	$\nu_1[^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)]$† 10,500 (0.19); $\nu_2[^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)]$† 16,700 (0.25)	1050
$Cu(isox)_2$	1.82	16,700 (sh, 0.40)	1670

* Figures in parentheses represent intensity of the band on the arbitrary Beckmann scale.
† For convenience pseudo-octahedral symmetry is assumed in assigning these bands.

$\rightarrow {}^4A_{2g}$ (ν_2) and ${}^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ (ν_3). However, it has been pointed out[12] that the transition ${}^4T_{1g}(F) \rightarrow {}^4A_{2g}$ corresponds to a two-electron jump and as such will have a much lower oscillator strength than the other two bands and will be much weaker. The reflectance spectrum of $Co(isox)_2 \cdot 4H_2O$ is similar to that formed by complexes in which Co(II) is surrounded by six O donor ligands. Since all the ligands are not identical the complex will not possess O_h symmetry, nevertheless, the departure from O_h seems small and for convenience assignments will be based on pseudo-octahedral symmetry. The single band at 8850 cm^{-1} has therefore been assigned to the ν_1 transition with the ν_2 and ν_3 bands considered to be obscured by the charge transfer edge. The reflectance spectra clearly show the complex to be octahedral and this is supported by the magnetic moment (5.25 BM) which lies in the range normally observed for a high spin cobalt(II) octahedral complex.[13]

The magnetic moment of the $Ni(isox)_2 \cdot 5H_2O$ complex, $\mu_{eff} = 3.4$ BM, does not distinguish clearly between spin-free hexacoordinate nickel(II) and tetrahedral nickel(II) in which there are low-symmetry components of the ligand field. The intensity and position of the reflectance spectra, however, suggests pseudo-octahedral symmetry for the nickel(II) ions. Magnetic moments as high as 3.41 BM are common for tetragonal octahedral complexes.[14] Three bands are expected for octahedral Ni(II) complexes and are assigned, assuming pseudo-O_h symmetry, in increasing order of energy, as the ${}^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$ (ν_1); ${}^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ (ν_2) and ${}^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$ (ν_3). The bands observed at 10,500 and 16,667 cm^{-1} are therefore assigned to the ν_1 and ν_2 transitions respectively with the ν_3 band obscured by the charge transfer edge. The absence of clear splitting of these bands indicates that the extent of departure from O_h symmetry is small.

The microanalysis and IR spectrum indicate that the $Cu(isox)_2$ complex is anhydrous. The copper(II) ion complex may therefore be a four coordinate monomeric complex or a tetragonally distorted polymeric six coordinate complex.* In that latter case the amido nitrogen atoms would be involved. The reflectance spectrum is similar to those reported[15] for copper compounds in which the copper ion is in either an essentially square coplanar environment or in an octahedral environment with a very large tetragonal distortion.

The reflectance spectrum of $Fe(isox)_3 \cdot 3H_2O$ is quite featureless except for a pronounced shoulder at 20,000 cm^{-1} on the edge of the charge transfer band. All *d–d* transitions are spin forbidden and therefore any absorption bands will be extremely weak for an octahedral d^5 ion. The magnetic moment of 5.4 BM is consistent with a high spin complex, being close to the expected spin-only value of 5.9 BM.

GENERAL DISCUSSION

The reflectance spectra and magnetic moments indicate a pseudo-octahedral structure for the $Co(isox)_2 \cdot 4H_2O$, $Ni(isox)_2 \cdot 5H_2O$ and $Fe(isox)_3 \cdot 3H_2O$ complexes (Table 3).

In the $M(isox)_2 \cdot nH_2O$ complexes, the divalent metal ion is coordinated by two chelate isoxicam mono-anionic ligands with two water molecules completing a pseudo-octahedral structure. The complexes are neutral but it is not possible to tell whether the compounds are obtained in the *cis-* or *trans*-form. The $Fe(isox)_3 \cdot 3H_2O$ complex contains three chelate mono-anionic isoxicam ligands giving pseudo-octahedral environment around the iron(III) ion.

The loss of the protonic hydrogen atom from the enol form of the drug produces the anionic ligand which completes bidentate metal attachment by utilising the carbonyl oxygen of the secondary amide group. This can be seen from the disappearance of the O—H absorption band in the complexes and the shift in the position of the C=O absorption band. The bonding of the isoxicam to the metal ion in this way results in six-membered chelate rings and the formation of compounds that resemble β-diketonate complexes.

Acknowledgements—We would like to thank Warner–Lambert/Park–Davis for the supply of isoxicam, Dr P. J. Sadler (Birkbeck College, London) for infrared studies, and The Royal Society for a research in schools award (to P.S.G.). One of us (P.S.G.) would like to thank Mr B. Rees (Headmaster), Dr P. J. Cheshire (Head of Science), the Governors of Rugby School, for the provision of research facilities, and the Rokeby Trust (Rugby School) for further financial assistance.

Abstract—Main group structural models for tetrahedral and octahedral transition metal clusters containing bridging hydrogens are developed using the MNDO quantum chemical technique. The bridging hydrogens in (hypothetical) Be_4H_8 and B_4H_8 tetrahedral systems (μ_3- and μ_2-respectively) are shown to mimic the bridging proton locations in the $H_4Re_4(CO)_{12}$ and $H_4Ru_4(CO)_{12}$ clusters in agreement with simple localized bond models. The perturbation of octahedral cluster bonding by bridging hydrogens is examined via the series $B_6H_6^{2-}$, $B_6H_7^-$ and B_6H_8 which demonstrates increasing preference for capped square pyramidal cluster geometry relative to octahedral with increasing protonation. Localized bond models suggest that frameworks which derive stability from localized bond resonance will be destabilized with increasing protonation relative to more classical forms. Framework protonation fixes 3-centre bond location and reduces the number of resonance structures. Alternatively, an analysis of Mulliken populations suggests that cluster frameworks in which charge asymmetry is significantly increased by protonation are disfavoured over those in which the asymmetry is decreased or maintained on protonation.

Cluster shapes are known to be related to the numbers of electrons that can be thought to hold the skeletal atoms together.[1–8] While specific relationships are well established for main group clusters, the situation for transition metal systems is much less rigorously defined.[9] Still, the detailed comparison of related main group and transition metal clusters provides a systematic way of exploring the latter for evidence of unique behaviour. Thus, we have previously demonstrated for some capped trimetal compounds that the main group analogues adequately explain not only subtle geometrical features but also important characteristics of the electronic structures of the metal compounds.[10] Having demonstrated in at least one system that the main group analogues of transition metal clusters can be used as more than formal models, we now use the same approach to explore the effects of ligand hydrogen atoms on cluster structure.

Recognition of the fact that the type, number and arrangement of hydrogen ligands affects cluster structure is nothing new. The influence of hydrogen atoms on cluster shapes and the site preferences they show are subjects of continuing interest to many researchers including ourselves.[10–15] For example, certain isoelectronic clusters exhibit shapes that differ with the number of hydrogen ligands, e.g. for tetranuclear clusters formally held together by seven skeletal bond pairs, the butterfly shape of tetraborane(10), B_4H_{10}, may be contrasted with the square planar shape of the cyclobutadiene dianion $C_4H_4^{2-}$. Both of these are *arachno* species formally related to the octahedron as the parent polyhedron (the former with a *cis*, the latter with a *trans*

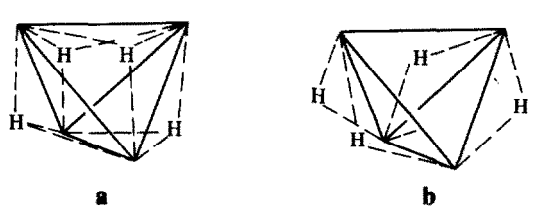
* Author to whom correspondence should be addressed.

arrangement of vacant sites), the difference being dictated by the bonding requirements of the extra six hydrogen atoms of B_4H_{10}. The difference between η^3-allyl-metal complexes (which contain a butterfly-shaped C_3M unit) on the one hand and η^2-carboxylate–metal complexes (which contain planar CO_2M units) on the other hand again reflects the bonding requirements of the extra hydrogen atoms of the former.

The positions preferred by ligands like hydrogen atoms or carbonyl groups tend to reflect the electron distribution in clusters, and vice versa. Hydrogen ligands tend to occupy sites in which they can acquire the most negative (or least positive) charge.[15] Metal carbonyl clusters bearing a relatively high negative charge tend to have more bridging (i.e. electron-withdrawing) carbonyl groups than analogous neutral clusters.[16] For carbonyl but not hydrogen ligands, there is the added complication of the relative capacities for π-bonding of different potential sites.

Addition of protons to anionic clusters to generate hydride clusters is a process that may be accompanied by structural changes that sometimes appear puzzling. For example, whereas $Os_6(CO)_{18}^{2-}$ and $HOs_6(CO)_{18}^{-}$ have octahedral arrangements of their metal atoms, the neutral cluster $H_2Os_6(CO)_{18}$ has a capped square pyramidal arrangement of its metal atoms.[11] Two questions arise: what causes the cluster structure to change on protonation, and is this behaviour peculiar to transition metal systems? This work seeks to answer these questions by exploring the effects of protonation on selected main group cluster systems.

Our approach is to use available quantum chemical techniques to explore aspects of the geometrical structures of main group analogues of specific transition metal cluster systems.[10,17] The calculational technique used is chosen to fit the problem. Here we concern ourselves with the site preferences shown by hydrogen ligands and the structural effects of these ligands when attached to two types of cluster compounds:



(1) Tetrahedral tetranuclear clusters held together by four or six skeletal bond pairs, exemplified by the species Be_4H_8 and B_4H_8 respectively. [The former represents a hypothetical molecular form of beryllium hydride, which is known only as the polymeric solid $(BeH_2)_n$;[18] the latter is a frequently invoked intermediate in the chemistry of B_4H_{10} and other boranes,[19] though too short-lived to have been isolated and/or structurally characterized.]

(2) Octahedral or capped square pyramidal hexanuclear clusters held together by seven skeletal bond pairs, exemplified by the hypothetical species $B_6H_7^-$ and B_6H_8.

TETRAHEDRAL TETRANUCLEAR CLUSTERS

Tetrahedral clusters of four tervalent units may be held together by four skeletal bond pairs (in four 3-centre face bonds, as in the case of B_4Cl_4[20] or six skeletal bond pairs (in six 2-centre edge bonds, as in tetrahedrane, C_4H_4, or derivatives thereof). In molecular orbital terms, in the former, the a_1 and t_2 skeletal bonding MOs are filled. In the latter, the e symmetry bonding MOs also are occupied.

The influence of electron numbers and electron distribution on ligand hydrogen sites is illustrated by the metal carbonyl hydride clusters $(Re_4(CO)_{12}H_4$ (**1**)[21] and $Ru_4(CO)_{12}H_4$ (**2**).[22] The former, with four skeletal bond pairs and μ_3-hydrogen atoms bridging the four triangular faces of the Re_4 tetrahedron (Scheme 1a), has an eclipsed configuration of its four $Re(CO)_3$ units with respect to the Re_4 tetrahedron edges. The latter, with six metal–metal bond pairs, has a staggered arrangement of its $Ru(CO)_3$ units, and the hydrogen ligands bridge four of the six Ru_4 tetrahedral edges (Scheme 1b). These differences, and the hydrogen site preferences in related tetranuclear clusters containing 3, 4 or 6 hydride ligands, have been discussed in detail by Hoffmann *et al.*,[23] who pointed out that the bridging hydrogen atoms occupy the sites that are closest to the regions of maximum metal–metal bonding electron density, as if the hydrides were formed from the parent anions $[M_4(CO)_{12}]^{4-}$ by protonation of the 3-centre face bonds in $[Re_4(CO)_{12}]^{4-}$ or by protonation of four of the 2-centre edge bonds in $[Ru_4(CO)_{12}]^{4-}$. Extended Hückel MO calculations on the species $Fe_4(CO)_{12}H_4^{4+}$ and $Fe_4(CO)_{12}H_4$ as models for **1** and **2** respectively, however, though favouring an eclipsed orientation of the carbonyl ligands in the former and a staggered orientation in the latter, indicated that face-bridging μ_3-sites would be preferred for the hydrogen atoms in both cases, although the energy difference between edge and face sites was small in the case of $Fe_4(CO)_{12}H_4$. These calculations therefore left unresolved the question of whether the hydrogen atoms in **2** occupy μ_2-edge-bridging sites because these are intrinsically preferred for bonding purposes, in spite of the indication to the contrary given by the calculations,

Scheme 1.

or whether these sites are occupied by the hydrogen atoms because the staggered $Ru(CO)_3$ orientation forces them there.

In order to obtain further information about such systems, and in the hope of clarifying the problem, we have carried out MNDO calculations[24]* on two key systems that may be regarded as the main group element "parent" systems for the above transition metal clusters, *viz.* Be_4H_8 as the parent species for $Re_4(CO)_{12}H_4$ (BeH and $Re(CO)_3$ units are isolobal[25] sources of one electron and three AOs for cluster bonding), and B_4H_8 as the parent species for $Ru_4(CO)_{12}H_4$ (BH and $Ru(CO)_3$ units are isolobal sources of two electrons and three AOs for cluster bonding). Possible structures for B_4H_8 have been discussed by Pepperberg, Halgren and Lipscomb[26] who calculated that a relatively open structure, of topology 2112C, in which one boron atom used only three of its four valence-shell AOs, was more likely than compact effectively *closo* structures based on roughly tetrahedral arrangements of the four boron atoms. In our own MNDO calculations on Be_4H_8 and B_4H_8, we therefore imposed a tetrahedral arrangement of the skeletal atoms, albeit capable of distortion from T_d to D_{2d} symmetry if edge-bridging sites were preferred by the extra four hydrogen atoms. Optimized geometries and heats of formation were calculated for both Be_4H_8 and B_4H_8 with (a) μ_3 face-bridging endo hydrogen atoms and (b) μ_2 edge-bridging endo hydrogen atoms in a D_{2d} array.

Be_4H_8: (a) $Be_4(H_{exo})_4(\mu_3\text{-}H_{endo})_4$. Calculation of the heat of formation of Be_4H_8 with bond distances assumed to be as follows: d(Be–H_{exo}), 1.16 Å; d(Be–H_{endo}), 1.30 Å; d(Be–Be), 1.80 Å; angle H_{exo}–Be–Be, 144.5°, gave a value of ΔH_f° of 614 kJ mol^{-1}. After total optimization, it was found that the tetrahedral symmetry and triply-bridging state of coordination of the endo hydrogen atoms were retained. The optimized structure was an expanded version of the original [Fig. 1(a)], placing the metal and endo hydrogen atoms at the vertices of an almost perfect cube, with d(Be–H_{exo}) 1.29 Å, d(Be–H_{endo}) 1.64 Å; d(Be–Be) 2.32Å, angle H_{exo}–Be–Be, 145.2°; and ΔH_f° −727 kJ mol^{-1}.

(b) $Be_4(H_{exo})_4(\mu_2\text{-}H_{endo})_4$. Calculation of the heat of formation of Be_4H_8 assuming d(Be–H_{exo}) = 1.19 Å; d(Be–H_{endo}) 1.32 Å; d(Be–Be) 1.81 Å (whether bridged by μ_2 hydrogen atoms or not) and bond angles H_{exo}–Be–Be, 144.5° and H_{exo}–Be–H_{endo}, 97.5°, gave a value for ΔH_f° of +546 kJ mol^{-1}. When totally optimized, the structure changed from the edge-bridged to the face-bridged structure $Be_4(H_{exo})_4(\mu_3\text{-}H_{endo})_4$ [Fig. 1(a)]. When the structure was allowed to refine while restricted to the edge-bridged geometry [Fig. 1(b)], the heat of formation ΔH_f° fell to −479 kJ mol^{-1}, still some 248 kJ mol^{-1} less stable than the optimized face-bridged form $Be_4(H_{exo})_4(\mu_3\text{-}H_{endo})_4$.

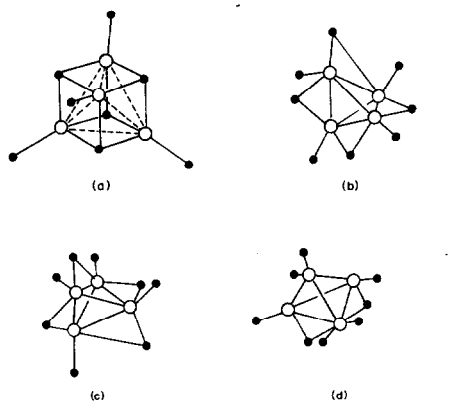


Fig. 1. Representations of the MNDO structures for: (a) Be_4H_8 fully optimized while retaining tetrahedral beryllium core; (b) Be_4H_8 edge-bridged; (c) B_4H_8 fully optimized while retaining cluster geometry; (d) B_4H_8 optimized beginning with face-bridging hydrogens. The open circles are Be or B while the closed circles are H.

B_4H_8: $B_4(H_{exo})_4(\mu_2\text{-}H_{endo})_4$. Calculation of the heat of formation of B_4H_8 assuming d(B–H_{exo}) 1.19 Å, d(B–H_{endo}) 1.32 Å, d(B–B) 1.81 Å (whether bridged or not), angles H_{exo}–B–B 144.5° and H_{exo}–B–H_{endo} 97.5°, gave a value of ΔH_f° = 297 kJ mol^{-1}. When totally optimized, the structure [Fig. 1(c)] retained the edge-bridging hydrogen characteristic, though the B_4 symmetry changed from T_d to D_{2d} as the bridged edges lengthened and the unbridged edges shortened. The optimized structure, with ΔH_f° 185 kJ mol^{-1}, has d(B–B) 1.66 Å (unbridged), 1.96 Å (bridged) d(B–H_{endo}) 1.37 Å, d(B–H_{exo}) 1.16 Å, angles H_{exo}–B–H_{endo} 102.5°, H_{exo}–B–B 138–172°.

(b) $B_4(H_{exo})_4(\mu_3\text{-}H_{endo})_4$. Calculation of the heat of formation of B_4H_8, assuming d(B–H_{exo}) 1.16 Å, d(B–H_{endo}) 1.30 Å, d(B–B) 1.80 Å and angle H–B–B 144.5°, gave a value of ΔH_f° = 1746 kJ mol^{-1}. Total optimization of this structure caused loss of the face-bridged feature, generating a structure in which two of the endo hydrogen atoms were edge-bridging, the other two becoming extra terminal hydrogen atoms. This structure [Fig. 1(d)] was calculated to have ΔH_f° = 95 kJ mol^{-1}. Optimization of the bond lengths while retaining the face-bridging $H_4B_4(\mu_3\text{-}H)_4$ structure gave a value of ΔH_f° of 1208 kJ mol^{-1}, some 1023 kJ mol^{-1} less stable than the edge-bridged structure.

The structural and thermodynamic data for these

* Note that we are not concerned with absolute values of energies but with trends in related compounds. In this way artifacts of the method cancel out.

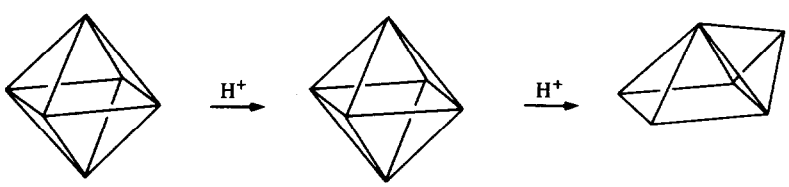
Table 1. Bond distances and angles in the totally optimized structures of $H_4Be_4(\mu_3\text{-}H)_4$ and $H_4B_4(\mu_2\text{-}H)_4$

	Bond distance (Å)			Bond angle (°)	
Compound	M–M	$M–H_{exo}$	$M–H_\mu$	$H_{exo}–M–H_\mu$	$H_{exo}–M–M$
$H_4Be_4(\mu_3\text{-}H)_4$	2.32*	1.29	1.64	145	145
$H_4B_4(\mu_2\text{-}H)_4$	1.96*	1.16	1.37	103	138–172

* Bridged skeletal distances; the unbridged B–B distance in $H_4B_4(\mu_2\text{-}H)_4$ is 1.66 Å.

Table 2. Enthalpies of formation and charges on bridging hydrogen atoms of edge- and face-bridged $H_4Be_4(\mu\text{-}H)_4$ and $H_4B_4(\mu\text{-}H)_4$ with MNDO-optimized structures

	ΔH_f° (kJ mol^{-1})		Atomic charges	
Compound	μ_2-H	μ_3-H	μ_2-H	μ_3-H
$H_4Be_4(\mu\text{-}H)_4$	−479	−727	−0.02	−0.14
$H_4B_4(\mu\text{-}H)_4$	+185	+1208	+0.02	+0.38



species are summarized in Tables 1 and 2. From these, it is clearly apparent that the face-bridged T_d structure $(H_{exo})_4Be_4(\mu_3\text{-}H_{endo})_4$ [Fig. 1(a)] is preferred to the edge-bridged structure for Be_4H_8, whereas for the boron compound B_4H_8, the reverse is true, the edge-bridged D_{2d} structure $(H_{exo})_4B_4(\mu_2\text{-}H_{endo})_4$ [Fig. 1(c)] being preferred. Moreover, neither of the alternative structures considered, viz. $H_4Be_4(\mu_2\text{-}H)_4$ for Be_4H_8 or $H_4B_4(\mu_3\text{-}H)_4$ for B_4H_8, was found to be in a potential energy well. The former reverted to the preferred $H_4Be_4(\mu_3\text{-}H)_4$ on optimization. The latter rearranged to $(H_{exo})_4(H_{endo})_2B_4(\mu_2\text{-}H)_2$ as an alternative preferred structure. For these admittedly simple systems, the findings support the intuitive picture that the endo hydrogen atoms occupy sites that represent regions of greatest skeletal bonding electron density.

HEXANUCLEAR CLUSTERS

In the previous section we found the location of the hydrogen ligands on the main group clusters considered mimicked quite well the analogous transition metal systems. The formation of these tetrahedral clusters might have been considered to take place via the sequential protonation of the anions $Be_4H_4^{4-}$ and $B_4H_4^{4-}$. Protonation/deprotonation of clusters is a real process in both main group as well as transition metal chemistry. Hence, another aspect of hydrogen ligand effects that may be informatively approached via main group analogues is the tendency for changes in cluster structure to occur with extent of protonation. As mentioned above there are known systems where cluster structure changes with protonation. A well established example chosen for discussion here is shown in Scheme 2 below.[11,27]

The dianion, $Os_6(CO)_{18}^{2-}$ formally contains 7 skeletal electron pairs and, in accord with the predictions of the electron counting rules, exhibits an octahedral (*closo*) core of metal atoms. On the other hand, protonation to $H_2Os_6(CO)_{18}$ causes cluster rearrangement and a capped square pyramidal structure is found, a cluster structure not observed in main group systems even though examples of mixed main group-transition metal clusters of this type are known.[8,28] This structural change, which is not predicted by skeletal electron counting rules, has been attributed to lowest coordination site preference of the bridging hydrogens[11] such as is generally observed in the boron hydrides.[29]

Aspects of the problem presented by this structural change have already been considered by Evans in work in which the extended Hückel method was applied to an energy analysis of idealized structures for $B_6H_6^{2-}$, $B_6H_7^-$ and B_6H_8.[30] Thus, he

$Os_6(CO)_{18}^{2-}$ $HOs_6(CO)_{18}^-$ $H_2Os_6(CO)_{18}$

Scheme 2.

found an octahedral structure for $B_6H_6^{2-}$, an edge-bridged octahedral structure for $B_6H_7^-$, and an octahedral structure with hydrogens on opposite edges for B_6H_8 to have the lowest energies. His calculations also showed that as protons were added to $B_6H_6^{2-}$, the trigonal prismatic and capped square pyramidal structures were stabilized relative to the octahedral arrangement and that while site preference for bridging hydrogens was not significant in fully triangulated polyhedra, there was preference for tetragonal faces over trigonal faces when both kinds of sites were available in the structure.

Brint, Spalding and co-workers have explored the lowest energy structures for $B_6H_6^{2-}$, $B_6H_7^-$ and B_6H_8 using MNDO and *ab initio* techniques in which the boron cluster core was not constrained in any fashion.[31] This work demonstrated that the boron core is disrupted by protonation to such an extent that a definable cluster structure is lost.

The work reported here supplements these earlier studies in that we approach the problem from another point of view and try to provide a simple rationale for the effects of protonation which has some predictive value. Our approach is to use the MNDO technique[24] to explore the protonation of octahedral and square-pyramidal $B_6H_6^{2-}$ while requiring the systems to retain these two core symmetries. Attention is focused on (a) the lowest energy site of protonation and (b) the relative energy of the two structures as a function of protonation, note being taken of changes in molecular orbital properties as a function of protonation. We also consider whether the changes that occur on protonation of $B_6H_6^{2-}$ can be used to explain the structural change observed when $Os_6(CO)_{18}^{2-}$ is protonated. Although the quantitative results of the calculations are reported, only the relative changes are considered significant.

Proton location. The optimized structures for $B_6H_7^-$ and B_6H_8 restricted to octahedral and square-pyramidal core geometries are shown schematically in Fig. 2. Complete optimization of $B_6H_6^{2-}$ resulted in a perfectly octahedral structure [Fig. 2(a)] with a ΔH_f° of 138 kJ mol^{-1}. This result is in agreement (both in energy and bond lengths) with that reported by Brint *et al.*[31] Complete optimization of $B_6H_7^-$ results in collapse of the octahedral arrangement whether the additional proton is placed on an edge or face, or is terminal. The resulting structure here also compares to that reported previously[31] with a ΔH_f° of -92 kJ mol^{-1} being obtained. In order to maintain an octahedral structure, the optimization was then limited to proton location, and the B_6 octahedron was held fixed. Starting conditions for the additional proton on typical terminal, edge, or face hydrogen sites were tried and Fig. 2(b) shows the resulting, lowest energy, structure with ΔH_f° of -24 kJ mol^{-1}.

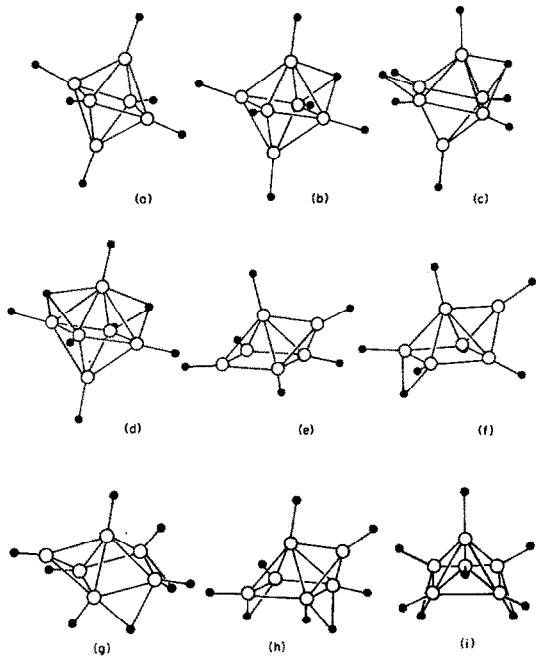


Fig. 2. Representations of the MNDO structures for: (a) $B_6H_6^{2-}$ fully optimized; (b) $B_6H_7^-$ optimized while retaining cluster geometry; (c) B_6H_8 optimized beginning with *trans* face-bridging hydrogens; (d) B_6H_8 optimized beginning with *cis* face-bridging hydrogens; (e) $B_6H_6^{2-}$ optimized while retaining capped square-pyramidal cluster geometry; (f) $B_6H_7^-$ optimized while retaining capped square-pyramidal geometry; (g), (h) and (i) B_6H_8 optimized while retaining capped square-pyramidal geometry. The open circles are B while the closed circles are H.

Calculation of the heat of formation of B_6H_8 also required constraint of the boron structure to an octahedral arrangement. The structure with all protons optimized is shown in Fig. 2(c). This result was obtained from starting conditions of two protons in *trans* faces of the octahedron. However, if one proton is understood to have remained in the starting face, the second proton has moved on to one of the edges of the face it originally capped. The ΔH_f° of this structure is 362 kJ mol^{-1}. Comparison of this energy with that derived from a "*cis*"-face starting condition with a ΔH_f° of 367 kJ mol^{-1} [Fig. 2(d)] shows only a slight preference for the former structure.

For the capped square pyramidal cases, the MNDO method was used to determine the optimized position of the capping boron for a square based pyramid having the same parameters as the octahedral structure used above. After the boron position had been established, the B_6 structure was

held in place while the H's were allowed to optimize to low energy positions [Fig. 2(e)]. Four starting positions for the additional proton of $B_6H_7^-$ were used: central in the bottom square face; back edge, opposite the capping boron atom; front edge, under the capping boron; and back face, opposite the capping boron. With the exception of the "front edge" starting position, which sought a high energy structure of 201 kJ mol^{-1}, the other three starting conditions resulted in a common structure shown in Fig. 2(f) ($\Delta H_f^\circ = 101$ kJ mol^{-1}). The additional proton is centered in an imaginary face trans to the boron cap.

In the case of B_6H_8, complete optimization of the protons gave three structures of similar energy [Fig. 2(g), 392 kJ mol^{-1}; 2(h), 415 kJ mol^{-1}; and 2(i), 420 kJ mol^{-1}]. In all three cases the protons are located approximately 1 Å below the basal plane occupying adjacent edges in the first instance and opposite edges in the second and third cases.

As with the tetrahedral clusters, we first sought a rationalization of the calculated stable proton locations using localized 2- and 3-centre bond descriptions of cluster bonding. For the two systems of interest, these have already been derived by Lipscomb and co-workers[32,33] and the rules for treating systems of this complexity are adequately described elsewhere.[34] Briefly, the two principal skeletal bond arrangements for the octahedral $B_6H_6^{2-}$ are shown in Fig. 3(a) where the number of resonance forms is also indicated. For each, half of the faces are occupied by a 3-centre bond while only one quarter of the edges accommodate 2-centre bonds. Therefore, in agreement with the lowest energy MNDO structure found, face protonation should be preferred if the incoming proton is thought to seek out the site of maximum available electron density. Once face protonated, susceptibility of the product $B_6H_7^-$ to further protonation will be different from that of $B_6H_6^{2-}$. The attachment of the first proton to $B_6H_6^{2-}$ creates a localized 4-centre B_3H bond in a face and, if one assumes this bond is fixed, then the disposition of the other 2- and 3-centre bonds can be easily determined. Considering only edges for the second protonation and again assuming maximum bond density is the controlling factor, the overall probabilities for the three types of edges *a*, *b*, *c* [Fig. 3(b)] are 0, 0.31, 0.38 respectively (MNDO point calculations for these idealized structures yield $\Delta H_f^\circ = 565{,}435$ and 414 kJ mol^{-1} respectively). Thus, the edge preferred on the basis of the MNDO technique is also the one marginally preferred by these localized bonding arguments. As is illustrated in Fig. 2, there is little difference between the MNDO energies for two locations for the second proton and this structural imprecision is reproduced, albeit in a different form, in the localized bond picture.

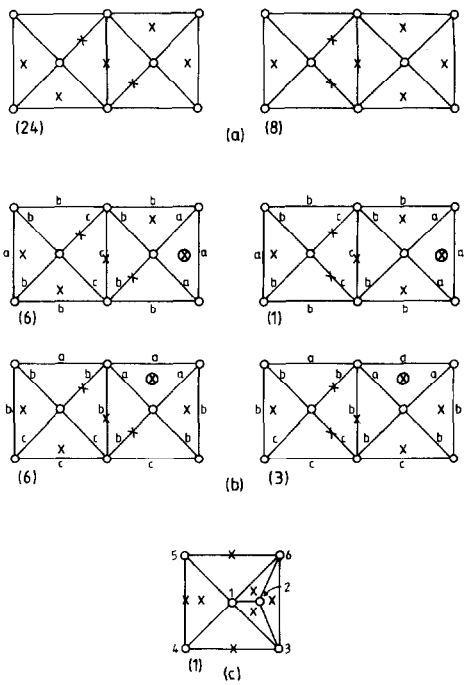

Fig. 3. (a) Localized bond networks for octahedral $B_6H_6^{2-}$. (The octahedron is shown cut open to yield two edge-fused square pyramids. Note that three edges are therefore shown twice.) The × 's indicate the "locations" of the seven cluster pairs. (b) Four possible localized bond networks for octahedral $B_6H_7^-$ where the ringed × indicates the location of the first proton on $B_6H_6^{2-}$. (c) Localized bond network for capped square-pyramidal $B_6H_6^{2-}$. Figures in parentheses show the numbers of equivalent resonance forms for each bond network.

For the capped square-pyramidal $B_6H_6^{2-}$-structure, the only localized bond scheme possible is shown in Fig. 3(c). It has the unsatisfactory feature of a 2-centre and 3-centre bond adjacent in one face.[33] With excessive electronic charge in the region of atoms 4 and 5, it is not surprizing that the preferred site for protonation [MNDO results (Fig. 2)] is the 4–5 edge. By converting the 2-centre B–B bond on that edge into a 3-centre BHB bond, protonation effectively moves this electron pair from too close proximity to the 3-centre bond in the adjacent face. The preferred site of the second proton is not obvious from this simple bonding picture and, indeed, the MNDO results give three possibilities of similar energy (Fig. 2).

Two ideas are suggested by this analysis: (a) in accord with the results on the tetrahedral clusters, proton location can be correlated with bond density in the original anion and (b) protonation effectively reduces the number of canonical forms in the valence

bond description. The latter idea provides a way of rationalizing the relative energies of possible cluster structures.

Cluster energetics on protonation. In Fig. 4 the energy difference between octahedral and square pyramidal structures is shown as a function of protonation (see also Table 3). Two sets of calculations are shown: one with fixed, reasonable BB distances and one in which the boron framework was allowed to partially relax to accommodate the spatial requirements of the added proton. The calculated heats of formation are given in Table 3. In both cases the same, relative, trend was observed, namely, a large decrease in energy difference as protons are added to the cluster. Indeed, when the cage is allowed to distort, the more stable diprotonated form is the square pyramid. Using the MNDO-optimized framework structures, Gaussian-70 and extended Hückel calculations were performed and yielded the same trend in stabilities. Hence, the energetics are consistent with Evans' findings[30] and also correlate with the observed behavior of $Os_6(CO)_{18}^{2-}$ on protonation.[11,27] Consistent with the main group model, the preference for capped square pyramidal structure in the transition metal system must be small as $Ru_6(CO)_{18}^{2-}$ retains an octahedral cluster geometry even on diprotonation.

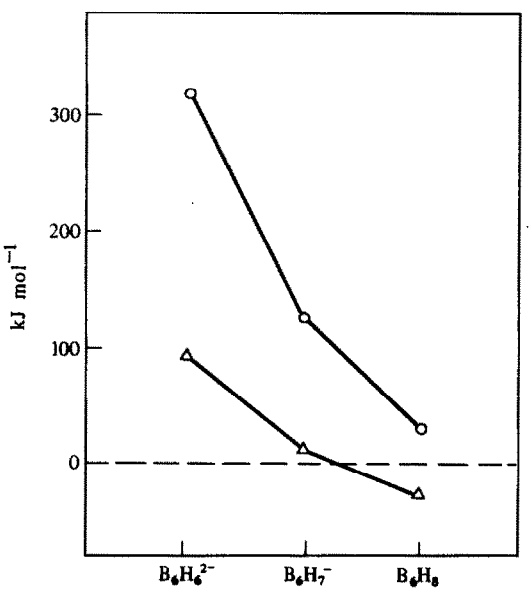

Fig. 4. Difference in enthalpies of formation of the capped square-pyramidal and octahedral cluster geometries for $B_6H_6^{2-}$ as a function of protonation. Open circles are frozen core geometries with total proton optimization while triangles are for partially relaxed core geometries (see text) with total proton optimization.

It is of interest to seek an explanation of this trend in energetics in the localized bond model as this approach was useful in rationalizing proton location. The pertinent localized bond descriptions of the two dianion structures are given in Fig. 3. The octahedral structure, and most stable form, has 32 resonance forms while the more classical capped square pyramidal structure has only one bond description. As was pointed out in the last section, the addition of a proton can be viewed as generating a localized 3-centre-2 electron bond thereby reducing by a factor of 2 the number of resonance forms available to the octahedral cluster structure. Further protonation again reduces the number of resonance forms. Hence, if one postulates that the octahedral form derives a significant portion of its stability from resonance stabilization, its stability should decrease on protonation relative to the square pyramidal form which has no apparent resonance stabilization. Indeed, the latter benefits from protonation and becomes favored as the extent of protonation increases. For the octahedral structure this conclusion is also reflected in the loss of a symmetrical charge distribution over the skeleton upon protonation (Table 4) whereas the square pyramidal structure, already having an asymmetric charge distribution, is much less affected.

CONCLUSIONS

For the main group model cluster systems studied, we have found that bridging protons tend to be located at sites which in the unprotonated cluster exhibit maximum available charge. Localized 2- and

Table 3. Enthalpies of formation (kJ mol^{-1}) for MNDO-optimized structures

3-centre bond treatments provide guides to the likely protonation sites of tetrahedral $Be_4H_4^{4-}$ or $B_4H_4^{4-}$, and of octahedral or capped square pyramidal $B_6H_6^{2-}$. Protonation creates fixed localized 3-centre 2-electron B_2H bonds or 4-centre 2-electron B_3H or Be_3H bonds and 2- or 3-centre skeletal bonds, so restricting the scope for resonance stabilization of the skeletal bonding. Forms that depend on such resonance stabilization (such as octahedral $B_6H_6^{2-}$) are therefore destabilized on protonation relative to forms (such as capped square pyramidal $B_6H_6^{2-}$) that offer little or no scope for resonance.

Protonation introduces significant cluster charge redistribution, and cluster forms in which charge asymmetry is significantly increased by protonation are disfavoured. Thus, even though protonation leaves the cluster electron count unaffected, it can constitute a perturbation large enough to cause structural rearrangement.

Our findings on this series of real and hypothetical tetranuclear and hexanuclear main group cluster systems reinforce our view that such systems serve as useful models for transition metal clusters, delineating the essential features of metal carbonyl cluster systems (notably various tetrahedral clusters $M_4H_4(CO)_{12}$, and capped square pyramidal species such as $H_2Os_6(CO)_{18}$) that superficially appear to pose problems that have no parallel in main group cluster chemistry.

Abstract—The crystal structures of 2-nitrophenoxyethanoic acid (2-NPAH), *catena*-[diaquabis(2-nitrophenoxyethanoato)manganese(II)] (**1**), tetraaquabis(2-nitrophenoxyethanoato)copper(II) dihydrate (**2**) and aquabis(2-aminopyrimidine)bis(2-nitrophenoxyethanoato)copper(II) (**3**) have been determined by X-ray diffraction. The planar 2-NPAH molecule undergoes conformational change upon coordination in complexes **1** and **2** but remains unchanged in **3**. Complex **1** is a distorted octahedral [Mn–O, 2.156–2.213(3) Å] with *trans*-related waters and unidentate bridging carboxyls giving a polymer structure. In contrast **2** is a discrete centrosymmetric monomer with two unidentate acid ligands [Cu–O 1.943(5) Å] and four waters [Cu–O 1.954(5), 2.578(7) Å] giving a tetragonally distorted octahedral coordination. **3** is five-coordinate square pyramidal with two unidentate carboxyls [Cu–O, 1.947(5) Å], two hetero-nitrogens from 2-aminopyrimidine ligands [Cu–N, 2.078(5) Å] and a single water [Cu–O, 2.211(7) Å] on a two-fold rotation axis. Single crystal X-ray data are also presented which confirms that the Zn(II) analogue of 2-NPAH is isomorphous with **1** and that the Co(II) and Ni(II) complexes are isomorphous with **2**.

Previous articles in this series[2,3] reported the unusual complex chemistry of (2-chlorophenoxy)ethanoic acid (2-CPAH). The pyridine adduct of nickel(II) (2-chlorophenoxy)ethanoate $[Ni_2(2\text{-}CPA)_4(py)_4(H_2O)]\cdot H_2O$ was found to be a bis-carboxylate-mono-aqua bridged dimer, involving facially linked octahedra.[2] The copper(II) complexes are similarly unconventional. Anhydrous copper(II) (2-chlorophenoxy)ethanoate, $[Cu_2(2\text{-}CPA)_4]_n$ and its 2-aminopyrimidine adduct $[Cu_2(2\text{-}CPA)_4(2\text{-aminopyrimidine})_2]_n$ are tetracarboxylate bridged dimer polymers.[3] In the anhydrous complex, the step-polymer forms through the axial positions of the dimers which are occupied by the oxygens from

* Part XV[1]. The Cd and Pb^{II} complexes of phenoxyethanoic acid, $[Cd(PA)_2(H_2O)_2]$ and $[Pb_2(PA)_4(H_2O)]_n$.

† Author to whom correspondence should be addressed.

adjacent carboxyl groups, similar to anhydrous copper(II) propanoate[4] and copper(II) butanoate.[5] The pyrimidine adduct is a zig-zag chain polymer, the off-sets provided through the meta-related nitrogens of the pyrimidine molecules in the axial dimer positions. In contrast, a third complex,[3] $[CaCu(2\text{-}CPA)_4(H_2O)_5]$, although a tetracarboxylate bridged dimer, has one "half" of the dimer comprising a conventional $Cu(O)_4(OH_2)$ moiety, the other "half" an eight-coordinate $Ca(O)_4(OH_2)_4$ unit.

In order to provide some clarification of this unusual phenomenon among the 2-chloro-substituted phenoxyalkanoates, a systematic investigation of the divalent metal complexes of other 2-substituted acids was initiated. The first of these, (2-nitrophenoxy)ethanoic acid (2-NPAH), provided a number of crystalline complexes suitable for X-ray examination, including some which showed polymorphic relationships. The crystal structures of $[Mn(2\text{-}NPA)_2(H_2O)_2]_n$ (**1**), $[Cu(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ (**2**) and $[Cu(2\text{-}NPA)_2(2\text{-aminopyrimidine})_2(H_2O)]$ (**3**) are reported, together with X-ray data confirming the isomorphism between **1** and the Zn(II) analogue, and between **2** and both the Co(II) and Ni(II) analogues. The crystal structure of the parent acid (2-NPAH) also allows comparison of the structural features of complexed and uncomplexed acid.

EXPERIMENTAL

Preparation of complexes

All complexes were prepared by mixing together hot aqueous solutions containing 2 : 1 molar ratios of the ammonium salt of 2-NPAH and the appropriate metal acetate. Crystals were allowed to grow from these solutions after partial room temperature evaporation over a period of several weeks. Complex **2** $[Cu(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ was found to acquire opacity and lose crystallinity presumably due to loss of water, even when stored in a closed sample vial. To prevent this the crystal used for X-ray data collection was coated with epoxy resin. Loss of crystallinity was not found to be a serious problem with the other complexes [Co(II) and Ni(II)], but stored samples underwent some efflorescent decomposition with formation of a red solution on the crystals. The supernantant liquors from the preparations of all three complexes also reverted to this red colour, presumably a breakdown product from the (nitrophenoxy)ethanoic acid.

Adduct **3** $[Cu(2\text{-}NPA)_2(2\text{-aminopyrimidine})_2(H_2O)]$ was prepared by digesting a 50% aqueous ethanolic suspension of **2** with a slight excess of 2-aminopyrimidine. Evaporation at room temperature gave blue crystals of the complex.

*Analyses**

(i) $[Mn(2\text{-}NPA)_2(H_2O)_2]_n$ (**1**). Found: C, 39.8; H, 3.36; N, 5.72%. Calc. for $C_{16}H_{16}MnN_2O_{12}$: C, 39.8; H, 3.34; N, 5.80%.

(ii) $[Zn(2\text{-}NPA)_2(H_2O)_2]_n$ (**1a**). Found: C, 39.0; H, 3.33; N, 5.70%. Calc. for $C_{16}H_{16}N_2O_{12}Zn$: C, 38.9; H, 3.27; N, 5.67%.

(iii) $[Cu(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ (**2**). Found:† C, 39.1; H, 3.37; N, 5.67%. Calc. for $C_{16}H_{24}CuN_2O_{16}$: C, 34.1; H, 4.29; N, 4.97%.

(iv) $[Co(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ (**2a**). Found: C, 34.8; H, 4.40; N, 5.06%. Calc. for $C_{16}H_{24}CoN_2O_{16}$: C, 34.4; 4.33; N, 5.01%.

(v) $[Ni(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ (**2b**). Found: C, 34.5; H, 4.40; N, 5.01%. Calc. for $C_{16}H_{24}N_2NiO_{16}$: C, 34.4; H, 4.33; N, 5.01%.

Crystallography

Crystal data and details of structure solution and refinement for [2-NPAH], **1**, **2** and **3** are contained in Table 1. Single crystal X-ray photographic data for the Zn(II), Co(II) and Ni(II) complexes were obtained using an Enraf–Nonius Weissenberg goniometer and are as follows:

(**1a**) $[Zn(2\text{-}NPA)_2(H_2O)_2]_n$, $C_{16}H_{16}N_2O_{12}Zn$, $Mr = 493.7$, $a = 14.3(1)$, $b = 7.9(1)$, $c = 4.5(1)$, $\alpha = 114(1)$, $\beta = 90(1)$, $\gamma = 90(1)°$; $V = 464$ Å^3, $Z = 1$, $\rho_c = 1.76$ g cm^{-3}, $\rho_f = 1.77$ g cm^{-3}, $F(000) = 252$, space group $P\bar{1}$.

(**2a**) $[Co(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$, $C_{16}H_{24}CoN_2O_{16}$, $Mr = 559.3$, $a = 6.4(1)$, $b = 5.1(1)$, $c = 36.6(1)$Å, $\beta = 100(1)°$, $V = 1176$ Å^3, $Z = 2$, $\rho_c = 1.58$ g cm^{-3}, $\rho_f = 1.59$ g cm^{-3}, $F(000) = 578$, space group $P2_1/c$.

(**2b**) $[Ni(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$, $C_{16}H_{24}N_2NiO_{16}$, $Mr = 559.1$, $a = 6.4(1)$, $b = 5.1(1)$, $c = 36.6(1)$ Å, $\beta = 100(1)°$, $V = 1176$ Å^3, $Z = 2$, $\rho_c = 1.58$ g cm^{-3}, $\rho_f = 1.58$ g cm^{-3}, $F(000) = 580$, space group $P2_1/c$.

* No analysis was possible on the complex $[Cu(2\text{-}NPA)_2(2\text{-aminopyrimidine})_2(H_2O)]$ (**3**) because of the small amount of available sample.

† $[Cu(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ (**2**) was found to effloresce rapidly at room temperature so that the results obtained represent something less than the six-hydrate of the X-ray determination. The Co(II) and Ni(II) complexes were more stable.

Data for 1 and 2 were collected on a Syntex $P2_1$ diffractometer, and solved by the heavy atom method and refined using SHELX-76.[6] Data for 2-NPAH and 3 were obtained on a Nicolet $R3m$ diffractometer and the structures solved and refined using the Nicolet SHELXTL[7] structure solution package. 2-NPAH was solved using direct methods while for 3 the heavy atom method was used. Anisotropic thermal parameters were used for all heavy atoms except those of the nitro groups which were apparently disordered (complexes 1 and 2). In these cases, allowance was made for the disorder by incorporating all the atoms in the refinement with their site occupancies fixed at values obtained from least-squares refinement. Hydrogens were located from difference-Fourier syntheses and included in the refinement at fixed positions with their isotropic U values set invariant at 0.05 Å^2. Neutral atom scattering factors were used,[8] while the heavy atoms were corrected for the effects of anomalous dispersion.[8] Final residuals R and Rw are defined as follows:

$$R = [\sum||F_o|-|F_c||/\sum|F_o|],$$

$$Rw = [(\sum w(||F_o|-|F_c||^2/\sum w|F_o|^2)^{1/2}].$$

Atomic coordinates, thermal parameters and observed and calculated structure factors have been deposited with the Editor as supplementary material; copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre. Bond distances and angles are given in Table 2.

DISCUSSION

2-*NPAH*

Molecules of 2-NPAH form centrosymmetric, hydrogen bonded cyclic dimers [O...O, 2.606(8) Å] similar to all known examples of phenoxyalkanoic acids.[9] This distance lies within the range for members of this series [2.654 Å mean for 16 examples].[9] The molecules are essentially planar (Fig. 1) with the oxoethanoic acid side chain torsion angles, C(2)–C(1)–O(7)–C(8), C(1)–O(7)–C(8)–C(9) and O(7)–C(8)–C(9)–O(11) being −178.8, +177.5, and −171.8° respectively. However, the oxygens of the nitro group are canted at an angle to the plane of the benzene ring [torsion angle C(1)–C(2)–N(2)–O(22), +144.9°]. The angle may be dependent upon the attainment of a discrete O(7) (ether) . . . O(21)(nitro) interactive distance (in this case, 2.650

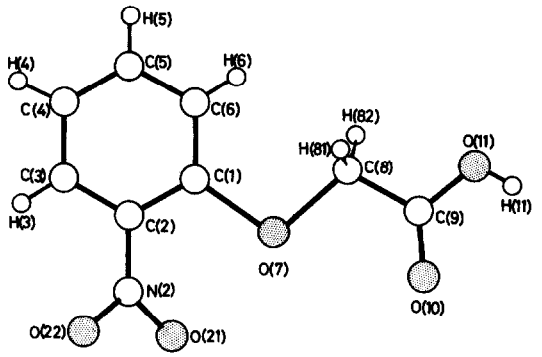

Fig. 1. Molecular conformation and atom numbering scheme for (2-nitrophenoxy)ethanoic acid (2-NPAH).

Å), which becomes too short in the planar conformation (*ca* 2.42 Å). However, there are no inter-dimer interactions involving the nitro groups, the regularly separated layers stacking down the approximate *c* direction of the cell.

Disorder of the nitro oxygens, evident in this structure as high atomic thermal parameters, also occurs in the complexed ligands in complexes **1–3**. This effect occurs to varying extent in these complexes, presumably due to steric effects imposed by the different modes of complexation found. It is considered feasible that this disorder in the nitro group is directly responsible for the difficulties encountered in the preparation of crystals of these complexes and their subsequent stability.

$[Mn(2\text{-}NPA)_2(H_2O)_2]_n$ (1)

The manganese(II) complex of 2-NPA (**1**) is centrosymmetric six-coordinate (Fig. 2) with the slightly distorted MO_6 octahedron occupied by two waters [Mn–O, 2.213(3) Å] and two carboxylate oxygens from unidentate 2-NPA ligands [Mn–O, 2.172(2) Å]. The remaining two coordination positions are filled by the second oxygens from the carboxyl groups of the adjacent complex units [Mn–O, 2.156(3) Å]. This results in infinite two-dimensional polymer chains which extend down the *c* crystallographic axis, with the Mn centres separated by the *c* cell parameter [4.558(2) Å]. In this respect, the complex is similar to *catena*-diaquabis(phenoxyethanoato-*O*)manganese(II) and its isomorphous and isostructural analogues of the type $[M(phenoxy)_2(H_2O)_2]_n$, where M = Co, Mg, Mn and phenoxy = phenoxyethanoato, (4-chlorophenoxy)ethanoato and (4-fluorophenoxy) ethanoato.[10,11] With the 2-NPA series, isomorphism has also been proved but between **1** and the zinc(II) complex, whereas in the general phenoxy series previously mentioned, the Zn(II) complexes are different but isomorphous with the Cd(II) complexes.[1,12]

The side-chain conformation of the 2-NPA ligands in **1** changes relative to the free acid, the torsion angles being −169.2, +160.0 and +144.9° respectively. Despite these changes, the O(7)...O(10) interactive distance [2.702(4) Å] is not significantly changed compared to 2-NPAH [2.628(8) Å]. Polymerization, with its more rigid stereochemical requirements is probably the primary interactive force in formation of these complexes, with the secondary packing effects, including the disordered nitro groups resulting in the conformational changes. The O(7)(ether)...O(21)A(nitro) distance is 2.577(4) Å while the only intermolecular association

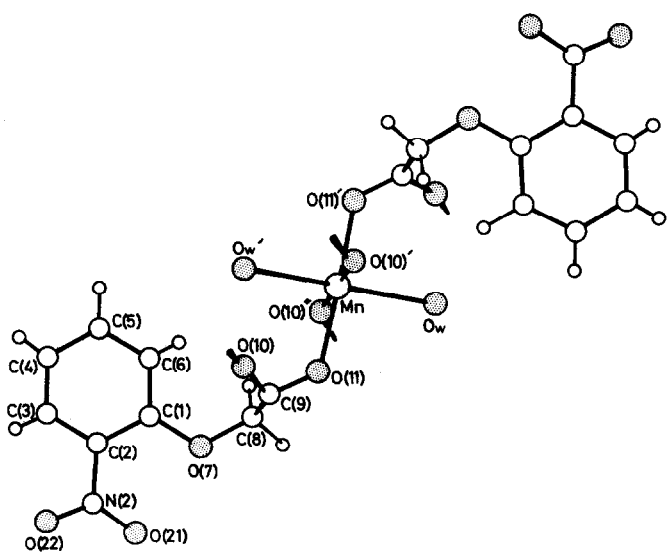

Fig. 2. Molecular configuration for $[Mn(2\text{-}NPA)_2(H_2O)_2]_n$ (**1**).

of note is between the coordinated water (Ow) and the nitro oxygen [O(21)] (2.884 Å).

$[Cu(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ (2)

The complex **2** has a centrosymmetric, tetragonally distorted octahedral coordination about copper (Fig. 3). The CuO_6 coordination polyhedron consists of two oxygens from unidentate 2-NPA carboxylate groups [Cu–O, 1.943(5) Å] and two waters [Cu–Ow(3), 1.954(5) Å] in the square plane, while another two waters [Cu–O, 2.578(7) Å] occupy the elongated axial positions. Although the O–Cu–O angles within the square plane are quite regular, one of the angles to the axial oxygen [O(11)–Cu–Ow(2), 100.0(2)°] is distorted, indicating possible repulsion away from the influence of the substituted phenoxy ring system. In common with the manganese complex **1**, the conformation of the oxoethanoate side-chain is considerably different compared to 2-NPAH. The equivalent torsion angles are +176.6, +79.8 and −173.4° respectively. The oxygens of the nitro group also adopt positions out of the plane of the benzene ring placing O(21) 2.572(9) Å from O(7) [the torsion angle C(1)–C(2)–N(2)–O(22) Å is −148.5°]. The water of solvation [Ow(1)] is associated with a coordinated water [Ow(3)] by relatively strong hydrogen bonds (2.66 Å) although this bond appears to be the one dissociated first, giving water loss followed by decomposition and loss of crystallinity in the solid state. The presence of the water then provides a route for further decomposition processes involving the nitro groups, a phenomenon observed also for the Ni(II) and Co(II) analogues. Such lability is, however, not reflected in any abnormal thermal parameter found for Ow(1) in the crystallographic analysis. This stability may arise because of hydrogen bonding associations with Ow(1) [to O(21), 2.872 (intramolecular); to O(10), 2.770 (inter); to Ow(2), 2.661 (inter)]. The molecules of **2** pack in the unit cell as discrete monomeric units with the only other intermolecular contacts involving the coordinated waters [Ow(3)] and the coordinated carboxyl oxygens [O(11)] [2.731 and 2.891 Å].

Data obtained from single crystal diffractometry and from elemental analyses confirm that the Co^{II} and Ni^{II} complexes of 2-NPA, $[Co(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ (**2a**) and $[Ni(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ (**2b**) are isomorphous and isostructural with (**2**).

$[Cu(2\text{-}NPA)_2(2\text{-}aminopyrimidine)_2(H_2O)]$ (3)

Complex **3** is five-coordinate, square pyramidal with molecular two-fold rotational symmetry coincident with crystallographic symmetry (Fig. 4). The MO_3N_2 coordination sphere consists of a single water [Cu–Ow, 2.211(7) Å], lying on the two-fold axis, two oxygens from unidentate carboxylate groups of the 2-NPA ligands [Cu–O, 1.947(5) Å], and two hetero-nitrogens from the 2-amino-pyrimidine molecules [Cu–N, 2.078(5) Å]. This stereochemistry is known among nitrogen base adducts of copper(II) phenoxyalkanoates, where two complexes, aquabis[(phenoxy)ethanoato]bis-(pyridine)copper(II)[13] and aquabis[(4-chloro-2-methylphenoxy)ethanoato]bis(pyridine)copper(II)[14] have the same five-coordination with crystallographically imposed two-fold symmetry. Some distortion of the ideal 90° angles about Cu, apparently arising from the interactive influence of the 2-amino group of the pyrimidine ligand [N(21)p . . . Ow, 3.094 Å] results in an N(1)p–Cu–N(1)p′ angle of 163.5(3)°. The effect may also be influenced

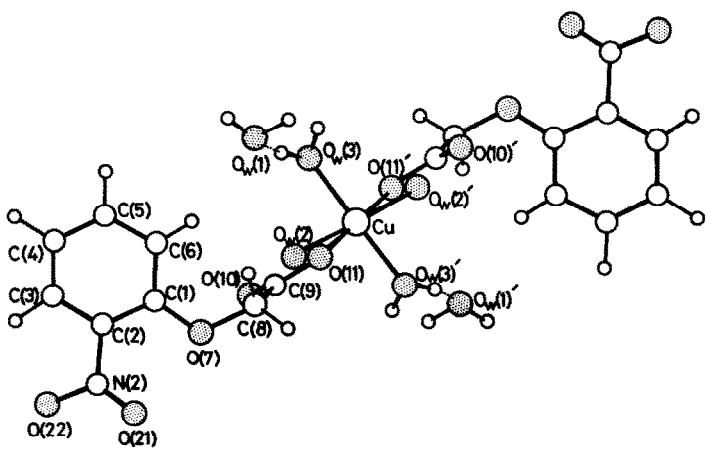

Fig. 3. Molecular configuration for $[Cu(2\text{-}NPA)_2(H_2O)_4]\cdot 2H_2O$ (**2**). Primed atoms are generated by the inversion operation.

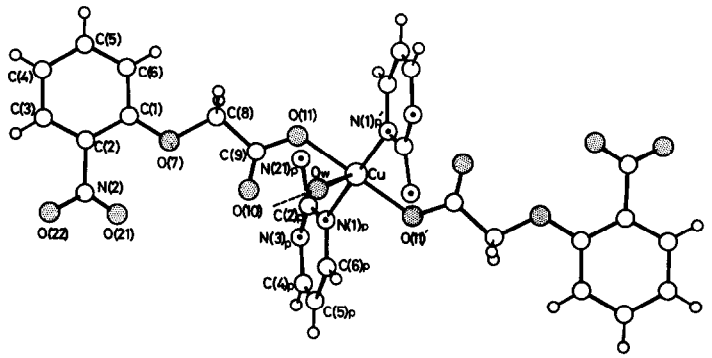

Fig. 4. Molecular configuration for [Cu(2-NPA)$_2$(2-aminopyrimidine)$_2$(H_2O)] (**3**). Primed atoms are generated by two-fold rotation.

by the relatively close approach of the second carboxyl oxygen [O(10)] to the Cu [2.685(5) Å], which stabilizes the structure. In addition, the water molecule is hydrogen bonded to the "free" carboxyl oxygen of an adjacent complex unit down the *b* axis of the cell in a manner similar to both the above pyridine adducts.[13,14]

The reason for the relatively greater stability of this structure compared to **1** and **2** appears to lie in the reversion to five-coordination and is furthermore reflected in the retention of the planar conformation of the free acid [comparative torsion angles, −174.8, −174.6 and −164.2° respectively]. The 2-aminopyrimidine group also exerts its influence on the complex stabilization as shown in the adducts with copper(II) (2-chlorophenoxy)ethanoate[3] [a tetracarboxylate bridged dimer polymer with the pyrimidine ring acting as an axial bridging ligand via the 1 and 3 hetero nitrogens] and copper(II) (4-fluorophenoxy)ethanoate[15] [a discrete tetracarboxylate bridged dimer with the 2-aminopyrimidines occupying the axial positions]. The structural features of the 2-aminopyrimidine molecule[15] undergo no significant change upon complexation. The same nitro group disorder exists with a closely similar O(7) . . . O(22) interactive distance [2.555(10)Å] while the C(1)–C(2)–N(2)–O(22) torsion angle is +161°.

SUMMARY CONCLUSIONS

The substituent group in the ortho-position in 2-substituted phenoxyalkanoic acids plays a steric role in determining the final sterochemistry of the metal complex formed. With complexes of 2-NPAH, there are large conformational changes which prevent one of the oxygens of the bulky nitro group approaching too closely the ether oxygen of the oxoethanoate side chain. In some cases, the oxygens of the nitro groups are rotationally disordered and this is considered to be the reason for difficulties in the preparation of stable crystals of these compounds.

Acknowledgements—We thank Professor B. R. Penfold of the Chemistry Department, University of Canterbury, Christchurch, New Zealand, for the use of facilities in relation to 2-NPAH and compound **3**, and Dr Vicki McKee for helpful advice. Also thanked are the University of Western Australia, The University of Queensland and the Queensland Institute of Technology Research and Development Committee for financial support in this project.

(*Received* 10 *May* 1984; *accepted* 4 *September* 1984)

Abstract—Electronic and ESR spectra of the complexes $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$, $[Cu(tpa_so)_4](NO_3)_2$ and $[Cu(tpa_so)_4](ClO_4)_2$ are discussed. Results showed the three complexes are square planar. X-ray powder diagrams show the complexes are not isomorphous, but the ESR spectra are very similar to each other, suggesting the same local square planar symmetry. For $[Cu(II)(tpa_so)_4]$ $[Cu(I)Cl_2]_2$ $g_{\|} = 2.324$; $g_{\perp} = 2.062$, $A_{\|} = 163.0$ and $A_{\perp} = 24.0$ gauss. For a single crystal of this complex three bands assigned to *d–d* transitions were observed at 13,000, 15,300 and 18,500 cm^{-1}.

Triphenylarsine oxide (tpa_so) forms solid complexes with several transition metal ions, including copper(II)[1,2] and the complexes are in general similar to the analogous complexes with triphenylphosphine oxide.[1]

Copper(II) complexes are difficult to characterize by considering only electronic spectra and magnetic susceptibility data. With $CuCl_2$ and $CuBr_2$, according to Goodgame and Cotton,[1] the tpa_so complexes have the formula $[CuX_2(tpa_so)_2]$. The chlorocomplex was yellow-brown and the bromocomplex was purple when freshly prepared but changed to olive-green when the complex was dried. On the basis of electronic spectra and magnetic susceptiblity measurements the authors could not characterize the two complexes. Later, by comparing the electronic spectra of the chlorocomplex with those of $[Cu(tpa_so)_4](ClO_4)_2$ previously described,[3] Rodley, Goodgame and Cotton[2] suggested the formula $[Cu(tpa_so)_4][CuCl_4]$ but the presence of the $[CuCl_4]^{2-}$ anion was not confirmed by the electronic spectra. $[Cu(tpa_so)_4](ClO_4)_2$ was considered by the last named authors as square planar. Electronic and vibrational spectra indicated the existence of the cation $[Cu(tpa_so)_4]^{2+}$ in both complexes.

The formula and structure of the olive-green bromocomplex remained uncertain. According to the same authors the formulation $[Cu(tpa_so)_4][CuBr_4]$ was improbable and the presence of the cation $[Cu(tpa_so)_4]^{2+}$ could not be confirmed by the electronic spectra.

The reaction between $CuCl_2$ and diphenylmethylarsine oxide gave two products: one blue and one brown. Nyholm[4] had already obtained these two products starting with $CuCl_2$ and diphenylmethylarsine. He suggested the formula $[Cu(II)(dpma_so)_4][Cu(I)Cl_2]_2$ for the blue product and the brown compound had the same composition as the blue but with 5–10% of $CuCl_2$, probably as the polymer ion $CuCl_3^-$.

The other complex considered in this paper is $[Cu(tpa_so)_4](NO_3)_2$ which was previously reported by Phillips and Tyree.[5] This complex is interesting because several other transition metal complexes contain the NO_3^- group coordinated to the metal ion. With triphenylphosphine oxide (tppo), for example, the complex is $[Cu(NO_3)_2(tppo)_2]$.[6]

* Author to whom correspondence should be addressed.

Coordination of a fifth arsineoxide or phosphine oxide ligand, or even a ClO_4^- anion, was shown by Hunter *et al.*[7] These authors studied complexes of the type $[ML_5]^{2+}$ and $[M(ClO_4)L_4]^{2+}$ where M = Mn(II), Fe(II), Co(II), Ni(II) and Cu(II), L = tmpo (trimethylphosphine oxide) or tma_so (trimethylarsine oxide). They observed a weak copper(II)–ligand interaction with tmpo and tma_so on the basis of the results from IR spectra. The same conclusion was applied for tppo and tpa_so complexes, for which the same pentacoordinated structure was suggested.

In an attempt to prepare the complex of $CuCl_2$ with tpa_so, following Goodgame and Cotton's procedure a brown complex of formula $2CuCl_2 \cdot 3(tpa_so)$ was obtained. Recrystallization in acetone yielded good blue crystals of the complex $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ whose structure we previously described.[8] This complex contains the square planar $[Cu(II)(tpa_so)_4]^{2+}$ cation and the linear $[Cu(I)Cl_2]^-$ anion.

The main goal of this paper is to describe electronic and ESR spectra of the Cu(II)–Cu(I) complex and to compare the spectroscopic data with those of the complexes $[Cu(tpa_so)_4](NO_3)_2$ and $[Cu(tpa_so)_4](ClO_4)_2$. The results showed that the three complexes contain the square planar $[Cu(tpa_so)_4]^{2+}$ species.

EXPERIMENTAL

Synthesis of the complexes

$[Cu(tpa_so)_4](ClO_4)_2$ and $[Cu(tpa_so)_4](NO_3)_2$ were easily obtained according to the procedure described in the literature.[3] Addition of tpa_so to $Cu(ClO_4)_2$ or $Cu(NO_3)_2$ dissolved in hot anhydrous ethanol precipitated the solid complexes immediately. Both complexes are insoluble in all solvents used and it was impossible to recrystallize them to obtain good crystals for X-ray diffraction measurements.

$[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$—the brown complex $2(CuCl_2) \cdot 3(tpa_so)$ was dissolved in hot acetone and on cooling a blue solid precipitated. A few days after filtration good blue crystals were formed in the filtrate at room temperature.

ANALYSIS

The complexes were analysed for carbon, hydrogen (microanalysis) and copper(II) in the case of the chlorocomplex. Copper(II) was determined with edta.

Found: C, 53.7; H, 3.90%. Calc. for $[Cu(tpa_so)_4](ClO_4)_2$: C, 55.72; H, 3.87%.

Found: C, 57.9; H, 4.14%. Calc. for $[Cu(tpa_so)_4](NO_3)_2$: C, 58.55; H, 4.06%.

Found: C, 53.3; H, 3.66; Cu, 11.86%. Calc. for $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$: C, 53.32; H, 3.70; Cu, 11.75%. (m.p. 243–244°C).

PHYSICAL MEASUREMENTS

Electronic spectra of the solid complexes were obtained at room temperature over a 2000–300 nm range on Cary Model 17 and Beckman DK-2 spectrophotometers using fluorolube mulls or a crystal in the case of $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ and quartz cells.

IR spectra of CsI pellets (4000–200 cm^{-1}) were recorded on a Perkin–Elmer 567 spectrophotometer.

ESR spectra were recorded on a Varian Model E-109 system spectrometer. Quartz sample tubes were employed for polycrystalline samples. Spectra were calibrated with diphenylpicrylhydrazyl (dpph, $g = 2.0036$) as a field marker.

X-ray powder diagrams were measured using a Phillips X-ray unit (model 1130/00) with horizontal goniometer (PW 1380/01) and a graph detection system mounted in our laboratory.

RESULTS AND DISCUSSION

X-ray powder diagrams of the nitrate and perchlorate complexes showed they are isomorphous. However, the powder diagram of $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ is quite different from those of the other two complexes. The differences are in the position and the number of lines. This result permits us to conclude the complex is not isomorphous with the nitrate and perchlorate complexes. This is probably due to the presence of the $[Cu(I)Cl_2]^-$ anion, which alters symmetry of the crystal structure.[8] This change does not occur with NO_3^- and ClO_4^- anions.

In spite of the fact that the three complexes are not isomorphous they show powder ESR spectra very

Table 1. The EPR parameters of the three copper complexes: $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$, $[Cu(tpa_so)_4](NO_3)_2$ and $[Cu(tpa_so)_4](ClO_4)_2$

Complex	$g_\parallel$ (0.003)	$g_\perp$ (0.003)	$A_\parallel$ (G)	$A_\perp$ (G)

* Single crystal sample.
† Powder samples.

similar to each other in type of lines and on values of parameters. Such ESR parameters are presented in Table 1. The similarity of ESR data suggests the same square planar local symmetry for the three complexes.

Figures 1 and 2 show the angular variation of the ESR spectrum of a crystal of the complex $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$; *a* and *b* are the crystal axes and c^* is the third triorthogonal axis. It is clear from Fig. 2 the hyperfine interaction lines with copper nuclear spin and the existence of two copper(II) ions magnetically inequivalent per unit cell in close agreement with X-ray data.

ESR parameters of $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ compared well with the ones extracted from the literature for $CaCuSi_4O_{10}$[9,10] which is square planar. The values obtained from ESR spectra confirm the axial symmetry of the square planar structures. The fitting was done by using the spin Hamiltonian with hyperfine interaction given by

$$\mathcal{H} = \mu_B \mathbf{H}\cdot\tilde{g}\cdot\mathbf{s}+\mathbf{I}\cdot\tilde{A}\cdot\mathbf{S}. \quad (1)$$

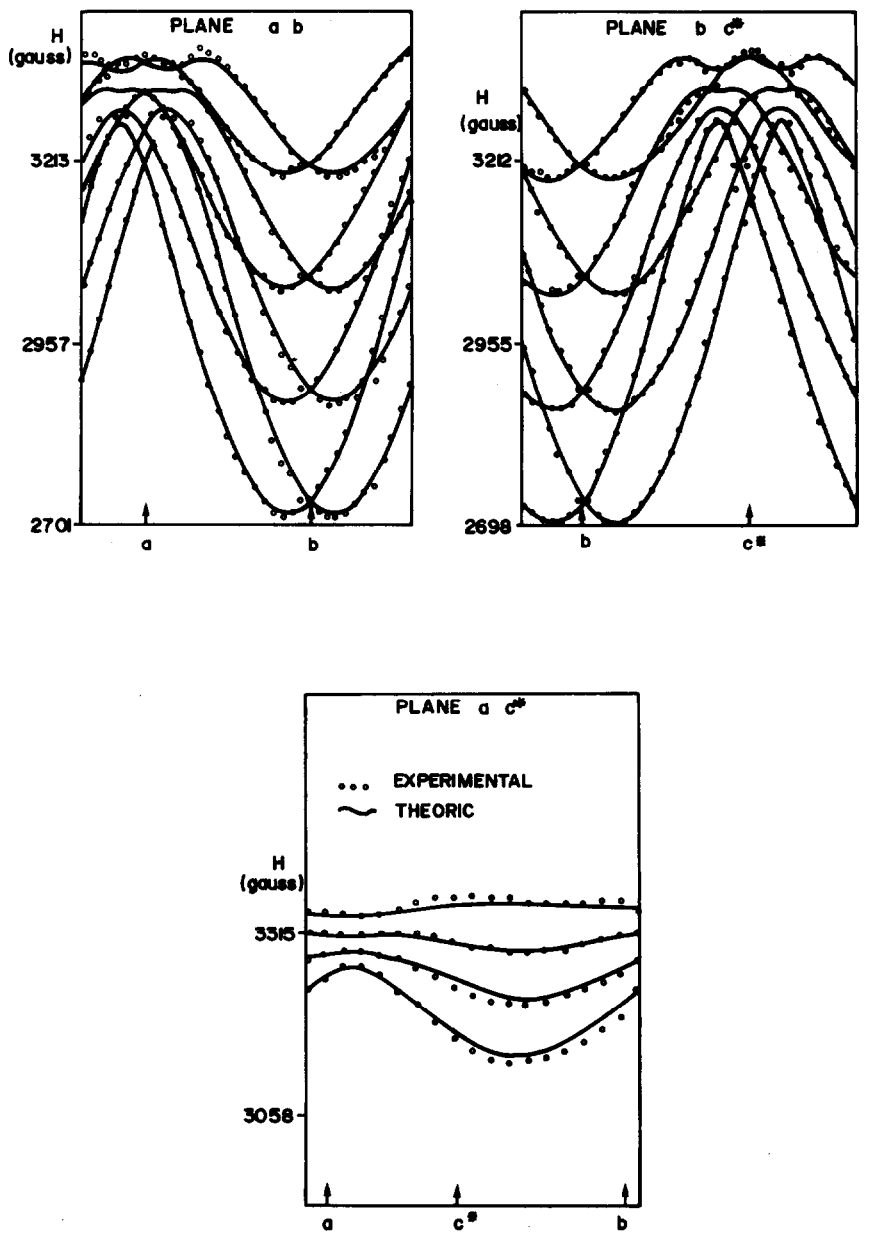

Fig. 1. The angular variation of the EPR spectra for the single crystal of the $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ complex. The *a* and *b* directions are the crystalline axes and c^* is the third three orthogonal axes.

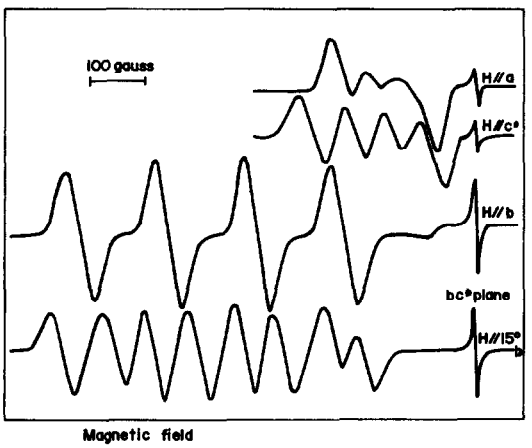

Fig. 2. The EPR spectra, with the hyperfine splitting of the Cu(II) ion in the $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ single crystal complex in four directions of the magnetic field H. The lowest spectrum shows the two magnetically inequivalent Cu(II) ions in the bc^* plane.

calculated to the second order[11] where the resonant magnetic field H is given by

$$H = \frac{h\nu}{g\mu_B} - \frac{A}{g\mu_B} M_I - \frac{A_\perp^2(A_\parallel^2 + A^2)}{4h\nu g\mu_B A^2}[(I+1)I - M_I^2] - \frac{(A_\parallel^2 - A_\perp^2)g_\parallel^2 g_\perp^2 \sin^2\theta\cos^2\theta}{2h\nu g^5 \mu_B A^2} M_I^2 \quad (2)$$

with

$$A^2 = \frac{1}{g^2}(g_\parallel^2 A_\parallel^2 \sin^2\theta + g_\perp^2 A_\perp^2 \cos^2\theta)$$

and

$$g^2 = (g_\parallel^2 \sin^2\theta + g_\perp^2 \cos^2\theta),$$

where ν is the microwave frequency; μ_B is a Bohr magneton; $g_\parallel$, $A_\parallel$ are the axial components and $g_\perp$, $A_\perp$ the perpendicular components of the gyromagnetic and hyperfine tensors; I and M_I are the copper nuclear spin and magnetic quantum number respectively. The fitting shows that some rhombic distortion exists, as suggested by X-ray data, but the distortion is very small. The system used for crystal orientation is shown in Fig. 3 in a schematical way, as well as the axial direction with respective angles.

Electronic spectra of the $[Cu(tpa_so)_4](NO_3)_2$ and $[Cu(tpa_so)_4](ClO_4)_2$ complexes are shown in Fig. 4. Both spectra are very similar to each other in type and position of bands. The following assignments were done: (a) d–d transitions for NO_3^- and ClO_4^- complexes: 14,900 cm^{-1}; 13,150 cm^{-1} (shoulder); 17,500 cm^{-1} and 18,500 cm^{-1}; (b) the band at 21,700 cm^{-1} which appears for both complexes is a charge-transfer band.

In the electronic spectrum of the $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ complex, also shown in Fig. 4, three bands are observed in the 10,000–22,500 cm^{-1} region. The three bands at 13,000, 15,300 and 18,500 cm^{-1} were assigned to d–d transitions. Measurements in the crystal were carried out at room temperature and at N_2 liquid temperature. There are some shifts and changes in relative intensities of the bands when we compare the spectra at these two temperatures. Crystal features (size and shape) did not permit us to obtain better details of the electronic spectra in the near infrared region with polarized light.

Spectroscopic and X-ray data for $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ compared well with those of the compound $CaCuSi_4O_{10}$[10] concerning the local symmetries.

By considering the same energy level diagram (Fig. 5) for d orbitals we can calculate $r_\parallel$, $r_\perp$, α and β parameters using ESR and electronic spectra data

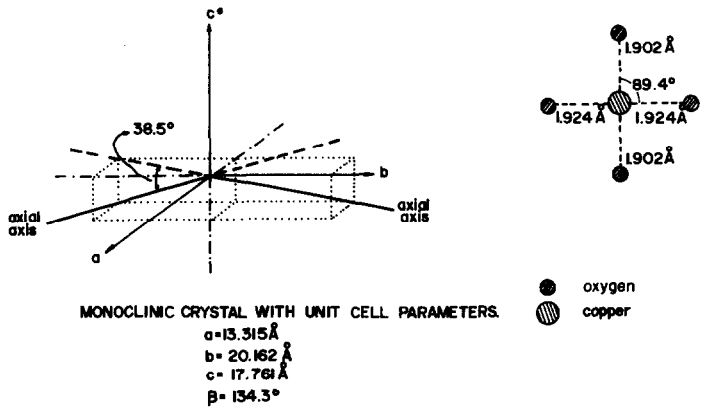

Fig. 3. Schematic diagram of the axial directions of the two Cu(II) complexes per unit cell and the square planar symmetry with the distances from the Cu(II) and oxygen atoms.

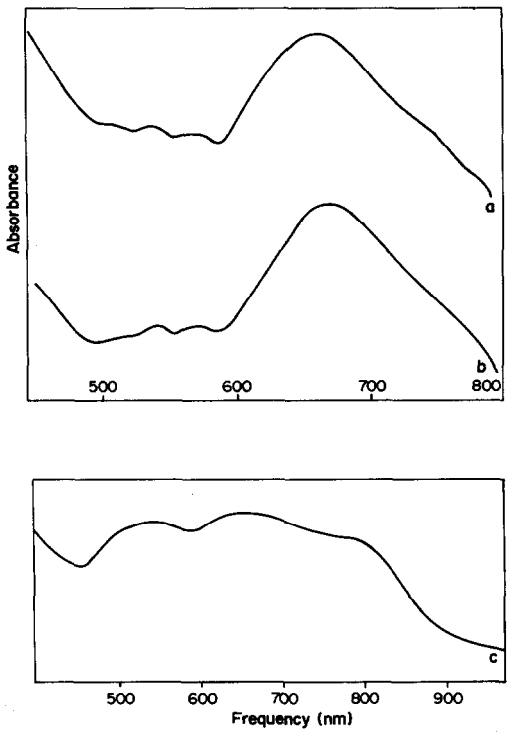

Fig. 4. Electronic spectra of the complexes (fluorolube mulls): (a) $[Cu(tpa_so)](NO_3)_2$, (b) $[Cu(tpa_so)_4](ClO_4)_2$ and (c) $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$.

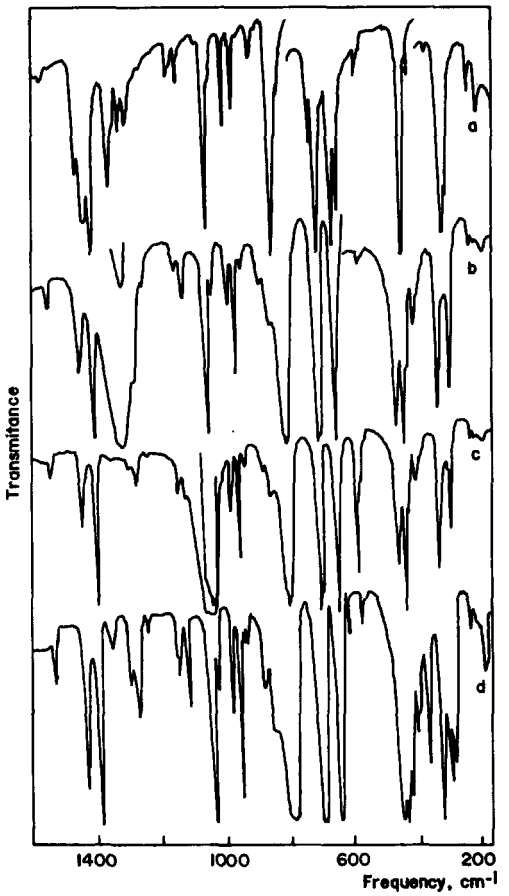

Fig. 6. IR spectra (CsI pellets): (a) tpa_so, (b) $[Cu(tpa_so)_4](NO_3)_2$, (c) $[Cu(tpa_so)_4](ClO_4)_2$, (d) $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$.

(see Table 2). The results obtained for these parameters are in good agreement with each other; α and β values show the degree of participation of d orbitals on the metal–ligand bond.[12]

Figure 6 shows the IR spectra of free tpa_so and of the three $[Cu(tpa_so)_4]^{2+}$ complexes. The (As–O) stretching frequency for $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ is at 838 cm^{-1} and for the free ligand at 880 cm^{-1}. For nitrate and perchlorate complexes $\nu_{(As-O)}$ occurs at 840–860 cm^{-1}. Bands typical of ionic NO_3^- and ClO_4^- groups are also observed. We found $\nu_{(Cu-O)}$ at 448 cm^{-1} for both NO_3^- and ClO_4^- complexes and at 470 and 418 cm^{-1} for $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$.[3,7] For the anion we found $\nu[Cu(I)Cl]$ at 235 cm^{-1}. The tpa_so bands of the cation $[Cu(tpa_so)_4]^{2+}$ present in the three complexes are very similar in the IR spectra.

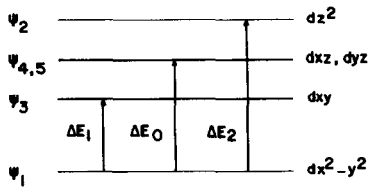

Fig. 5. Energy levels diagram showing the electronic transitions for $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$.

In conclusion, as discussed above, it is assigned that these three copper(II) complexes are in the same

Table 2. The spectroscopic parameters, calculated reduction factor $r_\parallel$ and $r_\perp$ and the d-wave functions covalence degrees α and β for the complexes $[Cu(II)(tpa_so)_4][Cu(I)Cl_2]_2$ and $CaCuSi_4O_{10}$ (Refs 10 and 12) and the assumed energy levels

Complex	ΔE_0*	ΔE_1*	ΔE_2*	$g_\parallel$	$g_\perp$	$r_\parallel$	$r_\perp$	α	β
$CaCuSi_4O_{10}$	15.8	12.9	18.8	2.326	2.054	0.80	0.72	0.80	0.90
$[Cu(II)(tpa_so)_4]^{2+}$	15.3	13.0	18.5	2.324	2.062	0.80	0.76	0.80	0.95

* The energy transitions are given in 10^3 cm^{-1}.

SPECIATION OF STRONTIUM IN HUMAN AND BOVINE MILK

GILLIAN L. SMITH, SIÂN B. REES and DAVID R. WILLIAMS*

(*Received* 14 *May* 1984; *accepted* 4 *September* 1984)

Abstract—The speciation of strontium in human and bovine milk has been computed using a chemical equilibrium model and the ECCLES program. The calculations show that the low-molecular-mass distribution of Sr(II) ions parallel that of Ca(II) ions. The analytical techniques used to remove strontium from milk include liquid–liquid extraction using dicyclohexyl-18-crown-6. This method relies on the selective complexation of Sr(II) ions by this ligand. The ability of dicyclohexyl-18-crown-6 to chelate both Sr(II) and Ca(II) ions in milk was investigated using the computer model.

The role of strontium in biological systems received but scant attention until the late 1940s, mainly because there were no reasons to suspect that the element was present in man and also, as with many ultra-trace elements, analytical methods were not available for detecting and measuring strontium. It is now known that strontium in mammals is inextricably linked with the biochemistry of calcium and that milk, being our principal source of calcium, also carries our main strontium-90 threat. This is not surprising since milk and dairy products are vitally important components of our diet, accounting for up to 90% of calcium intake.[1] Strontium, from group IIA of the Periodic Table, occurs with calcium and barium and has biological and physical properties similar to those for these elements.

Strontium presents a threat to man because of its radioactive isotopes. Strontium-90 is widely used in medical and research establishments and produced as a by-product of nuclear fission, 2 to 5 atoms of strontium-90 being produced for every 100 nuclei undergoing fission. Of the six strontium isotopes produced by nuclear fission, strontium-90 is the most important and the most prevalent. It is also the most persistent source of strontium radiation to man, since it has a half-life of 28 years.[2]

Inside the body, strontium-90 enters the blood by absorption from the gastrointestinal tract, from where it is continuously removed by incorporation into new bone or is lost from the blood by urinary and faecal excretion.[1,3] The distribution of strontium in the body parallels that of calcium, high levels being found in teeth, bones and other calcified tissues. Strontium's tendency to occur with calcium is also apparent in foodstuffs—those high in calcium also accumulating strontium. This was clearly demonstrated in the Windscale fire of 1957 in which iodine-131 and strontium-90 scattered over surrounding farmland resulted in the contamination of milk and dairy products. Strontium-90 reaches the milk within a few hours of ingestion by the cow, the maximum activity (which may be up to 4% of the total imbibed) occurring after about 2 days.

The majority of strontium in milk is bound to the protein casein. However, the smaller ultrafilterable portion is of nutritional importance, since the chemical speciation of strontium-90 in this fraction will dictate its bioavailability.

Although the total amount of strontium present in a given milk sample can now be accurately analysed (usually from analysis of the radioactive decay product, yttrium-90), its chemical speciation in such a biofluid is still beyond the reach of the most sophisticated analytical techniques. However, we have for many years used computer simulation models to evaluate the low-molecular-mass (LMM) metal-ion distributions in biofluids such as blood plasma. The approach relies on the assumption that many biological fluids approximate to a steady-state or equilibrium situation. It is thus possible to use thermodynamic chemical equilibrium models to compute the metal–ligand speciation of the biofluid based on analyses of total ligand and total metal ion concentration data and the relevant formation constants.

The ECCLES program has been used to establish

* Author to whom correspondence should be addressed.

simulation models for blood plasma, milk and other biofluids.[4,5] The milk model has now been extended to encompass the pollutant strontium. The total ligand concentrations in human[6–12] and bovine[6–13] milk are listed in Tables 1 and 2, respectively. Values for the total and free concentrations of the biologically essential metal ions are given in Tables 3 and 4.[3,13–15] Formation constants for these metal ions with the former ligands were as previously used in the blood plasma model.[4] The additional formation constants for the strontium system were extracted from literature compilations and corrected to blood plasma conditions of 37°C, I = 150 mmol dm^{-3} NaCl. Milk has an ionic strength of approximately 80 mmol dm^{-3} and the constants are not expected to differ much from those of blood plasma. The total ligand, free metal ion concentrations and formation constant data were used to compute the LMM metal-ion distribution of strontium in human and bovine milk at a pH of 6.8.

* Concentration in LMM fraction estimated from total concentration.

RESULTS AND DISCUSSION

The distribution of LMM strontium and calcium complexes in human milk are shown in Table 5. Those for bovine milk are given in Table 6. The similarities between the LMM distributions of calcium and strontium are clear. In human and bovine milk both of the metals are present mainly as the free metal ions, the major complexes present being citrate and phosphate species. Bovine milk has higher citrate and phosphate concentrations and this is reflected in the increased percentage of both calcium and strontium present complexed to these ligands. It is interesting to note that the strontium citrate complex is charged, whereas the strontium hydrogen phosphate species formed is neutral and thus more likely to cross cellular membranes and thus more bioavailable.

As a consequence of the chemical similarities between strontium and calcium, it is likely that analytical techniques used to remove Sr from milk will also deplete the biofluid of calcium. Analytical techniques have been developed which selectively remove strontium using ion exchange or nitrate

Table 4. Metal ion concentrations in bovine milk

Metal ion	Free concentration (mol dm^{-3})	Total concentration (mol dm^{-3})	Reference
Ca(II)	2.00×10^{-3}	3.76×10^{-3}	13
Mg(II)	8.10×10^{-4}	1.66×10^{-3}	13
Cu(II)	1.00×10^{-15}	5.72×10^{-10}	15*
Zn(II)	1.00×10^{-8}	1.55×10^{-4}	15*
Fe(III)	1.00×10^{-8}	1.00×10^{-15}	15*
Sr(II)	1.01×10^{-6}	1.34×10^{-6}	3*

* Concentration in LMM fraction estimated from total concentration.

precipitation. Kimura has developed a method of selectively removing strontium from milk involving liquid–liquid extraction using the macrocyclic ether dicyclohexyl-18-crown-6.[16] This method relies on the ability of the ligand to complex strontium more strongly than calcium. This was evaluated using the ECCLES program using formation constants for dicyclohexyl-18-crown-6 reported in the literature.[17] Tables 7 and 8 show the effect on the LMM distribution of Sr(II) and Ca(II) ions in human and bovine milk of the presence of 10^{-4} mol dm^{-3} of dicyclohexyl-18-crown-6. Clearly, the crown ether is selective for strontium ions mobilising some 80% of the strontium whilst the calcium distribution is virtually unaffected. This selectivity for Sr(II) ions is undoubtedly due to the difference in ionic radii between the Ca^{2+} and Sr^{2+} ions, Sr^{2+} being of optimum size to sit in the hole of the crown ether molecule. Hence, such liquid–liquid extraction techniques may successfully be used to selectively remove strontium from milk for analysis purposes.

(*Received* 30 *April* 1984; *accepted* 4 *September* 1984)

Abstract—Bis(tertiaryphosphine/arsine oxides), $Ph_2E(O)(CH_2)_nE(O)Ph_2$ react with iron(II) iodide and iron(II) tetracarbonyliodide forming complexes of the type: (i) $[Fe(L–L)_3]I_2mH_2O$(L–L, *n*, E, *m*; mdpo, 1, P, 2; tmdpo, 4, P, 1); (ii) $[Fe(L–L)_2I_2]\cdot mH_2O$(L–L, *n*, E, *m*: edpo, 2, P, 1; tmdao, 4, As, 0); (iii) $[Fe(L–L)_2][FeI_4]\cdot 2H_2O$(L–L, *n*, E: edao, 2, As) and (iv) $[Fe(L–L)(CO)_2I]I\cdot H_2O$[L–L = mdpo, edpo, edao, tmdpo, tmdao and (for *n* = 6, E = P) hmdpo]. All the complexes have been characterized through elemental analysis, IR, far-IR and UV–visible spectra, molar conductance, magnetic moments and t.g.a. studies. Iron(II) iodide complexes are high-spin with μ_{eff} values of 4.94–5.24 B.M., whereas the iron(II) tetracarbonyl iodide complexes show intermediate magnetic moment values (3.85–3.98 B.M.). The water is present as lattice water.

Although numerous complexes of bis (tertiaryphosphine/arsine oxides) with a number of metal ions are known, yet there are a few complexes reported with iron(III) and none with iron(II).[1–3] The coordination chemistry of iron is important from biological and industrial aspects. In order to understand in detail how the bidentate bis(tertiaryphosphine/arsine oxides) behave in case of iron systems, we undertook the detailed study of iron(II) and iron(III) complexes. Consequently, a number of new iron(II) and iron(III) complexes have been synthesised and characterized with various techniques including ESR, Mössbauer, etc. It was also intended: (i) to correlate the number of CH_2 groups connecting (PO) or (AsO) groups with the stoichiometry of the complexes; (ii) to compare the Lewis acidity of iron(II) with that of iron(III); and (iii) to compare the Lewis basicity of the (AsO) group with that of the (PO) group. In one of the papers[4] we have reported the complexes of iron(III) chloride and nitrate with bis(tertiaryphosphine oxides) with structures: *trans*-$[Fe(L–L)_2Cl_2][FeCl_4]$(L–L = mdpo, edpo, tmdpo, hmdpo); $[Fe(ONO_2)_3(L–L)]$ (L–L = tmdpo, hmdpo); $[Fe_2(L–L)_3(ONO_2)_4](NO_3)_2$ (L–L = mdpo) and $[Fe(L–L)_2(ONO_2)_2](NO_3)$ (L–L = edpo). In this paper, we are reporting the complexes of iron(II) with ditertiaryphosphine/arsine dioxides (I and II)

$$Ph_2P(O)(CH_2)_nP(O)Ph_2$$

I

$$Ph_2As(O)(CH_2)_nAs(O)Ph_2$$

II

where $n = 1$; mdpo-methylene bis(diphenylphosphine oxide); $n = 2$, edpo or edao-1,2-ethylene bis(diphenylphosphine or arsine oxide); $n = 4$, tmpdo or tmdao-1,4-tetramethylene bis(diphenylphosphine or arsine oxide); $n = 6$, hmdpo-1,6-hexamethylene bis(diphenylphosphine oxide).

EXPERIMENTAL

Ligands

The ligands were obtained by the oxidation of corresponding phosphines/arsines by 30% H_2O_2 in acetone or benzene.[1]

Preparation of the complexes

Iron(II) iodide complexes were obtained by adding the solution of a ligand in chloroform to iron(II) iodide solution in a 5:1 acetone:benzene

* Author to whom correspondence should be addressed.

mixture (1 : 1 molar solutions were reacted), followed by refluxing for half an hour. The complexes separated out as viscous liquids either after concentrating or on the addition of petroleum–ether (40–60°C). They were solidified on further treatment with petroleum–ether after removing the mother liquor. The solid complexes were filtered, dried and recrystallised from the mixture of solvents used for the preparation of the complexes.

The mixed ligand complexes with iron(II) tetracarbonyl iodide were obtained by adding the solution of a ligand in chloroform to iron(II) carbonyl iodide solution in a 5 : 1 acetone : benzene mixture (for tmdpo ligand, carbonyl iodide solution was in chloroform). The reaction was allowed to take place in a dark room at about 25°C. The complex separated out as a dark brown viscous liquid as such or after the addition of petroleum-ether (40–60°C) and solidified on further treatment with petroleum-ether. The solid thus obtained was filtered, washed several times with the solvents used in the preparation of the complexes and finally dried *in vacuo*.

The analytical data and the techniques used for characterization

The elemental analyses for carbon and hydrogen were carried out at the University College of Sciences, Calcutta (India). Iron was estimated by the phenanthroline method spectrophotometrically.[5] The molar conductances of millimolar solutions of complexes in nitrobenzene were measured with Toshniwal conductivity Bridge type CLOI/O2A. The IR spectra in the range 4000–650 cm^{-1} (in nujol) were recorded on spectromom 2000. The far-IR spectra in the range 650–200 cm^{-1} were recorded at the University of Surrey (U.K.). The reflectance spectra in the range 350–1000 nm were recorded with spectrophotometer VSU-2P type. The magnetic susceptibility measurements (solid samples) were carried out using Gouy's method. The apparatus was calibrated with $HgCo(NCS)_4$ and the diamagnetic corrections were applied employing Pascal's constants.[6] The X-ray diffraction patterns (powder) of iron(II) iodide complexes were taken by using Debye–Scherrer camera of radius 57.3 mm mounted

* Sparingly soluble in nitrobenzene.

on Phillips generator of the type PW-1720. The t.g.a. off iron(II) iodide complexes was carried out with a manually operated instrument supplied by FCI unit, Sindri (India).

RESULTS AND DISCUSSION

Iron(II) iodide complexes

The elemental analyses reveal the compositions: $FeI_2(L\text{–}L)_3 \cdot mH_2O$ (L–L, m; mdpo, 2; tmdpo, 1); $FeI_2(L\text{–}L)_2 \cdot mH_2O$ (L–L, *m*: edpo, 1; tmdao, 0) and $FeI_2(L\text{–}L)H_2O$ (L–L = edao). The complexes are turmeric in colour and the melting points of the complexes usually lie in the range of those of the ligands (Table 1). The molar conductance values (in nitrobenzene) for the complexes of mdpo and tmdpo lie in the range 50–55 $ohm^{-1}\ cm^2\ mole^{-1}$) and support the formulation: $[Fe(L\text{–}L)_3]I_2 \cdot mH_2O$. The complex of edao has a molar conductance of ~ 15 $ohm^{-1}\ cm^2\ mole^{-1}$ and is lower than expected for a 1:1 electrolyte (20–30 $ohm^{-1}\ cm^2\ mole^{-1}$). Nevertheless, in the literature, a number of iron(III) complexes have been reported to show low conductance values and still formulated as 1:1 electrolytes.[3,4] On the same basis, the complex of edao has been formulated as $[Fe(edao)_2][FeI_4] \cdot 2H_2O$. The complexes, $[Fe(L\text{–}L)_2I_2] \cdot mH_2O$ (L–L = edpo, tmdao) are nonelectrolytes.

In the IR spectra, the $\nu_{(PO)}$ and $\nu_{(AsO)}$ show usual downward shifts and appear as either single or double peaks (Table 2).[1,4,7,8] The decrease in $\nu_{(PO)}$ and $\nu_{(AsO)}$ is less than that found in iron(III) complexes.[3,4] This demonstrates that iron(II) iodide has poor Lewis acidity as compared to that of iron(III) halides. Thus a hard "O" will bind more strongly to iron(III) than to iron(II) which has been made considerably softer by iodide group. There is no change in $\nu_{(P\text{–}C)_{aromatic}}$ as compared to that of free ligand and this is unlike the behaviour of iron(III) complexes which have been observed to show a decrease of up to 30 cm^{-1}.[4,7] In the far-IR spectra, the assignments to $\nu_{(Fe\text{–}O)}$ have been made in the ranges 385–390 cm^{-1} and 360–365 cm^{-1} for the respective phosphine oxide and arsine oxide complexes.[1,8–12]

The water present in the samples is not coordinated as there are no peaks in the region 785–805 cm^{-1} attributable to rocking and wagging modes of coordinated water.[13] The content of the

* $\nu_{(H_2O)}$ and $\delta_{(HOH)}$ lie in the range 3200–3300 and 1620–1645 cm^{-1} respectively.
† The IR spectrum of *cis*-$[Fe(CO)_4I_2]$ shows two medium bands at 2135 and 2090 cm^{-1}.

water remains constant even if a sample is exposed for a prolonged period thereby confirming that the complexes are stoichiometrically hydrated. In the thermogravimetric analysis, the water is lost below 120°C in the complexes **1**, **2**, **3** and **4** and the loss in weight corresponds to $2H_2O$, $1H_2O$, $1H_2O$ and $2H_2O$ in the respective complexes.

In the ligand field of O_h-symmetry, the ground ^5D of the free iron(II) ion splits into $^5T_{2g}$ and ^5E_g states, whereas in a T_d symmetry, the order of splitting is the inverse. The reflectance spectra of the complexes of mdpo, edpo, tmdpo and tmdao show weak bands in the range 10,000–10,800 cm^{-1} attributed to $^5T_{2g} \rightarrow {}^5E_g$ transition (Table 2). The other weak bands, lie in the range 18,520–21,740 cm^{-1}. These assignments are in agreement with those reported for octahedral iron(II) systems.[11,12,14,15] The charge-transfer bands in the range 24,100–26,310 cm^{-1} have been detected in all the complexes.[16]

The magnetic moment values of the complexes lie in the range 4.94–5.24 B.M. (Table 2).[17–19] Somewhat low values for the complexes of edpo, edao and tmdpo may be due to orbital quenching on account of lower symmetry in the complexes. The X-ray-powder photographs of the complexes show that the complexes are crystalline, but efforts to grow a single crystal resulted in failure precluding detailed X-ray structure determination.

Substitution reactions in cis-$Fe(CO)_4I_2$

The substitution reactions of *cis*-$Fe(CO)_4I_2$ with the ligands under consideration yield mixed ligand complexes having 1:1 metal to ligand ratio. These are light-sensitive and not very stable. The molar conductance of the complexes in the range 20–34 ohm^{-1} cm^2 $mole^{-1}$ support the formulation: $[Fe(CO)_2(L\text{–}L)I]I \cdot H_2O$ (Table 1). All these complexes are paramagnetic with μ_{eff} values of 3.85–3.98 B.M., conforming to a triplet ground state and correspond to the moment expected for two unpaired electrons with an additional contribution of about 1.00 B.M. from the second-order Zeeman effect.[20] In the present case, low-lying excited levels of multiplicities 5 and 1 will be present and therefore, an increased contribution from the second order Zeeman effect may not be unexpected. Konig and Madeja[21] have reported μ_{eff} values of ~ 3.9 B.M. for a number of iron(II) complexes with N-donors. It would be relevant to point out here that *cis*-$Fe(CO)_4I_2$ is diamagnetic, its derivatives $[Fe(CO)_2(L\text{–}L)I]I \cdot H_2O$ paramagnetic with intermediate values and complexes of iron(II) iodide (as seen in the previous section) with ditertiaryphosphine/arsine dioxides are paramagnetic having μ_{eff} values corresponding to 4 unpaired electrons. Since the ligands under consideration are weak-field ligands, the replacement of two CO groups by one bidentate L–L, leads to paramagnetism and further loss of CO groups (observed under UV photolysis) leads to the complexes having normal μ_{eff} values. Thus it is apparent that intermediate values are on account of changing ligand field from strong field CO groups to weak field phosphine/arsine oxide ligands. Thus the species $[Fe(CO)_2(L\text{–}L)I]^+$ possessing two CO groups, one bidentate oxygen donor L–L, and iodide group generate a situation in which magnetic moment values become intermediate.

In the IR spectra, each complex shows two $\nu_{(CO)}$ peaks one each in the regions 2060–2080 cm^{-1} and 2010–2030 cm^{-1} respectively (Table 2). In *cis*-$Fe(CO)_4I_2$, one peak at 2135 cm^{-1} decreases to low energy by 55–75 cm^{-1} while the other peak at 2090 cm^{-1} by 60–80 cm^{-1}. The appearance of two peaks in the substituted derivatives show that the carbonyl groups are in the *cis*-position.[22,23] Thus the cations, $[Fe(L\text{–}L)(CO)_2I]^+$ may be assigned *cis*-trigonal bipyramidal structure with CO groups either in the equatorial plane or one in the axial and the other in the equatorial plane. The absorption due to $\nu_{(P\text{–}C)_{Ar}}$, $\nu_{(P\text{–}O)}$ and $\nu_{(As=O)}$ show the usual trends on complexation. The water is present as lattice water as shown by IR spectroscopy due to the absence of rocking and wagging modes in the region 785–805 cm^{-1}.[13] The t.g.a. of the light-sensitive iron carbonyl derivatives was not possible due to low-thermal stability. It may be added here that the water is present as stoichiometric water and its content does not change on exposure as was seen by the reproducible magnetic moments and other data. It may be worth remarking that the carbonyl complexes are probably the first examples among metal carbonyl chemistry (*d*-block) exhibiting intermediate μ_{eff} values.

At the end, it may be appropriate to add that the iron(II) iodide complexes did not show Mössbauer absorption (probably due to heavy atom absorption) and ESR spectra (due to large zero-field splitting) at room temperature.

CONCLUSIONS

The carbonyl complexes have all 1:1 metal to ligand ratio, i.e. the increase in number of CH_2 groups appears to have no effect on the stoichiometry and probably they have similar structure. The similar behaviour has been noted earlier in case of complexes of ditertiaryphosphine oxides with iron(III) halides.[4,7] The behaviour of complexes of iron(II) iodide is variable; mdpo and tmdpo forming 1:3 complexes, edpo and tmdao forming 1:2 complexes whereas edao forms a 1:1

complex. Further iron(II) iodide acts as a poor Lewis acid as compared to iron(III) halides with respect to phosphine oxide ligands. However, there is no difference in behaviour with respect to arsine oxide ligands. It is also inferred from here that arsine oxide ligands are better donors relatively speaking as compared to phosphine oxides with respect to iron(II) iodide.

EXTRACTION OF COPPER(II) AND NICKEL(II) BY LONG-CHAIN ALIPHATIC DIOXIMES

L. R. M. PAPING, C. P. J. RUMMENS, P. H. A. VRIENS, J. H. M. C. VAN WOLPUT and T. P. M. BEELEN*

(*Received* 18 *June* 1984; *accepted* 4 *September* 1984)

Abstract—In the search for a selective nickel extractant symmetric dialkyl dioximes have been studied in the extraction of copper and nickel ions from ammoniacal and acidic solutions. Extraction from ammoniacal solutions showed great differences between copper and nickel. Because of slow kinetics for nickel, much more copper than nickel was extracted at short contact times, but since nickel forms more stable chelates, more nickel than copper was extracted after long contact times. Because of steric hindrance and solubility the extraction was also dependent on the length of the alkyl chains of the aliphatic dioximes. Two different chelates, CuL_2 and $Cu_4L_3(OH)_2$, were involved in the extraction of copper from acidic solutions. Kinetic measurements of the extraction of nickel from acidic solutions showed a first order dependence in ligand and nickel concentrations and almost zero order in H^+ concentration, demonstrating that the reaction of Ni^{2+} with the first non-ionized dioxime molecule is rate determining.

From analytical chemistry it is well-known that nickel ions react with dimethylglyoxime to form quantitatively the red bis(dimethylglyoximato) nickel(II) chelate. The relatively low solubility of dimethylglyoxime in organic solvents makes this compound unattractive for extraction. Burkin and Preston[1] investigated some aliphatic *vic.*-dioximes with alkyl groups ranging from C5 to C7 and found extremely low extraction rates for nickel, especially with compounds containing secondary alkyl groups. From previous work[2,3] it became clear that the use of *vic*-bicyclic dioximes increases enormously the extraction rate for nickel. Unfortunately, however, in contrast with monocyclic *vic*-dioximes, their $pH_{1/2}$ values for copper are smaller than those for nickel. Navtanovich and co-workers[4] discovered that the extraction of Cu(II) and Ni(II) from ammoniacal solutions is dependent on the total number of carbon atoms. Equilibrium was not established in the extraction and re-extraction of nickel. The extraction of copper(II) and nickel(II) from ammoniacal solutions is not identical in character with the pH dependent extraction from acidic solutions.[2,3] Although, because of the ammonia, the pH is greater than 7, no precipitation of metal hydroxides occurs because metal ammine complexes are formed in the water layer. The expected extraction equation is

$$M(NH_3)_n^{2+} + 2H_2A \rightleftharpoons M(HA)_2 \cdot xNH_3 + 2NH_4^+ + (n-x-2)NH_3.$$

If copper forms a much stronger ammine complex than nickel, it is perhaps possible that under special conditions Ni^{2+} is extracted, but Cu^{2+} is held in the water layer.

In this study the extraction properties of dialkyldioximes of the type C_nH_{2n+1}–C(NOH)–C(NOH)–C_nH_{2n+1} are described. The ammoniacal extraction is compared with the pH dependent extraction from acidic solutions.

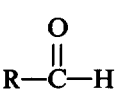
EXPERIMENTAL

UV–visible spectra were obtained on a Unicam Sp.800D, while ESR measurements were done at room temperature with a Varian E15 spectrometer.

The extraction experiments were carried out in a three-necked flask with a stirring device and continuous pH measurements. The starting volumes of water and organic solvent were both 250 cm^3.

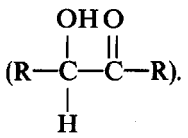
* Author to whom correspondence should be addressed.

Stirring was stopped when no further change of the pH was noticed, indicating that equilibrium was reached. For analysis equal small volumes of water layer and organic layer were withdrawn from the system. To measure the distribution coefficient as a function of pH thereafter a small quantity of 4N acid or base was added, and the process of stirring until equilibrium and withdrawal of small portions of the aqueous and organic solutions was repeated at a different pH. Care was taken to keep the volumes of the aqueous and organic solutions equal. Although in this procedure the electrolyte concentration does not stay constant, we preferred this model because it is convenient to execute and because in a separate experiment it was shown that in the applied concentration range the influence of the electrolyte concentration is negligible.



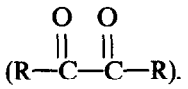
Organic solvents used were methylisobutylketone (MIBK) and chloroform and as inorganic salt metal nitrate was used. NaOH was used as base and HNO_3 as acid.

Kinetic measurements were carried out in a flask provided with a magnetic stirrer. The water layer containing the nickel nitrate was acidifed with 4N HNO_3 till the desired pH and then an equal volume (50 cm^3) of organic phase, in which the ligand was dissolved, was added. Under stirring 10 cm^3 of the mixture was withdrawn after 5, 10, 20 and 30 min. The two layers of these withdrawals separated immediately and it appeared that the volumes of both separated layers were equal (5 cm^3). UV spectroscopy applied to the organic phase gave the absorption at 30,500 cm^{-1}. Since the solvent and the ligand have no absorption below 35,000 cm^{-1} the absorption can be ascribed to the chelate formed during the extraction. According to the Lambert–Beer's law this absorption is proportional to the chelate concentration. When plotting the absorption against the contact time a straight line was obtained for the first 20 min and only a small deviation of the straight line was visible after longer reaction times. This straight line indicated that the initial reaction rate is not, or hardly, inhibited after 20 min, so the initial rate could easily be determined from this straight line.



SYNTHESIS OF DIALKYLDIOXIMES

All dioximes were prepared as described in the following general procedure.



Under nitrogen 0.39 mol freshly distilled alkylaldehyde

was dissolved in 120 cm^3 ethanol. 0.02 mol 3-benzyl-5-(2-hydroxyl-ethyl)-4-methyl-1,3-thiazolium chloride was added and subsequently 0.12 mol triethyl amine was added dropwise under vigorous stirring (Stetter synthesis).[5,6] After refluxing for two hours the reaction mixture was poured out into ice, filtered, washed with water and extracted with chloroform. The organic layer was washed with aqueous $NaHCO_3$, dried with Na_2SO_4 and distilled to give the dialkylhydroxy ketone

This dialkylhydroxy ketone was dissolved in 100 cm^3 2-ethoxyethanol with 30 cm^3 glacial acetic acid. To this solution, heated at 80°C, 0.044 mol Bi_2O_3 was added fast. After that the reaction mixture was heated for one and a half hours at 105°C, filtered and the residue was extracted with chloroform. The organic layer was washed with water till free from acid, dried and distilled to give the dialkyldiketone

0.4 mol $NH_2OH \cdot HCl$ and 0.32 mol NaOAc were dissolved in 25 cm^3 water and 50 cm^3 ethanol. To this 0.135 mol dialkyldiketone was added. The reaction mixture was refluxed for half-an-hour, cooled, and the residue filtered and washed with hot water. Recrystallization from diluted alcohol gave the pure dialkyldioxime (R–C(NOH)–C(NOH)–R) in an overall yield of about 25%. The results of elemental analyses are presented in Table 1.

RESULTS

In Fig. 1 the results are shown for the extraction of Cu(II) and Ni(II) from ammoniacal solutions by solutions of dialkyl dioximes in methylisobutylketone (MIBK) as a function of the number of alkyl carbon atoms at two different extraction times. Equilibrium was not yet reached after 240 min in the extraction of Ni(II) by dioximes with 5, 7 and 11 carbon atoms in the alkyl groups, but was reached after 48 h. By contrast, the equilibrium at about 80% extraction was reached within 10 min in the extraction of Cu(II) by dialkyldioximes with 3 and more carbon atoms in the alkyl groups.

The dependencies of the extractions of Cu(II) and Ni(II) by dipentyldioxime (dodecane-6,7-dione dioxime) on the NH_3 and NH_4^+ concentration are presented in Figs. 2 and 3.

Table 1. Synthesized dialkyl dioximes with analytical results

Compound	Found			Calc.		
	%C	%H	%N	%C	%H	%N

The pH dependent extraction of Cu(II) from nitrate solutions by a solution of dipentyldioxime in chloroform is shown in Fig. 4.

It is clear that at pH > 5 more than 50% (which is the theoretical limit if a CuL_2 chelate is formed) is extracted. The shape of the UV spectrum also changed at pH > 5. Thus it is clear that two different chelates are involved: chelate A at low pH and chelate B at pH > 5. When using an excess of Cu(II) compared to dioxime, the UV spectrum indicated that the extraction at pH = 4.3 resulted in chelate A with only a slight fraction of chelate B. Evaporation of the organic phase and recrystallization with ethanol and water gave a brown solid which was filtered and dried at 60°C. Elemental analysis of this compound gave: Cu, 13.8; N, 10.5; C, 55.2; H, 8.7%. After isolation the compound was only slightly soluble in chloroform, in contrast with the extracted chelate B. Further it was found that the extracted chelate A was unstable when the organic layer was dried with Na_2SO_4.

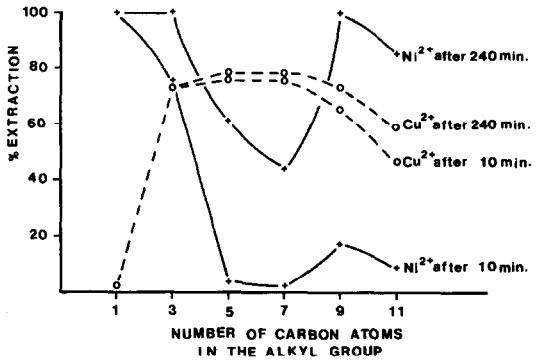

Fig. 1. Extraction of Cu(II) and Ni(II) by dialkyldioximes R–C(NOH)–C(NOH)–R as a function of the number of carbon atoms in the alkyl group R. Initial aqueous metal nitrate concentration 0.05 M. Initial dioxime concentration in methylisobutylketone (MIBK) 0.3 M. Initial NH_3 concentration 1.33 M. Initial NH_4NO_3 concentration 0.33 M.

The ESR spectrum of the chelate A in chloroform is depicted in Fig. 5.

The extraction of excess Cu(II) at pH = 8.4 resulted, according to the UV spectrum, in an organic solution containing nearly pure chelate B. Evaporation of the organic phase and recrystallization with dioxane and water gave a green solid that was dried at 60°C. Elemental analysis of this compound gave Cu, 23.5; N, 8.0; C, 46.8; H, 7.5%. After redissolving the compound in chloroform the UV spectrum deviated somewhat from that of the extracted chelate A. No ESR spectrum could be observed for this compound in solution at room temperature.

Kinetic measurements were done on the extraction of Ni(II) from a nitrate solution by dipentyldioxime to obtain some information why this reaction is so slow (no equilibrium within days).

If Figs. 6, 7 and 8 the initial extraction rate is presented as a function of initial H_2A, Ni^{2+} and H^+ concentrations. The order in dipentyldioxime concentration is calculated from the slope in Fig. 6 as 0.90. The order in Ni^{2+} concentration calculated from the slope of the line in Fig. 7 is 0.91. Because only

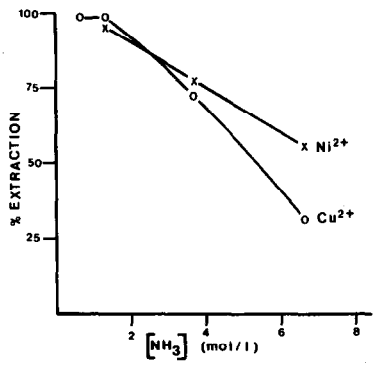

Fig. 2. Extraction of Cu(II) and Ni(II) by dipentyldioxime as a function of the initial NH_3 concentration after a contact time of 240 min. Initial dioxime concentration in MIBK is 0.55 M. Initial NH_4NO_3 concentration 0.33 M.

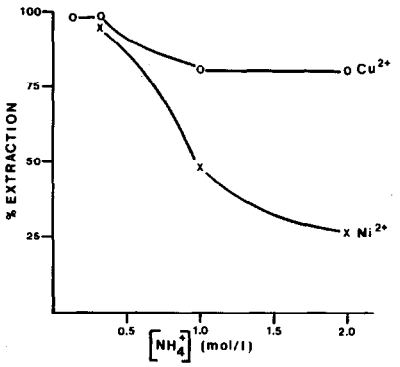

Fig. 3. Extraction of Cu(II) and Ni(II) by dipentyldioxime as a function of the initial NH_4NO_3 concentration after a contact time of 240 min. Initial dioxime concentration in MIBK is 0.55 M. Initial NH_3 concentration 1.33 M.

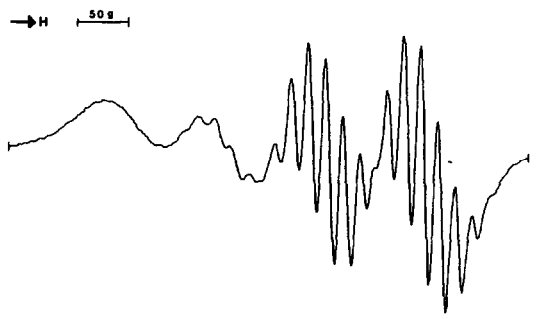

Fig. 5. ESR spectrum of the copper(II)–dipentyldioxime chelate (chelate A) in chloroform at room temperature.

two measurements were done for the hydrogen ion dependence, the order of -0.16 in H^+ should be regarded as an order of magnitude estimate.

DISCUSSION

Extraction of Cu(II) *and* Ni(II) *from ammoniacal solutions by aliphatic dioximes*

From Fig. 1 it can be seen that the only dialkyldioxime which is really selective for nickel above copper in the extraction from ammoniacal solutions is dimethylglyoxime. However, the extracted bis(dimethylglyoximato)nickel(II) chelate precipitates in the organic layer, and the back-extraction is blocked. Caton[7] explains this poor solubility by nickel–nickel interactions which prevent solvation. This interaction is possible because of the close packing of molecules in the crystal, a packing that cannot occur with larger alkyl groups according to Sharpe and Wakefield.[8] Dyrssen[9] stated that the bisdimethylglyoxymato)copper(II) chelate possesses two additional water molecules and that this chelate is soluble in water. The low percentage extraction of Cu(II) by dimethylglyoxime can be explained by the formation of such a hydrophilic aqua chelate. When larger alkyl groups are introduced in the dioxime the bulky hydrophobic substituents cause a change in the distribution coefficient of the copper chelate to the advantage of the organic layer. But also a destabilization of the two water molecules in the octahedral copper chelate is to be expected. In Fig. 1 it is clearly seen that from dipropyl to diheptyl dioxime these two effects keep each other in balance, but for longer alkyl groups the destabilization effect is stronger. Furthermore a small negative kinetic effect caused by steric hindrance can be seen for long alkyl groups.

In contrast with copper, nickel does not form octahedral chelates, but forms square planar chelates with dioximes. From the fact that after a contact time of 48 h the Ni extraction was almost complete, it can be concluded that the lower nickel

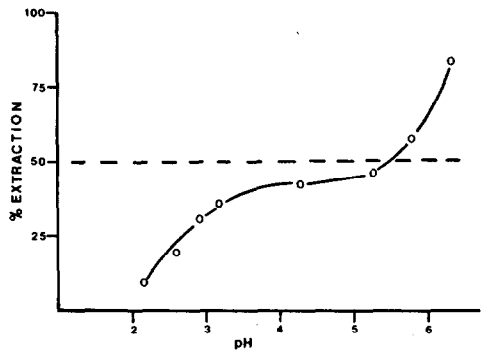

Fig. 4. Extraction of Cu(II) by dipentyldioxime as a function of the equilibrium pH. Initial aqueous copper nitrate concentration and the initial dipentyldioxime concentration in chloroform both are 0.001 M.

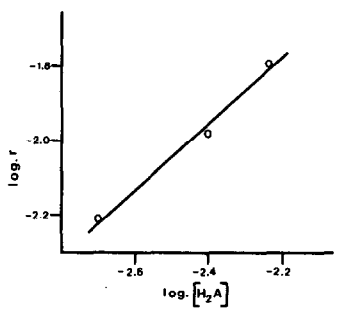

Fig. 6. Dependence of the initial rate of extraction of nickel by dipentyldioxime on the concentration of dipentyldioxime in chloroform. Initial pH is 3.52. Initial aqueous nickel nitrate concentration 0.00397 M.

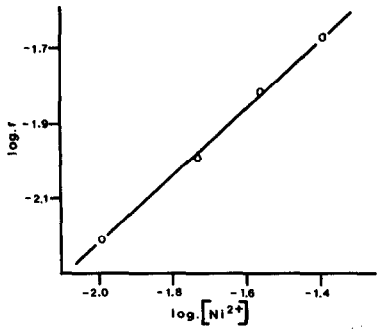

Fig. 7. Dependence of the initial rate of extraction of nickel(II) by dipentyldioxime on the concentration of Ni^{2+} in the aqueous phase. Initial dipentyldioxime concentration in chloroform is 0.00612 M. Initial pH is 3.65.

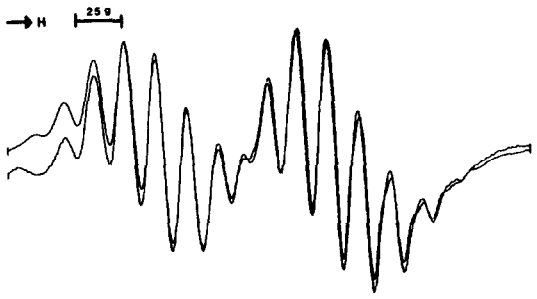

Fig. 9. The two high field copper bands from the ESR spectrum of Fig. 5 together with the computer simulation for a CuN_4 chromophore. The input values for the simulation are $A_{Cu} = 92$ G; $A_N = 16.2$ G; linewidth = 10.5/8.5 G; modulation 5 G; lineform Lorentz; ^{63}Cu = 70% and ^{65}Cu = 30%.

extraction observed for dioxime with pentyl, heptyl and undecyl groups after four hours is not caused by a difference in thermodynamic stability of the chelate formed, but is caused by a difference in extraction rate. This difference in extraction rate can be caused by steric hindrance. The steric hindrance from alkyl groups with 5 to 7 carbon atoms is most effective, according to Fig. 1. The reason why longer chains do not produce such a great hindrance is probably that longer chains are causing a greater insolubility of the dioxime in water, which means that the reaction takes place in the interface with the two long carbon chains pointed into the organic phase.

Comparing the extraction behaviour of Cu with that of Ni it can be noticed that after a contact time of 10 min, more Cu than Ni was extracted, because of favourable kinetics for Cu. On the other hand, after a long contact time more Ni than Cu was extracted, because Ni forms more stable chelates.

Figure 2 shows that the extraction of copper and nickel is dependent on the ammonia concentration. The dependence of copper is stronger which can be explained by the fact that copper forms more stable complexes with ammonia than nickel. Figure 3 shows that the extraction of copper and nickel also depends on the NH_4^+ concentration. The expected reaction equation for the extraction is:

$$M(NH_3)_n^{2+} + 2H_2A \leftrightharpoons M(HA)_2 + 2NH_4^+ + (n-2)NH_3.$$

The extracted copper chelate will probably have two water or ammonia molecules in the axial position.

A useful selectivity for nickel above copper is not found in the extraction by dialkyldioximes from ammoniacal solutions. At high ammonia concentrations and low NH_4^+ concentrations nickel is favoured but no good separation can be obtained.

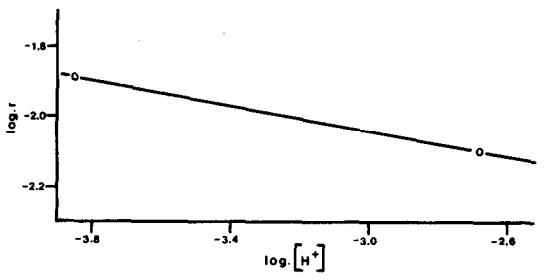

Fig. 8. Dependence of the initial rate of extraction of nickel(II) by dipentyldioxime on the concentration of hydrogen ions in the aqueous phase. Initial dipentyldioxime concentration in chloroform is 0.00415 M. Initial aqueous nickel nitrate concentration is 0.003 M.

The pH dependent extraction of Cu(II) *by dipentyldioxime*

The extraction (Fig. 4) and UV spectroscopic results demonstrate that two different kinds of chelate are involved in the extraction of Cu(II) by dipentyldioxime. Elemental analysis of chelate A formed at low pH values indicates that a CuL_2 chelate is formed. Found: Cu, 13.8; H, 8.7; N, 10.5; C, 55.2%. Calculated for $Cu(C_{12}H_{22}N_2O_2)_2$: Cu, 12.3; H, 8.5; N, 10.9; C, 55.9%. The percentage of copper observed is somewhat high, probably because of the presence of a small amount of chelate B, which has a higher percentage of copper (23.5%). No additional water molecules were found, but it is not excluded that these molecules were present in the extracted chelate and disappeared during heating at 60°C. The presence of water molecules also explains

the instability in solution with Na_2SO_4, a water absorber, and the change in solubility properties after drying at 60°C. If Na_2SO_4 absorbs the two axial water molecules, this means that these are fairly weakly coordinated and so it is not surprising that they dissociate at 60°C.

Cu^{2+} is a d^9 system with one unpaired electron, which means that four main lines can be expected in the ESR spectrum, because $I = 3/2$ both for ^{63}Cu and ^{65}Cu. The normal way of coordination for unstrained dioximes is the N,N-configuration. Because $I = 1$ for nitrogen, nine equidistant lines are to be expected on each copper line with intensity ratio of 1:4:10:16:19:16:10:4:1. Furthermore, we must take into account that copper consists of 59.1% of ^{63}Cu and for 30.9% of ^{65}Cu with a slight difference in magnetic moment (0.70904×10^{-4} vs 0.75958×10^{-4} rad. s^{-1} G^{-1}).

A computer simulation of the spectrum is shown in Fig. 9 together with the experimental spectrum and an excellent fit is noticeable.

The left part of the simulation is somewhat raised compared to the observed spectrum because the overlap with the third copper band could not be taken in account with our program. This simulation proves that indeed chelate A has N,N-coordination.

Chelate B is formed at high pH values (pH > 5) with an excess of copper. This phenomenon is also seen in the extraction of copper by δ-H_2CQD (see Ref. 2) and in the extraction of copper by α-benzildioxime (Einaga and Ishii).[10]

The elemental analysis of chelate B can be explained by assuming a $Cu_4(C_{12}H_{22}N_2O_2)_3(OH)_2C_4H_8O_2$ chelate. The expected elemental analysis for this chelate—Cu, 24.1; N, 8.0; C, 45.5; H, 7.2%—is in reasonable agreement with the observed values: Cu, 23.5; N, 8.0; C, 46.8; H, 7.5%. The dioxane molecule would then be introduced during the recrystallization. This would also explain why the UV spectrum changed after isolation. These results are insufficient to determine the structure of chelate B directly after extraction. The absence of an ESR spectrum points to the formation of a chelate with a strong copper–copper coupling, as was also found for the Cu:H_2CQD = 2:3 chelate.[2] A composition of $Cu_4(C_{12}H_{22}N_2O_2)_3(OH)_2 \cdot xH_2O$ is possible for the extracted chelate but other compositions cannot be excluded. The high copper extraction as observed in Fig. 4 can readily be explained by such a chelate. The significance of this chelate B for the extraction of copper is very small, because when dipentyldioxime is used in practical processes excess ligand will be used and the pH will be kept low (to prevent copper hydroxide precipitation) and under these circumstances no chelate B will be formed.

Kinetic measurements and pH dependency of the nickel extraction by dipentyldioxime

To find the rate-determining step kinetic measurements were performed on the extraction of nickel(II) by dipentyldioxime. From Fig. 6 the order in dipentyldioxime is calculated to be 0.90, which approximates 1 and not 2 as was found by Navtanovich and co-workers for the extraction from ammoniacal solutions. The order in Ni^{2+} is 0.91 (Fig. 7) in good agreement with the expected order of 1. The order in H^+ is 0.16 (Fig. 8) which is not far from zero. These orders can be explained when we assume the following reaction scheme:

$$\overline{H_2A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H_2A^*, \tag{1}$$

$$Ni^{2+} + H_2A^* \overset{k_2}{\rightleftharpoons} Ni(HA)^{+}{}^* + H^+, \tag{2}$$

$$Ni(HA)^{+}{}^* + H_2A \overset{k_3}{\rightleftharpoons} Ni(HA)_2^* + H^+, \tag{3}$$

$$Ni(HA)_2^* \overset{k_4}{\rightleftharpoons} \overline{Ni(HA)_2}. \tag{4}$$

Compounds marked with an asterisk are supposed to be in the interface or in the water layer and compounds marked with bars in the organic layer.

If reaction (2) is the rate-determining step, the initial extraction rate will be given by

$$r = k_2[H_2A^*][Ni^{2+}] = k_2 \cdot K_1[\overline{H_2A}][Ni^{2+}] \tag{5}$$

with

$$K_1 = \frac{k_1}{k_{-1}} = \frac{[H_2A^*]}{[\overline{H_2A}]}.$$

This would explain the first order in H_2A and in Ni^{2+} and the zero order in H^+.

Because of the low pH value it is unlikely that the dipentyldioxime dissolves in the water layer. The reaction, therefore, presumably takes place in the interface. The acidic water layer does not make it very attractive for the dioxime part of ligand (which is acidic too) to appear at the interface. Because of this low interfacial dioxime concentration equation (2) will be the rate-determining step. In ammoniacal solutions Navtanovich and co-workers[4] found a second-order rate dependence in H_2A, which means that in their case the reaction of Ni^{2+} with the second H_2A molecule was rate-determining. The ammonia causes a high pH value and it is reasonable to assume that the dioxime part of the ligand is pulled to the interface and is ionized. This causes a high interfacial dioxime concentration and as a result the normally expected second order in H_2A is found.

The overall extraction equation for Ni at low pH

$$Ni^{2+} + 2H_2A \rightleftharpoons Ni(HA)_2 + 2H^+$$

is completely different from the equation for the extraction from ammoniacal solutions. It is therefore not surprising that different orders are found.

^{1}H NMR STUDIES OF U(IV)–1,2-CYCLOHEXANE(DINITRILO)-*N,N,N',N'*-TETRAACETIC ACID COMPLEXES

LECHOSŁAW LATOS-GRAŻYŃSKI

Institute of Chemistry, Wrocław University, 50 383 Wrocław, 14 F. Joliot-Curie, Poland

(*Received* 30 *April* 1984; *accepted* 4 *September* 1984)

Abstract—^{1}H NMR spectrum of a U(IV)–*trans*-1,2-cyclohexane(dinitrilo)-*N,N,N',N'*-tetraacetic acid (CyDTA) complex (prepared by dissolving U(IV)(CyDTA)$(H_2O)_3$ in aqueous Na_2SO_4 solution) has been studied as a function of pH and temperature. The magnetic moment of the complex is 2.96 μ_B (pH = 2.7). The isotropic shift is mainly due to pseudocontact contribution. Three species for the U(IV)–CyDTA system in the presence of SO_4^{2-} are postulated in the pH range 5.5–8.0. The characteristic ^{1}H NMR spectrum of U(IV)–CyDTA in the absence of SO_4^{2-} has been observed (pH = 10). Eight, widely spread, acetate methylene resonances are present. Possible structures for all the observed species are discussed. The formation of dimers has been considered to account for the lowering of magnetic moments for high pH species. The assignment of resonances has been confirmed by selective deuteration of the acetate methylenes.

Polyaminepolyacetic acids can be treated as potential sequestering agents for the actinides.[1]

Ligands with a large number of donor sites (equal or larger than the coordination number of the actinide ion, e.g. diethylenetriaminepentaacetic or triethylenetetraaminehexaacetic acids, should be useful for such purposes. Hence, the study of the actinide–complexone systems in aqueous solutions are being pursued.

^{1}H NMR spectroscopy allows detailed studies of paramagnetic metal ion–complexone systems[2] to be carried out.

The formation of different ionic forms, dimerization and molecular rearrangement have pronounced influences on the ^{1}H NMR spectra.

Trans - 1,2 - cyclohexane(dinitrilo) - *N,N,N',N'* - tetraacetic acid (CyDTA) has been chosen for these studies as the flexibility of this ligand is restricted by its own molecular structure. This property differentiates essentially the studied system from those reported earlier in the literature, i.e. U(IV)–aminoacids,[3,4] U(IV)–EDTA.[5]

Previous potentiometric work on U(IV)–CyDTA and similar systems[6,7] indicated that a stable form of the 1:1 complex is U(IV)CyDTA$(H_2O)_2$ between pH 1 and 3.5. At high pH values the complex apparently loses a proton to form U(IV)CyDTA $(H_2O)(OH)$ which undergoes an olation reaction:

$$2[\text{U(IV)CyDTA}(H_2O)(OH)] \rightleftharpoons [\text{U(IV)CyDTA(OH)}]_2 + 2H_2O$$

to form dimeric hydroxo-bridged species.[6]

The influence of the pH, temperature and the addition of monodentate ligands on equilibria taking place in aqueous solutions has been analyzed in this paper by means of ^{1}H NMR spectroscopy.

Particularly, the solution structures of complexes have been a matter of interest.

EXPERIMENTAL

Reagents and solutions

Cs_2UCl_6 prepared by a literature method has been used as a convenient source of U(IV).[8]

U(IV)CyDTA$(H_2O)_3$ was prepared by adding 1 equiv. of CyDTA · H_2O (Merck) to an acidic solution of 1 equiv. of Cs_2UCl_6 and adjusting pH to 1.0 with aqueous NH_3. The greyish-green precipitate was filtered when the solution was hot and washed twice with water and once with acetone.

The resulting complex was analyzed for C, N, H. Found: N, 4.61; C, 26.22; H, 3.95%. Calc. for $UC_{14}H_{24}O_{11}N_2$: N, 4.41; C, 26.48; H, 3.81%.

The presence of three water molecules was confirmed thermogravimetrically. Aqueous solutions of 0.1–0.2 M UCyDTA in 1 M Na_2SO_4 or sarcosine (saturated solution) were prepared by adding the U(IV)CyDTA$(H_2O)_3$ complex to the hot solution of 1 M Na_2SO_4 (sarcosine) in D_2O (99.8% IBJ) with stirring until the solid dissolved. The resulting solutions were cooled and the pH adjusted with DCl (IBJ) or aqueous NH_3.

A D_2O solution of 0.2 M UCyDTA containing no Na_2SO_4 was prepared by adding D_2O to the U(IV)CyDTA$(H_2O)_3$ powder and stirring. Aqueous NH_3 was added until all solid dissolved (pH = 6).

Solutions containing 0.1 M UCyDTA for magnetic susceptibility measurements were prepared in a similar manner.

The complex of formula U(IV)(d_8-CyDTA)$(H_2O)_3$ (deuterated on acetate methylene groups of CyDTA) has been synthesized to achieve full resonance assignments. The Ni(CyDTA) complex was deuterated as described previously[9] (pH = 13.4, 95°C, 3 h heating).

The resulting solution was acidified to pH = 0 (RT), then the pH was adjusted to 3 with KOH and evaporated to dryness.

The dry residue was dissolved in D_2O and the deuteration was repeated under the same conditions as in the first stage. In this step an exchange of in-plane (deuterated) and out-of-equatorial Ni(CyDTA) plane acetate groups takes place.[9]

The procedure was repeated three times. 95% deuteration of the acetate methylene groups was achieved as shown by the ^1H NMR spectrum of the reaction mixture with added potassium cyanide. Diamagnetic $Ni(CN)_4^{2-}$ which formed did not interfere in the NMR spectrum of released d_8-CyDTA.

The final reaction mixture was acidified to give 6 M solution with respect to HCl and concentrated. KCl which precipitated during the concentration was filtered.

The residual solution contained: d_8-CyDTA (cationic form), uncoordinated Ni(II) and KCl.

Cs_2UCl_6 was added in the amount equimolar to CyDTA taken for the deuteration.

The pH was adjusted to 1 with aqueous NH_3. The greyish-green precipitate containing only U(IV)(d_8-CyDTA)$(H_2O)_3$ was filtered.

The process was feasible because of a larger stability constant for U(IV)–CyDTA[6] than for Ni(II)–CyDTA.[10]

Equipment

^1H NMR spectra were recorded with a JEOL PS 100 spectrometer operating in the CW or pulse mode depending on the sample concentration. The sample temperature was calibrated by measuring the peak separation of ethylene glycol or methanol.[11]

Chemical shifts were measured with respect to 2,2-dimethyl-2-silylpentane-5-sulphonate (Merck).

The magnetic susceptibilities of the U(IV)–CyDTA system were determined by Evans' technique[12,13] at 30°C.

Adjustments of pH were made with the Mera-Elmat 512 pH-meter. All reported values refer to the pH-meter readings for the solutions at room temperature. No correction was made for the large abundance of D_2O in the aqueous solutions.

RESULTS

The ^1H NMR spectrum of the U(CyDTA) complex at pH = 2.97 in 1 M Na_2SO_4 is shown in Fig. 1. The identical spectrum pattern was observed at the same pH in the presence of sarcosine. The

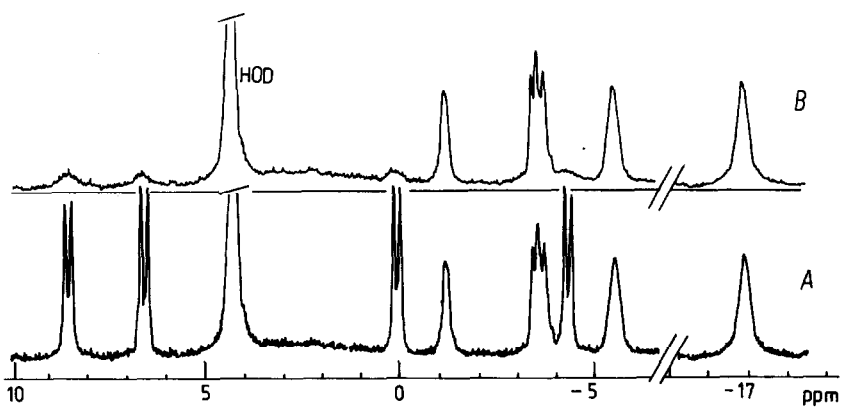

Fig. 1. ^1H NMR spectra of (A) 0.2 M U(IV)CyDTA and (B) 0.2 M U(IV)(d_8-CyDTA) in 1 M Na_2SO_4 (D_2O, 90°C, pH = 2.97).

synthesis of the selectively deuterated U(d_8-CyDTA) complex has allowed an unambiguous assignment of acetate methylene resonances of all species studied in this work in a similar manner as presented in Figs 1 and 2.

Two AX systems correspond to acetate methylene protons. The coupling constant between A and X is 16 Hz. This value agrees with coupling constants measured for other metal–CyDTA complexes.[14]

The remaining, paramagnetically shifted resonances have been assigned to the cyclohexane part of the ligand.

The Curie plot of U(CyDTA) (pH = 2.7, saturated solution of sarcosine) is presented in Fig. 2. The extrapolated chemical shift values ($T^{-1} \rightarrow 0$) are similar to those observed for diamagnetic CyDTA complexes.[14]

The characteristic deviation from linearity for only two acetate resonances probably results from the acetate chelate ring conformation changes. As these resonances participate in the same process they should belong to one set of acetate groups.

The Curie plot of U(CyDTA) in the presence of SO_4^{2-} (pH = 2.7, 1 M Na_2SO_4) demonstrated very similar features to those found for U(CyDTA)(sar). However, the curvature was well defined for all resonances.

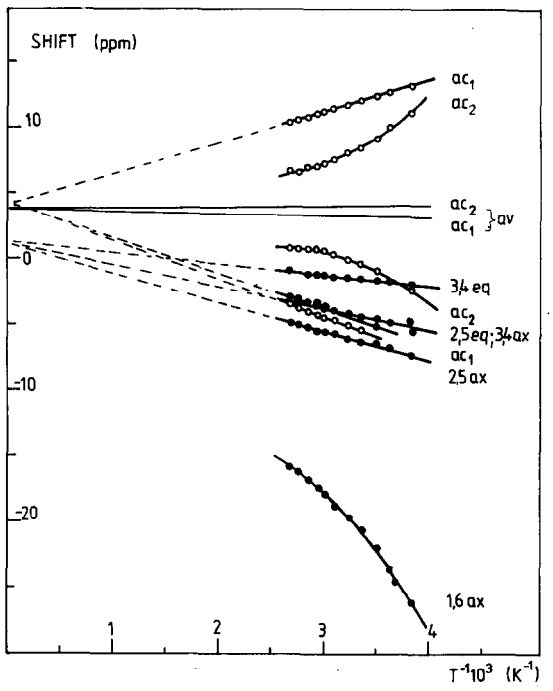

Fig. 2. Temperature dependence of the chemical shift of U(CyDTA) in the solution of sarcosine. Circles, acetate methylene protons; filled circles, cyclohexane protons; eq, equatorial; ax, axial; ac_i, acetate methylene equivalent by symmetry; ac_1, methylene carbon is in the antiperiplanar position to the 1, 6 ax proton; ac_2, methylene carbon is in the synclinical position to the 1, 6 ax proton; ac av, average shift of two methylene protons.

At pH below 1 the decomposition of U(CyDTA) unit was observed.

Above pH 3 the U(CyDTA) resonances become broader. In the pH range 3.5–6.5 (1 M Na_2SO_4, 30°C) the observed spectra are composed of two sets of resonances: one characteristic of the low pH form and the second one belonging to the form prevailing in the solution at pH 6.

Successive pH increase caused the appearance of two new sets of resonances dominating at pH 6.5–7 and 7.2–8.0 respectively (Figs 3 and 4).

Hence, the existence of three different species has to be considered to account for the observed NMR spectra for pH above 5.5 in the presence of SO_4^{2-}. The considerable resonance broadening and overlap made it difficult to carry out full assignments. However, the acetate methylene resonances could be distinguished (Figs. 3 and 4). The dependence of the chemical shifts on pH (1 M Na_2SO_4, 95°C) has been measured.

Contrary to the corresponding low temperature experiment no separate spectra for different ionic species could be seen above pH 5.5. Due to the fast exchange, the averaged shifts have been measured. The pH titration caused the smooth changes of resonances positions from those observed for pH 1–3 to those for pH 5–7.

Some small changes were observed as the pH was increased from 6.5 to 7.5 suggesting the presence of other forms in solution, the subsequent pH increase resulted in precipitation of U(CyDTA) hydroxo complexes.

The NMR spectra of U(CyDTA) solutions which do not contain Na_2SO_4 are essentially different from these discussed above (Fig. 5).

The spectrum of U(CyDTA) (pH = 10.0, 30°C, no Na_2SO_4 added) consists of eight acetate methylene resonances spreading from 10 to 100 ppm (85.4, 74.6, 66.7, 66.2, 30.5, 26.8, 11.2 and 10.4 ppm) and of the group of resonances assigned to the cyclohexane part of the ligand (12.0, 9.6, −7.2 and 13.3 ppm).

At 95°C the spectrum simplified and only four acetate methylene resonances were observed due to exchange processes averaging the peak positions for each acetate group independently.

The dependencies of chemical shifts on T^{-1} demonstrated large deviations from the regular Curie behaviour. The extrapolated chemical shift values ($T^{-1} \rightarrow 0$) fell in a region completely different than found for diamagnetic CyDTA complexes.

The lowering of pH from 10 to 6 resulted in a spectrum similar to that observed in 1 M Na_2SO_4 (Fig. 3).

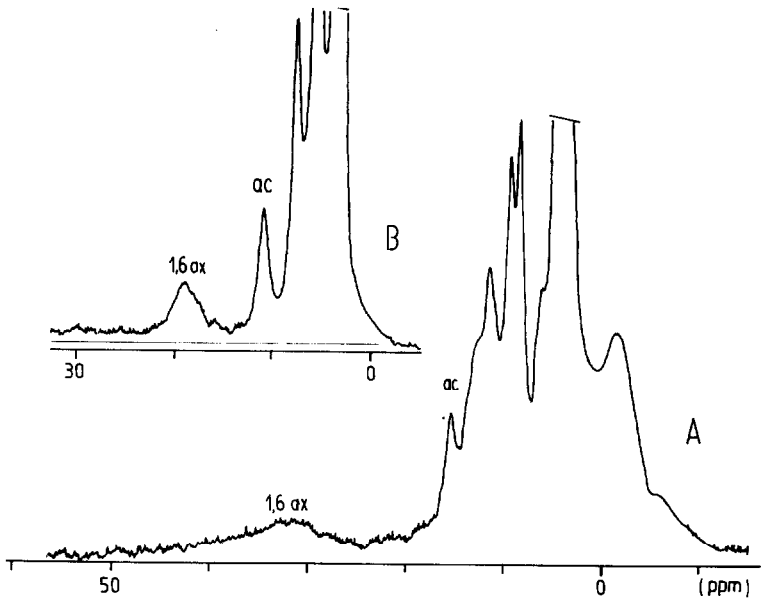

Fig. 3. ^{1}H NMR spectra of U(IV)–CyDTA in 1 M Na_2SO_4: (A) 30°C; (B) 95°C (pH = 5.7 at 30°C).

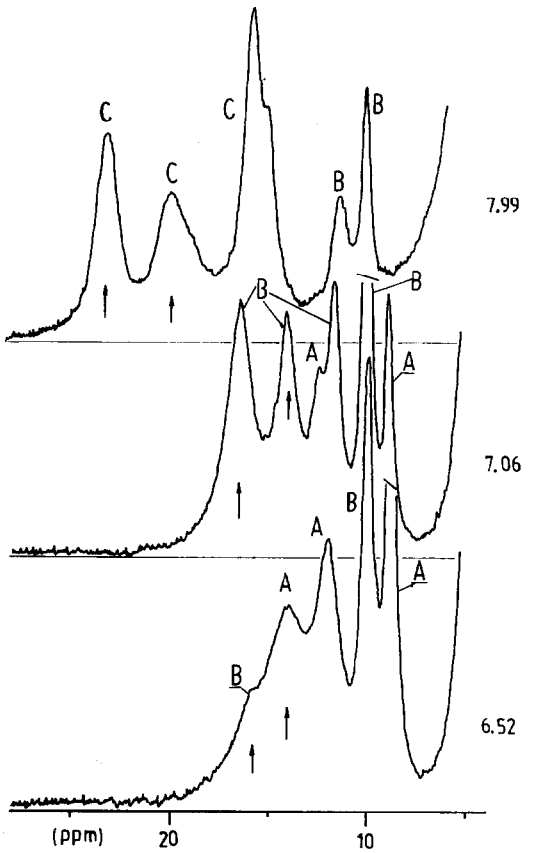

Fig. 4. ^{1}H NMR spectra of U(IV)–CyDTA in 1 M Na_2SO_4 (30°C, respective pH values marked in the figure). A, B, C correspond to species subsequently formed as pH increased. Arrows indicate the resonances of acetate methylene protons. Very broad resonance (32 ppm at 30°C, pH = 6.52) not shown.

Molar susceptibilities have been measured by the NMR procedure[12,13] as a function of pH. The measured values corrected for diamagnetic contributions are collected in Table 1.

Smooth changes of the susceptiblity and magnetic moment have been observed in the pH region where equilibria between several species have been postulated.

DISCUSSION

U(*CyDTA*)–SO_4^{2-} *system*

The U(IV)CyDTA$(H_2O)_3$ complex has limited solubility in water. The presence of additional ligands in the coordination sphere is necessary to increase the solubility in the pH range 1–3.

A complex of formula U(CyDTA)$(H_2O)SO_4$, analogous to the previously studied U(EDTA)$(H_2O)SO_4$,[5] accounts for the observed NMR spectra. The magnetic moment is 2.96 μ_B which may indicate the presence of two unpaired electrons in a cubic or slightly perturbed cubic symmetry for the U(IV) ion.[5] As the acetate methylene resonances are shifted downfield and upfield with respect to their diamagnetic positions a pseudocontact mechanism should dominate these paramagnetic shifts.

The respective geometric factors have been calculated assuming cubic symmetry (a square antiprism gave similar results).

The effective axial symmetry approach, frequently used for f^n ion complexes,[5,16,17] has been applied

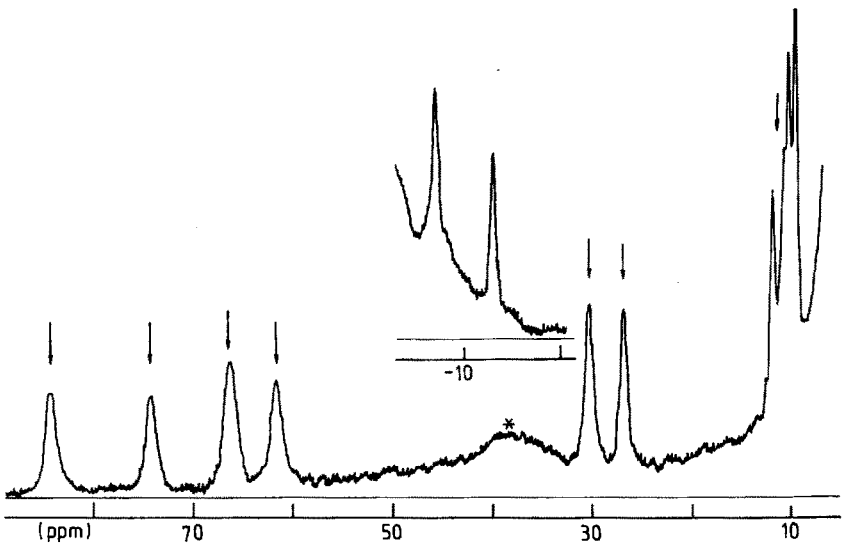

Fig. 5. ^{1}H NMR spectrum of the U(IV)CyDTA complex at pH = 10.0 (30°C). Arrows indicate the resonances of acetate methylene protons. Resonances overlapped with solvent signal not shown. *, resonance not identified.

with the main magnetic axis connecting the U(IV) with a centre of the C_1–C_6 ethylenic bond of the CyDTA ligand.

The chair conformation of cyclohexane ring and the puckered conformation of acetate chelate rings (the U–N–C_α and N–C_α–H dihedral angle equals 60–90°) have been considered.

The U–N and U–O bond lengths have been taken as 2.5 Å similar to those $Zr(NTA)_2$.[15]

A linear dependence of paramagnetic shifts on calculated geometric factors has been found (Fig. 6).

The resonance assignments have been confirmed by the analysis of the spin–spin couplings resolved in the cyclohexane part of the spectrum at 95°C (Table 2).

The observed linear correlation confirms the validity of the assumption stated above. Particularly, the term $\chi_{xx}-\chi_{yy}$ has to be relatively small allowing for the axial symmetry approximation.

The H_2O and SO_4^{2-} ligand occupying two of the eight available coordination places of U(IV) are required to be in fast exchange to achieve effective axial symmetry.

Lowering the temperature to 2°C increased the acetate methylene linewidths and the spin coupling was no longer observed.

This is in agreement with the mechanism mentioned above. As compared to $U(EDTA)(H_2O)SO_4$ the rigid structure of the CyDTA ligand prevents a

metal centred rearrangement which preserves the U(CyDTA)$(H_2O)SO_4$ structure up to 100°C.

Observation of AX patterns for the U(CyDTA) complex is caused by non-equivalency of the methylenic protons due to non-labile bonding between the metal ion and the two nitrogen donor groups of the CyDTA ligand.[14] However, some changes of conformation of the acetate chelate rings were noticed as deviation from Curie behaviour was observed for the acetate methylene resonances (Fig. 2).

Above pH 3 a variety of new U(CyDTA) forms has been found. The magnetic moment was noticeably smaller as compared to U(CyDTA)$(H_2O)SO_4$ (Table 1). This suggests considerable spin pairing through μ-oxo or μ-hydroxo bridges.[5] Hence, the formation of dimeric (polymeric) species is consistent with the magnetic susceptibility data.

The following equilibria were considered:

$$\begin{array}{c} \qquad\qquad\qquad\

contributions. However, there are no structural data available to distinguish between these two possibilities.

PRESSURE DEPENDENCE OF ^{35}Cl NQR IN HEXACHLORO- ($N_3P_3Cl_6$) AND OCTACHLORO- ($N_4P_4Cl_8$) CYCLOPHOSPHAZENES

V. KRISHNAN, K. R. SRIDHARAN and J. RAMAKRISHNA*
Department of Physics, Indian Institute of Science, Bangalore 560012, India

(*Received* 19 *June* 1984; *accepted* 4 *September* 1984)

Abstract—High pressure studies of ^{35}Cl NQR in the hexachlorocyclophosphazene $N_3P_3Cl_6$ and in the *K*- and *T*-forms of octachlorocyclophosphazene have been carried out at room temperature. For $N_3P_3Cl_6$, the pressure dependence of all the four lines is linear up to a pressure of about 3500 kg cm^{-2} when a significant change in the slope is observed for all the lines, due to a possible phase transition. In contrast, the pressure dependence of the two lines in the *K*-form (metastable) and the four lines in the *T*-form of the tetramer($N_4P_4Cl_8$), is observed to be non-linear. The results are discussed on the basis of competing dynamic and static effects.

Cyclophosphazenes belong to a family of inorganic ring polymers. There has been considerable interest in these compounds, due largely to their applications in diverse fields. The temperature dependence of ^{35}Cl NQR in a number of chlorocyclophosphazenes including $N_3P_3Cl_6$ and $N_4P_4Cl_8$ has already been reported.[1] Lucken[2] has found the asymmetry parameter in $N_3P_3Cl_6$ to be very small. Dalgleish *et al.*[3,4] have reported measurement of ^{35}Cl NQR in $N_3P_3Cl_6$ and in other exocyclic substituents in a small pressure range of 0–1000 kg cm^2. The maximum shift in the NQR frequency with pressure was found to be about 80 kHz kbar^{-1} in these compounds, which reveals appreciable volume effects even at a relatively small compression.

Since the $N_3P_3Cl_6$ molecule in the solid state is known to have a mirror plane, and the phosphazene ring deviates slightly from the planar structure (so that it has a tendency to have a chair conformation), it was thought worthwhile to investigate the effect of pressure. Similarly, the high pressure experiments on the two forms of $N_4P_4Cl_8$ the results of which are reported in this paper for the first time, were planned to study the effect of pressure on the two isomeric structures.

EXPERIMENTAL

A home-made super-regenerative spectrometer that could operate in the frequency range 20–40 MHz was used to record the ^{35}Cl NQR spectra, with lock-in detection. High pressures were generated using a locknut type high pressure cell[5] made of alloy steel. Liquid paraffin was used as the pressure transmitting medium.

The compounds $N_3P_3Cl_6$ and $N_4P_4Cl_8$ were recrystallized by slow evaporation from petroleum ether. The *T*-form of $N_4P_4Cl_8$ was obtained from the *K*-form by heating the sample to 75°C in a precision temperature controlled oven. The *K*-form (metastable) is known to pass irreversibly into the *T*-form at a temperature of about 65°C.[6]

RESULTS

$N_3P_3Cl_6$

The relative intensity of the 4 lines, which is 2:1:1:2 at atmospheric pressure, is retained at higher pressures as well. This indicates that these molecules continue to possess the mirror symmetry at higher pressures also. The pressure vs NQR frequency plots (Figs 1 and 2) for $N_3P_3Cl_6$ show a linear variation with an appreciable fall in the slope around a pressure of 3500 kg cm^{-2}. Changes in the slope of the pressure vs NQR frequency graph in compounds similar to $N_3P_3Cl_6$ have been reported[4] and these are attributed to minor changes in the packing of the molecules in the solid at high pressure.

The values of the derivatives $(\delta\nu/\delta P)_T$ of the NQR frequency obtained through least square fit of our data (up to a maximum pressure of 3250 kg cm^{-2} is given in Table 1. The corresponding values of Dalgleish *et al.*[3] are also given in the table for

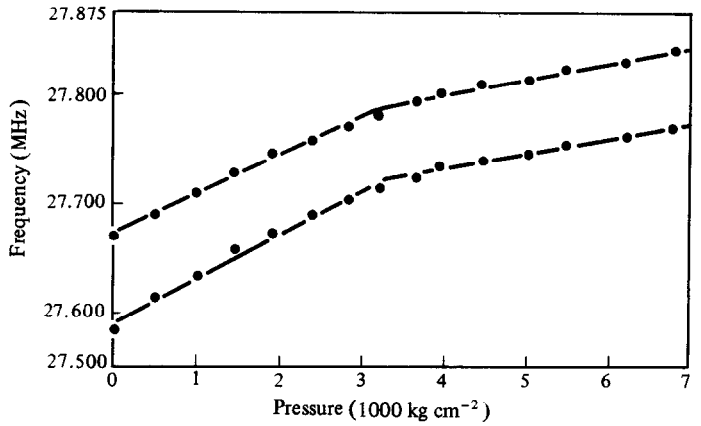

Fig. 1. Pressure dependence of ^{35}Cl NQR in $N_3P_3Cl_6$ (lines I and II) at room temperature (297 K).

comparison. The small differences between these two sets, could arise from a fall in the compressibility of $N_3P_3Cl_6$ at higher pressures (> 1000 kg cm^{-2}).

$N_4P_4Cl_8$—K-*form*

The ^{35}Cl NQR spectrum of this compound has two lines of almost equal intensity in conformity with its $\bar{4}$ site symmetry.[6] The frequency separation between the two lines is only about 130 kHz at room temperature. This separation reduces progressively with pressure becoming 15 kHz at a pressure of 7200 kg cm^{-2}. Such behaviour is consistent with the idea that the frequency separation is caused by thermal motion, i.e. the two sites are otherwise chemically equivalent.

The changes brought about by the pressure on the relative intensity of the two lines is yet another interesting observation. The intensity undergoes a perceptible change around a pressure of 2500 kg cm^{-2}, the higher frequency line becoming much stronger than the other line. Such an increase in relative intensity continues up to the maximum pressure investigated, at which the relative intensity is almost 4:1. Throughout this process, the linewidth of the two lines remain essentially unaffected, i.e. there are no observable line-broadening effects to account for the change in the intensities. Such a change in relative intensity with pressure therefore may be due to relaxation effects.

The pressure dependence of the NQR frequency in the *K*-form of $N_4P_4Cl_8$ is shown in Figs 3 and 4. The

pressure dependence is non-linear in direct contrast to the case with the trimer $N_3P_3Cl_6$. The pressure coefficient even becomes negative for the higher frequency line beyond a pressure of 5000 kg cm^{-2}.

$N_4P_4Cl_8$—T-*form*

$N_4P_4Cl_8$ *T*-form with a $\bar{1}$ site symmetry gives four ^{35}Cl NQR lines with relative intensities 2:3:2:3. The maximum frequency separation between the lines (I and IV) is about 1.350 MHz at room temperature. The doublet at the centre (lines II and III) has a frequency separation of about 55 kHz at room temperature.

The pressure dependence for the four ^{35}Cl NQR lines is shown in Figs. 5–7. The pressure dependence is non-linear, with the highest frequency line having the minimum pressure coefficient (at atmospheric pressure) and showing a decrease in the frequency with pressure beyond a pressure of 4000 kg cm^{-2}. These are similar to the observation made with the *K*-form. There were however no intensity anomalies

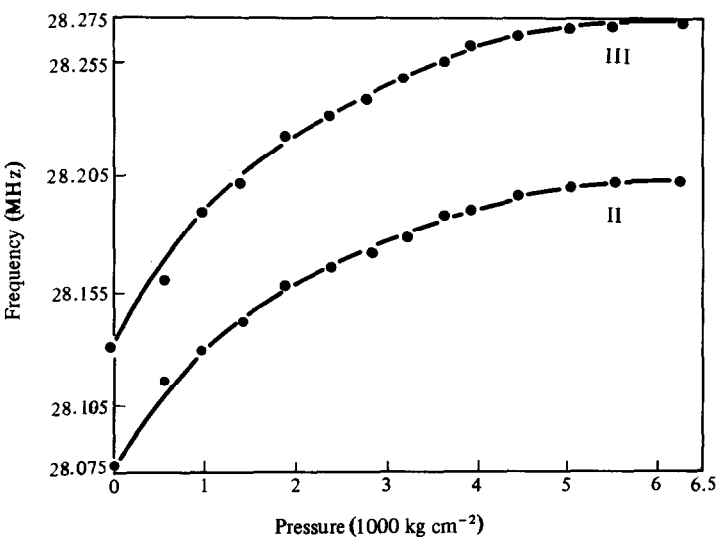

Fig. 6 Pressure dependence of ^{35}Cl NQR in $N_4P_4Cl_8$ (*T*-form) (lines III and II) at room temperature (297 K).

in the present case, throughout the range of pressure investigated. Also the absolute values of the pressure coefficients for the *T*-form are much higher than those for the *K*-form. Another contrasting feature concerns the frequency separation between the two lines at the centre (lines II and III) at higher pressures. While the separation narrows progressively with pressure in the *K*-form, it marginally increases in the *T*-form. This reveals the absence of any tendency for the molecule to acquire a two-fold axis of symmetry[6] at high pressure. (Addition of such a two-fold axis would lead to the merger of the two lines.)

PRESSURE DEPENDENCE OF NQR

The effect of torsional motions on the average value of the EFG can be expressed as

$$q = q_0(1 - 3/2\langle\theta^2\rangle) \qquad (1)$$

where $\langle\theta^2\rangle$ is the effective mean square amplitude of the torsional oscillations about the principal axes of the EFG tensor. q_0 is the EFG in the absence of all lattice vibrations. The variations of the first term on the r.h.s. with pressure, represents the effect of compression on the state lattice. Similarly the pressure dependence of the second term represents the damping of the torsional oscillations with pressure. Thus the second term leads to a positive pressure coefficient of NQR frequency. At high enough pressures, when the motions are effectively damped, the effects of compression of the static lattice, will become important. Negative pressure coefficients have also been reported in some molecular solids,[9] which have been explained as due to anisotropic polarisation of chlorine $3p_\pi$ orbitals of appropriate symmetry. (Static effects dominating over the dynamic effects.)

THERMODYNAMICAL ANALYSIS OF THE DATA

Using the thermodynamical relation[7]

$$\left(\frac{\partial v}{\partial T}\right)_P = \left(\frac{\partial v}{\partial T}\right)_V - \frac{\alpha}{\beta}\left(\frac{\partial v}{\partial P}\right)_T \qquad (2)$$

the partial derivative $(\partial v/\partial T)_V$ (Bayer term) that represents changes in the NQR frequency due to explicit temperature effects can be obtained from the observed values of $(\partial v/\partial T)_P$ and $(\partial v/\partial P)_T$. Very little data concerning the thermal expansion coefficient (α) and the isothermal compressibility (β) of covalent bonded phosphorus compounds are available. Dalgleish *et al.*[3] have obtained an approximate estimate for the ratio α/β, for similar compounds. The same is used in the present work. The $(\partial v/\partial T)_V$ so obtained are given in Table 2 for $N_3P_3Cl_6$; in Table 3 for $N_4P_4Cl_8$ *K*-form and in Table 4 for $N_4P_4Cl_8$ *T*-form. Whereas for $N_3P_3Cl_6$ a rigid vibrational motion of the whole molecule at a frequency 23 cm^{-1}, is also a localized PCl_2 bending mode at 55–60 cm^{-1}, is consistent with the observed value for $(\partial v/\partial T)_V$, a rigid vibrational mode around 20 cm^{-1} is consistent with our observation for $N_4P_4Cl_8$ *K*-form. The latter figure also compares very well with a reported[1] mean value of 19.4 cm^{-1} for this compound.

In the case of $N_4P_4Cl_8$ *T*-form, however, there seems to be some discrepancy between two sets of values for $(\partial v/\partial T)_V$. Part of this might be traced to the approximate value chosen for the ratio α/β in equation (2). It must however be pointed out that the same value used in the analysis of the data for *K*-form provides a satisfactory fit. In order to clarify this, the frequency of the vibrational mode, f_t, that could give a reasonable fit to the data was estimated using α/β as a variable parameter (Table 4). It appears from these

calculations that a lower value of about 15 for α/β (rather than 23 assumed earlier) provides a good agreement between the observed and estimated values for $(\partial\nu/\partial T)_V$. It is therefore quite probable (in the absence of precise data) that the ratio of α/β is appreciably small for the *T*-form compared to the *K*-form. One indication of such a possibility could be obtained from a comparison of the pressure coefficients for the two compounds near atmospheric pressure. The *T*- form has relatively higher coefficients which could result from relatively higher compressibility for this compound.

DISCUSSION

The trimeric ($N_3P_3Cl_6$) compound shows a linear variation for NQR frequency with pressure (up to about 3500 kg cm^{-2}) while both forms of the tetramer ($N_4P_4Cl_8$) reveal a non-linear pressure dependence. Non-linear pressure dependence of

* α = coefficient of thermal expansion (K^{-1}). β = isothermal compressibility (kg^{-1} cm^2).
† Kaplansky *et al.*[1]

NQR has been reported in a number of molecular solids.[8–10] The observed pressure dependence is the net result of the dynamic (resulting from a reduction in the torsional amplitudes) and static (resulting from an increase in intermolecular interaction, and bond polarisation effects) contributions to the volume effects. At higher pressures (> 5000 kg cm^{-2} in the present investigations) the static effects dominate over the dynamic effects. Negative pressure coefficients in 1,3,5-trichlorobenzene have been interpreted by Jones *et al.*[9] on the basis of anisotropic polarisation effects involving the lone pair electrons in the chlorine atoms. The anisotropic polarisation is assumed to result from the distortion of the $3p_\pi$ orbitals due to an admixture with $3d_\pi$ orbitals at higher pressures. Such an admixture increases in effect the size of the $3p_\pi$ orbital, thereby reducing the quadrupole coupling constant.

Dixon *et al.*[6] have invoked the presence of appreciable π-character for the P–Cl bonds in the *T*-form of the *tetramer*-$N_4P_4Cl_8$ to account for the large frequency separation (about 1.4 MHz) between the NQR lines. According to such a scheme, the lowest NQR frequency has been assigned to the chlorine atom that has the maximum π-character. The highest frequency line (line IV) is expected to have the lowest π-character; consequently the anisotropic polarisation effects of the $3p_\pi$ orbitals should be comparatively smaller for this line. Our results show that the highest frequency line, having maximum NQR frequency apart from having the lowest pressure coefficient exhibits fall in the NQR frequency at higher pressures. Anisotropic polarisation effects therefore seem to be inadequate to account for the observed pressure dependence in the compound. Other intermolecular effects that become significant in these non-planar molecules under high pressure conditions may have to be considered.

Abstract—The complexes $R_2SnCl_2 \cdot (H_2glygly)$, ($H_2glygly$ = glycylglycine) (R = Me, Bu^n, Oct^n, Ph) and $RSnCl_3 \cdot (H_2glygly)$ (R = Bu^n, Oct^n, Ph) have been prepared and characterised by chemical analysis, thermal properties and IR and Mössbauer spectroscopy. The IR data are consistent with the glycylglycine ligand acting as a monodentate ligand through the amino-nitrogen. The Mössbauer isomer shift data suggest the bonding in the diorganotin complexes is relatively weak between the tin(IV) moiety and the ligand. ^{1}H NMR spectroscopy was used to probe the nature in solution of the $Me_2SnCl_2 \cdot (H_2glygly)$ adduct.

The preparation and characterisation by infrared and ^{119}Sn Mössbauer spectroscopy of some organotin(IV) derivatives with biological molecules have been reported.[1–5] On the other hand there are only a few examples of adducts of glycylglycine acting as neutral ligand.[6,7] Owing to the increasing interest in glycylglycine derivatives, new compounds $R_nSnCl_{4-n} \cdot (H_2glygly)$ have been prepared for $n = 2$ with R = Me, Bu^n, Oct^n and Ph and for $n = 1$ with R = Bu^n, Oct^n and Ph and characterised by chemical analysis, their thermal behaviour and by infrared and ^{119}Sn Mössbauer spectroscopy in the solid state. ^{1}H NMR was used to assess the behaviour of $Me_2SnCl_2 \cdot (H_2glygly)$ adduct, as representative of the series, in D_2O solution. There have been no reports in the literature giving details of any thermal study on complexes related to those prepared in this work and one of the aims of the present study is to identify and assign the stages involved in the decomposition processes of the adducts. Two different types of glycylglycine adduct are examined, viz. monoorganotin(IV) derivatives whose parent organotin(IV) chlorides are liquids and diorganotin(IV) derivatives that have solid parent organotin(IV) chlorides.

EXPERIMENTAL

The organotin(IV) chlorides were a gift from Schering AG (Bergkamen). The organotin(IV) chloride glycylglycine adducts were prepared by refluxing 1:1 molar quantities of the appropriate organotin(IV) chloride and glycylglycine in dry methanol until the reaction mixture became clear. The products obtained on cooling the solution were washed with dry methanol and dried under vacuum.

* Author to whom correspondence should be addressed.

All operations were carried out under N_2 atmosphere.

The compounds were analysed for tin gravimetrically as SnO_2[8] and for chlorine by titration with mercuric perchlorate following the destruction of organic matter by the oxygen flask method. C, H and N were determined at the Laboratorio di Chimica Organica (Milano). Analytical data for the glycylglycine complexes are reported in Table 1.

The thermal behaviour of the adducts was studied on a Stanton Redcroft STA 780 simultaneous thermal analyser. Infrared spectra were obtained using a Perkin–Elmer 580 spectrophotometer as split mulls (CsI windows) for the solid adducts. The spectrum in D_2O solution for the $Me_2SnCl_2 \cdot (H_2glygly)$ adduct was measured with CaF_2 liquid cells (0.05 mm pathlength) using a compensation technique.

Mössbauer spectra were determined using apparatus and techniques previously described,[5,9] with a $Ca^{119}SnO_3$ source [10 mCi (Radiochemical Centre, Amersham)] at room temperature with constant acceleration and a triangular wave-form. The experimental spectra are computer fitted to Lorentzian shapes.

^1H NMR spectra were recorded with a Bruker WP 80 SY spectrometer operating at 80 MHz in the FT mode; the temperature of the probe was *ca.* 31°C.

RESULTS AND DISCUSSION

Thermal properties

In view of the difference in the nature of the mono- and di-organotin compounds, their thermal decomposition processes are discussed separately. To help assign the stages involved in the decomposition of these materials, the thermal analysis was also carried out on the individual parent materials and on an intimately ground 1:1 mixture of glycylglycine with the organotin halides.

R_2SnCl_2–glycylglycine systems

There appears to be no general pattern of decomposition of the complexes of the type $R_2SnCl_2 \cdot (H_2glygly)$ (where R = Me, Bu^n, Oct^n or Ph). The thermal decompositions are different and characteristic of the specific adducts. All of the parent diorganotin(IV) dichloride salts melt without decomposition and volatilise off at higher temperatures. Glycylglycine itself decomposes in three stages, losing 18% of its weight at 215°C, about 30% of its weight at 243°C and the remainder at temperatures above 300°C. The weight losses are assigned to loss of NH_3, loss of CO_2, and final volatilisation of the residue respectively. The data for the decomposition stages of the adducts, the mixtures and the organotin(IV) parent compounds are in Table 2.

The differential weight loss (DTG) curve for the volatilisation of the diphenyltin(IV)dichloride suggests that a two-stage process is involved. Such a process would be consistent with the known rearrangement of Ph_2SnCl_2 to give $SnCl_4$ and Ph_3SnCl whose decomposition temperatures are 114 and 240°C respectively. There is no evidence in the DTG curves, in the region of vaporisation, of the other diorganotin(IV)dichlorides for similar rearrangements.

$PhSnCl_3 \cdot H_2glygly$	27.9	2.81	6.57	24.7	27.6
	(27.66)	(3.02)	(6.45)	(24.49)	(27.33)

There is some similarity in the thermal decompositions of the mixture of R_2SnCl_2 with glycylglycine where R = Bu^n, Oct^n or Ph. In each, the diorganotin(IV)dichloride melts and the glycylglycine dissolves in the molten phase. Except for the case of the dioctyltin(IV)dichloride mixture, the melts decompose by volatilisation of most of the diorganotin(IV)dihalide leaving impure glycylglycine to decompose at a higher temperature. For the dioctyltin(IV)dichloride mixture, the weight loss due to the volatilisation of $Oct^n_2SnCl_2$ overlaps the weight loss due to the decomposition of glycylglycine. The dimethyltin(IV)dichloride–glycylglycine mixture loses 42% weight at 50°C before melting at 107°C and subsequently losing the organotin(IV)halide and glycylglycine residues by volatilisation at 133 and 248°C. These results can be explained if part of the dimethyltin(IV)dichloride undergoes rearrangement to give $Sn(CH_3)_4$ and $SnCl_4$ (boiling points 78 and 114°C respectively). A broad DTG feature is found over this temperature range and is more consistent with loss of two volatile

components than with a one-stage decomposition. During the evaporation of $SnCl_4$ there is evidence for a melting endotherm on the DTA trace that would be consistent with the melting and volatilisation of undecomposed Me_2SnCl_2.

The fact that the organotin(IV)dihalides volatilise off from molten mixtures at temperatures similar to their boiling points suggests that there is no strong interaction between the organotin moiety and the glycylglycine ligand in the adducts.

The thermal decomposition of the adducts fall into two classes, following one of two distinct mechanisms: viz. (1) in which the decomposition of the adduct follows a process similar to that of the mixture, and (2) in which the decomposition involves a reaction within the lattice which does not occur in the mixture.

Both the dioctyl- and dibutyltin(IV)dichloride derivatives of glycylglycine decompose following mechanism (1). Figure 1 shows the TG, DTG and DTA traces for the decomposition of: (A) $Oct_2^nSnCl_2$, (B) $Oct_2^nSnCl_2 + H_2glygly$ and (C) $Oct_2^nSnCl_2 \cdot (H_2glygly)$. The difference between the decomposition of the adduct, $Oct_2^nSnCl_2 \cdot (H_2glygly)$ and the mixture $Oct_2^nSnCl_2 + (H_2glygly)$ is that melting occurs at a lower temperature in the mixture allowing glycylglycine to dissolve in the melt but the adduct is stable to a higher temperature. The mixture containing dibutyltin(IV)dichloride and the adduct $Bu_2^nSnCl_2 \cdot (H_2glygly)$ both melt at approximately the same temperature and decompose in a similar manner, indicating that the bonding in the dibutyl adduct is weak.

Thermal decomposition of those adducts involving some reaction in the lattice which is absent in the decomposition of the mixtures, is evident in the dimethyltin(IV) and diphenyltin(IV) systems. The mechanism of decomposition of these complexes involves the elimination of HCl from the lattice to give a glycylglycinate which subsequently decomposes in a different manner to those of the mixtures. Figure 2 shows the TG, DTG, and DTA traces for the decomposition of: (A) Me_2SnCl_2, (B) $Me_2SnCl_2 + H_2glygly$ and (C) $Me_2SnCl_2 \cdot (H_2glygly)$.

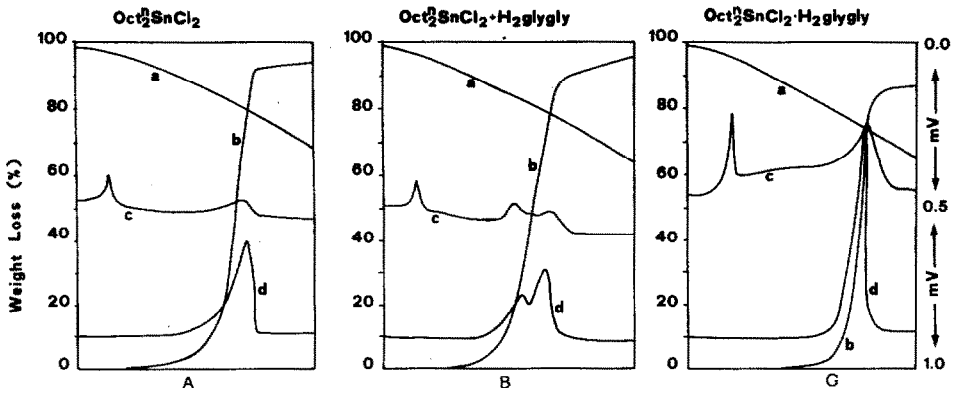

Fig. 1. TG, DTG and DTA traces of the decomposition of $Oct_2^nSnCl_2$(A); of equimolar mixture of $Oct_2^nSnCl_2$ and H_2glygly (B); and of the adduct $Oct_2^nSnCl_2(H_2glygly)$ (C). (a = temperature curve; b = TG curve; c = DTA curve; d = DTG curve.)

$RSnCl_3$–glycylglycine systems

All of the parent organotin trihalides, on reaching their boiling points, volatilise off losing 100% weight in one step. There is no evidence from differential weight losses to indicate decomposition occurring in more than one stage.

Both the octyl- and butyltin(IV)trichloride adducts with glycylglycine decompose at temperatures lower than the boiling points of their parent organotin compounds but in a similar manner to the mixtures $RSnCl_3$–glycylglycine (R = Bu^n, Oct^n). The two adducts appear to undergo a three-stage weight loss, although the unusually broad DTG peaks suggest that the decompositions are more complex. The three stages of weight losses are assigned to the initial elimination of HCl forming monoorganotin(IV)trichloride glycylglycinates followed by loss of organotin(IV)chlorides and finally by the break-down of the glycylglycine moiety. The mixture of octyltin(IV)trichloride and glycylglycine decomposes in a similar manner but the solid phase decomposes at a lower temperature. Although the decomposition of the mixture of Bu^nSnCl_3 and glycylglycine appears to be a multi-stage process, combination of certain weight losses gives a trace similar to that obtained for the adduct. Figure 3 shows the TG, DTG and DTA traces for: (A) Oct^nSnCl_3, (B) $Oct^nSnCl_3 + H_2$glygly and (C) $Oct^nSnCl_3 \cdot (H_2glygly)$. Both the adduct, $PhSnCl_3 \cdot (H_2glygly)$, and the mixture of $PhSnCl_3$ and glycylglycine begin to lose weight at 66°C which is the boiling point of $PhSnCl_3$. The complexity of the corresponding DTG peaks strongly suggests that the decompositions of the adduct and the mixture of the starting materials are not simple. The initial weight losses indicate it is possible to consider the rearrangements of $PhSnCl_3$ to form tetraphenyltin and $SnCl_4$, followed by the loss of the latter.

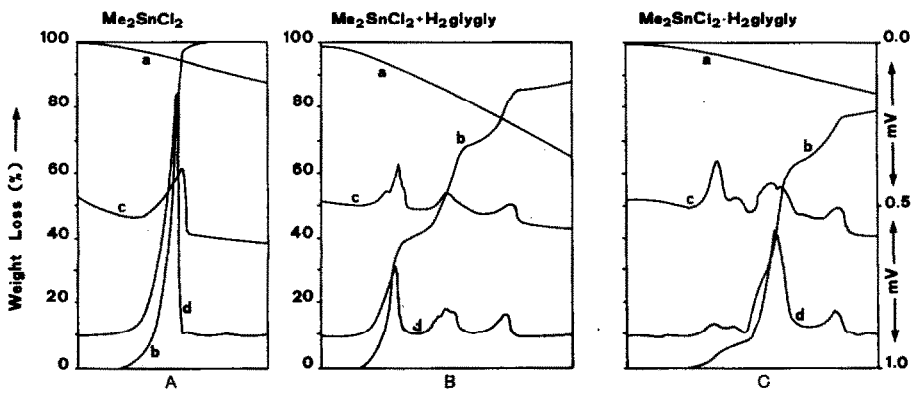

Fig. 2. TG, DTG and DTA traces of the decomposition of Me_2SnCl_2(A); of equimolar mixture of Me_2SnCl_2 and H_2glygly (B); and of the adduct $Me_2SnCl_2 \cdot (H_2glygly)$ (C). (a = temperature curve; b = TG curve; c = DTA curve; d = DTG curve.)

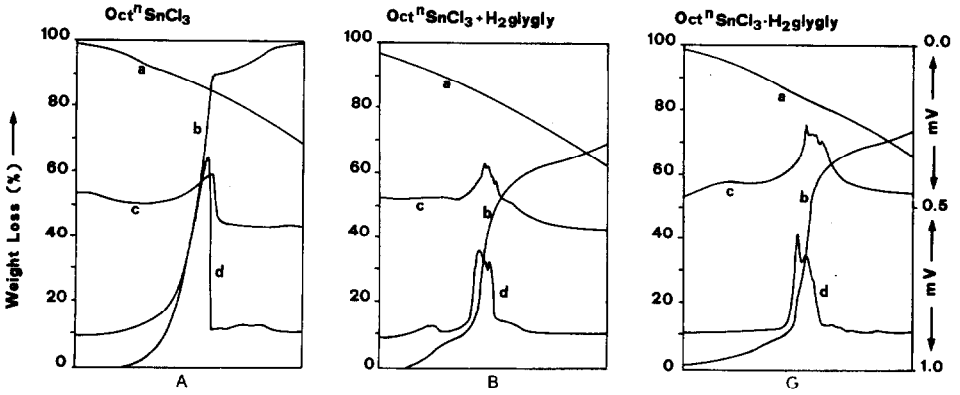

Fig. 3. TG, DTG and DTA traces of the decomposition of Oct^{n}SnCl$_3$ (A); of equimolar mixture of Oct^{n}SnCl$_3$ and H$_2$glygly (B); and of the adduct Oct^{n}SnCl$_3$·(H$_2$glygly) (C). (a = temperature curve; b = TG curve; c = DTA curve; d = DTG curve.)

IR spectra

Coordination by the amino group of aminoacids and simple dipeptides to (organo)metallic ions is reported to give rise to substantial shifts of the NH_2 stretching frequencies.[10] As pointed out, direct comparison should be made not with the zwitterion but with matrix-isolated species (where the NH_2 group in place of NH_3^+ is present) but this possibility is lacking for H_2glygly.

Therefore, the frequencies of the glycylglycine adducts are compared to a copper complex,[11] whose structure is chelated through the amino group as is that of trimethyltin(IV)glycylglycinate.[10]

Hardly any significant shift is observed for the 3300 cm^{-1} band in the spectra of all adducts. The broad absorptions which are observed, however, offer a striking contrast with the same vibration in the free ligand, where it is present as a relatively narrow peak. This suggests, although this is not a unique case,[12] that hydrogen bonding is prominent in these organotin(IV) derivatives, such as might be expected if the ligand, binding through the amino end, adopts a conformation which enables it to form inter- and/or intra-molecular hydrogen bonds via the COOH group. For some derivatives (Bu^{n}SnCl$_3$, Oct^{n}SnCl$_3$) the occurrence of more bands than expected symmetric and asymmetric stretching vibrations, is likely to be due to crystal effects.[10] In D_2O solution, a single broad band is observed at *ca* 3400 cm^{-1}.

The lower frequency broad bands (3230–3110 cm^{-1}) are probably due to a superimposition of $\nu_{s(NH_2)}$ and $\nu_{(N-H)(amide)}$.

The most relevant feature in the IR spectra of all solids is the appearance of the intense band at *ca* 1730 cm^{-1} (see Table 3) which is assigned to the un-ionised COOH group of the ligand. The same absorption, albeit reduced in intensity, is present in the D_2O solution spectrum which is somewhat shifted to lower wavelength in going from solid state to solution (Me_2SnCl_2 adduct). This frequency closely agrees with the solution spectra of both the ligand and metal.[13] The adduct of SiF_4 with glycine, binding with the amino nitrogen has been proposed.

Vibrations at 1678 and 1575 cm^{-1} are present in the adducts. The former is assigned to the amide I mode (mainly C=O stretching) of the peptide group[13] and appears virtually unshifted in D_2O solution (1675 cm^{-1}). The absence of absorptions in the region 1650–1600 cm^{-1} in the solid, rules out coordination of the peptide carbonyl oxygen to the organotin moiety. Indeed the shift of the 1678 cm^{-1} amide I vibration to lower wavelength (*ca* 1630) has been associated with binding to the peptide group through oxygen, both in the solid state and solution in a series of metal complexes.[11,13] Noticeably this frequency shift has been used[10] as a diagnostic tool in elucidating the different binding of Hglygly$^-$ in triorganotins. The amide carbonyl frequency in Me_3Sn(Hglygly) is observed at 1683 cm^{-1} and a five-coordinated, presumably trigonal–bipyramidal structure with carboxylic oxygen and amino nitrogen occupying axial positions has been proposed, while in (Cyh)$_3$Sn(Hglygly) (Cyh = cyclohexyl) the lowering of this frequency value to 1658 cm^{-1} has been taken as an indication of both the amide carbonyl oxygen and terminal amino group nitrogen atoms of the Hglygly$^-$ ligand being involved in coordination to tin to create a hexa-coordinated arrangement. Since all the obtained H_2glygly adducts exhibit the unshifted 1678 cm^{-1} $\nu_{(C=O)(amide\ I)}$ band, in addition to the un-ionised $\nu_{(COOH)}$ vibration, this suggests that only the amino

† See text for discussion of the assignment.

group is coordinated. Moreover, in D_2O solution the Me_2SnCl_2 adduct shows vibrations at 1595, 1483, 1443 and 1397 cm^{-1}. The 1595 and 1397 cm^{-1} absorptions are identical to those reported[13] for the Cu(II) complex at $2 < pH < 4.2$ which are assigned to the asymmetric and symmetric COO^- stretching vibrations respectively. Therefore, in solution, the adduct is likely to undergo a partial dissociation and/or ionisation of the COOH group. The main difference in the solution spectrum of the Me_2SnCl_2 adduct relative to those of the Cu complex in this pH region is the absence of the 1630 cm^{-1} vibration indicating the absence of peptide oxygen binding.

Vibrations in the 1575–1550 cm^{-1} range have been assigned[11] to the amide II mode [$\nu_{(CN)} + \delta_{(NH)}$] and to the NH_2 scissoring mode for solid complexes, while the former vibration is found at 1487 cm^{-1} in D_2O solution, which is shifted to 1508 cm^{-1} if peptide oxygen is coordinated.[13] In the solid adducts presented in this work, broad bands at *ca* 1570 cm^{-1} are observed (with the exception of the $Oct_2^nSnCl_2$ derivative) and are tentatively assigned to the amide II mode, although superimposition with the NH_2 scissoring cannot be excluded.

The absorption which is observed in the 1250–1200 cm^{-1} range is more intense in the dialkyltin(IV) adducts and, while some authors[14] have assigned it to a un-ionised COOH group vibration [$\nu_{C=O} + \delta_{(OH)}$] in glycinium fluoride and glycinium hexafluorosilicate and adducts of SiF_4 and glycine, an unambiguous assignment is difficult since CH_3, CH_2 and NH_2 vibrational modes are expected in this range. In the complex Me_2Sn(glygly-O,N)[15] this region of the spectrum is free from absorptions of comparable intensity, which might support the previous assignment. The bands at 1250 and 1230 cm^{-1} in the $PhSnCl_3$ and Ph_2SnCl_2 adducts respectively, suffer from the same ambiguity, since they are present also in the parent compounds.[16]

Skeletal vibrations of the organometallic moieties may in principle provide structural information, although the symmetry of the adducts is expected to be generally low, even in the most favourable case (Me_2SnCl_2L). In this instance both ν_{as} and $\nu_{s(SnC_2)}$ could be assigned (560 and 525 cm^{-1} respectively) which rules out a D_{2h} symmetry for the adduct such as might be envisaged in the rather unlikely case of an all-*trans* $Me_2SnCl_2L_2$ unit,[17] spanned by bridging H_2glygly units which are coordinated only with amino nitrogen and/or peptide oxygen alternately in a linear polymeric structure.

In the low frequency region under the heading Sn–Cl + ligand vibrations (Table 3), are listed all frequencies observed in the 400–200 cm^{-1} region, with the exception of a weak band at 390 cm^{-1} (Me_2SnCl_2 and Bu^nSnCl_3 adducts) and at 380 cm^{-1} ($Bu_2^nSnCl_2$ adduct).

The ligand itself shows absorptions in this range (400, 310, 235 cm^{-1}) and while some authors report[18] a shift to lower wavelength of the $\nu_{(Sn-Cl)}$ vibrations in a series of Me_2SnCl_2 adducts with *N*,*N*-dimethylnicotinamide-isonicotinamide and their thio-derivatives, there seems to be no general trend in the observed frequencies with respect to those of the organotin(IV) halides;[19,21] the frequencies found in the Me_2SnCl_2 adduct are virtually unchanged or shifted to higher wavelengths. Little change, if any, is observed for the Ph_2SnCl_2 and the previous examples, the Sn–Cl stretching modes are either absent or shifted to lower frequency.

^{119}Sn *Mössbauer spectra*

The ^{119}Sn Mössbauer parameters for the organotin(IV) chloride adducts are given in Table 4. The isomer shift values, δ, show the expected trends for adduct formation in that they are all lower than those of their parent organotin(IV) chlorides.[22] The isomer shifts, δ, for the monoalkyltin(IV) derivatives are lower than for the corresponding dialkytin(IV) adducts as would be expected owing to the increase in covalent bonding on replacement of a second chlorine with an alkyl group. Replacement of alkyl groups by phenyl groups is known to result in lower isomer shift values in organotin(IV) compounds and the parameters found for the phenyltin(IV) adducts in this work are consistent with previous data.[23]

Evidence of solid state intermolecular chemical interactions is afforded by a preliminary variable temperature ^{119}Sn Mössbauer study. ^{119}Sn Mössbauer resonance areas have been collected for

Table 4. Mössbauer parameters for R_nSnCl_{4-n} adducts with H_2glygly

Compound*	δ†	Δ‡

$77 < T < 127$ K. The plot of ln vs $A(T)$ is linear and the slope d ln $A/dT = -1.41 \times 10^{-2}$ K^{-1} has been calculated, for a series of eight points, which is lower than the slope (-1.8×10^{-2} K^{-1}) found for compounds of known structure consisting of non interacting monomeric molecules.[24,25]

^{1}H NMR

The solution properties of the $Me_2SnCl_2 \cdot (H_2glygly)$ specimen in D_2O have been investigated both by IR and ^{1}H NMR spectroscopy. In view of the physiological activity of many organotin derivatives, knowledge of specific binding sites and stability of complexes in aqueous solution may be of some interest.

The binding of metal ions by aminoacids and peptides as models for their interaction with proteins, has attracted considerable interest.[26] The complexes have been mostly detected and characterised by the pH titration method and complexation at the amino group of the *N*-terminal aminoacid has been evidenced. On the basis of NMR data[27,28] however, initial binding to the *C*-terminal end has been proposed. First of all the solution of the complex was compared with an equimolar mixture of Me_2SnCl_2 and $H_2glygly$. The pH value of a 0.2 M solution of the former is 4.08, while it is 2.87 for the latter. In three days there was no significant change in the pH's of the equimolar mixtures and the adduct. This is consistent with stability of the adduct in solution and the lack of conversion to a chelate complex, such as that observed[27] in the reaction of glycine with *cis*-$(NH_3)_2Pt(H_2O)_2^{2+}$ in water, in which glycine coordinates through oxygen only and slowly converts into the chelate $(NH_3)_2Pt(gly\text{-}O,N)^+$. In this work, the reverse process, is being observed namely the solution behaviour of the preformed adduct, which has been obtained under different conditions.

On the assumption that at pH 2.87, little, if any, coordination of $H_2glygly$ to the organometallic moiety has taken place in the equimolar mixture, the spectrum of the adduct could be interpreted in terms of a dissociation equilibrium which gives rise to free $H_2glygly$ along with the coordinated species (Table 5) as previously shown by the infrared spectra. The peaks at δ: 0.73 and 0.81 ppm are therefore assigned to the β- and α-methylene protons of the free ligand respectively.[25]

However, at pH 4 the possibility of carboxylate coordinated species cannot be discounted. The doublet pattern of the α-methylene resonances is absent, indicating fast exchange of the peptide proton with solvent and/or rapid exchange of $H_2glygly$ between the free and complexed forms.[25]

Table 5. ^{1}H NMR data*

Compound	δ_{CH_2}	$\delta_{CH_3(Sn)}$	^2J (^{119}Sn–^{1}H)† (Hz)
(A) Me_2SnCl_2 + $H_2glygly$‡	0.73 0.82	3.80	102.6
(B) $Me_2SnCl_2 \cdot H_2glygly$	0.61 0.73 0.80 0.81 0.94	3.72	100.2

* Chemical shifts (δ) in ppm relative to the DOH resonance. Positive shifts are upfield from DOH signal. This peak is reported (M. K. Kine and A. E. Martell, *J. Am. Chem. Soc.* 1969, **91**, 872) to vary in position depending on the concentration of solute and acidity of solution. Since pH only varies by *ca* 1 unit in going from solution A to B, reference to DOH is not expected to alter significantly the δ values of the resonances of identical species.

† $^2J(^{117}Sn–^1H)$ values are *ca* 4 Hz less than $^2J(^{119}Sn–^1H)$ values.

‡ Equimolar mixture, $C = 0.2$ M, to that of the adduct.

The resonances for the α-methylene protons of unionised $H_2glygly$, coordinated at the amino end in the adduct, are expected to follow the same trend as in the protonation, namely a down-field shift, while the methylene protons adjacent to the coordinated amino group are expected to show an up-field shift. Hence resonances at δ 0.61 and 0.94 ppm are assigned to the α- and β-methylene groups of the parent adduct. The resonance at δ 0.80 ppm might be accounted for by the rapid formation of a small amount of $Me_2Sn(glygly\text{-}O,N)^+$ complex, undetected in the infrared spectra, in which both the carboxylate and the amino end are coordinated, presumably to different organometallic moieties, since a seven-membered chelate ring is not normally stable. The complex might be expected to exhibit resonance at *ca* δ 0.80 ppm and δ 1.02 ppm on the basis of the data reported by Rabenstein *et al.*[25] for complexes of divalent metal ions (Cd^{2+} and Zn^{2+}) with simple peptides. Only one resonance due to the organometallic moiety is observed, flanked by satellites due to $^2J(^{119/117}Sn–^1H)$ coupling, indicating rapid exchange between aquated and complexed forms. The observed $^2J(^{119}Sn–^1H)$ value is indeed somewhat less than the value for the parent Me_2SnCl_2 in D_2O(106.8 Hz) and consistent with a hexa-coordinated species. The spectrum in DMSO-d_6 was also examined, although it bears little significance as to the nature of D_2O solutions. Since

the peptide hydrogen resonances are present at δ (from TMS) 8–9 ppm, this rules out any involvement in bonding of a negative peptide group.

COMPLEXES OF 4-METHOXY-2-(5-METHOXY-3-METHYL-PYRAZOL-1-YL)-6-METHYLPYRIMIDINE, AN ANTI-INFLAMMATORY AGENT—I. COPPER(II) PERCHLORATE COMPLEXES

J. GARCIA, M. MOLLA and J. BORRAS*
Departamento de Química Inorgánica, Facultad de Farmacia, Universidad de Valencia, Valencia, Spain

(*Received* 13 *February* 1984; *accepted* 9 *May* 1984)

Abstract—The preparation and properties of copper(II) complexes of 4-methoxy-2-(4-methoxy-3-methyl-pyrazol-1-yl)-6-methylpyrimidine, are reported. Complexes of formulae $[Cu(L)_2](ClO_4)_2$, $[Cu(L)_2(H_2O)](ClO_4)_2$ and $[Cu(L)(OH)]ClO_4$ were synthesized. The ESR spectrum of $[Cu(L)_2](ClO_4)_2$ indicates that the complex has a tetragonal symmetry, with the unpaired electron in the $d_{x^2-y^2}$ orbital. The *d–d* electron spectrum suggests that $[Cu(L)_2(H_2O)](ClO_4)_2$ has a bipyramidal trigonal geometry around the copper(II) ion.

In the present paper we initiate the study of interaction between metal ions and a biologically active pyrimidyl-pyrazole ligand, used as an anti-inflammatory agent:[1,2] 4-methoxy-2-(5-methoxy-3-methyl-pyrazol-1-yl)-6-methylpyrimidine (mepirizol, hereinafter L). We report for the first time the preparation and characterization of some copper perchlorates of L, as an integral part of our studies. The structure of the ligand is shown in Fig. 1.

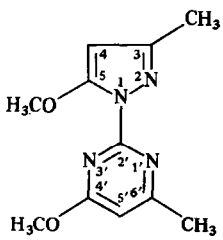

Fig. 1.

EXPERIMENTAL

The ligand kindly provided by "Laboratorios Robert" was purified by recrystallization from methanol. It melted at 92°C.[3]

Found: C, 56.2; H, 6.0; N, 23.8%. Calc. for $C_{11}H_{14}N_4O_2$: C, 56.4; H, 6.0; N, 23.9%.

Copper(II) was determined by iodometric titration, after prior decomposition by heating in sulphuric acid. Carbon, hydrogen and nitrogen were determined by elemental analysis.

Physical measurements

Molar conductances of the complexes were measured in methanol using a Radiometer CDC 304 electrode (cell constant 1.0 cm) in conjunction with a Radiometer CDM 83 conductivity bridge.

Magnetic susceptibility measurements were carried out in the solid state at room temperature (20°C) using a Gouy Balance with $[Ni(en)_3]S_2O_3$ as calibrant.

Electronic spectra were measured on a Perkin–Elmer Hitachi 200 spectrophotometer with reflectance attachment fitted.

IR spectra were obtained using a Perkin–Elmer 577 instrument, using Nujol mulls supported between CsI windows for the range 4000–200 cm^{-1}.

Thermal (TGA–DTG–DTA) analyses were performed using a Settaram simultaneous thermobalance.

X-band ESR spectra of powder samples were recorded at room temperature on a JEOL MES-3X spectrometer. The microwave frequency was determined using DPPH as a reference and the magnetic field calibrated with a Newport Instruments NMR magnetometer.

Preparation of the metal complexes

$[Cu(L)_2(H_2O)](ClO_4)_2$ (*compound* I). This was prepared by addition of 40 cm^3 of an aqueous solution

* Author to whom correspondence should be addressed.

of the ligand (2.5×10^{-2} M) to 200 cm^3 of aqueous solution of the copper(II) perchlorate (2×10^{-2} M) (acidified with 1 M $HClO_4$ to pH = 3). The compound separated immediately at room temperature, and was filtered, washed with cold water and dried over silica gel.

$[Cu(L)_2](ClO_4)_2$ (*compound* **II**). This compound was prepared by addition of 25 cm^3 of an ethanolic solution of copper(II) perchlorate (0.2 M) at pH = 3, to 500 cm^3 of an ethanolic solution of the ligand (3×10^{-2} M). The resulting solution was warmed in a water bath for 15 min and then cooled to room temperature. The product, which crystallized in a few hours, was collected by filtration, washed with ethanol and dried over silica gel.

$[Cu(L)(OH)](ClO_4)$ (*compound* **III**). 40 cm^3 of an aqueous solution of ligand (2.5×10^{-2} M) was added to 200 cm^3 of an aqueous solution of copper(II) perchlorate (2×10^{-2} M) at pH = 5. The compound precipitated immediately at room temperature. The compound was isolated following the same procedure as in the first case.

RESULTS AND DISCUSSION

Table 1 shows analytical data, colour and molar conductivity values of the complexes. The Λ values fall in the range expected for 1:2 electrolytes in compounds **I** and **II**, and 1:1 for compound **III**.[4]

The thermal study on the compound **I** shows a weight loss between 50 and 140°C. The DTA curve indicates that the weight loss up to 140°C is associated with two endothermic processes, one due to loss of a water molecule and the other due to a rearrangement of compound **I** to give compound **II** as indicated by the fact that the brown solid obtained after dehydration has an X-ray powder pattern identical to compound **II**.

Thermal study of $[Cu(L)_2](ClO_4)_2$ shows stability up to 201°C, at which temperature decomposition takes place through an exothermic process. Thermal study of $[Cu(L)(OH)](ClO_4)$ shows that this complex is stable up to 199°C.

Table 1.

Compound	Colour	Cu (%)		C (%)		N (%)		Cl (%)		Λ_M (Ω^{-1} cm^{-1})*
		Found	Calc.	Found	Calc.	Found	Calc.	Found	Calc.

* 10^{-3} M solution in methanol.

IR spectra

The IR spectra of ligand and compounds show a very large number of bands, in the range studied. Meaningful correlations between spectra and structure are difficult.

The band centred at *ca* 1600 cm^{-1} assigned to C–N vibrations is shifted in IR complexes to a high energy (15 cm^{-1}), indicating nitrogen atom participation in the coordination.

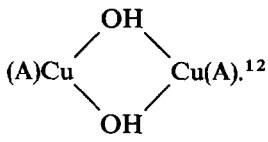
The presence of a strong band at *ca* 1090–1110

Table 2.

Compound	μ_{eff} (MB) (20°C)	Electronic spectra (kK)	ESR parameters $\langle g_0 \rangle$	$g_{\parallel}$	$g_{\perp}$	$A_{\parallel}$ (cm^{-1})
$[Cu(L)_2](ClO_4)_2 \cdot H_2O$	2.02	11.8, 25.0	2.166			
$[Cu(L)_2](ClO_4)_2$	1.91	13.9, 20.8	2.141*	2.294	2.065	163
$[Cu(L)(OH)](ClO_4)$	1.60	14.3, 27.0				
$[Cu(L)_2]^{2+}$ Water		12.8, 27.8				
Nitromethane		13.9, 23.0				

* From $\langle g_0 \rangle = (g_{\parallel} + 2g_{\perp})/3$.

cm^{-1} and a sharp one at *ca* 625 cm^{-1} in all complexes suggests that the perchlorate groups are ionic with T_d symmetry,[5] except perhaps for a weak interaction, since ionic and weakly coordinated monodentate perchlorate groups usually have very similar spectra.[6–8]



All IR complexes show two bands at 300 and 270 cm^{-1}, assigned to Cu–N vibrations (Cu–N pyrazole and pyrimidine rings respectively).[9,10]

The broad band at 3380 cm^{-1} shown by complex **I** is assigned to ν_{O-H} of water. The IR spectrum of complex **III** shows a sharp peak at 3560 cm^{-1} assigned to ν_{O-H} of the OH group and a peak at 500 cm^{-1} assigned to Cu–OH bridging vibration.[10,11]

Electronic properties

In Table 2 are listed the magnetic moment values, polycrystalline ESR parameters and spectral data for the complexes.

The μ_{eff} values for compounds **I** and **II** are well above the spin-only magnetic moment and are of little use as structural probes. The obtained value of μ_{eff} for complex **III** is lower then $\mu_{s.o.}$ and suggests the existence of an antiferromagnetic interaction between copper(II) ions. A similar behaviour has been observed in several other complexes of the type $[Cu(A)(OH)]_2X_2$ (where A is a bidentate ligand) containing the dimeric structural unit

[12]

The electronic spectrum of complex **I** contains a single broad band at 12 kK (Fig. 2). The spectrum is similar to those shown by complexes of the type $[Cu(A)_2(X)]Y$ for which a trigonal bipyramidal coordination environment for copper(II) is generally accepted.[13–16] Accordingly we propose here the same stoichiometry for $[Cu(L)_2(H_2O)](ClO_4)_2$. This interpretation is in agreement with the existence of $[Cu(L)_2(H_2O)]^{2+}$ in compound **I**.

The diffuse reflectance spectrum of $[Cu(L)_2](ClO_4)_2$ shows two broad bands at 13.9 and 20.8 kK. The band at 13.9 kK is consistent with a compressed tetrahedral stereochemistry for the copper(II) ion which results from coordination of copper(II) to four nitrogen atoms of the ligands. For steric reasons both ligands are rotated toward a tetrahedral geometry as is usually the case in similar complexes.[17,18]

The band at 20.8 kK is assigned to a metal–ligand ($t_{2g} \rightarrow \pi^*$) charge transfer.[19,20] The presence of a CT

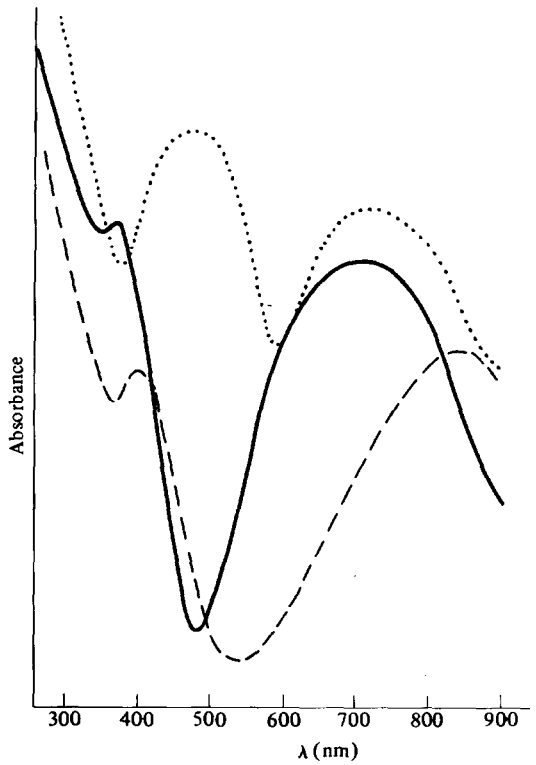


Fig. 2. Electronic reflectance spectra of $[Cu(L)_2(H_2O)](ClO_4)_2$ (– – –), $[Cu(L)_2](ClO_4)_2$ (···) and $[Cu(L)(OH)](ClO_4)$ (——).

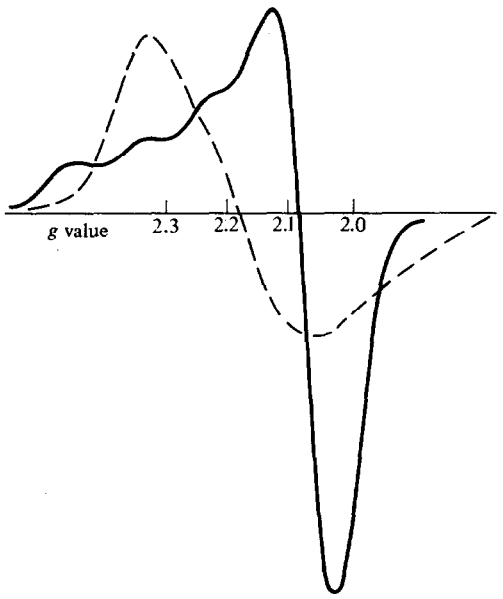

Fig. 3. Polycrystalline ESR spectra of $[Cu(L)_2](ClO_4)_2$ (——) and $[Cu(L)_2(H_2O)](ClO_4)_2$ (– – –).

band in the visible region has been previously reported for several systems where steric hindrance occurs.[21]

The electronic spectrum of $[Cu(L)(OH)](ClO_4)$ presents a broad band at 14.3 kK consistent with a tetrahedral compressed environment for the copper(II) ion.[22]

The polycrystalline ESR spectra of compounds **I** and **II** are shown in Fig. 3.

The spectrum of compound **III** is of poor resolution and contains a single peak at above 3100 G. Observation of ESR spectra of this type is relatively common in doubly bridged dimers such as $[Cu(A)(OH)]_2^{2+}$[23] and originates either from simple paramagnetic impurities or from a $\Delta m_s = \pm 2$ transition.[24,25]

The ESR powder spectrum of compound **II** is typical of a copper(II) ion in axial surroundings with a distorted tetrahedral environment. The nuclear hyperfine splitting of $g_{\|}$ is observed with three of the four components clearly resolved, the other one being obscured by the $g_{\perp}$ component. Measured g ($g_{\|} \gg g_{\perp} > 2$) and $A_{\|}$ values are indicative of $d_{x^2-y^2}$ (or d_{xy} ground state).[26,27]

The ESR powder spectrum of compound **I** is broad and nearly isotropic. This behaviour is common to other complexes with trigonal bipyramidal geometry such as $[Cu(bipy)_2(CN)](NO_3)\cdot 2H_2O$.[15]

(*Received* 30 *January* 1984; *accepted* 22 *May* 1984)

Abstract—ESR and optical absorption studies on Cu(II) chelates of 2-hydroxyacetophenone-, resacetophenone-, peonol- and 2-hydroxy-1-naphthaldoximes have been made in dimethyl formamide and pyridine. The studies show that both these solvents interact with copper in the axial plane and the interaction is greater with pyridine. The magnetic moment data indicate that all the chelates exist as monomers in both the solvents.

Oximes have been found to possess various insecticidal, miticidal and nematocidal activities.[1] They were employed as antidotes against organophosphorus poisons.[2] The oximes have good chelating properties and they were exploited as analytical reagents for the separation and determination of many metal ions. Considering the potential role of copper in biological systems and the growing importance of oximes as chelating agents it was considered desirable to investigate the nature of bonding in the chelates. Among the several *o*-hydroxyaromaticoximes, 2-hydroxyacetophenone-, resacetophenone-, peonol-(4-methoxy-2-hydroxyacetophenone) and 2-hydroxy-1-naphthaldoximes were used in the present investigation to prepare copper(II) chelates. The optical absorption and ESR spectral studies in dimethyl formamide and pyridine were carried out to study the solute–solvent interaction and to determine the covalency of metal–ligand bond.

EXPERIMENTAL

The copper complexes of 2-hydroxyacetophenone-, resacetophenone-, peonol- and 2-hydroxy-1-naphthaldoximes were prepared according to the procedures described in the literature.[3–6]

A Shimadzu-UV-180 Spectrophotometer was used to record electronic spectra. The solutions studied were dimethyl formamide and pyridine and the data were obtained at room temperature.

ESR spectra were recorded with a varian E-4 X-band Spectrometer employing 4–8 G modulation amplitude and operating at a frequency of 9.5 GHz. The spectra were recorded at room temperature (300 K) in dimethyl formamide and pyridine.

RESULTS AND DISCUSSION

Cu–2-hydroxyacetophenoneoxime, Cu–resacetophenoneoxime, Cu–peonoloxime and Cu–2-hydroxy-1-naphthaldoxime chelates are powders which are insoluble in water and soluble in dimethyl formamide and pyridine. They were found to be stable in air and non-hygroscopic. The results of elemental analysis gave 1:2 metal–ligand stoichiometry. Square planar structures have been assigned to these chelates by the earlier workers.[6,7]

The electronic spectra of all these chelates in dimethyl formamide and pyridine consist of very intense absorption bands in the 300–400 nm region. These are ascribed to charge-transfer and free ligand absorption. The absorption bands were also observed in the 500–600 nm region. These are weak and broad and are assigned to *d–d* transitions of copper(II) in tetragonal field.[8] The similarity of the spectra suggests identical coordination environments in these chelates.[9]

Belford and co-workers[10] have studied the spectra of copper acetylacetone in a variety of solvents which can coordinate along the *Z*-axis. The solvent molecules exert a *Z* component field proportional to their position in the spectrochemical series. Some solvents exert little or no effect since the basicity is extremely low whereas solvents with more basicity coordinate more strongly. Repelling the advance of solvent molecules are two electrons in the d_{z^2} orbital so only the most basic species can force their way in

* Author to whom correspondence should be addressed.

to form strong bonds. There are three *d–d* electronic transitions possible in a tetragonal complex, viz.:

$$d_{xz}, d_{yz} \rightarrow d_{x^2-y^2} \quad (\nu_1),$$
$$d_{xy} \rightarrow d_{x^2-y^2} \quad (\nu_2),$$
$$d_{z^2} \rightarrow d_{x^2-y^2} \quad (\nu_3).$$

The frequency of these transitions will be strongly dependent upon the field experienced by the various *d* orbitals. Frequency ν_2 should remain constant at $10\,Dq_{oh}$ since neither the d_{xy} nor $d_{x^2-y^2}$ orbital has a Z component. They should thus be completely unaffected by any incoming ligands on the Z-axis and the separation corresponds to the splitting $10\,Dq_{oh}$ in a hypothetical purely octahedral complex having six identical ligands. As the tetragonal field approaches the octahedral configuration as the Z field strength approaches that of x and y, ν_1 should diminish and approach ν_2. The third transition ν_3 should also decrease as Z ligand basicity increases eventually disappearing in the octahedral limit as x^2-y^2 and z^2 collapses to form the degenerate e_g orbitals.

The absorption band near 18,000 cm^{-1} for the chelates in dimethyl formamide suggests strong distortion from octahedral stereochemistry.[11] In the spectra of pyridine solutions of these oximates this band is lowered to 16,000 cm^{-1} region. A comparison of the absorption maxima values in both the solvents suggests that the distortion is less in pyridine solution than in dimethyl formamide. Suresh Babu *et al.*[7] determined the electronic spectra of these chelates in nujol mull and reported the absorption maxima in the region 18,690–19,280 cm^{-1}. They have assigned this band to a $^2B_{1g} \rightarrow {}^2E_g$ transition. In the present investigations this band is lowered and appeared in the 18,000 and 16,000 cm^{-1} regions in dimethyl formamide and pyridine respectively. This lowering can be attributed to the interaction of solvent molecules with copper along the Z-axis. The extent of lowering of this transition may be taken as a measure of the donor strength of the solvent. It is evident from the data (Table 1) that the interaction of pyridine with copper is more than with DMF which is also supported by the increased solubility of the oximates in pyridine through weak complex formation. The interaction of both the solvents leads to tetragonal distortion. However, the extent of distortion is less with pyridine suggesting that its coordinating ability is more compared to DMF. This is in good agreement with Belford and others.[10]

The room temperature ESR spectra of Cu–2-hydroxyacetophenoneoxime, Cu–resacetophenoneoxime, Cu–peonoloxime and Cu–2-hydroxy-1-naphthaldoxime in DMF and pyridine exhibit several interesting phenomena. Except for Cu–2-hydroxy-1-naphthaldoxime, curves of all the other three chelates consist of four apparently equally spaced absorption lines. These four lines in the multiplet correspond to the $(2I+1 = 4)$ spin orientations of the copper nuclei with $I = \frac{3}{2}$. The hyperfine structure in these solutions is resolvable at room temperature which is of some interest since Bagguely and Griffiths[12] found it impossible to resolve the hyperfine structure in dilute copper Tutton salts at room temperature due to a short spin–lattice relaxation time of about 2×10^{-9} s. Measurements on the resonance of $[Cu(NH_3)_4]^{2+}$ and $[Cu(H_2O)_6]^{2+}$ ions in water solution have also shown no hyperfine structure. Apparently the spin–lattice relaxation times in the present copper–oxime chelates are greater than in the ionic Tutton salts. This may be caused by much stronger bonds between the copper and its neighbours (O and N atoms of oxime) with the result that the oscillational frequencies are much higher giving a smaller Fourier component in the region of the resonance frequency. In the spectra of all the chelates the expected nuclear interaction between the unpaired electron and each copper

Table 1. Analytical and optical absorption spectral data of the chelates

Chelate	Colour	Metal (%)	Carbon (%)	Hydrogen (%)	Nitrogen (%)	Absorption maxima (cm^{-1}) DMF	Pyridine
Cu–2-hydroxyaceto-phenoneoxime	Brown	17.31 (17.48)	52.90 (52.80)	4.39 (4.40)	7.71 (7.70)	18,180	16,130
Cu–resacetophenoneoxime	Brown	16.10 (16.07)	48.85 (48.85)	4.11 (4.05)	7.14 (7.08)	19,040	16,940
Cu–peonoloxime	Light brown	15.00 (15.00)	51.00 (51.00)	5.10 (4.80)	6.70 (6.60)	18,180	16,920
Cu–2-hydroxy-1-naphthaldoxime	Light brown	14.42 (14.57)	60.80 (60.60)	3.70 (3.70)	6.37 (6.40)	18,520	15,880

Table 2. ESR, bonding and magnetic parameters of the chelates in DMF

Chelate	$\langle g \rangle$	$\langle A \rangle$ ($\times 10^4$ cm^{-1})	K	χ_m ($\times 10^6$ CGS)	μ_{eff} (B.M.)
Cu–2-hydroxyacetophenoneoxime	2.052	73.36	0.254	1315	1.777
Cu–resacetophenoneoxime	2.084	77.82	0.298	1363	1.805
Cu–peonoloxime	2.062	74.01	0.265	1329	1.785
Cu–2-hydroxy-1-naphthaldoxime	2.076	—	—	1348	1.798

isotope is not detected. It may be due to the fact that at room temperature the ESR signal of the less abundant copper isotope is obscured by the random motion of the paramagnetic centres.[13]

The Cu–2-hydroxy-1-naphthaldoxime chelate did not give a four line spectrum either in DMF or pyridine but showed only one line. However a normal spectrum was obtained when the chelate was diluted with a diamagnetic zinc complex of this oxime. It would therefore appear that the anisotropic molecular reorientation of the chelate in solution is responsible for this. Unusual spectra of this type have been noted earlier for complexes bearing large organic ligand substituents.[14–16]

The ESR spectra of most copper(II) complexes in solution at room temperature normally exhibit four hyperfine lines with spin dependent line widths due to the tumbling motion of the microcrystalline units.[17] This tumbling motion will average the anisotropic g and A values observed in solids. The ESR spectra of copper(II) complexes in glassy state give the principal g and A values.[18–21] If the solvent is non-interacting, the g and A values correspond to the molecular g and A values of the complex in the solid state. On the other hand if the electron donor solvents like pyridine interact with the complex weak complexes will be formed and the g and A values will also be different.

The values of $\langle g \rangle$ for Cu–2-hydroxyacetophenoneoxime, Cu–resacetophenoneoxime, Cu–peonoloxime and Cu–2-hydroxy-1-naphthaldoxime chelates are given in Tables 2 and 3. The values are greater in pyridine than in DMF suggesting that pyridine interacts to a greater extent compared to DMF. The greater interaction is also evidenced from the shift of the optical absorption peak to lower wave number region. It is known that square planar complexes of copper(II) usually form five coordinate square pyramidal complexes on adduct formation with amines or pyridine.[22–25] It is therefore very probable that the present copper oximates also form mono adducts with square pyramidal geometry. This causes the copper atom to move out of the plane as the fifth ligand is added causing a decrease in the in-plane binding and thereby also the covalency. The result would be a positive shift of the $\langle g \rangle$ values in pyridine.[26]

The hyperfine structure due to the anisotropic terms are averaged out in solution so that the observed splitting is due only to the isotropic term which according to Abragam and Pryce[27] is proportional to the square of the electron's wave function at the nucleus. The copper–oxime chelates under investigation showed lower values of $\langle A \rangle$ in pyridine than in DMF. The variation of the splitting with solvent thus indicates that the stronger the solvated complex the smaller the value of the unpaired electron's wave function at the nucleus. Apparently the bonding solvent pulls the electron away from copper.

The values for paramagnetic susceptibility (χ_m), magnetic moment (μ_{eff}) and the Fermi contact term are calculated using the following expressions:

$$\chi_m = N\beta^2\langle g \rangle^2 S(S+1)/3KT,$$

$$\mu_{eff} = \langle g \rangle \sqrt{S(S+1)},$$

$$K = \frac{\langle A \rangle}{P} + \langle g \rangle - 2.0023.$$

Table 3. ESR, bonding and magnetic parameters of the chelates in pyridine

Chelate	$\langle g \rangle$	$\langle A \rangle$ ($\times 10^4$ cm^{-1})	K	χ_m ($\times 10^6$ CGS)	μ_{eff} (B.M.)
Cu–2-hydroxyacetophenoneoxime	2.100	66.94	0.268	1378	1.819
Cu–resacetophenoneoxime	2.112	70.26	0.305	1394	1.829
Cu–peonoloxime	2.082	68.03	0.270	1355	1.803
Cu–2-hydroxy-1-naphthaldoxime	2.110	—	—	1392	1.827

The magnetic moment values of the chelates lie above the spin only value of 1.73 B.M. and occur in the range 1.8–2.0 B.M. normally found for Cu(II) complexes in the absence of any antiferromagnetic coupling. The values are consistent with an orbital non-degenerate ground state for the Cu(II) ion.[28] The slight increase above the spin-only value arises probably from the mixing in of orbitally degenerate excited state into the ground state via spin orbit coupling. The values further suggest that the copper oximates are mononuclear in both the solvents.

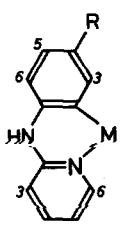
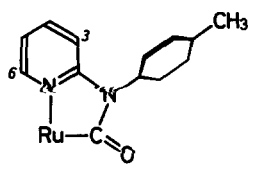
RUTHENIUM(II) COMPLEXES OF 2-(*p*-TOLUIDINO)PYRIDINE AND RHODIUM(III) COMPLEXES OF *N,N'*-DI(2-PYRIDYL)-1,3-DIAMINO-5-CHLOROBENZENE

MATSUO NONOYAMA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya, 464 Japan



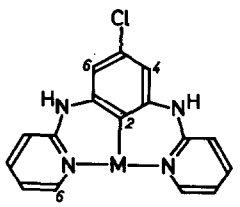
(*Received* 14 *February* 1984; *accepted* 7 *June* 1984)

Abstract—An attempted cyclometallation of 2-(*p*-toluidino)pyridine by dichlorotricarbonylruthenium(II) in refluxing 2-(methoxy)ethanol gave [$RuCl(CO)_2$(tpf)] containing the *N*-(*p*-tolyl)-*N*-(2-pyridyl)-formamide ligand coordinated to the ruthenium atom through the pyridine-N and amide carbonyl-C atoms. On the other hand *N,N'*-di(2-pyridyl)-1,3-diamino-5-chlorobenzene is, as expected, cyclometallated by hexachlorotetrakis(tri-*n*-butylphosphine)dirhodium(III) in refluxing xylene to give [$RhCl_2$(dcb)(PBu_3)], where the dcb is coordinated to the rhodium atom through the two pyridine-N and phenyl-2C atoms forming a fused six-membered metallaheterocycle. Cyclorhodation to form a six-membered metallaheterocycle is a rare example. The ligand H(dcb) is also easily cyclometallated with hexabromotetrakis(tri-*n*-butylphosphine)dirhodium(III) and lithium tetrachloropalladate(II). The adducts of pyridine and tri-*n*-butylphosphine are also prepared and characterized.



In a previous paper[1] 2-anilinopyridine derivatives

(p-R-C_6H_4–NH–C_5H_4N-2: R = H, CH_3, Cl)



have been reported to be easily cyclopalladated with tetrachloropalladate ion and to form six-membered pallada-heterocycles (partial structure I, M = Pd). Six-membered pallada-heterocycles are not so popular as the corresponding five-membered ones.[2] Therefore, it is interesting to investigate possibility of other metals and other ligands to form similar six-membered metalla-heterocycles. In this paper ruthenium(II) complexes of 2-(*p*-toluidino)pyridine, and rhodium(III) and palladium(II) complexes of *N,N'*-di(2-pyridyl)-1,3-diamino-5-chlorobenzene* have been studied as an extention of the previous study.[1]

RESULTS AND DISCUSSION

The reaction of 2-(*p*-toluidino)pyridine with dichlorotricarbonylruthenium(II) in boiling 2-(methoxy)ethanol gave [$RuCl(CO)_2$(tpf)] (**1**) (data in Table 1). 2-Anilinopyridine gave a similar complex (**4**). The IR spectrum (Nujol mull) of **1** shows no $\nu_{(N-H)}$ band. The spectrum shows $\pi_{(C-H)}$ of a phenyl ring at 809 cm^{-1} (the band is at 811 cm^{-1} for free 2-(*p*-toluidino)pyridine) and lacks the characteristic bands of a 1,2,4-trisubstituted benzene ring which

* H(tpf) = *N*-(*p*-tolyl)-*N*-(2-pyridyl)formamide. H(dcb) = *N,N'*-di(2-pyridyl)-1,3-diamino-5-chlorobenzene.

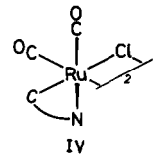

Table 1. Melting points, yields and analytical results for the complexes*

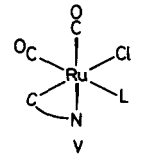
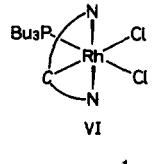
9	$[RhCl(dcb)(PBu_3)_2]Cl$	265(dec)	43	54.74 (54.96)	7.61 (7.61)	6.43 (6.41)

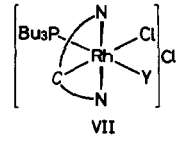


* Abbreviations: H(tpf), *N*-(*p*-tolyl)-*N*-(2-pyridyl)formamide; H(ppf), *N*-phenyl-*N*-(2-pyridyl)formamide; H(dcb), *N*,*N*'-di(2-pyridyl)-1,3-diamino-5-chlorobenzene; PBu_3, tri-*n*-butylphosphine; py, pyridine; dec, decomposition.

are at 814 and 877 cm^{-1} for the cyclopalladated 2-(*p*-toluidino)pyridine complex [PdCl(map)][1] (cf. partial structure I, R = CH_3). The most remarkable band is a very strong absorption at 1663 cm^{-1} and should indicate the presence of an organic carbonyl group (C=O).[3] A strong band at 1024 cm^{-1} also stands out. In the metal–carbonyl region, $\nu_{(C\equiv O)}$, two strong bands at 2066 and 1997 cm^{-1} are observed and coordination of Cl is suggested by two strong bands at 285 and 225 cm^{-1}.



Complex **1** was not soluble in common solvents without donor property but dissolved in dimethylsulphoxide (dmso). The ^1H NMR spectrum of the dmso-d_6 solution (60 MHz vs TMS) shows the signals of phenyl ring protons at δ = 7.13 *d* and 7.45 *d* ppm (the sum of the intensities amounts to 4 H) but it shows no signal due to an N–H group. The spectral pattern is very different from that of [PdCl(map)] (cf. partial structure I) which shows phenyl protons at 6.85 *s* ppm (an intensity of 2 H) and 7.46 *s* (1 H). Thus the possibility of cyclometallation is eliminated and the carbonylation of the amino group to produce an amide group (partial structure II) is suggested. For **1** is proposed structure **IV** (C–N represents the chelate ring of partial structure II). A doublet at 6.53 ppm (1 H) is remarkable and is assigned to 3-H of the pyridine ring because the 3-H is situated nearly above the benzene ring on the amide-nitrogen atom and should be shielded by the ring current. The low



IV

V

VI

VII

frequency $\nu_{(Ru-Cl)}$ bands are consistent with structure **IV**, where the Cl donor is coordinated *trans* to a σ-carbon donor with a strong *trans* influence.[4]

The reaction of **1** with pyridine (py) gave the adduct $[RuCl(CO)_2(tpf)(py)]$ (**2**) (Table 1). The IR

spectrum (CH_2Cl_2 solution) shows two $\nu_{(C\equiv O)}$ bands at 2068 and 1998 cm^{-1} to reveal *cis*-coordination of the two CO groups. The IR and ^1H NMR spectra are essentially similar to those of **1**, except for the signals and bands due to the added pyridine ligand. The coordination mode of partial structure **II** is held and structure **V** (I = py) is proposed for **2**. The tri-*n*-butylphosphine (PBu_3) adduct [RuCl(CO)$_2$(tpf)(PBu_3)] (**3**) (Table 1) shows a very broad $\nu_{(C\equiv O)}$ band at *ca* 1960 cm^{-1}. Distinction between *cis*- and *trans*-coordination of the two CO groups is impossible from the IR spectrum (CH_2Cl_2 solution). The ^{13}C NMR spectrum ($CDCl_3$ vs TMS) gave two signals at 202.5 and 208.6 ppm due to carbonyl groups, although the S/N ratio was not good (the former signal seems to be a doublet (J = *ca* 18 Hz) and the latter a broad singlet). The *cis*-coordination of the two CO groups is suggested [structure **V** (L = PBu_3)]. Low frequency $\nu_{(Ru-Cl)}$ bands at 272 (**2**) and 279 (**3**) cm^{-1} are consistent with structure **V**, where Cl is coordinated *trans* to a σ-carbon donor with a strong *trans* influence.[4]

N,*N*′-di(2-pyridyl)-1,3-diamino-5-chlorobenzene was easily cyclopalladated with lithium tetrachloropalladate to give the complex [PdCl(dcb)] (**5**) (Table 1). The IR spectrum (Nujol mull) shows $\nu_{(NH)}$ at 3343 and 3310 cm^{-1} and $\nu_{(Pd-Cl)}$ at 258 cm^{-1}. The ^1H NMR spectrum (dmso-d_6 vs DSS) shows a singlet of metallated phenyl ring 4,6-protons at 6.89 ppm (an intensity of 2 H) and a signal of amino protons at 10.11 ppm (2 H). In the spectrum, the triplet of the phenyl ring 2-H of free H(dcb) at 7.92 ppm (J = 1.8 Hz) disappeared. Partial structure **III** is proposed for **5** (in **5** the fourth site of coordination of partial structure **III** is occupied by Cl). The doublet of pyridine ring 6-H at 8.32 ppm of free H(dcb) is deshielded in **5** and appears at 9.10 ppm.

The ligand H(dcb) was also cyclometallated with hexachlorotetrakis(tri - *n* - butylphosphine) - dirhodium(III) in refluxing xylene to give [$RhCl_2$(dcb)(PBu_3)] (**6**) (Table 1). The IR spectrum (nujol mull) shows $\nu_{(NH)}$ as a complex pattern in the region 3100–3300 cm^{-1} and two strong bands at 233 and 200 cm^{-1} are assigned to $\nu_{(Rh-Cl)}$. The low frequency bands disappear in the spectrum of [$RhBr_2$(dcb)(PBu_3)] (**7**). The ^1H NMR spectrum (dmso-d_6 vs DSS) is broad and complicated, and difficult to be interpreted. Addition of pyridine to the dmso-d_6 solution simplifies the complex spectral pattern.

The ^1H NMR spectra of dmso-d_6 solutions of **6** and **7** in the presence of excess pyridine-d_5 show a signal of the amino group at 10.72 (**6**) or 10.38 ppm (**7**), a singlet of metallated phenyl ring 4,6-protons at 7.13 (**6**) or 7.12 (**7**), and a doublet (J = 6.4 Hz) of pyridine ring 6-protons at 9.15 (**6**) or 9.25 (**7**). Like **5**, **6** and **7** lack the signal of the phenyl ring 2-proton in the spectra. Structure **VI** for **6** and **7** is proposed (where N–C–N represents the chelate ring corresponding to partial structure **III**: for **7** Cl is replaced with Br).

The isolated complex [RhCl(dcb)(PBu_3)(py)]Cl (**8**) (Table 1) shows a similar IR spectrum to that of **6** with additional bands of the pyridine ligand, but one $\nu_{(Rh-Cl)}$ band is observed at 209 cm^{-1}. This may have structure **VII** (Y = py). A similar tri-*n*-butylphosphine complex [RhCl(dcb)(PBu_3)$_2$]Cl (**9**) gives $\nu_{(Rh-Cl)}$ at 202 cm^{-1} and the ^1H NMR spectrum ($CDCl_3$ vs TMS) is similar to that of the pyridine-d_5 adduct of **6**. A signal of NH is observed at 10.48 ppm, a singlet of phenyl 4,6-protons at 7.32, and a doublet (J = 6.4 Hz) of pyridine ring 6-protons at 9.50 ppm. Structure **VII** (Y = PBu_3) is assumed for **9**.

EXPERIMENTAL

Measurements

The measurements were carried out by the methods reported previously.[5]

Synthesis of the ligands

The method of preparation of 2-(*p*-toluidino)-pyridine was reported previously.[1] *N*,*N*′-di(2-pyridyl)-1,3-diamino-5-chlorobenzene was obtained similarly from 1,3-diamino-5-chlorobenzene and 2-chloropyridine at a yield of 53%. M.p. 159–161°C. Found: C, 64.62; H, 4.34; N, 18.85%. Calc. for $C_{16}H_{13}N_4Cl$: C, 64.76; H, 4.42; N, 18.88%. ^1H NMR (dmso-d_6 vs DSS) δ = 6.73–7.15 ppm (m; py 3,5-H), 7.60 (d, J = 1.8 Hz; Ph 4,6-H), 7.70 (t, 6.4 Hz; py 4-H), 7.92 (*t*, 1.8 Hz; Ph 2-H), 8.32 (d, 4.8 Hz; py 6-H), 9.25 (s; NH). IR (Nujol mull), 3230 and 3175, $\nu_{(NH)}$; other characteristic bands, 1614, 1578, 1290 and 761 cm^{-1}.

Synthesis of the complexes

Melting points, yields and analytical results of the complexes prepared are given in Table 1.

[RuCl(CO)$_2$(tpf)] (**1**). A mixture of 1 mmol of dichlorotricarbonylruthenium(II) and 1 mmol of 2-(*p*-toluidino)pyridine in 30 cm^3 of 2-(methoxy)ethanol was refluxed for 3.5 h. White precipitates formed were collected, washed with ethanol, and dried in air. [RhCl(CO)$_2$(ppf)] (**4**) was similarly prepared from 2-anilinopyridine but only in a low yield. The IR spectral data suggest that this has the structure corresponding to partial structure **II**. IR (Nujol mull) 2060 and 1990, $\nu_{(C\equiv O)}$; 1669, amide $\nu_{(C=O)}$; 285 and 218 cm^{-1}, $\nu_{(Ru-Cl)}$.

[PdCl(dcb)] (**5**). To a solution of lithium tetrachloropalladate, prepared *in situ* from 1 mmol of palladium(II) chloride and 2 mmol of lithium chloride in 30 cm^3 of methanol, was added 1 mmol of *N,N'*-di(2-pyridyl)-1,3-diamino-5-chlorobenzene and the mixture was stirred for 1 h at room temperature. Off-white precipitates were collected, washed with methanol, and dried in air. An attempt to prepare the bromo analogue in the presence of five-fold excess of lithium bromide (that is, lithium tetrabromopalladate was prepared *in situ* from 1 mmol of palladium(II) chloride and 5mmol of lithium bromide in 30 cm^3 of methanol) only resulted in formation of the compound of composition $[PdCl_{0.5}Br_{0.5}(dcb)]$ at a yield of 89%. M.p. 285°C (dec.). Found: C, 41.61; H, 2.50; N, 12.18%. Calc. for $C_{16}H_{12}N_4PdCl_{1.5}Br_{0.5}$: C, 41.79; H, 2.63; N, 12.18%. The spectroscopic properties of $[PdCl_{0.5}Br_{0.5}(dcb)]$ are very similar to those of **5**.

$[RhCl_2(dcb)(PBu_3)]$ (**6**). A mixture of 1/2 mmol of hexachlorotetrakis(tri - *n* - butylphosphine) - dirhodium(III)[6] and 1 mmol of *N,N'*-di(2-pyridyl)-1,3-diamino-5-chlorobenzene in 20 cm^3 of xylene was refluxed for 8 h with stirring to precipitate yellow powder. The product was collected, washed with xylene and *n*-hexane, and dried in air. The yellow bromo analogue (**7**) was prepared similarly by using hexabromotetrakis(tri-*n*-butylphosphine)-dirhodium(III) instead of hexachlorotetrakis(tri-*n*-butylphosphine)dirhodium(III) and the product was recrystallized from acetone.

*Pyridine and tri-*n*-butylphosphine adducts.* Addition of pyridine (excess) or tri-*n*-butylphosphine (a stoichiometric amount) to a dichloromethane suspension of the complexes prepared above gave a clear solution which was then treated with florisil. To the filtrate was added an equivolume of *n*-hexane and the mixture was concentrated to a small volume to crystallize the adduct.

Acknowledgement—I wish to thank Dr Y. Yoshikawa for the measurements of ^{13}C NMR spectra.

(*Received* 1 *February* 1984; *accepted* 9 *May* 1984)

Abstract—Platinum(II) complexes of 2,2′-diaminobiphenyl, $[Pt(R\text{-}pn)(dabp)]Cl_2$ and $[Pt(R,R\text{-}chxn)(dabp)]Cl_2$, where R-pn is the R-1,2-diaminopropane, R,R-chxn, the R,R-*trans*-1,2-diaminocyclohexane, and dabp the 2,2′-diaminobiphenyl, have been prepared. The dabp ligand has been found to coordinate in the λ conformation.

Investigations involving the 2,2′-diaminobiphenyl ligand have so far been limited to the octahedral cobalt(III) complexes.[1–3] The present work was undertaken to prepare pure chiral square planar platinum(II) complexes of 2,2′-diaminobiphenyl and to correlate their stereochemistry to the observed optical activity.

EXPERIMENTAL

2,2′-*Diaminobiphenyl*

A solution of 8.4 g of 2,2′-dinitrobiphenyl[4] in 200 cm^3 of absolute ethanol was shaken with 1.0 g of 10% palladium on charcoal in a Paar's hydrogenation apparatus. The catalyst was filtered off and the alcohol solution concentrated on a rotary evaporator. After recrystallisation from boiling aqueous ethanol the melting point was 76–78°C (m.p. lit.[4] 78–79°C). Found: C, 78.3; H, 6.5; N, 15.2%. Calc. for $C_{12}H_{12}N_2$: C, 78.2; H, 6.6; N, 15.2%. The yields were usually greater than 90%.

Resolution of 1,2-*diaminopropane*

This was resolved according to the method of Dwyer *et al.*[5] using *d*-tartaric acid. It was then converted to the dihydrochloride according to the procedure of Bailar *et al.*[6]

Resolution of trans-1,2-*diaminocyclohexane*

The method of Asperger and Liu[7] was modified to resolve *trans*-1,2-diaminocyclohexane. Equimolar amounts of *trans*-1,2-diaminocyclohexane and *d*-tartaric acid were dissolved in warm water, and then the two solutions were poured together and stirred. The laevorotatory compound precipitated when the solution was cooled in an ice bath. The R,R-*trans*-1,2-diaminocyclohexane-*d*-tartarate was recrystallized from hot water. It was suspended in ethanol and agitated. HCl gas was allowed to bubble through the mixture. Slowly the salt dissolved and after about one hour white crystals of the dihydrochloride began to form. Addition of HCl gas was continued for another hour. The mixture was cooled, filtered, washed successively with ethanol and ether, and then air dried. It was recrystallized from minimal water. The IR spectrum showed that the R,R-(−)-*trans*-1,2-diaminocyclohexane was free of tartaric acid. $[\alpha]_D = -29.6$. (Lit.[8] $\alpha_D = -26.4$.)

$[Pt(R\text{-}pn)Cl_2]$

This was prepared according to the method used for $[Pr(en)Cl_2]$[9] using R-1,2-diaminopropane in place of ethylenediamine. Found: C, 10.4; H, 2.9; N, 8.3; Cl, 20.8%. Calc. for $Pt(C_3H_{10}N_2)Cl_2$: C, 10.6; H, 3.0; N, 8.2; Cl, 20.8%.

* Authors to whom correspondence should be addressed.

[Pt(*R,R-chxn*)Cl_2]

This was prepared by the same method as that used for [Pt(en)Cl_2][7] using R,R-*trans*-1,2-diaminocyclohexane in place of ethylenediamine. Found: C, 18.9; H, 3.7; N, 7.2; Cl, 18.7%. Calc. for Pt($C_6H_{14}N_2$)Cl_2: C, 19.0; H, 3.7; N, 7.4; Cl, 18.6%.

[Pt(*R-pn*(*dabp*)]Cl_2

0.79 g of [Pt(R-pn)Cl_2] and 0.42 g of 2,2'-diaminobiphenyl were suspended in 500 cm^3 of water in a 1000-cm^3 three-neck flask equipped with a mechanical stirrer, thermometer, and condenser. The mixture was stirred and heated at a temperature of 60–70°C for 8 h. Gradually the suspension dissolved and the solution changed from yellow to almost colourless. The solution was cooled and filtered. It was concentrated on a rotary evaporator until crystallisation occurred. The mixture was placed in an ice bath. The white crystals were collected on a sintered glass funnel, washed successively with ice-cold water, ethanol, ether, and air dried. The product was recrystallized from warm water to which one drop of 3 M HCl was added. Yield: 0.57 g (48%). Found: C, 34.1; H, 4.2; N, 9.9; Cl, 12.6%. Calc. for Pt($C_3H_{10}N_2$)($C_{12}H_{12}N_2$)$Cl_2 \cdot H_2O$: C, 33.2; H, 4.5; N, 10.3; Cl, 13.1%.

[Pt(*R,R-chxn*)(*dabp*)]$Cl_2 \cdot 3H_2O$

Procedure was the same as that used for [Pt(R-pn)(dabp)]$Cl_2 \cdot H_2O$ using R,R-*trans*-1,2-diaminocyclohexane in place of R-1,2-diaminopropane. Yield: 0.47 g (55%). Found: C, 35.1; H, 5.2; N, 9.2; Cl, 11.6%. Calc. for Pt($C_6H_{14}N_2$)($C_{12}H_{12}N_2$)-$Cl_2 \cdot 3H_2O$: C, 34.9; H, 5.2; N, 9.1; Cl, 11.5%.

RESULTS AND DISCUSSION

Figure 1 shows the absorption spectra of [Pt(R-pn)(dabp)]Cl_2 and [Pt(R,R-chxn)(dabp)]Cl_2 along with that of 2,2'-diaminobiphenyl. Since the dabp absorbs very little in the 27.5–31.5 kK region, the intensity in this region of the corresponding Pt(II) complexes can be attributed to charge transfer. The dabp ligand has two very strong π–π^* transitions at 34.2 kK (ε = 5,000) and 41.7 kK (ε = greater than 13,00). The absorption bands at these energies for the platinum complexes probably originate from the π–π^* transitions of the ligand.

Examination of the absorption spectra reveals that for Pt(II) complexes some of the *d–d* transitions are buried under the much stronger charge transfer bands in the long wavelength region and the ligand transitions in the near UV. In the dabp complexes

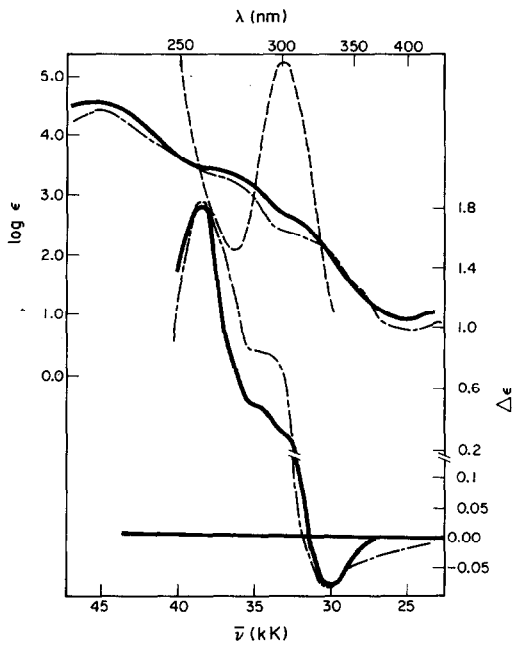

Fig. 1. Electronic absorption spectra of: [Pt(R-pn)(dabp)]Cl_2 (——), [Pt(R,R-chxn)(dabp)]Cl_2 (–·–·–), and electronic absorption spectrum of 2,2'-diaminobiphenyl (– – –).

there is still appreciable intensity in the 22–28 kK region. The bands below 22 kK have been assigned to the $^1A_{1g} \rightarrow {}^3E_g$ and $^1A_{1g} \rightarrow {}^3A_{2g}$ transitions in the $[PtCl_4]^{2-}$ complex.[10] They are weak (log ε less than 1) spin–forbidden transitions. The *d–d* transition of

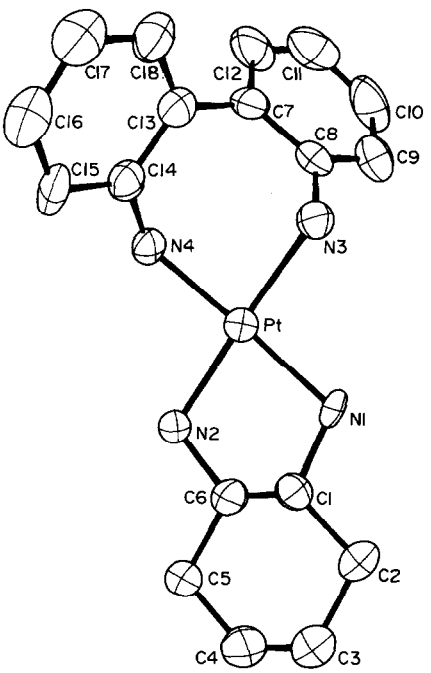

Fig. 2. The molecular structure of the Pt(R,R-chxn)(dabp) unit.

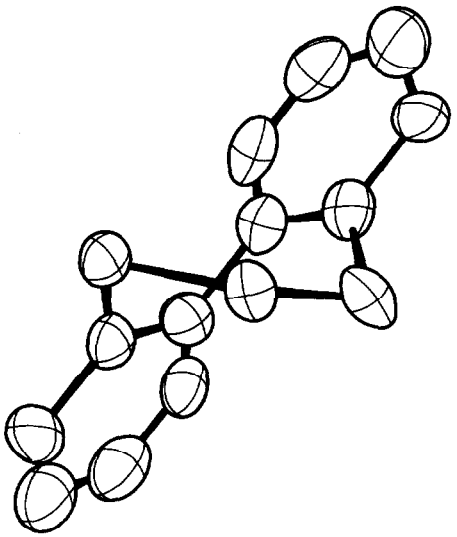

Fig. 3. View through 2,2′-diaminobiphenyl.

the dabp complexes gain intensity through coupling with allowed transitions on the aromatic ligands and charge transfer.

The CD spectrum of $[Pt(R\text{-pn})(dabp)]^{2+}$ and $[Pt(R,R\text{-chxn})(dabp)]^{2+}$ are also seen in Fig. 1. The two spectra are almost identical. Furthermore the intensities are comparable. The R-pn and R,R-chxn ligands should take the λ conformation[11–14] upon coordination to Pt(II) ion. The absolute configuration of $[Pt(R,R\text{-chxn})(dabp)]Cl_2$ has been unambiguously determined from X-ray crystallographic study.[14] As shown in Figs. 2 and 3, the dabp ligand was found to coordinate in the λ conformation. The similarity in the pattern and position of the negative and positive CD bands (Fig. 1) indicates that dabp has the same λ conformation in both complexes. The major contribution to the rotational strength comes from the λ conformation of the two chelate rings in each complex as opposed to the vicinal effect of the asymmetric carbon atom.

The dabp ligand has shown a remarkable stereospecificity upon coordination, considering the fact that statistically there is an equal probability that the freely rotating dabp molecules can assume either the λ or the δ conformation upon complex formation. Such behaviour can be understood from a study using molecular models of R-dabp and S-dabp, λ and δ, respectively, with each of the two Pt(II) complexes. In the diamine complexes containing R-pn and R,R-chxn with R-dabp, the hydrogens on opposing nitrogens are staggered. When the model containing S-dabp is made with those same two ligands in the λ conformation, on the other hand, the hydrogens are almost totally eclipsed. The complete stereospecificity observed should be due to such nonbonded interaction between the hydrogens bonded to nitrogens.

HISTORICAL SKETCH

COS AND C_3S_2: THE DISCOVERY AND CHEMISTRY OF TWO IMPORTANT INORGANIC SULFUR COMPOUNDS

MIHÁLY T. BECK*
Department of Chemistry, Kossuth Lajos University, H-4010 Debrecen, Hungary

and

GEORGE B. KAUFFMAN*
Department of Chemistry, California State University, Fresno, Fresno, CA 93740, U.S.A.

Abstract—Although CO and CO_2 have been known since the dawn of chemistry and although CS_2 was discovered as early as 1796,[1] COS and C_3S_2 were not discovered until 1867 and 1893, respectively. This article considers the circumstances surrounding their discoveries as well as later reports on their chemistries. Both compounds were first prepared by Hungarian chemists, and both are of great theoretical and practical importance. The discovery and preparation of COS by Károly (Karl) Than is a beautiful example of logical chemical thinking, whereas the serendipitous discovery of C_3S_2 by Béla Lengyel is a case study in careful experimentation and keen observation. The sesquicentennial anniversary of the birth of Than, who is regarded as the founder of modern Hungarian chemistry, makes this article of timely significance. Since both he and his student Lengyel and their accomplishments have been neglected by English-speaking chemists and historians of chemistry, they are briefly discussed in this article.

KÁROLY THAN (1834–1908)

Anton Károly Than (Fig. 1), the third son of Janos Than, an estate manager, and his wife Ottilia (née Petény), was born on 20 December 1834 in Óbecse, Hungary (now Bečej, in northeastern Yugoslavia).[2] At the age of fifteen, he enlisted in the Hungarian army during the war of independence (1848–1849) from the Austrian Empire. On returning home at the war's end, he found his mother dead and his father ruined financially. He became apprenticed to pharmacists in several Hungarian towns to earn money while attending school. He completed his secondary school studies in 1855 at Szeged and began to study pharmacy at the University of Vienna in the Faculty of Medicine, but the following year he switched to the Faculty of Liberal Arts to study chemistry. He obtained his doctorate in 1858 under the organic chemist Joseph Redtenbacher (1810–1870), whose personal assistant he became. He spent a *Wanderjahr* studying under Bunsen in Heidelberg and under Wurtz in Paris. Returning to Vienna in 1859, he became an assistant in Redtenbacher's laboratory and a *Privat-Dozent* (unsalaried lecturer) at the university.

By 1860 Hungarian was reintroduced as the language of instruction in Hungarian universities. Because Theodor Wertheim (1820–1864), Professor of Chemistry at the University of Budapest since 1853, was an Austrian and did not have the necessary command of the language, he left to teach at the University of Graz in Austria, and Than was called to Budapest to succeed him. In this post, which he occupied until his retirement in 1908, the year of his sudden and unexpected death on 5 July, Than exerted a great influence on Hungarian science and culture. He served as Director of the Chemistry Laboratory and designed the laboratories of the new Chemical Institute,[3] which opened in 1872, the year of his marriage to Ervina Kleinschmidt, by whom he had five children. He built the institute into an important scientific establishment, which acquired fame throughout Europe, became a model for other institutes, and is still in use today.

* Author to whom correspondence should be addressed.

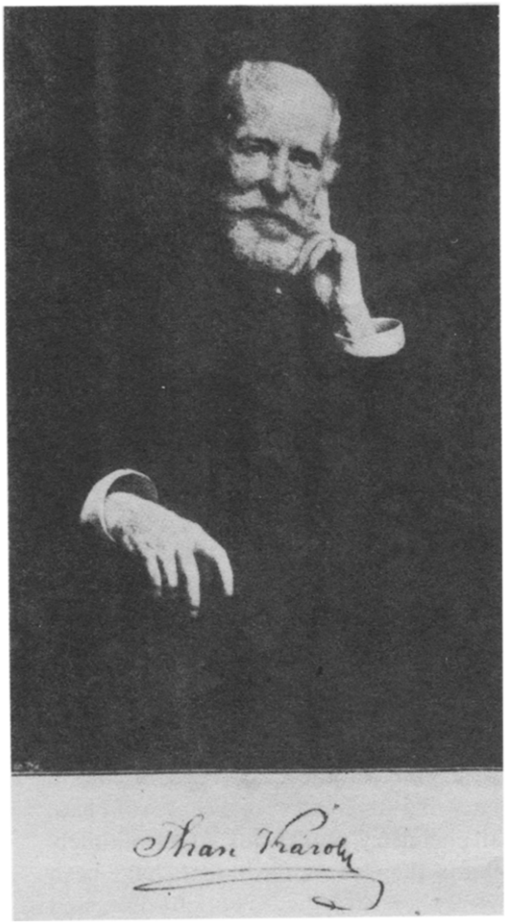

Fig. 1. Károly Than.

Than played a crucial role in the development of the teaching of chemistry in Hungarian universities and was an inspiration to several generations of chemists. He developed a plan for teaching chemistry in Hungarian secondary schools and established the first Pharmacopoeia Hungarica. He founded the Hungarian journal of Chemistry, *Magyar Chémiai Folyóirat*, which is still published today. In 1882, together with his student Loránd (Roland) Eötvös, he founded and edited the *Mathematische und naturwissenschaftliche Berichte aus Ungarn.*

President of the Hungarian Society of Natural Sciences from 1872 until his death, he was active in all of the other Hungarian scientific societies. A recipient of many honors, he was appointed a member of the Upper House of the Hungarian Parliament (House of the Magnates) in 1892 and was made a baron in 1908, shortly before his death.

Than's research embraced many fields of chemistry. His most important work in inorganic chemistry was the discovery of carbon oxide sulfide (COS),[4] but he also investigated platinum complexes[5] and the reaction of metals with alkylene halides.[6] In analytical chemistry he introduced the use of potassium bicarbonate[7] and potassium biiodate[8] as primary titrimetric standards, analyzed numerous mineral waters,[9] and two decades before Arrhenius' theory of electrolytic dissociation suggested that analytical results be reported as the elements rather than as acid or basic anhydrides.[10] In physical chemistry he showed that the anomalous vapor density of ammonium chloride is due to thermal dissociation,[11] he defined the concept of the molar volume of a gas,[12] he made various calorimetric measurements,[13] and he invented various pieces of apparatus.[14] His two-volume textbook, *The Elements of Experimental Chemistry*,[15] was one of the first to be based on concepts of physical chemistry.

COS

The Compromise (in German, *Ausgleich*; in Hungarian, *Kiegyezés*) of 1867 between Austria and Hungary played an important role not only in the history of those two countries and indirectly of all Europe but also in the discovery of carbon oxide sulfide (carbonyl sulfide) as well. In a paper, presented at a meeting of the Hungarian Academy of Sciences on 8 July 1867[4a] and later (dated 20 July 1867) published in German,[4b] Than reported the preparation of COS, which he called carbon oxysulfide (in Hungarian, *szén éleg kéneg*; in German, *Kohlenoxysulfid*) and regarded as the sulfide of the divalent radical CO. For a long time he had presumed the existence of this gaseous compound on the basis of the tetravalent nature of the carbon atom and the existence of the long known compounds carbon dioxide (CO_2) and carbon disulfide (CS_2), between whose compositions the composition of the new compound represents the mean. He also regarded the compound as CO_2 in which one atom of oxygen has been replaced by its congener, sulfur.

The Hungarian Compromise resulted in the imperial and royal Dual Monarchy (*kaiserliche und königliche Doppelmonarchie*) in which an Austrian and a Hungarian half coexisted in equal partnership. It was followed on 8 June 1867 in Buda by the crowning as King of Hungary of the Hapsburg ruler Franz Joseph I, who had been Emperor of Austria since 1848. The connection between this historic event and the discovery of COS is mentioned by Than in the Hungarian but not the German version of his paper:

> About one and half years ago I had already undertaken experiments which, at least partially, proved by guess [of the existence of COS]; however, because of my numerous other activities I was forced to interrupt these experiments until finally the coronation holidays made their successful continuation again possible.[4a]

Also, in the Hungarian version only, he states:

I do not want to bore the Honorable Academy with the enumeration of all those unsuccessful experiments which I have made in order to produce this compound.

Than first prepared COS by leading a mixture of carbon monoxide and excess sulfur vapor through a weakly glowing porcelain tube:

$$CO + S \rightarrow COS.$$

He obtained a "not insignificant" (*nicht unerheblich*) yield of the new compound, but always contaminated with much carbon monoxide, from which it could not be separated. Higher temperatures did not increase the yield because COS thermally decomposes into CO and S.*

Than prepared pure COS by the acid hydrolysis of thiocyanic acid

$$HSCN + H_2O \rightarrow COS + NH_3$$

analogous to the hydrolysis of cyanic acid

$$HOCN + H_2O \rightarrow CO_2 + NH_3.$$

He accomplished this by adding enough powdered KSCN to a cold mixture of 5 volumes of concentrated H_2SO_4 and 4 volumes of H_2O so that the mass remained fluid:

$$KSCN + 2H_2SO_4 + H_2O \rightarrow COS + KHSO_4 + NH_4HSO_4.$$

The evolution of gas began of its own accord, and the rate was controlled by warming or cooling the reaction vessel. The by-products, HCN, H_2O vapor, and CS_2 were removed by passing the product through HgO, chips of unvulcanized rubber, and $CaCl_2$, respectively, and the pure COS was collected over mercury, with which it does not react when dry. Klason[17] later modified this procedure to increase the yield (75%) and used triphenylphosphine to remove the CS_2. Later workers substituted NH_4SCN for KSCN.[18]

Although the discovery of COS is generally attributed to Than,[19,20] the fact that he determined its physical properties and chemical reactions is often overlooked. Than noted its smell (aromatic and similar to carbonated sulfur-containing mineral waters, e.g. those of the Harkány† and Parád springs, but not unpleasant) and the taste of its saturated solution (decidedly sweet with a peculiar pungent sulfur taste, similar to H_2S and H_2SO_3). He determined its density (2.1046 compared to air = 1.0000), molecular weight (60.61), acidity (weaker than CO_2), combustibility (complete combustion yields CO_2 and SO_2; incomplete combustion yields CO_2 and S; some mixtures with air are explosive), and thermal decomposition into CO and S, which he used to analyze the compound. He noted that the gas is absorbed by metal hydroxide solutions, and since such solutions, which are odorless, yield CO_2 and H_2S on acidification, he postulated the following absorption reaction:

$$COS + 4KOH \rightarrow K_2CO_3 + K_2S + 2H_2O.$$

He also observed the reaction of COS with various reagents and attempted unsuccessfully to isolate carbon monosulfide, CS. He acknowledged the assistance of his students Béla Lengyel and Loránd Eötvös in the work on COS. Gas phase reactions for the formation and decomposition reactions of COS are shown in Fig. 2.

Than did not continue to work with COS but left the investigation of its chemistry to his students, who studied it for several decades. For example, the kinetics of its hydrolysis in aqueous solution was thoroughly studied by Buchböck.[22]

Although interest in the new compound remained limited for many years, the number of articles dealing with this theoretically and industrially important gas has increased tremendously during the last two decades[20] (Fig. 3). This renaissance of interest in the chemistry of COS is due primarily to four reasons. (1) As a triatomic molecule consisting of three different atoms, it is ideal for spectroscopic investigations. (2) For the same reason the study of its reactions in the

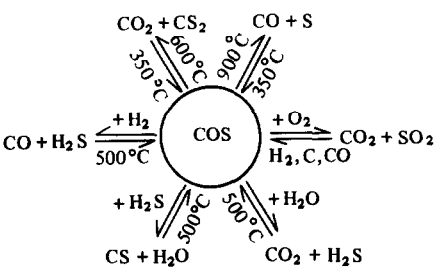

Fig. 2. Gas phase reactions for the formation and decomposition reactions of COS (Ref. 2, p. 40).

* Recent patents have been based on this reaction. For example, CO is led over a mixture of molten sulfur and Na_2S or K_2S at 300–400°C, and the product is obtained in yields > 95% after purification by being led over FeS, CoS, WS_2 or SnS at 250–450°C.[16a] CO is bubbled through molten sulfur at 300–440°C, and the mixture is reacted at 510–650°C. After removing unreacted sulfur, the yield of COS is 97.7%.[16b]

† Than soon discovered COS in Harkány mineral water.[21] He also predicted its occurrence in volcanic gases. Modern analytical techniques have revealed that COS is almost invariably formed whenever organic sulfur compounds are oxidized.

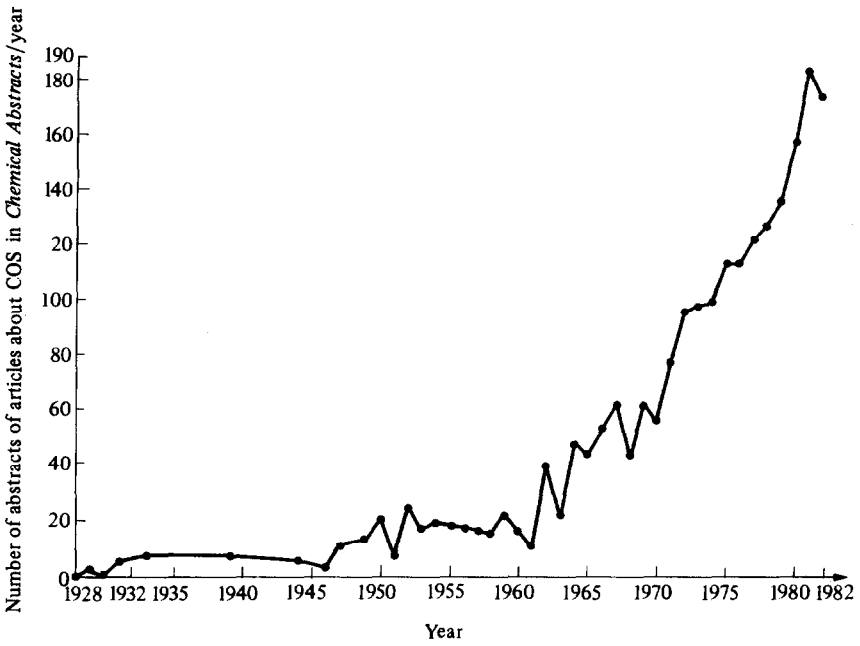

Fig. 3. Number of articles about COS in Chemical Abstracts (1928–1982).

gaseous phase, including photochemical reactions, offers a possibility for a deeper understanding of the details of reactions on a molecular level. (3) Sophisticated analytical methods have revealed that it occurs ubiquitously, e.g. in industrial wastes, cigarette smoke, and biological materials. (4) It is an excellent and versatile raw material for a number of industrially important reactions.

The first steps toward the application of COS to industrial processes were made by Than's students. For example, Izidor Weiser[23] described the reaction between carbon oxide sulfide and aniline:

$$2C_6H_5NH_2 + COS \rightarrow O{=}C(NHC_6H_5)_2 + H_2S$$

and its analogous reactions with toluidine ($CH_3C_6H_4NH_2$) and xylidene ($(CH_3)_2C_6H_3NH_2$). Furthermore, István Weiser and Emil Wolf[24] discovered that is today probably the most important reaction of COS, viz. its reaction with primary and secondary amines to give sulfur-containing organic compounds. Wolf, who founded Chinoin, Hungary's second largest pharmaceutical company, which still is in operation today, was interested in the practical applications of this type of reaction. However, at that time and even for several decades thereafter the compounds produced in these reactions found no practical applications. Today COS is widely used in manufacturing herbicides and pesticides and as a reactant or catalyst in polymerization reactions.

Whereas the discovery of COS is an excellent case study in logical chemical thinking, tricarbon disulfide (C_3S_2) was discovered serendipitously[25] by the careful experimentation and keen observation of Than's former student Béla Lenyel.

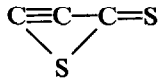
BÉLA LENGYEL (1844–1913)

Béla Lengyel (Fig. 4), a distant relative, student and later colleague of Károly Than's, was born on 4 January 1844 in Körösladány, Hungary.[26] In 1865 he began his university studies at Budapest where he became Than's assistant. In 1868 he made a study tour of Heidelberg, where he was Bunsen's assistant, and he became a *Privat-Dozent* (unsalaried lecturer) at the University of Budapest, where he became Professor of the second chair of chemistry in 1872 (Than was Professor of the first chair). Lengyel lectured on general, pharmaceutical and organic chemistry. In 1889 Vol. 1 of Lengyel's textbook on chemistry[27] appeared, which resulted in a bitter, public fight with his former mentor Than, who accused him of plagiarism (the battle was fought in the pages of Hungarian newspapers). A member of the Hungarian Academy of Sciences and an excellent experimenter and artistic glassblower, Lengyel died in Budapest on 11 March 1913.

Like Than, Lengyel carried out thousands of analyses of mineral waters.[28] He was particularly

Fig. 4. Béla Lengyel.

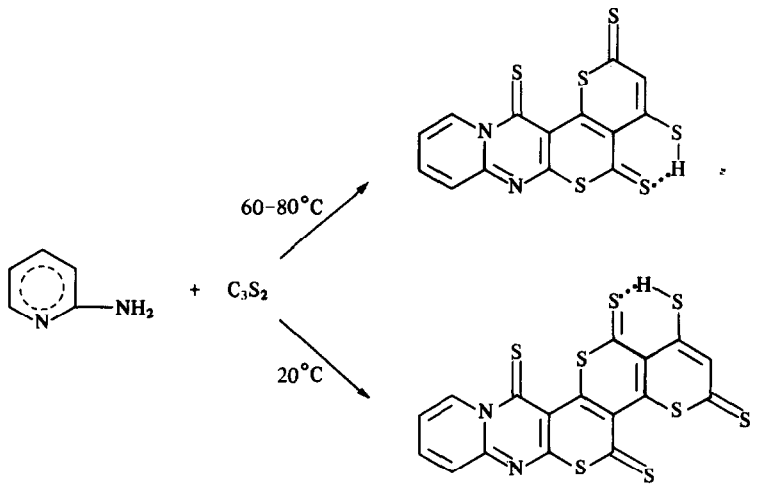
interested in the effects of light and electricity on chemical reactions. He studied the action of metals and gases on photographic plates and found that the effect is due to the reducing action of the hydrogen evolved.[29] He was the first to prepare and characterize calcium hydride[30] and to prepare metallic calcium in large quantites—by electrolysis of anhydrous calcium chloride.[30] He exhibited this calcium at the Paris Universal Exposition in 1900.



Lengyel prepared what he called "radioactive barium".[31] He fused uranium nitrate with 2–3% of barium nitrate, which he converted by heating to the oxide, fused in an electric arc and dissolved in nitric acid. Barium sulfate, carbonate, and chloride prepared from this barium nitrate was found to be strongly radioactive. Lengyel believed that this "synthesis" of radioactive substances, although preliminary, rendered doubtful the existence of radium and polonium recently discovered by the Curies. He also discovered a new amine of acetone, improved Bertram Boltwood's mercury air pump, and devised a titrimetric determination for nitrous acid. He designed a number of spectacular lecture demonstrations, one of which led to his discovery of what he called tricarbon disulfide.

C_3S_2

While preparing a demonstration of the formation of carbon disulfide, Lengyel observed the formation of a new substance when CS_2 vapors were passed through an electric arc with carbon electrodes.[32] The CS_2 solution became black, and after filtration and distillation *in vacuo* Lengyel obtained a cherry-red liquid with a remarkably strong odor, which caused great irritation to the eyes and mucous membrane. He removed free sulfur from the liquid by allowing it to stand over metallic copper for 6–8 days and then evaporating it with a current of dry air. Analysis showed the deep red liquid to have the composition C_3S_2,*† and Lengyel showed it to be monomeric by cryoscopically determining its molecular weight in benzene solution. The compound was later prepared by the thermolysis of CS_2 streaming through a quartz tube heated to 900–1100°C.[34]



Lengyel determined the physical properties of C_3S_2 (e.g. density = 1.27389 g ml^{-1}) and studied almost all of its known chemical reactions. He found that even at room temperature it slowly polymerizes to a hard, black solid; the rate of polymerization increases sharply with increasing temperature, and rapid heating causes polymerization with explosive violence. The liquid is immiscible with water but readily dissolves in ethanol, ether, chloroform, benzene and carbon disulfide. It burns with a luminous, smoky flame and yields carbon dioxide and sulfur dioxide. Concentrated sulfuric acid causes violent hissing and conversion to the solid modification, which is insoluble in water and all ordinary solvents. However, the polymer dissolves completely in aqueous potassium hydroxide, from which it is reprecipitated unchanged on addition of acid. It decomposes on heating with formation of sulfur.

Lengyel found that when bromide is added to a solution of C_3S_2 in chloroform, heat is evolved, and an aromatic-smelling, yellow precipitate, $C_3S_2Br_2$, insoluble or only slightly soluble in all solvents, is formed. Based on the reaction of this compound, whose structure is still unknown, with silver(I) oxide, he concluded that the bromide derivative has an unsymmetrical structure and that therefore C_3S_2 has the structure

* Several names have been given to this compound. *The Gmelin Handbuch der Anorganischen Chemie*, 8th edn, System No. 14, Part D4, pp. 1–7. Springer, Berlin (1977), which devotes only 6 pp. to the chemistry of this compound and its polymer, lists it as tricarbon disulfide, the name given to it by Lengyel. Its commonest, but ambiguous, name is carbon subsulfide, while *Chem. Abstr.* lists it as 1,2-propanediene-1,3-thione.

† Tricarbon disulfide, C_3O_2, the oxide analogue of C_3S_2, was later discovered by Otto Diels, of Diels–Alder fame, and Bertram Wolf,[33] but they neither mentioned the analogy nor referred to Lengyel's paper.

rather than the linear structure S=C=C=C=S.[35] Later structural determinations, however, have shown C_3S_2 to possess the symmetrical structure.[36] Reaction of chlorine with C_3S_2 yields a compound of the composition $C_3S_2Cl_4$.[37]

In the nine decades following Lengyel's discovery of C_3S_2 only a few studies of the compound were made. In a recent excellent review on conjugated inorganic carbon-based polymers only a few paragraphs are devoted to this compound.[38] At present only one or two articles dealing entirely or partially with the chemistry of C_3S_2 are published annually. However, there is some indication that an exponential increase in research on monomeric and polymeric C_3S_2, similar to that which had occurred with COS, may be about to begin. We predict three main areas for future research. (1) C_3S_2 is a promising reagent for producing highly condensed sulfur-containing compounds. For example, the reactions shown above take place with 2-amino-pyridine.[39] (2) C_3S_2 reacts with different transition metal complexes and is captured in the coordination sphere of the central ion.[40] Some of these complexes may have interesting catalytic properties. (3) The electrical conductivity of doped and undoped C_3S_2 polymers certainly deserves a thorough study, the results of which may contribute to the harnessing of solar energy.

The low yields in cumbersome procedures in the various syntheses of C_3S_2 may further delay the study and application of this intriguing compound. However, it is possible that the polymeric modification may be prepared in a simpler way by heating mixtures of graphite and sulfur. In 1961 different carbon- and sulfur-containing solids were obtained by heating a mixture of anthracene and sulfur.[41] This result was corroborated, together with a measurement of the relatively high electrical conductivity of the solids with higher sulfur content.[42] These species are probably related to polymeric C_3S_2.

THE UNEXPECTED DECARBONYLATION OF A MOLYBDENUM(0) DITHIOCARBAMATE AND THE FORMATION OF A MOLYBDENUM(V) DIMERIC PRODUCT: CRYSTAL STRUCTURE OF DI-μ-SULFIDO-BIS[OXO(PYRROLIDINEDITHIOCARBAMATO)MOLYBDENUM(V)]

E. C. ALYEA,* G. FERGUSON,* M. PARVEZ and A. SOMOGYVARI
(GWC)[2], Guelph Campus, University of Guelph, Guelph, Ontario, Canada N1G 2W1

(*Received* 3 *March* 1984; *accepted* 9 *May* 1984)

Abstract—The interaction of molybdenum hexacarbonyl with ammonium pyrrolidinedithiocarbamate in warm dimethylsulfoxide solution gives not the expected complex $[NH_4][Mo(CO)_4(S_2CN(CH_2)_4)]$ but the molybdenum(V) dimer, di-μ-sulfido-bis[oxo(pyrrolidinedithiocarbamato)molybdenum(V)]. The structure of this oxidized product $[MoO(S_2CN(CH_2)_4)S]_2$ (1) was determined by single-crystal X-ray diffraction analysis. The crystals are triclinic, space group $P\bar{1}$ with two molecules in a unit cell of dimensions $a = 8.775(1), b = 16.592(2), c = 6.661(1)$ Å, $\alpha = 97.67(1), \beta = 97.89, \gamma = 80.23(1)°$. The structure was solved by the heavy-atom method and refined by block-diagonal least-squares calculations to $R = 0.037$ for 3772 observed data. In the binuclear complex the two Mo atoms are bridged via two S atoms [Mo–S 2.303–2.317(1) Å]. Each Mo atom is also coordinated by a terminal O atom [1.688(4) and 1.682(4) Å] and two S atoms from the bidentate ligand [Mo–S 2.455–2.475(1) Å]. The geometry around the metal atoms is distorted square pyramidal.

Dithiocarbamate complexes of high oxidation states of molybdenum(IV, V, VI) are numerous and their chemistry has been widely studied due to their possible relevance to naturally occurring molybdenum–sulfur systems.[1] In contrast, molybdenum(0) dithiocarbamates have not been isolated, though their existence in dimethyl sulfoxide solution has recently been shown by their IR spectra in the carbonyl stretching frequency region.[2] During our studies to identify a wider range of zero-valent molybdenum complexes of the type $[Mo(CO)_4(L—L)]^-$ (L—L = dithiocarbamato, xanthato, and phosphorodithioato anions) *via* ^{95}Mo NMR spectroscopy[3] we observed that decarbonylation occurs in the reaction of ammonium pyrrolidinedithiocarbamate with molybdenum hexacarbonyl in warm DMSO solution. This paper reports the unexpected formation of a molybdenum(V) dimeric (1) product and its structural elucidation by X-ray analysis.

(1)

EXPERIMENTAL

Preparation of di-μ-sulfido-bis[oxo-(pyrrolidinedithiocarbamato)molybdenum(V)] $[MoO(S_2CN(CH_2)_4)S]_2$

Ammonium pyrrolidinedithiocarbamate (0.62 g, 3.8 mmol) was added under dinitrogen to a dimethylsulfoxide solution (50 cm^3) of molybdenum hexacarbonyl (1.0 g, 3.8 mmol). The reaction mixture was heated to 60–65° for 40 min, and upon cooling a few crystals precipitated from the solution. An X-ray crystal structure determination established the dimeric molybdenum(V) formulation of the title solid product. Infrared and ^{95}Mo NMR

* Authors to whom correspondence should be addressed.

spectroscopy of the solution indicated the absence of carbonyl species such as $[NH_4][Mo(CO)_4(S_2CN(CH_2)_4)]$. This latter complex is identified in solution [IR carbonyl bands at 1995, 1871, 1841 and 1795 cm^{-1}; $\delta(^{95}Mo) = -1388$ ppm (DMSO)][3] if the reaction is performed using potassium pyrrolidinedithiocarbamate or by changing the solvent to N-methylpyrrole.

Crystal data. $C_{10}H_{16}Mo_2N_2O_2S_6$, $M_r = 580.5$, triclinic, $a = 8.775(1)$, $b = 16.592(2)$, $c = 6.661(1)$ Å, $\alpha = 97.67(1)$, $\beta = 97.89(1)$, $\gamma = 80.23(1)°$, $V = 940.58$ Å^3, $D_c = 2.05$ g cm^{-3}, $Z = 2$, $F(000) = 572$, Mo-K_α radiation, $\lambda = 0.71069$ Å, μ(Mo-K_α) = 19.48 cm^{-1}. Space group $P\bar{1}$.

Structure solution and refinement. Data were collected to a maximum θ of 27° on an Enraf–Nonius CAD4 diffractometer by the $\omega/2\theta$ scan technique using monochromatized Mo-K_α radiation. Following machine location and centering of 25 reflections with θ in the range $10 < \theta < 15°$, accurate cell constants and the orientation matrix were obtained by a least-squares refinement. A total of 4094 reflections were collected of which 3772 had intensities greater than $3\sigma(I)$ and were used in structure solution and refinement. The intensities of three standard reflections monitored at regular intervals did not change significantly over the period of data collection. The data were corrected for Lorentz and polarization factors but not for absorption.

The structure was solved by the heavy-atom method. Initial refinement[4] by block-diagonal least-squares calculations with isotropic temperature factors for the non-hydrogen atoms lowered R to 0.110 which further dropped to 0.042 after six cycles of anisotropic refinement. A difference map calculated at this stage revealed maxima corresponding to the 16 hydrogen atoms which were included in the subsequent refinement in geometrically idealized positions (C—H 1.08 Å), and an overall isotropic thermal parameter (0.085 Å^2) was assigned to the hydrogen atoms. In the final cycles of refinement, weights were derived from counting statistics. Scattering factors used in the structure factor calculations were taken from ref. 5 for non-hydrogen atoms and ref. 6 for hydrogen atoms and allowance was made for anomalous dispersion.[7] Refinement converged with $R = 0.037$ and $R_w = [\Sigma w\Delta^2/\Sigma wF_o^2]^{1/2} = 0.045$. A difference map calculated at the conclusion of the refinement showed no significant features. Tables of atomic positional parameters and anisotropic thermal vibrational parameters each with estimated standard deviations, calculated hydrogen coordinates, molecular dimensions and observed structure amplitudes and calculated structure factors have been deposited.*

RESULTS AND DISCUSSION

Ionic complexes of the type [Cat][Mo(CO)$_4$ L—L] (Cat = Na, K, NH_4; L—L = dithiocarbamato, xanthato, phosphorodithioato) are not isolable but can be identified in DMSO solution by IR[2] and ^{95}Mo NMR[3] spectroscopy. In the reaction of ammonium pyrrolidinedithiocarbamate with molybdenum hexacarbonyl in warm DMSO solution, however, we do not observe the four infrared carbonyl bands and ^{95}Mo NMR chemical shift near −1400 ppm that is expected for the $[Mo(CO)_4(S_2CN(CH_2)_4)]^-$ anion. The crystals which precipitated from the reaction mixture are shown by our X-ray analysis to be a binuclear molybdenum(V) complex of a well known type $[(MoO(L—L))_2O_{2-x}S_x]$ ($x = 0$, 1, 2).[8–13] The mechanism of decarbonylation is unknown, though both ammonium ion and dimethylsulfoxide participation are implicated since the reaction does not occur in their absence. Previous examples[8–13] of molybdenum(V) dimers of this type were prepared from Mo(V) and Mo(VI) precursors.

The crystal structure of $[MoO(S_2CN(CH_2)_4)S]_2$ (**1**) consists of dinuclear molecules wherein Mo atoms are linked through a di-μ-sulfido bridge and the molecules have approximate mirror symmetry. A stereoview of the molecule drawn by the Graphics component of the NRC-Crystal Structure Package[4] showing the geometry of the complex is given in Fig. 1. The geometry around each Mo atom is distorted square pyramidal with four S atoms forming the distorted square planes. The Mo atoms lie above the

respective least-squares planes [Mo(1) 0.706 and Mo(2) 0.701 Å] with the terminal O-atoms in axial positions. The doubly bridged Mo(V) complex has the *syn*-configuration.[11] Important molecular dimensions are given in Table 1. The molecule is folded with an angle between the mean planes S(1), S(2), S(3), S(4) and S(1), S(2), S(5), S(6) of 159.2°. Alternatively, the bent Mo_2S_2 moiety has a dihedral angle between the two MoS_2 planes of 143.2°, as expected for the *syn*-form.[11]

The dimensions of the Mo_2S_2 bridge in (1)

[Mo—S 2.303–2.317(1) Å]

are similar to those in

$\{MoO[S_2CN(C_4H_9)_2]S\}_2$[12] [2.302–2.321(6) Å],

$Mo_2OS(\mu\text{-}S)_2(S_2CN(C_2H_5)_2)_2$[13] [2.309–2.322(7)Å]

and

$[MoS\{SCN(C_3H_7)_2\}\{S_2CN(C_3H_7)_2\}]_2$[14]

[2.242–2.340(2)Å].

Terminal Mo—S_t and Mo—O_t distances observed in (1) [2.455–2.475(1) and 1.668–1.682(4) Å, respectively] are comparable to the corresponding distances reported for

$\{MoO[S_2CN(C_4H_9)_2]S\}_2$[12]

[2.446–2.459(8) and 1.63–1.64(2) Å],

and

$[\{MoO[S_2P(OC_3H_7)_2\}_2OS]$[5]

[2.472–2.505(3) and 1.654(8) Å].

The Mo ... Mo distance of 2.803(1) Å is in the range observed for other complexes with Mo_2S_2 bridges [2.705–2.920(3) Å].[8–14] Similarly, the average Mo—S_b—Mo [74.64(4)°] and S_b—Mo—S_b [100.58(5)°] angles compare favorably with those reported for similar disulfido-bridged Mo(V) complexes.[8–14]

The remaining dimensions in (1) are as expected with mean distances: C—S 1.724(5), C—C 1.496(9), C—N 1.478(7) and C⋯N 1.299(7)Å.

A NEW SYNTHETIC PROCEDURE FOR THE PREPARATION OF PYRIDINIUM TETRAFLUOROBORATE AND HEXAFLUOROSILICATE

R. G. KALBANDKERI, K. SYED MOHAMED, D. K. PADMA* and A. R. VASUDEVA MURTHY

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560 012, India

(*Received* 29 *May* 1984; *accepted* 4 *September* 1984)

Abstract—Pyridinium tetrafluoroborate ($C_5H_5NHBF_4$) and pyridinium hexafluorosilicate [$(C_5H_5NH)_2SiF_6$] have been prepared in good yields and high purity by the reaction of pyridinium poly(hydrogen fluoride) with oxides and acids of boron and silicon respectively. The salts have been characterised by melting points, IR, ^1H and ^{19}F NMR spectroscopy and chemical analysis.

During the course of our investigations in introducing pyridinium poly(hydrogen fluoride) (PPHF) as an efficient and convenient reagent for the preparation of inorganic fluorinated compounds,[1,2] we have observed that it reacts with oxides and acids of boron and silicon to give rise to pyridinium salts of tetrafluoroborate and hexafluorosilicate respectively. This method gives the compounds in almost quantitative yields and of very high purity as compared to the reported methods.[3–6] The details of the investigations are presented in this paper.

EXPERIMENTAL

Materials and methods

All reagents employed in the present study were of LR/AR grade. All operations were carried out using polythene vessels in an efficient hood.

Pyridinium poly(hydrogen fluoride) reagent was prepared in two different concentrations according to the methods described earlier.[1,7] Reagent A contained 40% by wt of hydrogen fluoride and 60% wt of pyridine, and reagent B contained 70% by wt of hydrogen fluoride and 30% wt of pyridine.

The IR spectra of the compounds were recorded both in Nujol mull and as KBr discs using a Perkin–Elmer 599 spectrophotometer, ^1H (TMS standard) and ^{19}F ($CFCl_3$ standard) NMR spectra were recorded on Varian T60 and Varian FT 80A (74.84 MHz) NMR spectrometers using D_2O or DMSO-d_6 as solvent.

Preparation of $C_5H_5NHBF_4$ *and* $(C_5H_5NH)_2SiF_6$

Two procedures (1 and 2) were used for the preparation of the pyridinium salts. The reactions between PPHF and the oxides and acids were found to be highly exothermic and therefore the experiments were carried out around −10°C.

Procedure 1

To a cooled fine suspension of 3 g of boric oxide or 5 g of silicon dioxide or 7.5 g of silicic acid in 100 cm^3 of ether was added dropwise 30 cm^3 of PPHF(A) solution with stirring. The mixture was left aside for 30 min and the remaining ether evaporated. The contents were treated with chloroform to remove excess reagent and the solid separated was filtered, washed with chloroform, dried in vacuum and stored over phosphorus pentoxide. Pyridinium tetrafluoroborate was recrystallised from 95% alcohol while the pyridinium hexafluorosilicate was crystallized from hot methanol. The yields were ca 90% (Table 1).

Procedure 2

To a cooled solution of PPHF (A or B) was added portionwise 6 g of boric acid. To the separated crystalline white solid was added 100 cm^3 of chloroform. The solid was then filtered, washed with

Starting material	Compound prepared [yield (%)]	M.p. (°C)	IR spectral data (cm^{-1})	^{19}F NMR spectral data (ppm)
B_2O_3	$C_5H_5NHBF_4$ (87)	210–212[3]	3270, 3185, 3130 3105, 3080, 1630, 1602, 1530, 1480, 1330, 1285, 1248, 1150–1000, 970, 745, 670, 520	−146.5
H_3BO_3	$C_5H_5NHBF_4$ (89)			
SiO_2	$(C_5H_5NH)_2SiF_6$ (95)	154–158[6]	3200, 3140, 3120, 3040, 2985, 2935, 1630, 1600, 1525, 1478, 1330, 1245, 1235, 1185, 1050, 990, 735, 675, 480	−126.13
H_2SiO_3	$(C_5H_5NH)_2SiF_6$ (93)			

chloroform and dried. The compound was recrystallised from 95% ethanol. The yield was *ca* 87% (Table 1).

Analysis

Estimation of $C_5H_5NHBF_4$. Pyridinium tetrafluoroborate was estimated by the methods reported by Tatarskii *et al.*[8] with a slight modification as given below:

(a) About 0.25 g of $C_5H_5NHBF_4$ was treated with 50 cm^3 of 2 M $CaCl_2$ solution and 20 cm^3 of water. The mixture was gently boiled under reflux for 30 min and cooled. About 2 g of mannitol and five drops of phenolphthalein indicator were added and the solution was titrated against standard alkali (0.5 N NaOH). From the volume of the alkali consumed, the purity of the sample was calculated on the basis of the reaction.

$$C_5H_5NHBF_4 + 2CaCl_2 + 3H_2O \rightarrow C_5H_5NHCl + 3HCl + H_3BO_3 + 2CaF_2$$

1 cm^3 of 0.5 N NaOH ≡ 16.68 mg of $C_5H_5NHBF_4$.

(b) In a separate experiment $C_5H_5NHBF_4$ was also estimated by treating a known quantity of the sample dissolved in water with about 5 g of KCl and the contents shaken and cooled in ice. The acidity of the solution was titrated rapidly with 0.1 N NaOH using phenolphthalein as indicator to the first appearance of pink colour.

From both the experiments, the sample was found to be more than 99% pure.

Estimation of $(C_5H_5NH)_2SiF_6$. Pyridinium hexafluorosilicate was estimated by the method of Jacobson[9] with a slight modification. About 0.2 g of the sample was treated with a known excess of standard alkali (15 cm^3 of 0.5 N NaOH) and the solution boiled for 15 min and cooled. About 20 cm^3 of water and five drops of phenolphthalein were added and titrated against standard hydrochloric acid solution (0.5 N). The purity of the sample was calculated on the basis of the reaction.

$$(C_5H_5NH)_2SiF_6 + 6NaOH \rightarrow 2C_5H_5N + 6NaF + SiO_2 + 4H_2O$$

1 cm^3 of 0.5 N HCl ≡ 25.175 mg of $(C_5H_5NH)_2SiF_6$.

The sample was found to be more than 99% pure.

RESULTS AND DISCUSSION

From the results presented in Table 1, it may be inferred that PPHF reacts readily with oxides and acids of boron and silicon giving rise to the respective pyridinium complex fluoro salts of boron and silicon in good yields and of high purity. Pyridinium poly(hydrogen fluoride) acts as a source of hydrogen fluoride and the overall reactions are represented as follows.

$$B_2O_3 + C_5H_5\overset{+}{N}H(HF)_xF^- \xrightarrow{\text{ether}} 2C_5H_5\overset{+}{N}HBF_4^- + 3H_2O,$$

$$H_3BO_3 + C_5H_5\overset{+}{N}H(HF)_xF^- \longrightarrow C_5H_5\overset{+}{N}HBF_4^- + 3H_2O,$$

$$SiO_2 + C_5H_5\overset{+}{N}H(HF)_xF^- \xrightarrow{\text{ether}} (C_5H_5\overset{+}{N}H)_2SiF_6^{2-} + 2H_2O,$$

$$H_2SiO_3 + C_5H_5\overset{+}{N}H(HF)_xF^- \xrightarrow{\text{ether}} (C_5H_5\overset{+}{N}H)_2SiF_6^{2-} + 3H_2O.$$

The IR spectral data of the compounds presented in Table 1 show that the N–H stretching frequencies of $C_5H_5NHBF_4$ and $(C_5H_5NH)_2SiF_6$ appear at 3270 and 3200 cm^{-1} respectively. The very strong, broad band at 1150–1000 cm^{-1} and a strong band at 520 cm^{-1} could be assigned to $\nu_{(B-F)}$ and $\delta_{(B-F)}$ respectively of the BF_4^- anion. The strong bands at 735 and 480 cm^{-1} could be assigned to $\nu_{(Si-F)}$ and $\delta_{(Si-F)}$ respectively of SiF_6^{2-} anion. All the other absorptions are due to the pyridine moiety with the expected shifts due to salt formation. These observations are in good agreement with those reported in the literature for these compounds.[6,10,11]

The ^1H NMR spectra of these compounds show the characteristic pyridine pattern with a shift to lower field due to salt formation. The ^{19}F NMR peaks of BF_4^- and SiF_6^{2-} recorded for the first time appear at −146.5 and −126.13 ppm respectively. These values are in good agreement with those compounds containing the respective anions.[12]

It is of interest to point out that $C_5H_5NHBF_4$ and $(C_5H_5NH)_2SiF_6$ have been used as starting materials for the preparation of other salts of these anions such as alkali metal, ammonium and alkylammonium tetrafluoroborates and hexafluorosilicates respectively.[13]

3,3′-DICARBOMETHOXY-2,2′-BIPYRIDYL COMPLEXES OF PALLADIUM(II), PLATINUM(II) AND RHODIUM(III)

SMITA DHOLAKIA,* ROBERT D. GILLARD and FRANZ L. WIMMER*†
Department of Chemistry, University College, P.O. Box 78, Cardiff CF1 1XL, Wales, U.K.

(*Received* 15 *September* 1983; *accepted* 13 *September* 1984)

Abstract—3,3′-Dicarbomethoxy-2,2′-bipyridyl (DCMB) reacts with K_2MCl_4 (M = Pd, Pt) to give $M(DCMB)Cl_2$ and with $RhCl_3$ to give the *cis*-$[Rh(DCMB)_2Cl_2]^+$ ion. Attempts to prepare the tris (DCMB) complex with Rh(III) and analogous Co(III) complexes were unsuccessful.

2,2′-Bipyridyl (bpy) may reasonably be expected to coordinate as a monodentate, chelating or bridging ligand. However, in practice, only the chelating mode has been observed.[1] The monodentate form is generally agreed to be involved in the rate-determining step in the formation and dissociation of bipyridyl complexes.[2]

One way to prepare a monodentate bipyridyl complex is to quaternise one of the nitrogen atoms with an alkyl group; the resultant cation forms complexes of the type $M(bpyMe)X_3$ [M(II) = Co–Cu,[3] Zn–Hg,[4] Pd, Pt[5]; bpyMe = *N*-methyl-2,2′-bipyridylium; X = Cl–I]. An alternative route would be to place sufficiently bulky substituents in the 3,3′-positions, so that the ligand cannot attain a planar state, as has been observed for $[MeHg(3,3'\text{-dmbpy})]NO_3$[6,7] (3,3′-dmbpy = 3,3′-dimethyl-2,2′-bipyridyl). However, the dimethyl substituents in 3,3′-dmbpy do not prevent the molecule from coordinating in a bidentate manner.[8–12]

As part of our study of the metal complexes of skewed bipyridyls[3–5,13] we report the coordinating properties of 3,3′-dicarbomethoxy-2,2′-bipyridyl.

RESULTS

Platinum(II) *and palladium*(II) *complexes*

When a suspension of 3,3′-dicarbomethoxy-2,2′-bipyridyl (DCMB) in water was added to a warm solution of K_2PtCl_4 in water (2:1 molar ratio), a dark orange solid, soluble in ethanol, separated initially. This solid was not characterised. When heating was continued for a further 20 min, it did not dissolve completely but was converted to bright orange-yellow crystals.

An orange complex separated when DCMB and K_2PdCl_4 (2:1 molar ratio) in water were gently warmed for 2 min. The same compound is formed when Li_2PdCl_4 is used and the reaction is carried out in ethanol.

Elementary micro-analysis of the complexes gave an empirical formula of $M(DCMB)Cl_2$. The metal residues obtained from the thermogram indicate formula weights of 530 (Pt) and 440 (Pd). The ^1H NMR spectra of these compounds in $CDCl_3$ show only one methyl resonance (at δ 4.2) which suggests that the bipyridyl is coordinating as a chelating or a bridging‡ ligand. The field desorption mass spectra show molecular ions centred at *m/e* 538 (Pt) and 450 (Pd), indicating that the complexes are monomeric and that DCMB acts as a chelating ligand.

The bands due to DCMB in the IR spectra of the complexes $M(DCMB)Cl_2$ are virtually identical to those of the ligand in the region 4000–600 cm^{-1}. $Pt(DCMB)Cl_2$ shows strong bands at 350 and 342 cm^{-1} which are not present in the spectrum of the free ligand. These are assigned to the Pt–Cl stretching vibrations. One of the Pd–Cl stretching vibration for $Pd(DCMB)Cl_2$ can be assigned to the

† Author to whom correspondence should be addressed.

‡ There are no known examples where 2,2′-bipyridyl acts as a bridging ligand (although complexes containing bridging 4,4′-bipyridyl have been described). The blue-green solid formed by the interaction of $[Rh(CO)_2Cl]_2$ with bpy, formulated as $[Cl(OC)_2Rh(\mu\text{-bpy})Rh(CO)_2Cl]$[14] is in fact $[Rh(bpy)(CO)_2][Rh(CO)_2Cl_2]$[15] since a closely similar 1,10-phenanthroline complex has also been prepared.

§ Literature values[16]: 353 and 343 cm^{-1}.

band observed at 345 cm^{-1}, but the other vibration is not clear due to interference from the ligand bands (see Table 1). These M–Cl vibrations do not differ significantly from those for $M(bpy)Cl_2$[16] (M = Pt, Pd; Table 1).

The electronic spectra of $Pt(DCMB)Cl_2$ and $Pd(DCMB)Cl_2$ in chloroform are compared with those of $Pt(bpy)Cl_2$ and $Pd(bpy)Cl_2$ (in chloroform) in Table 2. They differ considerably, and this is probably due to different dihedral angles about the 2,2′-bond. In general, it seems that the absorptions shift to higher wavelengths in going from the bpy complexes to the analogous DCMB complexes, although the relative intensities remain approximately the same.

When a suspension of $Pt(DCMB)Cl_2$ was gently heated with an excess of aqueous pyridine, the solid dissolved gradually to give a pale yellow solution. Addition of solid sodium perchlorate gave white needles of $[Pt(DCMB)(py)_2](ClO_4)_2$. The bands at 350 and 342 cm^{-1} in the IR spectrum of $Pt(DCMB)Cl_2$ are absent in the spectrum of the product. $Pt(bpy)Cl_2$ reacts in a similar mannner: the chloro groups can be substituted with basic ligands such as pyridine, ammonia, ethylenediamine or bpy on mild heating.[17,18]

* This is in sharp contrast to $[Rh(bpy)_2Cl_2]Cl$ which is only slightly soluble in water.

Rhodium(III) *complexes*

DCMB reacts rapidly with $RhCl_3 \cdot nH_2O$ (ligand : metal ratio = 3 : 1) in hot aqueous ethanol to form *cis*-$[Rh(DCMB)_2Cl_2]Cl$. The complex was isolated as a yellow hygroscopic* solid. The non-hygroscopic perchlorate salt can be prepared by metathesis. When the same reaction mixture was boiled for 45 min or when the reactants were heated in the presence of hydrazinium monochloride as a catalyst,[19] the product, isolated as the perchlorate salt, was *cis*-$[Rh(DCMB)_2Cl_2]^+$ in both cases.

Hence, $[Rh(DCMB)_3]^{3+}$ cannot be prepared under these reaction conditions and the bis-complex is the sole product even in the presence of an excess of ligand. A tris complex cannot be prepared from the reaction between 1,10-phenanthroline and $RhCl_3$: this has been attributed[17,19] to the rigidity of phenanthroline. In a similar manner, placing bulky substituents in the 3,3′-positions of bpy would make the ring-closure step more difficult.

The medium intensity bands at 360 and 345 cm^{-1} in the IR spectrum of $[Rh(DCMB)_2Cl_2]Cl$ are assigned to the metal–chlorine stretching modes. The *cis*-isomer of the complex will have C_2 symmetry and therefore will give rise to two IR active M–Cl stretching modes. The analogous bands for $[Rh(bpy)_2Cl_2]Cl$, which is known to have the *cis*-configuration, are at 356 and 349 cm^{-1}.[20]

Attempts to prepare DCMB complexes of cobalt(III) using air oxidation of cobalt(II) chloride, in the presence of charcoal, proved unsuccessful.

DISCUSSION

In the absence of steric effects chelated bpy molecules are essentially planar.[21] When methyl substituents are placed in the 3,3'-positions of bpy, the molecule can still act as a chelating ligand, but with a concomitant increase in the dihedral angle between the pyridyl rings to 30–35°.[10–12] An exception is [MeHg(3,3'-dmbpy)]$^+$ which is two coordinate with a monodentate bpy ligand,[6,7] whereas the complex [MeHg(bpy)]$^+$ is three coordinate.[6]

It follows that if the size of the 3,3'-substituents is increased, a point will be reached at which the ring-closure step will be unlikely and monodentate coordination will result.

EXPERIMENTAL

The carbon, hydrogen, nitrogen and chlorine analyses were determined by the Microanalytical Service, University College, Cardiff. IR spectra were recorded as nujol mulls between caesium iodide plates on a Perkin–Elmer 457 grating IR spectrophotometer and were calibrated with polystyrene. Electronic spectra were recorded with a Beckman Model DK-2A ratio-recording spectrophotometer. Proton NMR spectra were recorded relative to TMS on a 90 MHz Perkin–Elmer R32 Spectrometer at 35°C. Thermogravimetric results were obtained with a Stanton Redcroft TG-750 temperature programmed thermogravimetric balance using samples between 5 and 10 mg. The samples were heated in air at a rate of 5° min^{-1}.

2,2'-Bipyridyl-3,3'-dicarboxylic acid (binicotinic acid)

Synthesis of binicotinic acid was carried out five times by the method of Inglett and Smith,[22] but the yield was 30–40% rather than the reported 85%. Hence the method was modified and binicotinic acid was obtained as follows.

1,10-Phenanthroline (16 g, 0.08 mol), sodium hydroxide (6.4 g, 0.16 mol) and potassium permanganate (38 g, 0.24 mol) were dissolved in water (700 cm^3) and the mixture was boiled in a 1.5 dm^3 Erlenmeyer flask while magnetically stirred. After heating for 2.5 h, the precipitate of manganese dioxide was removed by filtration and the filtrate evaporated to approximately 300 cm^3 on a rotary evaporator. The pH of the concentrate was adjusted to ~ 2 with concentrated hydrochloric acid, decolourising charcoal was added and the solution boiled. The carbon was removed and the filtrate concentrated to 200 cm^3. White needles of binicotinic acid were collected by filtration, washed with cold water and cold ethanol and dried *in vacuo* over P_4O_{10}. Yield = 75%. M.p. = 262°C, literature[22] = 260°C (decomp.).

3,3'-Dicarbomethoxy-2,2'-bipyridyl (DCMB)

To a solution of binicotinic acid (4 g, 0.017 mol) in absolute methanol (20 cm^3) was added concentrated sulphuric acid (4 cm^3; CARE on adding sulphuric acid to methanol). The mixture was heated under reflux for 5 h. The methanol was removed by evaporation, water (5 cm^3) was added and the

solution was neutralised with sodium carbonate. The white needles that separated were collected on a filter, washed with water, a few drops of cold ethanol and dried *in vacuo* (P_4O_{10}). Yield = 86%. M.p. = 152°C, literature[23] = 150°C.

Pt(*DCMB*)Cl_2

A suspension of DCMB (0.49 g, 1.82 mmol) in an aqueous solution of K_2PtCl_4 (0.38 g, 0.92 mmol) was warmed. A dark orange solid initially separates out but heating was continued, with stirring, for a further 30 min. The bright orange-yellow solid was isolated, washed several times with water, warm ethanol, a few drops of chloroform to remove any unreacted ligand, and ether, and air-dried. Found: C, 31.4; H, 2.2; N, 5.4; Cl, 14.2%. $C_{14}H_{12}Cl_2N_2O_4Pt$ requires C, 31.2; H, 2.2; N, 5.2; Cl, 13.2%.

Pd(*DCMB*)Cl_2

To a solution of K_2PdCl_4 (0.42 g, 0.78 mmol) in water was added, with stirring, DCMB (0.25 g, 1.58 mmol) in warm ethanol. An orange precipitate formed immediately; this was separated, washed with water, ethanol, a few drops of chloroform, ether and air-dried. (Found: C, 37.4; H, 2.6; N, 6.7; Cl, 16.5%. $C_{14}H_{12}Cl_2N_2O_4Pd$ requires C, 37.4; H, 2.7; N, 6.2; Cl, 15.8%.)

The platinum(II) and palladium(II) complexes are insoluble in water, ethanol, acetonitrile, slightly soluble in chloroform and extremely soluble in nitromethane.

[Pt(*DCMB*)py_2]$(ClO_4)_2$

Pt(DCMB)Cl_2 (100 mg) was suspended in a solution of pyridine (2 cm^3) in water (10 cm^3). The mixture was heated on a steam bath until all the complex had dissolved to give a pale yellow solution. Solid sodium perchlorate was added and the mixture was stored at 5°C for 3 days. The white needles of [Pt(DCMB)py_2]$(ClO_4)_2$ were collected, washed quickly with cold water and dried *in vacuo* over P_4O_{10}. Found : C, 36.3; H, 3.0; N, 6.7; Cl, 8.3%. $C_{26}H_{22}Cl_2N_4O_{12}Pt$ requires C, 36.8; H, 2.6; N, 6.6; Cl, 8.4%.

[Rh(*DCMB*)$_2Cl_2$]$Cl \cdot 3H_2O$

$RhCl_3 \cdot nH_2O$ (200 mg, 0.76 mmol) in warm water (10 cm^3) was mixed with DCMB (0.61 g, 2.24 mmol) in warm ethanol (10 cm^3) to give an orange solution. On warming for 3 min, a yellow solution was obtained. Heating was continued for 7 min on a steam bath. The solvent was removed by evaporation. The yellow oil obtained was dissolved in absolute ethanol and the solution was concentrated to a minimum volume. Carbon tetrachloride was added and the solution left at 5°C for 1 h. The yellow precipitate of [Rh(DCMB)$_2Cl_2$]$Cl \cdot 3H_2O$ was collected, washed with carbon tetrachloride and ether and recrystallised from ethanol–ether. The pale yellow solid was washed with ether and dried *in vacuo* over P_4O_{10}. Found: C, 41.9; H, 3.5; N, 7.2; Cl, 13.5%. $C_{28}H_{30}Cl_3N_4O_{11}Rh$ requires C, 41.6; H, 3.7; N, 6.9; Cl, 13.1%.

Attempted synthesis of [Rh(*DCMB*)$_3$]$^{3+}$

A solution of $RhCl_3 \cdot nH_2O$ (100 mg, 0.38 mmol) and DCMB (0.32 g, 1.18 mmol) in 50% aqueous ethanol was heated on a steam bath for 45 minutes to give a golden yellow solution. A concentrated aqueous solution of sodium perchlorate was added dropwise to the hot reaction mixture. The yellow oil crystallised on cooling to give pale yellow crystals of *cis*-[Rh(DCMB)$_2Cl_2$]ClO_4, which were collected, washed with water and ethanol and dried *in vacuo* over P_4O_{10}. Found: C, 40.3; H, 3.0; N, 7.0; Cl, 13.3%. $C_{28}H_{24}Cl_3N_4O_{12}Rh$ requires C, 41.1; H, 2.9; N, 6.9; Cl, 12.9%.

FORMATION OF PARAMAGNETIC MONONUCLEAR IRON NITROSYL COMPLEXES FROM DIAMAGNETIC DI- AND TETRANUCLEAR IRON–SULPHUR NITROSYLS: CHARACTERISATION BY EPR SPECTROSCOPY AND STUDY OF THIOLATE AND NITROSYL LIGAND EXCHANGE REACTIONS

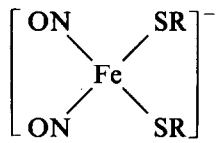
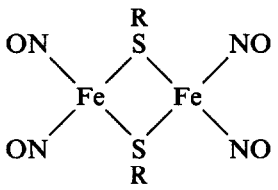
(*Received* 3 *July* 1984; *accepted* 13 *September* 1984)



Abstract—The diamagnetic Roussin esters $Fe_2(SR)_2(NO)_4$ readily underwent exchange with thiols R'SH to yield $Fe_2(SR')_2(NO)_4$: the exchange was faster in polar, coordinating solvents where paramagnetic, mononuclear complexes of types $[Fe(NO)_2(solvent)_2]^+$ and $Fe(NO)_2(SR)(solvent)$ were formed. With the corresponding thiolate anions RS^-, the esters $Fe_2(SR)_2(NO)_4$ formed the mononuclear complexes $[Fe(SR)_2(NO)_2]^-$, which were fully characterised by EPR spectroscopy for R = H, Me, Et, *i*-Pr, *t*-Bu and $PhCH_2$: assignments of hyperfine couplings were confirmed by use of ^{15}N. With $Fe_2(SR)_2(NO)_4$ and a different set of thiolate anion, $R'S^-$, in excess, thiol exchange occurred to give $[Fe(SR')_2(NO)_2]^-$. A mechanism for formation of $Fe_2(SR')_2(NO)_4$ from $Fe_2(SR)_2(NO)_4$ has been proposed. The paramagnetic mononuclear complexes $[Fe(SR)_2(NO)_2]^-$ were also readily formed from the diamagnetic clusters $[Fe_4S_3(NO)_7]^-$ and $Fe_4S_4(NO)_4$, together with $[Fe(SR)_3(NO)]^-$, and additionally from $[Fe(CO)_3NO]^-$. $[Fe(SMe)_2(NO)_2]^-$ was found to be a precursor of isolable $Fe_2(SMe)_2(NO)_4$, and $[Fe(SH)_2(NO)_2]^-$ to be the common precursor of both Roussin's red anion $[Fe_2S_2(NO)_4]^-$ and Roussin's black anion $[Fe_4S_3(NO)_7]^-$, interconvertible by appropriate adjustment of pH. The nitrosyl groups in these complexes were freely labile, and mononitrosyliron and dinitrosyliron fragments were readily interconvertible: Fe(NO) fragments were favoured by the dimethyldithiocarbamate ligand ($Me_2NCS_2^-$) and $Fe(NO)_2$ fragments by thiolate ligands, RS^-, regardless of the origin of the $Fe(NO)_x$ ($x = 1, 2$) fragment: both mono- and dinitrosyliron complexes persisted with $[(i\text{-}PrO)_2S_2]^-$ as ligand. Isotopic labelling showed the occurrence of rapid exchange of nitrogen between nitrosyl ligands and added nitrite in $Fe(NO)(S_2CNMe_2)_2$ and $[Fe(SR)_2(NO)_2]^-$.

It was first demonstrated[1] in 1965 that reaction between iron salts and nitric oxide in the presence of anionic ligands gave rise to four-coordinate complexes, of general stoichiometry $[Fe(NO)_2L_2]^{x+}$ and characterised by EPR spectra with isotropic g values of *ca* 2.03. In the specific cases of L = cysteine and penicillamine, the identification of the stoichiometry was particularly clear, and it was further inferred that the iron was formally present as d^9 Fe(−I). Subsequently there have been many studies of the reactions of iron salts with nitric oxide in the presence of a very wide range of additional ligands, including halides and pseudohalides,[2] alcohols and alkoxides,[3] mercaptides,[4,5] and mercapto-purines and mercapto-pyrimidines.[6] In all these cases,[2–6] the g values are close to 2.03, except when the additional ligands are bromide or iodide,[2] when g moves to rather higher values, as observed in other, independent, studies of $[Fe(NO)_2Br_2]^-$ and $[Fe(NO)_2I_2]^-$ and related species.[7,8]



Similar paramagnetic iron–nitrosyl complexes, characterised by usually anisotropic g values around 2.03 have been observed[9–11] in extracts of rat liver following administration of specific chemical carcinogens, such as aminoacetylfluorene[12] and *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine.[13] In addition, $g = 2.03$ complexes have been found[14] in extracts from many of the organs of several species of

* Author to whom correspondence should be addressed.

experimental animals maintained on a normal diet supplemented only by sodium nitrite and iron(II) sulphate. In each of these biological studies[9–11,14] the identification of the $g = 2.03$ species as being complexes of general type $[Fe(NO)_2L_2]^{x+}$ (i.e., the same as those produced from iron salts, nitric oxide and a ligand L) was far from definitive, and was based primarily upon a comparison of their EPR spectra with those of the complexes originally observed[1] by Phillips *et al.*: in each case the $g = 2.03$ complexes were assigned structures of type (I), where R remained unidentified.

I

II

Closely related to complex I are the neutral, diamagnetic complexes II, the esters of Roussin's red salt.[15,16] The methyl ester (II, R = CH_3) has been isolated from vegetable sources, and it has subsequently been implicated in the causation of oesophageal cancer.[17–20] The Fe_2S_2 core of naturally occurring esters II is presumably derived from iron–sulphur proteins, and indeed it has recently been demonstrated[21] that the HIPIP-type iron–sulphur centres in *Clostridium botulinum* are replaced by a $g = 2.03$ complex upon exposure to nitrite, with resultant destruction of the Fe_4S_4 iron–sulphur cluster.

Continuing our general study of iron–sulphur–nitrosyl complexes[8,22–26] we have made a study of the $g = 2.03$ complexes and report in the present paper the definitive characterisation of a range of complexes I, $[Fe(NO)_2(SR)_2]^-$; the ready interconversion of I and II, and consequent facile exchange of R groups in II [eqn (1)]; the ready formation of I and related mononuclear systems from II in polar media; and the

$$Fe_2(SR)_2(NO)_4 + 2R'SH \rightleftharpoons Fe_2(SR')_2(NO)_4 + 2RSH \quad (1)$$

formation of mononuclear complexes, not only from dinuclear precursors, but also from the tetranuclear complexes, $Fe_4S_3(NO)_7^-$ and $Fe_4S_4(NO)_4$.

Our observations provide important points of connection between the existing chemical[1–6] and biological[9–11,14,17–21] studies of these systems.

RESULTS AND DISCUSSION

Reactions of $Fe_2(SR)_2(NO)_4$

A range of esters $Fe_2(SR)_2(NO)_4$ were found to undergo ready exchange of SR groups with added thiols R'SH. Using an approximately 10:1 (w/w) excess of thiol over ester in THF solution, the results recorded in Table 1 were obtained, where the composition of the products was determined by ^1H NMR in $CDCl_3$ solution. The use of a representative range of substituents R,R' showed that exchange is generally complete or almost so. In all cases the total material recovered prior to NMR examination represented $\geqslant 95\%$ recovery, and the spectra showed that the exchange reactions were clean with no decomposition; nor were any products of side-reactions detected. The solvent dependence of the rate of exchange was examined qualitatively for the reaction of $Fe_2(SEt)_2(NO)_4$ with *i*-PrSH in a modest range of solvents, and the results are given in Table 2: as for the data of Table 1, the results represent the composition of the reaction mixtures after 72 h. These qualitative results show clearly that the exchange reaction is faster in polar solvents: we shall return to the question of the possible mechanisms of the exchange below.

Table 1. Results of exchange reactions of $Fe_2(SR)_2(NO)_4$ with added thiols R'SH, in THF

		Product composition (%)	
R	R'	$Fe_2(SR')_2(NO)_4$	$Fe_2(SR)_2(NO)_4$

$PhCH_2$	2.027	2.4	1.4 (4H)

These alkanethiol exchange reactions are of some synthetic value, as they can provide a very easy route, superior to that described previously[23] and based upon exchange reactions of $Fe_2(SR)_2(CO)_6$, to the formation of esters $Fe_2(SR)_2(NO)_4$ containing functionalised R groups, in particular those containing substituents which render the ester water-soluble.

We have described previously[23,26] the solvent dependence of the ^1H spectra of a range of esters $Fe_2(SR)_2(NO)_4$ and it was the observation[26] of rather broad, poorly resolved ^1H resonances for solutions of $Fe_2(SMe)_2(NO)_4$ in solvents such as DMF, DMSO and pyridine which first indicated the formation of paramagnetic species in these very polar solvents. Examination of these solutions by EPR spectroscopy has revealed the presence of paramagnetic centres.

The esters $Fe_2(SR)_2(NO)_4$ (R = Me, Et, *i*-Pr, *t*-Bu, $PhCH_2$) all gave weak EPR absorptions when dissolved in DMF: the spectra were centred at $g \simeq 2.03$, but no hyperfine coupling was resolvable. The intensity of each of these spectra was somewhat enhanced by addition of the corresponding RSH, although solutions of $Fe_2(SR)_2(NO)_4$ in RSH alone showed no evidence of the presence of paramagnetic species. Upon subsequent addition of a trace of MeS^-, acting as a base, a major enhancement of the spectral intensity occurred: the EPR spectra were all characterised by hyperfine coupling to two equivalent ^{14}N nuclei ($I = 1$) and to the α-hydrogens, where present, of two equivalent RS groups (Table 3), allowing the assignment of these spectra as arising from complexes $[Fe(SR)_2(NO)_2]^-$, formed according to eqn (2):

$$Fe_2(SR)_2(NO)_4 + 2RSH \xrightarrow{\text{base}} 2[Fe(SR)_2(NO)_2]^-. \quad (2)$$

In each example the paramagnetic species contained the alkyl group R from the added thiol, rather than CH_3 from the added base MeS^-.

When a solution of either $Fe_2(SMe)_2(NO)_4$ or $Fe_2(SPr\text{-}i)_2(NO)_4$ in DMF was heated to 350 K for 5 min, and subsequently cooled to 240 K, the spectral intensity was much enhanced over that of the initial solution, and in the case of R = *i*-Pr, at least, it was clear that two paramagnetic complexes were present in approximately equimolar concentrations. Comparison of the spectra obtained from $Fe_2(SPr\text{-}i)_2(NO)_4$ in DMF, DMF-d_7, and dimethyl acetamide (DMA) as solvents, together with the spectrum obtained from $Fe_2(SMe)_2(NO)_4$ in DMF, showed that these two species were $[Fe(NO)_2(DMF)_2]^+$ and $Fe(NO)_2(SR)(DMF)$ in which there is a hyperfine coupling to the unique hydrogen in DMF in addition to those involving the ^{14}N nuclei of the nitrosyl groups and the α-hydrogens of the SR group (Table 4).

Similar solvo-complexes of type $[Fe(NO)_2(solvent)_2]^+$ were formed in a range of heteroaromatic solvents (Table 4), while complexes of type $Fe(NO)_2(SR)(solvent)$ appear to be formed in a range of non-aromatic solvents. In none of the latter class, except when the solvent is DMF (but not however DMF-d_7 or DMA) was any hyperfine coupling observed to either hydrogen or nitrogen in the coordinated solvent molecules. Nevertheless, by analogy with the DMF solvo-complexes $Fe(NO)_2(SR)(DMF)$ where R = Me or *i*-Pr, we have assigned all these species constitution of the same type. In liquid ammonia solution at 200 K, $Fe_2(SMe)_2(NO)_4$ yielded a weak EPR spectrum having $g = 2.029$, in which no hyperfine couplings were resolvable: by analogy with other aliphatic amines, the complex $Fe(NO)_2(SMe)(NH_3)$ may have been formed.

Examination, by EPR spectroscopy at 275 K, of an aqueous solution of $Fe_2(SCH_2COOH)_2(NO)_4$ (which is rendered slightly soluble in water by the carboxylic acid groups) revealed a broad unresolved absorption, centred at $g = 2.030$. In aqueous ethanol solutions, the complex $[Fe(NO)_2(H_2O)_2]^+$ is reported[2] to give a broad unresolved absorption at $g = 2.033$, while in $[Fe(NO)_2(OH)_2]^-$, at $g = 2.027$, the hyperfine coupling to ^{14}N was resolved.[2] By analogy

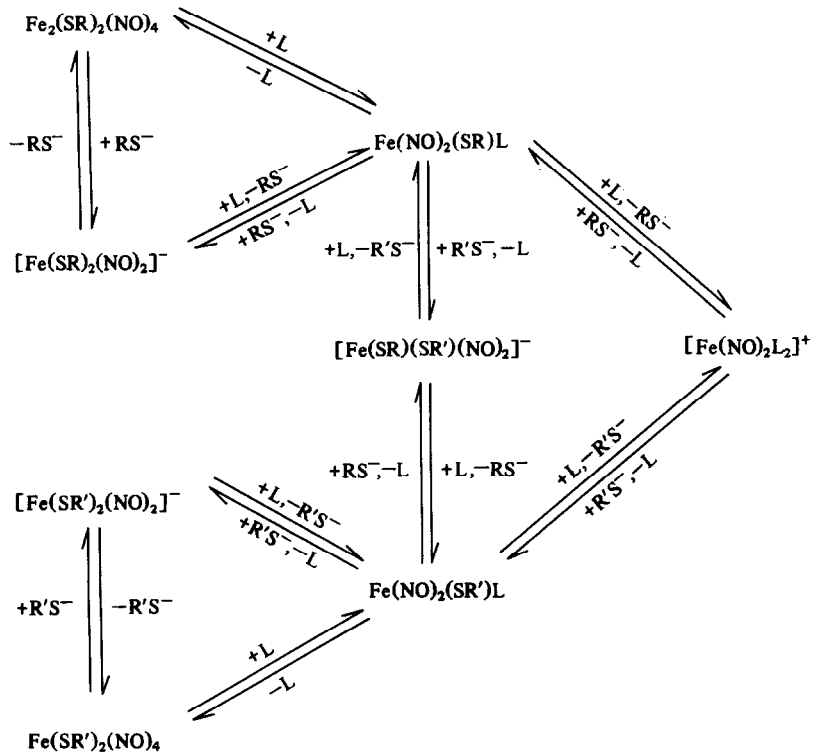
‡ No resolution of hyperfine coupling to ^1H or ^{14}N in coordinated solvent molecules.
§ S represents 2,6-dimethylpyridine, 2,4,6-trimethylpyridine or quinoline.
‖ No resolution of any hyperfine couplings; identity of paramagnetic complex doubtful (see text).
¶ Spectrum recorded at 200 K.

with these results, and allowing for the change of solvent from aqueous ethanol to pure water, we suggest that the $g = 2.030$ species observed here is $[Fe(NO)_2(H_2O)_2]^+$, or a mono-deprotonated form, resulting from solvolysis of $Fe_2(SCH_2COOH)_2(NO)_4$ by water.

With the exception of the solvo-complexes formed in DMF and DMA solutions, all the other solvo-complexes of Table 4 were formed at room temperature or below. Their formation is significant in that it demonstrates that the diamagnetic esters $Fe_2(SR)_2(NO)_4$ can spontaneously and very readily form paramagnetic centres, simply upon dissolution in a polar, coordinating medium, typical of physiological environments.

Despite any residual uncertainty about the constitution of the solvo-complexes formed by DMA, DMSO, and aliphatic amines, it is clear and unambiguous that there are two major points of difference between the solvo-complexes formed by hetero-aromatic and by aliphatic amines. The hetero-aromatic amines displace both RS groups and the resulting complexes show resolved hyperfine coupling to the coordinated solvent. In contrast, the aliphatic amines displace only one RS group and show no coupling to the solvent in the resulting



complexes. For a possible rationalisation of these observations we turn to a consideration of the differences in metal–ligand binding aliphatic and hetero-aromatic amines. Although no formation constants appear to be available for the interactions of amines acting both as solvent and as ligand towards a d^9 metal ion, we can nonetheless appeal to the properties of the ligands themselves. The spectrochemical f values for ammonia, the aliphatic amines, and hetero-aromatic amines are very similar[27] and allow no distinction of the several classes of ligand: however, the use of a two-dimensional spectrochemical series[28] shows that whereas aliphatic amines are essentially involved only in σ bonding with central metals, (i.e. $e_\pi \simeq 0$) hetero-aromatic amines such as pyridine, although somewhat weaker σ donors are also strong π acceptors (i.e. $e_\pi < 0$). This difference is expected to be accentuated with electron-rich central metals, and consequently we suggest that metal → ligand π-bonding is the major source of the differences between hetero-aromatic amines and other ligands as solvents. The more powerful metal–ligand interaction in the case of the hetero-aromatic amines is the principal factor underlying the displacement of both RX groups by these amines.

The identification of the two solvo-complexes in DMF solvent then allowed the assignment of the EPR spectra obtained from solutions of the esters $Fe_2(SR)_2(NO)_4$ in mixtures of RSH and DMF to similar pairs of solvo-complexes $[Fe(NO)_2(DMF)_2]^+$ and $Fe(NO)_2(SR)(DMF)$ for each of R = Me, Et and *i*-Pr. When R = *t*-Bu, no resolution of the very weak spectrum was achieved, but it seems unlikely that the composition of this solution was significantly different from those of the lower alkyl esters.

If instead of MeSH, the benzyl mercaptan $PhCH_2SH$ was added to a solution of $Fe_2(SMe)_2(NO)_4$ followed by base, the paramagnetic product identified by EPR spectroscopy was $[Fe(SCH_2Ph)_2(NO)_2]^-$, rather than $[Fe(SMe)_2(NO)_2]^-$. Similarly addition of EtS^- to a DMF solution of $Fe_2(SMe)_2(NO)_4$ gave $[Fe(SEt)_2(NO)_2]^-$ and addition of SH^- to $Fe_2(SPr\text{-}i)_2(NO)_4$ gave $[Fe(SH)_2(NO)_2]^-$ [reaction generalised in eqn (3)]:

$$Fe_2(SR)_2(NO)_4 + 2R'SH \xrightarrow{\text{base}} [Fe(SR')_2(NO)_2]^- . \quad (3)$$

The foregoing series of observations, namely: (i) that the rate of alkanethiol exchange [eqn (1)] is faster in more polar, coordinating, solvents; (ii) that in these solvents the esters $Fe_2(SR)_2(NO)_4$ readily yield mononuclear solvo-complexes; and (iii) that exchange of RS groups occurs readily in the mononuclear complexes $[Fe(SR)_2(NO)_2]^-$, allow the formulation of a tentative mechanism for the exchange reaction (see Scheme 1). Scheme 1 contains

Scheme 1.

all the potentially important equilibria involved in the overall exchange process with converts $Fe_2(SR)_2(NO)_4$ to $Fe_2(SR')_2(NO)_4$, and with the exception of $[Fe(SR)(SR')(NO)_2]^-$, all of the complexes of Scheme 1 and all the individual equilibria have been observed for at least one combination of R,R', and solvent acting as ligand L. Although the mixed anions $[Fe(SR)(SR')(NO)_2]^-$ have not been observed by EPR spectroscopy, we note that the reaction of equimolar quantities of $Fe_2(SMe)_2(NO)_4$ and $Fe_2(SEt)_2(NO)_4$ in DMF solution at room temperature yielded the mixed ester $Fe_2(SMe)(SEt)(NO)_4$, identified by mass spectrometry: in contrast reflux during 4 h of these two pure esters in chloroform solution gave no evidence for mixed ester formation. In solvents such as pyridine, the exchange appears to proceed solely via $[Fe(NO)_2L_2]^+$; in solvents such as Et_3N, solely via $Fe(NO)_2(SR)L$; and in solvent such as DMF, via both routes.

We have recorded elsewhere[8] the observation that $Fe_2(SMe)_2(NO)_4$ reacted, in DMF solution, with an excess of either bromide or iodide ions to yield the complexes $[Fe(NO)_2Br_2]^-$ or $[Fe(NO)_2I_2]^-$ respectively, identical with the species formed[2] by reaction of nitric oxide with mixtures of iron(II) salts and halides. In contrast, fluoride or chloride ions gave no paramagnetic halogeno complexes but rather a mixture, in each case, of the solvo-complexes $Fe(NO)_2(SMe)(DMF)$ and $[Fe(NO)_2(DMF)_2]^+$. The pseudohalide thiocyanate, NCS^-, yielded the complex $[Fe(NO)_2(NCS)_2]^-$ identical with that observed[2] in Fe(II)/NCS^-/NO reactions: cyanate, NCO^-, likewise yielded with $Fe_2(SMe)_2(NO)_4$ the complex $[Fe(NO)_2(NCO)_2]^-$, hitherto unreported, having $g = 2.030$, $A(^{14}N) = 2.6$G ($2 \times NCO$), 1.8 G ($2 \times NO$). Selenocyanate, $NCSe^-$, yielded a very complex spectrum, which we have been unable to interpret.

Reactions of $[Fe_4S_3(NO)_7]^-$ *salts*

The reactions of the Roussin black anion, $[Fe_4S_3(NO)_7]^-$ are inevitably more complex than those of the 2-Fe esters $Fe_2(SR)_2(NO)_4$ since in the anion there are two types of iron:[29,30] the unique apical iron carries a single nitrosyl ligand, whereas the three basal irons each carry two nitrosyl ligands. The structure observed[29,30] by X-ray analysis in crystalline salts is shown by ^{15}N NMR to persist in solution.[25]

Solutions of $[Fe_4S_3(NO)_7]^-$ in water at neutral pH gave no EPR spectrum, but in alkaline solution a weak 3-line EPR spectrum was observed having $g = 2.027$ and $A(^{14}N) = 4.7$ G. The intensity of this spectrum increased as the pH was raised, as previously observed,[1] but at any pH, the intensity decreased with time. No paramagnetic dinitrosyliron complexes were observed in these solutions, despite the fact that on a preparative scale, the reaction of $[Fe_4S_3(NO)_7]^-$ with alkali yields[15,31] Roussin's red anion $[Fe_2S_2(NO)_4]^-$.

In DMF solution, the anion $[Fe_4S_3(NO)_7]^-$ yielded a weak but complex EPR spectrum indicative of the presence of at least three paramagnetic species: we have not achieved a satisfactory interpretation of this spectrum. However if RS^- was then added (R = Me, Et, *i*-Pr, *t*-Bu or $PhCH_2$), this complex spectrum was immediately replaced by a new and much more intense spectrum which indicated the presence of $[Fe(SR)_2(NO)_2]^-$, identified as previously (Table 3), together with, in each case, a mononitrosyl complex having $g = 2.021$ with $A(^{14}N)$ varying from 6.9 G when R = Me to 5.0 G when R = *t*-Bu, but showing no hyperfine coupling to the hydrogens of the R groups. The use of $[Fe_4S_3(^{15}NO)_7]^-$ confirmed these assignments. After two days the spectrum of the mononitrosyl complex had in each case disappeared, leaving only the spectrum of $[Fe(SR)_2(NO)_2]^-$. The reaction of $[Fe_4S_3(NO)_7]^-$ with SH^- yielded similarly a mixture of $[Fe(SH)_2(NO)_2]^-$ (Table 3) and the mononitrosyl complex. The EPR parameters for the mononitrosyl complex produced by reaction of $[Fe_4S_3(NO)_7]^-$ with RS^-, or with[1] aqueous alkali, are essentially identical with those of the mononitrosyl complex produced[1] by reaction of iron(II) salts with nitric oxide in the presence of sulphide. The observation of a variation of A(N) with R, and the assumption of four-coordinate iron, as in $[Fe(SR)_2(NO)_2]^-$ lead then to the tentative assignment of the constitution $[Fe(SR)_3NO]^{x-}$ to these species: if these species were formed from the apical iron of $[Fe_4S_3(NO)_7]^-$ without change of oxidation state, then $x = 1$. The lack of any resolved hyperfine coupling to hydrogen in the SR groups may be the result of a small A(H) value, or a consequence of fast ligand exchange. When R = Me the initial concentration ratio of $[Fe(SMe)_2(NO)_2]^-/[Fe(SMe)_3NO]^-$, measured immediately after reaction, was *ca* 1:2 at 290 K and *ca* 4:1 at 240 K.

We may therefore write, for the reaction of $[Fe_4S_3(NO)_7]^-$ with RS^- the following [eqn (4)]:

$$[Fe_4S_3(NO)_7]^- \xrightarrow{9RS^-} 3[Fe(SR)_2(NO)_2]^- + [Fe(SR)_3(NO)]^- + 3S^{2-}, \quad (4a)$$

[3Fe(−I)(basal), 1Fe(I)(apical)]

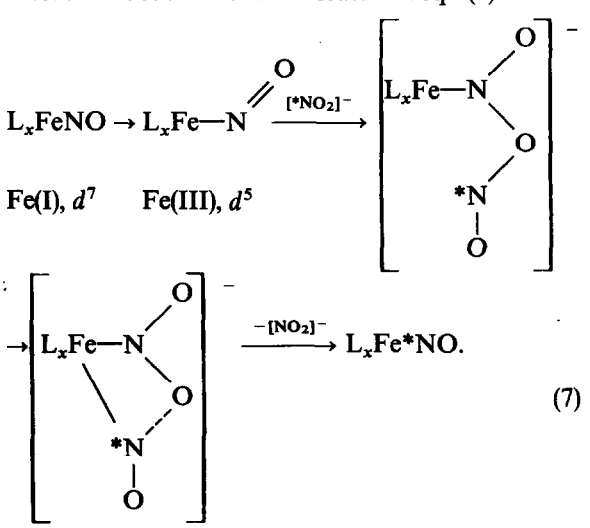
$$\rightarrow 3Fe(-I) + Fe(I), \quad (4b)$$

where the dinitrosyl complex is derived from the three basal irons of the 4-Fe anion, and the mononitrosyl complex from the apical iron. When R = alkyl, the complex $[Fe(SR)_2(NO)_2]^-$ appears to be the precursor of the ester $Fe_2(SR)_2(NO)_4$, as reaction of $[Fe_4S_3(NO)_7]^-$ with MeS^- on a preparative scale yielded $Fe_2(SMe)_2(NO)_4$ in 46% purified, isolated yield. On the other hand, reaction of PPN^+ $[Fe_4S_3(NO)_7]^-$ with NaSH yielded $(PPN^+)_2$ $[Fe_2S_2(NO)_4]^{2-}$, for the formation of which we propose the following [eqn (5)]:

$$[Fe_4S_3(NO)_7]^- \xrightarrow{SH^-} [Fe(SH)_2(NO)_2]^- \longrightarrow Fe_2(SH)_2(NO)_4 \xrightarrow[-H_2S]{+SH^-} [Fe_2S_2(NO)_4]^{2-}. \quad (5)$$

In general the anions $[Fe(SR)_2(NO)_2]^-$ lose one mole of RS^- and then dimerise to give $Fe_2(SR)_2(NO)_4$: if R = alkyl, this is the product which is isolated, but when R = H, deprotonation is effected by excess SH^-, followed by precipitation of the salt $(PPN^+)_2[Fe_2S_2(NO)_4]^{2-}$. In support of our suggestion that the initially formed $Fe_2(SH)_2(NO)_4$ is deprotonated in the presence of excess SH^-, we note that this compound has been isolated,[32] but that its formation by protonation of the anion $[Fe_2S_2(NO)_4]^{-2}$ required acids as strong as trifluoroacetic acid or HBF_4.

The complex $[Fe(SH)_2(NO)_2]^-$, produced by reaction of $[Fe_4S_3(NO)_7]^-$ with SH^-, was also formed when hydrogen sulphide was passed into a mixture of hydrated iron(III) chloride and sodium nitrite in DMF: no mononitrosyl was observed in this reaction, but a second dinitrosyl complex was formed, characterised by $g = 2.031$, $A(^{14}N) = 2.00$ G, and $A(^1H) = 1.90$ G, to which we assign the constitution $Fe(SH)(SH_2)(NO)_2$. When acetic acid was added to the foregoing mixture, the concentration of $Fe(SH)(SH_2)(NO)_2$ is increased at the expense of $[Fe(SH)_2(NO)_2]^-$: this was reversed upon addition of base. Substitution of dimethyl sulphide for hydrogen sulphide in the reaction of iron(III) with nitric oxide gave no detectable paramagnetic complexes having g near 2.0. Reaction of the sodium salt of $[Fe_4S_3(NO)_7]^-$, which crystallises from water as a monohydrate, with elemental sulphur in DMF, yielded again an EPR spectrum which indicated a mixture of $[Fe(SH)_2(NO)_2]^-$ and $Fe(SH)(SH_2)(NO)_2$, together with a trace only of the mononitrosyl $[Fe(SH)_3NO]^-$.



Reaction of $Na[Fe_4S_3(NO)_7]\cdot H_2O$ in DMF with sodium nitrite yielded a mixture of $[Fe(SH)_2(NO)_2]^-$ and $Fe(SH)(SH_2)(NO)_2$, but no mononitrosyl complexes were detected by EPR spectroscopy suggesting that all the Fe(NO) fragments have disproportionated to give $Fe(NO)_2$ species [eqn (6)]:

$$2[Fe(NO)]^{2+} \rightarrow [Fe(NO)_2]^+ + Fe^{3+}, \quad (6a)$$

$$2Fe(I) \rightarrow Fe(-I) + Fe(III). \quad (6b)$$

This conversion of $Fe(NO)^{2+}$ fragments to $Fe(NO)_2^+$ fragments appears to occur also during the ageing of the reaction products from $[Fe_4S_3(NO)_7]^-/RS^-$ reactions (see above). The reverse conversion, of $Fe(NO)_2$ to Fe(NO) fragments, occurs in the presence of the dimethyldithiocarbamate ligand, $[Me_2NCS_2]^-$. The EPR spectrum of a mixture of $[Fe_4S_3(NO)_7]^-$ and $[Me_2NCS_2]^-$ in DMF showed the presence of $Fe(NO)(S_2CNMe_2)_2$ as the sole paramagnetic complex detectable: similarly, this mononitrosyl complex was isolated from such a reaction mixture in 88% yield based upon total iron, i.e. not only the apical Fe(NO) group, but the basal $Fe(NO)_2$ groups in $[Fe_4S_3(NO)_7]^-$ were converted to $Fe(NO)(S_2CNMe_2)_2$.

The lability of the nitrosyl groups was further demonstrated by the use of ^{15}N labelling. When either $[Fe_4S_3(^{14}NO)_7]^-$ and $[^{15}NO_2]^-$, or $[Fe_4S_3(^{15}NO)_7]^-$ and $[^{14}NO_2]^-$ mixtures in DMF, containing similar ratios of $^{14}N/^{15}N$, were treated with $[Me_2NCS_2]^-$, essentially identical EPR spectra, each characteristic of a mixture of $Fe(^{14}NO)(S_2CNMe_2)_2$ and $Fe(^{15}NO)(S_2CNMe_2)_2$, were obtained from the two solutions. The spectra were identical when recorded immediately after mixing, and after one month, and represent an equilibrium distribution of ^{14}N and ^{15}N amongst the nitrosyl ligands. When $Fe(^{14}NO)(S_2CNMe_2)_2$ was treated in DMF solution with a large excess (> 10:1 mol/mol) of $[^{15}NO_2]^-$, its EPR spectrum was replaced, very rapidly and almost completely, by that of $Fe(^{15}NO)(S_2CNMe_2)_2$, indicating fast exchange of the nitrogen, presumably by a mechanism such as that indicated in eqn (7):

(7)

A further example of rapid conversion of a $Fe(NO)_2$ fragment to Fe(NO), combined with isotopic exchange at nitrogen, was observed when $Fe_2(SMe)_2(^{14}NO)_4$ was reacted, in DMF, with $[^{15}NO_2]^-$ and $[Me_2NCS_2]^-$: the resultant EPR spectrum showed the presence of both $Fe(^{14}NO)(S_2CNMe_2)$ and $Fe(^{15}NO)(S_2CNMe_2)_2$. Finally, an example of rapid isotopic exchange in a dinitrosyl species is provided by the reaction of $[Fe(SPr\text{-}i)_2(^{14}NO)_2]^-$ with $[^{15}NO_2]^-$: when the dinitrosyl anion, prepared from $Fe_2(SPr\text{-}i)_2(NO)_4$ in the usual way, was treated with $[^{15}NO_2]^-$ in DMF, its EPR spectrum was rapidly replaced by that of $[Fe(SPr\text{-}i)_2(^{15}NO)_2]^-$, again presumably by the mechanism outlined schematically in eqn (7).

Reactions of $Fe_4S_4(NO)_4$

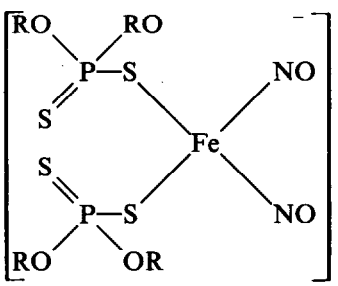
The tetranuclear complex $Fe_4S_4(NO)_4$ has a structure, in the solid state, based upon two intersecting Fe_4 and S_4 tetrahedra, yielding a distorted cubane skeleton, with a single, essentially linear, terminal nitrosyl ligand on each iron:[33,34] this structure has been shown by ^{15}N NMR spectroscopy[25] to persist in solution. In a variety of reactions of $Fe_4S_4(NO)_4$, the products are essentially the same as those derived from the anion $[Fe_4S_3(NO)_7]^-$, emphasizing again the great ease of migration of nitrosyl groups in these systems, and especially the interconversion of Fe(NO) and $Fe(NO)_2$ fragments.

In DMF solution, $Fe_4S_4(NO)_4$ alone yielded a very weak EPR spectrum which indicates the presence of at least three paramagnetic centres. Addition of RS^- caused replacement of this spectrum with a new spectrum, the principal features of which were those due to $[Fe(SR)_2(NO)_2]^-$ together with those which have been assigned earlier to $[Fe(SR)_3(NO)]^-$, and we postulate their formation according to eqn (8):

$$Fe_4S_4(NO)_4 \xrightarrow{12RS^-} 4[Fe(SR)_3NO]^- + 4S^{2-}, \quad (8a)$$

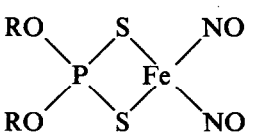
$$2[Fe(SR)_3NO]^- \rightleftharpoons [Fe(SR)_2(NO)_2]^- + [Fe(SR)_4]^-, \quad (8b)$$

$$2Fe(I) \rightleftharpoons Fe(-I) + Fe(III). \quad (8c)$$



As with the corresponding reactions of $[Fe_4S_3(NO)_7]^-$, the EPR spectrum of the mononitrosyl complex disappears as the solution is aged.

However, when R = H, the observed behaviour is rather different: the initial spectrum indicates the presence of the dinitrosyliron complex $[Fe(SH)_2(NO)_2]^-$ and the mononitrosyl complex $[Fe(SH)_3NO]^-$, having $g = 2.020$ and $A(^{14}N) = 5.0$ G. After one week the $[Fe(SH)_2(NO)_2]^-$ spectrum was still present but that of $[Fe(SH)_3NO]^-$ had been completely replaced by a new mononitrosyl spectrum having $g = 2.040$, $A(^{14}N) = 13.5$ G, but again showing no hyperfine coupling to hydrogen: after a further week, all evidence of the mononitrosyliron species had disappeared from the spectrum which indicated only a mixture of $[Fe(SH)_2(NO)_2]^-$ and $Fe(SH)(SH_2)(NO)_2$. Similar $A(^{14}N) = 13.5$ G mononitrosyliron species have been observed in the reactions of $Fe_4S_4(NO)_4$ with t-BuS^-, where it appeared concurrently with $[Fe(SR)_3NO]^-$; and in the reaction[8] of i-PrSH with $Fe_2I_2(NO)_4$ in mixed THF/Et_3N as solvent: in neither case was any hyperfine coupling to hydrogen resolved. Although we have not identified the 13.5 G species definitively, the alternative routes for its production suggest as a plausible possibility the constitution $[Fe(SR)_3NO]^{-3}$, i.e. a complex of iron(−I), possibly formed by an alternative disproportionation to that defined by eqns (8b) and (8c).



On a preparative scale, reaction of MeS^- with $Fe_4S_4(NO)_4$ in DMF yields the green solution characteristic of $[Fe(SMe)_2(NO)_2]^-$: on addition of a large volume of toluene the solution changed from green to red, and from the red solution the red ester $Fe_2(SMe)_2(NO)_4$ was isolated in 13% overall yield. This experiment demonstrated clearly the reversal of eqn (3) in a non-polar medium, and indicated that any precursor of $[Fe(SR)_2(NO)_2]^-$ can, in the appropriate solvent system, yield $Fe_2(SR)_2(NO)_4$.

Despite the great propensity of $Fe_4S_4(NO)_4$ to form dinitrosyliron complexes in its reactions with RS^-, upon reaction with $[Me_2NCS_2]^-$ in DMF solution, it forms the mononitrosyliron complex $Fe(NO)(S_2CNMe_2)_2$ in almost quantitative (94%) purified yield. Comparison of the reactions of $Fe_4S_4(NO)_4$ and $[Fe_4S_3(NO)_7]^-$ shows that the nature of the principal paramagnetic product (mononitrosyliron or dinitrosyliron complexes) is essentially independent of the structure of the starting complex, but that it depends rather upon the nature of the other ligands available in the system. In the presence of the non-chelating RS^- ligands, dinitrosyliron complexes are strongly favoured, and after an appropriate time interval are the sole detectable paramagnetic products: however if the chelating ligand $[Me_2NCS_2]^-$ is available in the system, the mononitrosyliron complex $Fe(NO)(S_2CNMe_2)_2$ is formed exclusively, and judging by the results of preparative scale experiments, it is formed virtually quantitatively (based upon total iron). However in the presence of a large excess of MeS^-, the complex $Fe(NO)(S_2CNMe_2)_2$ yielded $Fe_2(SMe)_2(NO)_4$ in 24% isolated yield.

In an attempt to explore further the relationship between the nature of the thio-ligands and the stoichiometry of the resulting complexes, we have also studied the reactions of the dialkyl dithiophosphate ion $[(i\text{-PrO})_2PS_2]^-$ with a range of iron nitrosyl substrates. Like $[Me_2NCS_2]^-$ this ligand could in principal act either as a monodentate or as a bidentate chelating ligand: the S···S bite in chelating $[(RO)_2PS_2]^-$ ligands is[35] *ca* 3.28 Å, whereas in $[Me_2NCS_2]^-$ it is[35,36] *ca* 2.97 Å. Reaction of $[(i\text{-PrO})_2PS_2]^-$ with $[Fe_4S_3(NO)_7]^-$ in DMF yielded an EPR spectrum which indicated the presence both of a dinitrosyl complex having $g = 2.033$, $A(^{14}N) = 2.3$ G and a mononitrosyl complex having $g = 2.030$, $A(^{14}N) = 2.2$ G: the spectral analysis was confirmed by use of $[Fe_4S_3(^{15}NO)_7]^-$. Essentially the same spectrum was obtained when $Fe_4S_4(NO)_4$, $Fe_2I_2(NO)_4$, $Fe_2(SMe)_2(NO)_4$ or $Fe_2(SPr\text{-}i)_2(NO)_4$ was employed in place of $[Fe_4S_3(NO)_7]^-$. In none of these systems was any hyperfine coupling to phosphorus (^{31}P, $I = \frac{1}{2}$) resolved. By analogy with $Fe(NO)(S_2CNMe_2)_2$ the mononitrosyl complex may tentatively be assigned the constitution $Fe(NO)[S_2P(OPr\text{-}i)_2]_2$ while in the dinitrosyl complex the dithiophosphate ligand might be monodentate (**III**) or bidentate (**IV**).

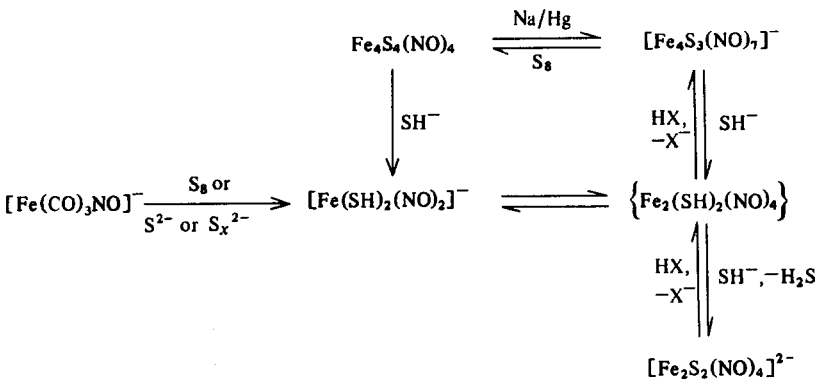
III

IV

All attempts to isolate and purify these complexes have been unsuccessful. The complexes derived from $[(RO)_2PS_2]^-$ are clearly less stable chemically than $Fe(NO)(S_2CNMe_2)_2$ derived from the related $[Me_2NCS_2]^-$. In confirmation of this we observed that excess $[(i\text{-PrO})_2PS_2]^-$ effected no displacement of $[Me_2NCS_2]^-$ from $Fe(NO)(S_2CNMe_2)_2$, whereas an excess of RS^- (R = Me, *i*-Pr, *t*-Bu) effected quantitative displacement of $[Me_2NCS_2]^-$, with conversion to the dinitrosyliron complexes $[Fe(SR)_2(NO)_2]^-$: when R = Me, the ester $Fe_2(SMe)_2(NO)_4$ was isolated.

We conclude that the larger $[(i\text{-PrO})_2PS_2]^-$ ligand is less suited to the stabilisation of dinitrosyliron complexes than the non-chelating RS^- ligands, and less suited also to the stabilisation of mononitrosyliron complexes than the chelating ligand $[Me_2NCS_2]^-$ of smaller bite.

Reactions of $[Fe(CO)_3NO]^-$ *salts*



The salt $(PPN)^+[Fe(CO)_3NO]^-$ gives no detectable EPR spectrum in DMF solution either after mixing at room temperature or heating to 350 K before the recording of the spectrum, although we note that several related but paramagnetic complexes are known containing only carbonyl and nitrosyl as ligands, thus: $Fe(NO)_3CO$,[37] $Co(CO)_3NO$,[38] $[Fe(NO)_2(CO)_2]^-$.[39]

Upon addition of elemental sulphur, the above solution readily gave an EPR spectrum characteristic of $[Fe(SH)_2(NO)_2]^-$. When the reaction of this salt with sulphur was carried out on a preparative scale, the presence of the anion $[Fe_4S_3(NO)_7]^-$ was detected by TLC and by IR spectroscopy immediately after mixing the reactants, and $(PPN)^+[Fe_4S_3(NO)_7]^-$ was subsequently isolated from the reaction mixture in 84% yield.

Prolonged reflux of $(PPN)^+[Fe_4S_3(NO)_7]^-$ with elemental sulphur in toluene solution gave no detectable formation of $Fe_4S_4(NO)_4$. This is in contrast both to the reaction of the mercurial $Hg[Fe(CO)_3NO]_2$ with elemental sulphur, under similar conditions, which yields $Fe_4S_4(NO)_4$ in good yield,[33] and to the similar reaction[23] of $Na[Fe_4S_3(NO)_7]$ with sulphur which is in fact our preferred method for the synthesis of $Fe_4S_4(NO)_4$. We note further that reaction of $Hg[Fe(CO)_3NO]$ with sodium polysulphide in methanol gave[23] $Na[Fe_4S_3(NO)_7]$ but no $Fe_4S_4(NO)_4$. Clearly the formation of $Fe_4S_4(NO)_4$ vs $[Fe_4S_3(NO)_7]^-$ from $[Fe(CO)_3NO]^-$ is subject to subtle factors involving the solvent and the solubilities of both the desired products and the by-products.

The observation of $[Fe(SH)_2(NO)_2]^-$ in the reaction mixture of $[Fe(CO)_3NO]^-$ and sulphur, which yields ultimately $[Fe_4S_3(NO)_7]^-$, suggests that just as the reaction of $[Fe_4S_3(NO)_7]^-$ with OH^- or SH^- proceeds via $[Fe(SH)_2(NO)_2]^-$ on its way to $[Fe_2S_2(NO)_4]^{-2}$, so the formation of $[Fe_4S_3(NO)_7]^-$ proceeds via the mononuclear complex $[Fe(SH)_2(NO)_2]^-$. This view is strengthened by the observation by EPR of this complex also in the reaction of $[Fe(CO)_3NO]^-$ with Na_2S, known[23] also to yield $[Fe_4S_3(NO)_7]^-$. Since preparative studies[15,31,32] have shown that $[Fe_2S_2(NO)_4]^-$ and $[Fe_4S_3(NO)_7]^-$ are interconvertible [eqn (9)]:

$$Fe_2S_2(NO)_4]^{2-} \underset{OH^-}{\overset{H^+}{\rightleftharpoons}} [Fe_4S_3(NO)_7]^- \qquad (9)$$

Scheme 2.

the fate of $[Fe(SH)_2(NO)_2]^-$ will in general depend primarily on the pH of the reaction medium. The relationships between all the complexes which are[15,23,31–33] interconnected via $[Fe(SH)_2(NO)_2]^-$ are summarised in Scheme 2.

Just as S^{2-}/SH^- reacts with $[Fe(CO)_3NO]^-$ to give $[Fe(SH)_2(NO)_2]^-$, so also *i*-PrS$^-$ and *t*-BuS$^-$ react to yield $[Fe(SPr\text{-}i)_2(NO)_2]^-$ and $[Fe(SBu\text{-}t)_2(NO)_2]^-$, observed by EPR spectroscopy, while MeS$^-$ yields $Fe_2(SMe)_2(NO)_4$, isolated in 78% yield. These reactions all provide further examples of the conversion of mononitrosyliron sources to dinitrosyliron products by the action of RS$^-$.

CONCLUSIONS

We have demonstrated, for the first time, the ready formation of paramagnetic, mononuclear complexes $[Fe(SR)_2(NO)_2]^-$ from a range of diamagnetic sources, not only from the dinuclear esters $Fe_2(SR)_2(NO)_4$ but also from the tetranuclear clusters $[Fe_4S_3(NO)_7]^-$ and $Fe_4S_4(NO)_4$, and from the mononuclear $[Fe(CO)_3NO]^-$. The characterisation of a range of these complexes $[Fe(SR)_2(NO)_2]^-$, allows definitive identification of the $g = 2.03$ complexes so often observed[9–11,14,21] but never adequately characterised, in biochemical studies related to chemical carcinogenesis. Of particular significance in this context are: (i) the wide range of iron–nitrosyl complexes which we have found to give rise to the $g = 2.03$ species, (ii) the ease of formation of paramagnetic complexes from diamagnetic precursors, by reaction with soft nucleophiles and/or polar solvents, and (iii) the great lability of nitrosyl ligands in these systems. Connected with the first two points is the ready formation, from a range of precursors, via $[Fe(SMe)_2(NO)_2]^-$ of the ester $Fe_2(SMe)_2(NO)_4$. This ester has been isolated[17] from natural vegetable sources in which it appears to be formed by reaction of exogenous nitrite with the natural iron–sulphur clusters of redox proteins, and it has been shown to be a mutagen and a tumour promotor.[18–20] The reaction of $Fe_2(SMe)_2(NO)_4$ as a nitrosating agent with secondary amines[20] has not been elucidated mechanistically, but it is likely to be connected with the lability of the nitrosyl ligands in these systems and possibly also with the ready formation of paramagnetic complexes. We turn our attention next to the mechanism of the nitrosation of amines by $Fe_2(SR)_2(NO)_4$ and related species, and to the formation of such iron–sulphur–nitrosyl complexes from naturally occurring iron–sulphur clusters.

EXPERIMENTAL

Literature methods were used for the preparation of $Fe_2I_2(NO)_4$,[40] $Fe_2(SR)_2(NO)_4$,[23] $Na[Fe_4S_3(NO)_7]$,[15,23] $Na[Fe_4Se_3(NO)_7]$,[23] $Fe_4S_4(NO)_4$,[23] $Fe(NO)(S_2CNMe_2)_2$[41] and $[N(PPh_3)_2][Fe(CO)_3NO]$:[7,42] ^{15}N labelled compounds were prepared by modification of the above procedures, using 99% $Na[^{15}NO_2]$ (MSD Isotopes Inc.).

All manipulations were carried out under an atmosphere of dry nitrogen: all organic solvents were dried and purged with dry nitrogen before use, and all manipulations of solutions were made under dry nitrogen.

EPR spectra were measured, usually at 240 K, in 1 mm quartz capillaries using a Bruker ER200D Spectrometer: di-*t*-butyl nitroxide was used as the standard for the measurement of line positions. NMR spectra were measured at 308 K using a Bruker WP-80 Spectrometer.

Exchange reactions

Samples (0.10 g) of $Fe_2(SEt)_2(NO)_4$ were dissolved in 50 cm^3 portions of DMF, THF, EtOH, or toluene and 1 cm^3 of *i*-PrSH was then added, and the mixtures stirred under nitrogen, at room temperature, during 72 h. The solvent and volatile products

were then removed on the vacuum system, and the residual solid was examined by ^1H NMR spectroscopy in $CDCl_3$ solution.

Samples (0.10 g) of $Fe_2(SR)_2(NO)_4$ were dissolved in 50 cm^3 portions of THF and a 1 cm^3 portion of R'SH was added. The mixtures were stirred under nitrogen, at room temperature, during 72 h, and then worked up and examined as before. The exchange reaction with H_2S was carried out in a sealed 5 dm^{-3} vessel at 1 atm pressure.

Reactions of $Na[Fe_4S_3(NO)_7]$

With CH_3SNa. To 0.10 g of $Na[Fe_4S_3(NO)_7]$ in DMF (30 cm^3) was added 0.10 g of CH_3SNa. The mixture was stirred under nitrogen during 15 min and then diluted with 50 cm^3 of CH_2Cl_2. The solution was washed with water (4×250 cm^3) and then filtered and dried over $MgSO_4$. The solution was reduced to small volume, and methanol was added to precipitate the product, $Fe_2(SMe)_2(NO)_4$, isolated in 46% purified yield, calculated on the basis of $Fe(NO)_2$ fragments.

With Me_2NCS_2Na. To a solution of 0.50 g $Na[Fe_4S_3(NO)_7]$ in 400 cm^3 water was added 2 g of NaOH and 2 g of Me_2NCS_2Na. The mixture was stirred for 10 min, and then quenched by addition of CH_2Cl_2 (100 cm^3). The organic layer was washed, dried, and then evaporated to dryness. Repeated extraction of the aqueous layer with further CH_2Cl_2, followed by washing and drying yielded further portions of solid material. The combined solids were recrystallised from CH_2Cl_2/CH_3OH to yield $Fe(NO)(S_2CNMe_2)_2$ (1.03 g: 88% yield based upon total iron, 354% based upon apical iron).

Preparation of $(PPN)_2[Fe_2S_2(NO)_4]$

To a solution of 0.10 g of $Na[Fe_4S_3(NO)_7]$ in 100 cm^3 water was added 0.5 g NaOH: the mixture was refluxed under nitrogen for 5 min before addition of 2 g of (PPN)Cl dissolved in the minimum volume of water. The whole mixture was cooled and extracted with $CHCl_3$ (1×100 cm^3). The extract was filtered, washed with water (2×100 cm^3), and dried over $MgSO_4$. The volume was reduced somewhat and the product precipitated by addition of cold methanol. Yield 0.031 g (6.7% based upon total iron, 7.5% based upon NO).

Reaction of $Fe_4S_4(NO)_4$ *with* Me_2NCS_2Na

Me_2NCS_2Na (0.27 g) was added to a solution of $Fe_4S_4(NO)_4$ (0.10 g) in DMF (20 cm^3). The mixture was stirred at room temperature, under nitrogen, during 45 min, and then diluted with 50 cm^3 of CH_2Cl_2. The resulting solution was washed with water (4×500 cm^3), filtered, and dried over $MgSO_4$. The solution was reduced to small volume, and methanol was added to precpitate the product, $Fe(NO)(S_2CNMe_2)_2$, isolated in 94% purified yield.

Reaction of $Fe_4S_4(NO)_4$ *with* MeSNa

MeSNa (0.70 g; 10 mmol) was added to a stirred solution of $Fe_4S_4(NO)_4$ (0.47 g; 1.0 mmol) in DMF (20 cm^3). The mixture was refluxed under nitrogen during 2 h, and then cooled. Toluene (100 cm^3) was added dropwise to the *green* solution, via a pressure-equalised dropping funnel, and the resulting *red* solution was filtered through a 1 cm depth bed of silica, and evaporated to dryness. The residue was dissolved in CH_2Cl_2 (30 cm^3), and washed with water (10×200 cm^4): the organic layer was dried over $MgSO_4$. The solution was reduced to small volume, and the product precipitated by addition of ice cold methanol. The product, $Fe_2(SMe)_2(NO)_4$ (0.040 g; 0.13 mmol; 13%) was isolated by filtration and dried *in vacuo*.

Reactions of $(i\text{-PrO})_2PS_2Na$

With $Na[Fe_4S_3(NO)_7]$. To a solution of $Na[Fe_4S_3(NO)_7]$ (0.30 g) in DMF (50 cm^3) under nitrogen was added 1.0 g of $(i\text{-PrO})_2PS_2Na$. The mixture was stirred for 10 h, and then reduced to a solid. This solid was dissolved in CH_2Cl_2 (50 cm^3) and the solution was washed with water, and dried over $MgSO_4$. Removal of the solvent gave a very labile black solid, having ν(NO)($CHCl_3$ solution), 1800 cm^{-1} (sharp and strong absorption). All attempts to purify this material, under nitrogen, proved unsuccessful.

With $Fe_2I_2(NO)_4$. Substitution of $Fe_2I_2(NO)_4$ for $Na[Fe_4S_3(NO)_7]$ yielded the same material as before: no successful purification was achieved.

In $CHCl_3$, very dilute solutions of this black solid gave EPR spectra indicative of the presence of two species, characterised by $g = 2.033$, $A(^{14}N) = 2.3$ G ($2^{14}N$) or $A(^{15}N) = 3.2$ G ($2^{15}N$) and $g = 2.030$, $A(^{14}N) = 2.2$ G ($1^{14}N$) or $A(^{15}N) = 3.1$ G ($1^{15}N$) respectively. Identical spectra were obtained from the reactions of $(i\text{-PrO})_2PS_2K$ with $Fe_4S_4(NO)_4$, $Fe_2I_2(NO)_4$, $Na[Fe_4S_3(NO)_7]$, $Fe_2(SMe)_2(NO)_4$ and $Fe_2(SPr\text{-}i)_2(NO)_4$.

Reaction of $Fe(NO)(S_2CNMe_2)_2$ *with* Na_2S

0.30 g of $Fe(NO)(S_2CNMe_2)_2$ was dissolved in 150 cm^3 of 1:1 (v/v) DMF/H_2O. An approximately 10-fold molar excess of Na_2S was added, and the mixture was refluxed under nitrogen for 60 h. The

solution was cooled, diluted with 850 cm^3 water, filtered, and washed with CH_2Cl_2 (8 × 100 cm^3). The remaining aqueous layer was evaporated to dryness, and the residue dissolved in 100 cm^3 ether: the ether layer was washed with water (4 × 250 cm^3), and then dried over $MgSO_4$. Removal of the solvent yielded 0.015 g of $Na[Fe_4S_3(NO)_7]$ (11% yield based upon Fe, 18% based upon nitrosyl groups).

Reaction of (PPN)[$Fe(CO)_3NO$] *with* MeSNa

To a stirred solution of (PPN)[$Fe(CO)_3NO$] (1.00 g; 1.40 mmol) in DMF (20 cm^3) was added a large excess (2.0 g; 28.6 mmol of MeSNa). The mixture was refluxed under nitrogen for 2 h, cooled, and filtered through silica. After evaporation to dryness, the residue was dissolved in CH_2Cl_2 (30 cm^3) and the resulting solution was washed with water (10 × 200 cm^3). The organic solution was dried over $MgSO_4$ and evaporated to small volume. This solution was applied to a 2.5 cm × 1.2 m silica chromatography column: a red product, $Fe_2(SMe)_2(NO)_4$ was eluted with methanol/CH_2Cl_2 [20:1 (v/v)], and isolated in 78% purified yield.

Reaction of (PPN)[$Fe(CO)_3NO$] *with sulphur*

(PPN)[$Fe(CO)_3NO$] (1.63 g) and elemental sulphur (1.5 g) were dissolved in toluene (200 cm^3). The mixture immediately turned black, and examination by IR spectroscopy and by TLC of an aliquot removed from the fresh mixture revealed the presence of $[Fe_4S_3(NO)_7]^-$. The mixture was then refluxed under nitrogen for 20 h, and then evaporated to dryness. The residue was repeatedly extracted with CH_2Cl_2, and the organic solution reduced to small volume. The product was precipitated by addition of methanol: TLC and UV and IR spectroscopy showed the product to consist solely of (PPN)[$Fe_4S_3(NO)_7$] (yield: 84% based upon NO). Prolonged reflux (1 week) of (PPN)[$Fe_4S_3(NO)_7$] with an excess of sulphur in toluene, caused no detectable conversion to $Fe_4S_4(NO)_4$.

Reaction of $Fe(NO)(S_2CNMe_2)_2$ *with* MeSNa

A solution of $Fe(NO)(S_2CNMe_2)_2$ (1.00 g; 3.1 mmol) and MeSNa (2.0 g; 28.6 mmol) in DMF (20 cm^3) was refluxed during 2 h under N_2. The resulting mixture was cooled and worked up exactly as for the reaction of (PPN)[$Fe/CO)_3NO$] and MeSNa to yield $Fe_2(SMe)_2(NO)_4$ in 24% isolated yield after chromatography.

Acknowledgements—We thank the Cancer Research Campaign for financial support. We thank Professor Wang Guang-hui (Academia Sinica, Beijing, China) for valuable discussions, and in particular for his initial observation that the stability of $Fe_2(SMe)_2(NO)_4$ in solution appeared to be enhanced by the presence of added thiols.

CYCLIC VOLTAMMETRIC STUDIES OF COPPER(II) AMINO ACID COMPLEXES: ELECTROCHEMICAL EVIDENCE FOR THE GENERATION OF COPPER(I) COMPLEX AS AN INTERMEDIATE

GEORGE THOMAS and P. S. ZACHARIAS*
School of Chemistry, University of Hyderabad, Hyderabad 500 134, India

(*Received* 23 *July* 1984; *accepted* 13 *September* 1984)

Abstract—The reduction of the title complexes is studied by cyclic voltammetry in aqueous media. It proceeds through a one-electron process generating the corresponding copper(I) amino acid complexes. The reduced copper(I) species undergo chemical reactions generating Cu(0) at the mercury electrode. The unreacted fraction of the copper(I) species is re-oxidised to the copper(II) complexes. The Cu(0) generated undergo a two-electron oxidation to Cu^{2+} at less cathodic potentials which get reduced to Cu(0) subsequently. pH-dependence of these complexes is also investigated.

The involvement of copper in the redox processes of many biological systems is well established.[1–4] Many of the low-molecular-weight copper(II) chelates of amino acids and peptides are reported to be able to catalyse superoxide dismutation.[5–8] It is reported that type 2 copper(II) undergoes a one-electron reduction[9] at a potential approximately 0.4 V vs NHE. Its optical spectral characteristics are similar to those of the copper(II) amino acid complexes. Several workers have studied the copper(II) amino acid complexes by spectral, analytical, structural etc. methods.[10–20] But there are no detailed studies of the redox behaviour of these low-molecular-weight copper(II) complexes. The cyclic voltammetric behaviour of dipeptide and ternary copper(II) complexes have been investigated.[21] In this context it seemed appropriate to study the redox behaviour of copper(II) amino acid complexes in aqueous media by cyclic voltammetric technique. Our results are presented and discussed in the following sections.

EXPERIMENTAL

Glycine, L-ornithine, L-lysine, L-asparagine and bathocuproin reagents were from Sigma Chemicals. Other amino acids were purchased from BDH, India. Basic copper carbonate was obtained from S.D. Chemicals and was used after estimating the copper content gravimetrically.[22] Analar grade sodium perchlorate was used throughout the work. Water, as well as mercury were used after distilling twice. The copper(II) amino acid complexes were prepared by the following general method. Stoichiometric amounts of the amino acid was added with stirring to a suspension of basic copper carbonate in water for about 1–2 h at about 50°C. The resulting blue solution was filtered to remove unreacted basic copper carbonate and the filtrate on concentration yielded blue crystals. These were filtered, washed several times with water and dried in vacuum at 100–110°C.

Copper(I) bathocuproin complex was prepared by adding a solution of bathocuproin reagent in amyl alcohol, to an aqueous solution of copper(I) ions [obtained by reducing $Cu(NO_3)_2$ with sodium metabisulphite]. The resulting yellow organic layer was separated, washed several times with water to remove bisulphite ions. This solution was used to record CV after adding TEAP (tetraethyl ammonium perchlorate) in acetone to it. The copper(I) ions generated during the electrode processes were trapped by using bathocuproin reagent as described below. A few cm^3 of the bathocuproin reagent solution in amyl alcohol was added to the aqueous solution of the copper(II) amino acid complex, taken in the electrolytic cell and stirred well to mix the two immiscible layers intimately. This mixture was then subjected to controlled potential electrolysis at −0.5 V over mercury pool electrode with stirring. After the completion of the electrolysis the deep yellow

* Author to whom correspondence should be addressed.

organic layer was separated from the aqueous layer. Optical spectra and cyclic voltammograms (CV) of this yellow layer were recorded.

Cyclic voltammetric experiments were carried out in a three-electrode cell with a metrohm E 410 hanging mercury drop electrode (HMDE) as working electrode and a platinum-wire as auxiliary electrode. All the potentials are referred to saturated calomel electrode (SCE) and are uncorrected for liquid-junction potentials. CV were recorded using PAR 175 universal programmer, PAR 174A polarographic analyser, and a PAR RE 0074 X-Y recorder. Controlled potential coulometry was carried out with PAR 173 potentiostat/galvanostat and a PAR 179 digital coulometer over mercury pool electrode. Electronic spectra were recorded on a Shimadzu 2000 S spectrometer and ESR on a JEOL-FE 3X spectrometer.

RESULTS AND DISCUSSION

The copper(II) amino acid complexes studied here are of general composition $[Cu(II)(AA)_2(H_2O)_n]$, where AA represents amino acid anion and n is one or two depending on the complex. The various copper(II) complexes prepared from the amino acids are listed in Table 1. The C, H, N and copper contents of these complexes agreed well with the above composition. The IR and visible spectra were similar to the reported[23,24] spectra of these complexes. Thus the identity of the starting complexes were established before proceeding with the investigations. Cyclic voltammograms were recorded in the potential range +0.1 to −0.6 V in aqueous solution of the complexes [10^{-3} mol dm^{-3}] at 298 K under nitrogen atmosphere with $NaClO_4$ (0.1 mol dm^{-3}) as supporting electrolyte at the dissolution pH ~ 7.5 (pH is not adjusted after dissolving the samples in water). All complexes show similar cyclic voltammetric behaviour and representative voltammograms are shown in Fig. 1. The relevant CV data for all complexes are collected in Table 1. There are no peaks in the positive potential range for any of the copper(II) complexes. None of the amino acids, in the absence of metal ions, show any peak in the potential range +1.0 to −1.0 V.

* A linear dependence on concentration of peak potentials of C and D is observed below 1 mM. The origin of this is not clear.

† Peak observed only during second and subsequent scans.

‡ Broad peak, difficult to measure precisely.

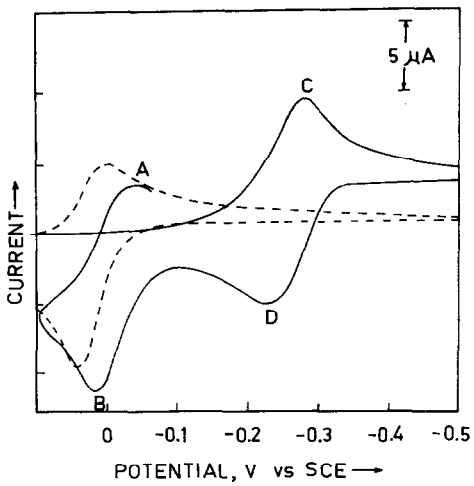

Fig. 1. (——) CV of $Cu(Gly)_2$ in 0.1 mol dm^{-3} $NaClO_4$ at HMDE of area 0.02 cm^2 : (– – –) CV of $Cu(ClO_4)_2$ in 0.1 mol dm^{-3} $NaClO_4$ at HMDE of area 0.02 cm^2.

The following observations are pertinent for discussing the cyclic voltammetric results. (i) During the first cathodic sweep, only one reduction peak C at ~ -0.26 V is observed. (ii) On the reverse scan well-defined anodic peak D at ~ -0.2 V and another peak B at $\sim +0.04$ V appear. (iii) A new cathodic peak A at ~ -0.05 V is apparent from the second scan onwards. (iv) An increase in the scan rate decreases the peak heights of A and B. (v) Holding the potential at a point well past the peak C for a few minutes and on scanning back, peaks A and B increase in height while peaks C and D remain unaffected. Similar effects are observed on multi-scans in the full potential range. (vi) If the potential scan is reversed after the peak A during the second and subsequent scans the heights of A and B decrease considerably. (vii) No CV response is observed if the potential sweep is reversed in the first scan itself before the appearance of peak C.

From an analysis of these observations the electrode processes can be inferred as follows: Since the starting complexes have the composition $Cu(II)(AA)_2$ peak C can originate from a one-electron reduction [$Cu(II) \xrightarrow{1e} Cu(I)$] or a two-electron reduction [$Cu(II) \xrightarrow{2e} Cu(0)$] of the $Cu(II)(AA)_2$ complexes. If the peak C is due to a one-electron reduction process, the generated Cu(I) species can undergo reoxidation to the starting complex giving the peak D. In that case the peak separation between C and D should be $\sim$ 60 mV and it is found to be in the range 60–80 mV (Table 1). These values also suggest that the electron-transfer is nearly reversible. Observations (iii), (v) and (vi) mentioned earlier clearly show that the first electron-transfer is a prerequisite for the observation of peaks B and A. On comparing these peaks with the redox peaks of free copper(II) ions under identical experimental conditions, it can be seen that A–B couple corresponds to the redox peaks of free copper(II) ions. For free copper(II) ions it has been established that the redox couple originates from a reversible two-electron transfer mechanism, $Cu(II) \overset{2e}{\rightleftharpoons} Cu(0)$. This evidence suggests that anodic peak B results from the two-electron oxidation of Cu(0) generated in solution to Cu(II) and the cathodic peak A from the two-electron reduction of the resulting copper(II) ions. Then the question is how is the Cu(0) generated at the electrode? The possibility is that Cu(0) can be the result of the decomposition or disproportionation of a fraction of the Cu(I) species which has not been reoxidised to Cu(II) complex. Thus the overall electrode processes can be represented by eqns (1)–(3):

$$Cu(II)(AA)_2 \overset{1e}{\rightleftharpoons} [Cu(I)(AA)_2], \quad (1)$$

$$[Cu(I)(AA)_2] \xrightarrow[\text{reactions}]{\text{Chemical}} Cu(Hg) + 2AA, \quad (2)$$

$$Cu(Hg) \overset{2e}{\rightleftharpoons} Cu^{2+}(aq). \quad (3)$$

Equations (1)–(3) represent an ECE mechanism.[25]

Equation (1), which generates the copper(I) amino acid complexes, represents the most important step in the overall process. The E_p, $C-E_p$, D values in Table 1 show a one-electron reversible character of this couple. Copper(I) complexes are stable only in tetrahedral or pseudo-tetrahedral geometries. The copper(I) species generated in these experiments can be expected to have a geometry distorted towards tetrahedral since the starting complexes, $Cu(II)(AA)_2$, possess a tetragonally distorted octahedral geometry.[12–16] The extent of stability of the copper(I) species depends on the degree of tetragonality. The transient existence of copper(I) complexes demonstrated by the CV pattern (peak D) shows that it has a life-time long enough to be detected by cyclic voltammetry. Further proof for the generation of copper(I) amino acid complexes as an intermediate was obtained by trapping copper(I) ion using bathocuproin (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline), a highly specific reagent for cuprous ions in forming stable complexes. The electrochemically generated copper(I) ions were complexed with bathocuproin reagent by adding a few millilitres of the reagent solution in amyl alcohol to an aqueous solution of the copper(II) complex and reducing it electrolytically. The electrochemically generated copper(I) bathocuproin complex is identical with the chemically generated bathocuproin complex (Cu(I) ions generated by chemical reduction of Cu(II) to Cu(I) and subsequently

complexes by bathocuproin reagent) in their spectral and cyclic voltammetric behaviour. Both have a characteristic high intensity band at 479 nm (ε = 14,150 dm^3 mol^{-1} cm^{-1})[21,26,27] and show an irreversibile reduction peak at −0.595 V in amyl alchol/TEAP medium at HMDE. Thus these results give additional evidence for the presence of copper(I) species in the electrode process and hence the first reduction of Cu(II)(AA)$_2$ does proceed by a one-electron process as depicted in eqn (1).

Equation (2) may be the result of a few reactions taking place in steps as in eqns (4) and (5):

$$Cu(I)(AA)_2 \rightleftarrows Cu^+ + 2AA, \quad (4)$$

$$2Cu^+ \rightleftarrows Cu^0 + Cu^{2+}. \quad (5)$$

Under the cathodic potential prevailing in the experimental conditions the predominant species in eqn (5) will be Cu(0) which is continuously removed as Cu(Hg) at the electrode.[28] Cu(0) thus generated can get oxidised by a two-electron process to Cu(II) giving the anodic peak B. Subsequent reduction of Cu(II) ions gives rise to the cathodic peak A and the two processes can be represented by eqn (3). CV of free copper(II) ions in aqueous media under identical experimental conditions give peaks similar to A and B at similar potentials, and its CV profile is shown in Fig. 1 for comparison. It should be noted at this point that peak A appears only from second scan onwards. This is so because there are no free copper(II) ions in solution to start with and they have to be electrochemically generated from Cu(0). This happens during the electrode processes shown in eqns (1)–(3). It is observed that $i_p/V^{1/2}$ for the peaks B and A decrease as the scan rate increases (Fig. 2). This shows that at high scan rates the chemical reaction represented in eqn (2) decreases due to lack of time which in turn decrease the $i_p/v^{1/2}$ value. As noted earlier peaks C and D do not get affected by holding the potential at a point (−0.5 V) well past the peak C, whereas the peaks B and A increase considerably. Such a situation can occur only when a steady concentration of the Cu(I)(AA)$_2$ species is maintained. This means that the process in eqn (1) is faster than that in eqn (2). On the other hand if the processes in eqn (2) are faster than that of eqn (1), the peak D would have decreased in height.[29]

Protonation

It is shown that copper(II) amino acid complexes with different modes of coordination exist in aqueous solution at various pH values. This has been studied by different methods over the years.[17–20] However no systematic study of the cyclic voltammetric behaviour of the copper(II) amino acid complexes in various pH conditions is reported. Here the CV response of these complexes at various pH values is studied and compared with the results discussed in the previous section.

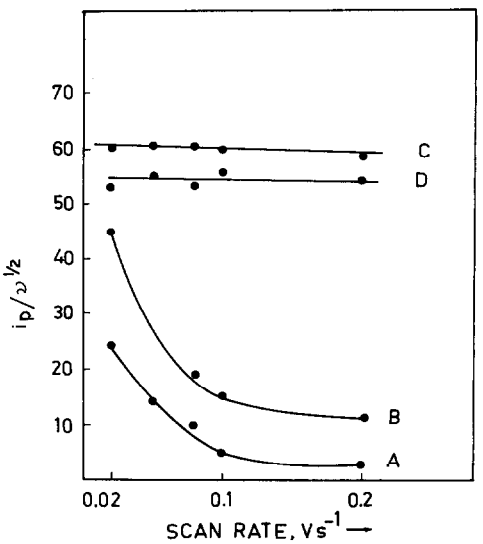

Fig. 2. Comparison of the effect of scan rate on the current function of various peaks of Cu(L-Ser)$_2$ under similar experimental conditions to Fig. 1. A, B, C and D correspond to the peaks in Fig. 1.

A gradual decrease in the pH of the aqueous solution was achieved by the step-wise addition of small amounts (μl) of a strong protonic acid, $HClO_4$, and cyclic voltammograms were recorded at different pH values. All amino acid complexes behave in a similar fashion. Representative cyclic voltammograms at different pH values for one of the complexes, are shown in Fig. 3 and the relevant CV

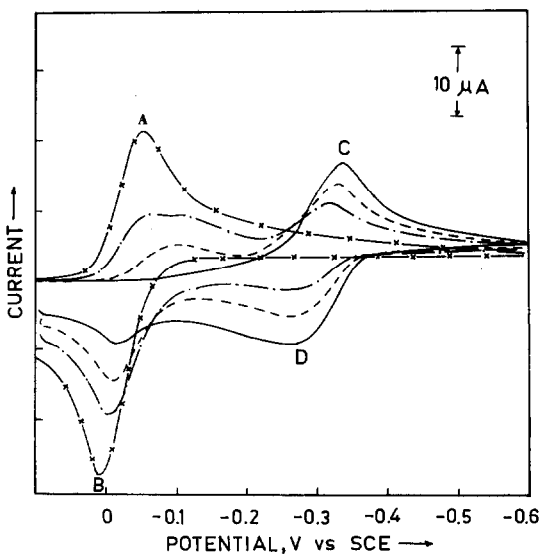

Fig. 3. CV of Cu(L-Pro)$_2$ at various pH values (——), pH = 7.48; (– – –), pH = 6.13; (–·–·–), pH = 5.14; (–×–×–), pH = 3.83.

† Peak absent.

data for one compound are collected in Table 2. The major changes of the CV profile occurring on protonation are the following. (i) Heights of C and D decrease gradually and they finally disappear at low pH values. (ii) Peak A begins to appear in the first scan itself. (iii) Peaks A and B increase in height accompanied by a decrease in "peak-broadening" of A along with an anodic shift.

It is known that as the pH is decreased the $Cu(II)(AA)_2$ gets protonated and gives rise to Cu(II)(AA) which on further protonation produces free Cu(II) ions.[17,18,20] Then, as the pH decreases, the Cu(II)(AA) and subsequently the free Cu(II) ions become the major species. The gradual decrease in the heights of peaks C and D with the decrease of pH imply the depletion of $Cu(II)(AA)_2$ because of the protonation and thereby affecting the process in equation (1). The new species, Cu(II)(AA) can undergo a one-electron reduction at a potential less cathodic to peak C. It appears that the "peak-broadening" observed at the peak A is due to the result of the overlap of the reduction peak of Cu(II)(AA) and that of free Cu(II) ions. If so, the "peak-broadening" should disappear with the further decrease of pH as it results in the complete conversion of Cu(II)(AA) to free Cu(II) ions. The generation of more and more free Cu(II) ions with the decrease of pH can shift the peak A anodically. The disappearance of peaks C and D at low pH values (< 4.0), indicate the complete conversion of the starting complex. The CV recorded at various pH conditions for $Cu(II)(L\text{-}Pro)_2$ shown in Fig. 3 show these features clearly.

The peaks A and B have been shown to originate from the process, $Cu(II) \overset{2e}{\rightleftharpoons} Cu(Hg)$. As the concentration of free Cu(II) ions depends on the pH conditions, a gradual increase of the peak heights of A and B with the decrease of pH is expected. Finally at low pH values they should be the only peaks in the CV. These changes are clearly observed. The entire process of protonation can be reversed on raising the pH by adding small amounts of NaOH solution. This cycle can be repeated several times showing the reversibility of the protonation processes. These results from the protonation studies support the electrode mechanism discussed earlier.

Controlled potential coulometry

To distinguish between one or two-electron reduction of the starting complex, $Cu(II)(AA)_2$, controlled potential coulometry (CPC) at a potential −0.6 V, well past the peak C, over mercury pool electrode was carried out. The CPC yielded coulombs which corresponded to $n = 2$. This shows that under the continued influence of the cathodic potential only the overall electron-transfer process, $Cu(II) \overset{2e}{\rightleftharpoons} Cu(0)$, involving two electrons is coulometrically observed. The absence of Cu(II) ions in the electrolysed solution is confirmed by the disappearance of copper ESR signals and the absorption band.

REDOX PROPERTIES OF BIS(1,10-PHENANTHROLINE)-(PYRIDINE)RUTHENIUM(II) COMPLEXES

GEOFFREY A. LAWRANCE
Department of Chemistry, The University of Newcastle, New South Wales 2308, Australia

(*Received* 13 *August* 1984; *accepted* 13 *September* 1984)

Abstract—The redox properties of a series of $[Ru(phen)_2(py)X]^{n+}$ cations (X = pyridine, NH_3, Cl, Br, I, CN, SCN, N_3 and NO_2) have been investigated in acetonitrile. Two reversible reduction steps are seen at −1.35 and −1.6 V vs Ag/AgCl; the invariance of these processes with X-group is indicative of electron addition to molecular orbitals mainly of phenanthroline ligand π^* origin. Irreversible multi-electron reductions follow below −2.20 V. The Ru(II)/Ru(III) couple is seen as a reversible wave near +0.8 V vs the normal hydrogen electrode, from calibration with ferrocene, except in the cases of the NO_2 and SCN complexes, where rapid reactions involving these ligands occur.

Ruthenium complexes of the π-conjugated ligands 2,2′-bipyridyl (bpy) and 1,10-phenanthroline (phen) have been extensively studied in recent years,[1] partly as a consequence of their photogalvanic and luminescence properties.[2–4] Mixed ligand complexes of the type $[Ru(bpy)_2L]^{n+}$ and $[Ru(phen)_2L]^{n+}$ have been studied, where L represents a third bidentate ligand, and the redox properties of such systems have been reported.[5–7] In such cases, interest has centred on the effect of the L ligand on the spectroscopic and electrochemical properties of the complexes.

The system $[Ru(phen)_2(py)X]^{n+}$ (py = pyridine), with two unidentate ligands coordinated in addition to two π-conjugated chelates, has been known for some time.[8,9] However, the redox properties of a series of these complexes have not been studied, and it was of interest to observe the variation in these properties with the sixth ligand X.

EXPERIMENTAL

The complexes $[Ru(phen)_2(py)X](ClO_4)_n$, and the method of synthesis, have been described previously.[9] Acetonitrile for electrochemical measurements was dried and distilled by standard methods. Tetra-*n*-butylammonium tetrafluoroborate employed as electrolyte (0.1 M) was recrystallized from acetonitrile.

All electrochemical measurements were made using a conventional three-electrode configuration with a Ag/AgCl(LiCl/acetone) reference electrode and a platinum auxiliary electrode. A conventional controlled-drop dropping mercury electrode (DME), stationary platinum billet or stationary gold billet electrode was employed as working electrode, with solvent-saturated argon as purge gas. Electrochemical controllers were either a BAS Model CV27 or PAR Model 170. Electrochemical measurements at ambient temperature quoted versus the reference electrode are uncorrected for junction potentials, except ferrocene was employed as an internal standard (E^0 + 0.400 V vs the normal hydrogen electrode)[10] for oxidations at stationary electrodes. Half-wave potentials ($E_{1/2}$) for the Ru(II)/Ru(III) couples and electrochemical reversibility was determined by cyclic voltammetry. Half-wave potentials for reductions were determined from d.c. polarograms via the Heyrovsky–Ilkovic equation, or from maxima in low-frequency a.c. polarograms. Complex concentrations were typically 1 mM.

UV–visible spectra were recorded using Varian 635 or Hitachi 220A spectrophotometers at ambient temperature in acetonitrile.

RESULTS AND DISCUSSION

The ruthenium(II) complexes $[Ru(phen)_2(py)X]^{n+}$ exhibit characteristic intense absorption bands in the visible and ultraviolet regions (Table 1). The low-energy metal-to-ligand charge-transfer (MLCT) bands in the visible region exhibit some variation with X-group, but the intense $\pi \rightarrow \pi^*$ phenanthroline intraligand transfers in the ultraviolet at 265 nm are invariant within ex-

[a] 0.1 M $(Bu_4N)(BF_4)$ electrolyte; [Ru] 10^{-3} M; ambient temperature; $E_{1/2}$ in V vs Ag/AgCl.
[b] $[Ru(phen)_3]^{2+}$ exhibits waves at −1.20, −1.34, −1.65 and −2.18 V (reduction), and at +1.4 V (oxidation).
[c] Irreversible reduction, associated in each case by a further irreverisble wave at ~ −2.4 V.
[d] Value in parentheses is E^0 vs NHE, calculated from addition of ferrocene (E^0 +0.400 V) as internal standard.
[e] Wave irreversible or complicated by rapid following chemical reaction.

perimental error (±2 nm). The decrease in intensity of the band from 12×10^4 M^{-1} cm^{-1} in $[Ru(phen)_3]^{2+}$ to ~ 8×10^4 M^{-1} cm^{-1} in the $[Ru(phen)_2(py)X]^{n+}$ complexes supports the contention that the absorption arises from a transition of phenanthroline.

The ultraviolet and visible spectra of a large number of $[Ru(bpy)_2L_2]^{2+}$ complexes (L an unsaturated unidentate ligand) have been reported.[5] In these analogues to the present system, the main $t_{2g}(Ru) \rightarrow \pi^*$(ligand) maxima occurs near 450 nm, and distinct shoulders are sometimes observed; a second band of lower intensity is usually reported below 390 nm. Spectra for series of $[Ru(bpy)_2(LL)]^{2+}$ and $[Ru(phen)_2(LL)]^{2+}$ are very similar,[6] and this is a general phenomenon. For $[Ru(bpy)_2L_2]^{2+}$ complexes, no separate $d[Ru(II)] \rightarrow$ L band was detected,[5] although a later study of similar complexes assigned high energy shoulders on the MLCT band as a $d[Ru(II)] \rightarrow \pi^*$(pyridine) transition.[11] The observation of a high energy shoulder in the $[Ru(phen)_2(py)X]^{n+}$ complexes may then be associated with such a $d[Ru(II)] \rightarrow \pi^*$ (pyridine) transition, although the assignment is tenuous.

The electrochemistry of $[Ru(phen)_2(py)X]^{n+}$ in acetonitrile shows a Ru(II)/Ru(III) couple near +0.8 V, and three clear one-electron reductions near −1.35, −1.6 and −2.20 V (Table 2). These reductions correspond to effective ruthenium oxidation states of 1, 0 and −1. A further multielectron wave is associated with the third reduction near −2.4 V in each case. The latter wave is presumably related to ligand dissociation from the nominally low-valent species, since free ligands are reducible to anion radicals at these very negative potentials; such behaviour has been observed in ruthenium complexes of π-conjugated ligands.[4] The various reduced species are not stable on the coulometric timescale, and cannot be isolated by conventional means.

The one-electron reductions show no appreciable variation with X-group. The two reductions at −1.35 and −1.6 V are essentially reversible from d.c. polarographic behaviour (Fig. 1b). Both reductions exhibit strong a.c. polarograms (Fig. 1d); however, adsorption phenomena, as evidenced from the strong quadrature signal in the 400 Hz a.c. polarogram (Fig. 1c) compared with the in-phase 400 Hz a.c. polarogram (Fig. 1d), did not allow assessment of reversibility on the a.c. polarographic timescale from variable-frequency data. The reductions below −2 V are irreversible.

The unpaired electrons in Li(bpy) and $Be(bpy)_2$ occupy molecular orbitals composed mainly of ligand π^* origin, from electron spin resonance evidence.[12–15] However, in low-valent chromium and vanadium complexes of bipyridyl, the highest occupied molecular orbital is a delocalized orbital composed mainly of a metal t_{2g} orbital, since metal hyperfine structure is seen in the electron spin resonance spectra.[12–16] This is not a general observation for metal complexes, since low-valent

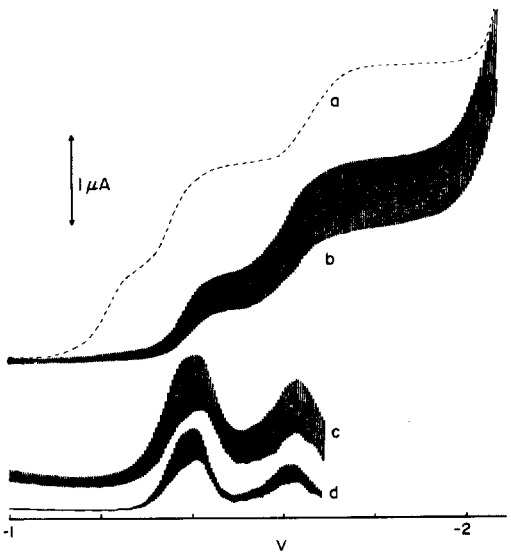

Fig. 1. D.c. polarograms of (a) 1 mM $[Ru(phen)_3]^{2+}$ and (b) 1 mM $[Ru(phen)_2(py)Br]^+$ in acetonitrile, and a.c. polarograms of $[Ru(phen)_2(py)Br]^+$ (400 Hz) in the quadrature (c) and in-phase (d) modes for a 1 mM solution in acetonitrile vs Ag/AgCl.

iron bpy complexes can be described like the Li and Be systems.[17–19] The $[M(bpy)_3]^{2+}$ system (M = Fe, Ru, Os) shows three one electron reduction waves between −1.2 and −1.8 V, which vary by less than 80 mV from Fe to Ru to Os.[20] Substitution on the bpy ligand causes shifts in positions with substituents, but the basic number and shape of waves is preserved. These observations support the view of the added electron occupying a molecular orbital contributed mainly by a ligand π^* orbital.

The highest occupied molecular orbital $[t_{2g}(\pi)]$ and the lowest unoccupied molecular orbital $[t_{1u}(\pi^*)]$ for octahedral Ru(II) will split under the low C_2 microsymmetry of the $[Ru(phen)_2(py)X]^{n+}$ ions into at least e_g and a subsets. Reduction may then lead to successively paramagnetic, diamagnetic and finally paramagnetic species, depending on orbital splitting, as proposed for $[Ru(bpy)_3]^{2+}$.[4] The invariance of the positions of the three reductions with X-group in this system supports the assertion that the available LUMO is dominantly of ligand π^* character, as argued for the $[Ru(bpy)_3]^{2+}$ analogue.[20]

One obvious difference between reduction of $[Ru(phen)_3]^{2+}$ and the $[Ru(phen)_2(py)X]^{n+}$ set is the observation of three one electron reduction waves between −1.2 and −1.8 V in the former and only two in the latter (Fig. 1a and 1b). This result parallels observations for $[Ru(bpy)_3]^{2+}$ vs $[Ru(terpy)_2]^{2+}$, where three waves occur in the former and only two in the latter.[20] The lowest π^* orbital in the bpy or tridentate terpy analogue complex is triply or doubly degenerate and localized in the π-conjugated ligand. In a simple sense, each electron added may occupy one vacant localized conjugated ligand orbital. Electronic repulsions between the added electron and other electron make further electron addition to that locality less facile, evolving a one electron per conjugated ligand rule. The difficulty of adding further electrons is shown in the present experiments, where a third electron is only added at potentials below −2 V, and the process is irreversible. While this simple rule has limited direct theoretical basis, it appears to operate experimentally.

The $[Ru(phen)_2(py)X]^{n+}$ complexes show a one electron and usually reversible oxidation at positive potentials at stationary platinum or gold billet electrodes (Table 2). The typical behaviour is shown in Fig. 2(a). There is some variation in E^0 with X-group, reflecting the differing electronic properties of those ligands, although a majority of values cluster around E^0 of +0.8 V. The difference from the invariance of E^0 for the first two reductions is clear, reflecting electron subtraction from a molecular orbital of metal character for the oxidation and electron addition to one of ligand character for the reductions. Since the five other ligation sites are invariant in this system, variation in the sixth site may be expected to cause only a relatively minor perturbation. The $E_{1/2}$ values have been determined from cyclic responses which usually exhibited $i_{pa} = i_{pc}$, $iv^{1/2}$ constant, and ΔE_p near 70 mV at scan rate at or below 50 mV s^{-1}. The one-electron nature of the couples was confirmed for the X = Cl complex by coulometry.

While most oxidations were well behaved reversible one-electron processes, several ligands offer the opportunity for more complex behaviour. The $X = NO_2$ system is complicated somewhat by disproportionation and oxidation reactions of the ligand on the Ru(III) complex. This system has been

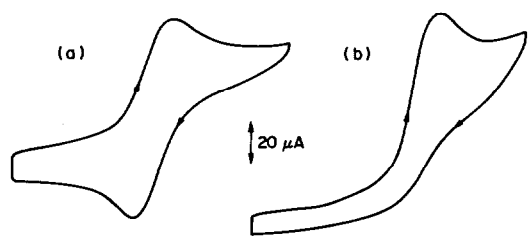

Fig. 2. Cyclic voltammograms at a stationary platinum billet working electrode for $[Ru(phen)_2(py)Br]^+$ [(a), scan rate 200 mV s^{-1}, $+0.6 \rightleftarrows +1.3$ V] and $[Ru(phen)_2(py)(SCN)]^+$ [(b), scan rate 200 mV s^{-1}, $+0.6 \rightleftarrows +1.3$ V].

studied extensively for $[Ru(bpy)_2(NO_2)Cl]$, where coordinated NO_3^- and NO^+ result.[21] The X = SCN complex exhibits a clearly irreversible wave [Fig. 2(b)]. Since the irreversible oxidation of SCN^- in aprotic solvents to NCS–SCN, which is stable in aprotic solvents, occurs at similar potentials,[21] then rapid electron transfer from the Ru(III) complex and ligand dimerization may be involved in this case. The behaviour of coordinated thiocyanate on ruthenium under electrochemical oxidation does not appear to have been studied previously, and detailed characterization of this reaction will be probed.

In closely related series of complexes, correlations of the MLCT band maxima with E^0 have been sought.[5,7,23–27] For the present system, the correlation is poor. Since the MLCT band is apparently a composite of transitions, defining the MLCT band energy is not simple; further, most E^0 values do not vary much. A similar poor correlation was obtained for a series of bis(bipyridyl(isonitrosoketonato)ruthenium(II) complexes,[7] although better correlations do exist for Ru(III) band maxima in that system. The dependence of E^0 on a number of free energy terms not directly related to electronic transitions limits the validity of such correlations which do occur.

Acknowledgements—The assistance of D. Bogsanyi, Research School of Chemistry, The Australian National University, in recording the a.c. polarograms is greatly appreciated. Financial support of the Senate Research Committee of the University of Newcastle is gratefully acknowledged.

(*Received* 12 *December* 1983; *accepted after revision* 13 *September* 1984)

Abstract—Substitution reactions take place following the photonic excitation of aqueous $K_4M(CN)_8$ (where M = Mo or W) in the presence of 1,10-phenanthroline and 2,2′-bipyridyl. Changes in absorbance with time show that the overall reaction is dependent on photochemical activation of potassium octacyanomolybdate(IV) and -tungstate(IV). The species $[K_2Mo(CN)_4(OH)_2(phen)]$, $[K_2W(CN)_4(OH)_2(phen)]$, $[K_2Mo(CN)_4(OH)_2(bipy)]$ and $[K_2W(CN)_4(OH)_2(bipy)]$ exist in solution. The final photosubstitution products $[Mo(OH)_3(CN)(phen)_2]\cdot 2H_2O$, $[Mo(OH)_3(CN)(bipy)_2]\cdot 3H_2O$, $[W(OH)_3(CN)(phen)_2]\cdot 2H_2O$ and $[W(OH)_3(CN)(bipy)_2]\cdot H_2O$ have been isolated in the solid state. Their IR spectra have been discussed. The quantum yield of the photosubstitution reactions has been determined and its variation with change of concentration of the complex as well as the H^+ ion concentration has been studied.

Recent studies[1–7] on the photochemical substitution reactions of coordination compounds of chromium, molybdenum and tungsten have been of considerable interest. The cyano complexes of these metals have been investigated in detail. The stoichiometry of the photochemical processes, photochemical kinetics, quantum yield and the electronic excited states responsible for the photoreactions have been studied. Ligand field photochemistry of hexacyanochromate(III), octacyanomolybdate(IV) and octacyanotungstate(IV) arising from continuous irradiation in aqueous medium is photoaquation of one CN^- ligand giving $[Cr(CN)_5H_2O]^{2-}$, $[Mo(CN)_7H_2O]^{3-}$ and $[W(CN)_7H_2O]^{3-}$ respectively. This behaviour is also observed in hexacyanocobaltate(II)[8] and -ferrate(II)[9] which produce aquopentacyanocobaltate(II) and -ferrate(II) respectively. Prolonged irradiation gives rise to secondary photochemical reactions giving the photoproducts $[Cr(CN)_4H_2O]^-$, $[Mo(CN)_4O(OH)]^{3-}$ and $[W(CN)_4O(OH)]^{3-}$.

In $K_4M(CN)_8$ (where M = Mo or W) only four cyanides can be replaced easily because the dodecahedral structure of these complexes is slightly favoured by π-bonding involving the $d_{x^2-y^2}$ orbital so four of the cyanides are better disposed for π-bonding than the others. The four cyanides may be replaced by hydroxide giving[10] the $Mo(CN)_4(OH)_4^{4-}$ ion. Anhydrous compound of molybdenum, $K_4MoO_2(CN)_4$, was first isolated by Steele.[11] The primary photoaquation reactions of $H_4Mo(CN)_8$ and $H_4W(CN)_8$ and the quantum yield of the formation of the photoproducts have been studied by Mohan *et al.*[12,13] Photosubstitution reactions of ferrocyanide ions in the presence of 1,10-phenanthroline and 2,2′-bipyridyl have been reported[14,15] but no work has been done on the photosubstitution reactions of potassium octacyanomolybdate(IV) and -tungstate(IV). In this paper the photosubstitution reactions of these complexes in the presence of 1,10-phenanthroline and 2,2′-bipyridyl have been reported. The stoichiometry of the photochemical reactions, isolation, analysis and IR spectra of the final photoproducts and the quantum yield of the formation of the photoproducts have been determined.

EXPERIMENTAL

Apparatus

Tungsten filament lamp (Wotan ultra vitalux, 300 W) was used whose radiation is centered

* Author to whom correspondence should be addressed.

around ~ 370 nm. The absorbance was recorded on Spectromom 361 using quartz cell. pH of the solution were recorded on Elico pH meter, type L 1/10 No. 305 and IR spectra were recorded by using Pye–Unicam, Sp 1200, grating IR spectrophotometer.

Materials

A.R. 1,10-phenanthroline and 2,2′-bipyridyl were used. $K_4Mo(CN)_8$ and $K_4W(CN)_8$ were prepared by the method of Leipoldt *et al.*[16] Ferrioxalate was used as chemical actinometer, which was prepared by the method of Parker,[17] with quantum yield of 1.21 at 370 nm. Light intensity was calculated by the method given by Murov.[18] The value obtained was 1.08×10^{20} photons A^{-1} cm^{-2} ($\simeq$ 370 nm).

The stoichiometries of the reaction between $K_4M(CN)_8$ and AA ligand (where AA = 1,10-phenanthroline or 2,2′-bipyridyl) were determined by the Job's method of continuous variation and mole ratio method. The solutions of the metal complex were mixed with different concentrations of ligand and the resulting solutions were exposed to UV light for 30 min, the colour of the solutions changed from yellow to green. The absorbance of the green coloured solution was measured at 400 nm for $K_4Mo(CN)_8$–AA complexes and 620 nm for $K_4W(CN)_8$–AA complexes, the maxima of the spectra of the two systems.

Isolation and analysis of the photosubstituted products

The solutions of $K_4M(CN)_8$ and AA ligands were mixed in stoichiometric ratio obtained by the Job's method and mole ratio method. These mixtures were exposed to UV light (~ 370 nm) for about 4 h and the resulting complexes were extracted by adding HCl in the exposed solutions. These coloured precipitates were filtered, washed several times with water and alcohol and dried in a desiccator over calcium chloride. The solid complexes were fused with aqua-regia, molybdenum[19] was estimated as oxinate and tungsten as oxide. The estimations of nitrogen were carried out using Coleman N-analyzer 29. The water of crystalization was estimated by heating the complexes at 100°C for 2 h.

Spectrophotometric determination of the quantum yield

The absorbance of the photolysed solution was measured at 440 nm for the octacyano molybdate complexes and 620 nm for the octacyano tungstate complexes with 1,10-phenanthroline and 2,2′-bipyridyl, these maxima were obtained by mixing the complex with ligand in the stoichiometric ratios obtained by the physical methods and exposing to UV light. The spectra were recorded at different intervals of time. Molar extinction coefficient (ε_{max}) of these complexes, required for the calculation of their concentration, was determined from the maximum absorbance. The absorbance measured for molybdenum and tungsten complexes at 440 and 620 nm respectively increased as more and more of CN^- was released, reached a maximum value and thereafter it decreased. Molar extinction coefficients were calculated from the maximum absorbance. The quantum yield was calculated by the method given by Calvert and Pitts.[20]

RESULTS AND DISCUSSION

The photochemical behaviour of the $Mo(CN)_8^{4-}$ and $W(CN)_8^{4-}$ ions under *d–d* irradiation has been extensively investigated by several workers[21–27] and is found to be very similar. The primary photochemical reactions leads to a red intermediate compound, while prolonged irradiation causes the formation of a blue final product which can be represented by the following photoaquation reactions[22,24,25,28]

$$M(CN)_8^{4-} + 2H_2O \overset{h\nu}{\rightleftharpoons} M(CN)_7(H_2O)^{3-} + HCN + OH^-,$$

$$M(CN)_7(H_2O)^{3-} + H_2O \overset{h\nu}{\rightarrow} M(CN)_4(O)(OH)^{3-} + 3HCN.$$

pH dependent photolysis of the octacyano-tungstate(IV) and kinetics of thermal reactions of the photoproducts were studied recently by Samotus *et al.*[6] and a general reaction scheme for the photochemical and thermal reactions in the irradiated $W(CN)_8^{4-}$ system as well as the over all kinetics equations for the thermal reactions of the photoproducts were proposed.

When $K_4M(CN)_8$ solution was exposed to UV light (~ 370 nm) in the presence of AA ligands, a green colour was developed after a certain time whose absorbance maxima (Figs 1 and 2) was obtained at 440 nm for the $K_4Mo(CN)_8$–(phen) and $K_4Mo(CN)_8$–(bipy) systems and 620 nm for $K_4W(CN)_8$–(phen) and $K_4W(CN)_8$–(bipy) systems.

The absorption spectra of the irradiated $K_4Mo(CN)_8$–AA system (in 1:2 ratio) show one maximum at 440 nm which increases with increase in time, showing the formation of new species in solution. The one at 365 nm which is due to the $K_4Mo(CN)_8$ alone decreases with exposure time.

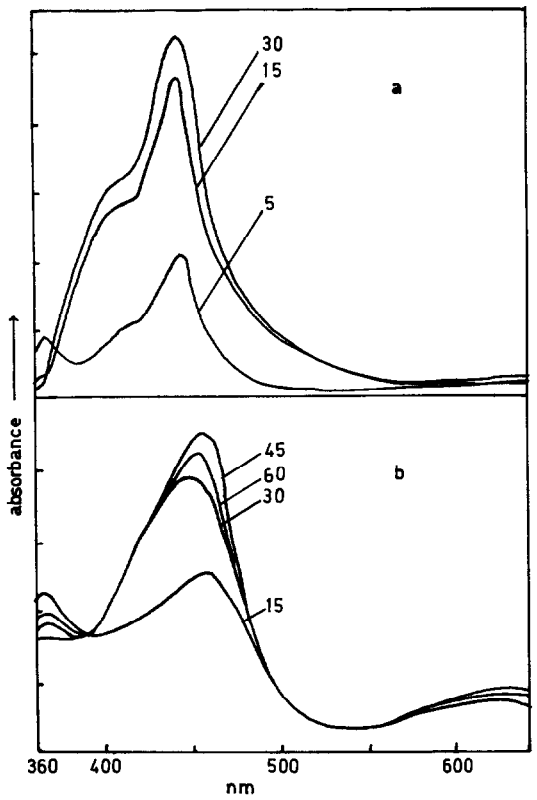

Fig. 1. Variation of absorbance with exposure time (1 cm light path): (a) 0.01 M $K_4Mo(CN)_8$ and 0.02 M 1,10-phenanthroline, (b) 0.01 M $K_4Mo(CN)_8$ and 0.02 M 2,2'-bipyridyl. The numbers indicate irradiation time (min).

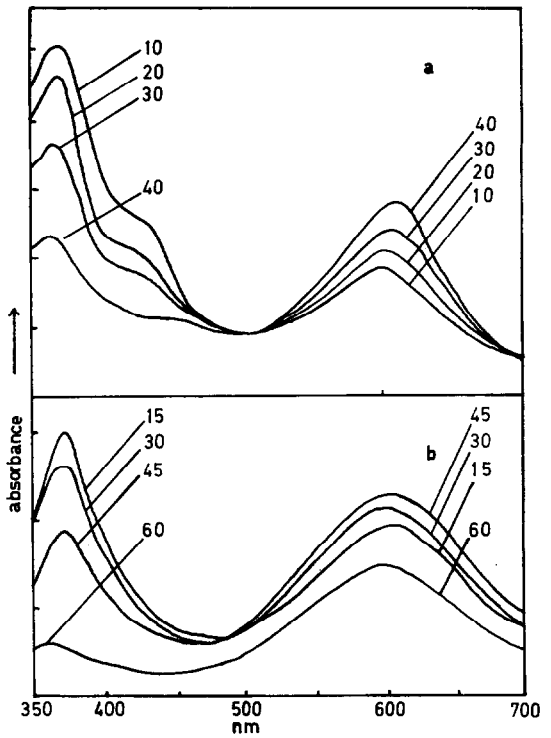

Fig. 2. Variation of absorbance with exposure time (1 cm light path): (a) 0.01 M $K_4W(CN)_8$ and 0.02 M 1,10-phenanthroline, (b) 0.01 M $K_4W(CN)_8$ and 0.02 M 2,2-bipyridyl. The numbers indicate irradiation time (min).

The spectra of the irradiated $K_4W(CN)_8$–AA system (in 1:2 ratio) also show one maximum at 620 nm which increases with increase in time indicating the formation of new species in solution. The maximum at 370 nm due to $K_4W(CN)_8$ decreases with exposure time. The variation of the pH with the exposure time was also studied (Fig. 3). It is found that the pH increases with exposure time which is due to the release of CN^- ions in solution which decompose water to form unionized HCN and OH^- ions in the solution.

The stoichiometry of these complexes was determined with the help of mole ratio and Job's methods. The stoichiometry by mole ratio method is 1:1 and 1:2 for $K_4M(CN)_8$–AA respectively. From Job's method it is 1:2 for the $K_4Mo(CN)_8$–AA systems and 1:1 for the $K_4W(CN)_8$–AA systems respectively.

Several attempts were made to extract these complexes with different organic solvents but without success. These complexes were precipitated as solid by adding dilute HCl in the photolysed system of $K_4M(CN)_8$ and AA in the ratio of 1:2 after development of intense green colour. From the analysis (Table 1), the compositions of the following complexes were established $[Mo(OH)_3(CN)(phen)_2]\cdot 2H_2O$, $[Mo(OH)_3(CN)(bipy)_2]\cdot 3H_2O$, $[W(OH)_3(CN)(phen)_2]\cdot 2H_2O$ and $[W(OH)_3(CN)(bipy)_2]\cdot H_2O$. The results of the analysis supported the stoichiometries obtained by physical methods. The reactions for these systems may be represented by the following equations:

$$M(CN)_8^{4-} + AA \xrightarrow[4H_2O]{h\nu} [M(OH)_2(CN)_4(AA)]^{2-} + 2OH^- + 4HCN, \quad (1)$$

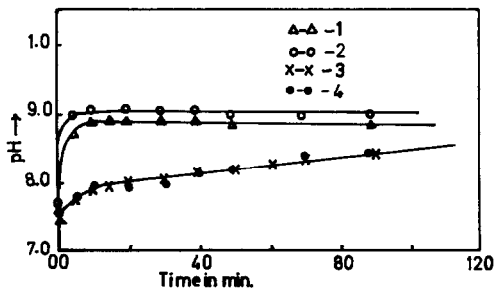

Fig. 3. Variation of pH with irradiation time curve: (1) $K_4Mo(CN)_8$–(phen), (2) $K_4Mo(CN)_8$–(bipy), (3) $K_4W(CN)_8$–(phen) and (4) $K_4W(CN)_8$–(bipy) systems.

$$[M(OH)_2(CN)_4(AA)]^{2-} + AA \xrightarrow[3H_2O]{h\nu} M(OH)_3(CN)(AA)_2 + 2OH^- + 3HCN. \quad (2)$$

The photochemical substitution reactions of potassium octacyano- molybdate and -tungstate in the presence of 1,10-phenanthroline and 2,2'-bipyridyl take place in two steps. In the first four CN^- ions are replaced by two OH^- and one AA and in the second further substitution of three CN^- ions by one OH^- and one AA.

The quantum yield[21,29] of the formation of the substitution products were determined. Its variation with concentration of the complex $K_4M(CN)_8$ was examined (Tables 2 and 3). The plot of quantum yield vs concentration of $K_4M(CN)_8$ is linear. It is found that the quantum yield increases with increase of the concentration of $K_4M(CN)_8$. The quantum yield was also determined at different pH (6–8.5), it has been found that it is not affected by the pH range studied. It has also been found that the quantum yield is not affected by the variation of the ligand concentration (Tables 2 and 3). The low values of the quantum yield show that the reaction is not a chain reaction and is completed in a few steps.

IR spectra of these complexes are very similar (Figs. 4–6). All the complexes display a broad band in the range 3300–3500 cm^{-1} characteristic of O–H stretching frequency, a single sharp peak in the range of 2100–2140 cm^{-1} characteristic of C≡N stretching, a sharp band 1600 cm^{-1} of H–O–H bending frequency. Bands are obtained at 700–800 cm^{-1} which correspond to the M–O stretching vibrations. Strong bands in the 700–900 cm^{-1} region

* $\lambda = 620$ nm, $I_0 = 1.08 \times 10^{20}$, $n_a = 20.01 \times 10^{-4}$, $t = 30°C$, pH = 8.5.

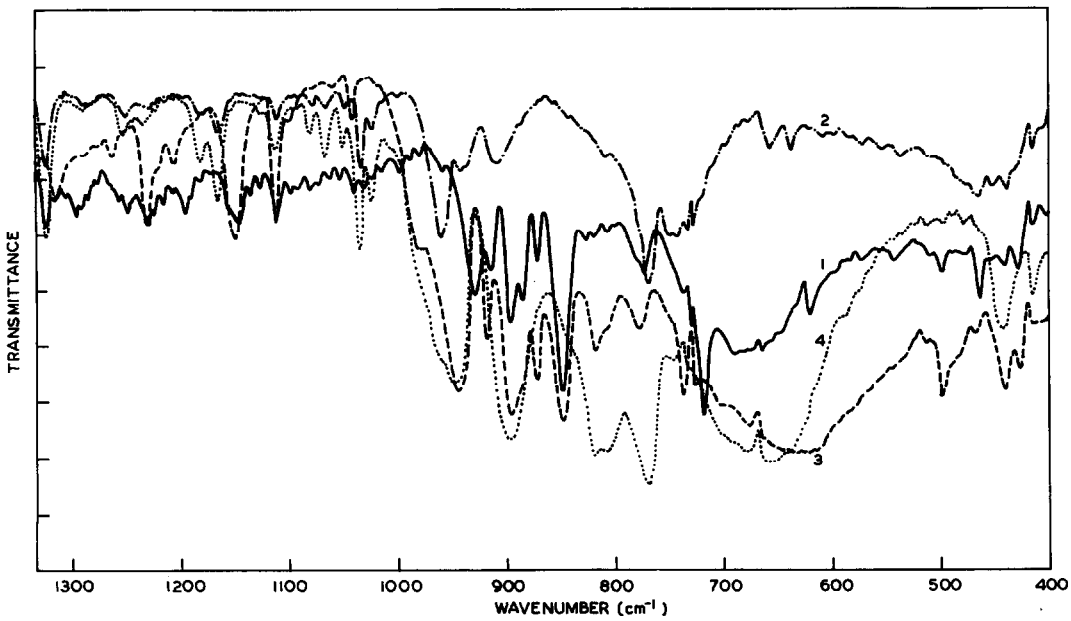

Fig. 4. IR spectra of: (1) $[Mo(OH)_3(CN)(phen)_2]\cdot 2H_2O$, (2) $[Mo(OH)_3(CN)(bipy)_2]\cdot 3H_2O$, (3) $[W(OH)_3(CN)(phen)_2]\cdot 2H_2O$ and (4) $[W(OH)_3(CN)(bipy)_2]\cdot H_2O$.

in spectra of aromatic hydrocarbons[30] have been identified with motions of ring hydrogen atoms moving in phase out of the plane of the ring. In $[Mo(OH)_3(CN)(phen)_2]\cdot 2H_2O$ and $[W(OH)_3(CN)(phen)_2]\cdot 2H_2O$ complexes two strong bands appeared at approximately 725 and 850 cm^{-1}. This is the number expected since there is one group of two and two groups of three adjacent hydrogen atoms in the ring system. In hydrocarbons, the frequency shifts upwards as the number of adjacent atoms in a group decreases. On this basis, the 725 cm^{-1} band is assigned to out of plane motion of the hydrogen atoms on the heterocyclic rings and 850 cm^{-1} band to the hydrogen on the centre ring. In the 2,2'-bipyridyl spectra, only one strong band was observed in this region as expected for two identical groups of four hydrogen atoms each. The pattern of splitting depends on the nature of the coordinated

atom. Two other sharp bands were obtained at ~ 1450 and $\sim 1600\ cm^{-1}$, these bands are most typical and usually the most intense of these ring frequencies. For example, in phenanthroline the first band occurs[31] at approximately $1450\ cm^{-1}$ and the second at $\sim 1605\ cm^{-1}$. The spectrum of 1,10-phenanthroline is quite similar,[30,32] one band is at $1505\ cm^{-1}$, the second appearing as triplet with the center component at $1590\ cm^{-1}$ and the third band shifting to $1423\ cm^{-1}$. All these bands move to higher frequencies on coordination. The $1423\ cm^{-1}$ band was least sensitive but others show shift in the order of 10–25 cm^{-1}. The spectra of $[Mo(OH)_3(CN)(bipy)_2]\cdot 3H_2O$ and $[W(OH)_3(CN)(bipy)_2]\cdot H_2O$ complexes have only three strong bands, one near $770\ cm^{-1}$ ascribed to out of plane bending of ring hydrogen, one near $1450\ cm^{-1}$ which is probably a ring frequency and a ring frequency is also near $1600\ cm^{-1}$. Numerous weak bands were observed between 900 and $1300\ cm^{-1}$. The peak at 1050–1070 cm^{-1} is assigned to out-of-plane M–O–H deformation mode. The cyanide stretching frequencies occur at higher energies for these complexes ($\sim 2100\ cm^{-1}$) than for the corresponding dioxo complexes ($2068\ cm^{-1}$). This suggests that metal–cyanide back-bonding is greater for complexes containing the O–M–O group than for the hydroxo-phenanthroline and hydroxo-bipyridyl complexes.

(*Received* 2 *April* 1984; *accepted* 7 *May* 1984)

Abstract—The reactions of *cis*-$(NH_3)_2PtL_2$ (L = 1-MeT or 1-MeU, the anions of 1-methylthymine or 1-methyluracil respectively) in water with various salts of Fe(II), Fe(III), Co(II), Ni(II), Cu(II) or Ag(I) have produced 14 new heteronuclear complexes of the general types: *cis*-$[(NH_3)_2PtL_2ML_2Pt(NH_3)_2]X_n \cdot mH_2O$ or *cis*-$(NH_3)_2PtL_2MX_n \cdot mH_2O$, and also with silver(I) perchlorate a complex of stoichiometry *cis*-$\{(NH_3)_2Pt(1\text{-}MeU)_2\}_2 \cdot 3AgClO_4 \cdot 6H_2O$. Comparisons are made with previously reported heteronuclear species derived from *cis*-$(NH_3)_2PtL_2$ and factors influencing the type of heteronuclear complex formed are discussed, particularly the versatility of binding patterns with Ag(I). A tetranuclear structure is suggested for the compound of stoichiometry *cis*-$(NH_3)_2Pt(1\text{-}MeU)_2 \cdot FeSO_4 \cdot 3H_2O$ involving iron(II) ions linked by sulphate bridges. The electronic spectra of the trinuclear complexes *cis*-$[(NH_3)_2Pt(1\text{-}MeU)_2M(1\text{-}MeU)_2Pt(NH_3)_2](NO_3)_2 \cdot mH_2O$ (M = Fe, Co or Ni) are reported. They show that the *trans*-MO_4Pt_2 geometry results in a very severely *trans*-elongated ligand field about the central metal ion, M. This conclusion is supported by the Mössbauer spectrum in the case of the iron(II) complex. The X- and Q-band EPR spectra of the Fe(III) analogue are also reported.

Complexes containing different metal ions have received considerable attention for reasons such as electron transfer,[1] magnetic exchange,[2] and their possible role in catalysis[3] or in metalloenzymes.[4,5] Heteronuclear complexes are readily formed with bi- or polyfunctional ligands and are usually synthesized in a stepwise manner. Examples of such ligands are acetylacetonates,[6] substituted phosphonites[7] or phosphites,[8] 2-mercaptoethylamine,[9] and many others,[10] including heterocyclic ligands such as pyrazine,[1] deprotonated imidazole,[11] or deprotonated pyrazole.[12]

We have been interested for some time in a group of compounds containing substituted uracils (pyrimidine-2,4-diones) attached through their N3 atom to Pt(II) and through their exocyclic oxygens to a variety of other metal ions. Depending on the Pt starting compound, mixed metal complexes with one or two eight-membered macrochelate rings or with an open structure were obtained (Fig. 1). Specifically, heteronuclear complexes of the following stoichiometries have been obtained and characterized (L = 1-methyluracil or 1-methylthymine anion, 1-MeU and 1-MeT, respectively):

Pt, M, L_2 from *cis*-$(NH_3)_2PtL_2$,[13]

Pt_2, M, L_4 from *cis*-$(NH_3)_2PtL_2$,[14]

Pt_4, M, L_4 from *cis*-$[(NH_3)_2PtL]_2^{2+}$ (*head–head*),[15]

Pt, M, L from *cis*-$[(NH_3)_2PtL(H_2O)]^+$,[16]

* Author to whom correspondence should be addressed.

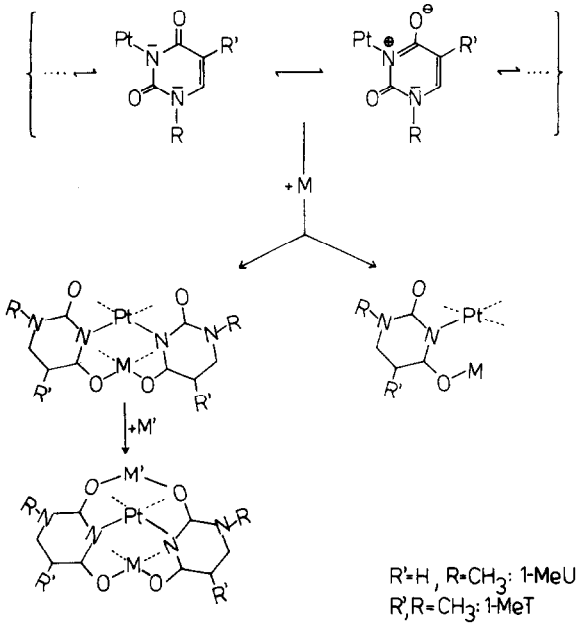

Fig. 1. Formation of heteronuclear complexes containing 1-methyluracil and 1-methylthymine ligands.

Pt_2, M_2, L_2 from *cis*-$[(NH_3)_2PtL]_2^{2+}$ (*head–tail*),[16]

Pt, M_2, L_2 from *trans*-$(NH_3)_2PtL_2$.[17]

There is, at present, no evidence for a biological role of these mixed metal complexes in connection with the mode of action of platinum antitumor drugs.[18] However, there are several observations that suggest that similar binding patterns of the DNA base thymine and the RNA base uracil may indeed play a more important role in nucleic acid–metal ion interactions than anticipated so far. For example, we found that a single L ligand attached through N3 {in *cis*-$[(NH_3)_2PtL(H_2O)]^+$}[16] either alone, or in conjunction with a second nucleobase having no particularly well coordinating site [in *cis*-$(NH_3)_2PtLL'$ with L = 1-MeU, L' = 1-methylcytosine (O2)[19] or 7,9-dimethylhypoxanthine(O6)][20] is sufficient to achieve binding of a second metal. Moreover, Beauchamp and coworkers have demonstrated a similar behaviour with Hg complexes of 1-MeT,[21] and the polymeric structure for Ag(1-MeT) reported by the same authors[22] reflects the tendency of L to use N3 *and* the exocyclic oxygens for metal coordination also. It has been suggested[14(a),23,24] that substitution of the proton at N3 of neutral uracil or its derivatives by the heavy metals Pt, Ag or Hg leads to a delocalization of the electron lone pair at N3 into the ring, thus increasing the basicity of the exocyclic oxygens O4 and O2.

In continuation of our previous work, we have studied in more detail the formation and spectroscopic properties of complexes of the two types Pt, M, L_2 and Pt_2, M, L_4 which were derived from *cis*-$(NH_3)_2Pt(1\text{-}MeU)_2$ and *cis*-$(NH_3)_2Pt(1\text{-}MeT)_2$, respectively. In particular, factors influencing the stoichiometries of the complexes formed, and the effect of the coordination geometry on the electronic state of the heterometals M were of interest. In the course of these studies we obtained, in crystalline form, a compound with yet another stoichiometry (Pt_2, M_3, L_4) with M being Ag(I).

EXPERIMENTAL

Preparation

cis-$(NH_3)_2Pt(1\text{-}MeT)_2 \cdot 2.5H_2O$ (**1**) and *cis*-$(NH_3)_2Pt(1\text{-}MeU)_2 \cdot 4H_2O$ (**2**) were prepared as previously described.[13,14(a)] The heteronuclear complexes were prepared by co-crystallizing *cis*-$(NH_3)_2PtL_2$ with suitable metal salts from aqueous solution. In a typical experiment, to 0.5 mmol of *cis*-$(NH_3)_2PtL_2$, dissolved in 8–15 cm^3 water, 0.25–4 mmol of the metal salt was added, either as solid or dissolved in a small amount of water. With Fe, Co, Ni and Cu salts there was an immediate colour change. The solution was filtered and then allowed to evaporate slowly. In a few cases, the heteronuclear complex precipitated immediately. The compound was collected on a filter, washed with a small amount of water and air dried. No attempts were made to optimize the yields. Reported yields are based on Pt. The following abbreviations are used: 1-MeT = $C_6H_7N_2O_2$ (1-methylthymine anion) and 1-MeU = $C_5H_5N_2O_2$ (1-methyluracil anion).

cis-$[(NH_3)_2Pt(1\text{-}MeT)_2Ni(H_2O)_2](CH_3COO)_2 \cdot 1H_2O$ (**3**) was prepared from **1** and $Ni(CH_3COO)_2 \cdot 4H_2O$ (Pt : Ni = 1) in a solution slightly acidified with CH_3COOH (pH 5.6). After evaporation to dryness, the sample was passed over Sephadex G 10, and the yellow fraction crystallized. Yellow microneedles, checked for absence of unreacted Ni salt by thin layer chromatography on silicagel (Merck 6D F254, methanol as solvent). Yield (after chromatography) 55%. Found: C, 26.08; H, 4.29; N, 11.20; Ni, 8.07%. Calc.: C, 26.03; H, 4.38; N, 11.39; Ni, 7.95%.

cis-$[(NH_3)_2Pt(1\text{-}MeT)_2Cu(H_2O)_2]SO_4 \cdot 1H_2O$ (**4**) was prepared from **1** and $CuSO_4 \cdot 5H_2O$ (Pt : Cu = 1). Evaporation to dryness, chromatography over Sephadex G 10, slow evaporation of yellow fraction gave yellow, transparent crystal plates, up to 1 mm long, losing water of crystallization in air. Yield (after chromatography) 70%. Analysis (of air dried sample). Found: C, 20.08; H, 3.82; N, 11.53; O,

24.47; S, 4.44%. Calc.: C, 19.98; H, 3.64; N 11.66; O, 24.41; S, 4.45%.

Compounds of type cis-$[(NH_3)_2Pt(1\text{-}MeT)_2M(1\text{-}MeT)_2Pt(NH_3)_2]X_n \cdot (H_2O)_m$

M = Co(II); X = CH_3COO^-, $n = 2$, $m = 4$ (**5**) was prepared from **1** and $Co(CH_3COO)_2 \cdot 4H_2O$ (Pt:Co = 1) as for **3**. Crystallization of the blue fraction after Sephadex chromatography gave a light blue microcrystalline material. Yield (after chromatography) 40%. Found: C, 26.50; H, 4.23; N, 13.63; Co, 4.3%. Calc.: C, 26.60; H, 4.31; N, 13.30; Co, 4.66%.

M = Ni(II); X = ClO_4^-, $n = 2$, $m = 2$ (**6**) was prepared from **1** and $Ni(ClO_4)_2 \cdot 6H_2O$ (Pt:Ni = 2). Pale yellow microcrystals, yield 50%. Found: C, 22.42; H, 3.73; Ni, 4.34%. Calc.: C, 22.03; H, 3.40; Ni, 4.49%.

M = Cu(II); X = NO_3^-, $n = 2$, $m = 3$ (**7**) was prepared from **1** and $Cu(NO_3)_2 \cdot 3H_2O$ (Pt:Cu = 2). Tiny, yellow columns, yield 50%. Found: C, 23.01; H, 3.72; N, 15.76; Cu, 5.30%. Calc.: C, 22.94; H, 3.70; N, 15.61; Cu, 5.06%. When $CuSO_4$ was used as starting material with $NaNO_3$ present in an equimolar concentration, **7** was obtained but not the SO_4 product.

cis-$(NH_3)_2Pt(1\text{-}MeU)_2 \cdot FeSO_4 \cdot 3H_2O$ (**8**). 0.5 mmol of **2** and 0.5 mmol $FeSO_4 \cdot 7H_2O$ were dissolved in 5 cm^3 water and the yellow solution (pH 4.4) kept in a partially covered beaker at 22°C. Within 1 day a crystalline precipitate had formed. After 8 days 160 mg (47%) of yellow–olive microplates were collected. In reflecting light the crystals look almost black. Found: C, 17.42; H, 3.03; Fe, 8.17%. Calc.: C, 17.52; H, 3.24; Fe 8.15%.

cis-$(NH_3)_2Pt(1\text{-}MeU)_2 \cdot AgNO_3 \cdot 2H_2O$ (**9**). 0.05 mmol of **2** and 4 mmol $AgNO_3$ were heated in 15 cm^3 water to 70–80°C, filtered, and the solution kept at 22°C for 1 day. As early as 1 h after filtration, **9** starts precipitating as colourless, transparent needles. Yield 200 mg (58%). Found: C, 17.96; H, 3.36; N, 14.03; Ag 15.40%. Calc.: C, 17.52; H, 2.95; N, 14.31; Ag, 15.74%.

cis-$[(NH_3)_2Pt(1\text{-}MeU)_2Zn(H_2O)_3]SO_4 \cdot 2H_2O$ (**10**) was prepared from **2** and $ZnSO_4 \cdot 7H_2O$ (Pt:Zn = 1). Colourless cubes, yield 65%. Found: C, 16.48; H, 3.62; N, 11.61; S, 4.48%. Calc.: C, 16.43; H, 3.59; N, 11.50; S, 4.39%.

Compounds of type cis-$[(NH_3)_2Pt(1\text{-}MeU)_2M(1\text{-}MeU)_2Pt(NH_3)_2]X_n \cdot (H_2O)_m$

M = Fe(II); X = NO_3^-, $n = 2$, $m = 5$ (**11**) was prepared from **2** and $FeSO_4 \cdot 7H_2O$ (Pt:Fe = 1). The yellow solution was filtered, passed through an anion exchange column in the NO_3^- form, the solution concentrated on a rotavaporator to small volume and allowed to evaporate at 3°C. Orange–yellow cubes, yield 45%. Found: C, 19.43; H, 3.39; N, 16.26; Fe, 4.45%. Calc.: C, 19.55; H, 3.45; N, 15.96; Fe, 4.55%.

M = Fe(III); X = NO_3^-, $n = 2$, $m = 4$ (**12**) was prepared from **2** and $Fe(NO_3)_3 \cdot 9H_2O$ (Pt:Fe = 1). The orange–red solution (pH 1.6) was allowed to evaporate at 3°C. Small, red columns losing transparency in air, yield 88%. Found: C, 18.78; H, 3.16; N, 16.37; Fe, 4.63%. Calc.: C, 18.87; H, 3.17; N, 16.51; Fe, 4.39%.

M = Co(II); X = NO_3^-, $n = 2$, $m = 6$ (**13**) was prepared from **2** and $Co(NO_3)_2 \cdot 6H_2O$ (Pt:Co = 1). The purple solution was concentrated to small volume by warming to 35°C. On cooling, light blue crystals formed. Yield 63%. Found: C, 19.33; H, 3.41; N, 16.00; Co, 4.5%. Calc.: C, 19.21; H, 3.56; N, 15.69; Co, 4.71%.

M = Co(II); X = ClO_4^-, $n = 2$, $m = 3$ (**14**) was prepared from **2** and $Co(ClO_4)_2 \cdot 6H_2O$ (Pt:Co = 1). It precipitated immediately on mixing aqueous solutions of the two components. Light blue powder, yield 90%. Found: C, 18.47; H, 2.75; Co, 4.1%. Calc.: C, 18.90; H, 3.02; Co, 4.64%.

M = Ni(II); X = NO_3^-, $n = 2$, $m = 6$ (**15**) was prepared from **2** and $NiSO_4 \cdot 7H_2O$ (Pt:Ni = 3:2). The yellow precipitate obtained after evaporation to dryness was redissolved and passed through an anion exchange column in its NO_3^--form, and the solution crystallized at 22°C. Yellow plates, yield 70%. Found: C, 19.21; H, 3.42; N, 15.79; Ni, 4.83%. Calc.: C, 19.22; H, 3.56; N, 15.70; Ni, 4.70%. An identical product was obtained in 80% yield by reaction of **2** and $Ni(NO_3)_2 \cdot 6H_2O$ (Pt:Ni = 1).

M = Ag(I); X = NO_3^-, $n = 1$, $m = 8$ (**16**) was prepared from **2** and $AgNO_3$ (Pt:Ag = 2). The colourless solution was concentrated to small volume until first signs of formation of a precipitate appeared. The sample was then slightly warmed to dissolve the precipitate and the sample placed in a refrigerator (3°C). Within 1 day colourless, transparent cubes had formed, which lose water of crystallization and their transparency in air. Yield 50%. Found: C, 18.72; H, 3.90; N, 14.31; Ag, 8.2%. Calc.: C, 18.87; H, 3.81; N, 14.31; Ag, 8.47%.

cis-$(NH_3)_2Pt(1\text{-}MeU)_2 \cdot 1.5AgClO_4 \cdot 3H_2O$ (**17**) was obtained as follows: **2** and $AgClO_4 \cdot H_2O$ (Pt:Ag = 1:8) were mixed in water, heated to 70°C, filtered hot, and the colourless solution slowly cooled to 22°C. Colourless, thin needles, yield 75%. Found: C, 14.41; H, 2.59; N, 9.96; Ag, 19.3%. Calc. C, 14.22; H, 2.63; N, 9.95; Ag, 19.16%.

Spectroscopy

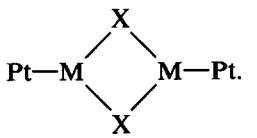
IR spectra were recorded as Nujol mulls (CsI windows) on Perkin–Elmer 577 and 580 grating spectrometers. Reference spectra of Cu(II), Cr(II) and Rh(II) acetate were taken and compared with the compounds containing acetate. EPR spectra were obtained as previously reported.[19] Electronic spectra of the powdered samples were measured with a Beckman DK 2 spectrometer and the standard reflectance accessory.

The Mössbauer spectrum of compound **11** was measured at 78 K using the apparatus described previously.[25]

RESULTS AND DISCUSSION

Formation of compounds

Table 1 lists the heteronuclear complexes prepared from *cis*-$(NH_3)_2Pt(1\text{-MeT})_2$ and *cis*-$(NH_3)_2Pt(1\text{-MeU})_2$, respectively. The Pt_2, M, L_4 stoichiometry appears to be the most common one with the metals M and counterions X used in this work. Two examples of this type have previously been examined by us using X-ray crystallography: a silver(I) complex[14(a)] and a manganese(II) complex[14(b)] each with L = 1-MeT. The two compounds differ in the coordination geometry of the heterometal: while Ag adopts a distorted tetrahedral coordination sphere, the Mn is square-planar. This difference leads to markedly different Pt–M–Pt distances, which are shorter in the case of the Mn compound, 2.704(1) Å vs 2.849(1) and 2.884(1) Å. Coordination of the heterometal M in both cases occurs through O4 of the four 1-MeT ligands, while Pt binds through N3. There is little doubt that all the compounds having Pt_2, M, L_4 stoichiometry, which are described in this work, are constructed in this way.



The Pt, M, L_2 stoichiometry is clearly less frequent. The crystal structure of one example, *cis*-$[(NH_3)_2Pt(1\text{-MeU})_2Cu(H_2O)_2]SO_4$, has been determined.[13] In this compound, Pt is coordinated through N3 of 1-MeU, and Cu through two exocyclic O4 oxygens of 1-MeU. Copper completes its coordination sphere by two oxygens from coordinated water molecules. As will be discussed

Table 1. Isolated heteronuclear complexes

		M	X	*n*	No.	Ref.

* This work.

subsequently, the formation of dinuclear Pt, M complexes most likely is not the only way to accommodate the Pt, M, L_2 stoichiometry. There exists the possibility of a polymeric arrangement with Pt and M alternating, and coordination of the counterion X to the heterometal may lead to a tetranuclear arrangement of the kind

Finally, with Ag(I) yet another stoichiometry (Pt_2, Ag_3, L_4) has been observed (*vide infra*).

From Table 1 and the details of the preparation of the compounds two conclusions can be drawn.

(1) The relative Pt : M ratio used in the preparation is not the only factor determining the stoichiometry of the product. The choice of the counter ion X has a similar, or even more pronounced, effect, either by influencing the solubility of the product and precipitating the least soluble one, or by coordination to the heterometal M. We have previously noted this in the Pt, Cu, 1-MeU system[13] and find it confirmed here. For example, while at a given Pt : Fe(II) ratio (1 : 1) the NO_3^- salt crystallizes as the Pt_2, Fe, L_4 product, the sulphate crystallizes with Pt, Fe, L_2 stoichiometry. With an excess of $AgNO_3$ over *cis*-$(NH_3)_2Pt(1\text{-MeU})_2$ the Pt, Ag, L_2 product is formed and not Pt_2, Ag, L_4. However, with $AgClO_4$ used in the same excess, Pt_2, Ag_3, L_4 is obtained instead.

(2) There appears to be little or no influence of the nature of the heterometal on the stoichiometry of the compound formed. We attribute this finding to the flexibility of the Pt, L_2 moiety which permits the heterometal in Pt, M, L_2 and Pt_2, M, L_4 to have a tetrahedral, a square-planar, or an octahedral (with Pt occupying a coordination site) coordination sphere. Moreover, in Pt, M, L_2 compounds the coordination sphere of M may be extended from 4 to 5 with the use of coordinated solvent molecules or counter ions.

Versatility of Ag *binding patterns*

With L = 1-MeT, two complexes of Pt, Ag, L_2 and Pt_2, Ag, L_4 stoichiometry have previously been obtained.[14(a)] With L = 1-MeU the two analogues have been prepared and in addition a compound having Pt_2, Ag_3, L_4 stoichiometry. Formation of the first two compounds, of both 1-MeT and 1-MeU, was dictated by the Ag : Pt ratio applied, favouring the Pt_2, Ag, L_4 product at low ratios (1 : 2) and Pt, Ag, L_2 at ratios of 2–8. The Pt, Ag, L_2 product of L = 1-MeU, like the 1-MeT compound, is of a very low solubility in water as compared to the dinuclear Cu(II) or Zn(II) complexes. This suggests that this compound does not consist of isolated dinuclear units but rather is polymeric. A structure as observed for Ag(1-MeT)[22] with Ag binding to N3, O4 and O2 would be consistent with this idea. The principal difference between Ag(1-MeT) and Pt, Ag, L_2 would be the replacement of the Ag binding to two N3 sites of 1-MeT by the $(NH_3)_2Pt(II)$ moiety. Depending on whether the PtL_2 unit assumes a head–head or a head–tail arrangement, a variety of Ag coordination patterns are possible in an assumed polymeric Pt, Ag, L_2 structure: for example, one Ag bound through four O4 sites, the second Ag bound through four O2 sites, or mixed O2, O4 coordination with identical donor atoms in mutual *cis*- or *trans*-positions. Moreover, the coordination geometries of the Ag ions might be tetrahedral as in $\{[(NH_3)_2Pt(1\text{-MeT})_2]_2Ag\}NO_3$[14(a)] or square planar as in $\{[(NH_3)_2Pt(1\text{-MeU})]_4Ag\}(NO_3)_5$;[15] yet it is clear that both Ag ions should have the same geometry.[13]

The stepwise addition of Ag to the Pt_2, Ag, L_4 unit gives a rationale for the other stoichiometries observed (Fig. 2). Formally, a polymeric structure of Pt, Ag, L_2 stoichiometry results if half an Ag ion is added twice to the still available exocyclic oxygens of L in Pt_2, Ag, L_4. Addition of yet another Ag leads to Pt_2, Ag_3, L_4, a product obtained from reaction of *cis*-$(NH_3)_2Pt(1\text{-MeU})_2$ with 8 equivalents of $AgClO_4$. If still another Ag is added, a Pt, Ag_2, L_2 stoichiometry can be expected. A compound of this composition is not yet known for the *cis*-Pt(II) system, but has recently been crystallographically confirmed by us with *trans*-Pt(II).[17] In this compound, the two Ag ions exhibit mixed O2, O4 coordination while Pt binds to two N3 sites of 1-MeU.

Complexes with Pt, M, L_2 *stoichiometry*

As mentioned before, *cis* - $[(NH_3)_2Pt(1\text{-MeU})_2Cu(H_2O)_2]SO_4 \cdot 4.5H_2O$ represents, thus far, the only crystallographically studied example of Pt, M, L_2 stoichiometry. The corresponding 1-MeT complex, **4**, appears to be isostructural with the former. The IR spectrum unambiguously reveals the presence of ionic SO_4^{2-} (ν_3 1115 cm^{-1}, ν_4 620 cm^{-1}). The compound *cis*-$[(NH_3)_2Pt(1\text{-MeU})_2Zn(H_2O)_3]SO_4 \cdot 2H_2O$ (**10**) according to its IR spectrum contains ionic SO_4^{2-} as well, but the coordination geometry is different from that of Cu (square-pyramidyl instead of square-planar).

One alternative to a dinuclear structure of Pt, M, L_2 compounds, a polymeric arrangement of Pt and M has been discussed in the preceding section. A

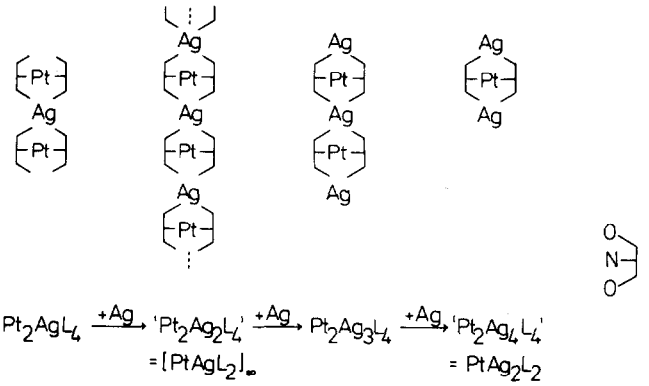

Fig. 2. Stepwise formation of $Pt_xM_yL_z$ stoichiometries, starting with Pt_2AgL_2 (L = 1-MeU).

second alternative, a tetranuclear arrangement with two bridging anions, is also feasible and possibly realized in *cis* - $(NH_3)_2Pt(1 - MeU)_2 \cdot FeSO_4 \cdot 3H_2O$ (**8**). The IR spectrum of this compound clearly demonstrates the presence of SO_4^{2-} in C_{2v} symmetry with bands at 975 cm^{-1}, *s* (ν_1), 1205, *s*, 1110, *s*, 1030 cm^{-1}, *s* (ν_3), and 600, *m*, and 660 cm^{-1}, *m* (ν_4). No straightforward differentiation between chelating and bidentate bridging sulphate is possible,[26] particularly as well characterized examples of Fe(II) sulphato complexes are lacking. Although we cannot, at present, assign the correct structure for *cis* -$(NH_3)_2Pt(1 - MeU)_2 \cdot FeSO_4 \cdot 3H_2O$, a tetranuclear structure as depicted in Fig. 3 seems quite reasonable.

The 1 : 1-product from reaction of *cis*-$(NH_3)_2Pt(1\text{-MeT})_2$ and $Ni(CH_3COO)_2$, compound **3**, was considered another possible candidate containing bridging anion ligands. However, its IR spectrum provides no evidence for bidentate bridging acetate. In the 600–700 cm^{-1} range, its IR spectrum shows no similarity with the spectra of the binuclear acetates of Cr(II), Cu(II) and Rh(II). While these compounds exhibit a characteristic pattern with an intense mode around 685–715 cm^{-1} and a weaker one around 630 cm^{-1}, **3** shows four bands of medium intensity at 615, 650, 670 and 680 cm^{-1}. At least one band (680 cm^{-1}), but possibly also the 670 cm^{-1} band must be assigned to a 1-MeT ring mode, leaving the other two bands to acetate modes. They compare with medium intensity bands at 646 and 615 cm^{-1} for $Na(CH_3COO)$.[27]

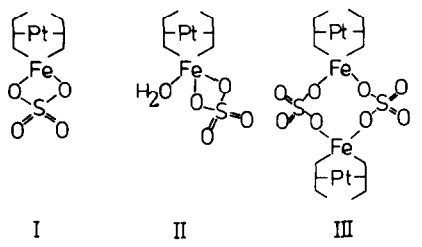

Fig. 3. Feasible geometries of *cis* - $(NH_3)_2Pt(1\text{-MeU})_2 \cdot FeSO_4 \cdot 3H_2O$ (**8**) containing chelating (I, II) and bidentate bridging (III) sulphate.

Electronic spectra of Pt_2, M, L_4 *complexes* [M = Fe(II), Co(II), Ni(II)]

In view of the very unusual ligand fields around the central metal ion M in these compounds we were interested to study their electronic spectra. Earlier work[28] on the EPR spectra of Mn(II) in the trinuclear complex ion *cis* - $[(NH_3)_2Pt(1 - MeT)_2Mn(1 - MeT)_2Pt(NH_3)_2]^{2+}$ showed that the platinum atoms in the axial positions result in a severe axial distortion of the field about the central metal ion. EPR studies on the related copper(II) species *cis* - $[(NH_3)_2Pt(1 - MeU)(1 - MeC)Cu(1 - MeU)(1 - MeC)Pt(NH_3)_2]^{4+}$ and *cis* - $[(NH_3)_2Pt(1 - MeU)_2Cu(1 - MeU)_2Pt(NH_3)_2]^{2+}$ revealed[19] that this distortion was a tetragonal elongation, i.e. that the ligand field effect due to the platinum atoms was less than the in-plane field generated by the exocyclic oxygen atoms of the heterocyclic ligands. Examination of the electronic spectra of the iron(II), cobalt(II) and nickel(II) compounds *cis* - $[(NH_3)_2Pt(1 - MeU)_2M(1 - MeU)_2Pt(NH_3)_2](NO_3)_2$ in the visible and near IR regions would provide an independent check on this conclusion, and also yield spectral information on what would appear to be one of the most distorted examples of a nominally six-coordinate environment for these metal ions.

The microcrystals were too small for single crystal spectroscopy but reflectance spectra of quite good quality were obtained in the 500–2200 nm region (Fig. 4). Sharp bands marked * in the 1400–2200 nm range are ligand vibrational overtones and combinations and these were identified by their invariance on changing the central metal ion, M, and by their presence in the reflectance spectrum of the

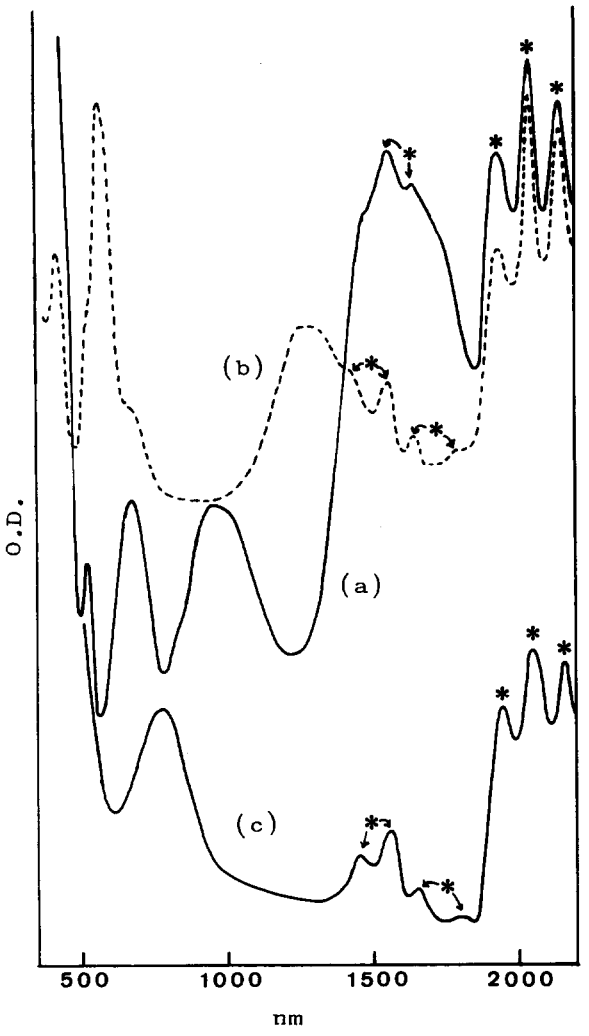

Fig. 4. Electronic reflectance spectra of *cis* - $[(NH_3)_2Pt(1\text{-}MeU)_2M(1\text{-}MeU)_2Pt(NH_3)_2](NO_3)_2(H_2O)_m$: (a) M = Ni(II) (compound **15**); (b) M = Co(II) (compound **13**); (c) M = Fe(II) (compound **11**).

iron(III) compound. Only in the case of the lowest energy *d–d* band of the nickel complex is there significant overlap of the vibrational and d–d bands, and then only by the weak vibrational set at 1400–1700 nm, which are seen as small additional features on that *d–d* band (Fig. 4).

We shall first consider the spectrum of the nickel complex, the *d–d* band energies of which are listed in Table 2. Analysis of the *d–d* spectra of tetragonally distorted six-coordinate nickel(II) complexes is now well documented. Two of the most severely distorted ligand fields are in the compounds $Ni(pyridine)_4I_2$[29] and $Ni(pyrazole)_4Br_2$.[30] The reported band energies and assignments (in D_{4h}) for these compounds are also listed in Table 2 for direct comparison with the results for the Pt–Ni–Pt complex. (An O_h–D_{4h} correlation diagram for the high-spin levels arising for d^7 and d^8 is shown in Fig. 5.)

The ligand fields generated by the exocyclic oxygens in uracil, thymine, and related ligands are known[31] to be low; significantly less than those produced by pyridine or pyrazole. Accordingly, we would expect the average ligand field in the Pt–M–Pt complexes to be quite weak as well as very distorted. The weakness of the overall field is also demonstrated by the electronic spectrum of the cobalt(II) complex (see later).

The strong band at 6250 cm^{-1} in the spectrum of the nickel complex is readily assigned as $^3B_{1g} \rightarrow {}^3E_g(1)$. Three bands [from the transitions $^3B_{1g} \rightarrow {}^3B_{2g}$, $^3A_{2g}(1)$, and $^3E_g(2)$] would then be expected in the 7000–16,000 cm region, but only two were observed, at about 10,000 cm^{-1} and at 14,500 cm^{-1}. The former band is asymmetric and becomes more so on cooling to *ca* 80 K, but the absorption could not be reliably resolved into two components. The $^3B_{2g}$ and $^3A_{2g}(1)$ levels are known to lie close together in $Ni(pyridine)_4I_2$ and $Ni(pyrazole)_4Br_2$, with $^3B_{2g} < {}^3A_{2g}(1)$. The corresponding levels, $^3B_2$ and $^3A_2(1)$ are also closely spaced in the square pyramidal (C_{4v}) complex [Ni(2-methylimidazole)$_4$Br]Br, but in that case $^3B_2$ (at 11,600 cm^{-1}) has moved above $^3A_2(1)$ (at 10,300 cm^{-1}).[32]

The Pt–Ni–Pt complex appears to represent the intermediate situation where the $^3B_{2g}$ and $^3A_{2g}(1)$ levels are too close to be resolved without the use of polarized light. Assignment of the 14,500 cm^{-1} band as either $^3B_{2g}$ or $^3A_{2g}(1)$ would be quite at variance with the results for other compounds given in Table 2. This problem does not arise with our preferred assignment of the 14,500 cm^{-1} band as $^3B_{1g} \rightarrow {}^3E_g(2)$.

The remaining band, at 18,700 cm^{-1}, is probably $^3B_{1g} \rightarrow {}^3A_{2g}(2)$ but, in view of Hitchman's observation[32] of the relatively high intensity of the $^3B_1 \rightarrow {}^1E(1)$ band at 17,300 cm^{-1} in the spectrum of

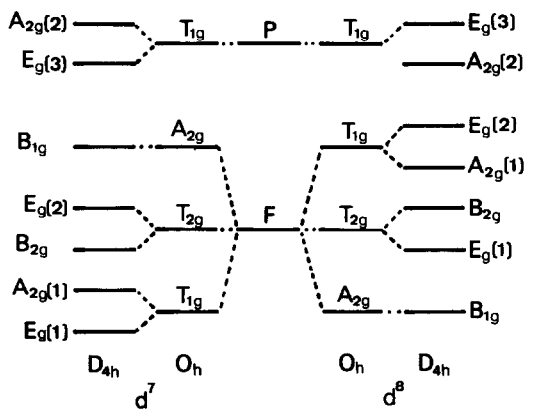

Fig. 5. O_h–D_{4h} correlation for high-spin terms arising from d^7 and d^8.

[Ni(2-methylimidazole)$_4$Br]Br, we cannot rule out an alternative assignment as $^3B_{1g} \rightarrow {}^1E_g(1)$ for this 18,700 cm^{-1} band.

The spectrum of the Pt–Co^{II}–Pt complex (Fig. 4b) has only one d–d band in the 4500–12,500 cm^{-1} region and this is at low energy (7750 cm^{-1}) for a nominally six-coordinate Co(II) species.

The spectra of strongly tetragonally distorted six-coordinate cobalt(II) complexes have received less detailed attention than their nickel(II) analogues. The effects of the tetragonal distortion of the ligand field upon the terms arising for the cubic d^7 case and the relative order of the resultant component levels have been discussed, *inter alia*, by Lever.[33]

Splitting of the original $^4T_{2g}$ term into the components $^4E_g(2)$ and $^4B_{2g}$ is quite sensitive to the extent of the distortion of the field from O_h symmetry. The spectra of compounds of the type CoL_4X_2 (L = heterocyclic amine; X = Cl, Br, I), in which the field is quite distorted but of only weak to moderate overall average strength, have the transitions to $^4E_g(2)$ and $^4B_{2g}$ in the 5000–9000 cm^{-1} region. There is, however, some disagreement as to the assignment of the two bands in this region for closely-related compounds. Some workers[34,35] place $^4E_g(2) > {}^4B_{2g}$ while others[36] prefer $^4E_g(2) < {}^4B_{2g}$. From low-temperature single crystal spectroscopy, Lever[37] assigns $^4E_g(1) \rightarrow {}^4B_{2g}$ at 6325 cm^{-1} and $^4E_g(1) \rightarrow {}^4E_g(2)$ at 9270 cm^{-1} for [$Co(EtNHCH_2CH_2NHEt)_2Br_2$], in which the diamine contributes no π-component to the equatorial field.

Notwithstanding the question of the order of the $^4E_g(2)$ and $^4B_{2g}$ levels in the compounds referred to above, our observations of only one band (at 7750 cm^{-1}) Pt–Co^{II}–Pt in the 4500–12,500 cm^{-1} region shows that the ligand field distortion experienced by the cobalt(II) ion in this compound is large, and also that the average field is weak. Making the reasonable assumption that here $DQ_{axial} < DQ_{equatorial}$, we assign the 7750 cm^{-1} band to the transition to $^4E_g(2)$. That to $^4B_{2g}$ either lies below 4500 cm^{-1} or is very weak and is obscured by the vibrational bands in 4500–5250 cm^{-1} region. (The reverse assignment would require a very low value for the equatorial ligand field produced by the exocyclic oxygen atoms.)

Our assignments of the other bands are given in Table 2. The weakness of the transition to $^4B_{1g}$ is as expected,[38] as are the relative intensities of the bands assigned to $^4E_g(3)$ and $^4A_{2g}(2)$. The splitting of the original $^4T_{1g}(P)$ level is large and is similar to those observed for the strongly tetragonally distorted compounds $[Co\{3(5)\text{-methylpyrazole}\}_4X_2]$ (X = Br, I).[35] (Bands for the iodide, from Ref. 35, are given in Table 2 for comparison.)

Assignment of the spectrum of Pt–Fe^{II}–Pt (Fig. 4c) is straightforward. The ^5E_g level arising for high-spin d^6 in O_h symmetry splits into $^5A_{1g} + {}^5B_{1g}$ in D_{4h}, and the effects of a tetragonal distortion on the spectra of six-coordinate iron(II) complexes are well documented.[35,39] In practice both transitions are generally intense enough for them to be detected in the region where vibrational bands also contribute, though the latter can sometimes reduce the precision with which the band maxima can be determined. Examples of compounds in which the tetragonal distortion is particularly large are FeL_4I_2 [L = 3(5)-methylpyrazole[35] or isoquinoline[39]] and the reported band energies for those compounds are listed in Table 2.

As in the case for the nickel and cobalt analogues discussed earlier, the Pt–Fe^{II}–Pt complex represents a more distorted situation than the quoted reference compounds, so that the lower energy component ($^5A_{1g}$) has moved below the limit of our study (4500 cm^{-1}). This $^5A_{1g}$ level is particularly sensitive to the degree of axial distortion and in the limiting case of the high-spin square configuration, as in the mineral gillespite,[40] it becomes the ground state.

These conclusions about the strongly distorted nature of the iron(II) environment in the Pt–Fe^{II}–Pt complex are supported by its Mössbauer spectrum, measured at 78 K (Fig. 6). This consists of a quadrupole split doublet (the peak asymmetry is attributed to partial orientation of the crystallites in the sample) with quadrupole splitting $\Delta = 2.045 + 0.007$ mm^{-1}, and isomer shift $\delta = 0.952 + 0.07$ mm^{-1} with respect to metallic iron. The δ value is particularly informative as it is significantly lower than those generally found[41] (typically *ca* 1.15–1.4 mm^{-1}) for high-spin iron(II) surrounded by an octahedron of oxygen donors. The observed δ value is not as low as that (0.75 mm^{-1}) reported[42] for the planar FeO_4 unit in gillespite, but is in the range for tetrahedral FeO_4 species[41] (a geometry ruled out by

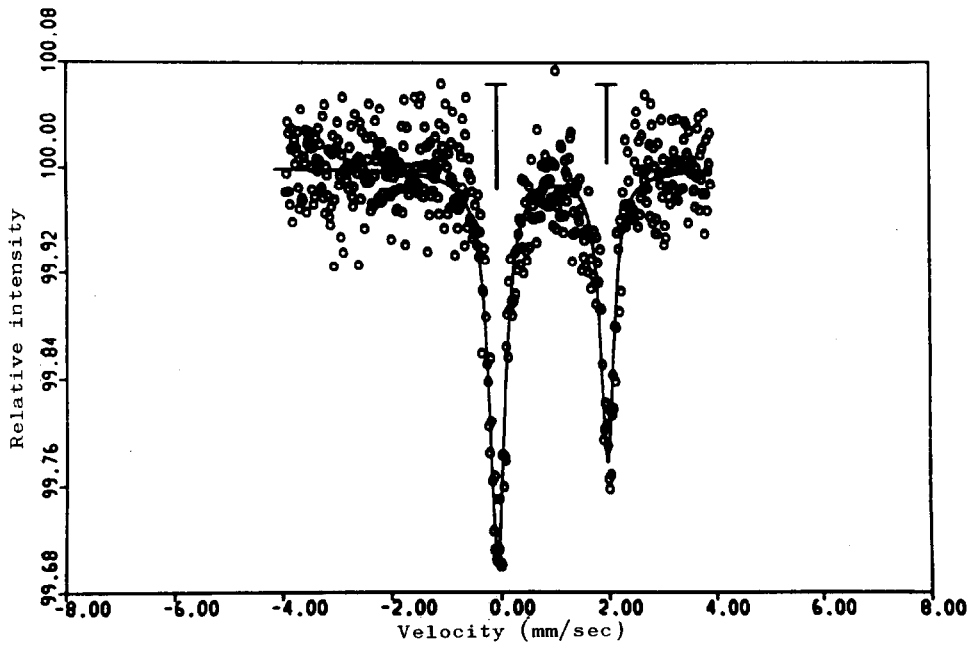

Fig. 6. Mössbauer spectrum (78 K) of *cis*-$[(NH_3)_2Pt(1\text{-MeU})_2Fe(1\text{-MeU})_2\text{-}Pt(NH_3)_2](NO_3)_2 \cdot (H_2O)_6$.

the electronic spectrum) and for very strongly distorted geometries, involving four short Fe–O bonds supplemented by two or more much longer Fe...O distances.[41,43]

The X-band EPR spectrum of a polycrystalline sample of the analogous iron(III) complex consisted of a very strong, asymmetric band in the $g_{eff} = 6$ region and a very weak $g_{eff} = 2$ band, indicative[44] of axial, or nearly axial, symmetry with a large tetragonal distortion (large D), as in the complex *cis*-$[(NH_3)_2Pt(1\text{-}MeT)_2Mn(1\text{-}MeT)_2Pt(NH_3)_2]^{2+}$.[28] The asymmetry in the $g_{eff} = 6$ band suggests that the symmetry about the iron(III) ion is not fully axial ($\lambda \neq 0$). Unlike the Pt–Mn–Pt trinuclear manganese complex, however, the $g_{eff} = 6$ band in Pt–Fe^{III}–Pt was not resolved into two components in the Q-band spectrum. The λ value, representing the rhombic component, must therefore be quite small.

In summary, the electronic spectral results for the Pt–M^{II}–Pt complexes (M = Fe, Co and Ni) substantiate the conclusions drawn from the previous EPR studies in showing a significant axial elongation of the ligand fields experienced by the central metal, M. They would appear to represent some of the most strongly distorted six-coordinate fields known.

ACTINIDE THERMODYNAMIC PREDICTIONS—II. STABILITIES OF ACTINIDE ANIONS IN LIQUID AMMONIA

STEVEN G. BRATSCH and J. J. LAGOWSKI*
Department of Chemistry, The University of Texas, Austin, TX 78712, U.S.A.

(*Received* 2 *July* 1984; *accepted* 25 *August* 1984)

Abstract—The stabilities (as ΔG_f^0) of monatomic actinide anions in liquid ammonia are estimated from a simple electrostatic model. It is shown that, with the possible exception of Md^-, the existence of actinide anions in this solvent is highly improbable.

This paper is the latest of a series concerning the thermodynamic properties of compounds and ions of the actinides.[1] In a previous paper[2] we have employed a simple electrostatic model to evaluate the thermodynamic stability of monatomic lanthanide anions in liquid ammonia solution. We extend our method here to the actinide anions.

The standard Gibbs free energy of formation of a metal anion M^- in liquid ammonia at 298 K is given by:[2,3]

$$\Delta G_f^0(M^-, am) = \Delta G_f^0(M^-, g) + \Delta G_{am}^0(M^-) + 354 \text{ kJ mol}^{-1}. \quad (1)$$

$\Delta G_f^0(M^-, g)$ can be derived from $\Delta H_f^0(M, g)$, the electron affinities EA(M) and the appropriate enetropy terms; these are given in Table 1 for the elements Fr-104 at 298 K. The scaling factor (354 kJ mol^{-1}) is $\Delta G_f^0(H^+, g) + \Delta G_{am}^0(H^+) = 1517.0–1163$ kJ mol^{-1} at 298 K.[2–4]

$\Delta G_{am}^0(M^-)$, the standard Gibbs free energy of solvation of M^- in liquid ammonia, may be estimated at 298 K by:

$$\Delta G_{am}^0(M^-) = -\frac{50.3}{r - 0.017} \pm 8.7 \text{ kJ mol}^{-1}, \quad (2)$$

where r is the crystal anionic radius expressed in nanometers.[2,3] The latter is estimated by:

$$r_{M^-} = \frac{2.41}{q + 14} + 0.190 \text{ nm} \quad (3)$$

where q is the sum of the $5f$ and $6d$ electrons in the anion and ranges from 0 (Fr^-) to 17 (104^-). Equation (3) is analogous to the equation given previously for lanthanide anions;[2] we estimate the radius of a given actinide anion to be 0.010 nm larger than that of the corresponding lanthanide anion.

Calculated values of r_{M^-}, $\Delta G_{am}^0(M^-)$, $\Delta G_f^0(M^-, am)$ and $E^\circ(M/M^-)$ are given in Table 2. The E^0 values are illustrated in Fig. 1. The stability of Fr^- is predicted to be only slightly less than that of Cs^-.[2,3] The latter species has been detected spectroscopically in cyclic ethers and organic amines, but not in liquid ammonia.[5–7]

Thermodynamic stability for a metal anion in liquid ammonia at 298 K requires that $E^0(M/M^-)$ be more positive than the solvated electron potential, which is -1.93 V.[8a] Of all the metal anions considered in this paper, only Md^- might be stable in liquid ammonia. Unfortunately, the uncertainty in the E^0 value is very large (-1.7 ± 1.0 V) and reflects the uncertainty in EA(Md).[1] It is doubtful whether the order of stability of actinide anions will change appreciably in moving from one solvent to another.

The detection of Md^- in any chemical environment would have to be at the tracer level because the half-life of ^{256}Md is only 77 min and a typical experiment might involve a million atoms or less.[9] We suggest two experiments:

(1) Solutions of alkali metals in liquid ammonia might dissolve Md metal as Md^-. Fm metal could be used as a control because Fm^- is not expected to be stable (Table 2).

* Equation (3). † Equation (2). ‡ Equation (1).

§ The quoted uncertainty reflects the cumulative uncertainties in $\Delta H_f^0(M, g)$, $EA(M)$ and eqns (1)–(3).

(2) The similarities in the crystal anionic radii of Md^- (0.276 nm) and Na^- (0.263 nm)[8b] may allow $Na^+C_{222}Md^-$ to cocrystallize with $Na^+C_{222}Na^-$ (C_{222} = 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo [8.8.8]hexacosane).[10] The short half-life of Md would require the development of a rapid crystallization technique. Also, as Na^- has not yet been detected in liquid ammonia,[3] it would be necessary to carry out this experiment in an organic amine.[10]

SYNTHESIS OF NOVEL TERMETALLIC ISOPROPOXIDES

M. AGGRAWAL* and R. C. MEHROTRA†
Chemical Laboratories, University of Rajasthan, Jaipur 302004, India

(*Received* 2 *July* 1984; *accepted* 24 *September* 1984)

Abstract—Novel termetallic isopropoxides are reported which may be represented by the general formulae: $[(Pr^iO)_3M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$, $[(Pr^iO)_2M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]_2$ [where M = Ti(IV), Zr(IV) and Hf(IV)] and $[(Pr^iO)_4M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ [where M = Nb(V) and Ta(V)]. Attempts to synthesize derivatives with the general formula, $[(Pr^iO)_7M_2(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ [where M = Ti(IV), Zr(IV) or Hf(IV)], were unsuccessful and in all such cases a mixture of $M(OPr^i)_4$ and $[(Pr^iO)_3M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ was obtained. All these derivatives are soluble in common organic solvents and with the exception of titanium(IV) derivatives, they can be volatilised without noticeable disproportionation. These products have been characterized by elemental analyses, molecular weights, IR, ^1H NMR and (in representative cases) mass spectral studies also.

Amongst the interesting series of compounds with more than one metallic centre,[1] bimetallic alkoxides which were initially considered as alkoxo salts[2,3] have been shown to be coordination compounds stabilized by alkoxo bridges.[4] Special interest has been aroused in these derivatives by the exceptional stability and volatility of bimetallic alkoxides of strongly electropositive alkali, alkaline earth and lanthanide metals such as $[M\{Zr_2(OPr^i)_9\}]$,[5,6] $[M\{Ta(OR)_6\}]$,[7] $[M'\{Nb(OR)_6\}_2]$[8] and $[M'\{Al(OR)_4\}_2]$,[9] and in $[Ln\{Al(OPr^i)_4\}_3]$[10] (where M = Li, Na, K, Rb, Cs; M′ = Mg, Ca, Sr, Ba; Ln = lanthanides and R = Me, Et, Pr^i, Pr^n, Bu^n etc.) and the same has been sustained by the synthesis of soluble, monomeric, volatile bimetallic alkoxides $[M\{Al(OR)_4\}_2]$ of metals (M = Be,[11,12] Zn,[11] Cd,[11] Hg,[11] Mn,[13] Co,[14] Ni[15] and Cu[16]), the simple alkoxides of which are all insoluble, polymeric, non-volatile compounds. A novel interest in these compounds is indicated by the use of bimetallic μ-oxoalkoxides as catalysts for the polymerization of propylene oxide, lactones, oxiranes, epoxides etc.[17,18]

In view of the interest in stable derivatives[1] with more than two metallic centres, it was considered worthwhile to try to synthesize some termetallic alkoxides with bridging ligands like $[Al(OPr^i)_4]^-$ and $[Zr_2(OPr^i)_9]^-$. The strategy planned for this was to synthesize 1:1 derivatives like $[(Pr^iO)M(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ and replace the terminal isopropoxy group attached to the metal "M" with other chelating alkoxy ligands involving metals other than aluminium. It has already been reported[11] that attempts to synthesize $[(Pr^iO)M(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ derivatives (M = Be, Zn, Cd and Hg) by a reaction of the following type:

$$MCl_2 + 2KOPr^i + Al(OPr^i)_3 \rightarrow [(Pr^iO)M(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + 2KCl$$

gave equimolar mixtures of insoluble $M(OPr^i)_2$ and soluble $[M\{(\mu\text{-}OPr^i)_2Al(OPr^i)_2\}]$ in all other cases except for the case of beryllium, in which a soluble and volatile product $[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ was isolated as a viscous liquid.

The species $[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$, on interaction with isopropoxides of titanium, zirconium, hafnium, niobium and tantalum results in the formation of a number of stable novel termetallic isopropoxides which are being reported for the first time. Amongst the characteristics of these new types of derivatives are their solubility in common organic solvents and volatility (in the majority of the derivatives) on heating under reduced pressure.

EXPERIMENTAL

Stringent precautions were taken to maintain anhydrous conditions throughout the experimental work in view of the extremely hydrolysable nature of

* Present address: Department of Chemistry, SLP College, Morar, Gwalior 474001, India.
† Author to whom correspondence should be addressed.

the newly synthesized derivatives. The general method of synthesis is as follows.

All of these derivatives were synthesized (Table 1) by dissolving each constituent metal alkoxide $Ti(OPr^i)_4$,[19] $Zr(OPr^i)_4 \cdot Pr^iOH$,[20] $Hf(OPr^i)_4Pr^iOH$,[21] $Nb(OPr^i)_5$,[22] $Ta(OPr^i)_5$[22] $[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$[11] in benzene, mixing them together and refluxing the total contents for ~ 1 h in each case. As $[ClBe(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$[23] is insoluble in benzene, its solution was prepared in isopropanol; on adding a benzene solution of $[K\{M_2(OPr^i)_9\}]$[6,24] (where M = Ti, Zr or Hf) to it, an exothermic reaction took place and the white insoluble product (identified as KCl) was separated out in this case by filtration. Excess solvent was stripped off under reduced pressure. With the exception of the titanium derivatives (which disproportionate), the products obtained distil unchanged on heating under reduced pressure (Table 1). All these termetallic derivatives are soluble in common organic solvents, e.g. benzene, chloroform and isopropanol.

Metal estimations (as mixed oxides) were carried out by standard methods.[25] Isopropoxy groups were estimated by dichromate oxidation[26] (Table 1).

IR and ^1H NMR spectra were recorded on a Perkin–Elmer 577 and R-32 spectrophotometer respectively. $CDCl_3$ was made anhydrous by storing over molecular sieves (type 4A) for ~ 24h. TMS was used as internal standard. Mass spectra were recorded on a JEOL DMX-300.

Molecular weights were measured in a semimicro ebulliometer (Gallenkamp) equipped with a thermistor sensor using benzene or isopropanol as solvent.

RESULTS AND DISCUSSION

During the successful synthesis of a 1 : 1 bimetallic isopropoxide of beryllium and aluminium $[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$, it was observed that this derivative exhibits a strong tendency to dimerize even on standing. This has been explained by the tendency of the tri-coordinate beryllium in the monomeric species to attain four-coordinate environment through dimerization.[17]

In view of the above tendency of beryllium atoms, it was conjectured that it might be possible to satisfy it by formation of new bridges with alkoxides of other metals, leading to the synthesis of stable termetallic alkoxides, with three different metals in the same molecule. This has been achieved by carrying out the reactions of the product $[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ with the isopropoxides of titanium, zirconium, hafnium, niobium and tantalum resulting in the preparation of a number of stable novel termetallic isopropoxides for the first time. The results obtained are discussed under the following heads:

Termetallic isopropoxides of titanium, zirconium or hafnium with beryllium and aluminium with the general formulae $[(Pr^iO)_3M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ *and* $[\{(Pr^iO)_2M\{(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2\}_2]$

These derivatives have been synthesized as represented by the following equations:

$$[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + M(OPr^i)_4{}^* \xrightarrow{C_6H_6} [(Pr^iO)_3M(\mu\text{-}OPr^i)_2 Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2], \quad (1)$$
$$(T_1)$$

$$2[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + M(OPr^i)_4{}^* \xrightarrow{C_6H_6} [(Pr^iO)_2M\{(\mu\text{-}OPr^i)_2 Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2\}_2], \quad (2)$$
$$(T_2)$$

where M = Ti(IV), Zr(IV) or Hf(IV).

Both types of derivatives, T_1 and T_2, synthesized as shown above are soluble in common organic solvents (Table 1). In the case of titanium, both the 1 : 1 (T_1) and 1 : 2 (T_2) products are pale yellow viscous liquids which disproportionate on heating under reduced pressure into $Ti(OPr^i)_4$ (45°C/0.05 mm) and $[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ (128°C/0.05 mm). By contrast, the corresponding derivatives in the cases of zirconium and hafnium, both (T_1 and T_2) types can be volatilised unchanged under reduced pressure to colourless viscous liquids at 139 and 137°C for the T_1 derivatives and at 132 and 129°C for T_2 derivatives (all at 0.05 mm pressure), the hafnium products exhibiting slightly lower boiling points compared to zirconium analogues for the both types of derivatives.

Ebullioscopic measurements indicate that the titanium derivative T_1 like all T_2 derivatives exhibits monomeric nature in benzene while their T_1 type zirconium and hafnium analogues depict dimeric behaviour (Table 1); these derivatives, expectedly depict monomeric nature in isopropanol: 683 obs. (616 calc). 698 (659) and 734 (746) for titanium, zirconium and hafnium derivatives respectively.

The above observations can be easily understood on

*In the cases of zirconium and hafnium isopropoxides, their crystalline adducts $M(OPr^i)_4 \cdot Pr^iOH$ were taken, but for simplicity these are represented by the reactive species $M(OPr^i)_4$.

† Disproportionated on heating under reduced pressure.

‡ Undistilled product.

the basis of known differences in the properties of titanium on the one hand and zirconium or hafnium on the other.

Of the termetallic isopropoxides described in Table 1 both the titanium derivatives (T_1 and T_2) disproportionate on heating under reduced pressure yielding volatile $Ti(OPr^i)_4$ (49°C/0.1 mm),[27] but the zirconium and hafnium products (both T_1 and T_2 type distil unchanged around 129–139°C/0.05 mm.

In fact, the extraordinarily low boiling point of $Ti(OPr^i)_4$ might actually facilitate the dissociation of termetallic isopropoxides, which might be represented by the following types of equilibria:

$$[(Pr^iO)_3Ti(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] \rightleftharpoons [Pr^iOBe(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + Ti(OPr^i)_4,$$

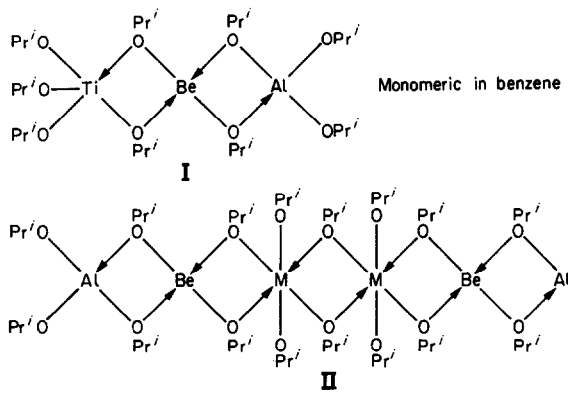
$$[(Pr^iO)_2Ti\{(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2\}_2] \rightleftharpoons 2[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + Ti(OPr^i)_4.$$

It appears that the extent of dissociation even in the titanium species (Table 1) is insignificantly low under ambient conditions to be detected by the traditional molecular weight measurements (which normally have an accuracy of ±5%), but during attempts to distil these products under reduced pressure, the equilibrium is gradually shifted to the right as the comparatively more volatile titanium isopropoxide is removed by distillation.

Conversely, the higher volatility of the termetallic T_1 isopropoxides of zirconium and hafnium [e.g. b.ps for T_1:Zr derivative, 139°C/0.05 mm, Hf derivative 137°C/0.05 mm as compared to the constituent simple isopropoxides (b.ps: $Zr(OPr^i)_4$, 172°C/0.35 mm and $Hf(OPr^i)_4$, 170°C/0.35 mm][20,21] would tend to shift the equilibria preferably to the formation of termetallic species as shown below:

$$[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + M(OPr^i)_4 \rightleftharpoons [(Pr^iO)_3M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2], \quad (T_1)$$

$$2[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + M(OPr^i)_4 \rightleftharpoons [(Pr^iO)_2M\{(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2\}_2], \quad (T_2)$$

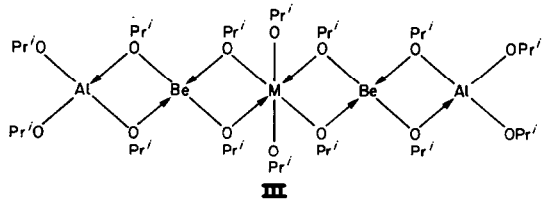


where M = Zr(IV) or Hf(IV).

The slightly higher boiling points of T_1 than T_2 derivatives may easily be understood by the observed dimeric nature of T_1.

The slightly lower boiling points of hafnium compared to zirconium ternary analogues are similar to the earlier reported[21] differences in boiling points of simple alkoxides of the two metals.

IR spectra of these derivatives mainly depict absorptions in four regions of interest, i.e. 1175–930 cm^{-1} {four or five [very strong (vs) or strong (s)] absorptions}: 850–800 cm^{-1} {two [vs, s or medium (m)] absorptions}: 770–630 cm^{-1} {three or four [vs, s or m] absorptions} and 630–530 cm^{-1} {two [vs, s, m or weak] absorptions}, which have been assigned [27–30] to ν_{OPr^i}, ν_{Be-O}, ν_{Al-O} and ν_{M-O}, are indicative of different modes of bonding. Though no definitive assignments have been made yet in general the higher ones are assignable to terminal while lower ones to bridging groups.[27–30]



On the basis of the above discussions, the following tentative structures (I–III) may be proposed for these derivatives:

I

Dimeric in benzene M = Zr(IV) or Hf(IV)

II

Monomeric in benzene M = Zr(IV) or Hf(IV)

III

* Solvent $CDCL_3$: m, multiplet; d, doublet; B, bridging; T, terminal.

† Overlapped each other and appeared to be a triplet.

‡ Integration could not be differentiated between bridging and terminal groups.

The ^1H NMR spectral data of all the products of the T_1 and T_2 (Table 2) show that as expected the spectra for zirconium and hafnium derivatives are similar in nature. In all the cases for T_1 derivatives, signals due to methine protons appear as the septets centred at 4.85 and 4.30 δ for titanium; and at 4.15 δ for zirconium as well as hafnium derivatives; these are as usual not so well defined. However, the methine protons in the spectrum for the titanium derivative T_1 (Table 2) showed rather a clear separation of almost two septets centred, as indicated above at 4.85 and 4.30 δ, with an integration ratio of $\sim 4:5$ in accordance with the structure I for the same. The absorptions occurring in the higher side may be assigned to terminal groups.[31–33] The relative ratio of the methyl signals (Table 2) assignable to terminal and bridging isopropoxy groups are in general (although not exact) conformity with the tentative structures suggested for the T_2 products except in the spectrum of titanium (T_2) product (Table 2) in which case a symmetrical unresolved spectrum only could be recorded. This might indicate the presence of more than one species, presumably due to dissociation of

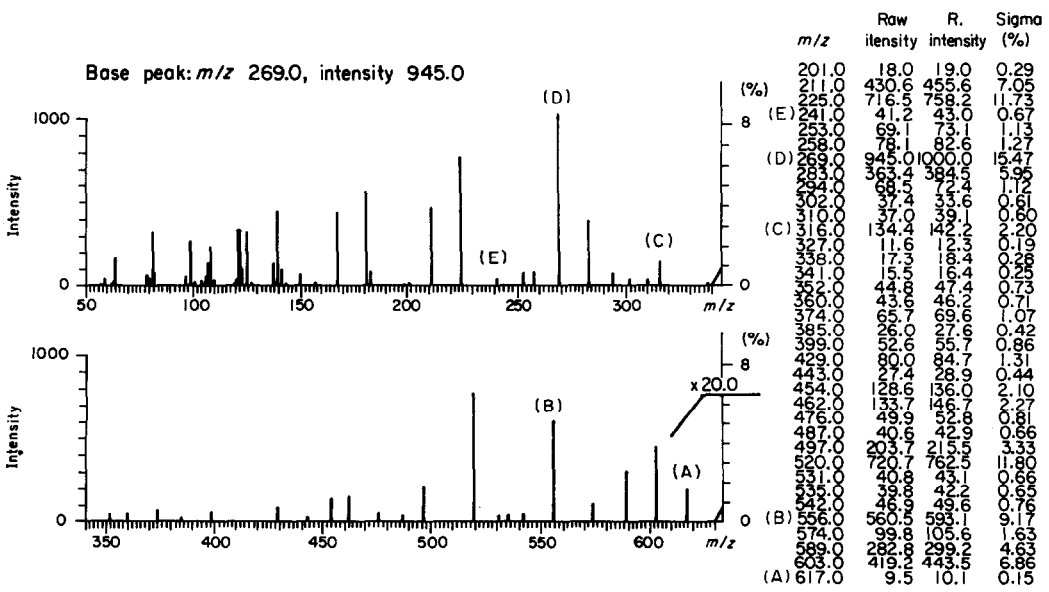

Fig. 1. Mass spectrum of $[(Pr^iO)_3Ti(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$.

this product to some extent, even at ambient temperatures (which might not be detectable by the ebullioscopic method) may be ascribed to the steric strain produced on the central titanium atom bonded to six isopropoxy groups. Thus, the pmr spectra also support the proposed structures for these derivatives.

Mass spectral studies of the product $[(Pr^iO)_3Ti(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ have been carried out and tentative assignments have been made. The mass spectral data of the derivative exhibited (Fig. 1) a weak signal of molecular ion at 617* (A) [molecular weight M = 615; (M + 2H)] and an intense signal at 556*(B) [M − 59(OPr^i)] (a usual fragment reported in isopropoxy derivatives of metals).[34–37] The identity of the termetallic product is also corroborated[37] by non-appearance of signals for the constituent alkoxides at 331* $[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ or at 284* $[Ti(OPr^i)_4]$. However, signals at 316*(C) [331 − 15(CH$_3$)], 269*(D) [(284 − 15(CH$_3$)] and 241*(E) [(284 − 43(Pr^i)] etc. were observed in notable intensity. These would have resulted either as fragments from termetallic species or could be due to fragmentation of products resulting from slight dissociation of the parent derivative to its constituent alkoxides. Assignments of other signals have been deliberately avoided as these would be more speculative in nature.

Attempted syntheses of the derivatives with the general formula $[(Pr^iO)_7M_2(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ *(where* M = Ti(IV), Zr(IV) *or* Hf(IV)

By analogy with the derivatives of the general formulae $[K\{Zr_2(OPr^i)_9\}]$[6] or $[Mg\{Zr_2(OPr^i)_9\}_2]$[38] etc. the synthesis of the derivatives with the composition $[(Pr^iO)_7M_2(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ was also attempted as represented by the following two different routes:

Instead of obtaining a single compound T_3 as represented by eqn (3) or (5), mixtures of two products were obtained in both the cases as represented by eqns (4) and (6); this was indicated by the observed apparent molecular weights of these products being almost half the theoretical values for T_3. Attempts were made to separate both constituents by dissolving them in limited amounts of isopropanol. The tetraisopropoxide isopropanolates, $M(OPr^i)_4 \cdot Pr^iOH$ (M = Zr or Hf) crystallized out in the cases of the zirconium and hafnium derivatives, eqns (4) and (6), due to their poor solubility in isopropanol; the remaining products were identified as derivatives T_1 as shown above. However, $Ti(OPr^i)_4$ could not be separated in the case of titanium derivative as it does not form a sparingly soluble isopropanolate. When the complex T_3 was heated under reduced pressure, it disproportionated and the total $Ti(OPr^i)_4$ contents distilled out 45°C/0.05 mm) followed by $[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ (128°C/0.05 mm).

Termetallic isopropoxides of niobium or tantalum with beryllium and aluminium with the general formula $[(Pr^iO)_4M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$

These derivatives have been synthesized by the interaction of $Nb(OPr^i)_5$ or $Ta(OPr^i)_5$ with $[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ in 1 : 1 molar ratios as indicated by the equation:

$$M(OPr^i)_5 + [(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] \xrightarrow{C_6H_6} [(Pr^iO)_4M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2], \quad (T_4)$$

where M = Nb(V) or Ta(V).

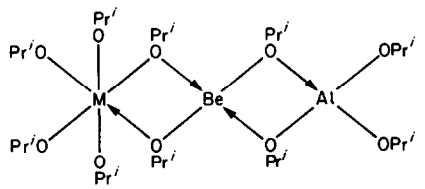
The derivatives T_4 could be distilled (Table 1) unchanged as colourless viscous liquids in almost quantitative (85–92%) yields at 112 and 120°C respectively at 0.05 mm for the niobium and

$$[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + 2M(OPr^i)_4 \text{*} \xrightarrow{C_6H_6} [(Pr^iO)_7M_2(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] \quad (T_3) \quad (3)$$

$$(T_3) \xrightarrow{C_6H_6} [(Pr^iO)_3M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + M(OPr^i)_4 \quad (T_1) \quad (4)$$

$$[Cl\,Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + [K\{M_2(OPr^i)_9\}] \xrightarrow{Pr^iOH} [(Pr^iO)_7M_2(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + KCl\downarrow \quad (T_3) \quad (5)$$

$$(T_3) \xrightarrow{C_6H_6} [(Pr^iO)_3M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2] + M(OPr^i)_4 + KCl\downarrow \quad (6)$$



where M = Ti(IV), Zr(IV) or Hf(IV).

* See footnote to eqn (2).

tantalum derivatives. Both these derivatives are soluble in benzene in which they are monomeric.

IR spectra of these complexes are similar to those of T_1 and T_2 derivatives, showing terminal and bridging ν_{OPr^i}, ν_{Be-O} and ν_{Al-O} in the same regions. ν_{Nb-O} and ν_{Ta-O} absorptions have also been observed in the expected regions [for T_4: 560vs, 530vs; 580m, 530w for Nb(V) and Ta(V) derivatives respectively], the higher ones being assigned to terminal and the lower ones to bridging isopropoxy groups.[27–30]

On the basis of molecular weight and IR spectral data, the derivatives T_4 could be assigned the following plausible structure:

IV

M = Nb(V) or Ta(V)

The ^1H NMR spectrum of $[(Pr^iO)_4Nb(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ (Table 2) appears to be in conformity with the above plausible structure. The methine signals appear in the form of two septets at δ-values of 4.95 and 4.35 in the ratio of $\sim 2:3$. Similarly the methyl signals appear in the form of two doublets centred at values of 1.47 and 1.33 in the ratio of $\sim 2:3$. For the tantalum analogue, the two septets for methine protons appeared (Table 2) at δ-values of 4.80 and 4.17 again in the ratio of $\sim 2:3$, which also corroborates with structure **IV**.

The methyl protons in the pmr spectrum of the latter tantalum product T_4, $[(Pr^iO)_4Ta(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$, however, are more complicated (Table 2). Although exact integration for terminal and bridging groups was not possible individually yet the spectrum could be considered to be consisting of two doublets centred at 1.40 and 1.28 δ with considerable overlapping at 1.21 and 1.14 δ in the ratio of roughly 2:3. Similar differences have been recorded[39] in the ^1H NMR spectra of niobium and tantalum pentaisopropoxides. The spectrum of tantalum penta-isopropoxide[39] showed three doublets in the methyl portion of the spectrum and nineteen peaks (about three septets) in the methine portion of the spectrum, in contrast to that of niobium penta-isopropoxide, which gave only a broad methine signal at 4.70 δ and an averaged doublet due to methyl portions at 1.20 δ.

Mass spectral studies have also been carried out in the case of $[(Pr^iO)_4Nb(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$. The mass spectral data of this derivative exhibited (Fig. 2) a molecular ion peak at 717*(A') [molecular weight M = 719; (M − 2H)] followed by a weak signal at 704*(B') [M − 15(CH_3)] and an intense signal at 660*(C') [M − 59(OPr^i)] which supported formation of the product.[35–38] Other notable signals can be tentatively explained as arising from the fragmentation of termetallic derivative according to the following assignments:

* *m/z* values.

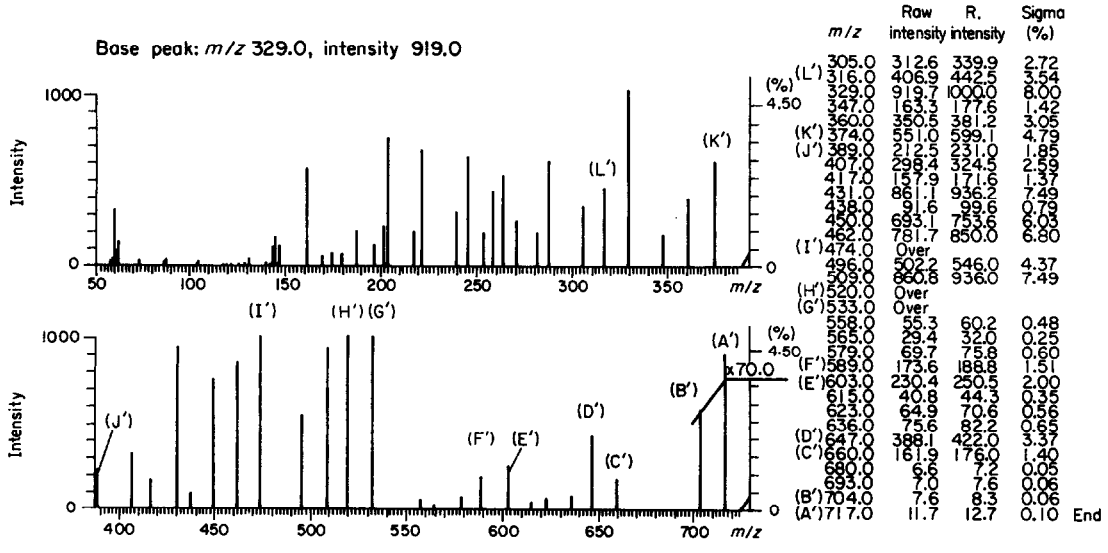


Fig. 2. Mass spectrum of $[(Pr^iO)_4Nb(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$.

647*(D') [M − 59(OPr^i) − 13(CH)], 603*(E') [647(Pr^i + 1H)], 589*(F') [603 − 14(CH_2)], 533*(G') [589 − 56(C_4H_8)], 520*(H') [533 − 13(CH)], 474*(I') [533 − 59(OPr^i)], 389*(J') [388{Nb(OPr^i)$_5$} + 1H], 374*(K') [388 − 14(CH_2)] and 316*(L') [331 − 15(CH_3)] etc. It may be emphasized that the spectrum did not exhibit signals for the constituent alkoxides, i.e. at 331* for [(Pr^{i}O)Be(μ-OPr^i)$_2$Al(OPr^i)$_2$] or at 388* for Nb(OPr^i)$_5$ which corroborates the identity of T_4 and shows that the termetallic product is not merely a mixture of the constituent alkoxides.[37]

Acknowledgements—We are grateful to Dr P. Ramachandran, Director, Defence Research and Development Establishment, Gwalior for providing facilities for spectroscopic studies at his Centre. A Teacher Fellowship to one of the authors (M.A.) by the University Grants Commission is also gratefully acknowledged.

DIOXOURANIUM(VI) COMPLEXES OF SOME SULPHUR DONOR LIGANDS

A. O. BAGHLAF,* M. ISHAQ, O. A. S. AHMED and M. A. AL-JULANI
King Abdulaziz University, College of Science, Department of Chemistry, P.O. Box 9028, Jeddah, Kingdom of Saudi Arabia

(*Received* 13 *March* 1984; *accepted after revision* 26 *September* 1984)

Abstract—Complexes of uranyl chloride and uranyl nitrate of the type $UO_2X_2 \cdot 2L$ and $[UO_2X_2 2L']$, where X = Cl or NO_3 and L = *N,N'*-tetramethylthiourea (TMTU); *N,N'*-dimethylthiourea (DMTU); monomethylthiourea (MMTU), monoethylthiourea (METU), pyridine-2-thiol (PYT) and L' = 4,6-dimethylpyrimidine-2-thiol (PYMT), have been prepared. The complexes were characterised on the basis of IR spectroscopy and by elemental analysis. In some cases Raman spectra are also reported.

Although there is a considerable amount of information available on coordination complexes of *d*-transition metals with ligands containing sulphur as the donor atom,[1] very little work has been reported on actinide complexes with such ligands. Among the ligands, sulphur donor substituted thiourea complexes of molybdenum carbonyl of the type $Mo(CO)_5L$ have recently been reported from these laboratories.[2] In our continued research into the nature of chemical bonding in such systems, we now report the preparation and characterisation of uranyl chloride and uranyl nitrate complexes with substituted thiourea as well as other ligands such as pyridine-2-thiol and 4,6-dimethylpyrimidine-2-thiol. Since these ligands are known to exist in the tautomeric form, the ambidentate nature of these ligands on coordination cannot be overlooked.

The IR spectra of these complexes show that the mode of metal–ligand coordination is through sulphur in the case of substituted thioureas and in pyridine-2-thiol, whereas in the case of 4,6-dimethylpyrimidine-2-thiol the possibility of coordination through nitrogen cannot be entirely ruled out. The complexes have the composition $UO_2X_2 \cdot 2L$ (where X = Cl or NO_3 and L = substituted thioureas or pyridine-2-thiol) and $[UO_2X_2 \cdot 2L'] \cdot H_2O$ (where L' = 4,6-dimethylpyrimidine-2-thiol).

EXPERIMENTAL

Materials

UO_2Cl_2 and $UO_2(NO_3)_2 \cdot 6H_2O$ were obtained from B.D.H. Chemicals Ltd, U.K. Methyl, monoethyl, *N,N'*-dimethyl-, *N,N'*-tetramethylthioureas, pyridine-2-thiol and 4,6-dimethyl pyrimidine-2-thiol were purchased from Aldrich Chemical Co. and were used without further purification. Ethanol and other solvents were dried by conventional methods before use.

Physical measurements

IR spectra were measured (KBr pellets or nujol mulls) using a Perkin–Elmer Model 683 IR spectrophotometer. Raman spectra of powdered samples were recorded using a Cary 82 Laser Raman spectrometer.

Elemental analyses. These were carried out by the Microanalysis Laboratory of King Abdulaziz University, Jeddah.

Preparation of the compounds

Preparation of $UO_2Cl_2 \cdot 2TMTU$. The complex was prepared by dissolving UO_2Cl_2 (100 mg/0.29 mmol) and TMTU (77 mg/0.58 mmol) separately in absolute ethanol. On mixing the two solutions a yellow solution was obtained which was stirred for

1 h at room temperature. The solvent was reduced to a minimum volume under vacuum and left overnight, giving an orange crystalline solid. This was washed twice with carbon tetrachloride and finally dried under vacuum.

Preparation of $UO_2(NO_3)_2 \cdot 2PYT$. This complex was prepared by dissolving $UO_2(NO_3)_2 \cdot 6H_2O$ (100 mg/0.2 mmol) and pyridine-2-thiol (44 mg/0.4 mmol) separately in absolute ethanol. The solutions were then mixed and stirred for about 2 h at room temperature. The colour of the solution changed to orange red. The solvent was reduced to minimum volume under vacuum and left overnight, giving a red crystalline solid. This was washed twice with carbon tetrachloride and finally dried under vacuum.

The rest of the compounds shown in Table 3 were prepared by the same general method by taking the uranyl salt and the corresponding ligand in a 1:2 mole ratio respectively.

RESULTS AND DISCUSSION

The nature of the NO_3 *ion*

The NO_3 ion of D_{3h} symmetry has four fundamental vibrations, three of which are IR active, $\nu_2(A_2)$, $\nu_3(E)$ and $\nu_4(E)$, while $\nu_1(A)$, $\nu_3(E)$ and $\nu_4(E)$ are Raman active. On coordination, its three-fold symmetry is lost giving C_{2v} symmetry when all six normal modes of vibration become IR active[3] as shown in Tables 1 and 2.

The nature of the UO_2^{2+} *ion*

The linear ion UO_2^{2+} has $D_{\infty h}$ symmetry with four normal modes of vibration. The non-degenerate, symmetric stretching frequency ν_1 is IR forbidden but is Raman active and appears at 871 cm^{-1} in UO_2Cl_2, while the non-degenerate antisymmetric stretching frequency ν_3 is IR allowed and occurs at 960 cm^{-1}.[2] Thus bands at 912 and 922 cm^{-1} can be assigned for $UO_2Cl_2 \cdot 2TMTU$ and $UO_2(NO_3)_2 \cdot 2TMTU$ respectively. These two bands are absent in the Raman spectra. In contrast, the bands at 820 and 840 cm^{-1} in the Raman spectra can be assigned for $UO_2Cl_2 \cdot 2TMTU$ and $UO_2(NO_3)_2 \cdot 2TMTU$ (non-degenerate, symmetrical stretching, frequency ν_1) respectively. See Table 4.

The nature of the C=S *stretching frequency*

The IR spectra of thiourea and *N*-methylthiourea complexes of transition metals have been reported.[4,5] Most of the internal ligand vibrations are mixed, the spectra are difficult to assign, and the mode of coordination is often uncertain. Lane and coworkers[6] have suggested that in *N*-methylthiourea complexes of Zn(II) and Cd(II) the mode of coordination to the metal is through sulphur, while in cases of Pd(II), Pt(II) and Cu(I) it is through a nitrogen atom. Two or three closely spaced bands usually appear near 1490 cm^{-1} in the spectra of the ligands. One contains some C=S stretching character and all of them C—N modes. If one of these bands shows an increase in frequency, coordination through the S atom could be indicated, in which case the band at 1060 cm^{-1}, with considerable C=S character, should show a large decrease in frequency. While both these changes are sometimes observed, in others the 1060 cm^{-1} vibration decreases in frequency only slightly. A band around 1120 cm^{-1} said to contain CN

Table 2. Tentative assignments of NO_3 vibrations (cm^{-1})

symmetrical stretching and N—CH_3 rocking character usually shows a small decrease in frequency. In the absence of pure C=S and C—N vibrations it is difficult to assign confidently the mode of coordination of the ligand. However, Schafer and Curran[7] have suggested for tetramethylthiourea complexes that an increase in the frequency of the 1504 cm^{-1} band (which they claim is mainly due to N—C—N antisymmetrical stretching vibration) and a decrease in the frequency at ν 1126 cm^{-1}, which is mainly due to a C=S band, means that the ligand–metal coordination is through sulphur. A similar trend showing M—S bond has been reported recently with substituted thiourea complexes of the type $Mo(CO)_5L$[2] (see the IR spectra of the complexes in Table 4).

The nature of the U—S *stretching frequency*

Far IR spectra of complexes showing a metal–sulphur bond feature have been reported[8] but the uranium–sulphur stretching frequency was not detected in these complexes. Presumably the U—S bond is long and therefore weak.

Uranyl–pyridine-2-thiol complexes. Pyridine-2-thiol is known to exist in a tautomeric form as "thione", as shown in Fig. 1(a).[9] Its complexes with various metals have also been reported.[10,11]

The IR spectra of all uranyl–pyridine-2-thiol complexes show that the "thione" form predominates and the coordination with the metal uranium is through sulphur. These findings are based on the following observations: (a) the N—H stretching feature in the complexes is more distinct and occurs ~ 25 cm^{-1} higher than that in the free ligand; and (b) the νC=S stretching feature is ~ 10 cm^{-1} lower as compared to the free ligand.

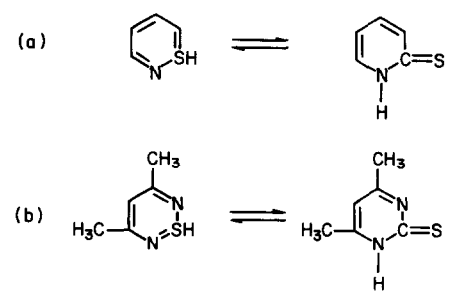

Fig. 1. Tautomeric structure of: (a) pyridine-2-thiol and (b) 4,6-dimethylpyrimidine-2-thiol.

However, uranyl–4,6-dimethylpyrimidine-2-thiol complexes do not show any noticeable change in νC=S frequency while the typical band in the region of 1600–1400 cm^{-1} which are due to the "ring breathing" modes, show very broad strong bands. Therefore the possibility of its coordination to the metal through one of the *N* atoms cannot be ruled out. Also, the presence of a broad and strong band around 3600–3500 cm^{-1} may be due to the free H_2O in these complexes.

Abstract—Stability constants of copper(II) complexes formed by 2-(2′-carboxymethylthiophenylazo)-5-nitrotoluene in dioxane–water solvent mixtures of several different compositions [50, 60 and 75% dioxane (v/v)] were determined from EMF measurements, at 25°C and 0.1 mol dm^{-3} $NaClO_4$ ionic medium. Graphical treatment of experimental data gives for the equilibria $nA^- + Cu^{2+} = CuA_n^{(2-n)+}$ ($n = 1$ or 2), in a solvent with $X\%$ (v/v) dioxane, the following values of $\log \beta_1$ and $\log \beta_2$ (given here successively). $X = 50$: 2.41, 6.77; $X = 60$: 3.36, 7.45; $X = 75$: 4.33, 7.64. The relation between solvent composition and the values found for the stability constants is discussed. From EMF measurements made with the copper(II) ion-selective electrode, at constant pH, the nature of the effective donor groups in this potentially terdentate ligand is inferred.

The study of metal-complex formation equilibria with the potentially terdentate ligand 2-(2′-carboxymethylthiophenylazo)-5-nitrotoluene raises two kinds of problems: those of a conceptual type, derived from the use of mixed solvents, such as dioxane–water mixtures, required because of the water-insolubility of the ligand and its complexes; and the others, of a structural type, derived from the presence in the ligand molecule of three donor groups, although two of them, the thioether sulphur and the azo bridge, show a relatively low coordinating power towards metal ions.

In a mixed solvent, such as dioxane–water, which contains an organic constituent with a low relative permittivity, changes in the content of this constituent, deeply modify the values of the stability constants of metal complexes. Although the theoretical study of the effect on these values of the composition of binary solvent mixtures has been the subject of relatively little attention, the changes in the stability constants were initially assigned to the variation of the relative permittivity of the medium with the contents of its organic constituent, variation which modifies the electrostatic interactions between the complex formers; the well-known Born equation[1] and other similar expressions[2,3] describe linear correlations between the log of stability constants and the reciprocal of the relative permittivity, or the mole fraction of dioxane in the system. Many experimental results, however, deviate from these correlations. Changes shown by stability constants in binary solvent mixtures, as a consequence, have to be assigned to other causes. Some of them must be mentioned here.

One of them is the change in the ligand protonation constant with solvent composition, already studied in the case of the present ligand;[4,5] another one stems from the changes introduced by the organic constituent in the solvation sphere of the implied ions, especially of the metal ion.[6,7] The hypothesis that ions are solvated virtually only by

* Author to whom correspondence should be addressed.

water molecules is no longer acceptable, since it was shown[8] that dioxane (solvating through its oxygen atoms) can form dioxane solvates or mixed solvates with metal ions, its effect on the anion sphere being much weaker. Furthermore, for a solvated ion in a mixed solvent, the complex formation reactions are substitution equilibria in which ligand molecules displace coordinated solvent molecules: the expressions for the corresponding equilibrium constants must include, besides the activities (or concentrations) of the ions and the complex, those of water and the second solvent.[9,10] This means that different contents in the second solvent can alter the values of the formation constant simply by modifying the concentration of the aqua-complex as a result of the change in the water activity in the system.

It seems, therefore, that the observed effects on the formation constants are due to several concurrent causes whose relative weights depend on the nature of the system under study.[11,12] It is in this context that the experimental determination of the log β variation for the copper(II) ion complexes with 2-(2'-carboxymethylthiophenylazo)-5-nitrotoluene as a function of dioxane content in the solvent has been undertaken. Complex formation can be followed by the usual pH titration technique, using either the glass electrode or a copper(II) ion-selective electrode, or both. The use of the latter at constant pH to obtain free copper(II) concentrations in solutions with different ligand-to-metal ratios gives some insight into the afore-mentioned structural problems, in this case derived from the presence of three potential donor centres in the ligand molecule. Although equilibria studies do not usually afford information of a structural nature, such as, for instance, information about the groups which are effectively acting as donors, in the present case the use of the copper electrode to follow the changes in free-metal ion concentration with changes in ligand concentration while working at constant pH, at suitable pH values, affords direct experimental information on the participation or not in complex formation of the donor groups which are prone to undergo protonation (in the case of the present ligand, the carboxylate ion).

EXPERIMENTAL

Reagents and solutions

2 - (2' - *Carboxymethylthiophenylazo*) - 5 - *nitrotoluene.* Synthethized and purified as described earlier.[5] A 10^{-3} mol dm^{-3} stock solution in anhydrous dioxane was prepared and titrated as in ref. [13].

Sodium perchlorate, sodium hydroxide, copper(II) *perchlorate, dioxane and other reagents.* Grade, preparation and standardization as described in ref. [13].

Apparatus

Metrohm compensator potentiometer, E 368 (precision ± 0.1 mV). Indicator glass electrode combined with a calomel reference electrode (Radiometer GK 2311C), with salt bridge containing 0.1 mol dm^{-3} NaCl solution in dioxane–water (with the same dioxane content as the test solution). Copper(II) ion-selective electrode (Orion, 94-98A). Indicator electrodes calibration was performed without buffer solutions by application of Gran's technique to the proper test solutions. Titration cell, which includes pure-nitrogen inlet and outlet, and magnetic stirring, was thermostatted at 25 ± 0.1°C.

Procedure

Complex formation equilibria in the system copper(II) ion and 2-(2'-carboxymethylthiophenylazo)-5-nitrotoluene in dioxane–water mixed solvents with different dioxane contents [50, 60 and 75% (v/v)] were studied through EMF measurements along the course of titrations performed in an ionic medium containing 0.1 mol dm^{-3} $NaClO_4$, at 25.0 ± 0.1°C, under a nitrogen atmosphere (N_2 purified by bubbling through an acidic vanadium solution and through sodium hydroxide solution, and equilibrated with a solution of the same ionic medium in the same mixed solvent as the test solution). EMF measurements were performed according to one of the following procedures.

Procedure A. A volume, V_o of the test solution (TS), with the following initial composition:

TS = $A_o$mol dm^{-3} HA, H_o mol dm^{-3} H^+,

B_o mol dm^{-3} $Cu(ClO_4)_2$, 0.1 mol dm^{-3} $NaClO_4$

is titrated with a sodium hydroxide solution, T_1 (aqueous solution, containing the proper concentration of $NaClO_4$). During the titration, ionic medium, solvent composition, total copper(II) concentration and total ligand (designed in the following HA) concentration are kept constant by adding from burettes, after each titrant addition, suitable volumes of a copper ion aqueous solution, T_2, and of a ligand solution T_3 in anhydrous dioxane. The free hydrogen ion concentration is measured from a reading obtained with the glass electrode (GE, cell I); the free copper(II) ion concentration with an ion-selective electrode (Cu–SpE, cell II). Both indicator electrodes are soaked in the same TS

solution, against the same reference electrode, RE:

Cell I GE/TS//0.1 mol dm^{-3} NaCl/RE

Cell II Cu–SpE/TS//0.1 mol dm^{-3} NaCl/RE

Before starting the titration, the initial hydrogen ion concentration H_o and standard electrode potential for the glass electrode, E°_H, are determined according to Gran's method:[14] a volume of a 0.1 mol dm^{-3} $NaClO_4$ solution in dioxane–water, slightly acidified with perchloric acid, is titrated with sodium hydroxide solution; then, the copper(II) ion selective electrode is standardized through emf measurements after successive additions into the former solution of small volumes of a standard solution of copper(II) perchlorate. Finally, the suitable volume of ligand solution is added, and the TS solution is now ready for titration with T_1 NaOH solution. Reversiblity of equilibria involved in establishment of electrode potential was checked by the usual technique[13] of "back titration" with an acid solution until the initial point was reproduced. Absence of polynuclear species was proved from titrations of several TS solutions covering a range of metal-to-ligand concentration ratios from 0.076 to 0.32 (a wider range was not used because of solubility limitations).

Procedure B. A cell similar to cell II is used, with a test solution TS containing copper(II) ion, but no ligand. This solution is titrated at constant pH with a ligand solution T_1. During the titration, solvent composition [a mixed solvent with 60% (v/v) dioxane was only used], ionic medium, total copper(II) ion concentration and free hydrogen ion concentration are kept constant through addition of suitable volumes (after each titrant addition) of a T_2 copper(II) ion solution and a T_3 hydrogen ion solution, containing both suitable concentrations of ionic medium and dioxane. Before starting titration, free acid in TS solution is determined, and both indicator electrodes (glass electrode only to be used to check pH constancy) are standardized by Gran's method, as described.

In both procedures, A and B, emf measurements are taken, after each titrant and associated additions, when equilibrium is reached, i.e. when potential readings reach stable values. Stabilization of electrode potentials was achieved in every case within less than 5–7 min.

DATA TREATMENT

Procedure A: glass electrode measurements

The experimental values $(V_{T_1}, E_H)_{A_o,B_o}$ obtained from the titrations of the TS with sodium hydroxide (T_1 solution) are transformed into the pairs $(\bar{n}, \log a)_{A_o,B_o}$ in order to build the formation curve which corresponds to each experiment. Calculation details have been described elsewhere.[13] The free hydrogen ion concentration, h, is calculated from the expression $E_H = E^\circ_H - g \log h$ ($g = 59.16$ mV at 25°C). E°_H values for the indicator glass electrode in the different mixed solvents, obtained from standardization according to Gran's technique, are given in Table 1. In Table 1 experimental data from some typical titrations are collected; in Figs 1–3 the evaluated formation curves are shown.

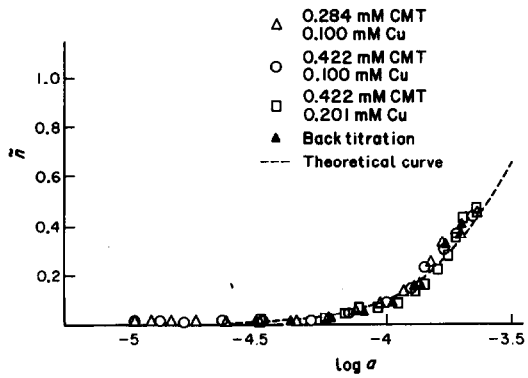

Fig. 1. Formation curve for the system 2-(2'-carboxymethylthiophenylazo)-5-nitrotoluene (CMT)–copper(II) ion in 50% (v/v) dioxane–water.

Data pairs $(\bar{n}, \log a)$ have been treated graphically by a curve-fitting method[15] and by a method of elimination introduced by Schwarzenbach,[16] according to usual procedures, as already described,[13] under the assumption that only the 1:1 and 1:2 complexes are formed. Figure 4 shows the bundle of straight lines resulting from application of the Schwarzenbach method to the data obtained for the present system in a solution in 75% (v/v) dioxane–water.

Procedure A: copper(II) ion-selective electrode measurements

Titrations of TS with sodium hydroxide are performed after checking the Nernstian behaviour of the copper(II) ion-selective electrode and determining its standard potential, E°_{Cu} (its values in the different solvent used are given in Table 2, where the experimental results from several typical titrations are collected). From the measured E_{Cu} for this electrode in each point of the titrations, the free copper(II) ion concentration, b, is first calculated from the expression $E_{Cu} = E^\circ_{Cu} - g \log b$ (where $g = 29.6$ mV at 25°C) and then the numerical value of the function $\eta = \log (B/b)$ (where B is the analytical total metal ion concentration) is evaluated. If only 1:1 and 1:2 complexes co-exist in solution, the

expression $10^{n} = B/b = 1+\beta_1 a+\beta_2 a^2$ holds, from which it is seen that, if a linear plot of B/b vs a is obtained, the 1 : 1 complex is strongly predominant in the solution, whereas a linear plot of B/b vs a^2 shows the predominancy of the 1 : 2 complex. In the general case of co-existence of noticeable amounts of both complexes, this expression can be put in the form $(B-b)/ab = \beta_1+\beta_2 a$, which shows that the plot of the left term vs a will be linear, and that β_2 can be evaluated from the slope and β_1 from the intercept of the resulting straight line.

In the calculation of the free ligand concentration, a, allowance must be made for the fraction of non-bound-to-copper ligand which is bound to hydrogen ion. Under the assumption that, under the experimental conditions used, the concentration of 1 : 1 species is, in a first approximation, negligible in comparison with that of the 1 : 2 species (assumption justified by the type of formation curves obtained in applying the curve-fitting method), the con-

centration of non-bound-to-copper ligand is: $[A^-]+[HA] = A_{tot}-2(B-b) = a+\beta_H ha$, where β_H is the protonation constant of the ligand. Consequently, and within the field of validity of the former assumption, the free ligand concentration (non-bound-to-copper, unprotonated) is: $a = [A_{tot} - 2(B-b)]/(1+\beta_H h)$.

Figures 5 and 6 show the plots of $(B-b)/ab$ vs a

and B/b vs a^2, for the system under study, in several dioxane–water solvents: (a) 50% (v/v) dioxane; (b) 60% (v/v) dioxane, and (c) 75% (v/v) dioxane.

Procedure B: copper(II) ion-selective electrode measurements at constant pH

In contrast with procedure A, the total ligand concentration is now not constant and must be evaluated for each experimental point. Calculation is made from known initial values and successive titrant and other additions made.

Experiments have been performed at pH 2.59 and 6.35. Data from typical titrations are given in Table 3. In the solvent used in these experiments [60% (v/v) dioxane–water] the acid dissociation constant of the arylthioacetic acid under study is $K_a = 2.95 \times 10^{-6}$ ($pK_a = 5.33$).[5] Thus, in solutions at pH 2.59, free ligand contains the carboxylate group practically only in its protonated form; in solutions at pH 6.35, free ligand is present in both forms, the greater fraction being that in unprotonated form. Let A' be the unprotonated ligand concentration, and A the total ligand concentration: from the expression for K_a it is found that, at pH 2.59, $A' = 1.15 \times 10^{-3} A$, and at pH 6.35, $A' = 0.868 A$.

For data treatment two alternative models can, in

principle, be assumed. In the first one, it is the unprotonated ligand (i.e. the ligand form which contains an anionic carboxylate group) that is assumed to take part in complexation. Since at pH 2.59 its concentration is extremely small, the 1:1 complex will predominate at this pH (unless the formation constant for the 1:2 complex be abnormally high), and the expression $B/b = 1 + \beta_1 a$ will hold. Since the 1:1 complex is not very stable one can, as a first approximation, take $a \simeq A'$. Plotting B/b vs A' does give a straight line (Fig. 7), but its slope yields a value of $\log \beta_1 = 6.21$. This value is too high and strongly deviates from the value previously obtained from the well-proven pH titration method (procedure A).

In the second model to be tested it is assumed that, at pH 2.59, the protonated form HA of the ligand

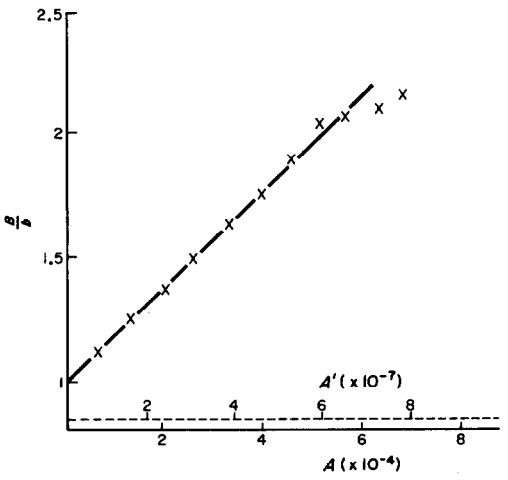

Fig. 7. Plot of the ratio total-metal/free-metal, B/b vs total ligand concentration, A, and unprotonated ligand concentration, A', in 60% (v/v) dioxane–water, at constant pH, 2.59.

is the form involved in copper(II) ion complexation; i.e. the complex formation equilibrium is: Cu + HA ⇄ Cu(HA). In the expression for B/b given before, the total concentration A (or, more exactly, $A - A'$, the true total concentration of protonated ligand) can now be substituted for a. The plot of B/b vs A is a straight line too (Fig. 7), but its slope yields now a value of $\log \beta_1 = 3.27$, which does agree with the value obtained from the procedure A.

Data from experiments performed in solutions at pH 6.35, where ligand fraction in unprotonated form

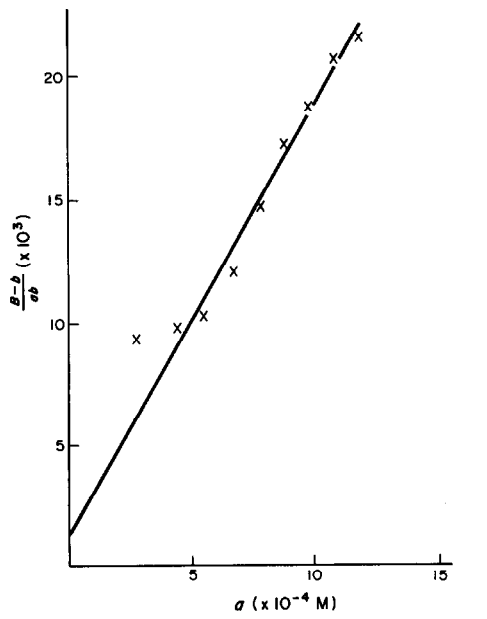

Fig. 8. Plot of the function $(B-b)/ab$ vs free-ligand concentration, a, in 60% (v/v) dioxane–water, at constant pH, 6.35.

Table 4. Overall summary of results for formation constants of copper(II) complexes with 2-(2'-carboxymethylthiophenylazo)-5-nitrotoluene in dioxane–water mixed solvents (0.10 mmol dm^{-3} $NaClO_4$, 25°C)

From glass electrode measurements	From copper(II) ion electrode measurements
(A) In 50% (v/v) dioxane	
$\log \beta_1 = 2.41 \pm 0.01$	$\log \beta_1 = 2.35 \pm 0.15$
$\log \beta_2 = 6.82 \pm 0.02$	$\log \beta_2 = 6.70 \pm 0.08$
(B) In 60% (v/v) dioxane	
$\log \beta_1 = 3.47 \pm 0.01$	$\log \beta_1 = 3.27 \pm 0.13$
$\log \beta_2 = 7.54 \pm 0.02$	$\log \beta_2 = 7.19 \pm 0.07$
(C) In 75% (v/v) dioxane	
$\log \beta_1 = 4.32 \pm 0.02$	$\log \beta_1 = 3.67 \pm 0.30$
$\log \beta_2 = 7.68 \pm 0.04$	$\log \beta_2 = 7.57 \pm 0.14$

is important, show co-existence of both 1:1 and 1:2 complexes. Thus, the plot of $(B-b)/ab$ vs a (as shown in Fig. 8) is a straight line which yields the values $\log \beta_1 = 3.27$ and $\log \beta_2 = 7.24$, as is to be expected from procedure A results.

The values for the stability constants in the different mixed solvents (50, 60 and 75% dioxane) are collected in Table 4.

DISCUSSION

Variation of $\log \beta_i$ *with dioxane content in the mixed solvents*

As is already known,[4] log values of protonation constants for 2-(carboxymethylthiophenylazo)-5-nitrotoluene (in 0.1 mol dm^{-3} $NaClO_4$, at 25°C) in dioxane–water mixed solvents change with dioxane content according to the Born equation. This is not the case with the stability constants of the copper(II) complexes of this ligand in the same ionic medium; neither $\log \beta_1$ nor $\log \beta_2$ show linear variation with the reciprocal of relative permittivity of the solvent; linearity is not observed either as a function of the dioxane mole fraction in the solvent. This behaviour shows, as it has been repeatedly observed,[17,18] although not as a general rule,[19] that complex formation is not governed by electrostatic factors alone. It is observed, however, that the stability of the copper complexes (1:1 and 1:2) grows bigger the higher is the dioxane content in the solvent, paralleling what happens with the observed stability of the proton–ligand complex. This is not a general behaviour of all known systems.[20,22]

Changes in $\log \beta$ [for protonation and copper(II) complex formation] in going through a range of dioxane content from 50 to 75% (v/v) in the solvents, all of them containing 0.1 mol dm^{-3} $NaClO_4$, cannot be assigned to the variation in the ionic strength of the medium caused by the different degree of ionic association which can be present in media with rather different relative permittivities. According to the classical Bjerrum expression for ionic association,[23] on account of the rather high value of the perchlorate ionic radius, ionic association effects in these solutions containing a moderate concentration of background electrolyte are of a minor importance, and their variation with relative permittivity cannot explain the observed deviations from linearity.

Other effects directly deriving from the varying dioxane content in the solvent can modify, even at constant ionic strength, the activity coefficients for the species involved in the equilibria under study, and hence the numerical values of their equilibrium constants. The effect of some solvent properties on the ionic atmosphere can be accounted for using the Davies equation to convert to zero ionic strength the values determined at 0.1 mol dm^{-3} ionic strength. If the value of the ion-size parameter a is taken as equal to 6 for copper(II) ion and to 8 for the arylthioacetate anion and the 1:1 cationic complex, and the appropriate values for the relative permittivity of the solvent mixture are introduced into the Davies equation, ionic activity coefficients can be evaluated. For the complex-forming equilibria (ionic solvation ignored): $M + iL \rightleftarrows ML_i$, the "thermodynamic" stability constants will be given, for the 1:1 complex, by: $\log(\beta_1)_{therm} = \log(\beta_1)_{conc} - \log \gamma_{Cu^{2+}}$, and for the 1:2 complex, by: $\log(\beta_2)_{therm} = \log(\beta_2)_{conc} - \log \gamma_L - 2 \log \gamma_{Cu^{2+}}$. Substitution yields the following values: in 50% dioxane–water, $\log(\beta_1)_{therm} = 3.39$ and $\log(\beta_2)_{therm} = 8.22$; in 60% dioxane–water, 4.73 and 9.47, respectively; and in 75% dioxane–water, 7.03 and 11.66, respectively. These values show a correlation with the reciprocal of relative permittivity which approaches linearity much more than the concentration constants, but it is not yet a linear correlation.

Dioxane content affects too the activity coefficients of both constituents of the solvent, particularly that of water. Since in the complex formation reaction water molecules are displaced by the ligand from the solvation sphere of metal ions, water should not be ignored in the formulation of equilibria and of equilibrium constants. Thus, for the 1:1 complex, the equilibrium would be: $Cu(H_2O)_x^{2+} + L^- \rightleftarrows [Cu(H_2O)_{x-n}L]^+ + nH_2O$, and in the formulation of equilibrium constants, water activity (with activity coefficients which vary from one solvent to another) would be explicitly included.

There are not in the literature the data needed for the evaluation of water activity coefficients in mixed solvents of the type studied here.[24] Another further complicating effect arises from the displacement of water by dioxane in the solvation sphere of the copper(II) ion.[25]

Inferences about the donor groups involved in 1:1 *and* 1:2 *complexes*

The fact that the maximum copper(II) complex detected is the 1:2 complex strongly suggests that the ligand acts as a bidentate one. To elucidate which groups in the ligand molecule effectively act as donors is a difficult matter.

If these groups were the carboxylate anion and the thioether sulphur, stability constants for the 1:2 complexes would be of about the same magnitude as those for other 1:2 copper(II) complexes of aryl- and alkylthioacetates. Since in the literature only a few of these constants are found, obtained from aqueous solutions and at several different ionic strengths, comparison cannot be made in a direct way. By a rough extrapolation of the results obtained here to a zero-dioxane content, an approximate value of $\log \beta_2 = 4.8$ is found, which can be considered to be in agreement with published values.[26]

It is surprising that the results suggest that the azo-group is not involved in the co-ordination of copper(II) ion, when it is well known that this group acts as a co-ordinating centre in the rather stable copper(II) complexes formed by azocompounds with *ortho*-substituents with donor properties. It could be assumed that the present ligand could act as terdentate in the 1:1 complex, the azo group being involved in this complex in the binding of copper ion. When this complex would add a new ligand molecule to form the 1:2 complex, the new carboxylate and thioether groups would displace the azo-nitrogen of the first co-ordinated molecule (and one solvent molecule) from the coordination sphere of copper(II) ion. If this assumption is valid, the stability of the 1:1 complex (which would contain two chelate rings) should be much higher than that of 1:1 copper(II) complexes of aryl- and alkylthioacetates (which form only one chelate ring). In aqueous solution, the latter have $\log \beta_1$ in the range 2.4–2.6; the extrapolation to zero-dioxane content of the results obtained in the present work for the former yields a very much lower value. The extrapolated value is very uncertain but, anyway, the underlying assumption must be rejected.

The lower stability of the 1:1 complex as compared with 1:1 copper complexes of aryl- and alkylthioacetates can be explained from the results obtained from the experiments performed at constant pH [procedure B, copper(II) ion-selective electrode measurements]. As has been shown, the results obtained for $\log \beta_1$ at pH 6.35 agree with those obtained from the acid–base titration technique; in contrast, the interpretation of results from experiments at pH 2.59 offer some difficulty. If it is assumed that at this pH 2.59 the 1:1 complex is predominantly formed (*vide infra*), and that practically all the ligand in the solution is present in its protonated form (its pK_a in 60% dioxane–water solution is 5.53), complex formation will be represented by the equation: $Cu + HA = Cu(HA)$. Under this assumption, data treatment yields a value of $\log \beta_1$ which coincides with that obtained from acid–base titrations. If the carboxyl group is not ionized, it does not participate in binding of copper(II) ion, and complex formation will take place through the thioether-sulphur and the azo-nitrogen donors. If the assumption were made that in the presence of copper(II) ion, this one displaces the carboxylic proton, even at pH 2.59, so that the complex-forming process is: $Cu + HA = CuA^- + H^+$, then, data treatment would require the use of the free unprotonated ligand concentration, and the result for $\log \beta_1 = 6.32$.

It must be noted that in the titrations performed at constant pH 2.59 (using as titrant a ligand solution), the formation degree $\bar{n} = 0.5$ for the system is never exceeded. It is difficult to accept that at this pH under the used conditions the 1:2 complex is formed in any noticeable amount. Experimental data treatment for a two-complex model yields very deficient results for $\log \beta_2$.

SYNTHESIS OF CHLORO-CARBONYL DERIVATIVES OF RHENIUM, RUTHENIUM, RHODIUM, IRIDIUM AND PLATINUM VIA REACTION OF THE METAL ATOMS WITH OXALYL CHLORIDE

PAUL R. BROWN, F. GEOFFREY N. CLOKE and MALCOLM L. H. GREEN*
Inorganic Chemistry Laboratory, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 29 *August* 1984; *accepted* 26 *September* 1984)

Abstract—Co-condensation of atoms of Re, Ru, Rh, Ir and Pt with oxalyl chloride gives metal chloro-carbonyl derivatives which may be used as precursors to the compounds $[Re(CO)_4Cl]_2$, $[Ru(PMe_3)_3(CO)Cl_2]$, α-$[Ru(CO)_3Cl(\mu\text{-}Cl)]_2$, $[Ru(PPh_3)_2(CO)_2Cl_2]$, $[Rh(CO)_2(\mu\text{-}Cl)]_2$, $[Rh(PPh_3)_2COCl]$, $[Ir(PPh_3)(CO)_2Cl_3]$ and *cis*-$Pt(CO)_2Cl_2$. Molybdenum atoms with oxalyl chloride give molybdenum-chloro derivatives.

Atoms of the more refractory transition metals are highly reactive. We have studied their reactions with oxalyl chloride in the expectation that chloro-carbonyl derivatives would be formed. This work is described here: a brief communication of part of this work has already appeared.[1]

RESULTS AND DISCUSSION

Co-condensation of rhenium atoms with oxalyl chloride and extraction of the products with tetrahydrofuran (THF) gave a red–brown solution which contained little unreacted metal. A large quantity of white crystals of the dimer $[Re(CO)_4(\mu\text{-}Cl)]_2$ (**1**)[2] were obtained from the reaction mixture in high yield, > 80%. This reaction represents a very convenient synthesis of **1** on a scale of 5–10 g per experiment.

Co-condensation of ruthenium atoms with oxalyl chloride gave a red THF extract and some insoluble green solid (**2**). When the THF solution was left standing for several days, or was treated with chloroform, a green solid separated. Removal of the THF gave a red oil which gave a green solid upon heating *in vacuo* or when washed with chloroform. The red oil showed bands in the IR spectrum assignable to terminal CO groups at 2150m, 2085s, 2025s and 1960s,br (mull). Due to the inability to further purify the compound it was not further characterised. The IR spectrum (mull) of the green solid (**2**) gave CO stretches at 2142w, 2079s, 2018s and 1970m,br. Microanalysis of the precipitated green solid showed the consistent presence of about 1.8% hydrogen and corresponded approximately to a stoichiometry of $[Ru(CO)_2Cl_2(THF)]_n$. Insolubility and involatility precluded further purification and obtaining NMR and mass spectral data.

Compound **2** was treated with carbon monoxide to give the dimer α-$[Ru(CO)_3Cl(\mu\text{-}Cl)]_2$ (**3**) in good yield. **3** was identified by the mass spectrum and by comparison of the IR spectrum with that of an authentic sample.[3] Treatment of **2** with triphenyl-phosphine gave white, air-stable, crystals of $[Ru(PPh_3)_2(CO)_2Cl_2]$ (**4**).[4]

Co-condensation of rhodium atoms with oxalyl chloride gave a bright red solid (**5**) which was highly reactive towards acetone and THF. It was unchanged by dichloromethane, chlorobenzene and hydrocarbons in which it was insoluble. Solutions in chloroform gave a brown precipitate within minutes.

The observation of seven distinct bands assignable to terminal carbonyl ligands suggests that **5** is complex or a mixture. Because of the reactivity and insolubility of **5** it was not possible to obtain sufficient information to characterize it further. Repeated microanalysis of **5** gave variable results showing *ca* 2% of hydrogen present. The only source of hydrogen was the dichoromethane used to wash the product from the metal vapour synthesis apparatus.

Treatment of **5** with carbon monoxide gave the well-known dimer, $[Rh(CO)_2(\mu\text{-}Cl)]_2$ (**6**).[5] Treatment of **5** with triphenylphosphine gave yellow, air-stable $[Rh(PPh_3)_2(CO)Cl]$ (**7**). The IR spectrum of compound **7** showed a band at 1969 cm^{-1},

* Author to whom correspondence should be addressed.

assignable to a terminal CO stretch. This compares well with the literature value.[6]

Co-condensation of iridium atoms with oxalyl chloride gave an orange solution together with a large quantity of an insoluble orange solid (**8**). Compound **8** was insoluble in all common solvents except acetone and THF, with which it instantly reacted. The IR spectrum of **8** showed bands at 2155w, 2120s and 2080s cm^{-1}. Since **8** could not be purified or further characterised spectroscopically some reactions were studied.

Treatment of **8** with triphenylphosphine gave white, air-stable crystals which were insoluble in hydrocarbon solvents but soluble in chlorobenzene, THF, diethyl ether and dichloromethane. The IR spectrum (mull) showed the bands assignable to $\nu(C{\equiv}O)$ at 2140s, 2103s and 2096s. However, the solution IR (THF) shows two bands assignable to terminal carbonyl stretching frequencies, at 2060 and 2036 cm^{-1} and the small separation of 24 cm^{-1} is unusually low. Normally the separation would be expected to be 60–80 cm^{-1}. However, the few compounds of this class which have been reported have been shown to have such a difference between the two terminal carbonyl stretching frequencies. For example, for $Ir(PPh_3)(CO)_2D_3$, where the difference between the carbonyl frequencies is only 17 cm^{-1}.[7] Microanalysis corresponded to the compound $[Ir(PPh_3)(CO)_2Cl_3]$ (**9**). Only a few dicarbonyl compounds of this type are known.[8,9]

Co-condensation of platinum atoms with oxalyl chloride gave colourless crystals of *cis*-$Pt(CO)_2Cl_2$ (**10**) in high yield. This compound was accidently described as the *trans*-isomer in Ref. 1. The authentic *trans*-$Pt(CO)_2Cl_2$ has recently been described.[10]

Co-condensation of molybdenum atoms with pure oxalyl chloride followed by extraction of the products with THF gave an orange–brown solution and there was no evidence for the presence of unreacted metal. The product could be separated into a THF-soluble orange–brown solution and a pink solid (**11**). The IR spectrum of **11** showed no evidence for the presence of carbonyl ligands. The data show the compound **11** to be the previously described $MoCl_3(THF)_3$.[11]

The IR spectrum of the solid obtained by removal of THF from the orange extract showed no bands assignable to carbonyl ligands. The solid was treated with PEt_3 giving dichroic, blue, crystals, which were identified (IR spectrum) as the binuclear compound $[MoCl_2(PEt_3)_2]_2$ (**12**).[12]

The metals were vapourised from a positive-hearth electron-gun furnace using a "bell-jar" reactor vessel, as described elsewhere.[13] In all the reactions no difficulty was experienced in vaporising the elements on a scale of several grams. In the metal atom reactions with oxalyl chloride it is not possible to identify whether the reactions involve simply isolated atoms, or, whether metal aggregates are formed upon warming and which subsequently react with the oxalyl chloride. Whatever the case, in all the reactions there was none or very little unreacted metal recovered from the initial reaction mixtures. In contrast, metal atom reactions often result in recovery of up to half of the metal vaporised from the furnace. Except for the platinum and rhenium atom reactions the initial metal-carbonyl products, although formed in high yield, were extremely sensitive to common solvents, involatile and rather intractable. However, in every case they could be reacted with donor ligands such as tertiary phosphines giving discrete chloro-carbonyl derivatives, again in high yields. It is clear that the initial carbonyl species are likely to be useful precursors for the synthesis of a range of carbonyl derivatives. In this work we were primarily concerned with finding whether oxalyl chloride provided a source of metal-carbonyl compounds and we have not tried further to study derivatives of the initial reactive products.

We conclude that compounds **1** and **10** are very conveniently available by this metal atom route. Further, the reactive chloro-carbonyl derivatives of ruthenium, niobium and iridium formed initially in the atom reactions with oxalyl chloride are useful synthetic precursors.

EXPERIMENTAL

All preparations, reactions and purifications, other than metal vapour synthesis reactions, were carried out under an inert atmosphere of nitrogen or argon unless otherwise stated.

The drying and purification of solvents was achieved by refluxing over a suitable drying agent followed by distillation under an atmosphere of nitrogen. Oxalyl chloride was purified by distillation under vacuum. Precious metal samples were received as powders and, in a separate operation, were melted into ingots, using the positive-hearth electron gun furnace, before use in the co-condensation experiments. The apparatus used in the metal atom synthesis experiments and the general procedures are described in Ref. 13.

Microanalyses were performed by the analytical department of the Inorganic Chemistry Laboratory or at Alfred Bernhardt Laboratory, in the case of very air-sensitive samples. IR spectra were recorded on a Pye–Unicam SP2000 double beam, grating spectrophotometer in the range 4000–200 cm^{-1} and were calibrated using polystyrene film. Proton NMR spectra were recorded on a JEOL MX60 (60 MHz) or a Brucker WH300 (300 MHz) spectrometer. Mass

spectra were recorded using an A.E.I. MS 902 spectrometer calibrated using PFK.

Reaction of rhenium atoms with oxalyl chloride: the preparation of **1**

Rhenium atoms (1.84 g, 9.9 mmol), evaporated from a rhenium ingot of 11.55 g at a power of 2.1 kW (6 kV at 350 mA), were co-condensed with oxalyl chloride (50 g, 0.40 mol) for 3.5 h. The vacuum during the co-condensation was 4×10^{-5} mbar. During the co-condensation the matrix slowly became orange–red but on warming at the end of the experiment the co-condensate became pale green. However, the product of the reaction emerged from the reaction chamber as a red solution in the excess oxalyl chloride together with some red solid. The product was washed from the reaction chamber with dichloromethane (200 cm^3) in which the product was slightly soluble. There appeared to be no unreacted metal present so the extract was not filtered. After the removal of the volatile components under reduced pressure there remained an oily red–brown solid.

Chlorobenzene (150 cm^3) was then added giving a slightly red solution which was heated to 70°C for 4 h. The solution was filtered from the residual solids, whilst still at 70°C, giving a red–orange solution. On cooling, a large quantity of pale crystals were deposited. The solution was allowed to cool to room temperature (r.t.) and left overnight. The supernatant liquor was then decanted from the crystals which were washed with chlorobenzene (2×10 cm^3) and petroleum ether (10 cm^3 : 100–120°C) and finally dried *in vacuo*.

This material was further purified by sublimation (140°C, 10^{-2} mbar), giving a white sublimate of pure **1**. IR spectrum, CCl_4: 2114w, 2025s, 1999m, 1967m.

Reaction of ruthenium atoms with oxalyl chloride: preparation of α-$Ru_2(CO)_6Cl_4$ *and* $Ru(PPh_3)_2(CO)_2Cl_2$

In a typical experiment, ruthenium atoms (1.40 g, 13.9 mmol) generated from a ruthenium ingot of 8.65 g at a power of 900 W (4.5 kV at 200 MA) were co-condensed with oxalyl chloride (45 g, 0.35 mol) for 4 h. The vacuum in the apparatus during the co-condensation was poor (*ca* 3×10^{-4} mbar) presumably due to the formation of carbon monoxide. The matrix during the co-condensation was orange–brown and colour persisted on warming to r.t. The product emerged from the apparatus as a deep red oxalyl chloride solution together with a small quantity of light green solid (**2**). The remaining product was washed from the apparatus with THF (200 cm^3), giving a red solution. In some of the preparations all of the light green solid would dissolve, in others a small quantity of this solid would persist. In no case was any unreacted metal observed in the extracts.

The volatile components were then removed from the solution under reduced pressure giving a red oil. This was redissolved in THF (100 cm^3) and the solution filtered free from residual solids. Chloroform (100 cm^3) was added to the filtrate causing the solution to become cloudy. After 1 h a green precipitate had separated and the solution became colourless. The solution was then decanted from the solid which was washed with 60–80°C petroleum ether (2×20 cm^3). The solid was dried *in vacuo*, giving a light green powder (**2**). Analysis (%): C, 17.7; H, 1.8; Cl, 27.1.

Preparation of **3**. The green solid (**2**) (200 mg) in THF (40 cm^3) was placed under carbon monoxide (1 atm). There was no immediate reaction at r.t. but after 1 day the solution had become light brown. Over 6 days the intensity did not change but the green solid slowly dissolved. The volatile components were removed under reduced pressure giving a light brown, waxy solid. This was sublimed (100°C, 10^{-2} mbar) giving a white sublimate of pure $[Ru(CO)_3Cl_2]_2$. IR in chloroform: 2132s, 2066s, 2016w cm^{-1}, which is identical to an authentic sample.[3]

Preparation of **4**. A suspension of the green solid (**2**) (0.2 g) in THF (50 cm^3) was treated with triphenylphosphine (1 g, 4 mmol) in THF (10 cm^3). The green solid rapidly dissolved and after 5 min the solution was concentrated (to 10 cm^3). Petroleum ether (40–60°C, 300 cm^3) was added causing precipitation of a white solid. This was collected and washed with petroleum ether (2×50 cm^3, 40–60°C) and dried *in vacuo*. The solid was dissolved in THF (30 cm^3), the solution filtered and the filtrate was concentrated (to 10 cm^3). On cooling to −30°C white crystals separated which were collected, were washed with diethyl ether (2×5 cm^3) at −30°C and dried *in vacuo*.

IR spectrum (mull): 2065 and 1997 cm^{-1} (cf. published values,[4] 2064 and 2001 cm^{-1}). Analysis (%): C, 60.6 (59.3); H, 4.0 (3.9); Cl, 9.4 (9.7).

Reaction of rhodium atoms with oxalyl chloride: preparation of $[Rh(CO)_2(\mu\text{-}Cl)]_2$

In a typical experiment, rhodium atoms (0.63 g, 6.1 mmol), generated from a rhodium ingot of 5.8 g at a power of 800 W (4 kV at 200 mA), were co-condensed over 3.5 h with oxalyl chloride (55 g, 0.43 mol). The vacuum during the co-condensation was very good (4×10^{-5} mbar). The co-condensate was red but on warming became light green. The colour of the

matrix again changed as it melted to a deep red. The product emerged from reaction chamber as an insoluble red solid suspended in the excess of oxalyl chloride. The chamber was flushed with dichloromethane (200 cm^3) to extract the insoluble solid. The product solids contained no visible evidence of metal. The solvents were removed under reduced pressure giving a slightly oily solid. This was washed with petroleum ether (2 × 50 cm^3, 40–60°C) and dried *in vacuo*, giving a scarlet powder (**5**) which was used in the experiments described below. Analysis (%): Cl, 32.7; C, 11.0; H, 2.2.

Preparation of **6**. A scarlet suspension of **5** (200 mg) in chloroform (50 cm^3) was treated with carbon monoxide (1 atm). Immediately the mixture turned orange–red and after 5 min all the solid dissolved. The volatile components were removed under reduced pressure and the resulting orange–red waxy solid was sublimed (100°C, 10^{-2} mbar), giving an orange–red sublimate of pure **6**, *ca* 80%.

Preparation of **7**. A suspension of **5** (500 mg) in chlorobenzene (30 cm^3) was treated with triphenylphosphine (3 g, 11.5 mmol) in chlorobenzene (20 cm^3). The mixture was then stirred at r.t. and the solution rapidly became orange. Within 90 min all the solid dissolved. The solution was filtered into petroleum ether (300 cm^3, 40–60°C), giving an orange precipitate. This was washed with petroleum ether (2 × 50 cm^3, 40–60°C) and dried *in vacuo*. The orange powder was dissolved in hot acetonitrile (200 cm^3, 60°C) and after filtration the filtrate was cooled giving crystals of $Rh(PPh_3)_2(CO)Cl$. These were washed with acetonitrile (2 × 5 cm^3) and dried *in vacuo*. Yield > 80%.

The reaction of iridium atoms with oxalyl chloride

Iridium atoms (1.62 g, 8.4 mmol), generated from an iridium ingot of 10.36 g at a power of 1.5 kW (5 kV at 300 mA), were co-condensed for 4 h with oxalyl chloride (35 g, 0.28 mol). During the co-condensation the pressure in the apparatus was 8×10^{-5} mbar and the matrix slowly developed a deep orange colour. This colour persisted as the matrix warmed and melted. The product emerged from the apparatus as an orange solid suspended in the unreacted oxalyl chloride. The solids were flushed from the reaction chamber with dichloromethane (300 cm^3). The product receiver was then changed and the chamber was flushed with THF (200 cm^3). This produced a deep grey–green solution. The two product mixtures were treated separately. The volatile components of the orange extract were removed under reduced pressure giving a slightly sticky orange solid (**8**). This was washed with petroleum ether (2 × 50 cm^3, 40–60°C) and dried *in vacuo*.

The volatile components were then removed from the grey–green solution giving a dark green oily solid. This was washed with toluene (2 × 50 cm^3) and petroleum ether (50 cm^3, 40–60°C) and dried *in vacuo*. However, the product remained as a dark green oily solid.

Preparation of **9**. A suspension of **8** (500 mg) in chlorobenzene (50 cm^3) was treated with triphenylphosphine (2 g, 7.6 mmol) in chlorobenzene (20 cm^3), giving a pale orange solution. This was filtered into petroleum ether (300 cm^3, 40–60°C) giving a light orange precipitate, which was collected and the solid was washed with petroleum ether (2 × 50 cm^3, 40–60°C) and dried *in vacuo*. The solid was dissolved in chlorobenzene (100 cm^3) at 60°C and after filtration the filtrate was allowed to slowly cool to r.t. giving silvery-white crystals which were washed with petroleum ether (2 × 20 cm^3, 100–120°C) and dried *in vacuo*, yield 750 mg. Analysis (%): C, 39.9 (38.9); H, 2.4 (2.4); Cl, 16.9 (17.2).

The reaction of patinum atoms with oxalyl chloride: preparation of **10**

Platinum atoms (1.32 g, 6.8 mmol), generated from a 9.87 g ingot of platinum at a power of 1.5 kW (5 kV at 300 mA), were co-condensed with oxalyl chloride (35 g, 0.28 mol) over 4 h. The matrix was pale orange but on warming became colourless. The product emerged from the reaction chamber as a colourless solution and was washed out with benzene (200 cm^3). There was only a trace of unreacted metal. The volatile components were removed under reduced pressure giving a very pale orange solid. This was sublimed (60°C, 10^{-4} mbar), giving a white sublimate. The compound was characterised by comparison of the IR spectrum with an authentic sample and by the mass spectrum [M/z (^{195}Pt, ^{35}Cl) 322].

Reaction of molybdenum atoms with oxalyl chloride: preparation of **11** *and* **12**

Molybdenum atoms (1.01 g, 10.5 mmol) were evaporated from a 7.7 g ingot of molybdenum and co-condensed with an excess of oxalyl chloride (45 g, 0.35 mol) for 4.5 h. The power used to generate the molybdenum atoms was 800 W (4 kV at 200 mA) and the vacuum in the apparatus during the co-condensation was *ca* 4×10^{-4} mbar. The resulting co-condensate matrix was deep red–brown and this colour persisted when the matrix was warmed to r.t. The product emerged from the reaction chamber as a slurry of red–brown solid in the excess oxalyl chloride. Initially, the reaction chamber was washed with toluene, in which the product appeared to be

insoluble. Further washing with THF (250 cm^3) was found to dissolve the product. The volatile components were removed from the combined washing under reduced pressure leaving a red–brown oil, This was washed with toluene (2 × 50 cm^3) and 40–60°C petroleum ether (2 × 50 cm^3) and dried *in vacuo*. THF (100 cm^3) was then added to the resulting oil giving a deep orange–brown solution and an insoluble pink solid. The solid was filtered and the residual solid was washed with THF and dried *in vacuo*. The pink solid and the filtrate were then treated separately.

The pink solid was recrystallized from hot THF (100 cm^3) giving red, microcrystalline **11** by comparison with an authentic sample.[11] IR data, Nujol mull: 1355w, 1258w, 1186w, 1050m, 1009s, 965, 930m, 859s. Analysis (%): C, 18.6; H, 3.5; Cl, 29.3.

Triethylphosphine (3 g, 25 mmol) was added to the orange–brown solution. The mixture was warmed to 60°C for 2 days and became dichroic red–blue. After filtration the solution was concentrated and cooled to −30°C for 12 h giving blue crystals, which were washed with THF and dried *in vacuo*. The yield of **12**[12] was *ca* 35%.

A NEW METHOD FOR THE PREPARATION OF Ru(IV) IN NON-COMPLEXING ACID MEDIUM: EVIDENCE FOR TETRAMERIC Ru(IV)

J. P. DELOUME,* G. DUC and G. THOMAS-DAVID
Laboratoire de Chimie Analytique II, Université Claude Bernard, Lyon I, 43 Boulevard du 11 Novembre 1918, 69622 Villeurbanne Cedex, France

(*Received* 20 *June* 1984; *accepted* 10 *October* 1984)

Abstract—A new method for the preparation of Ru(IV) in acid solutions is described. This method, avoiding the preparation of the highly reactive RuO_4, is based on the stoichiometric oxidation of Br^- ion of K_2RuBr_6 by BrO_3^- ion. Easy to control and reproducible the process leads to solutions of a well-known composition consisting of the tetrameric Ru(IV) ion.

Lack of reproductibility in Ru(IV) studies arise in most cases from the ruthenium(IV) solutions themselves, owing to their method of preparation. The main method consists in distilling and dissolving ruthenium tetroxide in either aqueous acid solutions or organic solvent. The Ru(VIII) is then reduced by electrochemical[1,2] or chemical[3,4] means. Hydrogen peroxide is currently the most used reducing agent. The reaction is uncontrollable and despite the slow addition of the reagent, oxygen evolves and sweeps some tetroxide. The knowledge of the composition of the final solution requires the titration of total ruthenium and titration of the oxidizing power of the solution, operations which are not very accurate. Nevertheless this method leads to solutions containing only Ru(IV) ion and the counter-ion of the strong acid.

We have worked out a new method avoiding the preparation of RuO_4, leading to a solution of known composition and a procedure which is easily reproducible.

PRINCIPLE OF THE METHOD

The potassium hexabromo ruthenate(IV) (K_2RuBr_6) is used as starting material. The method is based on the stoichiometric oxidation of bromide ions of $RuBr_6^{2-}$ by bromate ion in acid medium. Bromine, the resulting product of the oxidation is evolved from the solution and is displaced by a flow of inert gas. It is worth noting that the balance of the reaction depends on the nature of Ru(IV) ions in the solution. From previous results[2,3,5] on Ru(IV) ion we can write three overall reactions:

$$5RuBr_6^{2-} + 6BrO_3^- + 36H^+ \rightarrow 5Ru^{4+} + 18H_2O + 18Br_2 \quad (1)$$

$$5RuBr_6^{2-} + 6BrO_3^- + 26H^+ \rightarrow 5RuO^{2+} + 13H_2O + 18Br_2 \quad (2)$$

$$5RuBr_6^{2-} + 6BrO_3^- + 21H^+ \rightarrow \tfrac{5}{4}Ru_4O_6^{4+} + \tfrac{21}{2}H_2O + 18Br_2. \quad (3)$$

If titration of protons can be made with sufficient accuracy, we can get direct knowledge of Ru(IV) ion in such solutions.

EXPERIMENTAL

(a) Preparation of K_2RuBr_6: this salt is prepared according to the method of Ferguson and Greenaway.[6] Purity controls are provided by two different ways. First, X-ray powder diffraction photographs show a single phase ($a = 10.299$ Å) without $K_3Ru_2Br_9$[6] or $K_4Ru_2OBr_{10}$. Secondly, we estimate potassium, which is the easiest element to determine, by flame emission spectroscopy. The standardization of the spectrometer is achieved with solutions of potassium bromide containing ruthenium (from hydrated ruthenium trichloride) in the ratio [K]/[Ru] = 2.

(b) The oxidizing solution is prepared from sodium bromate (analytical reagent grade) by weighing known amounts of dried salt and dissolving in

* Author to whom correspondence should be addressed.

the appropriate volume to obtain a solution of *ca* 1 mol l^{-1}.

The acid medium is prepared in the usual way with the selected acid (methanesulfonic acid, analytical reagent grade).

Experiment leads as follows to a final solution 6×10^{-2} mol l^{-1} in Ru(IV); oxidizing solution (1.005 mol l^{-1}) is placed in an automatic titrator Tacussel EXB provided with a 5 cm^3 syringe (rather than a 10 cm^3 one, because of the speed of the plunger). 60.0 cm^3 of acid solution (2.000 mol l^{-1}) are introduced from a pipette into the reaction flask, stirred and bubbled with a nitrogen flow, the needle of the syringe being level with the solution. Then, we quickly pour K_2RuBr_6 salt into the solution as we start adding the bromate ion at the rate of 1 μl per second.

Here, we introduce 4.9965 g of K_2RuBr_6 (658.7 g/mol^{-1}), e.g. 7.585×10^{-3} mol which needs 9.102×10^{-3} mol of bromate ion contained in 9.057 cm^3 of solution.

Bromine vapour appears quickly and evolves continuously during the addition. As stoichiometry is reached we stop the titrator. Nitrogen is bubbled for one hour, then the solution is heated to 50–60°C for one further hour. This solution is cooled to room temperature and transferred, with rinsing water in a 125 cm^3 flask. At this time we can add an exact quantity of acid to obtain the required acidity, since we know the exact number of consumed protons in the reaction. Here the required final acidity is 1.5 mol l^{-1}. The flask is then adjusted to the mark.

ANALYTICAL

We need to know the bromine content which can exist as bromide ion, bromine or bromate ion. Consequently we have to use a reducing agent, which does not interfere with the titration method, to convert higher oxidation states of bromine into bromide ions. This ion is titrated by argentimetric (coulometric) method with an ordinary silver/mercurous sulphate potentiometric detector in 50–50 water–methanol medium. Synthetic solutions of known amounts of bromide and bromate ions were used to check the efficiency of the reducer (hydrazine) and of the electrolytic current. Ruthenium must be eliminated from the solution before titration by precipitation of ruthenium hydroxide and filtration; the basic solution is then acidified and processed as a synthetic one.

The oxidation state of ruthenium is determined after reduction of ruthenium(IV) by iodide ion. The classical method[1] is made easier by distillation of iodine under nitrogen in a solution of iodide ion and then titrated by thiosulphate standardized in the same way.

The acidity measurement is carried out by the Gran's method. Before each run we take care to determine correspondence between the pH read and $-\log [H^+]$ by titrating solutions of strong acid of the same ionic strength as the one of the ruthenium solution.

RESULTS AND DISCUSSION

(*a*) *Bromine content*

The results obtained with four different preparations are summarized in Table 1. They show that the average content in bromine is 3 or 4 bromine atoms per 100 ruthenium atoms. The ratio of this bromine concentration to the theoretical initial bromine concentration is 0.5% which corresponds to the accuracy of a volumetric method as the one used for this preparation.

(*b*) *Oxidation state*

In this new method, total concentration of ruthenium is exactly known from the weight of K_2RuBr_6 introduced (any unexpected loss by

Table 1. Percentage of bromine remaining in different ruthenium(IV) solutions (concentration in mol l^{-1})

Solution	No. 1	No. 2	No. 3	No. 4
[Ru(IV)]	1.01×10^{-2}	0.99×10^{-2}	1.00×10^{-2}	9.8×10^{-2}
[Br^-]	6.06×10^{-2}	5.94×10^{-2}	6.00×10^{-2}	5.98×10^{-1}
Theoretical from weighted K_2RuBr_6 [Br^-] in the Ru(IV) solution	3.3×10^{-4}	4.8×10^{-4}	2.6×10^{-4}	2.4×10^{-3}
(Br/Ru)·100	3.0	4.8	2.6	2.4

Table 2. Experimental oxidation number of ruthenium (concentration in mol l^{-1})

Solution	No. 1	No. 2	No. 3
[Ru(IV)]	3.56×10^{-2}	3.56×10^{-2}	3.57×10^{-2}
[oxidizer]	3.59×10^{-2}	3.59×10^{-2}	3.61×10^{-2}
oxidation	4.01	4.01	4.01

oxidation as RuO_4 is immediately made perceptible by the black powder it forms on rubber or grease). In this case we have only to titrate the oxidizing power of the solution. The results for three preparations are given in Table 2. They prove that ruthenium does not change oxidation state during elimination of bromide ion. Our method is convenient for the preparation of non-complexed ruthenium(IV) solution.

(c) *Existence of a* $Ru_4O_6^{4+}$ *or* $Ru_4(OH)_{12}^{4+}$ *species*

As we have already written, only three species can be suggested in those solutions, namely Ru^{4+}, RuO^{2+}, $Ru_4O_6^{4+}$ which need, respectively the consumption of 7.2, 5.2, 4.2 protons per ruthenium atom in the total reactions.

Unlike previous preparation methods, the titration of proton becomes valid because the yield in ruthenium is 100% in this method. The only source of errors lies in the Gran's method itself. The major one arising from ionic strength. The results for three identical preparations are 0.90, 0.88, 0.89 mol l^{-1}. They are reproducible within 1% from the mean value of acidity but to take into account the basic errors of the method, we assume the accuracy to be less, in the order of 3%. Thus the final acidity ranges from 0.86 to 0.92 mol l^{-1}. The calculation of consumed proton per ruthenium atom leads to:

$$(0.975-0.86)/2.47 \times 10^{-2} = 4.6\ H^+/Ru$$

$$(0.975-0.92)/2.47 \times 10^{-2} = 2.2\ H^+/Ru$$

Those equations show that the high acidity of the solutions is not favourable for a great accuracy. Nevertheless the calculated value does not reach the 5.2 H^+/Ru corresponding to the RuO^{2+} ion. The starting material being mononuclear ion, in which we only oxidize bromide ion, then the produced ion should be RuO^{2+} if this ion had some chance to exist. But as it does not, that proves the stability of the tetrameric form in strong acid medium. We state that the total reaction of the preparation is described by equation (3). This result agrees with the recently published one by Schauwers *et al.*[4]

This method is satisfactory fast, clean and accurate. Another advantage is the ability to work in acid solution other than perchloric acid without the trouble encountered sometimes by workers who try sulphuric or methanesulphonic acids. In any case, the composition of the solution is given by:

$$[Na^+] = 1.2[Ru(IV)]$$

$$[K^+] = 2[Ru(IV)]$$

$$[Br] = 3 \times 10^{-2}[Ru(IV)]$$

$$[H^+] = (H^+)_0 - 4.2[Ru(IV)]$$

$$[Anion] = [H^+]_0$$

where [Ru(IV)] is known by weighing K_2RuBr_6.

CHARACTERIZATION OF Cr(III)–Zr(IV) MIXED AND Sn(II) DOPED HYDROUS OXIDES

S. K. SRIVASTAVA* and C. K. JAIN
Department of Chemistry, University of Roorkee, Roorkee-247667, India

(*Received* 2 *April* 1984; *accepted* 9 *November* 1984)

Abstract—Surface and structural properties of chromium–zirconium mixed and Sn(II) doped hydrous oxide gels have been compared with chromium oxide hydrate gel by the use of thermal analysis, IR spectroscopy, X-ray diffraction, electron microscopy and magnetic measurements. The mixed and doped oxide gels were found to have a hexagonal close packed stacking of O, OH and H_2O ligands with chromium ions distributed in octahedral sites with little degree of order among them. The microstructure of the gels are characterized by the presence of large aggregates of chromium hydroxides, fine granular sheets due to $HCrO_2$ phase and $Cr(OH)_3$ microcrystallites. Magnetic susceptibility measurements indicate antiferromagnetic behaviour of these gels.

Chromium oxide hydrate gels find wide applications as advance technology materials apart from their traditional use in the manufacture of pigments, glasses, cement colourants, ceramic oxide coatings, absorbents and catalysts.[1,2] CrO_2 is the only transition metal oxide which is strongly ferromagnetic and is used in magnetic tapes.[3,4] The influence of the precipitation rate on the properties of porous chromia have been summarized by Sonnemans and Keijzer[5] while the effect of pH of the reactant solutions on the texture and surface properties are reported by Siddiq, Gilanyi and Zettlemoyer.[6] Electrical conductivity and thermal analysis studies have recently been reported by Natrajan and Secco[7] while structural evolution of α-Cr_2O_3 from chromium oxide hydrate gel has been studied by Ratnasamy and Leonard.[8] Extensive literature, available on this compound, reveals that its texture and surface properties depend on the conditions of preparation and heat treatment.

We have been working on the sorption characteristics of some pure and mixed hydrous oxides and have also investigated the electrochemical performance of their membranes. It is observed that the mixed oxide of chromium and zirconium (with chromium as a major constituent) exhibits manifold increase in its sorption capacity as compared to individual oxides, therefore it is essential to characterize these systems completely in relation to their utility in various processes involving ion-exchange adsorption etc.

In this paper we have made an attempt to characterize structurally the chromium–zirconium mixed hydrous oxide vis-à-vis the pure one and have also observed the doping effect of Sn(II).

EXPERIMENTAL

Reagents

Chromium chloride (BDH), zirconium oxychloride (AR) and stannous chloride (AR) were used as such and their solutions were prepared in double distilled water.

Preparation of mixed and doped hydrous oxide gels

Chromium chloride (0.2 M) and zirconium oxychloride (0.2 M) were mixed to give a molar ratio of 8:1 (optimum conditions at which the product show maximum anion as well as cation exchange capacity). The mixed hydrous oxide was coprecipitated slowly under constant stirring. The precipitate was left to stand with the mother liquor for two days at room temperature, washed several times with distilled water, filtered and dried at 80°C for 24 h. Doped oxide was prepared by adding 0.075 g of $SnCl_2$ to a 450 ml solution of chromium chloride and zirconium oxychloride in a molar ratio of 8:1 and was precipitated with ammonium hydroxide.

* Author to whom correspondence should be addressed.

Technique used

Thermal analysis, IR spectroscopy, X-ray diffraction, electron microscopy and magnetic measurements are the techniques used to characterize the gels.

Differential thermal curves were recorded on a Fisher Differential Thermalyzer model 260 P and thermogravimetric curves on a Stanton Redcroft TG-770 model instrument. Samples were passed through 100 mesh size sieves and heated in air atmosphere in platinum crucible from room temperature to 1000°C at a rate of 10° min^{-1}.

IR spectrum were recorded with a Beckman model IR-20 spectrophotometer operated in double beam mode. The samples were taken in the form of KBr pellets.

Diffraction patterns were recorded at room temperature at a speed of 2θ degree per minute (ranging from 1° to 2° min^{-1}) in Phillips Type PW 1140/9P X-ray diffractometer using Zr-filtered Mo-K_α radiation = 0.711 Å.

Transmission electron micrographs were recorded with Phillips EM-400 transmission electron microscope of 80–100 KV voltage. Samples were prepared by dilution of a small quantity of it in absolute alcohol after dispersing the sample in ultrasonic bath. Droplets of the diluted sample were taken from the middle of the test tube and put on a 200 mesh copper grid covered with a thin film of formvar. All the grids had been examined in the electron microscope prior to the sample deposition.

Magnetic susceptibility measurements were performed using Vibrating Sample Magnetometer model 155. Samples (0.05–0.10 g) were taken in the form of cylindrical pellets. The system was calibrated using the 3/32″ × 3/32″ cylindrical sample of high purity nickel. The saturated moment of Ni sample was found to be about 55 emu g^{-1} with a saturation flux of about 8000 G.

RESULTS AND DISCUSSION

Thermal analysis

Differential thermal and thermogravimetric curves for chromium oxide, zirconium oxide, Cr–Zr mixed oxide and Sn(II) doped oxide hydrate gels are shown in Figs. 1 and 2 respectively.

DTA curve of chromium oxide hydrate gel [Fig. 1(a)] apparently show three endothermic effects with their peaks centred at 120, 200 and 330°C. These are followed by the appearance of an exothermic effect at 400°C. The splitting of the exothermic effect of dehydration into distinct peaks possibly points to the structural inhomogeneity of the sample thereby

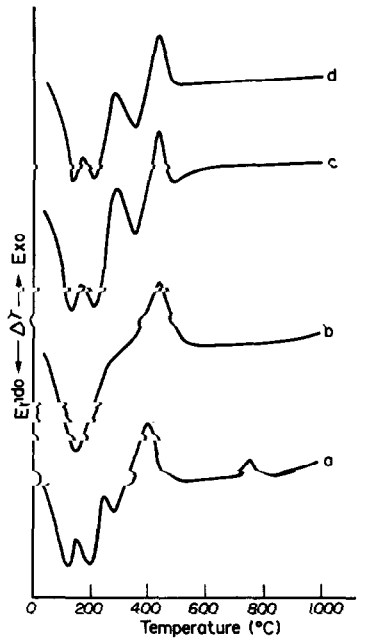

Fig. 1. DTA curves of hydrate gels: (a) chromium oxide; (b) zirconium oxide; (c) Cr–Zr mixed oxide; (d) Sn(II) doped oxide.

suggesting more than one type of phase possessing distinct structural features, being present in the gel. Observation of an exothermic effect at 400°C corresponds to crystallization of the disordered colloidal structure related to dehydrated skeleton of the gel to well developed α-Cr_2O_3. Features beyond 500°C in the DTA curve may be accounted for by the sintering

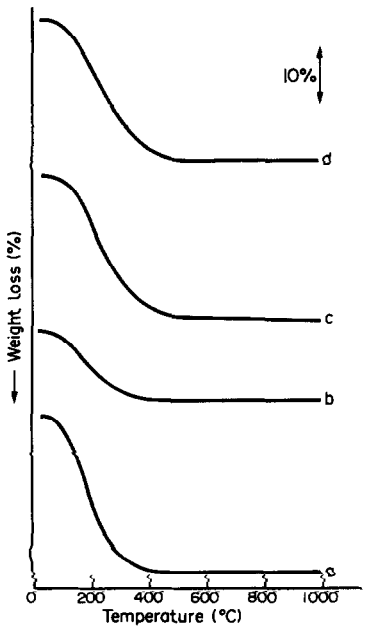

Fig. 2. TGA curves of hydrate gels: (a) chromium oxide; (b) zirconium oxide; (c) Cr–Zr mixed oxide; (d) Sn(II) doped oxide.

and grain growth of α-Cr_2O_3 with concomitant removal of lattice defects and inhomogeneities. A weak but distinct exothermic effect at 750°C is identifiable with the delayed start of crystallization of α-Cr_2O_3.[9] The DTA curve of zirconium oxide hydrate gel [Fig. 1(b)] shows an initial endothermic peak at 150°C, corresponding to dehydration, followed by a strong sharp exothermic peak at 430°C due to the transition of ZrO_2 from an amorphous state to crystalline variety.[10]

DTA curves of Cr–Zr mixed and Sn(II) doped oxide hydrate gels [Fig. 1(c), (d)] show endothermic effects with peaks at 130, 210 and 350°C associated with the removal of adsorbed water molecules and structural hydroxyl groups indicating the presence of more than one type of phase possessing distinct features. Exothermic effect around 430°C corresponds with the onset of crystallization of the mixed oxides. DTA curves of mixed and doped oxide hydrate gel are devoid of any peaks beyond 500°C in contrast to the curve obtained for pure chromium oxide hydrate gel that gave weak exothermic effect at 750°C due to crystallization of α-Cr_2O_3 formed from microcrystalline $Cr(OH)_3$ fraction. The variations in intensity and width of the endotherms suggest considerable variations in water content and microstructures of the gels.

The TG results (Fig. 2) show that the loss in weight takes place in different steps in a continuous manner at temperatures corresponding to the endothermic and exothermic peaks in DTA curves. The TG curves show a total weight loss of 27.0% for chromium oxide, 12.0% for zirconium oxide, 25.4% for Cr–Zr mixed and 25.0% for Sn(II) doped oxide hydrate gels respectively.

IR spectroscopy

IR spectra of chromium oxide hydrate gel show a very strong absorption band at 3440 cm^{-1}, a weak broad absorption extended over the region 2100–1600 cm^{-1}, sharp bands at 1640, 1470 and 1300 cm^{-1} and again an intense broad band centred at 530 cm^{-1} and some inflections in the region 1200–650 cm^{-1}. Absorption bands at 3440 and 1640 cm^{-1} are characteristic of stretching and bending modes of vibrations for water and structural hydroxyl groups.[11,12] The bands around 1380 and 1470 cm^{-1} are due to the presence of some CO_3^{2-} ions that may be incorporated in the gel due to absorption of CO_2 from the atmosphere at the time of precipitation.[13] Weak absorptions in the region 2000–1600 cm^{-1} and around 1200 cm^{-1} are observed in the spectrum which correspond with the presence of some rhombohedral $HCrO_2$ fraction.[14] The bands present in the region 1100–1000 cm^{-1} are due to Cr=O stretching vibrations which arise from the sorbed oxygen on coordinatively unsaturated chromium sites available in the gel.[14] The bands in the lattice vibration region at 530 cm^{-1} all the more indicate for a distribution of Cr^{3+} ions in octahedral sites available in hexagonal close packed structure of oxygen sublattice in the gel with a small degree of order among the chromium ions.

The IR spectra of Cr–Zr mixed and Sn(II) doped oxide hydrate gels compare well with the IR characteristics of chromium oxide hydrate gel. IR spectrum of chromium oxide hydrate gel is characterized by a broad band with absorption centred at 530 cm^{-1}. The IR spectrum of zirconium oxide hydrate gel is characterized by a broad band with absorption centred at 500 cm^{-1}. Inspection of the IR spectra of Cr–Zr mixed and Sn(II) doped oxide hydrate gels show that an increasing amount of chromium ions result in sharpening of the peak in the low frequency region. Incorporation of chromium ions in the mixed oxide cause displacement of IR absorptions towards higher frequencies. These features indicate the formation of Zr-substituted chromium oxide hydrate gel as dominant phase along with some Cr-substituted zirconium oxide hydrate gel.

X-Ray powder diffraction studies

X-Ray diffraction pattern of the chromium oxide hydrate gel shows the mainly amorphous nature of the product. However, some weak reflections at d-values associated with the presence of α-$Cr(OH)_3 \cdot xH_2O$ (bayerite like) and of rhombohedral $HCrO_2$ are observed.

The X-ray diffraction patterns of mixed and Sn(II) doped oxide hydrate gels compare well with the X-ray pattern of chromium oxide hydrate gel. Some weak reflections due to the presence of $Cr(OH)_3$ with Zr(IV) and Sn(II) incorporation are also observed showing some crystallinity in the gel.

Transmission electron microscopy

Selected electron micrographs of chromium oxide, Cr–Zr mixed oxide and Sn(II) doped oxide hydrate gels are displayed in Fig. 3(a–c) respectively.

The electron micrographs of chromium oxide hydrate gel show that the gel is composed of large aggregates and small discrete sub-unit particles with well separated edges. The microstructure of the gel is characterized by the simultaneous presence of three types of phase. The large canonical wedge-shaped opaque aggregates with irregular edges represent the formation of $Cr(OH)_3 \cdot xH_2O$. The second phase is the large fraction of chromium oxyhydroxide,

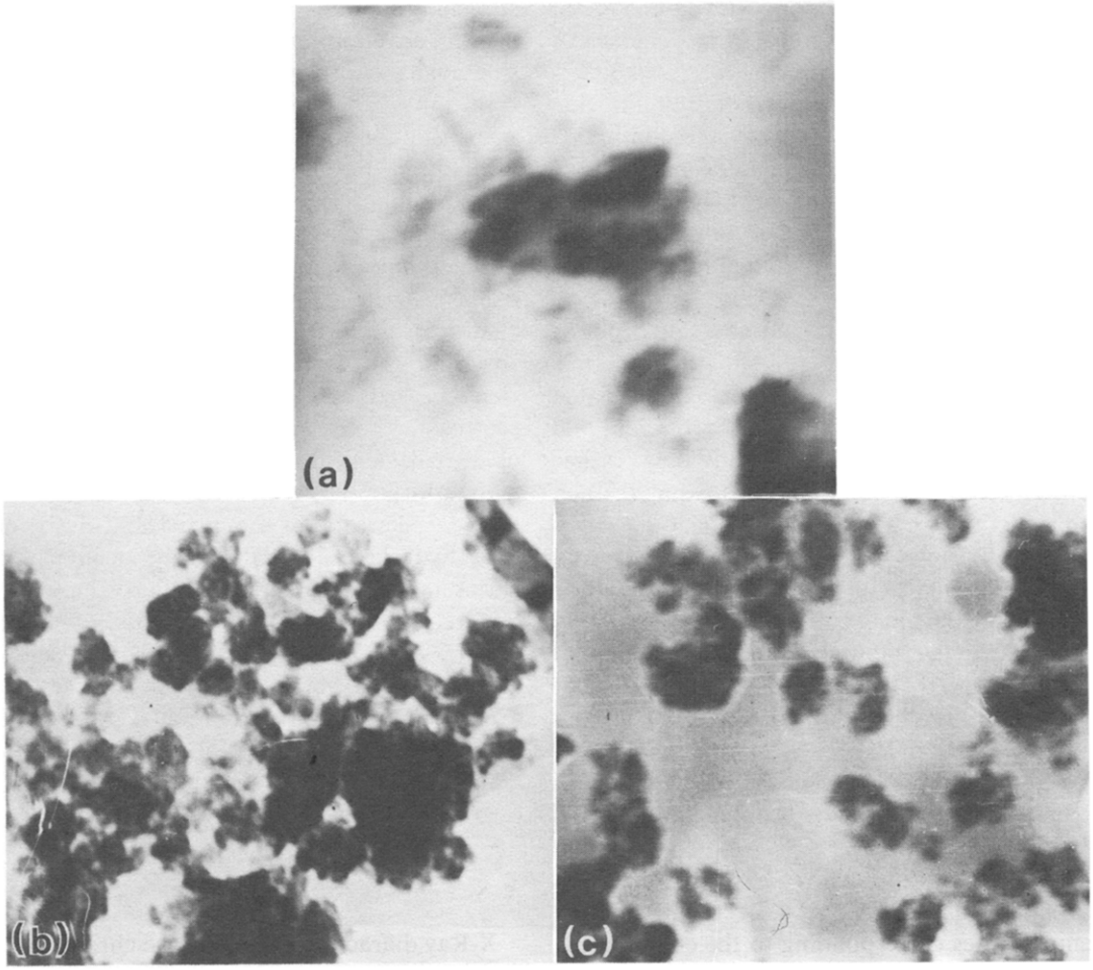

Fig. 3. Electron micrographs of hydrate gels: (a) chromium oxide, × 45,000; (b) Cr–Zr mixed oxide, × 58,000; (c) Sn(II) doped oxide, × 58,000.

$HCrO_2$. A small fraction of polygonal particles with well separated edges indicate the presence of some better defined microcrystallites of $Cr(OH)_3 \cdot xH_2O$.

Electron micrographs of Cr–Zr mixed and Sn(II) doped oxide hydrate gels show much resemblance to chromium oxide hydrate gel. These show the presence of large aggregates of chromium hydroxide, fine granular sheets due to $HCrO_2$ phase and $Cr(OH)_3$ microcrystallites. Incorporation of zirconium and tin in the chromium oxide hydrate gel probably results in a better definition of primary particles and microcrystallites. The coherency of these gels is comparable to that of chromium oxide.

Magnetic measurements

Figure 4 shows the variation of specific magnetization with varying field strength for chromium oxide, zirconium oxide, Cr–Zr mixed and Sn(II) doped oxide hydrate gels. A summary of the results of magnetic measurements is presented in Table 1. Room temperature magnetization of the gels are proportional to the applied field and increases with field values.

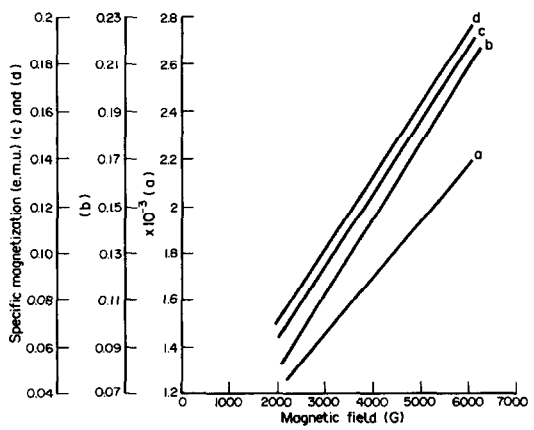

Fig. 4. Least squares fitted linear plots of specific magnetization vs. magnetic field for hydrate gels: (a) zirconium oxide; (b) chromium oxide; (c) Cr–Zr mixed oxide; (d) Sn(II) doped oxide.

Table 1. Values of specific magnetization (σ) with varying magnetic field (H) for chromium oxide, zirconium oxide, Cr–Zr mixed oxide and Sn(II) doped oxide hydrate gels

Field (G)	Specific magnetization (emu)			
	Cr oxide	Zr oxide	Cr–Zr mixed oxide	Sn(II) doped oxide
2500	0.097	1.340×10^{-3}	0.080	0.086
3700	0.139	1.650×10^{-3}	0.116	0.121
4800	0.171	1.880×10^{-3}	0.152	0.160
5800	0.200	2.180×10^{-3}	0.180	0.190
χ_g ($\times 10^{-6}$)[a]	34.8	0.241	30.6	31.3

[a] Values of χ_g have been calculated from the linear plots of specific magnetization vs field strength.

The field dependence and the magnetic susceptibility per gram, χ_g of the chromium oxide, Cr–Zr mixed oxide and Sn(II) doped Cr–Zr mixed oxide hydrate gels indicate antiferromagnetic behaviour for all these samples. The magnetic susceptibility value of the chromium oxide hydrate gel is in good agreement to that reported for chromia gel by Selwood.[15] In the case of α-Cr_2O_3, the spins are aligned antiparallel within the (111) planes. While antiferromagnetism of α-Cr_2O_3 is brought about by weak direct spin–spin interactions between Cr^{3+} ions over common faces and edges leading to relatively short Cr^{3+}–Cr^{3+} distance along the hexagonal axis. The antiferromagnetism of α-Cr_2O_3 is caused by spin–spin interactions between π antibonding t_{2g} electrons. As regards the structure of chromium hydrate gel, it consists of a hexagonal close packed stackings of O, OH and H_2O ligands with chromium ions distributed in octahedral sites with little degree of order among them. Occurrence of planar layers of octahedra $Cr(O, OH, H_2O)_6$ lack three-dimensional order because of the restricted number of unit cells. This is essentially responsible for poorly crystalline character of chromia gel. Low values of magnetic susceptibility for mixed and doped oxide hydrate gels correspond to an antiferromagnetic mixed phase with high surface area.

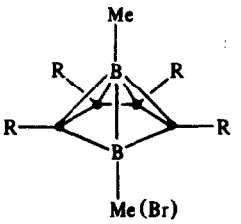
(*Received* 5 *November* 1984; *accepted* 18 *December* 1984)



Abstract—Attempts to reproduce the reported synthesis of peralkylated 1,4-dibora-2,5-cyclohexadienes (1) using the so-called "methylborylene-generating system", $2\,C_8K/MeBBr_2$, in the presence of 3-hexyne and 5-decyne were not successful. The *nido*-2,3,4,5-tetracarbaboranes(6) (2) contaminated with other carbaboranes and various organoboronhalides were obtained instead, irrespective of the nature of the C_8K used. Different samples of C_8K were prepared and characterized by X-ray diffraction and XPS spectra. The yields of the carbaboranes were much better when the well ordered stage 1 potassium graphite in hexane was used. In all experiments the first compounds identified from the reaction mixtures are the 1,2-haloboration products (3) and there is no indication for the intermediacy of methylborylene. Most of the organoboranes present in the reaction solution and in the final products could be readily assigned on the basis of ^{11}B- and ^{13}C NMR data, supported by GC/MS analysis.

The synthesis of unsaturated cyclic organoboranes has been a major challenge to many boron chemists for more than two decades.[1,2] The heteroaromatic character of neutral or anionic compounds of this type (e.g. borirenes,[3] borepines[4] and borine-anions[5] or borol-dianions,[6] respectively) has been shown in numerous studies.[2,7] The interest in those heterocycles which do not obey the Hückel rules has been focused on the boroles[2,6a,7,8] and on the 1,4-dibora-2,5-cyclohexadienes (1).[2,7,9]

Among the various synthetic strategies[2] monomeric boranediyles ("borylenes") have been frequently invoked.[10] Although it proved possible to trap monomeric fluoroborylene, BF, from the gas phase[9a] and to generate Ph_3SiB in a hydrocarbon matrix at −196°C,[10c] convincing evidence for the intermediacy of borylenes in solution is still lacking. However, in preliminary communications,[3a,11] and, more recently, in two full papers[12,13] the interaction between potassium-graphite, C_8K, and methylborondibromide, $MeBBr_2$, has been proposed as a methylborylene, MeB, generating system. We became intrigued by these reports mainly for two reasons: (i) We are interested in the application of potassium-graphite in synthesis.[14] (ii) Our own and other attempts to prepare polyalkylated[15] or peralkylated 1,4-dibora-2,5-cyclohexadienes[16] (1) have not been successful, whereas it is claimed[13] that these compounds 1 are the main products from the

reaction of C_8K with $MeBBr_2$ in the presence of alkynes (3-hexyne, 3-decyne, 4-decyne, 5-decyne, 6-dodecyne). With these alkynes the formation of *nido*-hexaalkyl-2,3,4,5-tetracarbahexaboranes (6) (2) is said to be of minor importance.

Unfortunately, various important experimental details which would help to reproduce these results[13] have been omitted. Thus, the potassium-graphite, C_8K, has not been fully described or characterized which can be a crucial point[17] considering the manyfold influences controlling heterogeneous reactions. Clearly, the electronic and, therefore, the chemical properties of the potassium-graphite will depend greatly on the amount of the residual non-intercalated potassium invariably present in the frequently used *in situ* preparation.[18] The diffusion-controlled gas phase-solid state reaction of potassium vapour with graphite may lead to products which are not in the thermodynamic equilibrium, meaning that the galleries between the graphite sheets are only partially filled depending on reaction conditions. Thus, it is possible that non-intercalated potassium may induce decomposition of the reactants and/or the products. Furthermore, the degree of undersaturation seems to determine the amount of charge transfer from potassium to graphite (ionicity) and, indirectly, it influences the stability of the intercalated state under reaction conditions. Furthermore, it has been shown that many organic compounds, i.e. commonly used solvents, are capable of forming ternary graphite intercalates.[19] The properties of these intercalates, which seem to contain solvated cations rather than metalloid potassium, are drastically different from the parent binary potassium-graphite, and several irreversible chemical reactions of potassium-graphite with solvents have been reported.[19,20]

The organoboranes reported to result from the reaction of C_8K with $MeBBr_2$ and various alkynes were not completely characterized:[13] Some MS data have been discussed, ^1H-, ^{13}C NMR data have been mentioned but only very few data have been given, and, most regrettably, ^{11}B NMR data which could provide decisive information on the structure of the organoboranes[21,22] have not been reported. We were also puzzled by contradictory statements on the mechanism: Although the title of the paper[13] as well as most of the discussion emphasizes the intermediacy of methylborylene, the authors finally conclude that they are unable to decide between methylborylene addition to alkynes and reduction of the haloboration products (3) by potassium. This unsatisfactory situation prompted us to undertake this study in order to characterize the system $C_8K/MeBBr_2$/alkynes, and to look for evidence for one or the other mechanism. In addition, we wanted to assess the composition and structure of the organoboranes in more detail.

3

RESULTS

Potassium-graphite

In order to obtain reproducible results in this study, first stage potassium-graphite was prepared in three different ways (**A** to **C**) (see Experimental). Although they all exhibited the same golden colour, the properties of these three preparations as determined by XRD and XPS are quite different (Table 1).

Figure 1 shows two energy dispersive X-ray diffractograms[17] of the parent potassium-graphite (method **A**) and of the same material after reaction with $MeBBr_2$ and 3-hexyne in hexane after 4 days.[23] The colour of the particles had changed from uniform golden to a mixture of gold, steel blue and black, typical for higher stage potassium-graphite intercalates. The XRD traces supported by energy-dispersive elemental X-ray analysis clearly indicate transformation of the ordered intercalate into a highly disordered state with potassium still present between the graphite layers. Neither the expected[14d] ordered higher stage structure nor pure graphite has been formed.[24]

Reactions

The arguments discussed so far strongly indicate that the reactivity of C_8K depends critically on the method of preparation. Therefore, two parallel sets of experiments were carried out. The reaction of the characterized compound C_8K (method **A**, **B**) with $MeBBr_2$ in the presence of alkynes (3-hexyne, 5-decyne) was studied under various conditions (solvent, temperature), and the mixture "C_8K" (method **C**) was treated in the same way.

In benzene

With C_8K (**A**, **B**) in the presence of 5-decyne, there was a visible change in the appearance of the solid after heating to reflux. The colour of the liquid turned reddish and the solid became dark. Slow addition of $MeBBr_2$ in benzene caused a vigorous reaction and

Table 1. Properties of potassium-graphite prepared via different methods

Method[a]	Preparation	Stage	J_C [pm]	K2p$_{\frac{3}{2}}$BE FWHM [eV]	"Ionicity"[b]
A	Vapour phase, 320°, 300°C powder graphite	1 (> 99%) only well-ordered	534.8	291.0 1.3	Metallic
B	Vapour phase, 310°, 290°C graphite stabs	1 (93%) + 2 (7%) well ordered	539.2 874.0	291.6 1.2	Partly ionic
C	"*In situ*" preparation in S40 flakes of natural graphite	1 (59%) + 2 (19%) + 3 (22%)[c] poorly ordered	541.7 877.2	291.0 292.4 1.6 1.2	Potassium metal on the surface and ionic states

[c] Disordered.

the powdery solid (**A**) became lumpy. The ^{11}B NMR spectrum taken of the reaction mixture immediately after addition of $MeBBr_2$ showed only traces of $MeBBr_2$, Me_2BBr. This indicates that essentially all $MeBBr_2$ has been converted into insoluble or highly polymeric material. The mixture was heated to reflux for 20 h but there was no change in the ^{11}B NMR spectrum of the solution.

The analogous reaction with the mixture "C_8K" (**C**) was somewhat different. There was no marked change in the appearance of the solid material before the $MeBBr_2$ was added. On addition of the $MeBBr_2$ a reaction took place, the solid went black and potassium metal could be seen. The ^{11}B NMR spectrum recorded immediately after the addition of $MeBBr_2$ showed only two resonances, one for $MeBBr_2$ and the other for the haloboration product **3b** ($R^1 = R^2 = Bu^n$). After heating the mixture to reflux for 18 h (lit.[13]: 20 h) the ^{11}B NMR spectrum showed no detectable resonances for organoboranes except very weak signals for traces of the *nido*-2,3,4,5-tetracarbahexaborane(6) (**2b**).

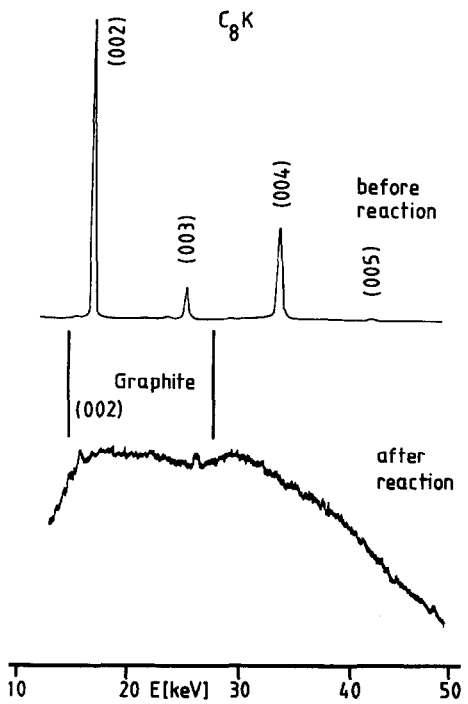

Fig. 1. Energy dispersive X-ray diffractograms[17] of powdered C_8K (method **A**) before reaction and after reaction with 3-hexyne and $MeBBr_2$ in hexane. The solid bars represent the positions of the two strongest reflections of pure graphite.

In hexane

After these disappointing results we decided to use a different solvent since it was reported that the 1,4-dibora-2,5-cyclohexadienes could also be obtained in cyclohexane.[13] We studied the reactions in hexane both at room temperature and under reflux since, according to literature,[13] the reactions under these conditions should afford either carbaboranes or diboracyclohexadienes, respectively. Furthermore, it is well known that benzene forms ternary intercalation products with potassium-graphite[14b,19] whereas hexane or cyclohexane do not react with C_8K.

The reaction of C_8K (**A**, **B**) with $MeBBr_2$ and the alkyne (3-dexyne or 5-decyne) proceeds slowly at room temperature and somewhat more rapidly when heated to reflux. There was no appreciable difference in the product distribution for the different

reaction conditions, and the two alkynes gave analogous products as could be deduced from the ^{11}B NMR spectra. At no stage of the reaction a significantly intense ^{11}B NMR signal could safely be assigned to the peralkylated 1,4-diboracyclohexadienes (**1**). Instead the ^{11}B NMR signals of various carbaboranes were steadily growing as the reaction proceeded whereas the ^{11}B resonances for the haloboration products **3a, b** decreased in relative intensity. In the room temperature reaction after 24 h there was a ^{11}B resonance of minor intensity (δ ^{11}B 58.8) which we cannot explain. This signal vanished after 48 h at room temperature and it was not found when the reaction mixture was heated to reflux.

The mixture "C_8K" (**C**) as a suspension in hexane together with 5-decyne was heated to reflux and $MeBBr_2$ in hexane was added. No visible change occurred. The ^{11}B NMR spectrum showed the presence of $MeBBr_2$ and the haloboration product **3b**. After 18 h in boiling hexane the typical ^{11}B resonances for carbaboranes, **2b**, appeared together with an intense signal for Me_2BBr and there was still much left of $MeBBr_2$ and **3b**. After 48 h the carbaborane ^{11}B-resonances are dominant but the overall intensity had much decreased which indicates decomposition and/or polymerisation.

Finally, we looked at the reaction between $MeBBr_2$ and C_8K (**B**) in hexane. The golden solid was attacked very slowly and a black powdery solid was formed. The ^{11}B NMR spectrum of the colourless supernatant solution taken after 4 days showed only the resonance of unreacted $MeBBr_2$.

The ^{11}B NMR data of the organoboranes identified are given in Table 2, together with data of known compounds for comparison. The haloboration reactions have been carried out independently and the ^{11}B NMR parameters are identical with those measured from the reaction solutions.

Further identification relies on ^{13}C NMR data of the reaction products which can be compared with known data of compounds synthesized independently. The various ^{11}B resonances have been related to the broad ^{13}C resonances of the boron-bonded carbon atoms by selective ^{11}B

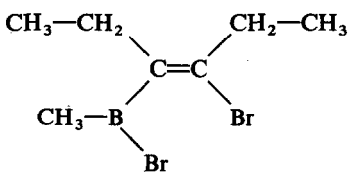
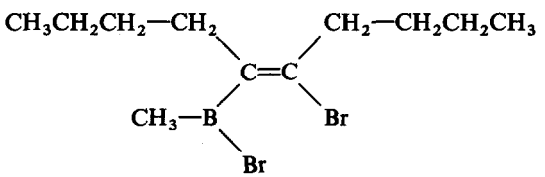
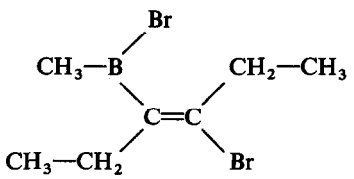
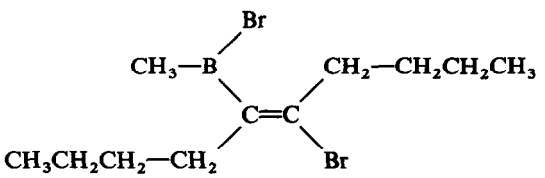
[f] Ref. 27 reports δ ^{11}B −6.3 in CS_2.

decoupling in heteronuclear triple resonance experiments ^{13}C $\{^{1}H, ^{11}B\}$. There are two ^{11}B resonances in the typical range for carbaboranes[22] at δ ^{11}B 6.9 and −13.7 for which no assignment is possible at present. Their intensity is much reduced after distillation and the identification of the compounds in the GC/MS analysis was not possible. However, selective ^{13}C $\{^{1}H, ^{11}B\}$ experiments[16b] related the ^{11}B resonance at −13.7 to a ^{13}C resonance of a quaternary carbon atom at δ ^{13}C 65.4. In the same experiment the ^{13}C resonances in the alkyl-region were not affected which indicates that the ^{11}B resonance at −13.7 belongs to B–Br units. Irradiating the ^{11}B resonance at δ ^{11}B 6.9 led to sharpening of ^{13}C resonances at δ ^{13}C −6.3 and δ ^{13}C 134.0. The ^{13}C resonances for C(2, 3, 4, 5) in the carbaboranes **2** are found in the same region as reported in the literature,[16b] between δ ^{13}C 99–110.









In order to enable stereochemical assignments of 1,2-haloboration products relevant δ ^{13}C-data of the (*Z*, *E*)-isomers **3a, b, 4a, b** are given in Table 3. The assignments rely on known substituent effects[25] and on ^{11}B decoupling which removes residual broadening due to $^{3}J(^{13}C^{11}B)$ across the double bond assuming that $^{3}J(^{13}C^{11}B)_{trans} > {}^{3}J(^{13}C^{11}B)_{cis}$.

The GC/MS analysis of the distilled products from the reaction of C_8K (**A, B**) in hexane with $MeBBr_2$ in the presence of 5-decyne confirmed the results from the ^{11}B- and ^{13}C NMR spectra. Apart from hexabutylbenzene the mixture contains mainly the carbaborane **2b** and small amounts of other carbaboranes. One of the other carbaboranes present in minor quantity is shown in the ^{11}B NMR and in the GC/MS analysis as a peralkylated C_4B_4-system, (**8**), which has been previously reported.[27]

DISCUSSION

All observations in this study are in support of the 1,2-haloboration[26] as the first step of the reaction leading to the compounds **3**. Under the reaction conditions the (*E*)-isomer, **4**, is also formed to a minor

Table 3. Some ^{13}C NMR data for the 1,2-haloboration products **3a, b** and **4a, b**

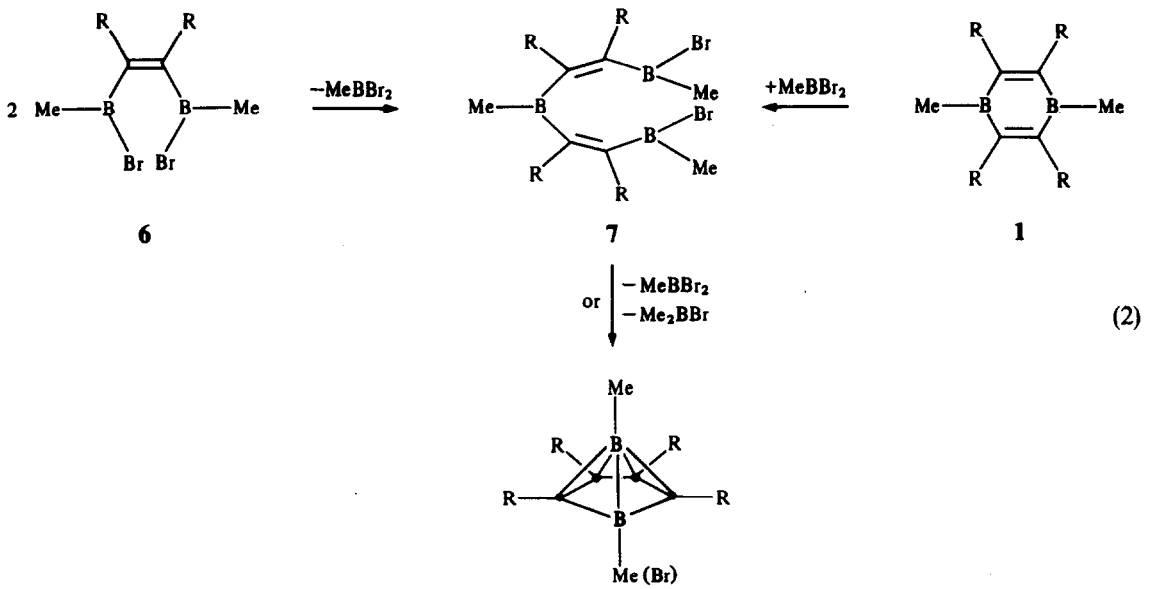
[b] In $CDCl_3$ (δ ^{13}C 77.0), 27°C.

extent. When the reaction is followed by ^{11}B- or ^{13}C NMR it is evident that the amount of the (*Z*)-isomer, **3**, decreases whereas the (*E*)-isomer seems to be more stable in the reaction solution. The appearance of signals for Me_2BBr shows that complex exchange reactions take place in addition to the reduction reactions. This is also evident from the fact that *nido* - 1,2,3,4,5 - pentaalkyl - 6 - bromo - 2,3,4,5 - tetracarbahexaboranes(6), (**2c, d**), are observed in the ^{11}B NMR spectra and in the GC/MS analysis. There are no ^{11}B resonances in the range expected[22] for the 1,4-dibora-2,5-cyclohexadienes, **1** (δ ^{11}B 55–65). We have no direct proof that the reduction of **3** leads to a borirene, **5**, which has been characterized for R = tert.-Bu[3,13] from the same type of reaction. However, the intermediacy of **5a, b** could explain the presence of various organoboranes identified in the reaction solutions. It can be expected that **5** reacts very fast with excess of $MeBBr_2$ by ring opening to give **6** [Eqn (1)]. Compounds of type **6** are precursors

As has been pointed out[13] the dimerization of the borirenes, **5**, can lead either to the 1,4-dibora-2,5-cyclohexadienes, **1**, or to the carbaboranes, **2**. If the formation of **1** is considered to take place ring opening of **1** in the presence of $MeBBr_2$ to give **7** has to be taken into account too [Eqn (2)], and this will lead to **2** again.

We are unable to account for the major differences between our results and those previously published.[13] Although, as has been mentioned, the preparation of the potassium-graphite may explain some differences, our failure to observe any 1,4-dibora-2,5-cyclohexadienes (**1**) at all is noteworthy. We may add that the mixtures obtained by fractional vacuum distillation had the same appearance as described[13], viscous, yellow, air and moisture sensitive. The GC/MS analysis of these mixtures revealed that the main organoborane component is the carbaborane **2** (proved by ^{11}B- and ^{13}C NMR) which, of course, has the same composition as **1**. The



(1)

3 **5** **6**

of carbaboranes **2** and **8**, either via direct reduction of **6** (leading to **8** in case of R = Et, Bu, and to a 1,3-diboretene in case of R = tert.-Bu[13,28]) or via compounds **7** (which tend to rearrange and to boron halides[15,16b]) [Eqn (2)].

air and moisture sensitivity, as well as the yellow colour was traced to small amounts of organoboron bromides like **3** or **4**. Therefore, it is concluded that the reported[13] synthesis of hexaalkyl-1,4-dibora-2,5-cyclohexadienes (**1**) is not firmly established. We

(2)

6 **7** **1** **2**

emphasize that ^{11}B NMR, in particular in combination with ^{13}C NMR, is very convenient to analyse complex mixtures of organoboranes.

EXPERIMENTAL

NMR spectra were recorded with a BRUKER WP-200 spectrometer operating in PFT-mode at 50.3 MHz (^{13}C) and 64.2 MHz (^{11}B). The ^{13}C-probehead was modified to perform $^{13}C\{^1H, ^{11}B\}$ heteronuclear triple resonance experiments. Energy dispersive X-ray diffractograms were recorded on a home-built apparatus.[17] The XPS data were obtained on a Leybold-Heraeu spectrometer with the EA 10 analyser. Spectra were taken at 80 K in a vacuum of 2×10^{-10} torr.

All operations were carried out under dry and oxygen-free nitrogen or argon. Solvents were carefully dried, degassed and saturated with nitrogen. The alkynes were commercial products, $MeBBr_2$ was prepared from Me_4Sn and BBr_3.[29] The purity of $MeBBr_2$ (BBr_3 and $Me_2BBr < 3\%$) was checked by ^{11}B NMR.

Potassium-graphite, C_8K

Method A. 25 g synthetic graphite powder (Lonza, KS 2.5) was filled in a two-bulb tube of 28 mm diameter and *ca* 55 cm length. After heating to 300°C/10^{-6} torr for 3 h the tube was transferred to an argon-filled box (water level *ca* 0.4 ppm). 10.1 g potassium (Merck, doubly distilled before use) to form $C_{8.05}K$ was added. The tube was then sealed under vacuum (10^{-6} torr) and placed for 24 h in a two-zone furnace with the graphite side at 320°C and the potassium side at 300°C. The resulting potassium-graphite was filled into various flasks for further reactions.

Method B. The preparation was carried out in a similar way as in A. Quadratic pieces of $5 \times 5 \times 0.2$ mm grafoil (Union Carbide) were used and the reaction was conducted at temperatures of 310°C (graphite) and 290°C (potassium) for 36 h.

Method **C**. The preparation was carried out as described.[18] Flakes (S40) of natural graphite were used.

Reactions of C_8K *with* $MeBBr_2$ *in the presence of alkynes*

6.75 g (50 mmoles) of C_8K (**A, B, C**) were suspended in 25 cm^3 benzene or hexane and 20 mmole 3-hexyne or 5-decyne were added. According to the experimental conditions required (see results) solutions of 3.72 g $MeBBr_2$ (20 mmole) in 10 cm^3 benzene or hexane were added dropwise over a period of *ca* 0.5 h. When the proceeding of the reaction had been checked by ^{11}B NMR the solid was separated by filtration and volatile materials were removed *in vacuo* from the dark brown liquid. Fractional distillation (40–80°C/10^{-3} torr) in case of potassium-graphite (**A, B**) gave mixtures of compounds as described (results), whereas in case of potassium-graphite (**C**) only traces of the carbaboranes **2a, b** could be recovered. For C_8K (**A, B**) the yield of **2a, b** (based on $MeBBr_2$) was *ca* 35%.

A DIPHOSPHIDE ADDUCT OF DITUNGSTEN-HEXAISOPROPOXIDE: X-RAY CRYSTAL STRUCTURE OF $W_2(OPr^i)_6(py)(\mu\text{-}P_2)$

MALCOLM H. CHISHOLM,* KIRSTEN FOLTING, JOHN C. HUFFMAN and J. J. KOH
Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 21 *January* 1985; *accepted* 1 *February* 1985)

Abstract—From the reaction between $W_2(OPr^i)_6(py)_2$ and $Co_2(\mu\text{-}P_2)(CO)_6$ in hexane at room temperature a black crystalline product has been shown to be $W_2(OPr^i)_6(py)(\mu\text{-}P_2)$ by a single crystal X-ray determination. There is a central pseudo tetrahedral W_2P_2 moiety with W—W = 2.695(1) Å, P—P = 2.154(4) Å and W—P = 2.45(2) Å (averaged) corresponding to essentially single bond distances. This new compound is an analogue of the ethyne adducts $W_2(OR)_6(py)(\mu\text{-}C_2H_2)$, where R = Bu^t and CH_2Bu^t, and these in turn are related to $Co_2(CO)_6(\mu\text{-}X)$ compounds (X = P_2, C_2R_2) by isolobal relationships.

There are many complementary aspects of the chemistry of the alkoxide and carbonyl ligands. Alkoxides may act as π-donors and stabilize high oxidation state early transition metal ions, which are d^n electron-poor, while carbonyl ligands are π-acceptors and stabilize the d^n electron-rich later transition elements in their low oxidation states. Both ligands may act as bridging ligands (μ_2 and μ_3) and often bridge $\rightleftharpoons$ terminal site exchange is rapid on the NMR time scale. The 15-electron fragment $Co(CO)_3$ and the d^3-fragments $W(OR)_3$ and $W(OR)_3(py)$ are isolobal.[1,2] The templates $Co_2(CO)_6$ and $W_2(OR)_6$ both support perpendicular alkyne adducts[3,4] and the alkylidyne capped compounds $Co_3(\mu_3\text{-}CR)(CO)_9$[5] and $W_3(\mu_3\text{-}CMe)(OPr^i)_9$[6] may also be viewed as isolobal analogues. We describe here our fortuitous discovery of $W_2(OPr^i)_6(py)(\mu\text{-}P_2)$, which provides a further extension of the $(W{\equiv}W)^{6+}$ and "$(CO)_3Co{\equiv}Co(CO)_3$" relationships.

We recently found that, in hexane at room temperature, the reaction between $W_2(OPr^i)_6(py)_2$[7] and $Fe_2(\mu\text{-}S_2)(CO)_6$[8] yields $W_2Fe_2S_2(OPr^i)_6(CO)_5(py)$.[9] This compound contains a planar W_2Fe_2 unit with two W—Fe bonds and one W—W and one Fe—Fe bond supported by two $\mu_3\text{-}S^{2-}$ ligands. This prompted us to investigate the reaction between the structurally related and isoelectronic compound $Co_2(CO)_6(\mu\text{-}P_2)$[10] and $W_2(OPr^i)_6(py)_2$. Under analogous conditions in hexane at room temperature the black crystalline compound $W_2(OPr^i)_6(py)(\mu\text{-}P_2)$ was isolated in *ca* 30% yield by cooling the solution to −15°C. The fate of the $Co(CO)_3$ fragments, which quite plausibly form $Co_4(CO)_{12}$, are currently not known. Further studies of this reaction and possible alternate, more direct synthetic routes to $W_2(OPr^i)_6(py)(\mu\text{-}P_2)$, such as a direct reaction between P_4 (one half equivalent) and $W_2(OPr^i)_6(py)_2$, are currently under investigation.

A view of the molecular structure of $W_2(OPr^i)_6(py)(\mu\text{-}P_2)$ deduced† from a single crystal

* Author to whom correspondence should be addressed.

† Crystal data for $W_2(OPr^i)_6(py)(\mu\text{-}P_2)$ at −162°C; a = 9.021(3) Å, b = 20.174(10) Å, c = 16.824(6) Å, β = 92.70(2)°, Z = 4, $d_{calc.}$ = 1.826 g cm^{-3}, and space group $P2_1/n$. Of the 7375 reflections collected using Mo-K_α, $6° \leqslant 2\theta \leqslant 45°$, 4120 were unique and the 3447 having $F > 3\sigma(F)$ were used in the least-squares refinement. H atoms were included as fixed-atom contributors in idealized positions. All other atoms were refined anisotropically. Final residuals are $R(F)$ = 0.0359 and $R_w(F)$ = 0.0352.

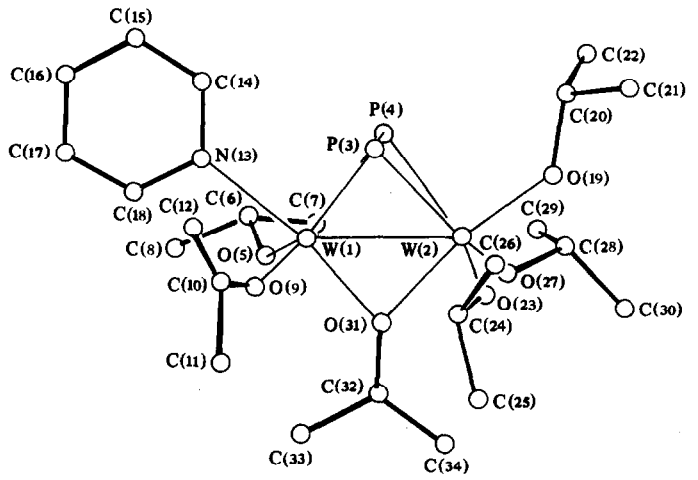

Fig. 1. A ball-and-stick drawing of the $W_2(OPr^i)_6(py)(\mu\text{-}P_2)$ molecule giving the number scheme for the atoms. Pertinent distances (Å) are: W(1)—W(2) = 2.695(1), W(1)—P(3) = 2.432(3), W(1)—P(4) = 2.428(3), W(1)—O(5) = 1.902(7), W(1)—O(9) = 1.892(7), W(1)—O(31) = 1.989(6), W(1)—N(13) = 2.258(8), W(2)—P(3) = 2.491(3), W(2)—P(4) = 2.462(3), W(2)—O(19) = 1.919(7), W(2)—O(23) = 1.901(7), W(2)—O(27) = 1.932(7), W(2)—O(31) = 2.074(7), P(3)—P(4) = 2.154(4).

X-ray determination is shown in Fig. 1. There is a central pseudo-tetrahedral W_2P_2 unit with W—W = 2.69 Å, P—P = 2.15 Å and W—P = 2.45(2) Å (averaged). The presence of one alkoxide bridge and one supporting pyridine ligand make this P_2 adduct a structural analogue of the compounds $W_2(OR)_6(py)(\mu\text{-}C_2H_2)$, where R = Bu^t[4] and CH_2Bu^t.[11] The compound $W_2(OPr^i)_6(py)_2(\mu\text{-}C_2H_2)$ also contains a central pseudo-tetrahedral W_2C_2 core but this is supported by two alkoxide bridges and has one pyridine ligand bonded to each W atom.[4] The presence of one or two OR bridges and one or two pyridine ligands is believed to reflect subtle steric differences between the various OR ligands. Since the alkoxide ligands can act as σ- and π-donors the total valence electron count for each tungsten atom is "buffered" with respect to the EAN rule and the presence of supplemental pyridine ligands. Thus the present compound is viewed as an analogue of $Co_2(CO)_6(\mu\text{-}P_2)$[10] and $Co_2(CO)_5(PPh_3)(\mu\text{-}P_2)$.[12]

The P—P distance in $W_2(OPr^i)_6(py)(\mu\text{-}P_2)$ is close to the single P—P distance, 2.21 Å, in P_4[13] and notably longer than the P—P distance, 2.019(9) Å, observed in $Co_2(CO)_5(PPh_3)(\mu\text{-}P_2)$.[12] This parallels the longer C—C distances seen in alkyne adducts of $W_2(OR)_6$ relative to "$Co_2(CO)_6$" and reflects the greater reducing power of the $(W{\equiv}W)^{6+}$ moiety.[4] The compounds $(Bu^tO)_3W{\equiv}P$ and $(Pr^iO)_9W_3(\mu_3\text{-}P)$, analogues of $(Bu^tO)_3W{\equiv}N$[14] and $(CO)_9(Co_3(\mu_3\text{-}P))$[15], may also be accessible.

Further studies are in progress.

SPECTROPHOTOMETRIC DETERMINATION OF STABILITY CONSTANTS OF Ni(II) AND Cu(II) COMPLEXES WITH *N*-SUBSTITUTED HYDRAZINEDITHIOCARBOXYLIC ACIDS

A. IZQUIERDO*
Departamento de Química Analítica, Facultad de Química, Universidad de Barcelona, Diagonal 647, Barcelona-8, Spain

and

J. GUASCH and F. X. RIUS
Departamento de Química Analítica, Facultad de Química en Tarragona, Universidad de Barcelona, Pl. Imperial Tárraco s/n, Tarragona, Spain

(*Received* 8 *February* 1985; *accepted* 26 *February* 1985)

Abstract—The stability constants of Ni(II) complexes with 2-methylhydrazinedithiocarboxylic and 3,3-dimethylhydrazinedithiocarboxylic acids and Ni(II) and Cu(II) complexes with 3-methyl-3-phenylhydrazinedithiocarboxylic acid have been determined in aqueous solution at 25°C and $I = 0.01$ M. The Bjerrum method of corresponding solutions has been applied, revealing the simultaneous presence of 1:1 and 1:2 complexes in solution.

The study of metallic complexes, in the solid state, of hydrazinedithiocarboxylic acids (dithiocarbazic acids)[1–3] and their derivatives[4–6] is currently drawing considerable attention. These compounds are extensively used as surfactants, pharmaceuticals, fungicides and in vulcanization processes. However, there is little information concerning their chemical equilibria in solution. Byr'ko *et al.*[7] found two ionization constants for the acid–base equilibrium of hydrazinium dithiocarbazate ($pK_1 = 3.87$ and $pK_2 = 8.90$) whilst Izquierdo *et al.*[8] recently reported the existence of only one protonation constant for the ligands: 2-methyldithiocarbazate ($pK = 5.42$), 3,3-dimethyldithiocarbazate ($pK = 4.73$) and 3-methyl-3-phenyldithiocarbazate ($pK = 6.18$). No data have been found in the literature relating to the stability constants of the dithiocarbazate metallic complexes.

In the present work, the spectrophotometric determination of the stability constants at 25°C and $I = 0.01$ M of 2-methyldithiocarbazate and 3,3-dimethyldithiocarbazate complexes with Ni(II) and 3-methyl-3-phenyldithiocarbazate complexes with Ni(II) and Cu(II) is reported.

EXPERIMENTAL

The synthesis of the ligands has been described elsewhere.[8] The Cu(II) (1.55×10^{-2} M) and Ni(II) (1.908×10^{-1} M) stock solutions were obtained by diluting the proper amount of $Cu(NO_3)_2 \cdot 3H_2O$ and $NiCl_2 \cdot 6H_2O$ respectively in distilled water. Their concentrations were determined electrogravimetrically.[9] Buffer solutions ($I = 0.01$ M) were prepared according to Perrin and Dempsey.[10]

A Beckman UV5260 spectrophotometer, equipped with 1.00-cm quartz cells was used for spectrophotometric measurements. pH values were measured in a Radiometer PHM-64 pHmeter using a G-202 glass and a K-401 saturated calomel Radiometer electrodes, standardized with buffer solutions of pH = 4.008 and 6.865 (25°C) according to the NBS.[11]

The absorbance of five different series of solutions for each complex studied was measured at two wavelengths in the region where the free ligands do

* $U = \sum_1^N (\bar{n}_{exp.} - \bar{n}_{calc.})^2$.

† $W = \left\{ \sum_1^N |(\bar{n}_{exp.} - \bar{n}_{calc.})100/\bar{n}_{exp.}|^2/(N-1) \right\}^{1/2}$.

not absorb. In each series, the analytical concentration of metal ion (M_T) was kept constant within the range 0.18×10^{-5}–5.3×10^{-5} M, while the analytical concentration of ligand (L_T) was varied within the range 0.6×10^{-6}–1.2×10^{-4} M, being the pH controlled by means of a buffer solution of I = 0.01 M. All solutions have been thermostatted at 25±0.1°C. The optimum conditions for the spectrophotometric study to be carried out were established beforehand.

The Bjerrum method of corresponding solutions was applied.[12] The preliminary overall stability constants (β_n), determined by means of graphical analysis from $[L]$ and $\bar{n}$ pairs of values, were used as input data for the MINI1W program computer for nonlinear minimax optimization,[13] by using a Digital PDP 11 | 60 computer.

RESULTS

Since, for all complexes studied, the most favourable pH range spans the interval 5.1–9.3, a phosphate buffer, pH = 7.70, was chosen on account of the small stability constants of the Ni(II) and Cu(II) complexes with this ligand.[14] The overall stability constants found are given in Table 1. When comparing the values found in the present work with those corresponding to Cu(II) complexes with several *N*-substituted dithiocarbamic acids,[15] greater values of the last-named ($\log \beta_1$ = 11–12.5, $\log \beta_2$ = 21–24) are noticed. On the contrary, Hulanicki[15] has found a value of the stability constant for the Ni(II) complex with bis(carboxymethyl)dithiocarbamic acid much lower ($\log \beta_2 = 7.9$) than those reported in this paper for the Ni(II)–dithiocarbazate complexes.

I. NATURE OF BONDING

A. Spectroscopic properties

(*a*) *IR.* The IR spectra of substituted and nonsubstituted benzene chromium tricarbonyl complexes have been extensively studied and reviewed.[1] This paper will focus on the carbonyl stretching frequencies and will give only the main conclusions.

All the complexes have two IR active stretching vibrations for the terminal carbonyl groups in agreement with the C_{3v} local symmetry (Tables 1 and 2). However, when high-resolution spectra are studied, and when unsymmetrically substituted arenes are involved, this C_{3v} local symmetry is of more restricted validity.

Here the degenerate $(E)\nu_{CO}$ band is split[2,3] but the splitting is small [$\leqslant 10\ cm^{-1}$ (Table 3)].

The IR absorptions of the $Cr(CO)_3$ groups are sensitive to the electronic effects of the substituent of the arene ligand transmitted through the metal to the carbonyls of the $Cr(CO)_3$ group[2,4–12] (Tables 1

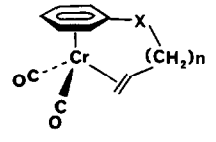
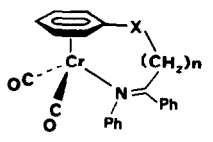
* $\Delta\nu = \nu[ArCr(CO)_3] - \nu[ArCr(CO)_2L]$.

and 2). The frequencies and the force constants calculated using the approach proposed by Cotton[13] are found to decrease slightly as the electron-donating power of the substituent increases. However there is practically no influence due to the relative position of the substituents within the ring.[4,5] Good correlations are also found between the force constant of the carbonyl (or the stretching frequencies) and the different Hammett constants of the substituents.[4,5,7] This behaviour indicates that an increase in π-electron density enables the chromium atom to transfer electrons into the antibonding orbitals of the C≡O groups, thus decreasing the CO bond order.



A decrease in the ν_{CO} frequencies is also observed when one of the C≡O is replaced by a phosphine,[14–16] an imine[17] or an olefin[11,14,18] (see Tables 4 and 5). Phosphines, imines and olefins are electron-releasing substituents which increase electron density on the chromium atom. Back-donation from the chromium atom occurs into the antibonding orbitals of the two remaining C≡O and thus decreases the CO bond order. Empty *d*-orbitals of the phospine as well as π-antibonding orbitals of the imines or olefins are obviously less available than those of C≡O for such back-bonding.

However, it must be noticed that replacement of one C≡O by malic anhydride increases the frequency of the *E* band by 20–28 cm^{-1}, the *A*-band being constant.[19,20]



(*b*) *NMR.* The most obvious characteristic of the ^1H, ^{13}C and ^{19}F NMR spectra is the upfield shift of the corresponding resonance upon complexation.

On complexation with $Cr(CO)_3$ aromatic protons undergo an upfield shift of about 1.5–2.5 ppm.[4–6,21,22] Some hypotheses were proposed to explain this diamagnetic shift. The upfield shift could be ascribed to a decrease of the "ring current" contribution to the chemical shift.[23] However, it has been shown that vinylic protons also undergo a 3–3.7 ppm upfield shift on complexation,[11] and that complexation with $Cr(CO)_3$ of compound **1** (to **2**) does not disrupt the aromatic ring current as the chemical shift of $H_a(\delta_a)$ does not change.[24]

Some recent X-ray and neutron diffraction data[25,26] showed a slightly distorted ring, the hydrogen being displaced by $2\text{–}4 \times 10^{-2}$ Å from the ring towards the chromium; however, the ^1H proton spectrum with ^{13}C satellites of benzene–$Cr(CO)_3$ oriented in a nematic phase does not allow the detection of such a deviation.[27] Hence, a change in hybridization may not be the only factor responsible for the shielding. It has been proposed that the magnetic anisotropy of the $Cr(CO)_3$ moiety and of the electrons in the ring–metal bond could produce an upfield shift of the ring proton resonance of the same order of magnitude as the observed shift.[28] This last hypothesis has not yet been refuted.

The most obvious features of the ^{13}C spectra are the large upfield shift—30–40 ppm—of the ring-carbon resonances, and the large downfield shift of the carbonyl-carbon resonances (relative to the uncomplexed C≡O).[29–31] This ring-carbon diamagnetic shift was first related to the change in mobile bond order.[29] Then changes in hybridization of the carbons (associated with the use of π-orbitals for σ-bonding with metal *d*-orbitals) were invoked.[30] It is also possible to account for the observed chemical shifts by postulating the presence of a negative charge on the complexed aromatic ring. But this approach requires the transfer of approximately one electron from the metal to the arene ligand.[31] More recently ^{13}C NMR paramagnetic shielding constants have been calculated using the SCCO MO method and the Pople–Karplus equation.[32] Although only a fair agreement is obtained between the calculated σ^p-values and observed shifts, it is gratifying to note that, in the case of benzene, an upfield shift is predicted as observed on complexation and that a downfield shift is predicted for the carbonyl carbon as observed (relative to free CO).

It is interesting to note that the ^{13}C resonance of methyls substituted in the ring are almost unaffected by the complexation.[24–31] It must be noted also that on complexation olefinic carbon resonances are also usually shielded, the same mechanisms being invoked to explain this behaviour.[33–37]

A correlation has been observed between the ^{13}C carbonyl chemical shifts and either the weighted average of the force constant[31] (calculated using the approach of Cotton[13]) or the carbonyl stretching frequencies[38] for a series of arene–$Cr(CO)_3$. The carbonyl resonance is deshielded when the electron-donating power of the substituent increases, that is with increasing electron density on the $Cr(CO)_3$ group. Thus, it has been proposed that the carbonyl chemical shift reflects the extent of transition metal $\rightarrow \pi^*$ carbonyl back-donation. The study of the transmission of the substituent effects from the arene ring to the $Cr(CO)_3$ group via an analysis of the carbonyl resonance shows a slight predominance of inductive effects and agrees with an important overlap of the metal orbitals with the σ-framework of the arene.[39]

A large upfield shift of about 20 ppm has been observed on complexation with $Cr(CO)_3$ of fluorobenzene[40] for the ^{19}F resonance signal. Such a large shift cannot be explained by the magnetic anisotropy of the $Cr(CO)_3$ moiety alone, which should equivalently contribute to the chemical shift of ^{19}F and ^1H (~ -2 ppm). However, as for ^{13}C, the paramagnetic term of the shielding constant contributes much to the chemical shift of ^{19}F, and changes in hybridization of the vicinal carbon upon complexation might also have a large influence on the ^{19}F chemical shift.

B. Electronic effects

(*a*) *Dipole moments.* Electric dipole moments of arene–$(CO)_3$ complexes, measured in benzene solution, are quite large: ranging from 3.5 to 6.3 D[41–45] (Tables 6 and 7).

Table 6. Dipole moments of arene–$Cr(CO)_3$ measured in benzene solution

Ligand	Dipole moment (D) (Ref.)	Averaged value
C_6H_6	4.81 (43) 4.92 (41) 5.08 (42) 5.03 (44)	4.96
C_6H_5Cl	4.25 (43) 5.08 (42)	4.66
C_6H_5F	4.75 (41) 4.91 (42)	4.83
C_6H_5Me	5.20 (41) 5.26 (42)	5.23
C_6H_5OMe	5.26 (41) 5.43 (42)	5.34
$C_6H_5NMe_2$	6.30 (42) 6.18 (44)	6.24
$C_6H_5NH_2$	5.40 (41) 5.50 (44)	5.45
C_6H_5COMe	4.97 (44)	4.97
$C_6H_5CO_2Me$	4.47 (41)	4.47

According to the IR results (see above), to the numerous studies of the inductive effect of the $Cr(CO)_3$ group and to theoretical data (see below) it is well accepted that in arene–$Cr(CO)_3$ complexes there is a transfer of electrons from the arene ligand through the metal to the carbonyl groups. Hence, owing to the molecular structure, as revealed by X-ray diffraction studies,[46] benzene–$Cr(CO)_3$ has a dipole moment directed along the tricarbonyl C_3-axis and oriented from the arene group to the tripod.[42,44]

The dipole moment of a monosubstituted-benzene–$Cr(CO)_3$ complex is not an additive vector, in that it differs from the vectorial sum μ[benzene–$Cr(CO)_3$] + $\mu(C_6H_5X) = \mu_o + \mu_x$. Both components μ_o and μ_x adopt modified values in the complex.[44]

According to the values of the dipole moments obtained for symmetrically *p*-disubstituted benzene–$Cr(CO)_3$ complexes, where the μ_x-component is 0 (Table 7), it is quite clear that electron-donating

Table 7. Dipole moments of arene–$Cr(CO)_3$ measured in benzene solution

p-$(NH_2)_2C_6H_4$	5.52 (44)
p-$(CO_2Me)_2C_6H_4$	3.52 (43)

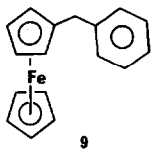
Table 8. pK_A[46]

$C_6H_5—CO_2H$ **3** 5.68	$\|C_6H_5—CO_2H\|Cr(CO)_3$ **4** 4.77	$p\text{-}NO_2—C_6H_4—CO_2H$ **5** 4.48
$C_6H_5—CH_2CO_2H$ **6** 5.64	$\|C_6H_5—CH_2CO_2H\|Cr(CO)_3$ **7** 5.02	$p\text{-}NO_2—C_6H_4—CH_2CO_2H$ **8** 5.01

substituents increase the μ_o-component while electron-withdrawing substituents decrease the μ_o-component.[42–44]

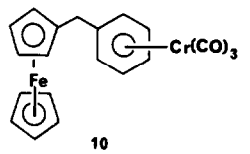
Hence the μ_o dipole moment component reflects the electron transfer from the ring to the carbonyls through the metal. However, in the case of disymmetric complexes the μ_x-component must be estimated first.[44]

(*b*) *Inductive effects.* Since the first synthesis of $C_6H_6Cr(CO)_3$ by Fischer[47(a)] and Nicholls[47(b)] the $Cr(CO)_3$ group has often been compared with the NO_2 group.



In 1959 the comparison of pK_A values of uncomplexed, complexed and p-NO_2-substituted acids (Table 8) led Whiting *et al.*[46] to the conclusion that the $Cr(CO)_3$ group has the same inductive effect as the NO_2 group.

However, the NO_2 group must have an extra capability to stabilize negative charges by resonance as the pK_A of **5** (4.48) is smaller than the pK_A of **4** (4.77).



It was already known that the $Cr(CO)_3$ group exerted a net electron-withdrawing effect on the ring as aniline–$Cr(CO)_3$ is a weaker base than aniline.[48]

Studying the polarographic oxidation of ferrocenyl compounds **9** and **10** according to eqn (1) Khandkarova *et al.*[49] found that the redox potential increases by 90–100 mV from **9** to **10** which confirms the inductive effect of the $Cr(CO)_3$ group:

$$\mathbf{9} \text{ or } \mathbf{10} \xrightarrow{-e} \mathbf{9}^+ \text{ or } \mathbf{10}^+. \tag{1}$$

9

10

A highly positive inductive aromatic constant, $\sigma_i = +0.31$, has been calculated for the $C_6H_5Cr(CO)_3$ group, close to that of strong electron-withdrawing substituents such as COMe (+0.28) and CHO (+0.31), but the main result of this study is the fact that coordination of the phenyl ring in **9** with the $Cr(CO)_3$ group giving **10** considerably influences the effective positive charge of the aromatic ring σ-carbon orbitals, thus increasing its electronegativity. Therefore, it should be accepted that coordination with the metal concerns the σ- rather than the π-orbitals of the ligand. This would be consistent with the general theory of the bond in the transition metal π-complexes developed by Chatt and Duncanson,[50] where there might be mutual compensation between direct donor–acceptor interaction from the ligand to the metal and back-donation from the metal to the ligand, resulting in an almost invariant π-electron density in the benzene molecule upon coordination.

The changes in chemical shifts of the fluorine atom in fluorobenzene on substitution with a $C_6H_5Cr(CO)_3$ group[51] (Table 9) are consistent with an electron-withdrawing effect of a $C_6H_5Cr(CO)_3$ group.

Table 9. ^{19}F NMR: $FC_6H_5 \rightarrow FC_6H_4—R$

R	*m*-C_6H_5	*p*-C_6H_5	*m*-$C_6H_5Cr(CO)_3$	*p*-$C_6H_5Cr(CO)_3$
$\Delta\delta_F$*	+0.05	+2.97	−0.66	−0.55

* $\Delta\delta_F = \delta_F$ (fluorobenzene) $- \delta_F$ (substituted fluorobenzene) (ppm).

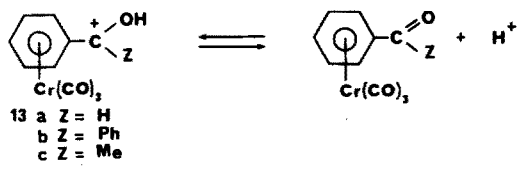
m-Cl—$C_6H_4CO_2Me$	−1.3686	+0.3483
o-Cl—$C_6H_4CO_2Me$	−1.8996	
$C_6H_5CO_2Me$	−2.0969	−0.2034
p-Me—$C_6H_4CO_2Me$	−2.5100	−0.5045
p-NH_2—$C_6H_4CO_2Me$	−3.5686	−1.5467

Estimation of the σ_i inductive and σ_R resonance constants gives +0.21 and −0.04. Comparison with the values obtained for C_6H_5 (+0.10 and −0.09) leads to the conclusion that there is a significant increase in the phenyl electron-withdrawing ability of the inductive type, whereas its tendency to conjugation is almost the same. In other words these results again suggest that coordination of benzene with the $Cr(CO)_3$ group essentially changes the effective positive charge on the σ-carbon orbitals of the aromatic ring while the total π-electron density changes negligibly.

Base-catalyzed hydrolysis of a number of substituted methyl benzoates uncomplexed and complexed with $Cr(CO)_3$[52] (Table 10) showed that the chromium complexes reacted considerably faster than the uncomplexed arene. The effect of the $Cr(CO)_3$ group on ester hydrolysis is almost exactly equal to that of a p-NO_2 group ($\log k = -0.2034$ and -0.1952 respectively). The enhanced reactivity of complexed benzoic esters can be best explained by a decreased electron density at the electrophilic centre and so by an increasing effective positive charge of the aromatic ring σ-carbon orbitals.



(*c*) *Stabilization of a positive charge in α or β-position.* Electronic spectra of complexed cation **11** have been measured in degassed 80% sulphuric acid and dilute solutions.[53] Determination of pK_{R^+}, eqn (2), by Deno's method[54] shows that the complexed cation **11** is more stable ($pK_{R^+} = -11.8$) than the uncomplexed cation **12** ($pK_{R^+} = -17.3$) and that a donor substituent in the *para* position on the complexed ring again increases the stability of cation **11** (p-Me, $pK_{R^+} = -11.0$; p-OMe, $pK_{R^+} = -10.2$):

(2)

with K_{R^+} = [alcohol][H^+]/[cation].

Complex cations such as **13a** and **13b** also proved to be more stable than the uncomplexed one[55] [eqn (3) and Table 11]:

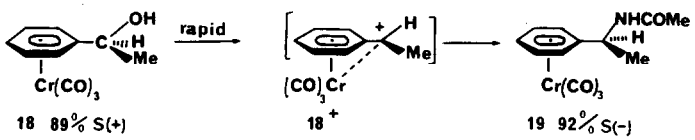
(3)

Table 11.

Z	pK_{BH^+} (free)*	pK_{BH^+} (complexed)*
H	−7.11	−5.46
Ph	−6.13	−5.68
Me	−5.91	−5.96

* $K_{BH^+} = [B][H^+]/[BH^+]$, B = aldehyde or ketone.

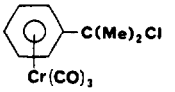
However, the behaviour of methyl is not very clear.

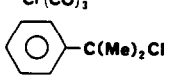


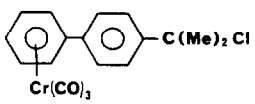
In solvolysis reactions (SN_1) a positive charge develops at the carbon which undergoes the reaction in the transition state and they provide good models to study the stabilization of a positive charge in the α-position.

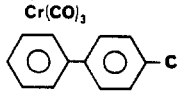
Holmes *et al.*[56] have shown that solvolysis of benzyl chloride–$Cr(CO)_3$ is 10^5 faster than the solvolysis of the uncomplexed benzyl chloride, the most reasonable explanation for this rate enhancement being a preferential stabilization of the cation intermediate due to increased back-donation from the chromium atom to the ligand.

Solvolysis of π-(tricarbonyl chromium) cumyl chloride (**14**) and *p*-[π-(tricarbonyl chromium)phenyl] cumyl chloride (**16**)[57] (Table 12) shows also that the $C_6H_5Cr(CO)_3$ group stabilizes an α-carbonium ($k_{compl.}/k_{lig.} = 28$). However the $C_6H_5Cr(CO)_3$ substituent, when separated from the reaction centre by a phenyl, stabilizes the cation less than the uncomplexed phenyl ($k_{compl.}/k_{lig.} = 0.4$), probably because of its known electron-withdrawing ability.



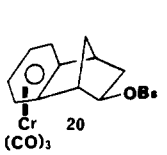






INDO molecular orbital calculations have been carried out on the free benzyl carbonium ion and on the coordinated cation $[(benzyl)Cr(CO)_3]^+$. The stability of the coordinated benzyl cation was shown to arise mainly via back-bonding from the chromium $d_{x^2-y^2}$ orbital into the non-bonding π-orbital of the benzyl ligand.[58]

The remarkable stabilization of a positive charge on the α-carbon via back-bonding from the chromium is confirmed by ^{13}C NMR results. At −50°C the *ortho*-carbons as well as the three carbonyl carbons of carbonium 18^+ display complete non-equivalence: 103.2, 106.7, 226, 226.5 and 227.[59(a)] And more recently Top and Jaouen[59(b)] found that the Ritter reaction on optically active complex **18** leads to an optically active complex, **19**, with complete retention of configuration [eqn (4)]:



18 89% S(+) 18+ 19 92% S(−) (4)

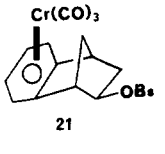


Table 12.

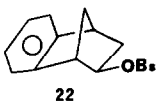
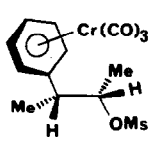
		10^5k (s^{-1})	Temperature (°C)	
14		360	25	$k_{compl.}/k_{lig.} = 28$
15		13	25	
16		33.4	25	$k_{compl.}/k_{lig.} = 0.4$
17		83.3	25	

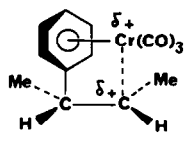


Solvolysis of the *syn-exo*-2 isomer of (benzonorbornen-2-yl) tricarbonyl chromium *p*-bromobenzenesulphonate, **20**, is 300 times faster than the solvolysis of **21**, the *anti-exo*-2 isomer, but the solvolysis of **21** is 400 times slower than the solvolysis of the free ligand **22**.[60(a)] The enhancement of the rate of solvolysis from isomer **21** to isomer **20** may be attributed to a direct interaction of *d*-filled non-bonding orbitals of the metal with the (+)β-carbon in the transition state. And the decrease of the rate of solvolysis from the free ligand **22** to the complex **21** may be explained by the fact that in complex **21** the π-electrons of the aromatic ring are less available for an hyperconjugative interaction with the vacant *p*-orbital of the (+)β-carbon than in the free ligand **22**.

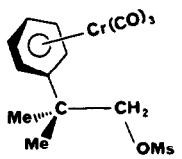
20



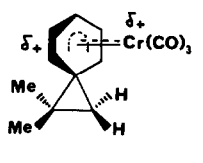
21



22

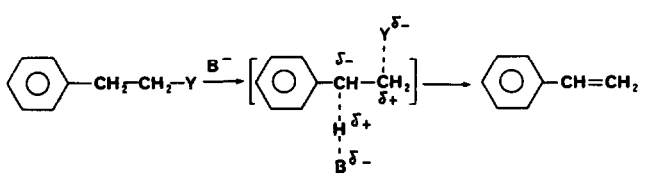


Ninety-four per cent retention of configuration obtained upon acetolysis of L-*threo*-3-[(phenyl) chromium tricarbonyl]-2-butyl methanesulfonate **23**[60(b),(c)] has also been attributed to a direct interaction of filled non-bonding *d*-orbitals of the metal with the (+)β-carbon, **23'**. However, the almost complete migration of the (phenyl) chromium tricarbonyl group during acetolysis of 2-[(phenyl) chromium tricarbonyl]-2-methyl-1-propyl methanesulphonate **24** must involve the cation **25**.



L(+) 23

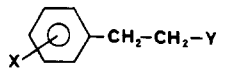
23'



24

25

(*d*) *Stabilization of a negative charge in the* α- *or* β-*position.* Base-catalysed elimination of 2-phenylethyl bromides and tosylates (E_2 type reaction) which develop a negative charge on the α-carbon in the transition state [eqn (5)] are good models for such studies:



(5)

Kinetic studies of such elimination reactions on compound **26**[61] [Table 13 shows that the $Cr(CO)_3$ group must be regarded, like NO_2, as a strong electron-withdrawing group as the olefin percentage increases from 38% (X = H, Y = OTs) to 97% (X = π-$Cr(CO)_3$, Y = OTs) and 100% (X = NO_2, Y = OTs)].

Complexing the phenyl group with $Cr(CO)_3$ strongly increases the rate of elimination and the extent of the acceleration is not the same in both cases: $k_{Cr(CO)_3}/k_H$ = 142 for OTs and 37 for Br. This difference probably originates in the different amount of negative charge present on the α-carbon in the transition states. The same effect occurs with NO_2; k_{NO_2}/k_H = 4020 for OTS and 1970 for Br. However there is a substantial difference between the kinetic effects of $Cr(CO)_3$ and NO_2; $k_{Cr(CO)_3}/k_H$ = 142 but k_{NO_2}/k_H = 4020 for OTs and $k_{Cr(CO)_3}/k_H$ = 37 but k_{NO_2}/K_H = 1970 for Br. This arises from a lower capacity of

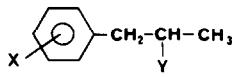


Table 13. E2 on compound **26**

$Cr(CO)_3$ to stabilize a developing negative charge at the α-carbon. A direct resonance interaction between the negative charge on the α-carbon and the substituent is present in the case of the NO_2 group but is absent when $Cr(CO)_3$ is involved. Hence it seems again that the transmission of the electronic effect through the ring involves mainly the σ-framework rather than the π-electron cloud. Kinetic studies of elimination reactions on compound **27** (Table 14) give consistent results.[62,63]

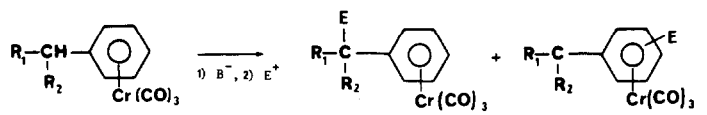
* From Ref. 66.
† From Table 15.



(*e*) *Basicity of benzylic protons vs aromatic protons.* The reactivities of benzylic protons vs aromatic protons in free aromatic ligands has received considerable attention and two general trends must be pointed out.[66] First, with *n*BuLi as base, α-alkyl substitution decreases the reactivity of benzylic protons relative to aromatic protons (Table 15).[66] Second, reactivities of benzylic protons relative to benzene decrease markedly according to the base in the order: BuOK/DMSO ≫ potassium amide > *n*-BuLi/TMEDA (Table 16).[66]

When the phenyl ring is complexed with a $Cr(CO)_3$ group, the results (Table 17)[67–69] show that with *n*-BuLi[67,68] at low temperature the reactivity of benzylic protons decreases relative to the free ligand [14 and 13% (Table 17) vs 89% (Table 16) and < 1% (Table 17) vs 37% (Table 16)]. However when the base is changed to *t*-BuOK[69,70] the only protons removed are the benzylic protons and, apparently, no reaction on the aromatic ring has been detected.

Nevertheless it is noteworthy that, as in the free ligand, α-alkyl substitution decreases the reactivity of benzylic protons relative to aromatic protons (14/69 when $R_1 = R_2 = H$ but < 1/80 when $R_1 = CH_3$ and $R_2 = H$) and that reactivity of benzylic protons relative to aromatic protons decreases markedly according to the base in the order: *t*-BuOK/DMSO ≫ *n*-BuLi.

In the presence of *t*-BuOK/DMSO Trahanovsky *et al.*[71] have shown that deuteration occurs only in the α-position of the complexed phenyl ring in complex **31** [eqn (7)], which indicates that under those

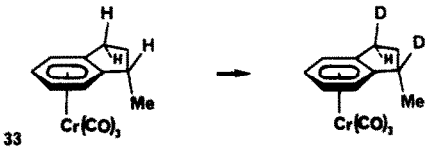
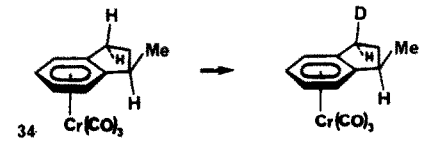
conditions the benzylic protons α to a $CrCO_3$-complexed ring are more acidic than those which are situated α to an uncomplexed phenyl ring:

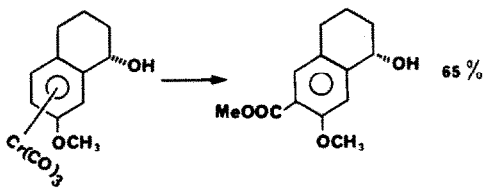


(7)



No deuteration on the ring was observed. It is noteworthy that in complex **32** only one proton of each $CH_2\alpha$ to the complexed ring was exchanged [eqn (8)]. In complexes **33** and **34** [eqn (9) and (10)] the *anti*-benzylic protons are preferentially removed. One possible explanation is that the back lobes of the sp^3 orbitals of the antibenzylic C—H bond are closer to the chromium atom and thus participation of the chromium moiety should be easier when these *anti*-protons are removed:

(8)



(9)

(10)

(*f*) *Metallation.* Alkyllithium compounds like MeLi, *n*-BuLi and *s*-BuLi can abstract aromatic protons in arene–$Cr(CO)_3$ complexes under mild conditions.[72–74] The main results are given in Table 18.

The selectivity proved to be high (and interesting for synthetic purpose) only in the case of OMe, F, Cl and *N*-disubstituted with large groups (entries 1–15) but quite poor in the other cases: Me, Et, *t*-Bu and $N(Me)_2$ substituents. When there are two possibilities, lithiation occurs at the less hindered position[74] as shown below

C. Theoretical calculations

The nature of the bonding in arene–$Cr(CO)_3$ complexes has been a topic of considerable interest since 1959.[75] Different methods have been used which appeared not to be quite as reliable as some calculations involve σ- and π-orbitals, and others only π-orbitals, and they do not emphasize the same parameters.

(*a*) *SCCC MO.* Carrol and McGlynn[76] reported in 1968 the results of semi-empirical molecular orbital calculations in which all the valence orbitals of the complex were included. Charge and configuration self-consistent Mulliken–Wolfsberg–Helmholz calculations were performed on $XC_6H_5Cr(CO)_3$ complexes (X = H, NH_2). The importance of the σ-orbitals of the ring in the metal–ring bonding was pointed out for the first time. The final charge distributions are shown in Fig. 1.

There is a net charge-transfer from the ring to the metal; despite this, the chromium is positively charged because of the electron-withdrawing effect of the carbonyl groups. The charge-transfer from the ring all the way to the oxygen of the carbonyls is more important in the case of aniline than for benzene, which leads to the prediction that the dipole moment of the aniline complex should be greater than that of the benzene complex, in agreement with the experiment. It is also pointed out that the π-back-donation from the metal to the carbonyl groups is larger (0.64e per CO) than the forward σ-donation from the carbonyl groups to the metal (0.534e per CO).

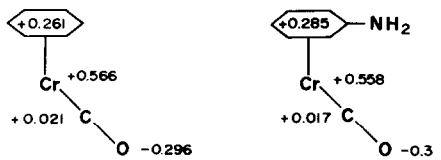

Fig. 1.

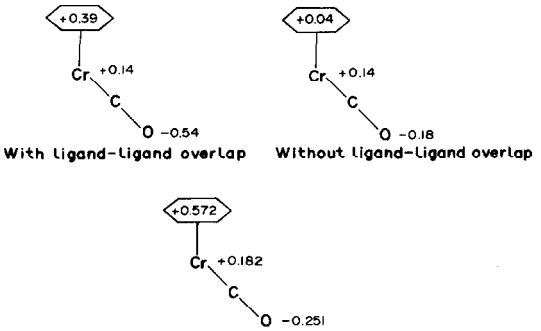

Fig. 2.

Application of SCCC MO theory by Brown[77,78] led to a somewhat different charge distribution (Fig. 2) but gave a satisfactory prediction of the first ionization potential (7.54 and 7.10 eV) compared to the known mass spectroscopic value of 7.39 eV.[79]

It is noteworthy that a charge transfer from the benzene ring (positively charged) to the metal towards the oxygen of the carbonyls (negatively charged) is also pointed out. When σ- and π-orbitals are involved in the calculations[80,81] it is found that the complexed aromatic ring is more negatively charged than before complexation (Fig. 3).

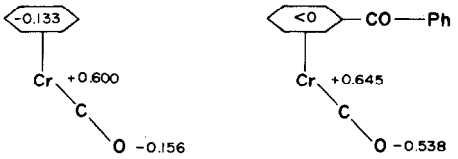

Fig. 3.

These results allowed the prediction of the upfield shift of the carbon atoms of the complexed ring using the Pople–Karplus equation[82] and assuming that changes in the paramagnetic term (σ^P) are alone responsible for the observed shifts.

(*b*) *CNDO/2.* The CNDO/2 formalism has been used by Kaufmann *et al.*[83] and Fitzpatrick *et al.*[84] They obtained quite different results for the charge distribution (Fig. 4) but they both concluded that the highest occupied orbitals are essentially metal orbitals in agreement with P.E. spectroscopic studies.[85] The metal–ring bond is apparently dominated by carbon-$2p_\pi$/chromium-$4p_\pi$ and -$3d_\pi$ interactions according to Kaufmann's results.

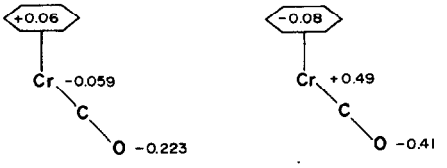

Fig. 4.

(*c*) Ab initio. *Ab initio* SCF MO calculations on a $C_6H_6Cr(CO)_3$ complex described by Guest *et al.*[86] led to very different charge distributions (Fig. 5) with net electron density on the ring, leading to the conclusion that the benzene ring is an acceptor of electron density into the π-orbitals in agreement with

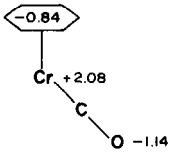

Fig. 5.

the neutron–X-ray diffraction study of Rees and Coppens,[27] but in disagreement with the known reactivity of the ring towards nucleophilic additions. However it was possible to correlate the calculated orbitals and the observed I.P. of the p.e. spectra with only minor adjustments of the level positions. It was also pointed out that metal-3*d*/ligand-2p_π interaction dominates the metal–ring bonding.

II. CHARGE-TRANSFER COMPLEXES

Although the effects of the $Cr(CO)_3$ group on the chemical properties of π-coordinated benzene ring are more like those of an electron-withdrawing group like NO_2, arene–$Cr(CO)_3$ complexes form charge-transfer complexes with electron acceptors such as 1,3,5-trinitro-benzene (TNB) and tetracyanoethylene (TCNE) but not with electron donors such as *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine (TMPD).[87]

TNB forms a molecular complex with arene–$Cr(CO)_3$ by a charge-transfer interaction toward the π-coordinated benzene ring in face-to-face contact of the counterpart benzene rings, as revealed by X-ray crystal structures[88,89] (Fig. 6).

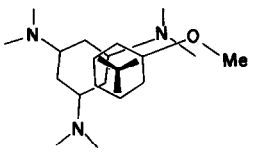

Fig. 6.

Until now structures of molecular complexes between TCNE and arene–$Cr(CO)_3$ have not been determined as they have not been isolated yet, but the presence of charge-transfer absorption bands in the UV indicates that there is formation of a molecular complex in solution.[87–91]

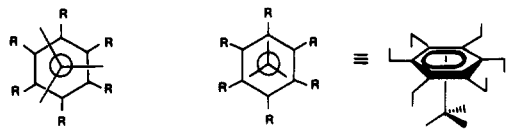
Since TCNE is a stronger acceptor (electron affinity 1.8[92]) than the TNB (electron affinity 0.7[92]) the charge-transfer band of toluene–$Cr(CO)_3$ with TCNE is shifted to a lower wave number (13,500 cm^{-1}) compared to the charge-transfer band of toluene–$Cr(CO)_3$ with TNB (20,200 cm^{-1}). Also, complex formation constants of 1 : 1 molecular complexes of arene–$Cr(CO)_3$ have been shown to be larger with TCNE than with TNB[87] (Table 19).

The stability of the TCNE complexes increases with the decrease in the ionization potential of the arene–$Cr(CO)_3$ evaluated from these charge-transfer bands, while the reverse holds for TNB molecular complexes. This suggests that TCNE forms charge-transfer molecular complexes with arene–$Cr(CO)_3$ with structures different from the TNB molecular complexes, and an inner-sphere charge-transfer interaction of TCNE with the central chromium atom of arene–$Cr(CO)_3$ has been proposed by Kobayashi *et al.*[87]

It has been concluded [section I(c)] that coordination of the benzene ring with the $Cr(CO)_3$ group affects essentially the σ-framework while the total π-electron density changes negligibly. However P.E.

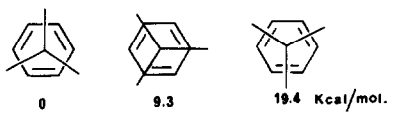
Table 19. *K* (l mol^{-1}) at 25°C of 1 : 1 molecular complexes of arene–$Cr(CO)_3$ with TCNE and TNB, and corresponding evaluated ionization potentials (IPs) (eV) of the arene–$Cr(CO)_3$

	TCNE		TNB	
Donor	*K*	IP	*K*	IP
$C_6H_6Cr(CO)_3$	1070	7.33	67	7.23
$C_6H_5MeCr(CO)_3$	661	7.40	70	7.18
o-$C_6H_4(Me)_2Cr(CO)_3$	952	7.42	56	7.16
$C_6H_5OMeCr(CO)_3$	265	7.47	76	7.17
$C_6H_5N(Me)_2Cr(CO)_3$	139	7.77	79	6.99



spectroscopy[85,93] shows that aromatic π-type orbitals in the complex are $\sim$ 1.06 eV lower (second ionization potential) than in the free ligand (first ionization potential), in good agreement with Hoffman's model.[94] On the other hand polarographic reduction of complexed acetophenone[95] shows that addition of the first electron is facilitated in the complex ($E_{1/2} = 0.5$ eV) in agreement with the Hoffmann model[94] which proposes that the LUMO (essentially localized on the metal) is slightly lowered in the complex. These arene–$Cr(CO)_3$ complexes are also electron-rich with a first ionization potential of about 7.2 eV[85,93] mainly due to metal *d*-lone pair. Hence the formation of charge-transfer complexes with electron acceptors is not so surprising. However the face-to-face structure found in the case of methoxyphenyl–$Cr(CO)_3$/TNB[88–90] should not have the best geometry and could be affected by symmetry and packing forces.

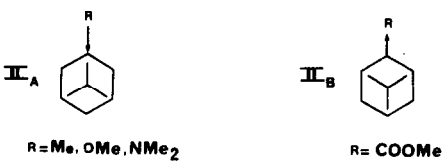
III. CONFORMATIONS



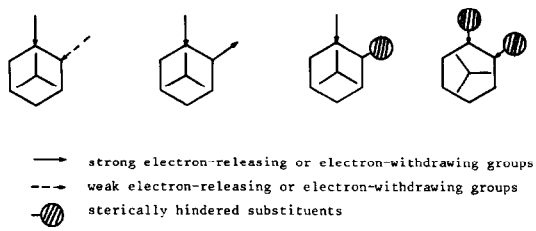
A. Conformation of the tripod

Since the beginning of modern structural chemistry conformation and magnitudes of rotational barriers in molecules have been of much concern to chemists.

In arene–$Cr(CO)_3$ complexes it has been found that the orientation of the $Cr(CO)_3$ tripod relative to the aromatic ring varies according to the nature of the substituents. X-ray[96,97] and neutron diffraction[27] showed that the staggered conformation **I** is preferred with benzene and hexamethylbenzene (D_{6h}) but that the eclipsed conformation **II** is preferred with hexaethylbenzene[98] (D_{3d}), where the methyl groups project alternately above and below the plane of the arene ring.



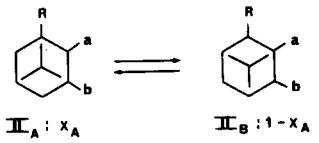
EHT calculations performed by Hoffmann *et al.*[94] on benzene–$Cr(CO)_3$ (postulating a delocalized structure for the benzene) showed that the staggered conformation **I** (R = H) was indeed more stable than the eclipsed conformation **II** (R = H). However the difference is only 0.3 kcal mol^{-1} in accord with electron diffraction[99] and NMR results,[100,101] which shows that the molecule is nearly an unhindered rotor in the gas phase. If the bonds in the benzene fragment were considered completely localized the relative energies calculated for the three possible conformations would have been too large to be



consistent with electron diffraction result. In the solid state mono- and disubstituted benzene–$Cr(CO)_3$ complexes have a tendency to adopt the eclipsed conformation[102–111] **II** unless strong steric effects are involved.[112–115]

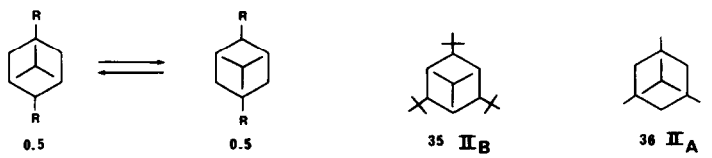
In monosubstituted benzene electron-releasing groups favour the *syn*-eclipsed conformation **IIA** over the *anti*-eclipsed conformation **IIB**[88,89,102,103] while the reverse holds for the electron withdrawing CO_2Me group,[104] but an exception has been found for the $COCH_3$ group,[105] for which a staggered conformation was found.

In disubstituted benzene–$Cr(CO)_3$ complexes (Fig. 1) the conformation of the $Cr(CO)_3$ tripod reflects the electron-releasing character of the substituents, and is *syn*-eclipsed with the more releasing substituent,[106,111] as well as the steric effect, which tends to twist the $Cr(CO)_3$ tripod[112–115] away from



the substituent. Two exceptions, which are not clearly understood, have been found with staggered conformations; *ortho*- and *meta*-toluate complexes (in which the minus charge may play an important role)[116] and paracyclophane complexes,[117] where the aromatic rings are known to be bent.[118]

Carter *et al.*[88,89,106] and, more recently, Hoffmann *et al.*[94] have proposed models which allow this behaviour to be rationalized by relating the conformation of the $Cr(CO)_3$ tripod either to the electronic density at the atoms of the aromatic ring or to the HOMO coefficient of the aromatic ring. These EHT calculations predict that the *syn*-eclipsed conformation **IIA** for aniline–$Cr(CO)_3$ is more stable than **IIB** by 1.3 kcal mol^{-1} (90% **IIA**/10% **IIB**).



Conformation in solution can be described by equilibrium 1, and have been studied by ^1H[119–124] and ^{13}C NMR[125,126] but most of these studies are not reliable[119–123,125,126] as the effects of substituents were ignored or considered to be invariant from the free ligand to the complexed ligand. This explains the discrepancies between those NMR results and the results predicted by the theoretical models (or obtained by X-ray). It should be noted also that a few studies have been confined to the effects of substituents, disregarding the conformational effect.[127–130]

In fact the averaged non-equivalence measured between *a*- and *b*-protons (or ^{13}C) depends not only on the conformers' populations but also on the difference in the substituent effect at the *ortho* and *meta* positions (equilibrium 1). Disubstituted symmetrical complexes where the conformers' populations are known (equilibrium 2) have been studied by Solladié-Cavallo and Suffert[124] leading to an *estimation* of the substituent effects for ^1H NMR. It was found that the effect of alkyl substituents (and OMe) were nil.

Equilibrium 1.

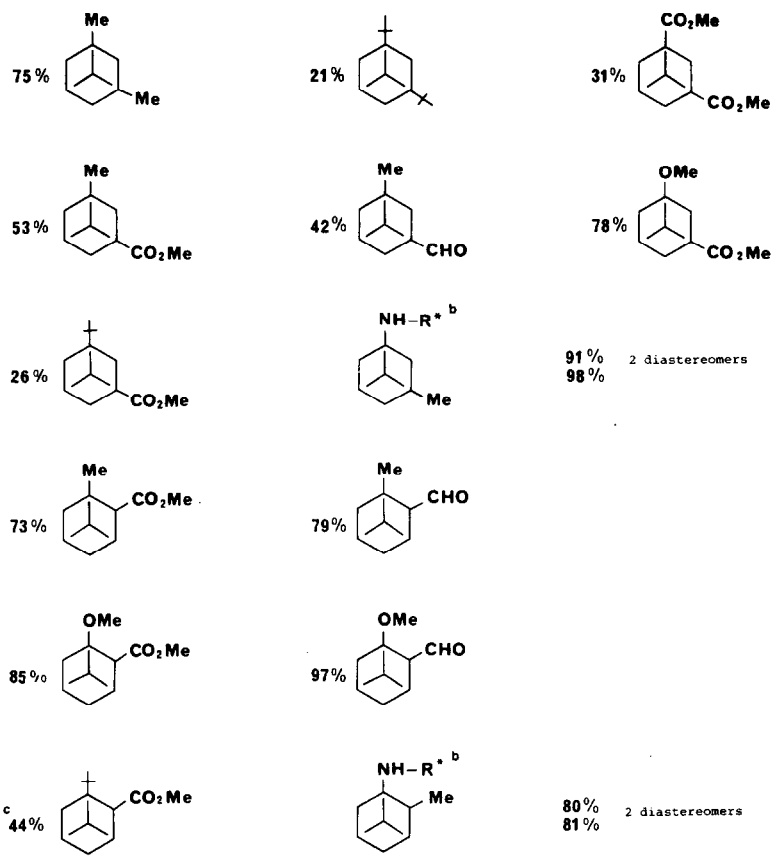
The difference in proton chemical shifts between 1,3,5-tri-*t*-butylbenzene–$Cr(CO)_3$, **35** (6.10 ppm[120,122]) and 1,3,5-trimethylbenzene–$Cr(CO)_3$, **36** (5.22 ppm[122,131]) could then be attributed to different conformations (**IIA** for **36** and **IIB** for **35**), showing that the aromatic proton is deshielded by 0.88 (d_6-acetone)–0.84 ($CDCl_3$) ppm when the C—H bond is eclipsed by the Cr–CO vector.

Equilibrium 2.

Table 20. Population x_A (%) of conformer **IIA** [evaluated with eqn (11)] in monosubstituted benzene–$Cr(CO)_3$

	CHO	COMe	CO_2Me	Me	Et	*n*-Pr	*n*-Bu	*t*-Bu	OMe	NH_2
$CDCl_3$	30		37	64		61	62	33	80	90
d_6-Acetone		37	43	63	58			32	73	

Using estimated substituent effects, $\Delta\delta_{max} = 0.84$–$0.88$ ppm (according to the solvent) and eqn (11) the population x_A of conformer **IIA** (equilibrium 1) has been calculated (Table 20) for different substituents:



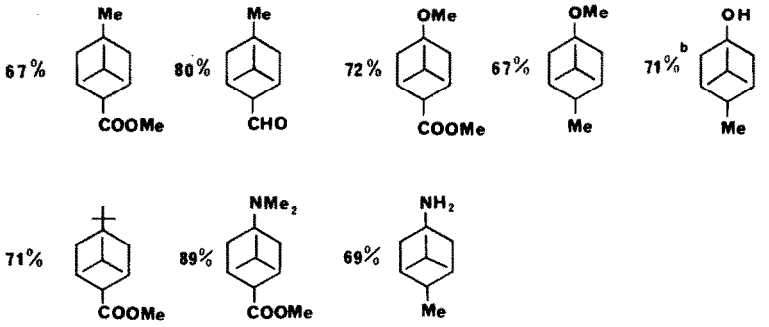
$$\langle\Delta\delta\rangle_{b-a} = (2x_A - 1)\Delta\delta_{max} + (m-o)_{compl.}, \quad \text{with} \quad \Delta\delta_{max} > 0, \quad \langle\Delta\delta\rangle_{b-a} > 0 \quad \text{or} \quad < 0. \tag{11}$$

These results now show that, according to the models of Carter[88,89,106] and Hoffmann,[94] electron-releasing substituents favour the *syn*-eclipsed conformation **IIA** while the reverse holds for electron-withdrawing substituents which favour the *anti*-eclipsed conformation **IIB**.

It should be noted too that there is, for these compounds, no dramatic change between the solid state and the solution; i.e. the conformer present in the solid state is the preferred one in solution.

The same kind of calculations[132] using eqn (11) may be performed on disubstituted complexes in solution. Proton chemical shifts were found in the literature.[122,123,127,128] Assignment of signals in symmetrically 1,3-disubstituted complexes is straightforward and the results (Table 21, line 1) are

Table 21.[a]



[a] The percentages correspond to the conformer drawn on the table and are averaged values obtained either by the use of $\Delta\delta_{5-6}$ and $\Delta\delta_{4-5}$ or by the use of $\Delta\delta_{4-3}$, $\Delta\delta_{4-5}$ and $\Delta\delta_{6-5}$.

[b] R* = $CH(CH_3)Ph$.[133]

[c] $\delta_4 \simeq \delta_5$.

Table 22.[a]

[a] The percentages correspond to the conformer drawn in the table.
[b] Substituent effects of OH are supposed to be nil, like for OMe.

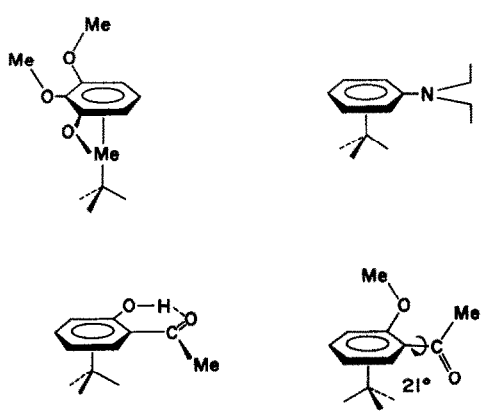
consistent with the previous results on monosubstituted complexes.[124] In unsymmetrically 1,3-, 1,2- and 1,4-disubstituted complexes assignment of some of the signals are not straightforward. Nevertheless this can be done using the above conclusions that the conformation of the $Cr(CO)_3$ tripod reflects the electron-releasing character of the substituents and that an aromatic proton eclipsed by a Cr–CO vector is deshielded. The results (Table 21, lines 2–4, and Table 22) are self-consistent.

The substituents as far as their ability to favour a *syn*-eclipsed conformation can be classified in the order: $N(Me)_2$, NHR, NH_2 > OMe ≫ Me ≫ *t*-Bu ~ CO_2Me > CHO.

B. Conformation of substituents

In the solid state, X-ray results show that the methyl of the methoxy group in (C_6H_5OMe)–$Cr(CO)_3$ stays in the plane of the aromatic ring (with a C_1–O length of 1.33 Å indicative of the presence of a partial double-bond character).[88] In the 1,2,3-trimethoxybenzene–$Cr(CO)_3$ complex the conformation is as shown in Fig. 7, with two methyls in the plane and one out of the plane of the aromatic ring.[10] The *N*,*N*-diethylaniline–$Cr(CO)_3$ complex exhibits a conjugative effect of the nitrogen with the arene ring with a N–C_1 distance of 1.357 Å characteristic of a partial double bond; hence the CH_2 are in the plane of the arene ring, but the methyls are alternatively up and down out of the arene plane.[103]

A few other X-ray results give information on the conformation of C(O)R groups in substituted arene–$Cr(CO)_3$ complexes. The COMe group[107] with an OH group in the *ortho* position, and COOMe group[104] remain in the plane of the aromatic ring. However, in the presence of an OMe group in the *ortho* position the COMe group is twisted out of the aromatic plane by 21°[107] (both steric and dipolar effects are responsible for the conformation), while the methyl of the methoxy stays in the plane of the aromatic ring (Fig. 7).



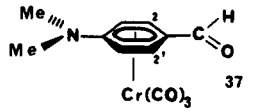


Fig. 7.

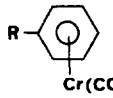
In solution conformations have been determined from dipole moments and electric birefrigence studies.[44,45]

Experimental and computed molar Kerr constants[45] lead to the conclusion that in each of the complexes, acetophenone–, benzaldehyde– and methylbenzoate–$Cr(CO)_3$ the preferred conformations are such that the substituent has a near-planar arrangement with the aromatic ring plane ($\phi \sim 0°$, CHO: $\phi \sim 5°$, $COCH_3$: $\phi \sim 10°$, COOMe). For aniline and *N,N*-dimethylaniline complexes the nitrogen was postulated to be pyramidal with rapid inversion; agreements between experimental and computed molar Kerr constants are less good but the best agreement is achieved when the nitrogen lone pair is *trans* to the $Cr(CO)_3$ group and perpendicular to the arene ring as has already been found by comparison of experimental and predicted dipolar moments.[44]

Ester carbonyl stretching vibrations have been reported[134] for several methyl benzoate–$Cr(CO)_3$ complexes and indicate that no loss of conjugation occurs in the complexes.

The barrier to internal rotation around the bond between the formyl group and the complexed ring in compound **37** was determined by ^{13}C NMR spectroscopy at variable temperature and complete line shape analysis.[135] The $\Delta G^{\ddagger}$ value (8.6 kcal mol^{-1}) is 1.6 kcal mol^{-1} lower than in the free ligand. However observation of de-coalescence indicates that the more stable conformation is planar:

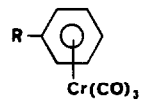


37

$T_c = -82°C$, $\Delta\delta_{2-2'} = 7.4$ ppm.

IV. STEREOELECTRONIC CONTROL OF THE REGIOSELECTIVITY

A. Nucleophilic reactions



Complexation with a $Cr(CO)_3$ group provides a temporary and powerful means of polarity inversion for aromatic rings and can lead to interesting synthetic applications. Shortly after the first synthesis of an arene–$Cr(CO)_3$ complex[46(a),(b)] was performed it was reported that halobenzene–$Cr(CO)_3$ complexes readily undergo nucleophilic substitution.[136–142] However, we will focus our attention on addition/oxidation reactions which provide overall substitution of a nucleophile for a hydrogen. Such carbanion additions on arene–$Cr(CO)_3$ complexes occur under mild conditions[143–145] and the

approach of the nucleophile may be considered *trans* to the $Cr(CO)_3$ group.[146] It should be remembered here, however, that, with certain alkyllithium species (like MeLi, *n*-BuLi and *s*-BuLi), proton abstraction from the ring occurs[67–69,145] and compete with the addition reaction. Nevertheless the regioselectivity of these nucleophilic additions on substituted arene–$Cr(CO)_3$ complexes were soon recognized[143,147–149] and used for synthetic purposes.[150–153] The main results are given in Tables 23 and 24.

Postulating that these reactions are mainly orbital-controlled, the regioselectivity has been first related to the LUMO coefficients of the free arene ligand,[148] leading to a quite good explanation for the inversion of regioselectivity between electron-releasing substituents (mainly *meta*) and electron-withdrawing substituents (mainly *para*). A close correlation was then observed between *meta* addition and the population (x_A) of the conformer **IIA** in solution, even for the *t*-butyl group[154] (Table 23). In general the products of nucleophilic attack are thought to be kinetically controlled. Hence, as the rotation of the $Cr(CO)_3$ tripod is fast, the Curtin–Hammett principle[155] must hold and (Fig. 8)

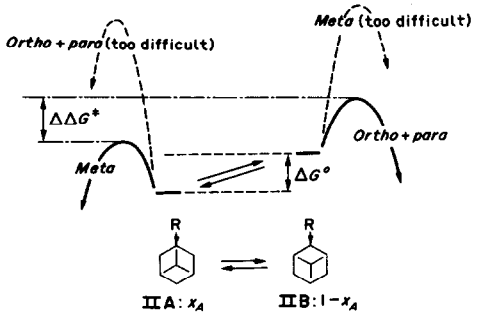

Fig. 8.

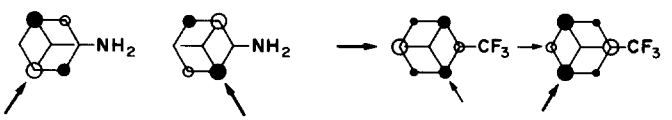
$\Delta\Delta G^+ \sim \Delta G^\circ$ is suggested for these reactions. However, the conformation of the $Cr(CO)_3$ tripod could have a strong effect on the arene-centred LUMO of the complexes. HET calculations for two types of substituents, NH_2 and CF_3,[154] led to the following conclusions (Fig. 9). The nature of the



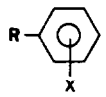


Fig. 9.

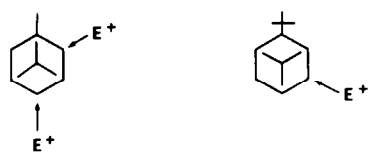
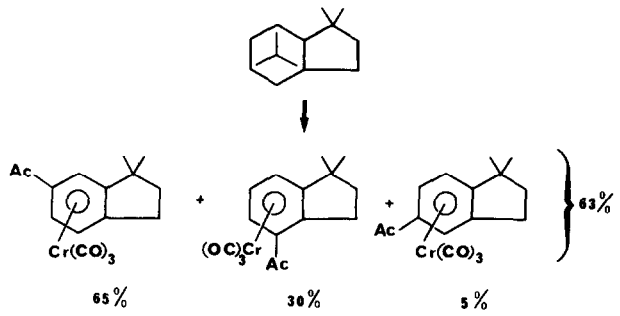
arene LUMO is not changed by the introduction of the $Cr(CO)_3$ group, whatever the conformation is. Polarization occurs with the greatest coefficients situated on the carbons eclipsed by a Cr–CO vector. Under orbital-controlled reactions attack will occur at the carbons eclipsed by a Cr–CO vector.

Hence a simple consideration of the first arene-centred LUMO could explain the quasi absence of *para* addition found in the case of electron-releasing substituents and the preferred *para* attack with the presence of *meta* attack in the case of CF_3 (Table 14). However, examination of charge-π, total-charge or consideration of the two closest arene-centred LUMOs to explain the absence of *ortho* addition in the case of CF_3 does not improve the model.



More sophisticated calculations published simultaneously[156] reached the same conclusions, that is: (1) the regioselectivity of attack on the arene should be controlled not only by the substituent on the arene but also by the conformation of the $Cr(CO)_3$ group; and (2) the arene carbons which are eclipsed with a Cr–CO vector are prefentially attacked by nucleophiles.

It was then pointed out by Semmelhack *et al.*[149] that, when the size of the substituent and/or when the size and the reactivity of the nucleophile change, the regioselectivity changes (Table 24). A rationalization based on a balance of orbital control and charge control was proposed. When the energy of the HOMO of the nucleophile is lowered (more stabilized carbanion) charge control begins to dominate and *para* addition can occur even with electron-releasing substituents.



B. Electrophilic reactions

While Nicholls and Whiting[136] mentioned that benzene–$Cr(CO)_3$ was rather inert toward electrophilic substitution ($CH_3COCl/AlCl_3/CS_2$ reflux), Reimschneider *et al.*[157] succeeded in the acetylation of this complex at 10°C under nitrogen (75%). Acetylation of toluene–$Cr(CO)_3$ led to a mixture of 39% *ortho*-, 15% *meta*- and 46% *para*-acylated complex while uncomplexed toluene gives, on acetylation, 9% *ortho*, 2% *meta* and 89% *para*.[158] Jackson and Jennings[159] noticed that alkylbenzene–$Cr(CO)_3$ complexes react much more slowly than the free ligand; their results (Table 25) demonstrate that the presence and orientation of the $Cr(CO)_3$ group strongly affect the regioselectivity.

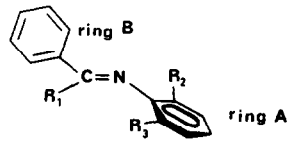
Here again the inversion of the regioselectivity from a methyl group (*ortho* + *para*) to a *t*-butyl group (*meta*) can be observed, suggesting that the attack of the electrophile occurs at the staggered arene carbons, as predicted by Albright and Carpenter.[156]

The dominance of the conformational effect in directing the regioselectivity of attack of both electrophilic and nucleophilic reagents has recently been pointed out.[160]

V. COMPLEXATION SITE ON DIAROMATIC LIGANDS

It is known that formation of arene–$Cr(CO)_3$ complexes according to eqn (12) is facilitated by electron-donating substituents.[136] This was confirmed by the study of dicomplexation of diaromatic ligands like diphenylamine and benzophenone:[161]

$$\text{arene} + Cr(CO)_6 \xrightarrow{\Delta} \text{arene–}Cr(CO)_3 + 3CO. \tag{12}$$



To compare the effects of electron-withdrawing and -donating substituents, complexation of imines (**38**) has been examined[162] (Table 26). In these compounds it is well accepted that ring A (with an η–π

Table 26. Complexation site in diaromatic imines (**38**)

interaction) is electron-rich, whereas ring B (with a π–π interaction) is electron-deficient.[163,164] However, it has been shown that, in the absence of methyl substituents on ring A, the electron-deficient ring B is preferred or that mainly dicomplexation occurs. It thus appears that electron density is not a unique determining factor and that the methyl group has a dramatic influence on complexation.

R_1=CH_3 R_2=R_3=H
R_2=H, R_3=CH_3
R_2=R_3=CH_3

Table 27. Complexation site in biphenyls **39** and **40**

	R	Complex on ring (%) A	B	AB	Yield (%)
 **39**	NH_2	84	10	6	69
	OMe	15	81	4	78
	OH	0	100	0	58
	COMe	8	92	0	63
 **40**	NH_2	93	7	0	47
	OMe	35	56	9	52
	OH	61	39	0	38
	COMe	37	63	0	45

Monosubstituted biphenyls, **39** and **40**, provide good models to study substituent effects on complexation. It has been shown that complexation of these biphenyls are thermodynamically controlled under the reaction conditions and the results[165] (Table 27) show that an electron-donating substituent favours complexation on the substituted ring, an electron-withdrawing substituent disfavours complexation on the substituted ring (the unsubstituted ring being preferred) and that OMe behaves like a weak "electron-withdrawing" substituent (the unsubstituted ring being slightly preferred) in accordance with Top and Jaouen's observation.[161]

The 100% complexation on ring B in the *ortho*-substituted biphenyl, **39c**, when R = OH may be atttributed to the presence (in the complex) of an intramolecular H-bond between the OH group and a carbonyl of the tripod, which is not possible in the *para*-substituted biphenyl, **40c**.

This substituent behaviour is in agreement with the fact that the σ-framework of the arene is mainly involved in complexation with $Cr(CO)_3$.

Acknowledgements—Thanks are due to Professor H. Walborsky for his stimulating interest and the fruitful discussions we had during my 2 months stay in his laboratory (Florida State University, Tallahassee, FL), during the summer of 1983.

(*Received* 20 *August* 1984; *accepted* 26 *September* 1984)

Abstract—^{1}H and ^{13}C NMR was used to investigate the structure of ion pairs formed by trioctylalkylammonium (alkyl = CH_3–C_8H_{17}) cation and rare earth-containing anions in nitrobenzene. The cation–anion distance in the investigated compounds increases from trioctylmethyl to trioctylbutylammonium salt, remaining constant with further growth of the *n*-alkyl chain. The ion pair formation changes the conformation equilibrium of the cation alkyl radicals to make easier the cation–counter-ion contact.

The NMR of paramagnetic complexes is now prominently placed in the arsenal of NMR approaches to the elucidation of molecular structure in solution.[1,2] This method has been used in conformational studies of ligand molecules and in studies of the coordination state of ions. It is applicable to a wide variety of molecules (including ion pairs) in organic solvents.[3–6] The method is based on the fact that the paramagnetic ion situated close to the nucleus under investigation can exert considerable influence on the signal position of this nucleus in the NMR spectrum. The difference between the positions of signals belonging to paramagnetic and diamagnetic compounds of similar structure is termed the paramagnetic shift. Although the paramagnetic shift is a three-component sum,[7] it was noted[2–4] that for ion pairs, formed by quaternary ammonium base (QAB) cations with rare earth pentanitrates, a shift observed in the ^{1}H NMR spectrum is due to only one of these components—an axial component of the dipolar shift. This component, δ_{ax}, is expressed by the McConnell–Robertson equation:[8]

$$\delta_{ax} = f(\chi)(3\cos^2\alpha - 1)/r^3, \quad (1)$$

where r is the distance between the paramagnetic ion and the nucleus studied, α is the angle formed by the vector r and the line connecting counter-ion centers. The expression $(3\cos^2\alpha - 1)/r^3$ is called the "geometric factor" denoted as GF. As the magnetic susceptibility function $f(\chi)$ is unknown, the ratio of axial shifts of different nuclei, equal to the ratio of corresponding geometric factors, is usually used:

$$\delta_{ax,i}/\delta_{ax,j} = GF_i/GF_j. \quad (2)$$

Using ^{13}C NMR studies of ion pairs it is impossible to use eqn (1) for structure calculation without proving the absence of a contact component of the overall paramagnetic shift value. To prove this, paramagnetic shifts of carbon nuclei of a compound under investigation are usually measured using different rare earths. Europium, erbium and ytterbium pentanitrates were used in our case.

It is known that the contribution of the contact shift into the overall paramagnetic shift value varies widely for different rare earths. This contribution is almost maximal in europium compounds, minimal in ytterbium ones, while erbium occupies the middle position. If δ_j denotes the experimentally obtained shift and δ_j/δ_i ratios are approximately constant for all the metals used, then we may safely assume that the Fermi contact shift is negligible and that eqn (1) may be used to calculate the structure of the compounds investigated.[1,2,9,10]

In the present work we have studied the structure of ion pairs formed by trioctylalkylammonium (with alkyl radicals CH_3–C_8H_{17}) cations with europium, erbium and ytterbium pentanitrates in nitrobenzene. Nitrobenzene was used because of its high dielectric constant, which minimizes possible QAB salt self-association in the organic solvent.[11]

EXPERIMENTAL

Trioctylmethyl (TOMA), trioctylethyl (TOEA), trioctylpropyl (TOPA), trioctylbutyl (TOBA), trioctylamyl (TOAA) and tetraoctylammonium (TetOA)

* Author to whom correspondence should be addressed.

nitrates were synthesized and purified according to our previous work.[12] Europium, erbium, ytterbium and lutecium (analytical grade) nitrates were extracted from their 0.4 M solutions in 8.2 M $LiNO_3$ (pH = 2) with 0.01 M trioctylalkylammonium nitrate in *n*-hexane (analytical grade) at $21 \pm 1°C$. The phase volume ratio was 5:1, the equilibration time was 20 min. Metal concentrations and QAB/metal ratios in the extracts were estimated radiometrically using a NRG-603 apparatus (Tesla, Czechoslovakia). After phase separation, hexane was vacuum-distilled off (15 mm Hg, 75–80°C). The investigated compounds were dissolved in the distilled nitrobenzene (analytical grade) and then additionally dried over molecular sieves (d = 5 Å) for 24 h.

^1H NMR spectra were obtained on a Varian NV-14 spectrometer, operating frequency 60 MHz, and ^{13}C spectra on a Bruker HX-270 spectrometer, operating frequency 70 MHz, at $37.0 \pm 0.1°C$. The accuracy of paramagnetic shift measurements was about ± 0.2 Hz.

The parameters of investigated compounds structure were calculated by a Videoton EC 1010 computer (Hungary) using a specially prepared computer program.

RESULTS AND DISCUSSION

Experimental data on the QAB/metal ratios in extracts are presented in Table 1. These ratios are close to 2 in all the cases. Therefore, the composition of the studied QAB–rare earth nitrate compounds corresponds to the formula $(TOAlkA)_2Ln(NO_3)_5$, where Ln is a rare earth metal, and TOAlkA denotes trioctylalkylammonium cation.

The dependence of the paramagnetic shifts on the ion pair concentrations for CH_3, α-CH_2 and β-CH_2 group signals in ^1H NMR spectra of TOMA cations are presented as an example in Table 2. These dependences point to dissociation of investigated ion pairs in nitrobenzene but constancy of the paramagnetic shifts ratio of α- and β-CH_2 groups allows us to neglect this process in the calculation of compound structure.

Table 1. The QAB/metal ratio in the extracts obtained

QAB	Eu	Er	Yb	Lu
TOMA	2.06	2.09	2.04	2.06
TOEA	2.06	2.03	2.08	2.03
TOPA	2.11	2.08	2.13	2.10
TOBA	2.04	2.03	2.09	2.07
TOAA	2.01	2.04	2.13	2.08
TetOA	2.04	2.07	2.02	2.06

Table 3 contains paramagnetic shift values of various groups of TOAlkA cations as regards the paramagnetic shift of β-CH_2 groups of octyl radicals. Approximate constancy of the paramagnetic shift ratios in NMR spectra of compounds, that differ only in the metal involved leads to the conclusion that the contribution of Fermi contact interaction to the overall shift value is negligible and can be ignored in further calculations.

For the sake of simplicity, let us introduce a system of Carthesian coordinates relevant to a QAB cation (Fig. 1). The nitrogen atom of the QAB cation is the origin of the coordinates. The Ox axis is directed along the N—α-carbon bond of the alkyl radical (one asterisk in Fig. 1), while one of the other three α-carbon atoms of the octyl chains (two asterisks) is located in the Oxy plane of symmetry. Therefore, the space around the nitrogen atom is divided into four sectors by the N—C bonds. Due to Coulomb attraction between the cation and anion and steric hindrances due to alkyl radicals, the anion is situated inside one of these sectors. Since the paramagnetic

		γ-CH_2	0.90	0.89	0.89
TOAA	Amyl and octyl	α-CH_2	1.44	1.43	1.46
		γ-CH_2	0.89	0.90	0.89
TetOA	Octyl	α-CH_2	1.43	1.44	1.44
		γ-CH_2	0.89	0.89	0.89

shifts of protons and carbon atoms of the short alkyl chain are maximal in TOMA, TOEA and TOPA compounds, the anion of these compounds cannot be located inside the sector formed by three octyl radicals. Let us now assume that the anion is located in one of other three identical sectors corresponding to positive values of x and y coordinates. Meanwhile according to shift values of protons and α-carbon atoms, all the four sectors in TOBA, TOAA and TetOA compounds are absolutely identical so that the anion is placed into one of them only for the convenience of the calculations. It is quite clear that a sufficiently symmetrical anion such as a rare earth pentanitrate[13] should be located in the Oxy plane of symmetry, as any deviation from this plane will prove unprofitable due to increasing steric hindrance. The problem of determining the geometry of ion pairs is therefore reduced to determining two polar anion coordinates R and ϕ (Fig. 1).

Let us consider a QAB cation in the Newman projection along the N—CH_2 bond (Fig. 2). The anion is located in the vicinity of the central axis of the sector which is situated opposite the **CH_2—N bond. The formation of the ion pair may influence the conformation equilibrium of the cation alkyl radicals due to the fact that the conformation (A) is sterically less profitable as compared to the others (Fig. 2). To analyse this phenomenon, we had to study four theoretical models:

(1) all possible conformations of the carbon skeleton are equally probable;

(2) carbon chains are in "zig-zag" *trans*-positions, and the factor that has to do with the formation of the ion pair is ignored;

(3) carbon skeleton conformation is governed only by the formation of the ion pair;

(4) alkyl radicals are in "zig-zag" *trans*-positions influenced by the ion pair formation.

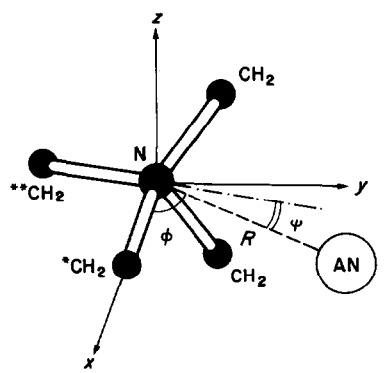

Fig. 1. The system of coordinates connected with the central part of trioctylalkylammonium cation. The α-carbon atom of the alkyl chain is marked by one asterisk, and the α-carbon atom located in the Oxy plane of symmetry opposite the anion is marked by two asterisks. R and ϕ are polar anion coordinates; ψ is an angle characterizing anion deviation from the central axis of the sector.

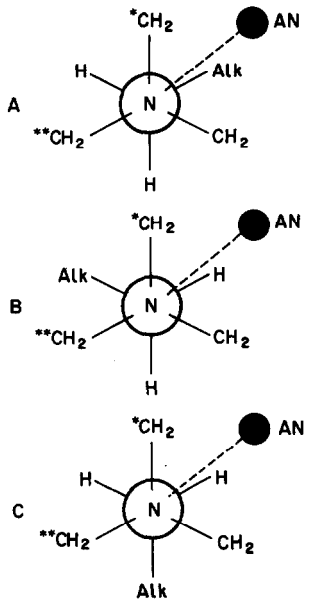

Fig. 2. Non-eclipsed conformation of a QAB cation as regards the N—CH_2 bond.

For each of these models, geometric factors of protons and carbon nuclei were determined in a prearranged area of change of R and ϕ values. Ratios of geometric factors were compared to experimentally obtained ratios of paramagnetic shifts. The following value served as a criterion of correspondence:

$$Q = \left(\sum_j [(\Delta_{obs.,j} - \Delta_{calc.,j})2/\Delta^2_{calc.,j}]\right)^{1/2},$$

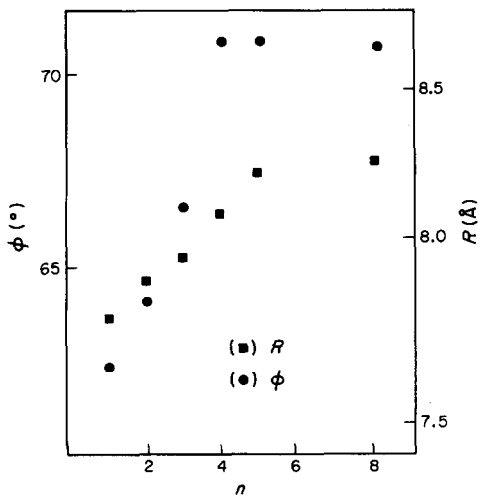

Fig. 3. Geometric parameters of the ion pairs in nitrobenzene depending on the number of carbon atoms (n) in the alkyl chain of the trioctylalkylammonium cation.

where

$$\Delta_{obs.,j} = \delta_j/\delta_{\beta\text{-}CH_2}$$

and

$$\Delta_{calc.,j} = GF_j/GF_{\beta\text{-}CH_2}.$$

As it turned out for compounds investigated only the last two of the above four models correspond to the experimental data. As the difference between energies of *trans*- and *gauche*-conformations constitutes approximately 1 kcal mol^{-1}; at room temperature, about 80% of the molecules are in the *trans*-conformation as regards the chosen bond, which is why model (4) is most probable.

The results of the geometry calculations for the ion pairs are given in Fig. 3. It should be noted that the found values of an angle ψ between the N—*CH_2 bond and the line connecting counter-ion centres in TOMA, TOEA and TOPA compounds are somewhat smaller than the value drawn from a suggestion that the anion is located in the sector axis (70.7°). This may be explained by the fact that the anion rotates around the axis Oz in such a way (Fig. 1) that the short alkyl group approaches the anion, while the sterically hindering long alkyl radicals are drawn away from it. Figure 3 shows that the steric hindrances for the counter-ion created by the alkyl radical increase from methyl to butyl, remaining about the same with a further lengthening of the alkyl chain.

COBALT(II) PERCHLORATE, TETRAFLUOROBORATE, NITRATE AND SULPHATE COMPLEXES WITH 4,6-DIMETHYLPYRIMIDINE-2(1H)-THIONE

RAFFAELE BATTISTUZZI
Istituto di Chimica Generale e. Inorganica, Università di Modena, 41100 Modena, Italy

(*Received* 13 *August* 1984; *accepted* 26 *September* 1984)

Abstract—Contrary to earlier reports in which no adducts of Co(II) metal ion with 4,6-dimethylpyrimidine-2(1H)-thione (HL) could be isolated starting from $Co(ClO_4)_2 \cdot 6H_2O$, we now report bis- and tris-ligand Co(II) complexes of the type $[Co(HL)_2(H_2O)_2]X_2 \cdot H_2O$ ($X = ClO_4$, BF_4), $[Co(HL)_2NO_3]NO_3$, $[Co(HL)_2SO_4] \cdot 0.5H_2O$ and $[Co(HL)_3]X_2 \cdot 0.5H_2O$ ($X = ClO_4$, BF_4). They have been synthesized by refluxing 2:1 and 3:1 mixtures of HL and $CoX_2 \cdot nH_2O$ in ethanol–triethyl orthoformate. We also describe new $Co(HL)_2X_2 \cdot nH_2O$ complexes in which for $X_2 = ClBr$, ClI and BrI, $n = 2$; for $X_2 = I_2$, $n = 1$ and for $X_2 = (SCN)_2$, $n = 0$. Structural characterization of the complex species is made from electronic and vibrational spectra, magnetic susceptibility measurements in the solid state and conductivity measurements in DMF solution. The magnetic and electronic spectral data together with ligand-field parameters suggest a pseudo-octahedral environment for all the Co(II) complexes, with the exception of $Co(HL)_2SO_4 \cdot 0.5H_2O$ in which the Co(II) ion appears to be pentacoordinated. The IR spectra are consistent with a coordination involving N,S-chelation of the ligand through the non-protonated ring nitrogen atom and the exocyclic sulphur atom.

It has previously been reported[1] that the interaction of 4,6-dimethylpyrimidine-2(1H)-thione (HL) with anhydrous Co(II) chloride and bromide in dry acetone, affords blue $Co(HL)_2X_2$ complexes containing tetrahedral $[Co(HL)_2]^{2+}$ units involving N,S-chelation, whereas the hydrated cobalt(II) salts in the same solvent, lead to the formation of Co(II) or Co(III) complexes depending on the counter-ion. In fact, in the presence of suitable coordinating anions such as chloride and bromide the oxidation state of the Co(II) ion is preserved with the formation of pink six-coordinated $Co(HL)_2X_2 \cdot 2H_2O$ sparingly soluble complexes. On the contrary, with weakly coordinating anions as perchlorate, on account of deprotonation, the HL ligand gives rise to the very soluble dark-green *fac*-octahedral $Co(III)L_3 \cdot$ acetone complex.[2]

From the above results, it seems that the reaction of Co(II) salts with HL ligand is rather complicated. Therefore the effect of solvating and/or coordinating H_2O-molecules of the starting Co(II) salts and solubility of the reaction products, are important factors in determining the coordination stereochemistry and the stabilization of a preferred electronic configuration of the central metal ion, together with chemical environment of the thioamido group thione $\rightleftharpoons$ thiol equilibrium, cobalt(II) counter-ion and atmospheric oxygen.[3]

In this context we report on the preparation and characterization of $Co(HL)_2X_2 \cdot nH_2O$ ($X = ClO_4$, BF_4, $n = 3$; $X = \frac{1}{2}SO_4$, $n = 0.5$; $X = NO_3$, $n = 0$) cobalt(II) complexes by reaction of HL with the corresponding hydrated salts in dehydrating media. New thiocyanate, iodide and mixed-halide $Co(HL)_2X_2 \cdot nH_2O$ complexes were also prepared and their stereochemistry and electronic structure discussed in relation to the 4,6-dimethylpyrimidine-2(1H)-one ligand[4,5] and of previously reported HL complexes.[1] The new complexes have been characterized using IR, optical and magnetic measurements as well as conductivity data.

EXPERIMENTAL

The ligand was prepared by the method previously reported.[6] The complexes were prepared as follows.

$Co(HL)_3X_2 \cdot 0.5H_2O$ ($X = ClO_4$, BF_4)

Three millimoles of hydrated salt were dissolved in 5 cm^3 of anhydrous EtOH and 15 cm^3 of triethyl

orthoformate (TEOF) as dehydrating agent, and the mixture allowed to stand at room temperature for 3 days in a stoppered flask. The initial violet solutions immediately turned to olive–green and finally to purple–brown on addition of the solid ligand (9 mmol) under stirring at 60–80°C for 4 h, and deposited the red–brown complexes.

$Co(HL)_2X_2 \cdot nH_2O$ ($X = ClO_4$, BF_4, $n = 3$; $X = NO_3$, $n = 0$)

These complexes were prepared as above using a metal–ligand molar ratio 1:2. Subsequent combination of the solid ligand (8 mmol) with the salt (4 mmol) solution at 60–80°C under stirring, led to the following behaviour with the variation of anion: nitrate, precipitation occurs after complete addition of the ligand to the salt solution; perchlorate and tetrafluoroborate, precipitation is obtained by reducing the initial volume (20 cm^3) of the solutions and cooling.

$Co(HL)_2SO_4 \cdot 0.5H_2O$

A suspension of 4 mmol of $CoSO_4 \cdot 7H_2O$ in 10 cm^3 of anhydrous EtOH and 15 cm^3 of TEOF was stirred at 60°C for 20 min and left to rest in a stoppered flask for 3 days at room temperature. On addition of the solid ligand (8 mmol) under stirring at 60–80°C the initial pink suspension changed rapidly to cream and at last after 1 h to purple giving a violet compound.

All the above reported compounds were filtered, thoroughly washed with ether–TEOF [3:1 (v/v)] and dried in an evacuated desiccator over phosphorus pentoxide.

$Co(HL)_2I_2 \cdot H_2O$

The compound was prepared by dissolving with stirring at room temperature the solid ligand (8 mmol) in a filtered acetone solution (15 cm^3) of the stoichiometric amount (4 mmol) of $CoI_2 \cdot 4H_2O$. The yellow precipitate was filtered off, washed with acetone and *vacuum* dried over KOH.

$Co(HL)_2XY \cdot 2H_2O$ ($X = Cl$, $Y = Br$; $X = Cl$, $Y = I$; $X = Br$, $Y = I$)

The appropriate hydrated cobalt dihalides (2 mmol : 2 mmol) were either dissolved in 15 cm^3 of acetone and refluxed for 1 h. The stoichiometric amount (8 mmol) of the solid ligand was added and the solutions left with stirring for 2 h at 70–80°C. After cooling at room temperature, the homogeneous compounds were filtered, washed with cold acetone and dried over KOH.

$Co(HL)_2(SCN)_2$

Anhydrous solid $Co(SCN)_2$ (3 mmol) was added to a suspension of ligand (6 mmol) in ethyl acetate (20 cm^3) and the green resultant solution, refluxed for 8 h and allowed to stand at room temperature for three days in a stoppered flask. The brick-red product was separated by filtration, washed with copious amounts of ethyl acetate and ether. The use of acetone as solvent gave an intractable dark-green oil.

Cobalt was determined by complexometric titration with EDTA, after destruction of the complexes with aqua regia. Carbon, hydrogen, nitrogen and sulphur were analyzed using a Carlo Erba Mod. 1106 Elemental Analyzer. Conductivity measurements were performed on freshly prepared 10^{-3} M solutions in DMF at 25°C with a WTW conductivity bridge LBR type.

IR spectra were obtained on the solids in KBr pellets and Nujol mulls on KBr disks (4000–250 cm^{-1}) and in Nujol mulls on polythene (500–50 cm^{-1}) with a Perkin–Elmer 180 spectrophotometer. Solid state electronic spectra were performed with a Shimadzu MPS-50L spectrophotometer as Nujol mulls on filter paper. Magnetic susceptibilities were measured at room temperature by the Gouy method and corrected for diamagnetism using the Pascal constants.

Thermogravimetric studies were carried out on a Mettler TG 50 Thermobalance in conjunction with a direct Mettler TC 10 TA Processor recorder.

RESULTS AND DISCUSSION

General

The elemental analyses, colours and molar conductivities in DMF solution are shown in Table 1. Analytical results demonstrate that, under the experimental conditions, HL forms 3:1 and 2:1 Co(II) complexes with relatively non-coordinating anions as perchlorate and tetrafluoroborate and only 2:1 Co(II) complexes with sulphate, nitrate, thiocyanate, iodide and mixed halides. Attempts to synthesize adducts of HL with $Co(CH_3COO)_2 \cdot 4H_2O$, $Co(CF_3COO)_2 \cdot 4H_2O$ and Co(acetylacetonate)$_2 \cdot 2H_2O$, under different experimental conditions (molar ratio 1:1, 2:1 and 3:1) in EtOH, MetOH, acetone, $CHCl_3$ or their mixtures, were unsuccessful and led invariably to the formation of an inner diamagnetic tris-chelate $Co(III)L_3 \cdot S$ (S = solvent molecule) complex.

All the solid complexes are sensitive to atmospheric moisture, but are stable if stored under an inert atmosphere with the exception of the nitrate complex which slowly decomposes with loss of NO_2

and probable oxidation of the central metal ion to Co(III) and/or of the ligand to disulphide or sulphenate or sulphinate anions.[3]

From electrolytic conductance measurements (Table 1) the iodide, bromo-iodide, nitrate and both the bis- and tris-ligand perchlorate and tetrafluoroborate complexes may be formulated as 1:2 electrolytes[7] indicating that in DMF solution these anions are not bound directly to the central metal ion. The chloro-bromide, chloro-iodide and thiocyanate complexes behave as 1:1 electrolytes, while the low molar conductance value observed for sulphate complex suggests that it is a non-electrolyte. Since the greater part of the solid complexes suffer change in colour in DMF solution, indicating extensive solvolysis with probable variation in the nature of the coordination sphere about the Co(II) centre, physical measurements in the solid state were mainly used to tentatively infer the probable structures of the compounds.

Table 2 shows the results of thermogravimetric dehydration studies performed on the hydrated complexes isolated from the ethanol–TEOF mixture. The good agreement between the observed and expected weight losses confirms the compounds stoichiometries.

For $Co(HL)_3X_2 \cdot 0.5H_2O$ ($X = ClO_4$, BF_4) and $Co(HL)_2SO_4 \cdot 0.5H_2O$ complexes water loss occurs gradually in a single step up to *ca* 200°C. This behaviour, in agreement with IR data, suggests that the water is involved in hydrogen bonding with the anions.[8] The thermogravimetric analysis data of the $Co(HL)_2X_2 \cdot 3H_2O$ ($X = ClO_4$, BF_4) complexes reveal that the weight loss corresponding to three water molecules takes place in two steps in the 50–180°C temperature range. Consideration of the relative molar masses involved for $Co(HL)_2X_2 \cdot 3H_2O$ complexes, indicate that two for perchlorate, and one-half for fluoroborate, of the three water molecules are lost in the first stage; the remaining water fractions are lost in the second step. This dissimilar behaviour for apparently similar complexes, suggests that caution must be taken in using thermal information to determine the nature of the water molecules involved in metal complexes. This would seem particularly true when the anions are capable of hydrogen bonding to water as is the case in this study.

IR SPECTRAL STUDIES

The ligand

The IR spectral data of the reported Co(II) complexes when compared with those of the free HL, give positive indication of the donor atoms of the

ligand, the mode of bonding of the counter-ion and the presence in the solid complexes of possible solvent molecules.

As reported in Table 3 all the water-containing complexes present in the IR spectra one or two broad bands in the 3300–3200 cm^{-1} region characteristic of ν(OH) absorptions. In addition, the presence of aqua-ligand is demonstrated by the identification of the metal-sensitive bands attributable to $\nu(Co—O)_{aqua}$ modes in the range 390–370 cm^{-1}.[5] Bands corresponding to δ(H—O—H), rocking and wagging modes of coordinated or hydration water are presumably masked, in most cases, by the ligand absorptions.

Since it is known that in a large number of metal complexes HL coordinates to metal ions *via* both the unprotonated ring nitrogen atom (strongly) and exocyclic sulphur atom (more weakly), giving a four-

membered chelate ring,[1,6] and since it is known that the C=S and C=N stretching frequencies of the S ‖ —C—N=C— group change upon coordination to metal ions, we have looked in more detail at the region in the IR where the C=N and C=S stretching frequencies are to be expected.

In the 1650–1500 cm^{-1} range the ligand spectrum displays three very strong bands at 1623, 1567 and 1545 cm^{-1} which may be assigned to a combination of C=C and C=N bonds stretching vibrations which do not form part of an aromatic skeleton.[9]

In all the complexes the first two bands remain almost unchanged, while the third one, with prevailing ν(C=N) contribution, decreases both in frequency (15–20 cm^{-1}) and intensity indicating N-coordination of the ligand through the non-protonated ring nitrogen atom. Furthermore, only the bands at 1220 and 1185 cm^{-1} [with prevailing of ν(C=S) mode], out of the three HL bands in the 1240–1160 cm^{-1} region, to which a ν(NCN) + ν(CNS) + ν(C=S) contribution was previously assigned,[6] are shifted upon complexation to lower frequency. This indicates an involvement of exocyclic sulphur in the metal coordination.

The anions

As regards the behaviour of the anions, the IR spectra of the bis- and tris-ligand complexes of both perchlorate and tetrafluoroborate (1 : 2 electrolytes in DMF solution), show splitting of the ν_3 and ν_4 (ClO_4, BF_4) modes, while ν_1 and ν_2 modes are IR active (Table 4). This fact clearly indicates that some distortion for ClO_4 and BF_4 groups from T_d symmetry occurs in the solid complexes caused by solid state effect and/or most probably by hydrogen bonding with water molecules present in the complexes[10] rather than to anion–Co(II) interaction. This would explain why the water is not completely eliminated in the presence of TEOF in $Co(HL)_3X_2 \cdot 0.5H_2O$ (X = ClO_4, BF_4) complexes, in which the Co(II) ion achieves an octahedral coordination through the three N,S-chelate ligands. These two complexes do not show IR bands at 400–350 cm^{-1} attributable to $\nu(Co—O)_{aqua}$.[5,11]

This would also explain why the bis-ligand complexes have three water molecules while, in such a case, only two aqua ligands are required, together with the two N,S-chelate ligands, for the completion of the octahedral coordination.

On the basis of the previous evidence, of the thermogravimetric analyses results and of the fact that the $Co(ClO_4)_2$ and $Co(BF_4)_2$ complexes appear to be hexacoordinated (*vide infra*), the bis- and tris-ligand complexes may be formulated as $[Co(HL)_2(H_2O)_2]X_2 \cdot H_2O$ and $[Co(HL)_3]X_2 \cdot 0.5H_2O$ respectively, with ionic counter-ions interacting with water molecules.

The IR spectrum of the sulphato complex clearly shows the presence of the coordinate sulphate group. In fact, both the ν_4 and ν_3 fundamental vibrational modes of sulphate group are split into two and four components respectively, and ν_1 and ν_2 modes are IR active (Table 4). This behaviour is indicative of a bidentate sulphate group of C_{2v} symmetry,[12] and furthermore the absence of a band around 1250 cm^{-1} suggests that this group is bridging rather than chelating.[12,13] Therefore in this complex the metal ion is probably six-coordinated with the sulphate group bridging two Co(II) ions of two $[CoN_2S_2]$ units or five-coordinated (*vide infra*) with the SO_4 group in direct contact with the cobalt ion of a $[CoN_2S_2]$ unit and at the same time engaged in hydrogen bonding with lattice water[8] as in perchlorate and tetrafluoroborate complexes.

The observed IR spectral absorptions of

thiocyanate anion in the $Co(HL)_2(SCN)_2$ complex are the well-known fundamentals ν(CN), ν(CS) and δ(NCS) (Table 5). According to Nakamoto,[12] usually the position of ν(C=S) at *ca* 800 cm^{-1} is taken as indicative of the *N*-coordination mode of the thiocyanate anion. In addition the presence of a single sharp band due to δ(NCS) at 470 cm^{-1} and a single ν(Co—NCS) mode at 241 cm^{-1} suggests[14] that the metal ion has most probably a six-coordinated octahedral environment achieved through two equatorial N,S-chelate ligands and two axial N-bonded NCS groups.

Also the IR spectrum of the nitrato complex was investigated to obtain evidence for ionic or coordinated nitrate ions, the bands due to these groups together with probable assignments are included in Table 6.

Since in the case under study all modes (ν_1, ν_2, ν_3 and ν_4 in D_{3h} symmetry) are IR active, shifts in band positions and intensities are observed and there is splitting of the ν_3 and ν_4 bands, this suggests that the nitrate groups are present in some coordinated form. The presence of the band at 1385 cm^{-1} indicates again the existence of some ionic species.[15] The coordination mode of the nitrato group cannot be unequivocally deduced from these data, but all the physicochemical characteristics of this complex are compatible with a polymeric structure with a nitrato group bridging two $[CoN_2S_2]$ units and an ionic nitrato group in the lattice.

Metal–ligand and metal–anions vibrations

Additional information about the coordination of HL–Co(II) compounds and about the strength of the metal–ligand and metal–anions bonds can be

reached from far-IR spectra; the main results are listed in Table 7.

Tentative metal–ligand band assignments were based on the previous ν(M—L) assignments for other metal complexes with HL[4,5,16] and in agreement with the fact that unprotonated ring nitrogen atom, which is the protonated site in the H_2L^+ cation,[17] has a donor tendency greater than that of the exocyclic sulphur atom.

Except the sulphate, all the bis-ligand hydrated complexes, show a broad band in the 395–370 cm^{-1} region assignable to the ν(Co—OH_2) mode of the coordinated water.[5]

The presence, in the far-IR spectra, of only one ν(Co—N) mode for all the bis-ligand complexes, except the thiocyanate and sulphate complexes, in conjunction with the low intensity of the electronic bands, indicates a probable *trans*-ligand arrangement leading to a centrosymmetric octahedral coordination geometry.

In agreement with medium IR spectra, only nitrate, thiocyanate and sulphate, of the bis-ligand complexes, exhibit any pronounced ν(Co—anion) activity. The band positions are in the expected ranges for ν(Co—NCS),[14] ν(Co—ONO_2),[18,19] and ν(Co—OSO_3)[19,20] stretching modes for Co(II) in octahedral complexes.

The low frequency IR spectra of the mixed halides compounds are similar to each other and to those of the pink $Co(HL)_2X_2 \cdot 2H_2O$ (X = Cl, Br),[1] showing in the 300–150 cm^{-1} region, no halogen dependent bands, and this fact suggests that the complexes should be formulated as $[Co(HL)_2(H_2O)_2]X_2$.

On the basis of electronic spectra, no splitting of ν_1 band, the $Co(HL)_3X_2 \cdot 0.5H_2O$ (X = ClO_4 and BF_4) compounds appear to be similar to the $CoL_3(ClO_4)_2$ (L = 2-thio-1,4,6-trimethylpyrimidine or 2-thio-1-methylpyrimidine) for which a *fac*-octahedral arrangement of the ligands was proposed.[21,22] In addition the presence in the far-IR of two ν(Co—N) and two ν(Co—S) modes, $A_1 + E$ in C_{3v} symmetry group,[23] is consistent with a *fac*-octahedral $[Co(HL)_3]^{2+}$ cation.

Magnetic moments and ligand field spectra

Room temperature magnetic moments and diffuse reflectance spectral band energies with their assignments, as well as derived ligand field parameters are listed in Table 8.

The magnetic moment of the iodo-complex occurs in the range associated with octahedral cobalt(II), whereas the remaining values occur in the upper portion of the range observed for tetrahedral Co(II) complexes.[24] However, room temperature magnetic moments of the order of 4.4–4.6 B.M. have been also reported for pseudo-octahedral complexes of Co(II) with *N*- and *S*-coordinating heterocyclic molecules.[25,26]

The reported cobalt(II)–HL complexes, except the sulphate, exhibit solid state spectra typical of octahedral species.[27] Two main absorptions are observed in the 7200–9500 cm^{-1} and 18,000–20,700 cm^{-1} ranges respectively, which are assigned to the $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ and $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ transitions.

In all the octahedral cobalt(II) complexes the ν_3 and ν_1 bands are split in two or three components of almost equal intensities, except for the tris-ligand perchlorate, fluoborate and bis-ligand thiocyanate complexes, where only ν_3 band is split. It seems plausible to believe that the splitting shown by both

Table 8. Electronic bands* and parameters *Dq* and *B* (cm^{-1}) ($\beta = B/971$) and magnetic moments [μ_{eff} (B.M.)] at room temperature of HL complexes

* Averaged values; calc. values in parentheses.

ν_1 and ν_3 bands in most of the complexes as well as the lower magnetic moment values are due to the presence of the low symmetry ligand field components.[28]

Ligand field parameters were calculated on the basis of octahedral geometry from the averaged values of the ν_1 and ν_3 bands taking the centre of gravity of the total intensity[29] by using Konig's method,[30] the ν_2 frequencies were calculated from the equation $\nu_2 = \nu_1 + 10Dq$.

In agreement with the rule of the average environment[31] the Dq values of the tris-ligand complexes $[CoN_3S_3]$, and the Dq of bis-ligand thiocyanate complex $[CoN_2S_2N'_2]$, are intermediate between the values given for $[CoN_6]$ (higher than 1000 cm^{-1}) and $[CoS_6]$ (770–860 cm^{-1}) chromophores.[32]

In the case of the $Co(HL)_2I_2 \cdot H_2O$ complex, besides the electronic spectrum consistent with an octahedral geometry, a low-energy charge-transfer band is present at *ca* 23,000 cm^{-1}; this fact is normal when iodide ions are coordinated to cobalt(II).[4] Moreover, in the far-IR spectrum, there is a band at 169 cm^{-1} not present in the spectra of the other complexes and assignable to a ν(Co—I) mode; these observations are consistent with the presence of a $[CoN_2S_2OI]$ chromophore.

For the bis-ligand perchlorate, tetrafluoroborate, nitrate and mixed-halide complexes, the visible and IR spectral data suggest the existence of a common $[CoN_2S_2O_2]$ chromophore. Consequently in the mixed-halide complexes $Co(HL)_2XY \cdot 2H_2O$ the X or Y groups would not be coordinated to the cobalt as pointed out above, and the low conductivity data for the chloro–bromo and the chloro–iodo complexes would be explained by considering strong —N—H$\cdots$Cl or $OH_2\cdots$Cl hydrogen bonds.

The spectral parameters Dq, B, β, and ν_2/ν_1 are consistent with the proposed pseudo-octahedral stereochemistries and the results strongly support the IR conclusions.

The reflectance spectrum of the violet $Co(HL)_2SO_4 \cdot 0.5H_2O$ differs significantly from the spectra of the other complexes. The number of the bands and their characteristic energies enable us to exclude tetrahedral and octahedral environment for the cobalt ion. The low magnetic moment (4.30 B.M.) and the characteristics of the reflectance spectrum [bands at 19,584m and 18,587sh, 17,035m and 15,330m, 10,810m, 5405sh, assignable to the transitions $^4A_2(F) \rightarrow {}^4E''(P)$, $\rightarrow {}^4A'_2(P)$, $\rightarrow {}^4E'(F)$, $\rightarrow {}^4E''(F)$ respectively] are similar to those corresponding to $CoL_2X_2 \cdot nH_2O$ (L = acetone-thiosemicarbazone, cyclohexanone-thiosemicarbazone; X = Cl, Br, I) complexes for which cobalt coordination number is five and the structures are trigonal bipyramidal.[33,34] Presumably a similar coordination in this complex is achieved through two N,S-chelate ligand molecules and one oxygen atom of the monodentate sulphato group.

Acknowledgement—The IR spectra were recorded in the Centro Strumenti of University of Modena.

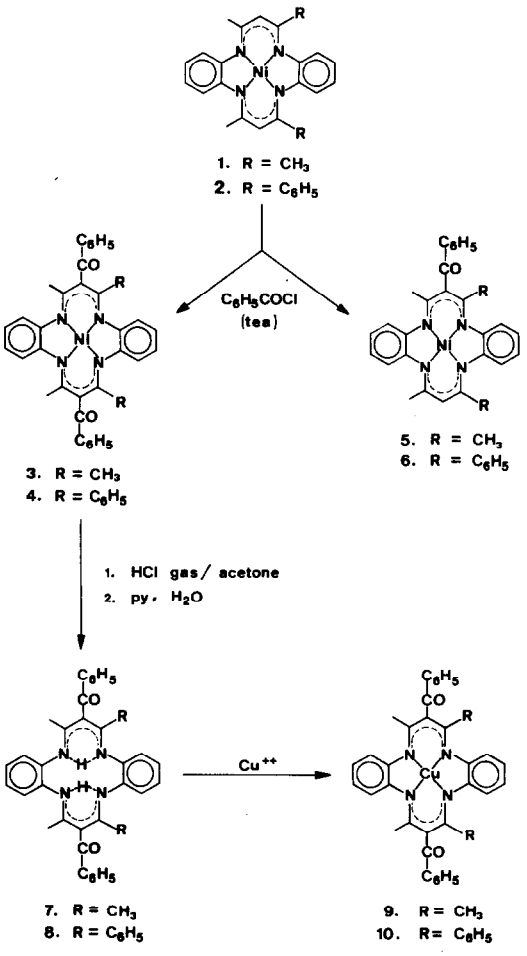
BENZOYLATION OF MACROCYCLIC JÄGER TYPE Ni(II) COMPLEXES AND AN EFFICIENT DEMETALATION OF γ,γ'-DIBENZOYLATED PRODUCTS

JULITA EILMES
Institute of Chemistry, Jagiellonian University, Karasia 3, 30-060 Cracow, Poland

(*Received* 27 *July* 1984; *accepted* 26 *September* 1984)

Abstract—The reaction of [Bzo_2Me_4[14]hexaenato(2−)N_4]Ni(II) and [$Bzo_2Me_2Ph_2$[14]hexaenato(2−)N_4]Ni(II) with benzoyl chloride leading to mono- and disubstituted derivatives is reported. The condition of the reliable demetalation of γ,γ'-dibenzoylated complexes by means of gaseous HCl are described. The Cu(II) complexes are synthesized from free ligands. All new compounds are characterized by elemental analysis, IR, ^{1}H NMR and MS data.



The reactivity of macrocyclic tetraaza metal complexes towards various reagents can be employed to introduce a large number of substituents into macrocyclic ligands. These substituents appended to macrocyclic complexes provide points of attachment for further structural modifications. Consequently, they offer the possibility of producing the more complex compounds which can serve as models for biologically important macrocyclic systems. For many macrocyclic ligands the presence of the coordinated metal greatly assists in these transformations.

From the synthetic point of view such a way of construction of peripherally substituted compounds is especially useful when the starting macrocyclic complexes are easily accessible (e.g. by high-yield, one-step template synthesis) and when the new, modified products can be successfully demetalated. Thus, replacement of the central metal atom by other transition metals is possible and the usually laborious, multi-step, non-template syntheses of peripherally substituted ligands can be avoided.

Very often, however, as it arises from many reports, numerous difficulties with the demetalation and the free ligand isolation procedure renders such synthetic approach unpractical. For example, the destruction of macrocyclic ring[1,2] and the loss of substituents,[2,3] caused by the standard conditions of this reaction, has been observed. Recently, Jäger has mentioned an extreme resistance of the γ,γ'-dicarbonyl derivatives of tetraaza macrocyclic complexes towards strong demetalation agents.[4]

This paper reports benzoylation of [Bzo_2Me_4[14]hexaenato(2−)N_4]Ni(II) (**1**)[2] (Scheme 1) and [$Bzo_2Me_2Ph_2$[14]hexaenato(2−)N_4]Ni(II) (**2**)[6] and a non-destructive demetalation of their γ,γ'-dibenzoylated derivatives.

Further experiments suggest that the conditions

Scheme 1.

reported here of removing of a metal atom are more general and can be successfully applied to other meso-disubstituted macrocyclic complexes.

RESULTS

Benzoylation

The reaction between **1** and benzoyl chloride in a 1 : 2 molar ratio in the presence of triethylamine was carried out in boiling benzene and led to the γ,γ'-dibenzoylated product **3** in 92% yield. A 1 : 1 molar ratio of these reagents produce a mixture of approximately equal quantities of the parent complex **1**, the monobenzoylated product **5** and the dibenzoylated compound **3**. The separation of products of the crude reaction mixture can be achieved by means of column chromatography (silicagel).

In the case of starting complex **2** the reaction with benzoyl chloride in 1:2 molar ratio was accomplished identically as for **1**. This reaction proceeds, however, with lower yield and results in a mixture of about 40, 20, 40% of **2**, **4** and **6** respectively. Similarly a chromatographic procedure allowed the separation of the products **6** and **4**.

A very useful, quick control of the composition of a crude benzoylation product is performed by TLC [silicagel, chloroform–benzene (1 : 1)].

Demetalation

The passage of anhydrous hydrogen chloride through a suspension of γ,γ'-dibenzoylated Ni(II) complexes in acetone produced the change of colour from green to orange–red and resulted in the abundant precipitation of a yellow, crystalline solid. This solid is a mixture of the disubstituted macrocyclic ligand hydrochloride and the nickel chloride. The metal-free hydrochloride of the dibenzoylated macrocyclic ligands was separated from the nickel salt by treatment with dilute hydrochloric acid.

The hydrochlorides of γ,γ'-dibenzoylated ligands are insoluble in water and are unchanged in cold solutions of acids and alkalis. They can be conveniently liberated from HCl by two procedures:

(i) dissolving of a crude hydrochloride in cold pyridine followed by precipitation of a free base with water;

(ii) dissolving of a crude hydrochloride in the solution of chloroform and triethylamine (ratio 2 : 1) followed by dilution with *n*-hexane. Isolation of the solid triethylamine hydrochloride and concentration of the filtrate results in crystallization of a free base, which, after washing with water, becomes completely HCl-free.

The hydrochlorides of γ,γ'-dibenzoylated ligands are insoluble in water and in this respect they differ from the water-soluble hydrochlorides of mono- and non-substituted ligands. Therefore, it is not necessary to purify chromatographically a crude product of the benzoylation reaction before a demetalation procedure. A successful separation of ligand hydrochlorides can be easily achieved.

Synthesis of Cu(II) *complexes*

Cu(II) complexes **9** and **10** were formed in fair yield when the macrocyclic ligands **7** and **8** were subjected to the action of a small excess of copper(II) acetate monohydrate in refluxing ethanol.

EXPERIMENTAL

General

Melting points are uncorrected. IR spectra were recorded in Nujol and hexachlorobutadiene on a Zeiss UR-10 spectrometer. ^{1}H NMR spectra were taken on a JEOL 100 MHz and on a Tesla BS487 80 MHz in $CDCl_3$ using TMS as internal standard. Mass spectra were taken on an LKB 900 instruments.

Parent complexes **1** and **2** were prepared by the template syntheses reported earlier.[5,6]

[2,3 : 9,10 - *dibenzo* - 6,13 - *dibenzoyl* - 5,7,12,14 - *tetramethyl* - 1,4,8,11 - *tetraazacyclotetradeca* - 2,4,6,9,11,13 - *hexaenato*(2−)]*nickel*(II) ([*Bz*$_2$*bzo*$_2$ *Me*$_4$[14]*hexaenato*(2−)]Ni(II)) (**3**). A slurry of 6 g (0.015 mol) of [Bzo$_2$Me$_4$[14]hexaenato(2−)N$_4$] Ni(II) (**1**) and triethylamine (7 cm^3) in dry benzene (100 cm^3) was treated with a solution of 4.2 g (0.03 m) of benzoyl chloride in benzene (10 cm^3), then refluxed for 1.5 h with stirring and protecting from the moisture. The reaction mixture was then allowed to stand at room temperature for 24 h.

A grey-green crystalline precipitate, consisting of the dibenzoylation product and triethylamine hydrochloride, was filtered off, dried and treated with hot water with stirring. Black, crystalline material (cubes) with slightly blue, metallic sheen was collected, washed carefully with hot water and dried *in vacuo*.

A small amount of the product can be additionally isolated from the reaction filtrate by concentration to small volume followed by precipitation with *n*-hexane.

Yield 8.3 g (92%). The product can be recrystallized from chloroform–acetone, xylene or benzene (as a solvate). M.p. > 320°C.

Found: C, 70.47; H, 5.0; N, 9.4; Ni, 9.2%.

Calc. for $C_{36}H_{30}N_4O_2Ni$: C, 70.96; H, 4.96; N, 9.2; Ni, 9.64%.

MS: 608 (P^+, ^{58}Ni) (calc. 609.29); IR: 1650 cm^{-1} (s) ($\nu_{C=O}$). ^1H NMR (δ, ppm): 1.9s (12H)—CH_3, 6.6b.s (8H) *o*-C_6H_4, 7.6m (6H) —CO—C_6H_5, 8.2m (4H) —CO—C_6H_5.

[6 - *benzoyl* - 2,3:9,10 - *dibenzo* - 5,7,12,14 - *tetramethyl* - 1,4,8,11 - *tetraazacyclotetradeca* - 2,4,6,9,11,13 - *hexaenato*(2−)]*nickel*(II) ([*Bzbzo*$_2$ *Me*$_4$[14]*hexaenato*(2−)N_4]Ni(II)) (**5**). A reaction of [Bzo_2Me_4[14]hexaenato(2−)N_4]Ni(II) (**1**) with benzoyl chloride in a 1:1 molar ratio was performed similarly to the procedure described above. After standing for 24 h, a small amount of solid was separated and treated as above. The filtrate was evaporated under reduced pressure to a small volume, cooled and diluted with *n*-hexane. A green, solid material was collected, dried, then treated with hot water with stirring, filtered off and washed carefully. The whole amount of a crude product of the reaction, dissolved in the minimum quantity of chloroform was chromatographed on a column of silicagel (0.05–0.2 mm, Merck). Three fractions—the unreacted complex **1**, the monosubstituted complex **5** and the disubstituted complex **3**—were eluted successively by means of benzene, benzene–chloroform (1:1) and chloroform. Yield of **5** 20%. Analytical sample of **5** was recrystallized from chloroform–acetone (cubes). M.p. 266°C.

Found: C, 68.4; H, 5.0; N, 11.4; Ni, 11.1%.

Calc. for $C_{29}H_{26}N_4ONi$: C, 68.94; H, 5.18; N, 11.09; Ni, 11.62%.

MS: 504 (P^+, ^{58}Ni) (calc. 505.2); IR: 1650 cm^{-1} (s) ($\nu_{C=O}$); ^1H NMR (δ, ppm): 1.9s(6H)—CH_3, 2.1s (6H) —CH_3, 6.6m (8H) *o*—C_6H_4, 7.6m (3H) —CO—C_6H_5, 8.2m (2H) —CO—C_6H_5, 4.86s (1H) =CH.

[2,3:9,10 - *dibenzo* - 6,13 - *dibenzoyl* - 7,12 - *dimethyl* - 5,14 - *diphenyl* - 1,4,8,11 - *tetraazacyclotetradeca* - 2,5,7,9,11,13 - *hexaenato*(2−)]*nickel*(II) ([*Bz*$_2$*bzo*$_2$*Me*$_2$*Ph*$_2$[14]*hexaenato*(2−)N_4]Ni(II)) (**4**) *and* [6-*benzoyl*-2,3:9,10 - *dibenzo* - 7,12 - *dimethyl* - 5,14 - *diphenyl* - 1,4,8,11 - *tetraazacyclotetradeca* - 2,5,7,9,11,13 - *hexaenato*(2−)]*nickel*(II) ([*Bzbzo*$_2$ *Me*$_2$*Ph*$_2$[14]*hexaenato*(2−)N_4]Ni(II)) (**6**). The reaction of 5.24 g (0.01 m) of [$Bzo_2Me_2Ph_2$[14] hexaenato(2−)N_4]Ni(II) (**2**), 3.3 g (0.023 mol) of benzoyl chloride and 10 cm^3 of triethylamine in dry benzene (150 cm^3) was conducted in the same manner as for complex **1**.

A grey, crystalline solid which was filtered off from the reaction mixture was composed of triethylamine hydrochloride and the unconverted starting complex (0.7 g).

A deep-green filtrate was worked-up identically as in the case of monosubstituted complex **5**. A bright-green solid (6 g) dissolved in a minimum amount of chloroform was chromatographed by the usual procedure [silicagel (0.05–0.2 mm, Merck)]. Elution with benzene, benzene–chloroform (1:1), chloroform, allowed the isolation of the parent complex **2**, the monosubstituted product **6** (yield 1 g) and the disubstituted complex **4** (yield 2.9 g, 39.5%). The product **4** was recrystallized from aqueous ethanol, m.p. 320°C, **6** from chloroform–acetone, m.p. 310°C.

Found (**4**): C, 74.82; H, 4.26; N, 7.52; Ni, 7.5%.

Calc. for $C_{46}H_{34}N_4O_2Ni$: C, 75.33; H, 4.67; N, 7.64; Ni, 8.0%.

Found (**6**): C, 74.05; H, 5.12; N, 8.8; Ni, 8.85%.

Calc. for $C_{39}H_{30}N_4ONi$: C, 74.43; H, 4.8; N, 8.9; Ni, 9.33%.

MS: 628 (P^+, ^{58}Ni) (calc. 629.33); IR: 1640 cm^{-1} (s) ($\nu_{C=O}$); ^1H NMR (δ, ppm): 2.17s (3H)—CH_3, 2.22s(3H)—CH_3, 5.0s (1H)=CH, 5.7m (4H)AA'BB' *o*-C_6H_4, 6.7m (4H) *o*-C_6H_4, 7.0m (5H)—C_6H_5, 7.3m (8H) —C_6H_5, —CO—C_6H_5, 7.7m (2H) —CO—C_6H_5.

2,3:9,10 - *dibenzo* - 6,13 - *dibenzoyl* - 5,7,12,14 - *tetramethyl* - 1,4,8,11 - *tetraazacyclotetradeca* - 2,4,6,9,11,13 - *hexaen* (*Bz*$_2$*bzo*$_2$*Me*$_4$[14]*hexaen* N_4) (**7**). A stream of anhydrous hydrogen chloride gas was bubbled through a magnetically stirred suspension of 5 g (0.0082 mol) of **3** in 150 cm^3 of acetone. The solution slowly turned yellow and a yellow precipitate began to separate. The reaction was complete after about 15 min, when the solution became orange–yellow and an abundant, orange–yellow solid accumulated. The reaction mixture, sealed carefully in the reaction flask, was left overnight, at room temperature with magnetic stirring.

The quantity of the solid diminishes in time. It seems that diacetone alcohol which forms in considerable amount partially dissolves the nickel chloride precipitate, whereas the metal-free product remains insoluble.

The crystalline solid which consisted of the macrocyclic ligand hydrochloride (orange–yellow crystals) and the nickel chloride (pale-yellow precipitate) was filtered off. After washing with acetone and drying it was treated with 100 cm^3 of cold, dilute (1:10) hydrochloric acid, stirred vigorously and quickly filtered off. It was then washed carefully with dilute hydrochloric acid and then immediately with acetone, while still wet.

The free macrocyclic base was isolated by

dissolving the crude material (4 g) in cold pyridine (50 cm^3), followed by dropwise addition of water (50 cm^3) with continuous magnetic stirring. Such a procedure was repeated three times. The method (ii) of the conversion of the hydrochloride into the free base can also be applied with similar result. Yellow cubes, m.p. 265°C. Yield 3.4 g (75.5%). The product **7** can be recrystallized from chloroform–hexane.

Found: C, 78.1; H, 5.33; N, 10.1%.

(*Received* 30 *August* 1984; *accepted* 26 *September* 1984)

Abstract—Equilibrium constants have been determined for the adduct formation of 10 copper(II) chelates of the derivatives of 1-hydroxypyrazole 2-oxide with nine substituted pyridines at room temperature in chloroform solution. These adducts were shown to have 1 : 1 stoichiometry. All the stabilities of the adducts were governed by : (1) σ-donating ability of the nitrogen atom in the substituted pyridines to the copper(II) chelates, (2) electron-attracting forces of substituents at the 3- and 4-positions of the phenyl ring in the chelate ligands, and (3) the magnitude of the polar substituent constant of the substituents in the pyrazole ring of the chelate ligands.

It is well known that the square planer copper(II) chelates behave as Lewis acids and react with a variety of Lewis bases in the axial positions to form either five-coordinate 1 : 1 or six-coordinate 1 : 2 adducts, and many papers on the adduct formation of the copper(II) chelates are now available.

In the present investigation, we have undertaken to obtain more detailed information on the effect of the substituents in both the ligands of the copper(II) chelates and Lewis bases on adduct formation. The derivatives of 1-hydroxypyrazole 2-oxide, which were first reported by Hansen *et al.*[1] as the conjugate ligands of the bivalent metal complexes, were chosen as the ligands of the copper(II) chelates because a variety of the derivatives could be synthesized according to the method proposed by Freeman *et al.*[2] Nine substituted pyridines (pys) were used as Lewis bases. Bases were selected so as to cover the effects of different basicities.

EXPERIMENTAL

Synthesis of derivatives of 1-*hydroxypyrazole* 2-*oxide*

The ligands synthesized in this investigation, according to the literature,[2] and their abbreviations are listed in Table 1. The analytical data and ^{1}H NMR spectral data of the ligands are as follows.

Preparation of copper(II) *chelates*

Ten kinds of copper(II) chelates were prepared by shaking a mixture of a chloroform solution of the ligand and an aqeuous solution of copper(II) nitrate in a mole ratio of 2 : 1 for 20 min. After the chloroform solution containing the chelate formed was washed with water to remove excess copper(II) ion, a crude product was obtained by evaporating the solvent under reduced pressure. The resulting precipitate was filtered, recrystallized from chloroform–ethanol and air-dried. The analytical data are shown in Table 2.

Reagents and apparatus

Analytical-grade py and 4-dimethylaminopyridine (4DMAP) were used without further purification. Liquid bases, 3-methylpyridine (3MP), 4-methylpyridine (4MP), 3,4-dimethylpyridine (3,4DMP) and 3,5-dimethylpyridine (3,5DMP), were dried over a molecular sieve (Type 4A) for 2–3 days, then fractionally distilled under reduced pressure prior to use. Among the solid bases, 3-aminopyridine (3AP) and 4-aminopyridine (4AP) were recrystallized from benzene, and 3-cyanopyridine (3CP) from ether. Chloroform as a solvent

for the equilibrium study was purified by the usual method. Electronic spectra were recorded on a Hitachi EPS-3T spectrophotometer equipped with a constant temperature cell housing. Correction of wave-number was done with benzene. Vapour proof 5 cm cells were used. Temperature was controlled at 20 ± 1°C. Chloroform was used as the reference. ESR spectra (X-band) were measured with a JES-FE 3X ESR instrument. ^{1}H NMR spectra were recorded with tetramethylsilane as an internal reference with a Hitachi R-24 spectrometer.

Calculation of equilibrium constant

The equilibrium constant of a 1:1 adduct, K, formed between a copper(II) chelate and a substituted py was determined spectrophotometrically using the following Lang's equation:[3]

$$\frac{ab}{d-d_0} = \frac{1}{\varepsilon_{add}}\left(a+b-\frac{d-d_0}{\varepsilon_{add}-\varepsilon_c}+\frac{\varepsilon_c ab}{d-d_0}\right)+\frac{1}{K\varepsilon_{add}},$$

where a and b are the initial concentrations of the copper(II) chelate and the substituted py, respectively, ε_c and ε_{add} are the molar extinction coefficients of the copper(II) chelate and the adduct, respectively, d_0 is the absorbance of the copper(II) chelate only and d is the absorbance of the adduct at a certain wavelength. In this equation, the values for ε_{add} and K are unknown; accordingly, a tentative value of ε_{add} is determined by using data from two solutions and solving the equation simultaneously for ε_{add} and K. This procedure is repeated until a consistent set of values for both ε_{add} and K has been obtained from two successive plots. In this study, the consistent values for ε_{add} and K were yielded by three-times repetition of a computation procedure. In determining the equilibrium constants of the adducts, absorbance measurements were carried out by using 5 cm cells at 825 nm, where the substituted py and chloroform as a solvent do not absorb.

RESULTS AND DISCUSSION

Copper(II) chelate

As summarized in Table 2, the composition of all copper(II) chelates was Cu(ligand)$_2$. These chelates were soluble in chloroform but not so soluble in other usual organic solvents. The *d–d* absorption bands measured in chloroform solution were in the region of 14,200–14,500 cm^{-1} (molar extinction coefficient 30–50), showing no appreciable differences in the spectral features due to the kind of substituent in the ligands.

Composition of adduct

As a typical example, successive absorption curves of chloroform solutions containing [Cu(PhMeMe)$_2$] at constant concentration and py at variable concentrations are shown in Fig. 1. At least seven different py concentrations were used to provide data for each determination. They pass through a clear isosbestic point, showing an equilibrium between two absorbing species in solution. Accordingly, the following equilibrium is expected to be present:

$$\text{chelate} + \text{py} \rightleftharpoons \text{chelate} \cdot \text{py}, \qquad \text{(A)}$$

or

$$\text{chelate} + 2\text{py} \rightleftharpoons \text{chelate(py)}_2. \qquad \text{(B)}$$

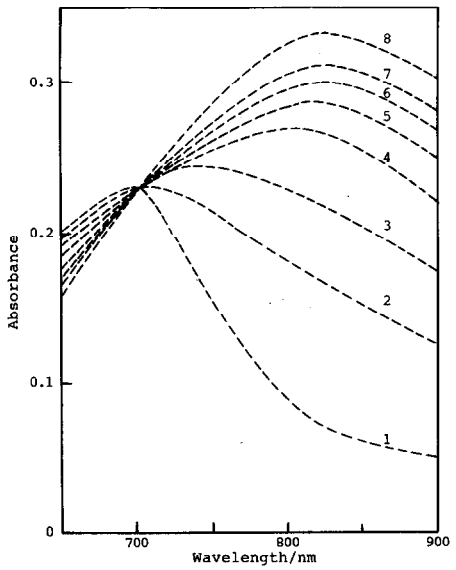

Fig. 1. Spectral change of $[Cu(PhMeMe)_2]$–py mixture in chloroform. Concentration of $[Cu(PhMeMe)_2] = 5.488 \times 10^{-3}$ mol dm^{-3}, concentrations of py: (1) 0, (2) 0.177, (3) 0.354, (4) 0.708, (5) 1.062, (6) 1.416, (7) 1.770, (8) 3.504 mol dm^{-3}.

To confirm equilibrium (A) or (B), the following two independent methods were used: Rose–Drago's[4] and Benesi–Hildebrand's methods.[5] As illustrated in Fig. 2, the curves calculated by the Rose–Drago's method have a common point by an assumption of 1 : 1 adduct formation.

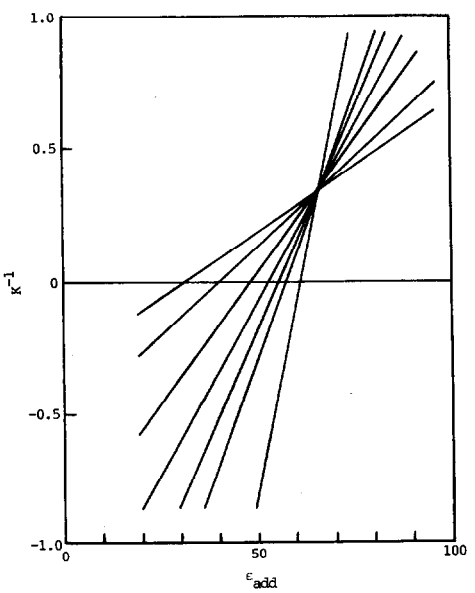

Fig. 2. Graphical solution of Rose–Drago equation[4] for the $[Cu(PhMeMe)_2]$–py system by assuming 1 : 1 adduct formation from the data in Fig. 1.

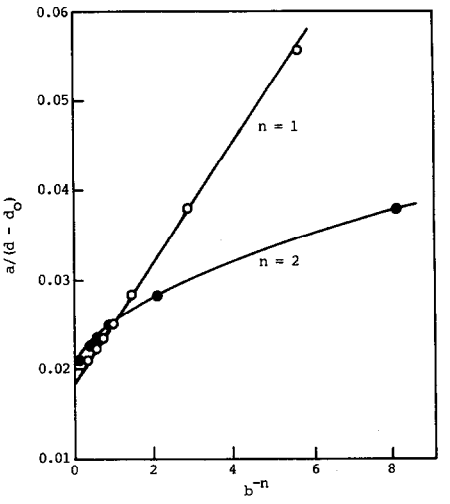

Fig. 3. Plots of Benesi–Hildebrand equation[5] for the $[Cu(PhMeMe)_2]$–py system using the data in Fig. 1.

Furthermore, in the case of equilibrium (C), Benesi and Hildebrand have proposed that the plots of b^{-n} vs $a/(d-d_0)$

$$\text{chelate} + n \cdot \text{py} \rightleftharpoons \text{chelate(py)}_n \qquad \text{(C)}$$

should give a straight line. As shown in Fig. 3, the straight line was obtained when $n = 1$. Hence equilibrium (A) is clearly confirmed to be present by this method too.

ESR spectra of copper(II) chelate and its adduct

The ESR spectra of $[Cu(2Cl\text{-}PhMeMe)_2]$, as a typical example, in chloroform (a) at room temperature and py (b) at liquid nitrogen

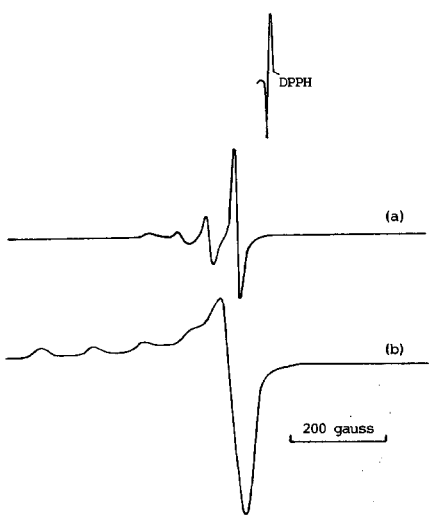

Fig. 4. ESR spectra of $[Cu(2Cl\text{-}PhMeMe)_2]$ in chloroform (a) at 293 K and py (b) at 77 K.

temperature are given in Fig. 4. As can be seen from spectrum (a), a hyperfine structure of the copper nuclei was observed in chloroform solution, indicating that the copper(II) chelate existed as a monomeric structure. In addition, it was seen from spectrum (b) that the py adduct possessed a tetragonal structure.

Kogane *et al.*[6] investigated the ESR spectra of the adducts of $Cu(acac)_2$ (acac = aetylacetonato) with Lewis bases, and reported that a new signal due to 1:2 adduct formation appeared on the lower-field side of the signal corresponding to the 1:1 adduct. However, such a signal was not observed in this study, showing no 1:2 adduct formation for the present systems studied.

Equilibrium constant of adduct

In Table 3, the equilibrium constants for the 1:1 adduct formation between 10 kinds of copper(II) chelates and nine substituted pys are listed, and the Hammett's σ-values of the substituted pys are also listed for illustration in Figs 5–7. The equilibrium constants for the set of 3CP were obtained only for the five adducts having relatively large equilibrium constants.

An effect on the adduct formation due to the substituents in the ligands of the copper(II) chelates and the py derivatives was discussed from the following three viewpoints.

Effect of the substituents in py derivatives. As can be seen from Table 3, it is apparent that the differences in the substituents in py derivatives are largely reflected in the equilibrium constants. Generally, the electronic effect of a substituent bound to aromatic nuclei, including heterocyclic aromatic rings,

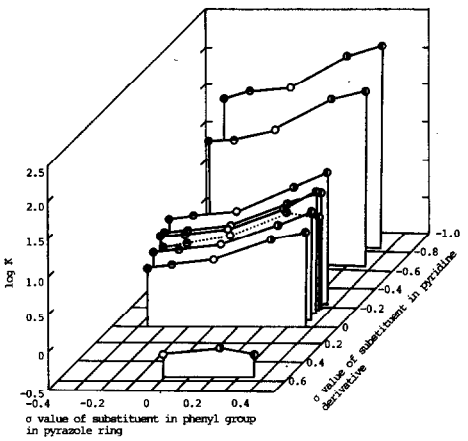

Fig. 6. Plots of Hammett's σ-values of substituents X in [Cu(X-PhMeMe)$_2$] type chelates against equilibrium constants. (●) X = 4CH$_3$O; (◒) X = 4CH$_3$; (○) X = H; (◑) X = 4Cl; (◐) X = 3Cl.

appears as the sum of the induced and resonance effects. Quantitative representation of these effects can be made by Hammett's rule.

The stabilization of the adduct will occur both by contributions from σ-donation, which is an electron transfer from the nitrogen atom in py to the copper(II) chelate, and from π-back donation from the copper atom to the nitrogen. Silva *et al.*[7] reported that, if the back donation is predominant, there is not so good a correlation between the equilibrium constant of the adduct and the Hammett's σ-values, which is a measure of σ-bonding ability, and, in that case, a better correlation of the Hammett's σ-values vs π-stabilization factors, defined as a measure of π-back donation ability, is present.

The plots of the σ-values of the substituted pys vs equilibrium constants of the 1 : 1 adducts obtained in this study are illustrated in Fig. 5. In all cases, the plots had a strong correlation, especially the [Cu(PhMePh)$_2$] and the substituted pys system showed a good correlation, with a coefficient of 0.9989. These results indicate that the stabilization of the adduct studied is thoroughly governed by the electron-donating ability of the nitrogen atom in the substituted py rings, and hence the adduct formation can be carried out by coordinating the nitrogen atom to the square planar copper(II) chelate without steric hindrance.

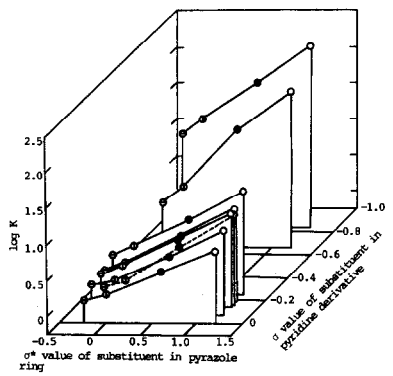

Fig. 7. Plots of Taft's σ^*-values of substituents in pyrazole ring vs equilibrium constants. (⊖) 1Et-PrMeMe; (◑) MeMeMe; (●) PhMeMe; (○) PhMePh.

Among the substituted pys studied, the equilibrium constants for 3AP and 4AP with [Cu(MeMeMe)$_2$], [Cu(2CH$_3$O-PhMeMe)$_2$] and [Cu(1Et-PrMeMe)$_2$] systems deviated slightly from each plot of log K vs σ-value. We cannot explain this deviation so clearly, but it is likely that some interaction of these pys with the copper(II) chelates affected spectral features.

Effect of substituent X in [Cu(*X-PhMeMe*)$_2$] *type chelates.* In all adducts studied, the equilibrium constants increase in the order of X: 2CH$_3$O < 4CH$_3$O < 4CH$_3$ < H < 2Cl < 4Cl < 3Cl. Except for the 2-substituted phenyl group in the copper(II) chelates {[Cu(2CH$_3$O-PhMeMe)$_2$] and [Cu(2Cl-PhMeMe)$_2$]}, this order agreed well with the electron-attracting abilities of X. A substituent in the 2-position of the phenyl group is usually considered to hinder sterically the copper(II) chelate formation. The order H < 2Cl, however, obtained in this study also indicated that the trend of the equilibrium constants of this series should be dependent primarily on the electronic effect of X, and not on the steric factor of X.

Figure 6 shows the plots of the Hammett's σ-values of the substituent X vs the equilibrium constants for the series [Cu(X-PhMeMe)$_2$] other than X = 2CH$_3$O and 2Cl. As can be seen from Fig. 6, correlations of the σ-values against log K are not as good compared to those in Fig. 5, presumably because the electronic effect of X would be transported to the copper atom via the pyrazole ring. As a whole, however, it is clear that the stabilization of the adducts is governed by the electron-attracting ability of the substituent X.

Effect of the substituents R^1 *and* R^3 (R^1 *and* R^3 = *phenyl or alkyl group in pyrazole ring*) *in* [Cu(R^1MeR^3)$_2$] *type chelates.* On changing the methyl group in the [Cu(MeMeMe)$_2$] chelate to [Cu(PhMeMe)$_2$] and [Cu(PhMePh)$_2$], the equilibrium constants of the adduct formation increased linearly for all the substituted pys. This shows that the substituent effect of R^1 and R^3 is considered to be additive for the equilibrium constants, because the positions of R^1 and R^3 in the conjugating pyrazole ring are electrically equivalent.

Taft *et al.*[8] proposed that the polar substituent constant, σ^*, as a measure of an inductive effect of an aliphatic substituent. That is, when $\sigma^* > 0$, the substituent is more electron-attracting than the methyl group, and, if $\sigma^* < 0$, the substituent possesses an electron-donating ability compared to that of the methyl group.

The relations between the σ^* values and the equilibrium constants of the adducts for $[Cu(1EtPrMeMe)_2]$, $[Cu(MeMeMe)_2]$, $[Cu(PhMeMe)_2]$ and $[Cu(PhMePh)_2]$ are illustrated in Fig. 7, in which σ^* values of $C_6H_5 = 0.600$, $H = 0.490$, $CH_3 = 0.000$ and $(C_2H_5)_2CH = -0.225$ were used for illustration. As is apparent from Fig. 7, positively linear correlations are obtained. This tendency shows that the electron density on the copper atom would also be governed by the inductive effect of the substituents in the pyrazole ring.

Acknowledgements—We wish to express our thanks to Professor Sigeo Kida and Associate Professor Hisashi Ōkawa of Kyushu University for help in obtaining the ESR data. (*Received* 13 *August* 1984; *accepted* 1 *October* 1984)

Abstract—Stable, pentacoordinated iridium(I) complexes have been synthesised by the replacement of the chlorine in $IrCO(PPh_3)_2Cl$ by bidentate chelating ligands such as β-diketones, *N*-benzoyl-*N*-phenyl hydroxylamine, salicylaldehyde, 8-hydroxyquinoline, 2-hydroxybenzophenone and 2-hydroxy 4-methoxybenzophenone. Most of them gave stable oxygen adducts $IrCO(PPh_3)_2(L)O_2$ and all of them underwent oxidative addition with bromine in methylene chloride giving $IrCO(PPh_3)_2(L)Br_2$. These chelated iridium(I) compounds reacted with liquid sulphur dioxide to produce two types of SO_2 insertion products.

Square planar iridium(I) complexes are well known for their catalytic activities.[1–4] Although these sixteen electron systems have been studied in detail,[5] the corresponding pentacoordinated iridium(I) derivatives have been only briefly explored.[6–10] Our interest lies in the synthesis of stable electron rich iridium(I) complexes derived from monobasic bidentate chelating ligands having varying degrees of Lewis basicity. Here we report the synthesis and reactions of pentacoordinated iridium(I) complexes.

EXPERIMENTAL

The Vaska complex *trans*-$IrCO(PPh_3)_2Cl$ was prepared as mentioned in the literature.[11] The organic ligands were of the highest purity available in the market. Organic solvents were dried, distilled and degassed before use. All experiments were carried out under oxygen-free nitrogen atmosphere.

The IR spectra were recorded on a Perkin–Elmer IR spectrophotometer Model 599 using CsI optics, and the UV spectra on a Pye Unicam SP8-100 UV–VIS spectrophotometer. ^1H and ^{31}P NMR spectra were recorded on a Bruker-90 Fourier Transform Spectrometer operating at 90 MHz. Chemical shifts are reported relative to TMS for ^1H and 85% H_3PO_4 for ^{31}P. The XPS were recorded using an ESCA-3MK-11 Electron Spectrometer (VG Scientific Ltd, U.K.), equipped with Mg-K_α (1253.6 eV) and Al-K_α (1486.6 eV) anodes at 50 eV analyser energy and 4 mm entrance slit width. The core electron binding energies of Ir $4f_{5/2}$, $4f_{7/2}$ were referred to C_{1s} level of carbon present in the complexes. The binding energy of C_{1s} line was taken as 285.0 eV. The magnetic susceptibility measurements were carried out on a CAHN-1000 Research Model instrument with a Faraday type balance.

Preparation of the 8-hydroxyquinolinato complex

Sodio-derivative of 8-hydroxyquinoline was prepared by stirring a mixture of the ligand (0.145 g; 1 mmol) and sodium hydride (0.027 g; 1.1 mmol) in ether (25 cm^3) at room temperature for 3 h. Ether was then removed under reduced pressure and benzene (25 cm^3) was added along with the Vaska compound $IrCO(PPh_3)_2Cl$ (0.780 g; 1 mmol) and the mixture was refluxed for 12 h. The contents were then cooled, centrifuged and the clear solution was concentrated *in vacuo* to obtain orange crystals of the product, which were washed with hexane and again dried under reduced pressure at room temperature. The crystalline product weighed 0.63 g (yield 70%). M.p. 191°C.

Other compounds listed in Table 1 were prepared similarly.

Preparation of the oxygen adduct

Pure oxygen was slowly bubbled through the reaction flask while refluxing the sodio-derivative of the ligand with the Vaska complex (12 h). The contents were cooled, centrifuged, and the clear

* NCL Communication No. 3575.
† Author to whom correspondence should be addressed.

solution concentrated under reduced pressure to obtain the desired product as a micro-crystalline solid. It was washed with hexane and dried *in vacuo*. Yields were nearly quantitative.

Preparation of the bromine addition compound

The iridium complex $IrCO(PPh_3)_2$(oxinate) (0.088 g; 0.1 mmol) dissolved in methylene chloride (5 cm^3) and bromine (0.016 g; 0.1 mmol) in methylene chloride (5 cm^3) were mixed and stirred for 30 min at room temperature. The solution was concentrated *in vacuo* to get crystals of the product in quantitative yield.

The sulphur dioxide insertion reaction

Sulphur dioxide gas was dried using concentrated sulphuric acid and condensed into liquid in a long-necked flask, in which the complex $IrCO(PPh_3)_2$(Ba) about 0.3 g was kept, by keeping the flask immersed in ice–salt mixture. Moisture was rigorously excluded. After 1 h, when about 10 cm^3 of liquid sulphur dioxide had collected over the sample in the flask, the flow of gas was discontinued. The contents were allowed to remain for 2 h with occasional shaking. The green crystals separated from the liquid were isolated by decantation from the yellow solution. The crystals were washed with hexane and dried *in vacuo*; the portion soluble in liquid sulphur dioxide was separated by evaporating the liquid followed by washing the yellow solid with hexane and drying *in vacuo*. For the green solid $[IrCO(PPh_3)_2SO_2]_2O$. Found: C, 53.80; H, 3.58; P, 7.40; SO_2 8.01%. Calc. for $C_{74}H_{60}O_7P_4S_2Ir_2$: C, 54.40; H, 3.70, P, 7.58; SO_2, 7.84%. For the yellow solid $[IrCO(PPh_3)_2SO_2(Ba)]$. Found: C, 57.92; H, 3.95; P, 6.02; SO_2, 6.85%. Calc. for $C_{47}H_{39}O_5P_2SIr$: C, 58.19; H, 4.05; P, 6.38; SO_2, 6.60%.

RESULTS AND DISCUSSION

The chlorine atom of the Vaska complex $IrCO(PPh_3)_2Cl$ was readily replaced by chelating ligands containing potential hydroxyl group employing sodium hydride as a base:

$$IrCO(PPh_3)_2Cl + NaL \rightarrow IrCO(PPh_3)_2L + NaCl.$$

The products separated from benzene as orange yellow micro-crystalline solids were stable in nitrogen atmosphere (Table 1). When oxygen was bubbled through their solutions (in chloroform or benzene) most of them were oxidized to the corresponding oxygen addition compounds. Some of them were considerably stable in solution as seen from their IR and UV spectral data. For example, the iridium(I) complexes of benzoylacetone, 8-hydroxyquinoline and *N*-benzoyl-*N*-phenyl hydroxylamine did not dissociate in chloroform suggesting these ligands to be harder bases compared to the remaining ones. All the new complexes underwent oxidative addition reaction with bromine in methylene chloride as indicated by the IR stretching frequencies of the products in the carbonyl stretching region ($\sim 2000\ cm^{-1}$).

IR spectra of the complexes were run as Nujol mulls and in chloroform solutions (Table 2). The Vaska complex $IrCO(PPh_3)_2Cl$ shows absorption bands at

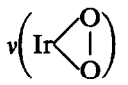
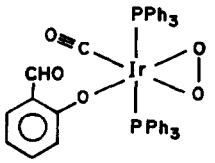
1955(s) and 1900(sh) cm^{-1} due to terminal carbonyl vibrations. In the chlorine free complexes, however, this band is observed mostly in the lower frequency region; this can be attributed to stronger metal–CO interaction as a result of change in the hybridization of the metal from square planar to trigonal bipyramidal and increased donating property of oxyanions compared to chlorine.

The IR spectrum of the 8-hydroxyquinolinato complex $IrCO(PPh_3)_2$(oxinate) shows ν (C≡O) at 1935 cm^{-1}. The band due to the phenolic ν (C–O) is observed at 1320 cm^{-1}, 40 units to higher frequency, suggesting an increased C–O bond order as the result of proton replacement. In the far IR region, the ν (Ir–CO) is seen at 655 cm^{-1} which is 45 units higher than that of the Vaska complex. The electronic spectrum of the 8-hydroxyquinolinato complex in chloroform shows three well-defined absorption bands in the UV–Visible spectral region; λ_{max} = 430 nm (ε = 8000), 372 nm (ε = 8000), 320 nm (ε = 8600), suggesting iridium in its +1 oxidation state.[12] The large molar extinction coefficient of the absorption bands when compared to those of the Vaska complex, λ_{max} = 438 nm (ε = 683), 386 nm (ε = 4239), 336 nm (ε = 320), has been assigned to strong metal–ligand charge-transfer interaction. Similar features are observed in the case of benzoylacetonate and *N*-benzoyl-*N*-phenyl hydroxylaminate complexes. The stability of these complexes was tested by leaving their dilute chloroform solutions for 24 h in an inert atmosphere; they retained all the absorptions in the UV–Visible region.



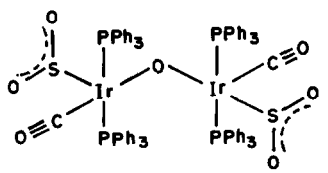
The X-ray photoelectron spectrum of the 8-hydroxyquinolinato complex [$IrCO(PPh_3)_2$(oxinate)] gives Ir 4*f* binding energies at $4f_{5/2}$ = 64.4 and $4f_{7/2}$ = 61.8, and the total electronic charge on iridium in this complex is nearly the same as that of Vaska, $4f_{5/2}$ = 64.6, $4f_{7/2}$ = 61.6.[13] Substitution of chlorine by oxine could have increased total electron density on iridium atom thereby reducing the Ir 4*f* binding energies. The electronic changes due to substitution are obviously compensated by the presence of CO as has been observed from the reduction in the stretching frequency of the C≡O band.

All this evidence suggests that the structure of the oxinate complex is:



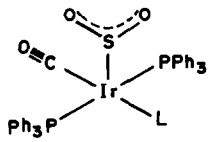
I

Salicylaldehyde and 2-hydroxynaphthaldehyde when reacted with the Vaska complex always gave unstable iridium(I) compounds. However, stable oxygen adducts of the type $IrCO(PPh_3)_2(Sal)O_2$ and $IrCO(PPh_3)_2(Naph)O_2$ could be separated as pale yellow micro-crystalline diamagnetic solids. The IR spectrum of the salicycladehyde derivative shows ν(C≡O) at 2010 cm^{-1} suggesting a higher oxidation number for iridium. The aldehydic carbonyl stretching mode is shifted to lower wave number (1615 cm^{-1}) which could be attributed to conjugative electron drain from carbonyl to oxidised iridium. The phenolic ν (C–O) observed in free salicylaldehyde at 1280 cm^{-1} has been shifted to 1295 cm^{-1} due to complex formation. The presence of a medium band at 835 cm^{-1} due to



confirms the oxygen adduct formation. Proton decoupled ^{31}P NMR spectrum of the salicylaldehyde derivative [$IrCO(PPh_3)_2(Sal)O_2$] shows a singlet at δ −7.24 ppm. This downfield shift when compared to that of the Vaska complex (δ −24.43 ppm) is indicative of the higher oxidation state for iridium. The Ir 4*f* binding energies for the salicylaldehyde complex are $4f_{5/2}$ = 65.16 and $4f_{7/2}$ = 62.40. These values are nearly one unit higher than those for iridium(I) complexes and suggest an increased positive charge on iridium.

Hence the structure of the salicylaldehyde complex is suggested to be:



II

Iridium(I) chelates when reacted with liquid sulphur dioxide gave two types of insertion products. A green crystalline solid separated from liquid sulphur dioxide solution (in all cases) did not show the presence of bidentate chelating ligand as confirmed from elemental analysis and spectral data. The IR spectrum shows ν (C≡O) at 2020 cm^{-1} which can be interpreted as a reflection of the oxidaton of the univalent iridium complex. In the SO_2 stretching region, two strong bands are seen due to ν_{as} (SO_2) and $\nu_s(SO_2)$ at 1195 and 1050 cm^{-1}, suggesting the coordination of sulphur to iridium. The presence of an additional medium broad band at 810 cm^{-1} could be attributed to the presence of an Ir—O—Ir linkage.[14,15] The conversion of Ir(I) to Ir(III) in the liquid sulphur dioxide medium with the simultaneous cleavage of the bidentate chelating ligand can be explained by the presence of traces of moisture in the cryogenic system. Hence the structure of the green product is proposed to be:

III

The portion soluble in liquid sulphur dioxide upon isolation in each case gave yellow powdery substances. In their IR spectra, bands associated with chelating ligands are retained with slight increase in the stretching frequency region of the ketonic group in the case of β-diketone derivatives. The ν(C≡O) is shifted to 2000 cm^{-1} which suggests a higher oxidation state for iridium. The $\nu_{as}(SO_2)$ and $\nu_s(SO_2)$ are seen at 1195 and 1050 cm^{-1} respectively. These data support the structure given below:

STABILISATION OF COPPER(II) TERTIARY-PHOSPHINE OR -ARSINE COMPLEXES—II. ROLE OF INDUCTIVE EFFECT AND REACTION CONDITIONS IN STABILISING COPPER(II)–ARSINE COMPLEXES OF HYBRID OXYGEN–ARSENIC LIGANDS FROM *o*-$R_2AsC_6H_4CO_2H$

SWARN S. PARMAR,* HARKEERAT K. BHARAJ and MANOHAR L. SEHGAL
Chemistry Department, Guru Nanak Dev University, Amritsar-143 005, India

(*Received* 5 *July* 1984; *accepted* 1 *October* 1984)

Abstract—The characterization of the products of reactions between anhydrous/hydrated copper(II) acetate and the title acids having R = Me, C_6H_{11}, Ph and *p*-tolyl in different solvents and at different temperatures with the help of elemental analysis, TGA, DTA, room temperature magnetic susceptibility, IR, and UV–VIS and EPR spectral data reveal that a competition exists between the chelation of arsine to copper(II) on one side and the reduction of copper(II) to copper(I) and the subsequent chelation of the arsine to copper(I) and/or that of the arsine oxide to copper(II) on the other. This competition which is expected to be normally governed by the inductive effect of group R is disturbed by the change in reaction conditions leading to the conclusion that the reaction conditions rather than the inductive effect of the group R control the mode of reaction.

All earlier attempts[1–8] to prepare copper(II)–arsine complexes of tertiary arsines invariably yielded either a copper(I)–arsine or a copper(II)–arsine oxide complex due to the rapid reduction of copper(II) to copper(I) and simultaneous oxidation of arsine to arsine oxide. In 1968 we reported the preparation of two copper(II)–arsine complexes, $Cu(o\text{-}R_2AsC_6H_4CO_2)_2$, by reacting copper(II) acetate monohydrate with the title acids (A) having R = Ph and *p*-tolyl.[9] Subsequent attempts[10–15] yielded only four

A

copper(II)–arsine complexes, $Cu(hfac)_2(AsPh_3)_n$ (hfac = hexafluoroacetylacetonate; $n = 1$ or 2)[13] and $[Cu(o\text{-}H_2NC_6H_4AsR_2)_2](ClO_4)_2$ (R = Me or Ph).[14] Recently we have reported 20 such complexes using ligand A with R = Ph and its *p*-isomer and have also accounted for the earlier failures.[16] In continuation, we now report the characterization of the products of reactions between anhydrous/hydrated copper(II) acetate and ligands having R = Me, C_6H_{11}, Ph and *p*-tolyl in different solvents and at different temperatures in order to determine whether the reaction conditions or inductive effect of group R controls the stabilization of copper(II)–arsine complexes. The present work is altogether different from the reported[17] limited role of the different sets of the solvents and anions in determining the relative stability of copper(II) and copper(I) since here the ligand anion ($o\text{-}R_2AsC_6H_4CO_2^-$) itself is a reducing agent whose strength depends upon the inductive effect of group R.

EXPERIMENTAL

Preparation of ligands, their sodium salts and complexes **1a**, **1b**, **2a**, **2b**, **3** and **11**, the elemental analysis and other physical measurements have been described earlier.[9,16,18] EPR spectra of the copper(II) complexes isolated in the present investigation were recorded on a Varian EPR spectrophotometer at IIT, Madras.

$Cu(o\text{-}Ph_2AsC_6H_4CO_2)\cdot 0.5H_2O$ (4)

Stirring of a reaction mixture of a solution of the acid (A) (0.1 g, 2 mmol) in 95% EtOH (20 cm^3) with a suspension of copper(II) acetate monohydrate (0.2 g,

* Author to whom correspondence should be addressed.

1 mmol) in 95% EtOH (10 cm^3) resulted in the separation of a green solid, after 15 min, whose colour gradually changed to chocolate brown and finally to white on continuous stirring (5–6 h). It was filtered, washed with 95% EtOH and dried *in vacuo* (yield 82%). The same compound was also obtained on prolonged stirring of each of the copper(II)–arsine complexes **1a**, **1b**, **2a**, **2b** and **3**.

$Cu(o\text{-}Me_2AsC_6H_4CO_2)\cdot 0.5H_2O$ (**5**)

Boiling of a reaction mixture containing **A** (1.8 g, 8 mmol) in *n*-PrOH (30 cm^3) and a suspension of copper(II) acetate monohydrate (0.8 g, 4 mmol) under reflux for 30 min gave a creamy white solid which was filtered, washed with *n*-PrOH and dried *in vacuo* (yield 52%).

$CuO(o\text{-}Me_2As(OH)C_6H_4CO_2)_2$ (**6**)

A blue–green solid was obtained when the dark green filtrate from the above reaction was concentrated to 2–3 cm^3 and treated with ether (30–40 cm^3). It was filtered, washed with ether and dried *in vacuo* (yield 15%).

Stirring of the reaction mixture of **A** (0.9 g, 4 mmol) in 95% EtOH (20 cm^3) and a suspension of copper(II) acetate monohydrate (0.4 g, 2 mmol) in 95% EtOH (3 cm^3) for 2 h gave a green solution which was evaporated to dryness. The whitish green solid residue when treated with hot *n*-PrOH (20 cm^3) gave a white solid which was filtered, washed with *n*-PrOH and dried *in vacuo*. Addition of ether into the green filtrate after concentration to 2–3 cm^3 yielded a green solid which was filtered, washed with ether and dried *in vacuo*. The white and green solids were found to be identical with **5** and **6** respectively.

$Cu(o\text{-}Me_2AsC_6H_4CO_2)_2\cdot H_2O$ (**7a**)

Refluxing of the reaction mixture containing **A** (1.8 g, 8 mmol) in EtOH (30 cm^3) and anhydrous copper(II) acetate (0.74 g, 4 mmol) in the same solvent (10 cm^3) for 15 min afforded a dark green solution. A green solid separated out on the addition of ether to the concentrated solution. It was filtered, washed with ether and dried *in vacuo* (yield 60%).

$Cu(o\text{-}Me_2AsC_6H_4CO_2)_2\cdot H_2O$ (**7b**)

Stirring of the mixture of **A** (1.35 g, 6 mmol) solution in *n*-PrOH (30 cm^3) with a suspension of copper(II) acetate monohydrate (0.6 g, 3 mmol) in the same solvent (10 cm^3) for 30 min gave a dark green solution which was concentrated to 2–3 cm^3. Its treatment with ether yielded a green compound which was filtered washed with ether and dried *in vacuo* (yield 60%).

$Cu(o\text{-}(C_6H_{11})_2AsC_6H_4CO_2)\cdot 0.5H_2O$ (**8a**)

Stirring of the reaction mixture obtained by mixing **A** (0.72 g, 2 mmol) in 95% EtOH (12 cm^3) with a suspension of copper(II) acetate monohydrate (0.2 g, 1 mmol) in 95% EtOH (10 cm^3) yielded a dirty green solid which gradually changed to dirty white during 6 h. It was filtered, washed with 95% EtOH and dried *in vacuo* (yield 81%).

$Cu(o\text{-}(C_6H_{11})_2AsC_6H_4CO_2)\cdot 0.5H_2O$ (**8b**)

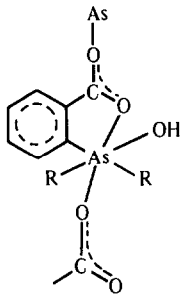
Refluxing of a reaction mixture obtained by mixing a solution of **A** (1.4 g, 4 mmol) in MeOH (30 cm^3) with a methanolic solution (20 cm^3) of copper(II) acetate monohydrate (0.4 g, 2 mmol) for 1 h afforded a dirty white solid which was filtered, washed with MeOH and dried *in vacuo* (yield 70%).

$Cu_2O(o\text{-}(C_6H_{11})_2AsC_6H_4CO_2)_2\cdot 2H_2O$ (**9**)

Boiling of a mixture containing **A** (1.45 g, 4 mmol) solution in EtOH (25 cm^3) and a suspension of copper(II) acetate (0.37 g, 2 mmol) in the same solvent (10 cm^3) under reflux for 45 min gave a brown solid, which was filtered washed with EtOH and dried *in vacuo* (yield 73%).

$Cu_2O(o\text{-}(p\text{-tolyl})_2AsC_6H_4CO_2)_2\cdot 2H_2O$ (**10**)

Refluxing of the reaction mixture containing a solution of copper(II) acetate monohydrate (0.4 g, 2 mmol) in MeOH (20 cm^3) and of **A** (1.5 g, 4 mmol) in MeOH (40 cm^3) for 2 h afforded a light green solid which was filtered washed with MeOH and dried *in vacuo* (yield 57%).



RESULTS AND DISCUSSIONS

The complexes obtained here can be classified as: (i) copper(I)–arsine complexes **4**, **5**, **8a** and **8b**; (ii) copper(II)–arsine complexes **7a**, **7b**, **9** and **10**; and (iii) a copper(II)–arsine oxide complex **6**. The presence of water in these complexes is supported by the appearance of IR bands[19] due to ν(OH) and δ(HOH) at 3000–3400 and 1620–1635 cm^{-1} respectively, and their TGA and DTA data (Table 1). The assignment of formula **6** is based on the appearance of bands at 2350 [ν(AsOH)], 1310, 1195, 765 and 700 cm^{-1} (sh) which are missing in the spectra of arsine and arsine complexes and are present in the spectrum of the

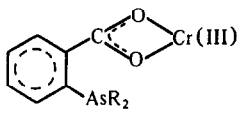
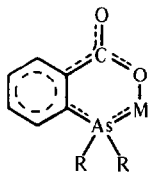
* Position of DTA peak corresponding to dehydration or decarboxylation. The remaining DTA peaks have been mentioned in the Discussion.



B

arsine oxide which has been assigned structure **B** on the basis of UV and IR data.[20,21]



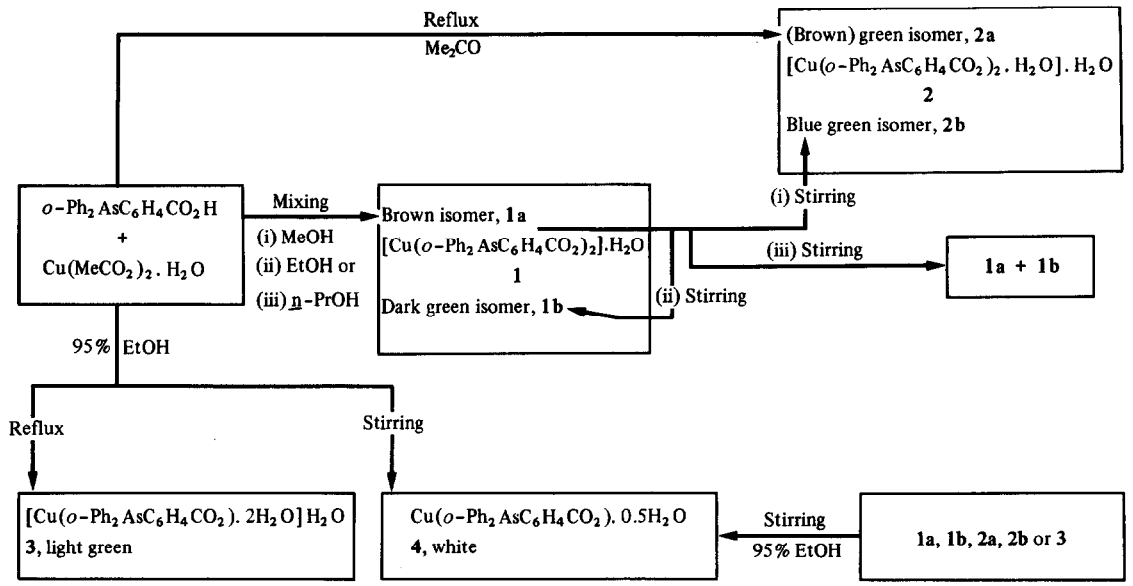
The DTA curve of isomer **8a** shows a phase transformation at 135°C and contains two exothermic peaks instead of the one observed in that of isomer **8b**. The main difference in the DTA curves of isomers **7a** and **7b** is in the number of exothermic peaks which are three in **7a** (310, 373, 400°C) and two in **7b** (156 and 280°C). The identical positions of all the IR bands of both isomers in complexes **7** and **8** and the different DTA curves may be explained in terms of some type of conformational difference. The TGA and DTA data of complexes **9** and **10**, $Cu_2O(o\text{-}R_2AsC_6H_4CO_2)_2 \cdot 2H_2O$, show that only the former loses a molecule of CO_2 between 160 and 200°C while the latter suffers two phase transformations (*endo*-197 and 222°C). The dehydration appears to be followed by decarboxylation in complexes **6** and **8a** also. Thermal decarboxylation of copper carboxylates leading to the formation of various aryl copper species is well documented in literature.[22–25]

Recently the lowering of $\nu_{as}(CO_2)$ of the ligand sodium salts from 1595 to 1520–1535 cm^{-1} and a slight lowering or raising of $\nu_s(CO_2)$ in the complexes of these ligands with chromium(III)[18] and lead(II)[20] has been explained in terms of the chelation of the carboxylate ion with the metal ion (**C**) leaving the

C

arsenic(III) uncoordinated. On the other hand the appearance of $\nu_{as}(CO_2)$ close to that of the sodium salt has been attributed to the simultaneous coordination of carboxylate ion and arsenic(III) leading to the formation of structures **D**[26] in complexes of these ligands with zinc(II), cadmium(II) and mercury(II). These results have also been supported on the basis of UV and PMR data.[20] Application of these criteria to the IR data (Table 2)

D



of the copper(II)–arsine and copper(I)–arsine complexes favour the chelation of the ligand (**D**) in both the types of complexes. Splitting of both the $\nu_{as}(CO_2)$ and $\nu_s(CO_2)$ bands observed in the spectra of copper(I)–arsine complexes suggests the presence of two coordination bonding modes of the carboxylate ion[27–30] leading to polymerisation as evidenced by their insolubility in common organic solvents. Their insolubility handicapped the recording of PMR spectra.

The IR spectra of complex **6** and the arsine oxide (**B**) are almost identical in the range 3000–200 cm^{-1}. This appears to indicate that copper(II) ion fits in the interstices without disturbing the solid structure of the oxide with adjacent chains facing each other so that the metal ion is surrounded by four planar carboxylate oxygens. The cationic charge of the metal ion being neutralised by the oxide ion acting as an axial bridge between the adjacent planar CuO_4 chromophores.

The experimental room temperature μ_{eff} values of all the copper(II) complexes are almost normal with the exception of complex **9** which possesses a highly subnormal value of 1.4 B.M. equal to that of the copper(II) acetate monohydrate known to possess a dimeric bridged structure. Its complete EPR spectrum could not be recorded due to the limitation of the instrument used. However, the partial spectrum resembles the corresponding part of the reported[31] spectrum of copper(II) acetate monohydrate. These results favour some type of structure involving spin–spin interaction leading to antiferromagnetism. The EPR spectral data of complexes **7a** ($g_{\|} = 2.378$, $g_{\perp} = 2.04$, $A = 120$ G) and **10** ($g_{\|} = 2.387, g_{\perp} = 2.06, A = 120$ G) suggest an elongated octahedral coordination around copper(II) with $d_{x^2-y^2}$ ground state and C_{4v} axial symmetry. Slightly higher experimental $g_{\|}$ values may be attributed in terms of large amount of distortions leading to the mixing of $d_{x^2-y^2}$ and d_{z^2} under the action of second order spin orbit coupling. The EPR spectra of complexes **6** and **7a** need scanning at 77 K since appreciable absorption could not be obtained at room temperature. The appearance of a broad *d–d* band in the UV–VIS spectra of all the copper(II) complexes at 12,000–13,000 cm^{-1} ($10Dq$) favour a distorted octahedral

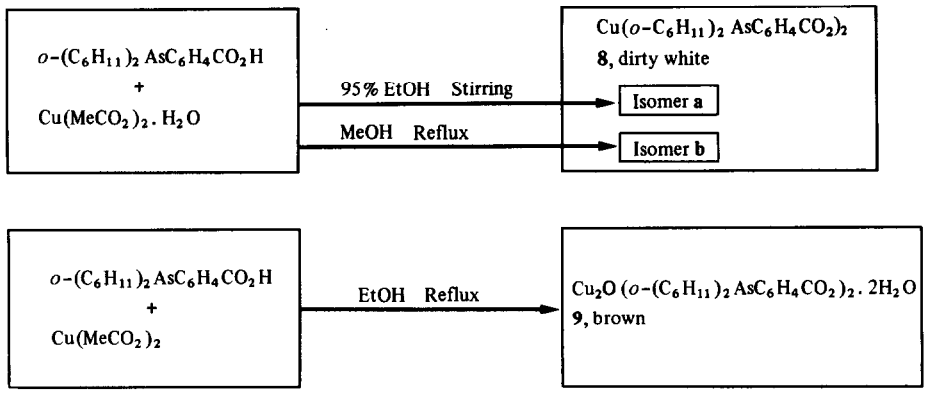
stereochemistry. These experimental $10Dq$ values are slightly lower than normally found (14,000–16,000 cm^{-1}) for octahedral copper(II) complexes. However these lower values are consistent with their experimental higher $g_{\|}$ values.



A with R = Ph, reported[16] to yield a variety of copper(II)–arsine complexes (**1a**, **1b**, **2a**, **2b** and **3**) (Scheme 1),[9,16] now reacts, on stirring, with a suspension of copper(II) acetate monohydrate in 95% EtOH to give a green compound that slowly changes to a white copper(I)–arsine complex which can also be obtained by prolonged stirring of all the

Scheme 2. Reactions of o-$Me_2AsC_6H_4CO_2H$. *Previously, the compositions of **5** and **11** have been erroneously reported[9] to be $Cu(o\text{-}Me_2AsC_6H_4CO_2)\cdot 2H_2O$ and $Cu(o\text{-}(p\text{-tolyl})_2AsC_6H_4CO_2)_2$ respectively in the absence of C and H analyses.

said copper(II)–arsine complexes. Conversely the ligand with R = Me, under similar conditions, yields a mixture of copper(I)–arsine complex (**5**) and a copper(II)–arsine oxide complex (**6**), and complex **5** alone, under reflux. However, a copper(II)–arsine complex (**7a**) is formed on refluxing a suspension of anhydrous copper(II) acetate and **A** in EtOH alone. These observations (Scheme 2) suggest that the presence of water in the reaction medium initiates the reduction of copper(II) to copper(I) which is partial at room temperature and is complete at the solvent boiling point. The formation of copper(II)–arsine complex **7b** from the reaction of the ligand with copper(II)–acetate monohydrate in n-PrOH at room temperature and that of a mixture of **5** and **6** under reflux indicate that the water of crystallization is not effective in initiating the reduction of copper(II) to copper(I) at room temperature which takes place only partially at higher temperature.

The observations outlined in Scheme 1 suggest that the inductive effect of R = Ph is such that even in the presence of water in the reaction medium, chelation of the arsine to copper(II) precedes the reduction of copper(II) to copper(I) to yield a kinetically more stable copper(II)–arsine complex (**3**) that changes to a thermodynamically more stable copper(I)–arsine complex (**4**) on prolonged stirring. On the other hand, the electron releasing property of R = Me (Scheme 2) facilitates the reduction of copper(II) to copper(I), which takes precedence over the chelation of arsine to copper(II), in the presence of water in the reaction medium, to afford a copper(I)–arsine complex (**5**) and/or copper(II)–arsine oxide complex (**6**). However, in the absence of water it is the chelation of the arsine to copper(II) that takes the lead to yield a copper(II)–arsine complex (**7a**).

Consideration of the inductive effect alone predicts the formation of copper(II)–arsine complexes with the chelating agents for R = Ph and p-tolyl and those of copper(I)–arsine and/or copper(II)–arsine oxide complexes with the remaining two. The formation of both the types of complexes with all the ligands except the one with **R** = p-tolyl (Schemes 1–4) by changing experimental condition leads to the conclusion that the suitable reaction conditions rather than the favourable inductive effect of group R play a crucial role in determining the mode of the reaction.

SYNTHESIS OF VANADIUM SPINELS BY HYDROGEN-REDUCTION OF OXIDE PRECURSORS

A. MANTHIRAM
Department of Chemistry, Madurai Kamaraj University, P.G. Extension Centre,
St. John's College Campus, Palayamkottai 627 002, India

(*Received* 29 *August* 1984; *accepted* 6 *October* 1984)

Abstract—Two series of vanadium spinels, viz. AV_2O_4 and $A_{1.5}V_{1.5}O_4$ (A = Mg, Mn and Zn) have been prepared at significantly lower temperatures (700–850 K) by hydrogen-reduction of the corresponding oxide precursors, AV_2O_6 and $A_2V_2O_7$ respectively. The cation distribution in these phases have been determined by X-ray powder diffraction intensity analysis. The former vanadium(III) spinels have a cation distribution of $(A^{2+})_t[V_2^{3+}]_oO_4$ while the latter mixed-valence vanadium spinels have a distribution of $(A^{2+})_t[A^{2+}_{0.5}V^{3+}_{1.0}V^{4+}_{0.5}]_oO_4$.

Spinel oxides of vanadium constitute an interesting class of compounds as they exhibit a wide variety of electronic properties[1–3] depending upon the cation–cation distances; when the V–V distance is less than the critical distance of 2.97 Å a collective-electron behaviour is observed and when it is greater than the critical distance a localised-electron behaviour is encountered.

Vanadium spinels such as AV_2O_4 and $A_{1.5}V_{1.5}O_4$ (A = Mg, Mn and Zn) have generally been prepared by high temperature (~ 1450 K) reaction between the component oxides in an inert atmosphere or in evacuated sealed silica tubes.[1,4–6] The synthesis of pure vanadium spinels by this method is especially difficult as the starting component oxides are refractory and relatively unstable with respect to oxidation by air; also this traditional ceramic method requires prolonged and repeated high temperature heating with frequent regrindings. To avoid these harsh reaction conditions, it is necessary to look for alternative simple preparative methods.

Recently there has been considerable interest in the low-temperature preparation of complex metal oxides employing solid state precursors[7,8] in view of obtaining higher-surface-area materials. It is worthwhile to synthesise vanadium spinels by hydrogen-reduction of oxide precursors and thereby avoiding the severe reaction conditions involved in the conventional ceramic method. In the present investigation, attempts have been made to synthesize two series of vanadium spinels, viz. AV_2O_4 and $A_{1.5}V_{1.5}O_4$ (A = Mg, Mn and Zn) by hydrogen-reduction of the precursors AV_2O_6 and $A_2V_2O_7$ respectively with an aim to obtain these spinels at low temperature and in pure condition. This method was successful in giving single-phase materials and the results are reported in this paper.

EXPERIMENTAL

AV_2O_6 and $A_2V_2O_7$ for A = Mg, Mn and Zn were obtained by reaction between required quantities of AO (A = Mg and Zn) or $AC_2O_4 \cdot 2H_2O$ (A = Mn) and V_2O_5 first at 750 K and later at 900 K for about 48 h with one grinding in between. The formation of these oxides was confirmed by X-ray powder diffraction. AV_2O_6 oxides so obtained were reduced in a stream of oxygen-free, dry hydrogen at about 850 K for 20 h to give AV_2O_4 and $A_2V_2O_7$ oxides were reduced at about 700 K for 20 h to give $A_{1.5}V_{1.5}O_4$. The reduction reaction was monitored by determining the weight loss. The reduction products were analysed for total and lower-valent vanadium by a potentiometric method using Ce(IV) as oxidant.[9] The composition of the reduction product as well as the oxidation state of vanadium in the reduction product was fixed from the weight loss and chemical analysis data. Crystal-chemical characterisation of the reduction products was carried out by X-ray powder diffraction using a Philips X-ray diffractometer (PW 1050/70) employing Cu-K_α or Fe-K_α radiation.

RESULTS AND DISCUSSION

Weight loss and chemical analysis results (Table 1) show that AV_2O_6 (A = Mg, Mn and Zn) oxides can be reduced to give stable vanadium(III) oxides of

Table 1. Weight loss and chemical analysis data for the reduction products of AV_2O_6

A	% weight loss: Expected for reaction (1)	% weight loss: Observed	Reducing power of V* (equivalents/mole)
Mg	14.40	14.3	1.99
Mn	12.66	12.7	2.0
Zn	12.16	12.1	1.98

* Expected value for AV_2O_4 is 2.0.

composition AV_2O_4 at 850 K:

$$A^{2+}V_2^{5+}O_6 + 2H_2 \rightarrow A^{2+}V_2^{3+}O_4 + 2H_2O. \quad (1)$$

Hydrogen-reduction of $A_2V_2O_7$ (A = Mg, Mn and Zn) may be expected to give ilmenite type AVO_3 oxides similar to the hydrogen-reduction of $A_2V_2O_7$ (A = Sr and Ba) yielding AVO_3 perovskites:[10]

$$A_2^{2+}V_2^{5+}O_7 + H_2 \rightarrow 2A^{2+}V^{4+}O_3 + H_2O. \quad (2)$$

However, quite surprisingly, the hydrogen-reduction of $A_2V_2O_7$ (A = Mg, Mn and Zn) gives mixed-valence compounds of composition

$$A_{1.5}^{2+}V_{1.0}^{3+}V_{0.5}^{4+}O_4$$

as indicated by the weight loss and chemical analysis data (Table 2):

$$3A_2^{2+}V_2^{5+}O_7 + 5H_2 \rightarrow 4A_{1.5}^{2+}V_{1.0}^{3+}V_{0.5}^{4+}O_4 + 5H_2O. \quad (3)$$

Prolonged hydrogen-reduction of $A_2V_2O_7$ at 700 K does not result in any further weight loss indicating that complete reduction to V^{3+} state is not possible and $A_2V_2O_7$ can be reduced to yield stable mixed-valence compounds of formula $A_{1.5}^{2+}V_{1.0}^{3+}V_{0.5}^{4+}O_4$. These results are in agreement with that found by Palanisamy *et al.*[11] with $Zn_2V_2O_7$.

X-ray powder diffraction data (Table 3) of the reduction products of AV_2O_6 and $A_2V_2O_7$ are characteristic of a spinel structure. There were no reflections corresponding to the precursors or the component oxides AO, V_2O_3 or VO_2 revealing that the hydrogen-reduction of AV_2O_6 and $A_2V_2O_7$ yields monophasic spinel type AV_2O_4 and $A_{1.5}V_{1.5}O_4$ respectively. The diffraction patterns could be indexed on the basis of a cubic spinel type unit cell. The lattice parameters given in Table 4 agree closely with those reported in the literature.[2] In the case of A = Mn and Zn, there is an increase in lattice parameter from AV_2O_4 to $A_{1.5}V_{1.5}O_4$ but no such increase is observed with A = Mg. This can be explained on the basis of effective ionic radii[12] of A^{2+} and vanadium ions. As we go from $A^{2+}V_2^{3+}O_4$ to $A_{1.5}^{2+}V_{1.0}^{3+}V_{0.5}^{4+}O_4$, 50% of V^{3+} (r = 0.64 Å) ions are replaced by equal amounts of A^{2+} ($r_{Mg^{2+}}$ = 0.72 Å, $r_{Mn^{2+}}$ = 0.83 Å, $r_{Zn^{2+}}$ = 0.74 Å) and V^{4+} (r = 0.58 Å) ions. The average radii of Mn^{2+} and V^{4+} or Zn^{2+} and V^{4+} are slightly higher than the radius of V^{3+}, while the average radius of Mg^{2+} and V^{4+} is almost identical to that of V^{3+}. Hence in the former cases, a definite increase in lattice parameter is found from AV_2O_4 to $A_{1.5}V_{1.5}O_4$ while in the latter case no detectable increase is observed.

Cation distribution in spinel oxides is sensitive to the temperature at which the phases are prepared. As the phases in the present study have been prepared at fairly low temperatures, it is of interest to investigate the cation distributions in these phases. Cation distributions in spinels can be fixed by comparing the calculated and observed X-ray diffraction intensity ratios of certain pairs of (*hkl*) reflections[13,14] such as I_{400}/I_{220}, I_{220}/I_{311} and I_{220}/I_{440}. The calculated intensity ratios for the possible cation distributions are given in Table 4 along with the observed ratios for all the six compounds. The results indicate a cation distribution of $(A_{1.0}^{2+})_t[V_2^{3+}]_oO_4$ for AV_2O_4 and $(A_{1.0}^{2+})_t[A_{0.5}^{2+}V_{1.0}^{3+}V_{0.5}^{4+}]_oO_4$ for $A_{1.5}V_{1.5}O_4$ oxides (where the subscripts t and o refer to tetra-

† Calculated with $a_o = 8.560$ Å.

hedral and octahedral sites respectively). The distributions are the same as that observed for the phases prepared at high temperatures.[2] These cation distributions are compatible with that expected on the basis of crystal field stabilisation energies (CFSE); $V^{3+}(d^2)$ and $V^{4+}(d^1)$ ions having definite CFSE values in octahedral weak fields prefer octahedral sites while Mg^{2+} (d^0), Mn^{2+} (d^5) and Zn^{2+} (d^{10}) having no CFSE either in tetrahedral or in octahedral weak fields occupy tetrahedral (in the case of AV_2O_4) or both tetrahedral and octahedral (in the case of $A_{1.5}V_{1.5}O_4$) sites.

Considering the hydrogen-reduction reactions, it is found that in the case of AV_2O_6 oxides, all the V^{5+} ions are completely reduced to V^{3+} ions while in the case of $A_2V_2O_7$ oxides, part of the V^{5+} ions are reduced to V^{4+} and the remaining to V^{3+}. This difference in behaviour appears to be controlled by the structural stability of the oxide formed. Spinel structure is one of the versatile structures adopted by

several ternary oxides.[15] The preponderant stability associated with the spinel lattice favours the formation of a spinel oxide in both the cases thus causing the reduction to proceed completely to the 3+ state in the case of AV_2O_6 and to a mixed valence state of average oxidation state 3.33+ in the case of $A_2V_2O_7$. The formation of a mixed-valence spinel oxide, $(A^{2+}_{1.0})_t[A^{2+}_{0.5}V^{3+}_{1.0}V^{4+}_{0.5}]_oO_4$ from $A_2V_2O_7$ rather than an ilmenite-type vanadium(IV) phase, $A^{2+}V^{4+}O_3$ or a new vanadium(III) phase of composition $A^{2+}V^{3+}O_{2.5}$ seems to be controlled by the basicity of the A cation in addition to the above stability considerations. A previous study[10] has indicated that the stabilisation of V^{4+} in hydrogen-reduction reactions can be achieved only in the presence of strongly basic cations like Sr^{2+} and Ba^{2+} (hydrogen-reduction of $Sr^{2+}_2V^{5+}_2O_7$ gives $Sr^{2+}V^{4+}O_3$ perovskite) and even the slightly less basic Ln^{3+} (Ln = lanthanide) cations cause the reduction to proceed to the 3+ state (hydrogen-reduction of $Ln^{3+}V^{5+}O_4$ gives $Ln^{3+}V^{3+}O_3$ perovskites and not $Ln^{3+}_2V^{4+}_2O_7$ pyrochlores). In the present investigation, the comparatively less basic nature of the A (A = Mg, Mn and Zn) cations together with the structural stability of the product oxide formed favour the formation of a mixed-valence spinel from $A_2V_2O_7$.

The present hydrogen-reduction study suggests that complex oxides of lower valence vanadium can conveniently be obtained in pure condition at significantly lower temperatures and shorter times by the hydrogen-reduction of suitable oxide precursors. This kind of low-temperature preparation from solid state precursors would be particularly useful to obtain higher-surface-area materials required in catalytic applications.

Acknowledgements—I am grateful to Professor C. N. R. Rao, FRS and to Dr J. Gopalakrishnan, Indian Institute of Science, Bangalore for providing part of the experimental facilities and for their keen interest and encouragement.

(*Received* 10 *September* 1984; *accepted* 6 *October* 1984)

Abstract—Alkyl- and alkoxy-substituted quinoline-2-carboxylic acids were synthesized and tested for metal extraction. Zn^{2+} and Cu^{2+} were extracted from aqueous sulphate solutions by reagents containing 8-alkoxy substituents at lower pH values than were Fe^{2+} or Fe^{3+}. Reagents without this substituent were unselective in this respect. A possible explanation for the selectivity may be that the 8-substituent influences the coordination geometry of the metal chelates in favour of tetrahedral complexes.

The development of chelating reagents for metal extraction has attracted much interest in recent years. Various ligands have been designed for selective recovery of metal ions using solvent extraction,[1,2] liquid membrane extraction and adsorption on chelating resins.

Quinoline-2-carboxylic acid (quinaldic acid) is known to form stable complexes with several metal ions. This reagent can be used for the gravimetric determination of, e.g. Cu^{2+}, Zn^{2+}, Cd^{2+} and UO_2^{2+} and colorimetric analysis of Fe^{2+}.[3] Quinaldic acid reagents have also been developed for solvent extraction.[4,5]

We have studied substituted quinaldic acids with the objective of preparing reagents that can extract Zn^{2+} and Cu^{2+} in the presence of Fe^{2+} and Fe^{3+}. This paper reports the syntheses and extractant properties of some new substituted quinaldic acids.

RESULTS

Alkyl- and alkoxy-substituted quinoline compounds were prepared by various routes using known reactions (Scheme 1). (1) O-Alkylation of hydroxyquinoline-2-carbonitriles afforded the 8-substituted reagents **1–6** and the 6- and 7-alkoxyquinaldic acids **14** and **15** (Table 1). (2) The

Scheme 1.

ethyl 1,4-dihydro-4-oxoquinaldates **7a** and **8a** were alkylated to give the 4-alkoxy-substituted reagents **7–9**. (3) Radical alkylation[6] yielded the 4-(3-heptyl)quinaldic acid extractants **10** and **11**. (4) Reagents **12** and **13** were prepared by Claisen rearrangement[7] of 8-dodecenyloxyquinoline-2-carbonitrile.

The reagents **1–15** (Scheme 1) were assessed for their ability to extract Cu^{2+}, Zn^{2+}, Fe^{2+}, Fe^{3+}, Ni^{2+}, Co^{2+}, Cd^{2+} and K^+ from aqueous sulphate solutions at pH 2 and 4 into a chloroform phase. The metal concentrations in the water phase were measured by atomic absorption spectrophotometry and are reported here as $pH_{1/2}$ values (Table 1). These values were calculated from mixed metal extraction tests and in three cases, **1–3**, from single metal extraction experiments. The results of systems where the formation of a third phase was noticed are not included in Table 1. Only small amounts of Ni^{2+}, Co^{2+} and Cd^{2+} were extracted at the low pH used.

The 6-, 7- and 8-alkoxyquinaldic acids **14**, **15** and **1** were also tested for Cu, Zn and Fe extraction using 20 mM chloroform solutions of the reagents and 10 mM metal sulphate solutions. The results for reagent **14** were (% extracted, pH_{eq}): Cu^{2+} (86%, 1.7), Fe^{2+} (5%, 2.0), Zn^{2+} (24%, 2.5) (precipitates were formed in the first and last case). Reagent **15** extracted Cu^{2+} (85%, 1.9), Fe^{3+} (36%, 1.7) and Zn^{2+} (22%, 2.6) and reagent **1** Cu^{2+} (72%, 1.7), Fe^{2+} (0%, 2.0) and Zn^{2+} (34%, 2.3).

Metal complexes of some substituted quinaldic acids were studied by ^1H NMR and electronic spectroscopy. Chloroform solutions of isolated chelates were examined by electronic spectroscopy

† The complex was not isolated but obtained by extraction.

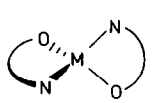
in the range 5000–25,000 cm^{-1} (Table 2). Cu^{2+} and Fe^{2+} complexes formed by extraction with reagent **1** were found to have the same absorption bands as the isolated chelates.

The number of ligands coordinating Zn^{2+} in its complex with **1** was determined by ^1H NMR. The H-3 and H-4 peaks of the free ligands and of the zinc complex had different chemical shifts, i.e. δ, 8.28 and 8.35 ppm in the free ligand and 8.63 and 8.65 ppm in the complex. Zinc acetate dissolved in CD_3OD was added in portions to a $CDCl_3$ solution of **1** and the separate peaks from H-3 and H-4 in the free ligand and in the zinc complex were integrated. The results show that a 2:1 complex was formed. In the ^1H NMR spectrum of the Co(II) complex of **1** the geminal methyl groups appeared at −2.09 and −2.25 ppm. The OCH_2-protons in reagent **1** appeared as a doublet (J = 5.8 Hz) at 4.80 ppm. However, these peaks in the zinc complex were shifted upfield and were separated into two doublets of doublets at 4.14 ppm (J = 6.1 and 13.4 Hz) and 4.30 ppm (J = 5.1 and 13.4 Hz).

DISCUSSION

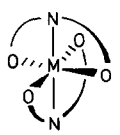
For assessing the Zn/Fe and Cu/Fe selectivity the reagents may be divided into main groups: I, those having alkoxy groups in the 8-position and II, 8-unsubstituted compounds. Reagents which extract Zn^{2+} and Cu^{2+} selectively in the presence of Fe^{2+} and Fe^{3+} belong to group I, whereas group II reagents lack this selectivity. The selectivity of group I reagents may be due to interligand repulsion of the 8-alkoxy substitutents. Steric crowding in the metal chelates is expected to favour the formation of tetrahedral coordination compounds over *trans*-planar complexes and octahedral tris-complexes. The lower extraction of iron with group I reagents may be ascribed to steric factors since Fe(II) prefers octahedral coordination whereas zinc(II) has little sterochemical preference and may readily form 4-coordinate tetrahedral complexes.

The extractant properties of group I reagents also depends on the structure of the alkoxy substituent. The decreasing order of extraction ability of, e.g. zinc: **1** > **5** > **6** may be a result of the higher stability of the chelates where the alkyl branch points are far away from the coordination site. These extractants have branch points at C(5), C(3) and C(2) respectively. The length of the alkyl chain is also of importance for the extractants performance. On extraction with **4** which has a linear C_6 alkoxy substituent a third phase was formed.



The introduction of an alkoxy group in the 4-position in the quinoline ring improved the extraction ability, as shown by comparison of **7** with **2**. This substitution may have changed the electron donor and π-acceptor properties as well as the pK_a values of the quinaldic acid. The presence of a branched alkyl group in the 7-position resulted in poor extraction with the type I reagent **12**. A possible explanation may be the steric interference of the 7- and 8-substituents in the metal chelates. The 8-methyl substituted quinaldic acid **11** showed poor extractant ability. Hence the low stability of its metal complexes may be attributable to metal–CH_3

interactions. The red colour of chloroform solutions of Fe(II) chelates of the group I reagents **1** and **2** is stable for about one day in the presence of air.[8] However, the red Fe(II) complexes of reagents **9** and **10** turn yellow rapidly (15–30 min) in chloroform solution in the presence of air due to oxidation to Fe(III). Also, in an extraction test with reagent **9** (20 mM in chloroform) and $FeSO_4$ (2 mM, initial pH 2.1), the extracted iron was found to be (partly) oxidized to Fe(III).



Electronic absorption studies of Cu(II) chelates with N_2O_2 donor atom sets have shown that a distortion from planar towards pseudo-tetrahedral geometry is accompanied by red shifts of the main *d–d* bands.[9]

The Cu(II) complexes of **1** and **2** have absorption maxima at higher wavelengths than Cu(II) complexes of the group II reagents **9** and **10** (Table 2) These data are in agreement with pseudo-tetrahedral structures of the Cu(II) complexes with **1** and **2** and with more flattened structures of the complexes with **9** and **10**.

The stereochemistry of metal chelates has previously been studied by ^1H NMR spectroscopy using methylene groups and geminal dimethyl groups as diastereotopic probes.[9] The separate proton resonances from the geminal methyl groups in the paramagnetic Co(II) chelate of **1** show that a *trans*-planar structure does not form. The two quinoline rings are twisted out of plane thereby decreasing the steric interference of the opposite alkoxy and carboxyl groups. A tetrahedral structure **A** and a bisected octahedral structure **B** offer the least

A

B

steric hindrance. In the diamagnetic Zn(II) chelate of **1** the OCH_2-protons had different chemical shifts, most likely due to the magnetic anisotropy of the aromatic rings in a tetrahedral arrangement. The large upfield shifts (0.9 ppm) observed for the olefinic protons in this complex are also in agreement with a perpendicular orientation of the quinoline rings.

EXPERIMENTAL

Instrumentation

All melting points are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 257 spectrophotometer, and mass spectra were run on an LKB 9000 mass spectrometer. A Varian EM-360 instrument or a Bruker WP 200 spectrometer were used for ^1H NMR spectra at 60 and 200 MHz, respectively. Visible and near IR spectra were recorded on Varian Cary 219 (400–900 nm) and Beckman DK-2 spectrophotometers. A Perkin–Elmer 603 atomic absorption spectrophotometer was used for metal determinations.

Elemental analyses were performed by Mikroanalyslaboratoriet, Centrala Analyslaboratoriet or Mikro Kemi AB in Uppsala, Sweden and were within 0.4% unless otherwise noted.

Metal extraction tests

Aqueous solutions of a mixture of equal parts of metal sulfates: Cu^{2+}, Zn^{2+}, Ni^{2+} and Co^{2+} or Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+} and Cd^{2+} or Cu^{2+}, Zn^{2+}, Fe^{3+}, Cd^{2+} and K^+ were prepared by dissolving the metal salts in dilute sulfuric acid. The metal concentrations were about 2 mM and the pH was adjusted to a value of *ca* 2 or 4. A 20 mM chloroform solution of the reagent was prepared and equal volumes of the two phases were agitated until equilibrium was reached. The two phases were then separated by centrifugation and the amount of metal present in the aqueous phase was determined by atomic absorption spectrophotometry.

Preparation of substituted quinaldic acids

8-(5,5,7,7-Tetramethyl-2-octenyloxy)quinoline-2-carbonitrile (**1a**). A mixture of 8-hydroxyquinoline-2-carbonitrile[10] (34 g, 0.20 mol), K_2CO_3 (28 g, 0.20 mol) and DMF (150 cm^3) was stirred at 60°C for 20 min, then 1-chloro-5,5,7,7-tetramethyl-2-octene (40 g, 0.20 mol) was added. After 17 h at 60°C the mixture was poured into water (0.8 cm^3) and extracted with ether. The organic phase was washed with 2% *aq.* KOH and water. The solvent was evaporated to yield a brown oil (60.0 g). Recrystallization from petroleum ether yielded white crystals, m.p. 63–6°C.

IR (KBr): 2950, 2870 (C–H), 2240 (C≡N), 1550, 1500 (aromat.), 1260 (C–O), 970 cm^{-1} (CH=CH-*trans*). ^1H NMR (CCl_4): δ 0.93 (s, CH_3), 0.97 (s, CH_3), 1.2 (s, CH_2), 2.0 (d, CH_2), 4.7 (d, CH_2), 5.4–6.2 (m, CH=CH), 7.1 (dd, J = 6.8 and 2.2 Hz, H-7), 7.35 (dd, J = 8 and 2.2 Hz, H-5), 7.5 (dd, J = 8 Hz, H-6), 7.6 (d, J = 8.2 Hz, H-3) and 8.2 (d, J = 8.2 Hz, H-4). MS *m/z* (rel. int.): 336 (3, M^+), 223(9), 209(6), 171(16), 170(100), 142(6), 110(9), 95(11), 57(31), 41(7).

8-(5,5,7,7-Tetramethyl-2-octenyloxy)quinoline-2-carboxylic acid (**1**). The crude nitrile **1a** (60 g) was hydrolyzed by heating under reflux (11 h) with KOH (113 g) in EtOH (805 cm^3) and water (140 cm^3). *Ca.* 200 cm^3 of solvent was evaporated and the solution

was washed with petroleum ether. The ethanol solution was acidified with 2 M HCl (700 cm^3) and extracted with ether. The organic phase was washed with water and dried. The solvent was removed and cyclohexane was added yielding the product as white crystals (37.8 g, 53% yield), m.p. 78–82°C. IR (CCl_4): 3300 (O–H), 1780 (C=O), 970 cm^{-1} (CH=CH-*trans*). ^1H NMR ($CDCl_3$): δ 0.98 (15 H, s, CH_3), 1.26 (2 H, s, CH_2), 2.10 (2H, d, J = 7 Hz, CH_2), 4.80 (2 H, d, J = 5.8 Hz, CH_2O), 5.81 (1 H, dt, J = 16 Hz and 5.7 Hz, CH=C<u>H</u>CH_2O), 6.00 (1 H, dt, J = 16 Hz and 7.1 Hz, C<u>H</u>=CHCH_2O), 7.18 (1 H, dd, J = 7.8 Hz and 1.2 Hz, H-7), 7.3 (1 H, bs, OH), 7.49 (1H, dd, J = 8.3 Hz and 1.2 Hz, H-5), 7.60 (1 H, dd, H-6), 8.28 (1 H, d, J = 8.5 Hz), 8.35 (1 H, d, J = 8.5 Hz).

8-(*Dodecyloxy*)*quinoline*-2-*carboxylic acid* (**2**), 8-(*tetradecyloxy*)*quinoline*-2-*carboxylic acid* (**3**) *and* 8-(*hexyloxy*)*quinoline* - 2 - *carboxylic acid* (**4**). These reagents were prepared in analogy with **1** by alkylation with 1-bromoalkanes. The nitriles and carboxylic acids precipitated out on addition of water and 1 M H_2SO_4 respectively to the reaction mixtures.

2: M.p. 95–96°C (EtOH–H_2O).

3: 68% yield, m.p. 98–100°C (EtOH–H_2O).

4: 72% yield, m.p. 73–76°C (MeOH).

8-(3,7-*Dimethyloctyloxy*)*quinoline*-2-*carboxylic acid* (**5**) and 8 - (2 - *ethylhexyloxy*)*quinoline* - 2 - *carboxylic acid* (**6**). These reagents were prepared in analogy with **1** by alkylation with toluene-4-sulphonate esters. The nitriles were obtained by extraction with CH_2Cl_2 and purified by column chromatography (SiO_2/CH_2Cl_2).

6-*Hydroxyquinoline*-2-*carbonitrile* (**14a**).[4] 6-Hydroxyquinoline (2.64 g, 18 mmol) was treated with 90% 3-chloroperbenzoic acid (4.0 g) in chloroform (200 cm^3) over 2 h at room temperature. The solvent was evaporated and 3-chlorobenzoic acid was removed by sublimation at 80°C *in vacuo*. To the residue (mostly *N*-oxide) was added dimethyl sulfate (2.30 g, 18 mmol) and a few cm^3 of acetonitrile, and the mixture heated at 70°C for about 4 h. Evaporation of the solvent *in vacuo* gave 5.25 g of methylated *N*-oxide. This product was dissolved in water (13 cm^3) and was added over 45 min to an ice-cooled solution of sodium cyanide (2.6 g) in water (13 cm^3) under a nitrogen atmosphere. Acetic acid–water 1 : 1 (6 cm^3) was then added after an additional 4 h in the cold. The product was filtered off and washed with water to give **14a** (1.70 g, 56% yield), m.p. 217–219°C (toluene), lit.[11] 218–219°C.

6-*Dodecyloxyquinoline*-2-*carbonitrile* (**14b**). This compound was prepared by alkylation of 6-hydroxyquinoline-2-carbonitrile as described for **3**. M.p. 86–87.5°C (MeOH).

6 - *Dodecyloxyquinoline* - 2 - *carboxylic acid* (**14**). The above nitrile (**14b**) was hydrolyzed with KOH in 80% EtOH to give the carboxylic acid (79% yield based on **14a**), m.p. 148–150°C (toluene). IR ($CHCl_3$): 2920 (C–H), 1765, 1755 cm^{-1} (C=O). ^1H NMR ($CDCl_3$): δ 0.88 (3H, m, CH_3), 1–1.7 (18 H, m, alkyl). 1.88 (2 H, m, CH_2), 4.12 (2 H, t, J = 6.3 Hz, CH_2O), 7.14 (1 H, d, J = 2.6 Hz, H-5), 7.47 (1 H, dd, J = 2.6 and 9.2 Hz, H-7), 8.04 (1 H, d, J = 9 Hz, H-8), 8.21 (1 H, d, J = 8.5 Hz, H-3 or H-4), 8.24 (1 H, d, J = 8.5 Hz, H-3 or H-4), 10.5 (1 H, s, OH).

7 - *Hydroxyquinoline* - 2 - *carbonitrile* (**15a**). Compound **15a** was prepared analogously to **14a** starting from 7-hydroxyquinoline[12] in a yield of 54%, m.p. 248–250°C. IR (KBr): 3100 (O–H), 2220 (C≡N), 1240, 1230 cm^{-1} (C–O). ^1H NMR (acetone-d_6): δ 7.38–7.44 (2 H, m, H-6, H-8), 7.70 (1 H, d, J = 8.3 Hz, H-3), 7.98 (1 H, d, J = 9.5 Hz, H-5) and 8.47 (1 H, d, J = 8.1 Hz, H-4).

7-(5,5,7,7-*Tetramethyl*-2-*octenyloxy*)*quinoline*-2 - *carbonitrile* (**15b**). This compound was prepared from 7-hydroxyquinoline-2-carbonitrile in analogy with the 8-hydroxy compound. M.p. 109–111°C (cyclohexane). IR (KBr): 2950 (C–H), 2240 (C≡N), 1620, 1500 (aromatic), 1220 (C–O), 970 cm^{-1} (CH=CH-*trans*). The ^1H NMR spectrum is consistent with the suggested structure.

7-(5,5,7,7-*Tetramethyl*-2-*octenyloxy*)*quinoline*-2 - *carboxylic acid* (**15**). The acid was obtained by hydrolysis of the nitrile as described for the 8-substituted compound. Yield ≈ 51% based on **15a**, m.p. 96–98.5°C (petroleum ether b.p. 80–110°C). IR (KBr): 3100–2600 (O–H), 1700 (C=O), 970 cm^{-1} (CH=CH-*trans*). ^1H NMR ($CDCl_3$): 0.96 (9 H, s, *t*-Bu), 0.98 (6 H, s, CMe_2), 1.25 (2 H, s, CH_2), 2.08 (2 H, d, J = 7.2 Hz, CH_2), 4.73 (2 H, d, J = 5.9 Hz, CH_2O), 5.75 (1 H, dt, J = 6 and 15.3 Hz, C=C<u>H</u>CH_2O), 5.99 (1 H, dt, J = 7.5 and 15.1 Hz, C=C<u>H</u>CH_2C), 7.38 (1 H, dd, J = 2.2 and 9.1 Hz, H-6), 7.57 (1 H, bs, H-8), 7.83 (1 H, d, J = 9.1 Hz, H-5), 8.17 (1 H, d, J = 8.1 Hz, H-3), 8.34 (1 H, d, J = 8 Hz, H-4 and 9.22 (1 H, bs, OH).

Ethyl 8 - *dodecyloxy* - 1,4 - *dihydro* - 4 - *oxoquinoline* - 2 - *carboxylate* (**7a**). 2-Dodecyloxyaniline hydrochloride[13] (2.01 g, 6.4 mmol) was stirred at room temperature with diethyl oxalacetate sodium salt (1.37 g, 6.4 mmol), anhydrous Na_2SO_4 (2 g) and absolute ethanol (10 cm^3) for two days. Workup by ether extraction gave 2.71 g (95% yield) of the condensation product. This product was added to boiling diphenyl ether over 6–7 min and the resultant solution heated under reflux (15–30 min). Most of the solvent was distilled off at reduced pressure and column chromatography on silica gel (CH_2Cl_2 and CH_2Cl_2–EtOH 20 : 1) yielded a partially crystalline product (1.79 g, 70% yield). ^1H NMR ($CDCl_3$): δ 0.6–2.4 (26 H, m, alkyl), 4.15

(2 H, t, $J = 6$ Hz, $C\underline{H}_2OAr$), 4.5 (2 H, q, $J = 7$ Hz, CH_2O), 6.95 (1 H, d, $J = 3$ Hz, H-3), 7–7.4 (2 H, m, H-6, H-7), 7.9 (1 H, dd, $J = 8$ Hz and 1 Hz, H-5), 9.4 (1 H, bs, NH).

Ethyl 1,8 - *bis(dodecyloxy)quinoline* - 2 - *carboxylate* (**7b**). The above quinolone (**7a**) (1.64 g, 4.1 mmol) and K_2CO_3 (0.6 g) were stirred in DMF (6 cm^3) at 75–80°C, and 1-bromododecane (1.1 g, 4.4 mmol) was added. The reaction mixture was worked up by ether extraction after $2\frac{1}{2}$ h to give 1.7 g (73% yield), m.p. 62–63.5° (petroleum ether). IR (KBr): 2920, 2850 (C–H), 1740, 1720 (C=O), 1595 cm^{-1} (aromat.). ^1H NMR (CCl_4): δ 0.6–2.3 (48 H, m, alkyl), 4–4.6 (6 H, m, CH_2O), 6.9 (1 H, dd, $J = 8$ and 1 Hz, H-7), 7.3 (1 H, dd, $J = 8$ Hz and 8 Hz, H-6), 7.35 (1 H, s, H-3), 7.6 (1 H, dd, $J = 8$ Hz and 1 Hz, H-5).

1,8 - *Bis(dodecyloxy)quinoline* - 2 - *carboxylic acid* (**7**). This compound was obtained by hydrolysis of the ethyl ester with 5% KOH in 80% EtOH at reflux (3 h). Yield: 67%, m.p. 77–78.5°C. IR (CCl_4): 2920, 2850 (C–H), 1770 cm^{-1} (C=O). ^1H NMR (CCl_4); δ 0.5–2.3 (46 H, m, alkyl), 3.9–4.3 (4 H, m, CH_2O), 6.7–7.7. (4 H, m, aromat.), 10.0 (1 H, s, OH).

4 - (2 - *Ethylhexyloxy)quinoline* - 2 - *carboxylic acid* (**8**) *and* 4 - (5,5,7,7 - *tetramethyl* - 2 - *octenyloxy)-quinoline* - 2 - *carboxylic acid* (**9**). These reagents were prepared by alkylation of ethyl 1,4-dihydro-4-oxoquinaldate[14] with 2-ethylhexyl toluene-4-sulphonate and dodecenyl chloride (K_2CO_3/DMF, 40°C and 70°C respectively, 20 h). Alkaline hydrolysis of the esters afforded **8**: 53% yield, m.p. 106–107.5°C (MeOH). IR (KBr): 3360 (O–H), 1630 cm^{-1} (C=O). ^1H NMR ($CDCl_3$): δ 0.8–1.1 (6 H, CH_3), 1.1–1.8 (8 H, CH_2), 1.99 (1 H, m, $C\underline{H}(CH_2)_3$), 4.37 (1 H, d, $J = 5.5$ Hz, CH_2O), 7.73 (1 H, dd, $J = 8$ Hz, H-6 or H-7), 7.91 (1 H, s, H-3), 7.99 (1 H, ddd, $J = 1.5$, 8.8 Hz, H-6 or H-7), 8.31 (1 H, d, $J = 8$ Hz, H-5 or H-8), 8.86 (1 H, d, $J = 8$ Hz) and 9.37 (1 H, s, OH).

9: 76% yield, m.p. 85–87°C (EtOH–H_2O). IR ($CHCl_3$): 1770 (C=O), 970 cm^{-1} (CH=CH-*trans*). ^1H NMR ($CDCl_3$): δ 0.98 (s, CH_3), 1.00 (s, CH_3), 1.27 (s, CH_2), 2.11 (d, $J = 7.5$ Hz, CH_2), 4.95 (d, $J = 6$ Hz, CH_2O), 5.8 (m, CH=CH), 6.03 (m, CH=CH), 7.7 (dd, $J = 8$ Hz, H-6/7), 7.82 (s, H-3), 7.92 (dd, $J = 8$ Hz, H-6/7), 8.33 (d, $J = 8$ Hz, H-4/8), 8.56 (d, $J = 8.6$ Hz, H-4/8).

8 - *Methylquinoline* - 2 - *carbonitrile* (**11a**). 8-Methylquinoline-*N*-oxide[15] (1.78 g, 11 mmol) was heated with dimethyl sulphate (1.41 g, 11 mmol) for 3 h at 75°C. The product was dissolved in water (7 cm^3), the solution filtered and added dropwise to sodium cyanide (1.65 g, 34 mmol) in water (7 cm^3) at 0°C. After 2 h stirring at 0°C the product was filtered off and recrystallized from cyclohexane to give **11a** (0.90 g, 48% yield), m.p. 125–127°C. IR (KBr): 2940 (C–H), 2230 (C≡N), 1495, 1585 cm^{-1} (aromat.). MS *m/z* (% rel. int.): 168 (100, M^+), 169 (2.8), 167 (8.4), 166 (1.7), 141 (2.3), 140 (2.4), 114 (1.4), 70 (1.8), 63 (1.4), 39 (1.2). ^1H NMR ($CDCl_3$): δ 2.8 (3 H, m, CH_3), 7.8 (3 H, m, aromat-H), 7.79 (1 H, d, $J = 8.4$ Hz, H-3) and 8.35 (1 H, d, $J = 8.4$ Hz, H-4).

4 - (3 - *Heptyl)* - 8 - *methylquinoline* - 2 - *carbonitrile* (**11b**).[6] 8-Methylquinoline-2-carbonitrile (0.84 g, 5 mmol), 2-ethylhexanoic acid (3.60 g, 25 mmol), 1 M H_2SO_4 (5 cm^3), CH_3CN (5 cm^3) and $AgNO_3$ (0.17 g, 0.1 mmol) were heated to 70°C. To this mixture was added $(NH_4)_2S_2O_8$ (3.42 g, 15 mmol) in water (8 cm^3) over 0.5 h with stirring. Stirring was continued for 40 min, then the mixture was poured into ice-water and ammonia and extracted with ether. The organic phase was washed with 2 M NaOH and water. Chromatography on silica gel (60 g) with ethyl acetate–petroleum ether 1:10 as the eluant gave the product (0.59 g, 44% yield) together with unreacted starting material (0.11 g). The product was distilled at 175°C/23 Pa. IR (film): 2960, 2930 (C–H), 2230 (C≡N), 1585, 1505 cm^{-1} (aromat.). ^1H NMR (CCl_4) δ 0.5–2 (14 H, m, alkyl-H), 2.8 (3 H, s, C(8)–CH_3), 3.4 (1 H, m, Ar–CH) and 7.3–8.1 (4 H, m, aromat-H).

4 - (3 - *Heptyl)* - 8 - *methylquinoline* - 2 - *carboxylic acid* (**11**). The above nitrile was hydrolyzed with KOH in ethanol–glycol to give the acid (yield 82%) as a yellow oil. IR (CCl_4): 3300 (O–H), 2960, 2930 (C–H), 1770 (C=O) cm^{-1}. ^1H NMR (CCl_4): δ 0.6–2.2 (14 H, m, alkyl-H), 2.9 (3 H, s, C(8)–CH_3), 3.5 (1 H, m, ArCH), 7.4–8.2 (4 H, m, aromat-H) and 10.8 (1 H, s, CO_2H).

4 - (3 - *Heptyl)quinoline* - 2 - *carboxylic acid* (**10**). This compound was obtained from quinoline-2-carbonitrile and 2-ethylhexanoic acid, followed by hydrolysis of the nitrile group.[6] Yield: 57%, m.p. 102–103°C.

7 - (1 - *Ethenyl* - 3,3,5,5 - *tetramethylhexyl)* - 8 - *hydroxyquinoline* - 2 - *carbonitrile* (**12a**). Crude 8-dodecenyloxyquinoline-2-carbonitrile (**1a**) (29.5 g) in decalin (290 cm^3) was heated under reflux (5.5 h) then most of the decalin was distilled off under reduced pressure. The product was filtered off and recrystallized from petroleum ether (b.p. 40–60°C) yielding 19.2 g (57% yield based on 8-hydroxyquinoline-2-carbonitrile), m.p. 96–98°C. Additional recrystallization gave a product with m.p. 98–99°C. IR (KBr): 3360 (O–H), 2950 (C–H), 2240 (C≡N), 1505 (aromat.), 1250 (C–O aryl), 990, 910 cm^{-1} (vinyl). ^1H NMR ($CDCl_3$): δ 0.92 (3 H, s, CH_3), 0.94 (3 H, s, CH_3), 0.96 (9 H, s, *t*-Bu), 1.31 (1 H, d, $J = 14$ Hz, CH_2), 1.34 (1 H, d, $J = 14$ Hz, CH_2), 1.91 (2 H, d, $J = 6.1$ Hz, $C\underline{H}_2$–CH), 4.23 (1 H, m, $J = 6.1$, 7, 1.5 and 1.3 Hz, CH-aryl), 4.99 (1 H, m, $J = 9.9$, 1.6, 1.5 Hz, $=CH_2$), 5.02 (1 H, m, $J = 17.2$, 1.6, 1.3 Hz, $=CH_2$), 6.08 (1 H, m, $J = 17.2$, 9.9, 7 Hz, vinyl-H), 7.39 (1 H, d, $J = 8.5$ Hz, H-5), 7.59 (1 H, d, J

= 8.5 Hz, H-6), 7.67 (1 H, d, J = 8.5 Hz, H-3), 8.044, 8.047 (1 H, O–H) and 8.26 (1 H, d, J = 8.5 Hz, H-4). MS m/z (rel. int.) 336 (18, M^+), 279(7), 265(7), 224(19), 223(100), 210(27), 209(100), 195(15), 183(9), 57(25).

A small amount of the 5-alkenyl isomer, 5-(5,5,7,7-tetramethyl-2-octenyloxy)quinoline-2-carbonitrile (**12b**) was also isolated, m.p. 104–106°C. IR (KBr): 3370 (O–H), 2950 (C–H), 2240 (C≡N), 1630, 1560, 1505 (aromat.), 1240 ($C–O_{aryl}$), 965 cm^{-1} (–CH=CH-*trans*). ^1H NMR ($CDCl_3$): δ 0.905 (s, CH_3), 0.942 (s, CH_3), 1.187 (s, CH_2), 1.957 (m, CH_2), 3.710 (m, CH_2), 5.55 (m, CH=CH), 7.22 (d, J = 7.8 Hz, H-7), 7.47 (d, J = 7.8 Hz, H-6), 7.73 (d, J = 8.5 Hz, H-3), 7.84 (s, OH), 8.51 (d, J = 8.5 Hz, H-4). MS m/z (rel. int.) 336 (21, M^+), 225 (17), 224 (100), 223 (20), 209 (24), 207 (9), 183 (36), 113 (11), 57 (94), 41 (9).

7 - (1 - *Ethenyl* - 3,3,5,5 - *tetramethylhexyl*) - 8 - *octyloxyquinoline* - 2 - *carboxylic acid* (**13**). Alkylation of **12a** with 1-bromo-octane and subsequent hydrolysis of the nitrile group gave the above product in 87% yield.

7 - (1 - *Ethenyl* - 3,3,5,5 - *tetramethylhexyl*) - 8 - *hydroxyquinoline* - 2 - *carboxylic acid* (**12**). The corresponding nitrile (**12a**) (2.0 g, 6.0 mmol), was hydrolyzed in 10% KOH in EtOH at reflux during two days. The carboxylic acid (2.1 g) separated after addition of water and 2 M HCl. Found: C, 73.35; H, 8.17; N, 3.81. Calc. for $C_{22}H_{29}NO_3$: C, 74.33; H, 8.22; N, 3.94%. IR (CCl_4): 3380 (O–H), 1730 (C=O), 915 cm^{-1} (vinyl). ^1H NMR ($CDCl_3$): δ 0.9 (CH_3), 1.3 (2 H, s, CH_2), 1.9 (2 H, d, J = 6 Hz, CH_2), 4.3 (1 H, m, CH-aryl), 4.8–5.2 (2 H, m, $C=CH_2$), 6.1 (1 H, m, vinyl-H), 7.35 (1 H, d, J = 8 Hz, H-5 or H-6), 7.5 (1 H, d, J = 8 Hz, H-5 or H-6), 8.3 (2 H, s, H-2, H-3) and 10.1 (2 H, s, O–H, CO_2H).

Preparation of metal complexes

Metal complexes of the reagents **1** and **9** were prepared by adding aqueous solutions of Cu(II) or Co(II) acetate or $FeSO_4$ to hot ethanol solutions of the appropriate quinaldic acid, neutralized by NaOH. The molar ratio of metal: ligand was 1:2. The precipitates were filtered off, washed with water and dried *in vacuo*. The Fe(II) complexes were prepared under nitrogen atmosphere. The Zn(II) and Ni(II) complexes were obtained from the acetates using $MeOH/CHCl_3$ and CH_2Cl_2, respectively as solvents. These chelates were recrystallized from toluene and toluene–$CHCl_3$ respectively.

MÖSSBAUER SPECTRA AND ELECTRIC CONDUCTIVITIES OF BIDENTATE BASE BRIDGED IRON(II) PHTHALOCYANINE

HO-HSIANG WEI*
Department of Chemistry, Tamkang University, Tamsui, Taiwan

and

HUEY-LIH SHYU

(*Received* 13 *August* 1984; *accepted* 6 *October* 1984)

Abstract—Bidentate bridging base polymer complexes of iron(II) phthalocyanine FePcL, where L = pyrazine (pyz), 4,4′-bipyridine (bpy), *trans*-1,2-bis(4-pyridyl)ethylene (bpe), 1,2-bis(4-pyridyl)ethane (bpa) and 4,4′-trimethylene bipyridine (tmbpy), have been prepared, characterized and oxidized by iodine to give a range of iron(II) and iron(III) complexes $(FePcL)_n \cdot I_x$. The electrical conductivities and Mössbauer parameters both change with respect to the kinds of bidentate bridging bases. The conjugation of bridged ligand markedly effects the conductivity of the complexes.

Recently, several face-to-face linked metallophthalocyanines have been studied.[1–7] Hanack *et al.* reported that phthalocyaninato–iron(II) which polymerized via a bidentate bridging heterocyclic amine, has an electrical conductivity higher than that of the monomer species. However, the electronic properties of the iron atom in these complexes was not known.

In the course of our studies of the iron(II) polymer complexes which is relevant to this type of material,[6] we now report independently the preparation and characterization of several additional neutral and iodine-oxidized bidentate-base bridged iron(II) phthalocyanine complexes $(FePcL)_n$ (Fig. 1) together with the results of their Mössbauer spectra and electrical conductivities.

EXPERIMENTAL

Iron phthalocyanine (FePc) was prepared by the reaction of phthalonitrile and iron pentacarbonyl in a solution of 1-chloro-naphthalene at 258°C and recrystallized from chlorobenzene.[7] Bidentate bridged complexes of iron(II)phthalocyanine, $(FePcL)_n$

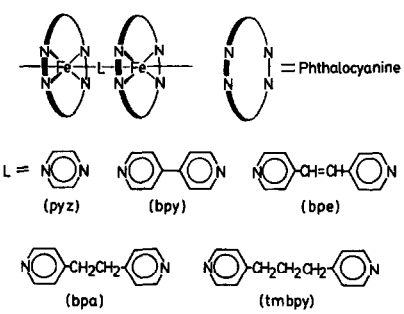

Fig. 1. Structural formula for $(FePcL)_n$.

(L = pyz, bpe, bpy, bpa and tmbpy) were prepared under nitrogen according to the following method.

Bidentate base ligand (10 mmol) was dissolved in chlorobenzene (30 cm^3) and iron phthalocyanine (10 mmol) in chlorobenzene was added dropwise with stirring at 110°C. The mixture was refluxed for 2 h and filtered. The solid residue was washed several times with methanol and dried under high vacuum.

Poly-salts of $(FePcL)_nI_x$ were prepared by oxidizing the neutral complexes with I_2 in chlorobenzene solution for 2 days to give a series of products with a range of stoichiometries.

Table 1. Electronic spectral data for $(FePcL)_n$ complexes at 298 K

Compound	λ_{max} (nm)							
$[FePc(pyz)]_n$	1280,	1080,	795,	718,	630,	559,	398,	363
$[FePc(bpe)]_n$	1235,	1060,	700,	624,	538,	404,	360	
$[FePc(bpy)]_n$	1240,	1100,	760,	625,	573,	402,	358	
$[FePc(bpa)]_n$	1260,	1050,	715,	614,	556,	410,	365	
$[FePc(tmbpy)]_n$	1215,	1030,	680,	606,	570,	415,	368	

Electronic spectra were recorded on a Hitachi 330 UV-visible-NIR spectrophotometer. Solid samples were examined as pellets between quartz plates.

The conductivities of the compressed pellets of the complexes at room temperature were obtained with Gen-Rad 1657 RCL digibridge.

The Mössbauer spectra of the complexes at room temperature were measured with an Austin S-600 constant acceleration type Mössbauer spectrometer, using a $^{57}Co(pd)$ source. Isomer shifts are quoted with respect to the centroid of the iron foil. The spectral fittings were performed by a microcomputer least squares method. The line-shape was assumed to be Lorentzian.

RESULTS AND DISCUSSION

The electronic spectra for the adducts are reported in Table 1 to provide a convenient means for identifying them. The weak absorptions in the near infrared 1215–1280 nm, medium absorptions at 795–680 nm and strong absorptions at 630–360 nm in $(FePcL)_n$ can be assigned to metal *d–d* transition, charge-transfer of $d\pi$–$L\pi^*$ (between metal and Pc or bidentate ligand) and ligand-centred π–π^* (Pc and L) transitions respectively.[8–10]

Typical Mössbauer spectra of $(FePcL)_n$ and iodinated $(FePcL)_nI_x$ at 298 K are shown in Figs. 2 and 3 and Table 2 summarizes the Mössbauer parameters.

From the data in Table 2, it can be seen that I.S. and Q.S. values of the divalent iron(II) ion for these iron complexes, $(FePcL)_n$ with respect to ligands (L) increase in the order: pyz > bpe > bpy > bpa > tmbpy. A possible explanation for the lower I.S. and Q.S. values of iron for the first two ligands (pyz and bpe) lies in the greater participation of π-acceptor property, since $3d\pi$-electrons of iron are

† Precision on all runs ± 0.02 mm s^{-1}.

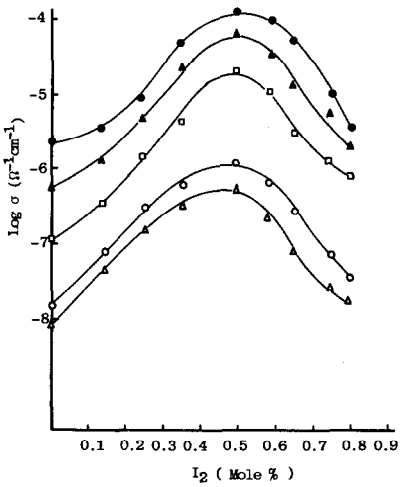

Fig. 4. Conductivity vs mole fraction of I_2 for $[FePc(pyz)]_nI_x$ (●), $[FePc(bpe)]_nI_x$ (▲), $[FePc(bpy)]_nI_x$ (□), $[FePc(bpa)]_nI_x$ (○) and $[FePc(tmbpy)]_nI_x$ (△).

delocalized onto the bridged ligand. This in turn leads to a decrease in *d*-electron population and decrease the shielding of *s*-character for the iron atom. The ~ 50% iodinated $[FePc(pyz)]_nI_x$ at 298 K have two kinds of Mössbauer absorption spectra characterizing mixed-valence of Fe(III)·Fe(II), the trivalent Fe(III) species has Mössbauer parameters of I.S. = 0.37, Q.S. = 0.80 mm s^{-1} and a small contribution of magnetic hyperfine component (an internal magnetic field of *ca.* 458 K Oe, cf. Fig. 3) which is unambiguously assigned to high-spin Fe(III) species.

Table 2 lists the results from four-probe conductivity measurements on the $(FePcL)_n$. The plots of conductivity versus the mole fraction of iodine are shown in Fig. 4. For all samples; the conductivity maximized at *ca.* 50% iodine. The general trend in conductivity as a function of base ligands is: pyz > bpe > bpy > bpa > tmbpy. This trend correlates with increasing conjugation of ligands (going from tmbpy to pyz). It is known from Mössbauer studies that the positive charge in the π-conjugated bidentate base complexes of $(FePcL)_n$ is preferentially localized on iron atom. Thus, conjugate assistance of electron transfer through the π-system markedly effects the conductivity.

NEUTRAL COMPLEXES OF Ga_2X_4 (X = Cl, Br) CONTAINING Ga–Ga BONDS: THE CRYSTAL AND MOLECULAR STRUCTURE OF $Ga_2Cl_4 \cdot 2$PYRIDINE

JOHN C. BEAMISH, ALAN BOARDMAN, RONALD W. H. SMALL and IAN J. WORRALL*

Department of Chemistry, The University, Lancaster LA1 4YA, U.K.

(*Received* 13 *August* 1984; *accepted* 6 *October* 1984)

Abstract—The complexes $Ga_2X_4 \cdot 2L$ (L = pyridine, 3-methylpyridine, 4-methylpyridine, morpholine, 1,4-thioxane, 1,4-dithiane, tetrahydropyran, tetrahydrofuran, tetrahydrothiophene and dimethylsulphide) have been prepared. Vibrational spectra indicate that they all contain Ga–Ga bonds and this is confirmed for $Ga_2Cl_4 \cdot 2$pyridine by a crystal structure determination which shows it to be isostructural with the bromide analogue. We were unable to synthesize complexes of stoichiometry $Ga_2X_4 \cdot 4L$ which had previously been reported.

Complexes of the ionic gallium halides were first reported by Brewer *et al.* in 1959. They reported the synthesis of many complexes of stoichiometry $Ga_2X_4 \cdot 2L$ for ligands with two donor sites and $Ga_2X_4 \cdot 4M$ for monodentate ligands. They concluded that the complexes were ionic with structures $GaL_2^+GaX_4^-$ and $GaM_4^+GaX_4^-$.[1,2] More recently we have shown that $Ga_2X_4 \cdot 2$dioxane (X = Cl, Br) and $Ga_2Br_4 \cdot 2$pyridine have ethane-like structures with Ga–Ga bonds.[3–5] In view of the conflict between Brewer's conclusions and our structural findings a further investigation is desirable.

EXPERIMENTAL

All reactions were carried out in a nitrogen filled dry-box or *in vacuo*. We began the synthetic work using the previous methods fully described by Brewer *et al.*[1,2] involving benzene solutions of the gallium dihalides, with a representative sample of ligands reported to form stable complexes. The ligands used were anisole, 1,4-dioxane, morpholine, acetylacetone, ethylamine, triethylamine, R_2S (R = methyl, ethyl), and selanophane. Isolable compounds were obtained for only two ligands, dioxane and morpholine. The remainder generally produced mixtures of gallium and gallium(III) halide complex. Our successful synthetic methods generally involve either the direct reaction of the ligand and dihalide or ligand displacement reactions.

Synthesis of $Ga_2X_4 \cdot 2L$ (X = Cl, Br; L = 1,4-*dioxane, morpholine, tetrahydrofuran, tetrahydropyran, tetrahydrothiophene, dimethylsulphide,* 1,4-*thioxan) and* $Ga_2Cl_4 \cdot 2$*diethylsulphide.*

The dihalide was cooled in liquid nitrogen and excess pure dry ligand was condensed on to it *in vacuo*. The temperature was allowed to slowly rise to the melting point of the ligand and the resulting slurry rapidly stirred until a colourless solution formed. The excess ligand was then slowly removed under vacuum and white compounds remained. Analytical data are given in Table 3.

Synthesis of $Ga_2X_4 \cdot 2L$ (X = Cl, Br; L = *pyridine,* 3-*methylpyridine and* 4-*methylpyridine*)

These could not be prepared by the method described above and were synthesized by ligand replacement reactions on $Ga_2X_4 \cdot 2$dioxane. Excess pyridine was condensed on the liquid nitrogen-cooled dioxane complex *in vacuo* and the temperature allowed to rise slowly to the melting point of the ligand. The resulting slurry was vigorously stirred until a clear solution formed; excess solvent was removed under vacuum and the remaining white powders analysed as shown in Table 3. The powders are soluble in excess ligand and crystals suitable for X-ray diffraction were obtained for the pyridine complex.

Synthesis of $Ga_2Cl_4 \cdot 2$*dithiane*

A dilute solution of dithiane in CS_2 was slowly added dropwise to a well cooled suspension of

Ga_2Cl_4 in CS_2. After a slight excess of ligand had been added the precipitate was stirred for four hours, filtered and dried *in vacuo*; analytical data are given in Table 3.

Raman spectra were recorded on solid samples using a Carey–Anaspec 81L spectrometer and IR on a Nicolet MX-1 Fourier transform spectrometer.

X-Ray structure analysis of $Ga_2Cl_4 \cdot 2$*pyridine*

Crystal data (measured at room temperature). $C_{10}H_{10}Cl_4Ga_2N_2$, $M = 439.5$, monoclinic, $C2/m$, $a = 15.43(2)$ Å, $b = 7.527(5)$ Å, $c = 7.350(5)$ Å, $\beta = 113.49(3)°$, $z = 2$, $U = 782.8$ Å^3, $D_c = 1.86$ mg m^{-3}, $D_m = 1.85$ mg m^{-3}, $F(000) = 428$, $\mu = 3.96$ mm^{-1}, Mo-K_α-radiation, $\lambda = 0.7107$ Å.

Data collection and solution

Stoe STADI-2 circle diffractometer; layers $l = 0$–8 were measured with the crystal set about the c-axis. Absorption corrections and scaling of data were carried out using SHELX.[6] After elimination of those for which $I < 3\sigma(I)$ there remained 1108 reflections. An E map, obtained by the MULTAN program,[7] revealed the positions of the Ga and Cl atoms; $F_o - F_c$ maps then gave the positions of the remaining atoms (apart from H). Using unit weights, full matrix least squares refinement of all atomic positions and anisotropic U_{ij} values was carried out until convergence was reached at $R = 0.0426$, $R_w = 0.0426$. Atomic scattering factors are given in Refs 8 and 9. Final atomic coordinates, anisotropic thermal parameters and lists of structure factors have been deposited with the Editor,* from whom copies are available on request.

DISCUSSION

Stoichiometry of complexes

The analytical data given in Table 3 shows that without exception the complexes have stoichiometry $Ga_2X_4 \cdot 2L$ regardless of the potential monodentate or bidentate nature of the ligand. This is in direct conflict with the findings of Brewer *et al.*[1,2] They reported 1:4 complexes with a number of monodentate O, N, S and Se ligands. We were unable to repeat this work and only with dimethylsulphide and diethylsulphide could stable compounds be isolated and these had 1:2 stoichiometry. Both 1:2 and 1:4 complexes are known for the indium analogues.[12]

Vibrational spectroscopy

This is a valuable technique for distinguishing between ionic type complexes containing the GaX_4^- ion proposed by Brewer *et al.* and Ga–Ga bonded species found in $[Ga_2X_6]^{2-}$,[10] $Ga_2X_4 \cdot 2$-pyridine and $Ga_2X_4 \cdot 2$dioxane (X = Cl, Br).[3–5] We have previously reported that the dioxane complexes have similar spectra to the anions $[Ga_2X_6]^{2-}$; in particular their Raman spectra each contain a very intense band in a similar position. This band has been assigned by Taylor *et al.*[10] to a totally symmetrical mode in which the Ga–Ga bond stretches in phase with Ga–halogen bonds. The presence of this intense band may be used to identify compounds containing Ga–Ga bonds.[11] Similar spectra are observed for analogous indium compounds.[12]

Raman spectra were recorded for all complexes over the range 0–3500 cm^{-1} and IR 210–3500 cm^{-1}. A few complexes produced poor quality IR spectra and these are not included. The discussion below is restricted to the region 100–400 cm^{-1} which is the useful region for Ga–Ga bonded compounds and contains Ga–Ga and Ga–halogen frequencies.† Bands due to the simple GaX_4^- ions are absent in all cases thus eliminating the structures previously proposed. It would be expected that Ga–Ga bonded species with ethane-like structures would contain an intense band associated mainly with Ga–Ga stretching, four bands associated with Ga–halogen stretching and two bands arising from Ga–ligand stretching. The vibrational spectra in the region 100–400 cm^{-1} are given in Tables 2 and 3 together with possible assignments which are based mainly upon those of Taylor *et al.* for $[Ga_2X_6]^{2-}$.[10] Although the assignments are labelled ν(Ga–Ga), ν(Ga–X) and ν(Ga–L) mixing of these modes as found in $[Ga_2X_6]^{2-}$ will occur. It is seen that the overall pattern of the spectra are similar and with few exceptions contain a very intense band close to the position of the intense band observed in $[Ga_2X_6]^{2-}$. These bands are assigned ν(Ga–Ga); they vary over the range 145–170 cm^{-1} for bromide complexes and 214–258 cm^{-1} for chloride complexes. The wider range of the latter may be partly associated with mass effects since the formal replacement of X^- in $[Ga_2X_6]^{2-}$ by ligand is larger and it has been shown that mass effects contribute substantially to band position in the mixed halide complexes, e.g.

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

† Detailed spectroscopic data are given in Ref. 13.

$[Ga_2X_{6-r}Y_r]$.[11] Although the intensity of the band is much reduced in pyridine and substituted pyridine complexes of Ga_2Cl_4, the crystal structure described below confirms the Ga–Ga bonded structure for the pyridine complex.

Bands in the range 300–400 cm^{-1} and 200–330 cm^{-1} may be assigned to ν(Ga–Cl) and ν(Ga–Br) respectively; generally where both Raman and IR spectra have been recorded the required number of bands is observed.

The four crystal structures so far determined have revealed two structural types: C_{2h} in $Ga_2X_4 \cdot 2$-pyridine (X = Cl, Br) in which the *trans* conformation is adopted and C_1 in $Ga_2X_4 \cdot 2$dioxane (X = Cl, Br). Since mutual exclusion should be operative in the former type, spectroscopy should distinguish between the *trans* and lower symmetry structures. It is seen that although mutual exclusion is not strictly adhered to, fewer bands and simpler Raman and IR spectra are observed. Considering other complexes where both Raman and IR spectra were obtained it is possible to predict tentatively that substituted pyridine complexes are *trans* and $Ga_2Cl_4 \cdot 2L$, (L = thioxane, tetrahydrothiophene, dithiane and dimethylsulphide) have structures of lower symmetry. The structure is a possible consequence of the packing in the solid state. In the pyridine complexes the *trans* conformation allows chain-like packing of the planar pyridine rings.[5]

A comparison of Cl and Br complexes of the same ligand allows the tentative assignment of Ga–ligand modes, these are also given in Tables 1 and 2. ν(Ga–N) lies in the range 218–276 cm^{-1} and there are many examples known which support our assignment.[16] The range 255–274 cm^{-1} for ν(Ga–S) is lower than observed in $GaX_3 \cdot SR_2$ complexes[16] (297–328 cm^{-1}) and may be a consequence of mixing. Bands due to ν(Ga–O) are to be expected in the region 400–550 cm^{-1} [17,18] but usually are very weak, broad and often not observed.[17] Since many of the ligands used in this work have bands in this region no reliable assignments could be made.

In complexes containing ambidentate ligands, i.e. morpholine and thioxane, ligand attachment is believed to occur via N in the former and S in the latter. This view is supported by the presence of bands at 275 and 254 cm^{-1} (ν(Ga–N)) in the morpholine complexes with a shift in ν(N–H) of -56 cm^{-1} (Cl) and -44 cm^{-1} (Br)[14] from the free ligand value (3340 cm^{-1}). For the thioxane complexes small

* Abbreviations as in Table 1.

shifts of $-10\ cm^{-1}$ are observed in the ν(C–S) at 655 and 688 cm^{-1} in the free ligand with no shift in ν(C–O) indicating a monodentate S attachment.[15]

Crystal structure of $Ga_2Cl_4 \cdot 2pyridine$

$Ga_2Cl_4 \cdot 2$pyridine exists as a single discrete molecule (Fig. 1) with a *trans* configuration and has $2/m$ (C_{2h}) symmetry (by space group requirement); it is isostructural with the bromide analogue.[5] Important bond distances and angles are given in the Table 4; the Ga–Ga bond length is 2.403(1) Å, and compares with 2.406(1) Å found in $Ga_2Cl_4 \cdot 2$-dioxane, 2.395(6) Å in $Ga_2Br_4 \cdot 2$dioxane and 2.421(3) Å in $Ga_2Br_4 \cdot 2$pyridine.

CONCLUSION

A series of neutral Ga–Ga bonded complexes, $Ga_2X_4 \cdot 2L$ has been synthesized with monodentate and bidentate ligands containing O, N, and S. No evidence was found to support previous reports of the existence of ionic 1 : 4 complexes.

PALLADIUM(II) HALIDE COMPLEXES WITH 2,5-DIMETHYL-, 2-AMINO-, 2-AMINO-5-METHYL-, 2-ETHYLAMINO- AND 2-MERCAPTO-5-METHYL-1,3,4-THIADIAZOLE

ANTONIO C. FABRETTI, GIANCARLO FRANCHINI, WANDA MALAVASI and GIORGIO PEYRONEL*

(*Received* 4 *May* 1984; *accepted after revision* 6 *October* 1984)

Abstract—Some palladium(II) halide complexes with 2,5-dimethyl- (DTZ), 2-amino- (ATZ), 2-amino-5-methyl- (MATZ), 2-ethylamino- (EATZ) and 2-mercapto-5-methyl-1,3,4-thiadiazole (MTTZ) have been prepared and studied: $PdX_2 \cdot 2L$ (L = DTZ, ATZ, MATZ: X = Cl, Br, I; L = EATZ: X = Br, I; L = MTTZ: X = I), $PdCl_2 \cdot 2.5EATZ$, $PdCl_2 \cdot 3MTTZ$, $PdBr_2 \cdot 1.5MTTZ$ and $PdX_2 \cdot L$ (L = DTZ, ATZ, MATZ, EATZ: X = Cl, Br; L = MTTZ: X = $Cl(H_2O)$, Br). In the $PdX_2 \cdot 2L$, $PdCl_2 \cdot 2.5EATZ$ and $PdCl_2 \cdot 3MTTZ$ complexes the palladium ions are *cis*-(2X, 2L)-coordinated, the coordination sites being N_{ring} for DTZ, NR_2 for ATZ, MATZ, EATZ and C = S for MTTZ. $PdBr_2 \cdot 1.5MTTZ$ may be formulated as *cis*$[PdBr_2 \cdot 2L] \cdot [PdBr_2 \cdot L]$. In the $PdX_2 \cdot L$ complexes the ligand very likely acts as bidentate by using a ring-nitrogen atom as the second coordination site.

Mono- and di-substituted 1,3,4-thiadiazoles have pharmacological properties[1–3] and are potential coordinating agents. The 2,5-dimethyl-1,3,4-thiadiazole (DTZ) has three possible coordinating endocyclic sites (2N, S). Besides them the 2-amino- (ATZ), 2-amino-5-methyl- (MATZ) and 2-ethylamino-1,3,4-thiadiazole (EATZ) have an exocyclic amino nitrogen atom and the 2-mercapto-5-methyl-1,3,4-thiadiazole (MTTZ) has an exocyclic sulphur atom as possible coordination sites. In order to establish the coordination behaviour of these ligands toward palladium(II) some of their complexes with this metal ion were prepared and investigated.

EXPERIMENTAL

All the reagents were of the highest purity commercial grade.

$PdCl_2 \cdot 2L$ (L = DTZ, ATZ, MATZ), $PdCl_2 \cdot 2.5EATZ$ *and* $PdCl_2 \cdot 3MTTZ$

A warm solution of $PdCl_2$ (1 mmol) and NaCl (2 mmol) in H_2O (2 cm^3) and EtOH (2 cm^3) was slowly added to a warm solution of the ligand (4 mmol) in EtOH (4 cm^3) and H_2O (4 cm^3) for DTZ and EATZ, in EtOH (12 cm^3) and H_2O (12 cm^3) for ATZ, in EtOH (16 cm^3) for MATZ and in EtOH (16 cm^3) and conc. HCl (2 cm^3) for MTTZ. The EATZ derivative was precipitated by adding Et_2O and was recrystallized from $CHCl_3$.

$PdBr_2 \cdot 2L$ (L = DTZ, ATZ, MATZ, EATZ) *and* $PdBr_2 \cdot 1.5MTTZ$

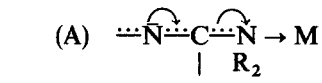
A warm solution of $PdBr_2$ (1 mmol) in H_2O (10 cm^3) was slowly added to a warm solution of the ligand (4 mmol) in EtOH (4 cm^3) and H_2O (4 cm^3) for DTZ and EATZ, in EtOH (12 cm^3) and H_2O (12 cm^3) for ATZ, in EtOH (16 cm^3) for MATZ and in EtOH (16 cm^3) and conc. HBr (2 cm^3) for MTTZ.

$PdI_2 \cdot 2L$ (L = DTZ, ATZ, MATZ, EATZ, MTTZ)

A warm solution of PdI_2 (0.25 mmol) and KI (10 mmol) in H_2O (4 cm^3) was slowly added to a warm solution of the ligand (1 mmol) in EtOH (1 cm^3) and H_2O (1 cm^3) for DTZ and EATZ, in EtOH (3 cm^3) and H_2O (3 cm^3) for ATZ, in EtOH (4 cm^3) for MATZ and in EtOH (4 cm^3) and conc. HI (1 cm^3) for MTTZ.

* Author to whom correspondence should be addressed.

$PdX_2 \cdot L$ (L = DTZ, ATZ, MATZ, EATZ: X = Cl, Br; L = MTTZ: X = Cl(H_2O), Br)



A warm solution of L (1 mmol) in EtOH (1 cm^3) and H_2O (1 cm^3) for DTZ and EATZ, in EtOH (4 cm^3) and H_2O (4 cm^3) for ATZ, in EtOH (4 cm^3) for MATZ and in EtOH (4cm^3) and conc. HX (0.5 cm^3) for MTTZ was slowly added to a warm solution of PdX_2 (1 mmol) and NaCl or KBr (2 mmol) in H_2O (2 cm^3) and EtOH (2 cm^3).

Elemental analyses are reported in Table 1. The molar conductivities were determined with a WTW conductivity bridge. Infrared spectra (Tables 2 and 3) were recorded with a Perkin–Elmer 180 spectrophotometer on the solid compounds in KBr disks (4000–250 cm^{-1}) and as Nujol mulls in polythene (500–50 cm^{-1}).

RESULTS AND DISCUSSION

In DMF solution all the soluble complexes behave as non-electrolytes except the MTTZ complexes which have molar conductivities close or corresponding to those of 1:1 electrolytes (Λ_M = 65–90)[5] probably because MTTZ may act as (N, S) chelating ligand and therefore favours the ionization of one halide ion in solution.

Some infrared bands observed (Table 2) in the 1545–1507 cm^{-1} region for ATZ, MATZ and EATZ may be assigned to ring vibration modes containing a high ν(C=N) contribution. For all the $PdX_2 \cdot 2L$ complexes their frequencies increase in agreement with the electronic shift (A) from the ring nitrogen

(A) 

atom toward the aminic nitrogen atom due to its coordination to the metal ion. For EATZ also the band at 1198 cm^{-1}, lying in the range of ν(C–NR_2) frequencies,[4] is shifted in the complexes to lower frequencies in agreement with the electronic shift (A).

The bands observed at 642 cm^{-1} for DTZ, 680 and 610 cm^{-1} for ATZ, 685 and 649 cm^{-1} for MATZ and 610 cm^{-1} for EATZ, lying in the frequency range given for C–S stretching frequencies (720–570 cm^{-1}),[4] are in agreement with the ν(C–S) frequencies given for 2-amino-5(*o*-hydroxyphenyl)-1,3,4-

thiadiazole (650 cm^{-1})[6] and 2-amino-5-phenyl-1,3,4-thiadiazole (648 cm^{-1}).[7] Their frequencies increase for the $PdX_2 \cdot 2L$ and for most of the $PdX_2 \cdot L$ complexes in agreement with an electronic shift from the ring sulphur atom toward the ring, excluding a coordination of this atom to the metal ion. For DTZ the coordination site(s) is or are therefore the ring nitrogen atom(s).

The ligand MTTZ does not show any ν(SH) band in the 2600–2500 cm^{-1} region in which this stretching frequency is generally expected[4] and is therefore mainly in its thioketo form.[8] Its band at 1268 cm^{-1} may be assigned to the ν(C–N) mode while the band at 740 cm^{-1} may be assigned to the ν(C=S) mode. The frequencies of these bands increase and decrease, respectively, in the $PdX_2 \cdot 2L$ complexes in agreement with he electronic shift due to the coordination of the ligand through the thiocarbonylic sulphur atom.

(B) 

In the $PdX_2 \cdot 2DTZ$ complexes DTZ is bonded as N-monodentate ligand, the resulting unsymmetrical molecule showing two ν(C–S) bands at higher frequencies than the single ν(C–S) band of the symmetrical free ligand molecule. In the $PdX_2 \cdot DTZ$ complexes DTZ acts as a N,N-bridging ligand re-establishing the molecular symmetry with two equivalent C–S bonds having the same ν(C–S) frequency.

In the other $PdX_2 \cdot 2L$ complexes ATZ, MATZ and EATZ are bonded through the exocyclic amino nitrogen atom and MTTZ through the exocyclic thiocarbonylic sulphur atom. Their $PdX_2 \cdot L$ complexes may achieve the square planar coordination by bridging either the halide ions or the ligand molecule. Some of the infrared bands of these complexes are different in frequency and/or intensity from those of the corresponding $PdX_2 \cdot 2L$ complexes, indicating a different coordination of the ligand molecule in the two cases.

Some new bands in the far-infrared spectra may be assigned to ν(PdX) or ν(PdL) modes. The $PdX_2 \cdot 2L$, $PdCl_2 \cdot 2.5EATZ$, $PdCl_2 \cdot 3MTTZ$ and $PdBr_2 \cdot 1.5MTTZ$ complexes show two ν(PdX) bands with normal frequencies for terminal PdX bonds[9–12] and two ν(PdL) bands corresponding to a square planar *cis* coordination. Some of the ν(PdX) bands are superimposed or coupled with ν(PdN) or ν(PdS) bands. The $\nu(PdN_{ring})$ frequencies are, as expected, lower than those of the $\nu(PdNR_2)$ bands involving exocyclic nitrogen atoms. The ν(PdS) frequencies are in agreement with those observed for PdS bonds involving thiocarbonylic sulphur atoms.[9,13,14] The $PdCl_2 \cdot 2.5EATZ$, $PdCl_2 \cdot 3MTTZ$ and $PdBr_2 \cdot 1.5MTTZ$ complexes may therefore have the constitution $[PdCl_2 \cdot 2EATZ]0.5EATZ$, $[PdCl_2 \cdot 2MTTZ]MTTZ$ and $[PdBr_2 \cdot 2MTTZ][PdBr_2 \cdot MTTZ]$.

For the $PdX_2 \cdot DTZ$ complexes, in which DTZ acts as N,N-bidentate ligand, the number of ν(PdX) and $\nu(PdN_{ring})$ bands (Table 3) indicates that the chloride and the bromide could have a *trans* and *cis* 2X, 2N)-coordination, respectively. For most of the other $PdX_2 \cdot L$ complexes besides the band due to the coordination of the exocyclic atom another band due to the coordination of an endocyclic nitrogen atom may be assigned, supporting the view that L acts as a bidentate ligand in these complexes.

Acknowledgement—Infrared spectra were recorded in the Centro Strumenti of the University of Modena.

THE TRIS(PICOLINATE)VANADATE(II) ION: REDOX PROPERTIES AND ELECTRON TRANSFER KINETICS WITH COBALT(III) AMINES

HENRIQUE E. TOMA* and FERNANDO T. P. LELLIS
Instituto de Quimica, Universidade de São Paulo, CP 20780, São Paulo, SP, Brazil

(*Received* 2 *July* 1984; *accepted after revision* 6 *October* 1984)

Abstract—Vanadium(II) ions form with the pyridine-2-carboxylate ligand a deep blue, tris-substituted complex absorbing at 660 nm ($\varepsilon = 7.2 \times 10^3\ M^{-1}\,cm^{-1}$) with a shoulder at 450 nm. Reversible spectroelectrochemistry and cyclic voltammetry were observed for this complex, with $E_{1/2} = -0.448$ V vs NHE, and $\Delta S^{\circ}_{rc} = -6\ cal \cdot mol^{-1} \cdot deg^{-1}$. Electron transfer kinetics with $[Co(en)_3]^{3+}$ led to $k_{12} = 3100\ M^{-1}\,s^{-1}$, $\Delta H^{+} = 12.4\ kcal \cdot mol^{-1}$ and $\Delta S^{+} = -0.9\ cal \cdot mol^{-1} \cdot deg^{-1}$ ($I = 0.10$ M). For the related $[Co(NH_3)_6]^{3+}$ complex, $k_{13} = 1.9 \times 10^4\ M^{-1}\,s^{-1}$. The self-exchange rate constant and activation parameters were analysed in terms of relative Marcus theory.

This work deals with the properties and reactivity of the tris(picolinate)vanadate(II) ion.[1] Vanadium(II) complexes are extraordinary in terms of redox reactivity, particularly with respect to oxygen, water and dinitrogen. Because of this, however, only a few complexes have been investigated in aqueous solution.

The $[V(pic)_3]^-$ complex is not an exception in terms of reactivity; however, its unusual deep blue color, in addition to a long life-time in aqueous solution, stimulate spectroscopic and electrochemical studies which are particularly important in vanadium(II) chemistry. The π-conducting picolinate ligand is expected to improve the electron transfer characteristics of the vanadium(II) complex, e.g. increasing the adiabaticity making it useful as a strongly reducing probe in studies of redox reactivity of inorganic and biological complexes.[2,3] To evaluate this point, we have studied the kinetics of the $[Co(en)_3]^{3+}[V(pic)_3]^-$ and $[Co(NH_3)_6]^{3+}$ $[V(pic)_3]^-$ electron transfer reactions, including a relative Marcus theory evaluation of the self-exchange rate constants and the corresponding activation parameters.

EXPERIMENTAL

Aqueous vanadium(II) ions were generated from vanadium(III) trichloride (Alfa) or vanadyl trifluoroacetate solutions, in the presence of zinc amalgam, under argon atmosphere. Lithium picolinate was prepared by reacting picolinic acid (Aldrich) and lithium hydroxide (Fisher), and recrystallized several times from aqueous solution, after a treatment with activated charcoal to remove eventual oxidizing impurities. The tris(picolinate)vanadate(II) complex was always freshly prepared by reacting aqueous vanadium(II) ions with an excess of the picolinate ligand, under argon atmosphere. The ionic strength was adjusted with lithium trifluoroacetate, because vanadium(II) ions are not stable in perchlorate solutions. The complexes $[Co(NH_3)_6](ClO_4)_3$, $[Co(en)_3]I_3$ and $[Co(en)_3]Cl_3$ were prepared as described in the literature.[4,5]

All the measurements in this work were carried out under argon atmosphere. Cyclic voltammetry was performed with a Princeton Applied Research Corporation instrument, consisting of a 173 potentiostat and a 175 Universal programmer. A gold disk electrode was employed for the measurements, with Ag/AgCl (1 M KCl) as the reference electrode, using the conventional Luggin capillary arrangement to minimize the ohmic drop. A platinum wire was used as the auxiliary electrode. Temperature dependence studies were performed using a non-isothermic arrangement, as described in the literature.[6]

The electronic spectra of the complexes in the visible and near-UV region were recorded on a Cary 17 spectrophotometer, fitted with thermostatted cell

* Author to whom correspondence should be addressed.

compartments. Spectroelectrochemical measurements were performed with a PAR 173 potentiostat, in parallel with the Cary 17 spectrophotometer. A three electrode system was designed for a rectangular quartz cell of 0.3 mm internal optical pathlength. A gold minigrid was used as transparent working electrode, in the presence of a small Ag/AgCl reference electrode and of a platinum auxiliary electrode.

The stopped-flow kinetics were carried out with a Durrum D-150 instrument, equipped with a Kel-F flow system. The kinetics were studied under pseudo-first order conditions, by following the decay of the absorption band of the $[V(pic)_3]^-$ complex at 660 nm, in the presence of an excess of the oxidizing agent.

RESULTS AND DISCUSSION

Vanadium(II) ions react with picolinate ligands producing violet–blue complexes in aqueous solution. A small excess of the free ligand, e.g. 10^{-3} M, is enough to convert the intermediate successive complexes to the tris(picolinate)vanadate(II) ion, which has a stability constant of 7.6×10^{13} M^{-3}, at 25°C, and $I = 0.6$ M (lithium trifluoroacetate).[1]

The deep blue color of $[V(pic)_3]^-$ fades within a few hours in deaerated solutions, even under continuous flow of argon. For this reason, the spectra of the tris-picolinate ion were obtained spectroelectrochemically, as shown in Fig. 1, with a gold minigrid electrode kept at −800 mV vs Ag/AgCl (1 M KCl). A strong absorption band is observed at 660 nm, with a shoulder around 450 nm. The extinction coefficients are 7.2×10^3 and 4×10^3 $M^{-1}\,cm^{-1}$, respectively. We assigned these bands to charge transfer transitions from the metal d_π orbitals to the ligand p_π orbitals, in comparison to the spectra of the iron(II) picolinates and related complexes.[7]

Spectroelectrochemistry of $[V(pic)_3]^-$ is Nernstian up to −0.600 V, corresponding to a reversible monoelectronic oxidation process, with $E^\circ \cong -0.68$ V vs Ag/AgCl (1 M KCl), at 28°C, in the presence of 0.100 *M* lithium picolinate and 0.400 *M* lithium trifluoroacetate. Oxidation proceeds irreversibly above −0.500 V, generating vanadium(IV) complexes.

Cyclic voltammograms of the tris-substituted complex, in the presence of 0.35 M lithium picolinate and 0.60 *M* lithium trifluoroacetate were reversible, with a linear behaviour of the peak currents vs the concentration of the vanadium complex, and the square root of the scan rates. The peak separation is close to 60 mV, with $E_{1/2} = -0.670$ V vs Ag/AgCl (1 M KCl) or −0.448 V vs NHE, and a diffusion coefficient of 4.8×10^{-6} $cm^2\,s^{-1}$, at 25°C. The

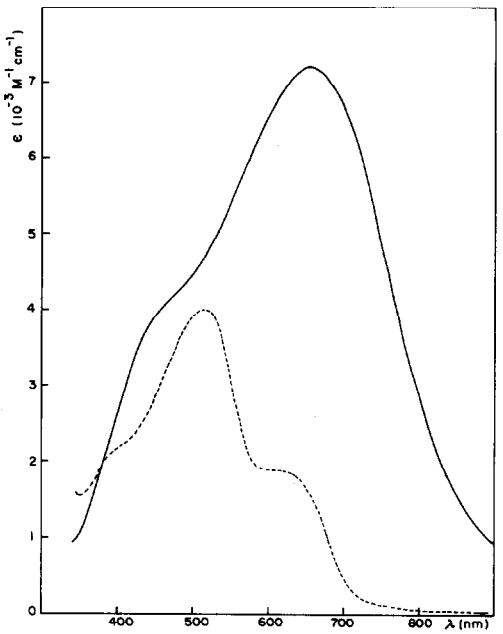

Fig. 1. Electronic spectra of $V(pic)_3^-$ (——) and $V(pic)_3$ (– – –) obtained spectroelectrochemically at −800 and −500 mV vs NHE, respectively, in the presence of 0.10 M lithium picolinate and 0.40 M lithium trifluoroacetate.

half-wave potentials measured at 5, 15, 35 and 45°C were −0.664, −0.667, −0.672 and −0.675 V, respectively. From these values we have calculated the redox couple entropy, $\Delta S^\circ_{rc} = -6$ $cal \cdot mol^{-1} \cdot deg^{-1}$.

The equilibrium constant of the tris(picolinate)vanadium(III) complex, based on equation (1) is 2.1×10^{15} M^{-3}, with $E^\circ_{V(H_2O)_6^{3+/2+}} = -0.253$ V.

$$\Delta E^\circ_{V(pic)_3^{0/-1}} = \Delta E^\circ_{V(H_2O)_6^{3+/2-}} + \frac{RT}{nF} \ln \frac{\beta_{II}}{\beta_{III}}. \quad (1)$$

The electron transfer reaction of $[V(pic)_3]^-$ and $[Co(en)_3]^{3+}$ proceeds according to a first order kinetics for at least three half-lives, in the presence of an excess of the cobalt(III) complex.

$$[V(pic)_3]^- + [Co(en)_3]^{3+} \xrightarrow{k_{12}} V(pic)_3 + [Co(en)_3]^{2+}$$

$$-\frac{d[V(pic)_3^-]}{dt} = k_{12}[V(pic)_3^-][Co(en)_3^{3+}]. \quad (2)$$

The experimental rate law is consistent with an outer sphere mechanism, where $k_{12} = 3100$ M^{-1} s^{-1}, at 25°C, and $I = 0.100$ *M* (KCl, or lithium trifluoroacetate). No evidence for rate saturation has been detected under the conditions employed for the experiments. The kinetics data at several temperatures are shown in Table 1.

To evaluate the self-exchange rate constants for the $[V(pic)_3]^-$ complex, we have employed the Marcus theory with the Wherland–Gray[8] formalism for the work terms, W_{ii} and W_{ij}. The reorganization free energies, ΔG_{ii}^{**} are given by the equation,

$$\Delta G_{11}^{**} = 2\Delta G_{12}^{**} - \Delta G_{22}^{**} - \Delta G_r^\circ(1-\alpha_{12}), \quad (3)$$

where

$$\alpha_{12} = \frac{\Delta G_r^\circ}{4(\Delta G_{11}^{**} + \Delta G_{22}^{**})} \quad (4)$$

and

$$\Delta G_{12}^{**} = \Delta G_{12}^{*} - W_{12} \quad (5)$$

$$\Delta G_{11}^{**} = \Delta G_{11}^{*} - W_{11} \quad (6)$$

$$\Delta G_{22}^{**} = \Delta G_{22}^{*} - W_{22} \quad (7)$$

$$\Delta G_r^\circ = \Delta G_{12}^\circ - W_{12} + W_{21}. \quad (8)$$

Analogously to Wherland and Gray,[9] we have used a pre-exponential factor of 6×10^{12} $M^{-1}\,s^{-1}$ (instead of 10^{11} $M^{-1}\,s^{-1}$) in the Marcus equation, as in the semiclassical formalism[10]

$$k = \kappa_{el}\Gamma_n V v_n \exp-(\Delta G^*/RT), \quad (9)$$

where the product of the electronic and nuclear tunneling factors, $\kappa_{el}\Gamma_n$, is close to unity; $V = 4\pi Nr^3/300$; v_n is the nuclear vibration frequency, and $V\cdot v_n \cong kT/h$.

The self-exchange rate constant, k_{22}, for the $[Co(en)_3]^{3+}$ complex has been measured by Lewis *et al.*[11] and by Dwyer and Sargeson[12] as 5.2×10^{-5} $M^{-1}\,s^{-1}$ and 7.7×10^{-5} $M^{-1}\,s^{-1}$ (25°C, $I = 1$ M), respectively. The extrapolated value at $I = 0.1$ M is 2.75×10^{-5} $M^{-1}\,s^{-1}$. The input and output parameters are given in Table 2.

The calculated self-exchange rate constant for the $[V(pic)_3]^{0/-}$ couple, based on the $[Co(en)_3]^{3+}$–$[V(pic)_3]^-$ reaction is 9.7×10^5 $M^{-1}\,s^{-1}$, at $I = 0.100$ M. This value is in good agreement with preliminary data based on Co(sepulchrate)$^{3+}$ and bis(histidinate)–cobalt(III) complexes.[1] In comparison to the self-exchange rate constant for the $[V(H_2O)_6]^{3+/2+}$ couple, ($k_{ii} = 1.0\times10^{-2}$ $M^{-1}\,s^{-1}$ at $I = 1.0$ M), one can see that electron-transfer in the picolinate complex is more effective by seven orders of magnitude. Part of this difference arises from the work term, which is null for $[V(pic)_3]^{0/-}$ and 0.79 kcal mol^{-1} for $[V(H_2O)_6]^{3+/2+}$. The major contribution, however, comes from the smaller reorganization barrier, ΔG_{ii}^{**}, of the $[V(pic)_3]^-$ complex.

The reorganization entropies, ΔS_{ii}^{**} and ΔS_{ij}^{**}, are given by

$$\Delta S_{12}^{**} = \left(\frac{\Delta S_{11}^{**}}{2} + \frac{\Delta S_{22}^{**}}{2}\right)(1-4\alpha_{12}^2) + \frac{\Delta S_r^\circ}{2}(1+2\alpha_{12}), \quad (10)$$

where

$$\Delta S_{11}^{**} = \Delta S_{11}^{*} + \frac{\partial W_{11}}{\partial T} \quad (11)$$

$$\Delta S_{22}^{**} = \Delta S_{22}^{*} + \frac{\partial W_{22}}{\partial T} \quad (12)$$

$$\Delta S_{12}^{**} = \Delta S_{12}^{*} + \frac{\partial W_{12}}{\partial T} \quad (13)$$

$$\Delta S_r^\circ = \Delta S_{12}^\circ + \frac{\partial W_{12}}{\partial T} - \frac{\partial W_{21}}{\partial T}. \quad (14)$$

The reaction entropy ΔS_{12}° can be obtained from the difference of the experimental redox couple entropies:

$$\Delta S_{12}^\circ = \Delta S_{rc[Co(en)_3^{3+/2+}]}^\circ - \Delta S_{rc[V(pic)_3^{0/-}]}^\circ. \quad (15)$$

Derivation of the work terms is given by[10]

$$\frac{\partial W}{\partial T} = -\frac{W}{2T(1+\beta r I^{1/2})}\left[2\left(\frac{\partial \ln D_s}{\partial \ln T}\right) + \beta r I^{1/2}\left(\frac{\partial \ln D_s}{\partial \ln T}\right) - \beta r I^{1/2}\right] \quad (16)$$

or alternatively,[13] by

$$\frac{\partial W}{\partial T} = Z_1 Z_2 \left(0.868 I^{1/2} + \frac{19.5}{r}\right) \times \exp\left(-0.329 r I^{1/2}\right), \quad (17)$$

where D_s is the static dielectric constant, r is the metal–metal separation in the activated complex, and the other terms have the conventional meanings. For an adiabatic mechanism,[10]

$$\Delta S^* = \Delta S^{**} - \frac{\partial W}{\partial T} - R \quad (18)$$

and

$$\Delta H^* = \Delta H^{**} + W - T\frac{\partial W}{\partial T} - RT. \quad (19)$$

The calculated activation parameters for the $[Co(en)_3]^{3+/2+}$–$[V(pic)_3]^-$ reaction are presented in Table 2. As one can see in Table 2, the use of equations (16) and (17) leads to similar results for the $[V(pic)_3]^-$ complex.

In the present work we assumed an adiabatic mechanism for $[Co(en)_3]^{3+}$, based on recent theoretical calculations[14] and discussion.[15] As a matter of fact, the Franck–Condon or nuclear factors related to ΔG_{ii}^{**} have been estimated as 10^{-4}, in comparison to 10^{-3}–10^{-2} for the electronic factor associated with non-adiabaticity.[14] On the other hand, it has been shown that the electronic factor spans the range 10^{-3}–1 for typical iron and ruthenium complexes.

The reaction of $[V(pic)_3]^-$ with $[Co(NH_3)_6]^{3+}$ follows a rate-law analogous to that for the $[Co(en)_3]^{3+}$ reaction, with $k_{13} = 1.9 \times 10^4$ M^{-1} s^{-1}, as shown in Table 1. According to Marcus theory, the ratio k_{13}/k_{12} for electron transfer with hexaamine and ethylenediamine complexes should be relatively constant.[15] Typical values from the literature for V^{2+}, Cr^{2+}, $Cr(bipy)_3^{2+}$ and Co(sepulchrate)$^{2+}$ reactions with $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ complexes vary from 2.9 to 18.1. Our experimental value of k_{13}/k_{12} is 6.1.

Using the calculated self-exchange rate constant for $[V(pic)_3]^-$, we have estimated k_{33} for the $[Co(NH_3)_6]^{3+/2+}$ couple, assuming $r(Co^{II}) = 0.34$ nm, $r(Co^{III}) = 0.32$ nm and $E_{rc}^\circ = 0.057$ V,[16] or 0.018 V.[17] Our result for k_{33} was 2.5×10^{-6} M^{-1} s^{-1}, or 6.7×10^{-7} M^{-1} s^{-1}, respectively. This is in good agreement with the range of values recently proposed in the literature.[15,19]

Abstract—The interaction of 2 equivalents of 2,3-dimethyl-2,3-butandiol (pinacol-H_2) with $W(NPh)Cl_4$ in the presence of *t*-butylamine leads to the complexes $W(pinacol)_3$ (**1**), and $[W_2(NHPh)_2(\mu\text{-pinacol})(pinacol)_4]$ (**2**). A side-product of the reaction is $[W_2(NPh)(\mu\text{-O})(pinacol)_2(pinacol\text{-}H)_2]$ (**3**). When 3 or more equivalents of diol are used (**1**) is the sole product. The structures of (**2**) and (**3**) have been determined by single-crystal X-ray diffraction methods. Crystals of (**2**) are monoclinic, space group $C2/c$ with $a = 15.086(3)$, $b = 18.370(5)$, $c = 18.428(5)$ Å and $\beta = 106.04(2)°$; crystals of (**3**) are orthorhombic, space group *Pbca*, with $a = 10.571(1)$, $b = 22.449(12)$, $c = 34.142(5)$ Å. Both structures were solved by Patterson and Fourier methods and refined to an R value of 0.059 for the 1023 observed data of (**2**) and to $R = 0.071$ for the 1212 observed data of (**3**). In the amido complex (**2**) the W–N bond length is 2.02(2) Å with the longest W–O bond length of 2.00(2) Å lying *trans* to it. In the imido complex (**3**) the W–N bond length is 1.75(5) Å; the *trans* W–O bond length at 2.30(4) Å indicates lone-pair donation by the imido N.

Dialkylamido complexes ($M\text{–}NR_2$) of the transition metals are well known[1] but monoalkyl analogues (M–NHR) are less common. Attempts to prepare the latter can lead to polymerisation[2] or to formation of the imido group ($M{\equiv}NR$) by proton loss.[3] However stable complexes have been obtained by reaction of metal halides with amines[4] or silylamines[5] and by reduction of organoimido complexes with sodium–mercury amalgam.[6] Recent work has indicated that the nitrogen of earlier transition metal organoimides might act as a nucleophile[7] so that under appropriate conditions, protonation could lead to an amido complex. The 4-electron donor imido function is however generally robust[3] and apart from the amination of alkenes by osmium(VIII) organoimides,[8] few reactions have been reported.[9]

Recently it has been suggested that a potentially strong π-donating ligand, such as alkoxide, placed *trans* to an organo-imido function might force the M–N bond to act essentially as a 2-electron donor and thus enhance reactivity.[10] To this end we earlier prepared a series of d^0 tungsten phenylimido alkoxides but only lone-pair electron donation was found for ligands in the *trans* position.[11] In this paper we describe the results of our studies with the potentially chelating diol, 2,3-dimethyl-2,3-butandiol.

RESULTS AND DISCUSSION

Reactions of $W(NPh)Cl_4$ were carried out with 2,3-dimethyl-2,3-butandiol(pinacol-H_2), 2,3-butandiol, 2,4-dimethyl-2,4-pentandiol and 2,4-pentandiol using Et_3N or Me_3CNH_2 as proton acceptor to remove HCl and prevent cleavage of the imido function. However we have only been successful in identifying products for the reaction with pinacol-H_2. Thus reaction of 2 equivalents of this diol with $W(NPh)Cl_4$ in the presence of 5 equivalents of

t-butylamine gave a red solution from which a red crystalline solid was obtained along with both yellow and colourless crystals. Attempts to recrystallise the physically separated red material invariably led to a lightening of solution colour and deposition of further yellow products. The colourless product also formed when the red crystals were reacted with pinacol-H_2.

With 3 or more equivalents of pinacol-H_2 the colourless product formed in good yield and was identified as W(pinacol)$_3$ (**1**). Aniline was produced as a product of the reaction. The complex shows apparent air stability but decomposes above 210°. In the IR spectrum, OH stretches are absent and a strong absorption occurs at 1140 cm^{-1} which is characteristic of ν(C–O).[12] Positive identification of ν(W–O) is not possible due to similarities of complex and free ligand but strong bands occur at 700 and 620 cm^{-1} similar to those in phenylimido tungsten alkoxides.[11] The ^{1}H NMR spectrum shows the absence of hydroxyl protons with the methyl groups appearing as two singlets, the one to higher field at the δ value of the free ligand methyl protons. Similarly the ^{13}C NMR spectrum contains two methyl carbon resonances and a single quaternary carbon resonance shifted 22 ppm downfield from the free ligand. We note that to reduce hydrogen interactions, the chelate rings would adopt a *gauche* conformation with its resulting ring puckering. Molecular models indicate that for this geometry, protons of two methyl groups would experience anisotropy effects from other chelate ring oxygens, leading to a downfield shift for half the methyl group proton resonances. While no attempt has been made to identify optical isomers, a recent report[13] indicates that in the presence of (+)-1-(9-anthryl)-2,2,2-trifluoro ethanol, one methyl group resonance in the ^{1}H NMR spectrum of W(pinacol)$_3$ splits into a doublet demonstrating a racemic mixture of both enantiomers of the chiral complex.

On prolonged standing of the reaction mixture at −20°C, large crystals of the red product formed and were separated manually. The IR spectrum was similar to W(pinacol)$_3$ (ν(C–O), 1130 cm^{-1}, ν(W–O) 620 cm^{-1}) and in addition contained absorbances characteristic of an aromatic ring (3020, 758 and 720 cm^{-1}); a weak band at 3325 cm^{-1} suggested NH or OH groups. Although not stable in $CDCl_3$ the ^{1}H NMR spectrum indicated one phenyl group to approximately 2.5 diols based on the ratio of phenyl and methyl protons. This evidence suggested species such as $W_2(NHPh)_2(pinacol)_5$ or $W_2(NPh)_2(pinacol)_4$(pinacol-H) but whereas C and H analytical data were close for these formulations, nitrogen analyses were always low.

An X-ray crystallographic structural analysis of the complex showed it to be the amido species $W_2(NHPh)_2(pinacol)_5$ (**2**) with one diol ligand bridging two tungsten atoms, the two halves being related by a C_2 crystallographic axis of symmetry. Each tungsten atom adopts a distorted octahedral geometry with the sites occupied by oxygens of two chelating diols and one half of the bridging diol, as well as a nitrogen of the phenylamido ligand. The dimers are loosely packed and there are no significantly short intermolecular contacts. One half of the molecule is shown in Fig. 1 and selected bond distances and angles are given in Table 1.

The bite angles of the bidentate ligands (74.1(8)° and 76.6(8)°) distort the octahedral geometry about the tungsten atom. Chelate ring puckering occurs with the expected *gauche* arrangement being adopted. This ensures that the methyl substituents are well separated with the torsion angle C(92)–C(9)–C(10)–C(102) of 40° being the smallest observed. In spite of this the coordination geometry dictates that the molecule is a sterically crowded one and a number of short intramolecular contacts occur particularly between methyl protons and oxygen atoms.

Although the NH proton was not located the W–N bond distance (2.02(2) Å) and W–N–C bond angle (134(2)°) indicate a phenylamido group. The W–N bond distance shows a small contraction (0.11–0.18 Å) compared with the Re–N distances found in the low valent phenylamido complexes Re(NHPh)$N_2(PMe_3)_4$ (Re–N, 2.200(14)Å) and

Bond lengths (Å)		Bond angles (°)	
W–O(1)	1.92(2)	O(1)–W–O(2)	76.6(8)
W–O(2)	1.85(2)	O(3)–W–O(4)	74.1(8)
W–O(3)	1.96(2)	O(1)–W–O(3)	160.1(8)
W–O(4)	2.00(2)	O(2)–W–O(5)	159.7(8)
W–O(5)	1.80(2)	O–W–O(*cis*)	87.7–107.6(8)
W–N	2.02(2)	N–W–O(4)	157.6(8)
O–C	1.36–1.55(4)	N–W–O(*cis*)	82.1–110.6(9)
N–C(1)	1.39(3)	W–O–C	118–148(2)
C–C	1.42–1.65(5)	W–N–C(1)	134(2)

$Re(NHPh)C_4H_6(PMe_3)_3$ (2.13(3) Å)[6] in which 18 electron configurations are achieved without the need for pπ donation.* However the present W–N bond distance of 2.02(2) Å is similar to that found in $W(NMe_2)_6$ 2.03(3) Å where a degree of amido pπ donation is expected.[15] To achieve an 18 electron configuration O → Wπ donation is necessary in the equatorial plane where the W–O bond lengths range from 1.80(2) to 1.96(2) Å (estimated W–O single bond lengths are *ca.* 2.06 Å†). The W–O(4) bond (2.00(2) Å) which is *trans* to the phenylamido N is the longest of the W–O bonds observed (although not significantly different from W–O(3) at 1.96(2)) and probably involves the smallest amount of π-donation of all the donors. However a delicate balance between oxygen and nitrogen π-donation is likely to exist since both π systems are not necessarily required to satisfy the EAN rule. Since the *cis* W–O bond distances are 0.06–0.22 Å shorter than the W–N bond, whereas the bond radii of N and O differ only by *ca.* 0.05 Å,[14] it appears that oxygen π-bonding is the more dominant.

An X-ray analysis was also carried out on the yellow product obtained in small quantities by crystallisation of the original reaction mixture. The molecular structure consists of two tungsten atoms bridged by a single oxo ligand with further coordination about each metal by one phenylimido and two chelating diol ligands (Fig. 2). The bridging

* The expected reduction due to the difference in single bond metallic radii between W and Re is only 0.02 Å.[14]

† Mo–O bond lengths are calculated at 2.06 Å[16] and W and Mo have similar single bond metallic radii.[14]

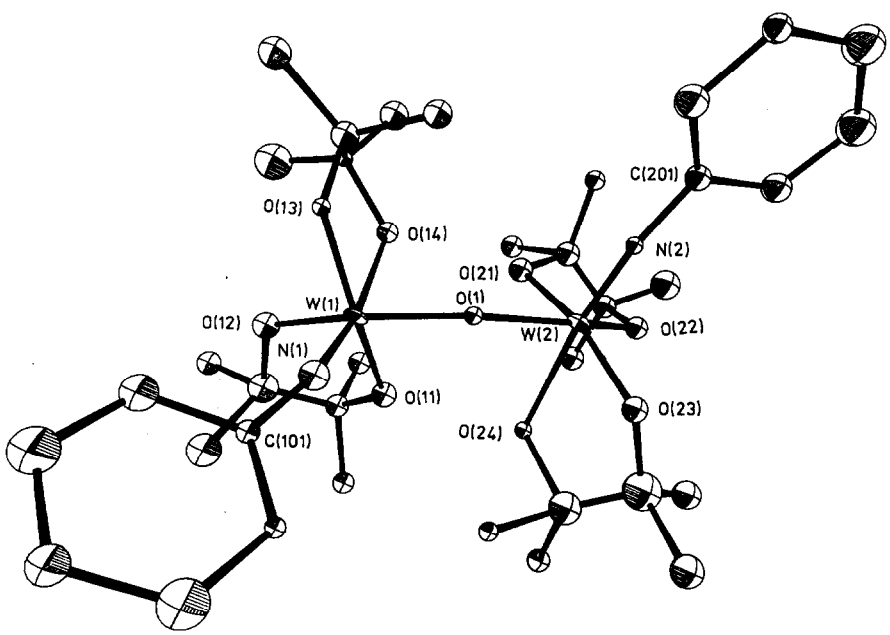

Fig. 2.

oxygen lies on an approximate two-fold rotation axis. Selected bond lengths and angles are given in Table 2.

The bite angles and puckering of the chelate rings are similar to those of the previous structure and again lead to a distorted octahedral geometry. To retain the +VI oxidation state for W, one chelate oxygen in each octahedron remains protonated and these are found to lie *trans* to the imido functions where the considerably longer W–O bond distances of 2.29(4) and 2.30(3) for W(1)–O(14) and W(2)–O(24), respectively, are observed (cf. 2.06 Å, estimated for a W–O single bond[16]). Although the hydroxyl protons were not located, calculated positions indicate the possibility of hydrogen bonding across the dimer (O(14)–H . . . O(21) and O(24)–H . . . O(11) with O . . . O distances of 2.54 and 2.55 Å, respectively, and estimated H . . . O approaches of 1.58 and 1.53 Å, respectively) which may contribute to the size of the W–O–W bond angle (157(2)°) as well as the octahedral distortion. The bridging W–O bond lengths are the same within the limits of accuracy of the structure (1.87(4) and 1.92(4) Å) indicating similar electron donation to both tungstens.

The structure thus shows similarities to [Mo (= O)(pinacol)(pinacol-H)]$_2$O where a symmetric Mo–O–Mo bridging system is observed and where a bent Mo–O–Mo angle of 162° is found.[17] In this molecule similar intramolecular hydrogen-bonding of the pinacol-H proton also occurs. However in the oxo-bridged trimer [W(NPh)(μ-O)Me$_2$(PMe$_3$)]$_3$ the oxygen lies *trans* to the imido function and an asymmetric bridging geometry is observed.[18]

The W–N bond distances (1.75(5) and 1.74(4) Å) shows considerable multiple bond character. Although they do not differ significantly from the value predicted for a W–N triple bond (4-electron donor)[3] and lie within the range observed for other organomido complexes of tungsten[3,11,18–21] their agreement with data for the recently reported complex [W$_2$(NPh)$_2$(OCMe$_3$)$_2$(μ-OCMe$_3$)$_2$] (W–N bond lengths 1.737(5), 1.738(5) Å)[22] is particularly relevant. The bond length agreement is also paralleled by close agreement in the W–N–C bond angles 165.3(5) and 164.2(5)°[22] although the data for complex (3) (164(5), 163(4)) barely differs significantly from that for ideal linear geometry. Thus it seems likely that the W–N bond order is a little less than 3.0.

The imido ligand is clearly the dominant π-bonder although O → W π-bonding must also be present to achieve an 18 electron count. The W–O bond lengths are longer than in the amido complex (**2**) and thus compete less successfully than the imido nitrogen as a π-donor. A similar situation exists in other phenylimido tungsten alkoxides.[11]

Several points emerge from the chemical and

structural studies. The reaction of pinacol-H_2 with $W(NPh)Cl_4$ in the presence of *t*-butylamine, unlike monohydroxylic alcohols, where only chlorines are replaced,[11] leads to protonation of the imido function. We believe this to be the first example of the formation of the relatively rare amido complexes achieved by this process. Clearly at some stage in the reaction, protonation of the imido function competes with the *t*-butylamine-assisted removal of HCl to finally give aniline [equation (1)]. While it is tempting to postulate a lengthening of the imido function prior to metal-amide bond formation [equation (2)] there is no evidence for this at present.

$$W{\equiv}N{-}Ph \xrightarrow{diol} W{-}NHPh \xrightarrow{diol} NH_2Ph \quad (1)$$

$$W{\equiv}N{-}Ph \longrightarrow W{=}\overset{\displaystyle Ph}{\overset{|}{N}} \longrightarrow W{-}NHPh. \quad (2)$$

However it is likely that electron density at the imido nitrogen would need to be substantially increased before protonation so that distortions within the molecule (structure **2**) and/or potential for W–O single or multiple bonding *trans* to the imido function (structure **2**) may assist the process. The amido group could be formed by protonation from an OH group orientated in the equatorial plane but intermolecular protonation could also occur. In this respect nitrogen reacts essentially as a nucleophile. We note that the reaction is similar to that of pinacol-H_2 with $W(C_2Ph_2)Cl_4$ were the alkyne functions as a strong π-bonding, dianionic, ligand protonating before producing PhCH=CHPh and $W(pinacol)_3$.[13]

One interesting facet of the imido complex described is the origin of the oxygen bridge. Since this complex is only a very minor component of the reaction mixture and molecular oxygen was rigorously excluded, the likely source is a small amount of water present in the undried diol, rather than the diol itself.

We note in passing that several organoimido complexes of tungsten have now been structurally characterised and some trends are apparent. For all d^0 complexes, lone-pair donation has been observed exclusively *trans* to a single terminal organoimido 4-electron donor,[3,11,18–21] but in the d^0 diimido complex, $[W(NPh)(NCMe_3)Cl_2\text{-}(NH_2CMe_3)]_2$ a chloro group lies *trans* to a bridging imido group.[23] In the d^1 and d^2 phenylimido complexes $W(NPh)Cl_3(PMe_3)_2$ and $W(NPh)Cl_2(PMe_3)_3$ a chloro group binds *trans* to a 4-electron donor imido group and only in the former is a *trans* lengthening observed.[20,21] The d^2 complexes $W(NPh)Cl_2(L)_3$ are extremely resistant to reduction and as yet d^3 tungsten organoimides are unknown.[24]

EXPERIMENTAL

Microanalyses were performed by Dr A. C. Campbell and associates, University of Otago, New Zealand.

Spectrometers. IR: Perkin–Elmer 597; spectra in Nujol mulls between CsI plates. NMR: JEOL FX 60 (^1H, 60 MHz, ^{13}C, 15 MHz).

All operations were performed under oxygen-free nitrogen and solvents were dried over sodium and distilled from sodium wire or sodium/benzophenone except for chlorinated hydrocarbons which were dried and distilled from CaH_2. Light petroleum had b.p. 40–60°. $W(NPh)Cl_4$ was prepared by reaction of $WOCl_4$ with phenyl isocyanate.[21] *t*-Butylamine was distilled from CaH_2 and 2,3-dimethyl-2,3-butandiol (K and K) was used as supplied. Melting points were determined in sealed tubes under nitrogen.

$W(pinacol)_3$ (1)

2,3-Dimethyl-2,3-butandiol (0.9 g, 7.6 mmol) in benzene (25 cm^3) was added slowly to a rapidly stirred suspension of phenylimido tungsten tetrachloride (1.0 g, 2.5 mmol) in benzene (30 cm^3) whereupon a homogeneous green solution formed. *t*-Butylamine (1.7 cm^3, 16.2 mmol) in benzene (10 cm^3) was added slowly and the mixture stirred for 3 h to give a pale orange solution and a white crystalline solid of amine hydrochloride. After filtering, the solvent was removed *in vacuo* and the residue held under vacuum for 1 h to remove any excess diol. The white solid was extracted with benzene or chloroform (30 cm^3), the solution filtered and the volume reduced to about one third. Cooling the solutions (benzene: iced-water, chloroform: −20°C) gave the complex as a white crystalline solid. Yield 0.58 g, 46%. M.p.: decomposes above 210°C. Found: C, 39.3; H, 6.8; $C_{18}H_{36}O_6W$ requires: C, 40.6; H, 6.8% (crystallised from benzene).

IR 1360 s, 1242 m, 1202 s, 1140 s, 1002 s, 960 s, 914 m, 880 s, 854 s, 788 m, 708 s, 620 s, 552 w, 498 s, 454 w, 387 s, 328 s, 280 w.

^1H NMR (δ, $CDCl_3$) 1.28 and 1.47 (2s, 12H, Mes). Free ligand 1.28, (s, 12H, Mes) 3.45 (s, 2H (D_2O exchange), OH).

^{13}C NMR (δ, $CDCl_3$) 24.71, (Me), 25.97 (Me), 97.17 (C–O). Free ligand 24.61 (Me), 74.87 (C–O).

Aniline from the reaction was identified as follows: The amine hydrochloride was dissolved in water and made alkaline with 0.1 M NaOH. Concentrated aqueous NaCl was added and the solution extracted with the solvent removed from the original reaction mixture. After separation and drying the solvent was removed. The residue contained aniline (t.l.c. comparison) and was purified (prep t.l.c.).

Reaction of pinacol-H_2 with $W(NPh)Cl_4$

2,3-Dimethyl-2,3-butandiol (0.74 g, 6.3 mmol) and *t*-butylamine (1.65 cm^3, 15.7 mmol) in petroleum ether (50 cm^3) were added slowly to a suspension of finely ground phenylimido tungsten tetrachloride (1.3 g, 3.1 mmol) in petroleum ether (160 cm^3) and the mixture stirred for 8 h whereupon an orange–red coloured solution was obtained along with precipitated amine hydrochloride and some unreacted $W(NPh)Cl_4$. After filtration the solvent was removed *in vacuo* to give an orange–red residue which was extracted with petroleum ether (100 cm^3). The resulting solution was filtered, the volume reduced and on standing for several days at −20°C crystalline products formed which were separated manually from other amorphous material.

(*a*) $[W_2(NHPh)_2(\mu\text{-}pinacol)(pinacol)_4]$ (**2**). This complex formed as large red crystals which were not obtained analytically pure. For example, Found: C, 42.1; H, 7.1; N, 1.5; $C_{42}H_{72}N_2O_{10}W_2$ requires: C, 44.5; H, 6.4; N, 2.4%. Redissolving the sample in petroleum ether, toluene or chloroform led to a lightening of solution colour and on cooling other yellow material deposited along with the red crystals.

IR 3325 w (NH), 3020 w (aromatics) 1594 m and 1585 m (aromatics), 1265 s, 1244 m, 1194 m, 1185 m, 1130 s (C–O), 1080 w, 1000 m, 984 m, 960 s, 890 s, 880 s, 860 s, 830 m, 758 s, 720 s, 708 s, 690 m, 765 m, 620 s (W–O), 510 w, 490 m, 454 w, 390 m, 323 m, 280 w, 270 w, 256 w.

^1H NMR (δ, $CDCl_3$). The solution lightens in colour to become yellow–orange. 1.32 and 1.48 (Mes of coordinated pinacol), 1.37 to 1.45, several resonances (Mes), 7.0 to 7.8, (m, 5H, aromatics). Ratio of aromatic and methyl protons 5:34. The final characterisation of the complex was by X-ray crystallography.

(*b*) $[W_2(NPh)_2(\mu\text{-}O)(pinacol)_2(pinacol\text{-}H)_2]$ (**3**). Very few crystals of this complex formed and these were used for an X-ray crystallographic examination.

(*c*) $W(pinacol)_3$ (**1**). The colourless crystalline material formed had identical decomposition point, IR and ^1H NMR spectra to the previously prepared compound.

Reaction of $W_2(NHPh)_2(\mu\text{-}pinacol)(pinacol)_4$ with pinacol-H_2

Petroleum ether (50 cm^3) was added to the red amido complex (0.2 g, 0.18 mmol) and 2,3-dimethyl-2,3-butandiol (0.05 g, 0.42 mmol) and the solution stirred for 2 h. Removal of the solvent and recrystallisation of the residue from toluene gave colourless crystals of $W(pinacol)_3$ (**1**) which had identical decomposition point, IR and ^1H NMR spectra to the previously prepared compound.

Crystallographic studies

Crystal data. Compound (**2**) $[W_2(NHPh)_2(\mu\text{-pinacol})(pinacol)_4]$: $C_{42}H_{72}N_2O_{10}W_2$, M = 1132.76, monoclinic, a = 15.086(3), b = 18.370(5), c = 18.428(5) Å, β = 106.04(2)°, U = 4908 $Å^3$; space group $C2/c$, Z = 4, D_c = 1.533 g cm^{-1}, $F(000)$ = 2264, μ(Mo-K_α) = 91.7 cm^{-1}.

Crystal data. Compound (**3**) $[W_2(NPh)_2(\mu\text{-O})(pinacol)_2(pinacol\text{-H})_2]$: $C_{36}H_{60}N_2O_9W_2$, M = 1032.59, orthorhombic, a = 10.571(1), b = 22.449(12), c = 34.142(5) Å, U = 8102 $Å^3$; space group $Pbca$, Z = 8, D_c = 1.693 g cm^{-1}, $F(000)$ = 4080, μ(Mo-K_α) = 60.7 cm^{-1}.

Data collection. Compound (**2**). CAD4 diffractometer, Cu-K_α radiation (λ = 1.5418 Å), $\omega/2\theta$ scan mode. Crystal (0.41 × 0.12 × 0.11 mm), sealed under N_2 in a quartz-glass capillary tube, 2532 data measured (θ_{max} = 49°). The intensities of three standard reflections, monitored during the data collection (2 h), showed an overall isotropic decline of 15%; the appropriate corrections were made to the complete data set.[25] Corrections were also made for absorption,[26] minimum and maximum correction factors being 0.876 and 0.999 respectively.

Data collection. Compound (**3**). CAD4 diffractometer, Mo-K_α radiation (λ = 0.7107 Å), graphite monochromator, $\omega/2\theta$ scan mode. Crystal (0.24 × 0.16 × 0.08 mm), sealed under N_2 in a quartz-glass capillary tube, 4872 data measured (θ_{max} = 21°); intensity drop, isotropic, 7% appropriate corrections made.[25] Corrected for absorption[26] minimum and maximum correction factors being 0.806 and 0.999 respectively.

Structural solution and refinement of compounds (**2**) *and* (**3**). Both structures were solved by Patterson and Fourier methods and refined by a full-matrix least-squares technique.[27] The final refinement cycle for compound (**2**) converged to values of 0.059 and 0.060 for R and R_w respectively for the 136 variables and 1023 data for which $F^2 > 3\sigma(F^2)$. The function minimized was $\sum w(|F_o| - |F_c|)^2$ with the weight, w, being defined as $0.9152/[\sigma^2(F) + 0.004549F^2]$. The final cycle for compound (**3**) converged to values of 0.071 and 0.074 for R and R_w respectively for the 231 variables and 1212 data for which $F^2 > 3\sigma(F^2)$; w being defined as $0.6840/[\sigma^2(F) + 0.009672F^2]$.

For compound (**3**) the oxygen atoms *trans* to the imido ligands are expected to be protonated [from the W–O (*trans*) bond lengths and electron counting assuming W(VI)]. However, the hydrogen atoms could not be located with certainty from a final difference Fourier synthesis and they were omitted

from the final refinement cycle; all other hydrogen atoms for both (2) and (3) were included in calculated positions (C–H, N–H; 1.08 Å).

For both complexes isotropic thermal parameters were assumed for all atoms other than tungsten (anisotropic thermal motion was assumed for these). All hydrogen atom temperature factors were fixed at $U = 0.10\,e\,\text{Å}^{-2}$. The amido and imido phenyl groups were treated as ideal C_6 hexagons (C–C 1.395 Å). The atomic scattering factors were taken from the tabulations of Cromer and Mann,[28] anomalous dispersion corrections were by Cromer and Liberman.[29]

Final atomic coordinates for both complexes, tables of anisotropic thermal parameters, complete listings of bond distances and angles and lists of F_o/F_c have been deposited with the Editor as supplementary material.*

(*Received* 4 *January* 1984; *accepted after revision* 10 *October* 1984)

Abstract—Reaction of dimethyldiacetoxysilane with aluminium isopropoxide was carried out in 1:2 molar ratio in refluxing cyclohexane and a mixed [Si(IV), Al(III)] μ-oxo-isopropoxide of the composition $Me_2SiO_2Al_2(OPr^i)_4$ was isolated. This compound was characterised by elemental analysis and IR and NMR spectral studies. The tertiary butanol derivative, $Me_2SiO_2Al_2(OBu^t)_4$, was prepared by alcoholysis. Reactions of this mixed [Si(IV), Al(III)] μ-oxo-isopropoxide with monobasic bidentate carboxylic acids, such as *trans*-cinnamic acid (HCA) and dihydrocinnamic acid (HDCA) and with dibasic tridentate carboxylic acids such as salicylic acid (H_2SA) and benzilic acid (H_2BA) were also studied. Products of the type $Me_2SiO_2Al_2(OPr^i)_{4-n}(L)_n$ [where HL = *trans*-cinnamic acid (HCA), dihydrocinnamic acid (HDCA) and $n = 1, 2, 3$ or 4] and $Me_2SiO_2Al_2(OPr^i)_{4-2n}(L)_n$ [where H_2L = salicylic acid (H_2SA), benzilic acid (H_2BA) and $n = 1$ or 2] were isolated and characterised by elemental and spectral studies.

Metal siloxides have aroused considerable interest in recent years because of their applicability in the synthesis of polymeric substances.[1] Synthesis of alkoxy siloxy derivatives of aluminium has been reported by Mehrotra and Pant[2] starting with trimethylacetoxysilane and aluminium isopropoxide. Preparation of polyaluminoorganosiloxanes reported by Zudanov and Andrianov[3] involves the interaction of aluminium butoxide and dialkyldiacetoxysilane. Reactions of alkylacetoxysilanes with aluminium isopropoxide were carried out by Yasuaki Nakaido[4] and Sugio Otani *et al.*[5] and the compounds so prepared were used for polymer preparation under the name "inorganic polymers". Literature survey reveals that there is no report on the synthesis of mixed [Si(IV), Al(III)] μ-oxo-isopropoxide. It was therefore, considered of interest to synthesise this mixed [Si(IV), Al (III)] μ-oxo-isopropoxide by reacting dimethyldiacetoxysilane with aluminium isopropoxide in 1:2 molar ratio in refluxing cyclohexane. The reaction can be represented as follows:

$$Me_2Si(OAc)_2 + 2Al(OPr^i)_3 \xrightarrow[\text{under reflux}]{\text{Cyclohexane}} Me_2SiO_2Al_2(OPr^i)_4 + 2Pr^iOAc\uparrow.$$

Due to its applicability in the synthesis of polymeric substances,[1] it was considered of interest to study the reactions of mixed [Si(IV), Al(III)] μ-oxo-isopropoxide with monobasic bidentate carboxylic acids like *trans*-cinnamic acid (HCA) and dihydrocinnamic acid (HDCA) and dibasic tridentate carboxylic acids like salicylic acid (H_2SA) and benzilic acid (H_2BA).

EXPERIMENTAL

All-glass apparatus with standard joints was used throughout the work. Utmost care was taken to exclude moisture from the system. Fractionating column of 30 cm length packed with Raschig rings and fitted with a variable reflux ratio still head was used.

Cyclohexane (B.D.H.), benzene (A.R., B.D.H.), isopropanol (B.D.H.), *tert*-butanol (B.D.H.) and ether (Alembic) were dried and purified by standard methods. *Trans*-cinnamic acid (HPC), dihydrocinnamic acid (Fluka), benzilic acid (Sisco) and salicylic acid (A.R., B.D.H.) were purified by recrystallization before use.

Dimethyldiacetoxysilane[6] (b.p. 44–45°C/3 mm) and aluminium isopropoxide[7] were prepared by standard methods.

* Author to whom correspondence should be addressed.

IR spectra were recorded on a Perkin–Elmer-621 spectrophotometer in Nujol mull and in thin film form using potassium bromide plates. NMR spectra were recorded in $CDCl_3$ on a Perkin–Elmer R-32 spectrometer. Isopropanol was estimated by oxidimetric method[8] using 1 N $K_2Cr_2O_7$ in 12.5% sulphuric acid. Aluminium[9] was estimated by titration with EDTA and silicon[10] was estimated gravimetrically as silicon dioxide. Carbon and hydrogen were determined by the microanalytical laboratory of Chemistry Department, Delhi University, Delhi.

Synthesis of mixed [Si(IV), Al(III)] μ-oxo-isopropoxide

Aluminium isopropoxide (22.44 g, 110 mmol) was weighed into a two-necked 250 cm^3 round bottom flask and 50 cm^3 of dry cyclohexane was added to it. To one neck of the flask was fitted a fractionating column and to the other neck of the flask, a dropping funnel containing dimethyldiacetoxysilane (9.68 g, 55 mmol) in 20 cm^3 of dry cyclohexane. The contents of the flask were allowed to reflux at a bath temperature of 110°C before starting the addition of the organo-silicon compound in such a manner that the solvent vapours reached up to the top of the column. The dimethyldiacetoxysilane contained in cyclohexane was now added dropwise from the funnel to the aluminium isopropoxide in the flask and for each drop of silane dropped, a drop of binary azeotrope of isopropyl acetate–cyclohexane was collected at 78–79°C. The addition of silane was completed in 2–3 h and thereafter the contents of the flask were further refluxed for another 2 h and the solvent coming out was collected at the top. The compound remaining in the flask with some cyclohexane was vacuum dried at a temperature of 30°C/0.3 mm. The colourless viscous liquid obtained was purified by vacuum distillation—b.p. 100–105°C/1 mm; yield (13.5 g, 65%).

Found: Al, 13.7; Si, 7.15; C, 44.3; H, 9.3; Pr^iOH, 60.5. Calc. for $Me_2SiO_2Al_2(OPr^i)_4$: Al, 14.2; Si, 7.37; C, 44.2; H, 8.95; Pr^iOH, 63.16%.

IR frequencies of $Me_2SiO_2Al_2(OPr^i)_4$ (cm^{-1}): 2980s, 2920s, 2860s, 2620w, 1740w, 1460s, 1390s, 1370s, 1360s, 1350m, 1330m, 1255s, 1210sh, 1170sh, 1120sb, 1080sb, 1040s, 960m, 945m, 880m, 860m, 835s, 820sh, 780s, 720sh, 680s, 630sb, 615sb, 570s, 540m, 510w, 475m, 450m, 440m, 430m, 420m, 410m, 390m.

^1H NMR of $Me_2SiO_2Al_2(OPr^i)_4$ in $CDCl_3$ solution shows a doublet at δ 1.1–1.35 and multiplet at δ 4.2 due to CH_3 and CH protons of the isopropoxy groups respectively and a singlet at δ 0.00 due to CH_3 protons of the dimethyl silyl group.

Reaction of $Me_2SiO_2Al_2(OPr^i)_4$ with excess of *tert*-butanol:

The mixed [Si(IV), Al(III)] μ-oxo-isopropoxide (1.25 g, 3.29 mmol) was refluxed with excess of *tert*-butanol (~5 cm^3) in 50 cm^3 of benzene for about 8 h at a bath temperature of 110°C and the liberated azeotrope of benzene–isopropanol collected between 72 and 80°C was estimated for isopropanol by oxidimetric method.[8] The *tert*-butanol derivative left in the flask along with some benzene was dried under vacuum at 35°C/0.3 mm for nearly 2 h, whereby a colourless thick liquid was obtained which solidified on keeping. The compound was purified by distillation under vacuum; b.p. 125°/0.6 mm; yield, 80%. The compound was soluble in benzene.

Found: Pr^iOH in azeotrope 0.79 g; Al, 12.25; Si, 6.2; C, 49.0; H, 9.4. Calc. for $Me_2SiO_2Al_2(OBu^t)_4H$: Pr^iOH in azeotrope, 0.79 g; Al, 12.39; Si, 6.42; C, 49.54; H, 9.63%.

Reactions of mixed [Si(IV), Al(III)] μ-oxo-isopropoxide with *trans*-cinnamic acid (1:1 molar ratio):

The mixed [Si(IV), Al(III)] μ-oxo-isopropoxide (1.08 g, 2.84 mmol) was refluxed with (0.428 g, 2.84 mmol) of *trans*-cinnamic acid in approximately 50 cm^3 of benzene for about 4 h using a fractionating column and the liberated azeotrope of isopropanol-benzene was collected at 72–80°C. The isopropanol in the azeotrope was estimated by oxidimetric method.[8] The acid complex left in the flask along with some benzene was dried under vacuum at 35°C/0.4 mm for about 1 h, when a white crystalline solid was obtained; yield, ~70%.

Found: Pr^iOH in azeotrope, 0.18 g; Al, 11.7; Si, 5.73; C, 50.9; H, 6.8. Calc. for $Me_2SiO_2Al_2(OPr^i)_3$ (CA): Pr^iOH in azeotrope, 0.18 g; Al, 11.54; Si, 5.98; C, 51.28; H, 7.26%.

RESULTS AND DISCUSSION

The mixed [Si(IV), Al(III)] μ-oxo-isopropoxide was synthesised taking aluminium isopropoxide and dimethyldiacetoxysilane in 2:1 molar ratio. The μ-oxo-isopropoxide so formed is a colourless, viscous liquid, which distils at 100–105°C/1 mm. The IR spectrum of $Me_2SiO_2Al_2(OPr^i)_4$ shows a band at 1255 cm^{-1}, assigned to the presence of Me_2Si group, a similar band appears at 1240 cm^{-1} in $Me_2Si(OOCCH_3)_2$. The strong absorption in the region 1040–1080 cm^{-1} is presumably due to Si–O bonds.[11]

The ^1H NMR spectrum of dimethyldiacetoxy-silane shows two singlets at δ 2.05 and δ 0.5 due to

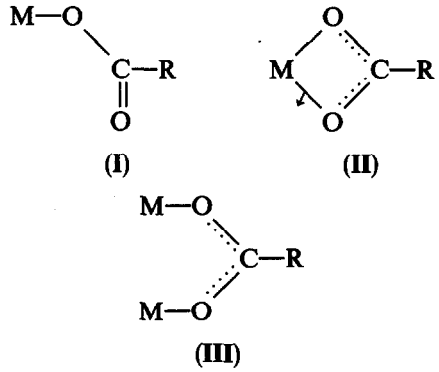
* Yield obtained was in the range 60–80%.

the methyl protons of acetoxy and dimethyl silyl groups respectively. However, in the complex absence of peak at δ 2.05 indicates the replacement of acetoxy group and appearance of a doublet and a multiplet in the region δ 1.1–1.3 and δ 4.2 ppm respectively due to CH_3 and CH protons of isopropoxy group, confirming the presence of isopropoxy groups. The methyl proton due to $\begin{matrix}Me\\ \diagdown\\ \diagup\\ Me\end{matrix}$Si of the compound appears as a singlet in the region δ (0.0 ppm), while in the case of dimethyldiacetoxysilane it appears at δ (0.5 ppm). The proton ratio of the methyl protons of $\begin{matrix}Me\\ \diagdown\\ \diagup\\ Me\end{matrix}$Si, methyl protons of isopropoxy group and methine protons of isopropoxy group was found to be 6:24:4 in the μ-oxo-isopropoxide synthesised from aluminium isopropoxide and dimethyldiacetoxysilane. Thus, spectral as well as elemental studies establish the formation of $Me_2SiO_2Al_2(OPr^i)_4$.

Alcoholysis reaction of the mixed [Si(IV), Al(III)] μ-oxo-isopropoxide was carried out with excess of tertiary butanol in refluxing benzene and a compound of the formula $Me_2SiO_2Al_2(OBu^t)_4$ was obtained and characterised by elemental analysis. The reactions of mixed [Si(IV), Al(III)] μ-oxo-isopropoxide with bidentate carboxylic acids like *trans*-cinnamic acid and dihydrocinnamic acid and tridentate carboxylic acids like salicylic acid and benzilic acid in different molar ratios proceed according to the following equation:

$$Me_2SiO_2Al_2(OPr^i)_4 + nHL \xrightarrow[\text{Reflux}]{\text{Benzene}} Me_2SiO_2Al_2(OPr^i)_{4-n}(L)_n + nPr^iOH\uparrow$$



where HL = *trans*-cinnamic acid (HCA), or dihydrocinnamic acid (HDCA) and n = 1, 2, 3 or 4.

$$Me_2SiO_2Al_2(OPr^i)_4 + nH_2L \xrightarrow[\text{Reflux}]{\text{Benzene}} Me_2SiO_2Al_2(OPr^i)_{4-2n}(L)_n + 2nPr^iOH\uparrow$$

where H_2L = salicylic acid (H_2SA) or benzilic acid (H_2BA) and n = 1 or 2.

It was found that the reaction proceeds with the removal of all the four isopropoxy groups from the mixed μ-oxo-isopropoxide. The complexes formed with dihydrocinnamic acid are all liquids and are soluble in chloroform and carbon tetrachloride. All other acid complexes are crystalline solids which are sparingly soluble in benzene, chloroform and carbon tetrachloride. All complexes are soluble in dimethylformamide and dimethylsulphoxide. Other details regarding the physical properties of the complexes are given in Table 1.

The IR spectra of the complexes of *trans*-cinnamic acid (HCA) and dihydrocinnamic acid (HDCA) show no absorption in the region 2700–2500 cm^{-1}, which indicates the replacement of the hydroxylic proton of the carboxylic group from the ligands. Apart from this, ν_{asym}(COO) of *trans*-cinnamic acid and dihydrocinnamic acid complexes which appears in the free acids at 1675 and 1705 cm^{-1} respectively shifts to 1550–1580 cm^{-1} (Δ 125 cm^{-1}) in the complexes, indicating that the carbonyl oxygen of the carboxylic group is strongly coordinated to aluminium in these complexes. The IR spectra of the complexes formed with salicylic acid and benzilic acid show no absorption in the regions 3420 and 3400 cm^{-1}, indicating the absence of hydroxy groups (phenolic, alcoholic) of salicylic and benzilic acid respectively. The disappearance of the band in the region 2700–2500 cm^{-1} indicates the removal of hydroxylic protons of carboxylic group of these two acids. The asymmetric carbonyl stretching frequency which appeared at 1720 cm^{-1} in benzilic acid and at 1665 cm^{-1} in the case of salicylic acid has shifted to lower frequency (1600 cm^{-1}, 1600 cm^{-1}) (Δ 120, 65 cm^{-1}) respectively, indicating the coordination of oxygen of C=O group of carboxylic to aluminium in the complexes. In general, the metal carboxylates can adopt the following modes of coordination:

The difference between the chelated (II) and bridging (III) structures can be understood on the basis of separation (Δ) between ν_{asym}(COO) and ν_{sym}(COO) frequencies. The coordination of both oxygen atoms to the same metal causes OCO angle to decrease and consequently the two CO bonds tend to be more equivalent, resulting in the low separation (Δ) values. In the present case of acid derivatives with $Me_2SiO_2Al_2(OPr^i)_4$, low separation values (125, 120, 65 cm^{-1}) may, therefore, be attributed to the presence of chelate (II) type of coordination. IR spectra of *trans*-cinnamic acid derivatives show no

noticeable shift in ν(C=C), which suggests that olefinic double bond is not involved in coordination. The other characteristic IR bands are given in Table 2.

^1H NMR spectra of the complexes formed with dihydrocinnamic acid were taken in $CDCl_3$. ^1H NMR spectra of the complexes $Me_2SiO_2Al_2(OPr^i)_3DCA$, $Me_2SiO_2Al_2(OPr^i)_2(DCA)_2$, $Me_2SiO_2Al_2(OPr^i)(DCA)_3$ and $Me_2SiO_2Al_2(DCA)_4$ do not show any signals at δ (10.8 ppm), which indicates the absence of the hydroxylic proton of the carboxylic groups. The resonance due to C_6H_5 and CH_2–CH_2 protons changed relatively little in the spectra of the complexes from their values in the free acid. In addition to the above peaks, these complexes show resonance due to methyl group of isopropoxy in general as a doublet in δ (1.1–1.3 ppm) region. The methine proton of isopropoxy group was observed at δ (4.5–5.0 ppm) as a complex multiplet.

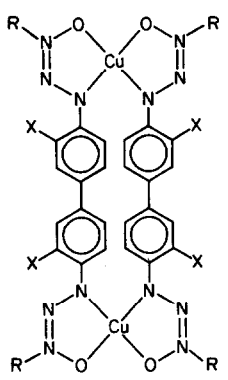
IDENTIFICATION OF Cu(II)/Cu(III) COUPLES IN BINUCLEAR COPPER(II) COMPLEXES



P. S. ZACHARIAS* and A. RAMACHANDRAIAH
School of Chemistry, University of Hyderabad, Hyderabad 500 134, India

(*Received* 17 *July* 1984; *accepted* 10 *October* 1984)

Abstract—A new series of binuclear copper(II) complexes were synthesised and studied by magnetic, spectral, ESR and cyclic voltammetry methods. The μ_{eff} values per copper atom correspond to the values observed for mononuclear copper(II) complexes. ESR spectral data in solution indicate weak interactions resulting from the electron delocalisation through the ligand system. Two nearly reversible red-ox couples are identified at $\tilde{+}0.50$ V and $\tilde{+}0.75$ V vs SCE. They correspond to Cu(II) $\rightleftharpoons$ Cu(III) red-ox processes, successively occurring at the two copper sites in the binuclear complexes.

The electron-transfer properties of binuclear copper(II) complexes are of current interest as models for the oxidoreductive functions of copper proteins.[1] A search for synthetic analogues of binuclear copper(II) systems to mimic the type 3 active site of copper proteins has resulted in the synthesis and study of a large number of binuclear systems.[2–5] Electrochemical studies of such binuclear complexes showed two distinct types of reduction behaviour associated with them. In one case the two copper(II) centres undergo a two-electron transfer involving both the copper centres at identical standard potential,[6–8] while in the other case they have two successive and distinct mono-electronic steps.[9–12]

Although oxidation of Cu(II) $\rightleftharpoons$ Cu(III) is known in many mononuclear tri- and tetra-peptide complexes[13,14] with potentials varying from $\tilde{+}0.40$ to +1.0 V, no examples of synthetic binuclear copper(II) systems with successive single electron oxidation steps are known except for the recent report of single electron oxidation occurring in trinuclear copper(II) systems.[16] Here we wish to report the first example of a binuclear copper(II) system undergoing two successive Cu(II) $\rightleftharpoons$ Cu(III) oxidation-reduction processes. A preliminary report on this system, appeared earlier.[17] The ligand framework and the structure of the copper complex are shown in structure 1. For convenience the complexes will be abbreviated as R–Cu_2–X where R refers to alkyl substituent and X to the substituent on the biphenyl ring. For example, bis {3,3′-dimethoxy-4,4′-bis(3-methyl triazene-3-oxide)biphenyl} di-copper will be represented as Me–Cu_2–OMe.

EXPERIMENTAL

The CHN analyses were done by the Australian Micro Analytical Service. Molecular weight measurements were carried out using a Knauer Osmometer in chloroform. Electronic spectra were recorded either on Cary 17 D or Shimadzu UV 200 S spectrophotometers. Magnetic susceptibility measurements were done by the Gouy method on a Bruker BM-6 set up. $Hg[Co(SCN)_4]$ was used as the calibrant. ESR spectra were recorded on a JEOL JES PE 3X model spectrometer. Cyclic voltammograms

* Author for correspondence.

were recorded on EG and G Electrochemistry system provided with PAR 174 A Polarographic Analyser and PAR 175 Universal Programmer and PAR X–Y recorder, in acetonitrile with tetraethyl ammonium perchlorate (TEAP) as the supporting electrolyte. Aqueous Saturated Calomel Electrode (SCE) as reference, platinum wire as auxiliary and platinum disc as the working electrodes constituted the three electrode system. Combined ESR-electrolysis experiment was done in an ESR electrolytic cell recording the spectra simultaneously.

Synthesis of the ligands. The ligand systems can be synthesised by adopting the procedure described earlier for the preparation of triazene-1-oxides.[15] It involved the tetrazotisation of the biphenyl diamines followed by coupling with alkylhydroxylamines. In a typical experiment 2.44 g (10 mM) of *o*-dianisidine was tetrazotised using 4.5 cm^3 of conc. HCl and 1.6 g (~ 20 mM) of sodium nitrite at 5–10°C. The tetrazotised solution was added to 1.7 g (~ 20 mM) of N-methyl hydroxylaminehydrochloride in water. The pH of the solution was adjusted to 8.0 by the addition of 10 g of sodium acetate in water, whereby the ligand precipitated instantaneously. The product was filtered and recrystallised from acetone.

Complexation with copper. The copper complexes were prepared by adding an aqueous solution of 200 mg (1 mM) of copper acetate dropwise to a hot acetone solution of 1 mmol of ligand while stirring. The black shining crystals which separated after cooling, were recrystallised from acetone and dichloromethane mixture (2 : 1).

RESULTS AND DISCUSSION

Magnetic and spectral data

The analytical data and molecular weight values of the copper complexes are shown in Table 1. These results agree well with the binuclear structure shown in structure 1. The room temperature magnetic moment values are also given in Table 1. They are comparable to the μ_{eff} values observed for many of the mononuclear copper(II) complexes. Variable low-temperature (14–298 K) magnetic moment measurements showed that the μ_{eff} values are constant, indicating the absence of any strong antiferromagnetic interaction, between the electrons on the two copper centres. The electronic spectral data are also presented in Table 1. There is only one band located at ~ 11,000 cm^{-1}. The similarity of spectra of both X = OCH_3 and X = CH_3 complexes suggests near identical environments for the copper atom in these complexes implying the non-participation of the potentially coordinating OCH_3 group in any observable degree of bond formation. Monomeric planar copper(II) complexes of triazene-1-oxides show only one electronic absorption band[17] at ~ 13,000 cm^{-1}. The shift of the band maxima to longer wave lengths in the binuclear systems compared to mononuclear systems is the

result of distortion from the planar to tetrahedral environment. An X-ray crystal structure determination carried out on Me–Cu_2–OMe shows that the geometry at the two copper(II) centres is best described as tetrahedrally distorted square planar.[18]

The ESR X-band powder spectra showed a strong absorption at $g \approx 2.080$. In chloroform solution at room temperature they showed seven line spectra with equal spacing between the lines. In frozen solution seven hyperfine components were resolved in the parallel region with no resolution of the hyperfine splitting in the perpendicular region. ESR spectra for a representative compound is shown in Fig. 1. Relevant ESR data calculated from RT and LNT chloroform spectra are presented in Table 2. Since the two copper centres are in the +2 oxidation state (μ_{eff} values are normal) the presence of seven equally spaced lines implies that the unpaired electrons are interacting equally with two copper nuclei. The predicted intensity ratio is 1:2:3:4:3:2:1. The observed intensities are qualitatively consistent with the predicted ratio, the central line being most intense. The deviations may be due to the overlapping of lines and M_I-dependent line width variation of hyperfine components. The g_{iso} of the dimer in solution is close to that of the monomer. The hyperfine spacings of the dimer is approximately half ($A_{iso} \approx 40$ G), of that for the monomer ($A_{iso} \approx 75$ G) as expected from the theory of isotropic exchange involving two equivalent copper ions. It is shown from the X-ray crystal structure data that the two copper centres are separated by ~ 12 Å in these complexes and hence direct copper–copper exchange can be ruled out. The exchange interaction then should be by electron delocalisation through the ligands. This can be expected since the *p* orbital of the nitrogen in the conjugated ligand system partly can overlap with the *d* orbital of the copper atom thereby providing a path for electron movement. The A_o values of these complexes both in liquid as well as frozen solution are much lower than those of planar copper species but slightly higher than the values of tetrahedral species. The lowering of A_o values is an indication of the distortion of the copper environments from planar to pseudotetrahedral.[18] This has been inferred from electronic spectral data and confirmed by X-ray data.

Electrochemical data

Typical cyclic voltammograms of Me–Cu_2–OMe at different scan rates are shown in Fig. 2. The relevant CV data for all complexes are collected in

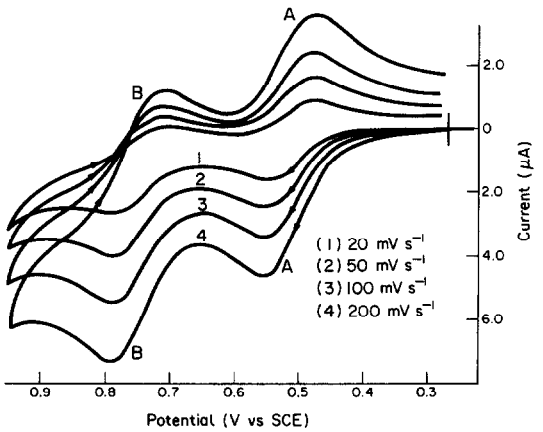

Fig. 2. Cyclic voltammograms of Me–Cu_2–OMe in acetonitrile at different scan rates. Solution concentration $\approx 1 \times 10^{-3}$ M, TEAP concentration $\approx 1 \times 10^{-1}$ M.

Table 3. All the compounds show the presence of two distinct couples *A* and *B* in the positive potential range, *A* being the couple at lower potential. In the negative potential range at ~ -1.1 V an irreversible peak complicated by adsorption was observed. The ligand system of these complexes do not have any cyclic voltammetric peaks in the potential range from 0.0 to +0.90 V. The observed E^o for couples *A* and *B* are at $\tilde{+}0.50$ V and $\tilde{+}0.75$ V respectively. The E_p values show that only a single electron is involved in each couple. The ΔE_p and i_{pa}/i_{pc} values also show the nearly reversible character of these redox couples. It can be seen from Table 3 that the separation between the two couples is 230 mV. It is known that non interacting metal centres of similar environments do not have a separation larger than $\sim$ 50 mV.[19,20] The weak copper–copper interaction in the present binuclear complexes (*vide infra* ESR) can induce CV wave splitting of a magnitude of a few hundred millivolts.

The two couples *A* and *B* can originate from either two Cu(II)$\rightleftharpoons$Cu(I) or two Cu(II)$\rightleftharpoons$Cu(III) one-electron processes. The nature of the elctron transfer process in these complexes has been identified by doing combined electrolysis, ESR and spectral studies in acetonitrile. Three potentials were selected to carry out these experiments: (i) 0.0 V, cathodic to both *A* and *B* couples: (ii) +0.65 V, cathodic to *B* and anodic to *A* (a potential between the two couples); (iii) +0.85 V, anodic to both *A* and *B*. The results of these experiments on one compound *n*-Pr–Cu_2–OMe are shown in Fig. 3. The electrolysis at 0.0 V did not change the ESR signals of the starting

complex even after a prolonged period. If the process at the copper site was a reduction, electrolysis at this potential should have resulted in the disappearance of the ESR signals since Cu(I) species is ESR inactive. This does not happen. Electrolysis at the potential +0.65 V resulted in partial loss of ESR signal intensities. This is expected since electrolysis at this potential will affect only one copper centre. Electrolysis at the potential +0.85 V, completely removed the ESR signals. These observations are compatible only with the oxidation of Cu(II) to Cu(III). The electrode processes can now be visualised as

$$\text{Couple } A: Cu_2(II) \rightleftharpoons Cu(III)Cu(II)$$

$$\text{Couple } B: Cu(III)Cu(II) \rightleftharpoons Cu_2(III)$$

Cu(III) (d^8) can be expected to be ESR inactive in planar or distorted planar configurations.

In another set of experiments, the electronic spectral behaviour of the same complex was analysed while electrolysis was done at the three potentials. The electrolysis at 0.0 V did not change the electronic spectral band at $\sim 11{,}000\ cm^{-1}$ of the starting Cu(II) complex even after a prolonged period. But this band completely disappeared when electrolysed at +0.85 V.

THE REACTION OF AQUA-(ETHYLENEDIAMINETETRA-ACETATO)RUTHENIUM(III) WITH *o*-PHENYLENEDIAMINE UNDER AEROBIC CONDITIONS

YUKICHI YOSHINO,*† MICHIO KASAHARA and MASAMI SAITO
College of Arts and Sciences, The University of Tokyo, Meguro-ku, Tokyo 153, Japan

(*Received* 30 *April* 1984; *accepted* 20 *October* 1984)

Abstract—An electron-transfer reaction between [Ru(III)(Hedta)(H_2O)] and *o*-phenylenediamine in the presence of O_2 takes place to give a Ru(II)-edta complex with coordinated (bidentate) *o*-benzoquinone diimine. The complex obtained has been characterized by analysis, magnetic measurements, electronic, IR, ^1H and ^{13}C NMR spectral data.

The extraordinary substitution reactivity of the pentadentate edta complex of ruthenium(III), [Ru(Hedta)(H_2O)], has been reported by several authors.[1–5] In the course of our studies on the substitution reaction of [Ru(Hedta)(H_2O)] with aromatic amines in solution, we have noticed that *o*-phenylenediamine (*o*-pda) gave an unusually intense red colour. A close examination of the reaction product revealed that an unexpected reduction of Ru(III) to Ru(II) and oxidation of *o*-pda to *o*-benzoquinone diimine (*o*-bqdi) had taken place during chelation under aerobic conditions.

EXPERIMENTAL

Preparation of complexes. [Ru(III)(Hedta)(H_2O)]. The complex was prepared by a modification[1] of the method of Mukaida *et al.*[6]

Ru(II)(H_2edta)(*o*-bqdi)]·$2H_2O$. A hot aqueous solution containing 0.817 g (2.0 mmol) of [Ru(III)(Hedta)(H_2O)] and 0.238 g (2.2 mmol) of recrystallized *o*-phenylenediamine was heated for several hours on a water bath. After standing overnight, the reaction mixture was evaporated and concentrated on a water bath. On cooling the solution, the reddish purple crystals separated and they were washed with ethanol and diethyl ether. Yield, 87%. Found: C, 36.31; H, 4.53; N, 10.53. Calc. for $C_{16}H_{24}N_4O_{10}Ru$: C, 36.02; H, 4.53; N, 10.50%.

Physical measurements. The electronic and IR spectra were recorded on a Hitachi 124 spectrophotometer and JASCO 403G IR spectrophotometer, respectively. The magnetic susceptibility was measured by a Gouy magnetic balance at room temperature. ^1H and ^{13}C NMR spectra were obtained by JEOL PMX 60 (60 MHz) NMR spectrometer using DMSO-d_6 and D_2O solutions at an ambient temperature. Tetramethylsilane was used as an internal standard.

RESULTS AND DISCUSSION

When an aqueous solution of

[Ru(III)(Hedta)(H_2O)]

was mixed with a slight excess of *o*-phenylenediamine the reaction mixture gave reddish purple colour and after heating for several hours the electronic spectrum showed an absorption maximum at 480 nm ($\log \varepsilon = 4.14$). The mole ratio plot of the extinction of the reaction mixture revealed that the ruthenium-edta complex and *o*-phenylenediamine react in a 1 : 1 ratio. Together with the analytical data given above, the results suggest that the product is a complex in which Ru, edta and *o*-pda (or its reaction product) are combined in a ratio 1 : 1 : 1.

The magnetic measurements showed that the product complex was diamagnetic. In the IR spectra, besides bands at 1630 cm^{-1} (COORu) and 1723 cm^{-1} (COOH), those at 3216 cm^{-1} (NH) and 1600 cm^{-1} (C=N + C=C) were observed.[7,8] In the

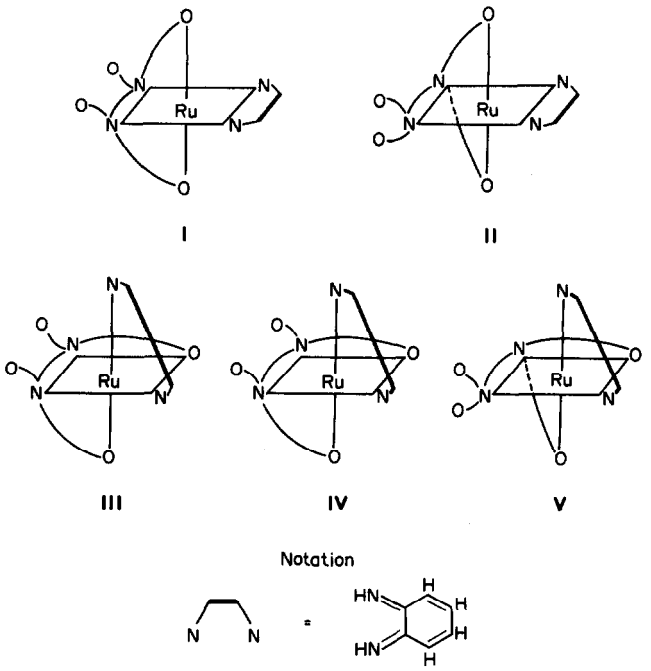

Fig. 1. Possible geometrical isomers for Ru(II) complexes with tetradentate edta and bidentate *o*-benzoquinone diimine.

^{1}H NMR spectrum, the resonance due to imine appeared at 12.7 ppm and this may correspond to that of $K_2[Fe(CN)_4(o\text{-bqdi})]$ at 11.9 ppm.[9] From the pH titration curve, the pK values were calculated as $pK_1 = 3.1$ and $pK_2 = 3.9$ at 30°C and ionic strength 0.1.

On the basis of these observations, it was presumed that, in the reaction of *o*-pda with [Ru(Hedta)(H_2O)], Ru(III) is reduced to Ru(II) and *o*-phenylenediamine is oxidized to *o*-benzoquinone diimine,[7,9] thus

$$[Ru(III)(Hedta)(H_2O)] + o\text{-pda} + \tfrac{1}{4}O_2 \rightarrow [Ru(II)(H_2edta)(o\text{-bqdi})] + \tfrac{3}{2}H_2O.$$

For the octahedral complex with tetradentate edta and bidentate *o*-benzoquinone diimine five geometrical isomers are possible as shown in Fig. 1. When the glycinate arms occupy both equatorial and axial positions (III, IV and V), the ^{13}C NMR spectrum of edta should give seven peaks. In our case, however, only five peaks were observed. It can therefore be presumed that the glycinate arms occupy axial positions (I and II). For the tetradentate edta complex, [Ru(H_2edta)($CH_3CN)_2$], Diamantis and Dubrawski[5] suggested a structure corresponding to I from the stereochemical consideration of the formation route. Similar reasoning will be applicable to the structure of [Ru(H_2edta)(*o*-bqdi)] and we conclude that the most likely isomer is I. The assignments of the observed ^{13}C NMR chemical

AMINOARSOLANES—II. CONFORMATIONAL STUDIES[1]

L. K. KRANNICH, C. L. WATKINS* and R. K. KANJOLIA
Department of Chemistry, University of Alabama at Birmingham, Birmingham, AL 35294, U.S.A.

(*Received* 27 *July* 1984; *accepted after revision* 1 *November* 1984)

Abstract—^{1}H and ^{13}C NMR spectra of six dialkylaminoarsolanes were obtained as a function of solvent, concentration, and temperature. CI mass spectral data were also obtained as a function of retention time for the same compounds. These results suggest that the As–N bond is not labile as compared to the As–Cl bond in chloroarsolanes. No evidence for dimer formation was noted either in solution or the gas phase under the investigated experimental conditions. The averaged solution conformation of the 1,3-dioxarsolane ring is discussed in terms of rapid intramolecular conformational averaging; nature of substituents at the 2, 4, and 5 positions; and effects of temperature, solute concentration and solvent type.

Several NMR studies of 1,3,2-dioxarsolanes (X = Y = O; see Scheme 1) and related five-membered ring compounds (X = Y = S; X = O, Y = S, Z = Cl, OCH_3, SPh, SCH_3, CH_3, OPh, Ph, $N(Ph)_2$, $N(R)_2$, where R = alkyl) have been reported, the primary goal of these studies being to understand the solution conformation of the arsolane ring.[2–14,23]

The study of the solution conformation of these five-membered rings is complicated by the fact that there is often ease of interconversion between several equi-energy conformers. Previous NMR studies have demonstrated that the 1,3,2-dioxarsolane ring adopts a nonplanar conformation with rapid intramolecular averaging between two half-chair (C_2) or twist-envelope forms, the barrier to interconversion being very low.[2–8,12–14] However, inversion at the arsenic is slow on the NMR time scale, the barrier being calculated to be at least 105 kJ/mol.[3,8,9,15–18] Thus, unsymmetrical substitution at the C(4) and C(5) positions can lead to the formation of *cis* and *trans* isomers, which may be detected by ^{1}H and ^{13}C NMR spectroscopy.[4–6,8,9,13]

The appearance of the ^{1}H and ^{13}C NMR spectra of the 1,3,2-dioxarsolanes and related compounds can be directly affected by intermolecular exchange processes, if the processes cause inversion at the arsenic. For such processes to occur in the present study, the As–Z bond must be labile. For example, concentration and temperature dependent ^{1}H NMR studies on solutions of 2-chloro-1,3,2-dioxarsolane and related compounds demonstrate that a rapid bimolecular exchange process occurs that involves chlorine exchange. This leads to apparent inversion at the arsenic.[3–7,9,12,19]

As previously reported, dialkylaminoarsolanes readily undergo transamination at room temperature in the presence of ammonia, primary, or secondary amines,[1] indicating that the As–N bond is quite reactive in the presence of species containing the weakly protonic N–H group. However, the lability of the As–N bond cannot be necessarily inferred from its reactivity. Two preliminary ^{1}H NMR studies on the solution stability of aminoarsolanes have been reported[2,11] in which the ^{1}H NMR spectra were temperature independent, indicating no intermolecular exchange processes occurring on the NMR time scale. In the present study, the ^{1}H and ^{13}C NMR data for compounds I–VI have been obtained as a function of temperature, concentration, solvent, and magnetic field strength in order to assess the relative importance of intramolecular and intermolecular exchange processes in determining the solution conformation of these aminoarsolanes. These studies thus allow a comparison of the As–Cl versus the As–N bond lability in the arsolane ring system. Also, chemical ionization (CI) mass spectral studies were conducted for comparison with the previously reported electron impact (EI) mass spectral studies[1,20] and a CI mass spectral study in which dimerization of the aminoarsolanes in the gas phase was reported.[21]

EXPERIMENTAL

Synthesis. The aminoarsolanes, compounds **I–VI**, were synthesized as previously reported.[1,22] Satisfactory elemental analyses for C, H, N, and As were obtained.

NMR studies. The ^{13}C and ^{1}H NMR spectral data were obtained on a Nicolet NMC-300/WB Fourier-transform NMR spectrometer operating at 75.475 MHz for ^{13}C and 300.132 MHz for ^{1}H. The ^{1}H NMR spectra for the six compounds were obtained at four concentrations ranging from 0.0032 M to 0.2 M in each of the three solvents benzene-d_6, toluene-d_8, and chloroform-*d*. A temperature dependent ^{1}H NMR study, over the liquid range of the solvent, was conducted for each compound in each solvent and at each concentration. The ^{1}H NMR spectra were also obtained at 25°C for each of the compounds in carbon tetrachloride solution for comparison with previously reported ^{1}H NMR values for compound **IV**.[11] Temperature dependent ^{13}C NMR spectra were obtained for compounds **I–VI** in the solvents benzene-d_6 and chloroform-*d* at a solute concentration of 0.2 M. The ring protons of compounds **IV–VI** exhibit AA'BB' non first-order ^{1}H-NMR spectra. The spectra were analyzed using the Nicolet library program ITRCAL. 400 MHz ^{1}H NMR spectra of compounds **IV–VI** were obtained on a Bruker WH-400 NMR spectrometer (25°C, 0.2 M) in order to verify the accuracy of the calculated ^{1}H chemical shifts and coupling constants. The spectra were analyzed using the Bruker library program PANIC. The two sets of calculated results agree within experimental error. The ^{13}C NMR spectra of the $-OCH_2CH_2O-$ moiety of **IV–VI** were of the AA'BB'X type and were analyzed using the ITRCAL program. The free induction decay in each experiment consisted of 32K data points, yielding a real spectrum of 16K data points. The corresponding digital resolution was 0.50, 0.25, and 0.10 Hz per data point for the decoupled ^{13}C, coupled ^{13}C and ^{1}H NMR experiments, respectively.

Mass spectral studies. Low resolution CI mass spectral data were obtained on a Hewlett–Packard 5985A GC/MS/DS mass spectrometer using isobutane as the ionizing gas. The source temperature was maintained at 200°C with no heating at the probe. The source pressure was 1.0 torr.

RESULTS AND DISCUSSION

^{1}H NMR studies. The ^{1}H NMR spectra of compounds **I–III** are similar, exhibiting two equally intense resonances for the CH_3 groups at the C(4) and C(5) positions. The higher frequency resonance is assigned to R(1) and R(2)—the CH_3 groups *syn* to the $-NR_2$ substituent.[23] The fact that two resonances are present for the methyl group protons indicates that there is rapid intramolecular conformational averaging, presumably between half-chair forms, with no inversion at the arsenic.[2–8,12–14] A static nonplanar structure would be expected to exhibit four methyl resonances whereas one resonance would arise from an averaged planar structure. The ^{1}H NMR chemical shifts of compounds **I–III** are given in Table 1 (0.2 M, 25°C) where Δf(Hz) represents the chemical shift difference between the ring methyl groups.

The ^{1}H NMR spectra of compounds **IV–VI** exhibit a 24-line non first-order pattern for H(1)–H(4), which is analyzed to be that of an AA'BB' type, as previously reported for arsolanes.[11,12,23] The existence of an AA'BB' spectral pattern instead of an ABCD type indicates rapid intramolecular conformational averaging. Analysis of the AA'BB' spectrum leads to two chemical shifts and four coupling

[b] Additional coupling, $^4J(^1H, ^1H) = 0.5$ Hz.

constants. These calculated values for compounds IV–VI are given in Table 2 (0.2 M, 25°C). The downfield ^{1}H NMR chemical shift is assigned to the two protons *syn* to the dialkylamino group. The values of the geminal coupling constant ($^2J(1, 3)$, $^2J(2,4)$) range from −8.92 to −9.12 Hz in agreement with reported values for analogous arsolanes[23] and phospholanes.[24,25] The two *cis* coupling constants ($^3J(1, 2)$, $^3J(3, 4)$), however, are not identical as reported in a previous 1,3,2-dioxarsolane study,[23] but differ slightly (5.2–5.4 vs 5.82–6.05 Hz). A theoretical basis for the nonequivalence of *cis* couplings in five membered ring compounds has been recently proposed.[39] The *trans* coupling constant, $^3J(2, 3)$, is larger than the *cis* coupling constants, as previously observed.[23] The variation in the *cis* and *trans* coupling constants of the –O–CH_2–CH_2–O– moiety reflects changes in the corresponding torsional angle. The *R* factor method of Lambert[26] has been employed to calculate the torsional angle for compounds IV–VI (Table 2). An average value of 46° is obtained in comparison with previous studies on 2-chloro-1,3,2-dioxarsolane[12] (46°), 2-dimethylamino-1,3,2-dioxarsolane in CCl_4 solution[11] (47°), and other 2-substituted dioxarosolanes[23] (46°). *R* value calculations on a series of five-membered rings including dithiarsolanes, dithiaphospholanes, dithiolanes, dioxaphospholanes, dioxolane, diazarsolanes, and diazaphospholanes give torsional angle values in a range of 41–55°.[23]

The CH_3, C_2H_5, and n-C_3H_7 protons in the dialkylamino functional group each exhibit only one set of first-order ^{1}H NMR resonances for compounds I–VI suggesting that the two given alkyl groups are magnetically equivalent and there is no restricted rotation about the As–N bond. The ^{1}H NMR chemical shift values observed are typical values for secondary amines and are listed in Table 1. The ethyl and *n*-propyl groups exhibit typical first-order coupling patterns, where the average $^3J(^1H, ^1H)$ value = 7.2 ± 0.2 Hz.

The ^{1}H NMR spectra of compounds I–VI were determined as a function of concentration in order to determine if any self-association or intermolecular conformational averaging occurred for the solute molecules in the four solvents. Adler and Kober[27] reported that compounds I and IV form dimers in benzene solution as evidenced by vapor pressure osmometry molecular weight measurements. They also argued that as the size of the alkyl substituent was increased, that dimer association would decrease. The ^{1}H NMR chemical shifts for the six solute molecules are essentially concentration independent in each of the solvents, indicating no

intermolecular exchange processes as in 2-chloro-1,3,2-dioxarsolane[3–7,9,12,19] and indicating no measurable monomer–dimer equilibria in solution. Previously reported cryoscopic molecular weight determinations[1] in benzene solution for compounds I–VI indicate monomeric species only to be present.

A comparison of the ^{1}H NMR chemical shift data for a given compound in the four solvents demonstrates general medium effects (Tables 1 and 2). For compounds I–III, the methyl ring and alkyl ^{1}H NMR resonances are shifted to lower frequency (higher field) in the two aromatic solvents, compared with the same resonances in $CDCl_3$ solution. For compounds IV–VI, the ring hydrogen and alkyl ^{1}H NMR resonances are shifted to lower frequency in the aromatic solvents and to higher frequency in $CDCl_3$ in comparison with CCl_4 solution. The Δf value for an individual compound is independent of solvent suggesting no strong preferential solute–solvent interactions. Solvent effects have been previously observed in the ^{1}H NMR spectra of ethylene sulfite, $\overline{OCH_2CH_2OSO}$, and attributed to solvent magnetic anisotropy effects in the case of benzene and intermolecular hydrogen bonding in the case of $CDCl_3$.[25] A comparison of the ring methyl resonances for compounds I–III for a given solvent indicates that the medium effects are dependent on the nature (size) of the R group in the dialkylamino moiety. For example, the ring methyl resonances move to lower frequency in C_6D_6 solution as R is changed from *n*-C_3H_7 to C_2H_5 to CH_3, while the same resonances move to higher frequency in $CDCl_3$ solution. The same trends for R group substitution are observed for the ring hydrogen resonances in compounds IV–VI. However, there is no chemical shift dependence on the R group in CCl_4 solution.

The temperature dependent ^{1}H NMR studies indicate no major changes in the spectral patterns for compounds I–VI in any of the investigated solvents. However, solvent medium effects were observed as discussed above. No intermolecular conformational averaging (amino group exchange) was observed, indicating that the As–N bond, in contrast to the As–Cl bond, is not labile under these experimental conditions. No monomer–dimer equilibria were noted in the temperature studies. The dialkylamino R groups remain magnetically equivalent even at −90°C ($C_6D_5CD_3$ solution) indicating no restricted rotation about the As–N bond. The Δf values are essentially temperature independent and the spin–spin coupling and torsional angle values are temperature independent, suggesting that the intramolecularly exchange averaged half-chair conformation(s) exists over all experimental conditions in the present study. The ^{1}H NMR chemical shifts are mildly temperature dependent for both the ring and alkyl group protons for the six compounds. As would be expected, the ^{1}H NMR resonances move to lower frequency with decreasing temperature in the aromatic solvents and to higher frequency with decreasing temperature in $CDCl_3$ solution, due to the solvent effects previously discussed. No

Table 3. ^{13}C NMR chemical shifts and ^{13}C–^{1}H coupling constants of compounds I–VI[a–c]

temperature dependence of the ^{1}H NMR chemical shifts was noted in CCl_4 solution.

^{13}C NMR studies. The ^{13}C NMR chemical shifts and ^{13}C–^{1}H coupling constants are given for compounds I–VI in Table 3 (0.2 M, C_6D_6 solution, 25°C). Two methyl ring resonances are observed for I, the difference in their chemical shifts, Δf, being 14.1 Hz in C_6D_6 solution and 6.4 Hz in $CDCl_3$ solution. The ^{13}C chemical shifts at lower frequency are assigned to R(1) and R(2), the methyl groups *cis* to the 2-substituent, based on previous assignments in analogous dioxaphospholanes,[28–30] dioxolanes,[31] and dioxarsolanes.[23] The chemical shift difference between the *cis* and *trans* methyl groups depends on solvent and the nature of the substituent group at the 2-position. As Z changes fron $-N(CH_3)_2$ to $-N(n\text{-}C_3H_7)_2$ in I–III, Δf decreases from 14.1 to 0.9 Hz in C_6D_6 solution. However, only I exhibits two distinct methyl group resonances in $CDCl_3$ solution. The variation in chemical shift of the ring methyl resonances with solvent, temperature, and substituent group at the 2-position is small, indicating that the average solution conformation of the five-membered ring is affected only slightly by these factors.[32] The ^{13}C chemical shifts of C(4) in IV–VI (66.96–66.53 ppm, C_6D_6 solution) are similar to those previously reported for the 1,3,2-dioxarsolanes where Z = Cl (68.7 ppm), OCH_3 (67.8 ppm), OC_6H_5 (67.7 ppm), SCH_3 (67.7 ppm), and SC_6H_5 (67.5 ppm),[23] suggesting that the relative effect of the 2-substituent on the C(4) ^{13}C chemical shift is small. Substitution of four methyl groups at the C(4) and C(5) positions causes a downfield chemical shift of C(4) by 13.9–14.3 ppm in I–III. The chemical shift effect of methyl substitution on the ring carbons in five-membered rings has been previously reported.[31,33,34] Simple α and β effects of methyl group substitution on alkyl chains[35] are not sufficient to explain the observed shifts. Consideration of the parameters of Eliel, Rao, and Pietrusiewicz[33] for 1,3-dioxolanes (α, β, γ, *vic*, *gem*)[34] plus the previously reported data on 1,3,2-dioxarsolanes by Aksnes and Lie[23] indicate that the α,β, *vic* parameters for 1,3,2-dioxarsolanes are very similar to those of 1,3-dioxolanes. (Sufficient data were not available for the evaluation of the γ and *gem* parameters.)

Such evidence implies that substitution on the five-membered ring causes conformational changes dictated by the steric requirements of the substituents.[30,32] An analogous study of methyl group substitution in the 1,3,2-dioxaphospholanes concluded that there was a modification of the geometry about the phosphorus atom and in the $-O-CH_2CH_2-O-$ torsional angle upon introduction of four methyl groups at the C(4) and C(5) positions.[30]

The ^{13}C NMR spectra of the dialkylamino groups in I–VI in each case consist of only one set of equivalent resonances, even at low temperature, further suggesting no restricted rotation about the

As–N bond. The ^{13}C chemical shifts can be adequately explained for the alkyl groups by consideration of simple α, β, and γ intrachain and interchain shielding effects.[35] The one-bond ^{13}C–^{1}H coupling constants for the diakylamino groups in **I–VI** and the ring methyl groups in **I–III** (Table 3) exhibit typical values.[35]

The analysis of the coupled ^{13}C NMR spectra for the C(4) and C(5) carbons in **IV–VI** is rather difficult due to accidental degeneracy and the fact that the analogous ^{1}H NMR spectra are non first-order. The spectra were analyzed as those of the AA'BB'X type (X = ^{13}C) with no correction for isotopic shifts. The data (Table 3) indicate that the $^{1}J(^{13}C, ^{1}H)$ values are slightly different ($^{1}J(1, 5)$ vs $^{1}J(3, 5)$) and large compared to typical aliphatic $^{1}J(^{13}C, ^{1}H)$ values due to the electronegative substituent effect of the directly bound oxygen. The $^{2}J(^{13}C, ^{1}H)$ values are within the range normally expected for aliphatic molecules containing electronegative substituents (−5 to 2 Hz)[23,36] with $^{2}J(4, 5)$ more negative than $^{2}J(2, 5)$ in each case. The data are in excellent agreement with those previously reported for 1,3,2-dioxarsolanes.[23]

The ^{1}H and ^{13}C NMR data are consistent with the proposed model that there is rapid intramolecular conformational averaging of the ring and no inversion at the arsenic. Additionally, there appears to be no restricted rotation about the As–N bond. Interestingly, the ^{1}H NMR chemical shifts of **I–VI** are subject to medium effects, which are reflected in the temperature-dependent spectra. Variation of the substituent at the 2-position has only a small influence on the ^{1}H and ^{13}C NMR spectral parameters. The above factors seem to have little, if any, influence on the average solution conformation. The As–N bond is not labile as is the As–Cl bond in the 2-chloro-1,3,2-dioxarsolanes. **I–VI** exist as monomers in solution under all investigated conditions. The substitution of four methyl groups at the C(4) and C(5) positions alters the average ring geometry in a manner which minimizes steric interaction of the substituent groups.

Mass spectral studies. EI mass spectral investigations on aminoarsolanes have suggested that fragmentation proceeds via amino group elimination to give stable five-membered cyclic arsenium ions.[1,20] The fragmentation pathways have been proposed on the basis of the observed metastable peaks. CI mass spectral data have been previously reported on some of these aminoarsolanes.[21] The results have been interpeted in terms of dimerization of the parent ion.[21,38] Also, molecular weight determinations by vapor pressure osmometry on

these and related compounds indicate molecular association to be occurring in benzene solution.[27,37] However, in our previous report on the synthesis of **I–VI** cryoscopic molecular weight determinations in benzene solution indicate the existence of only monomeric species.[1] Furthermore, the present ^1H and ^{13}C NMR studies suggest no self-association (dimerization) to be occurring in solution. CI mass spectral studies have been systematically conducted in order to investigate possible association in the gas phase. The data are given in Table 4.

The CI mass spectral data are dependent on retention time for each compound. The spectra obtained at low retention time exhibit $[M+H]^+$ as the base peak with the other major peak being assignable to $[M-NR_2]^+$. No evidence of $[M_2+H]^+$ or subsequent dimer fragments[21] was noted at low retention time, indicating the absence of dimers in the vapor phase under our experimental conditions. As the retention time is increased, chemical self-ionization ensues and an associated species of the type $[M_2-NR_2]^+$ forms, which becomes the major peak. No species of the type $[M_2+H]^+$ was detected under the present experimental conditions as previously proposed.[21] The formation of $[M_2-NR_2]^+$ via a chemical self-ionization process is further substantiated by single ion monitoring where the ion-current of $[M+H]^+$ remains constant, but the ion-current of $[M_2-NR_2]^+$ increases as a function of time.

ELECTROCHEMICAL SYNTHESIS OF COPPER(II) CARBOXYLATES

J. S. BANAIT* and P. K. PAHIL
Department of Chemistry, Punjabi University, Patiala-147002, India

(*Received* 2 *July* 1984; *accepted after revision* 1 *November* 1984)

Abstract—A number of copper(II) carboxylates have been synthesized by anodic oxidation of copper. The reactions were found to proceed with current efficiencies of 0.95 to 1.00 eq./Faraday. Reaction products have been characterized by infrared spectral studies and analysis of copper.

Reactions of carboxylic acids at inert anodes have been found to depend upon the nature of the carboxylic acids, e.g., monocarboxylic acids yield hydrocarbons (Kolbe reaction),[1,2] α-substituted carboxylic acids yield aldehydes and ketones,[3,4] unsaturated carboxylic acids yield alkynes[5,6] and dicarboxylic acids yield a number of degradation products.[7] All these reactions proceed through the formation of free radicals at the electrode surface. Recently, Tuck *et al.*[8–10] have shown that the free radicals formed electrochemically react with the active electrodes to yield inorganic and organometallic compounds. In the present communication, reactions of various carboxylic acids at the copper anode are reported.

EXPERIMENTAL

Material and equipment. Conductivity water was prepared by the usual method and had been used as solvent. Carboxylic acids (BDH AnalaR) and tetrabutylammonium chloride (Reidel, pure) were used without further purification.

H-type electrolysis cell made of pyrex glass was used to carry out the electrochemical reactions. The cathode and anode compartments were separated from each other by a sintered disc of G-3 porosity. Volume of one of the compartments was almost three times that of the other one.

Platinum foil, 1 × 1 cm, was used as cathode. A thick layer of copper had been deposited electrochemically[11] on a sheet of copper, 5 × 5 × 0.2 cm, in order to ensure the purity of the anode material.

Direct current was obtained with the help of a Toshniwal electrophoresis power supply.

Procedure. All the carboxylic acids were studied voltametrically using tetrabutylammonium chloride as supporting electrolyte and Radilkis, AC/DC (Type OH-103) polarograph. The cathode and anode were made of platinum and copper respectively.

Solution of the carboxylic acid (5 g) in 250 cm^3 of water was taken in the electrolysis cell. Copper plate freshly electroplated with copper was dipped in the larger compartment and platinum foil in the other one. Necessary connections were made with the power supply and potential across the electrodes was then adjusted so that a current of about 20 mA passed through the cell. Electrolysis was carried out for 6 h. The solution in the anode compartment was then taken out and concentrated under reduced pressure to a volume of 20–30 cm^3. On cooling, crystals separated out which were filtered, washed with methanol and recrystallyzed.

Copper(II) carboxylates of all these acids had been synthesized by the method reported by Graddon and Munday.[12]

Infrared spectra of the products of electrochemical reactions and the synthetic copper(II) carboxylates were scanned on Beckmann IR-20 spectrophotometer in Nujol using sodium chloride plates in the region of 4000–600 cm^{-1} and polythene plates in the region of 600–200 cm^{-1}.

Copper contents in the products were estimated volumetrically.[11]

RESULTS AND DISCUSSION

Solutions of propionic, *n*-butyric, benzoic, oxalic, succinic, phthalic, isobutyric, salicylic, tartaric and crotonic acids in water have been first studied voltametrically. Current–potential curves of these

* Author to whom correspondence should be addressed.

acids show that all the acids react at the copper anode at a potential less than even 2 V. Electrolysis of the acids at a potential corresponding to the plateau of the current–potential curve and under the conditions similar to that of voltametry produce blue/green coloration in the anode compartment. However, several attempts including column chromatography, preparative TLC, fractional crystallization, etc., failed to separate the product from the reaction mixture in the purified form even if the electrolysis have been carried out for 2–3 days. This may be because of the fact that at a potential of less than 2 V, a current of only a few microamperes passes through the cell resulting in the formation of a very small amount of the product and separation of the inorganic compound (which is ionic or highly polar in nature) from a solution containing sufficient quantity of the supporting electrolyte is difficult.

Electrolysis of the acid solutions (5 g/250 cm^3 of water) has therefore been carried out at a sufficiently higher potential[13] so that a current of about 20 mA passes through the cell. As the conductance of the solutions at such a high concentration of the acids is very high, no supporting electrolyte has been added and the solution has also been stirred during electrolysis. Under these modified conditions sufficient amounts of the products have been isolated. The electrolysis characteristics have been summarized in Table 1.

All the compounds formed are soluble in water. Except for the compound of salicylic acid, the solubility of all these compounds is significantly high and the solutions of these compounds in water are highly conducting, showing thereby the ionic nature of these compounds. In commonly used organic solvents, these compounds are almost insoluble. However, in acetone the compound of benzoic acid is highly soluble and those of other carboxylic acids are partially soluble.

Melting points of all these compounds have been found to be higher than 200°C.

Copper contents in these compounds determined volumetrically correspond to the respective copper(II) salts of these acids with appropriate water molecules associated with the crystal lattice of the product. All the relevant data are recorded in Table 1.

Infrared spectra of the products obtained from the electrochemical reactions and the copper(II) salts prepared by the reported methods[12] have been recorded in the region of 4000–200 cm^{-1}.

All the compounds show characteristic absorption bands in the regions; 1650–1550, 1400–1320 and 790–650 cm^{-1} which have been assigned to the asymmetric, symmetric and bending vibrations respectively of the carboxylate ion.[14–16] In addition to the absorption bands in these regions, some of the products show a broad absorption band in the region of 3600–3200 cm^{-1}. This can be attributed to the water molecules associated with the molecules of these salts.

The infrared spectral data thus show that the products of the present electrochemical reactions are copper(II) salts of these acids and thus support the analytical data. This has been further confirmed as the infrared spectra of the electrochemical products and the corresponding synthetic copper(II) carboxylate are superimposable on each other.

In the present studies, electrolysis of aliphatic and aromatic carboxylic acids of different types, i.e., monocarboxylic, dicarboxylic, substituted and unsaturated carboxylic acids have been conducted. The results reveal that all the acids yield copper(II) carboxylates, irrespective of the nature of the acid. The behaviour of carboxylic acids at the copper anode is thus entirely different from that at the inert anode.[1–7]

Current efficiencies of these reactions have also

Crotonic acid	25	$C_8H_{10}O_4Cu$	Blue	1.00	26.49	27.65

been determined and are recorded in Table 1. Perusal of Table 1 reveals that the current efficiencies for most of these systems vary from 0.95 to 1.00 eq./Faraday showing thereby that the reactions leading to the formation of copper(II) carboxylates are the predominant reactions of these systems. Such a high value of current efficiency of these systems suggest that these electrochemical reactions can be of commercial use for the production of copper(II) carboxylates.

(*Received* 24 *September* 1984; *accepted* 7 *November* 1984)

Abstract—The preparation and properties of the compounds $[Mo(\eta\text{-}C_7H_7)(dppe)Y]$ (Y = Cl, I, Me, H), $[Mo(\eta\text{-}C_7H_7)(dppe)Cl]^+A^-$ (A = PF_6, Br or I), $\{[Mo(\eta\text{-}C_7H_7)(dppe)Br]PF_6\}$, $\{[Mo(\eta\text{-}C_7H_7)(dppe)I]PF_6\}$ and $\{[Mo(\eta\text{-}C_7H_7)(dppe)L]PF_6\}$ (L = CO, MeCN, or dppe) are described.

The functional group properties of the η-bonded $\eta\text{-}C_nH_n$ ligands, where $n = 4$–8, in their transition metal complexes are best determined by an exploratory synthetic approach followed by a more quantitative study. As part of a development of the chemistry of the $\eta\text{-}C_7H_7$ ligand we have set out to study derivatives of the system $[Mo(\eta\text{-}C_7H_7)(dppe)]$.

Prior to this work and during the course of these studies there have been reports of other $\eta\text{-}C_7H_7$–molybdenum compounds.[1] In particular, the reactions of $[Mo(\eta\text{-}C_7H_7)(CO)_3]BF_4$ have been studied in considerable detail.[2,3] The $\eta\text{-}C_7H_7$ ring of this cation undergoes nucleophilic addition, e.g. of $P(Pr^i)_3$,[4] CN^-, OMe^- and Ph^-,[5] whilst displacement of carbon monoxide with dppe gives $[Mo(\eta\text{-}C_7H_7)(dppe)CO]BF_4$.[6] Substitution of one CO group by halides ions, X = Cl, Br or I, forms the neutral $Mo(\eta\text{-}C_7H_7)(CO)_2X$.[7] Treatment of the latter with tertiary phosphines causes successive replacement of the two CO groups[8] whilst with cyclopentadienide salts the compound $Mo(\eta^3\text{-}C_7H_7)(CO)_2(\eta\text{-}C_5H_5)$ is isolated.[9] The compound $[Mo(\eta\text{-}C_7H_7)(CO)_3]BF_4$ reacts under photolysis with arenes giving the mixed sandwich compounds $[Mo(\eta\text{-}C_7H_7)(\eta\text{-arene})]BF_4$.[10] However, with acetonitrile the $\eta\text{-}C_7H_7$ ring is displaced, forming $Mo(MeCN)_3(CO)_3$.[5]

The compounds $[Mo(\eta\text{ - }C_7H_7)(\eta\text{ - arene})]A^-$ readily undergo displacement of the η-arene ring leading to many derivatives and, in particular, the compounds $[Mo(\eta\text{-}C_7H_7)L_3]A$, where L = MeCN or Me_2CO.[10,11] These solvate molecules are highly reactive towards substitution of the solvent ligands. Treatment of $[Mo(\eta\text{-}C_7H_7)(\eta\text{-arene})]A$ with methoxide or halides forms the dimers $[(\eta\text{-}C_7H_7)Mo(\mu\text{-}X)_3Mo(\eta\text{-}C_7H_7)]$, X = OR, Cl, Br or I.[12,13] An unusual tetrameric compound $[Mo(\eta\text{-}C_7H_7)(\mu^3\text{-}OH)]_4$ has been described.[14]

It appears that the $Mo(\eta\text{-}C_7H_7)$ moiety is more resistant to ring displacement and to nucleophilic addition reactions in those derivatives where CO ligands are absent.[15]

A preliminary communication of part of this study on the $Mo(\eta\text{-}C_7H_7)$dppe moiety has been published.[16]

RESULTS

Treatment of the compound

$$\{[Mo(\eta\text{-}C_7H_7)(\eta\text{-}C_6H_5Me)]PF_6\},$$

1, in acetone or acetonitrile with one equivalent of bis-1,2-(diphenylphosphino)ethane (dppe) causes displacement of the $(\eta\text{-}C_6H_5Me)$ ligand. The acetonitrile solutions give the red crystalline compound $\{[Mo(\eta\text{-}C_7H_7)(dppe)MeCN]PF_6\}$, **2**. The compound isolated from the acetone solution was a brown oily material. It was not found possible to either obtain consistent analyses or to isolate a crystalline sample. However, the material behaves as though it were the compound $\{[Mo(\eta\text{-}C_7H_7)(dppe)(Me_2CO)]PF_6\}$, **3**. For example, treatment of **3** with carbon monoxide gives $\{[Mo(\eta\text{-}C_7H_7)(dppe)CO]PF_6\}$, **4**. The compound **4** has been described previously and was prepared from $[Mo(\eta$-

* Author to whom correspondence should be addressed.

$C_7H_7)(CO)_2I]$, dppe and NH_4PF_6.[8] Addition of a chloride ion to solution of **3** forms [Mo(η-C_7H_7)(dppe)Cl], **5**, which crystallises from dichloromethane or toluene as green crystals which contain solvent molecules of crystallisation. The crystal structure of the compound [Mo(η-C_7H_7)(dppe)Cl]·toluene has been determined and is presented in Scheme 1 (Mo–Cl, 2.52; Mo–P, 2.50, 2.49 Å).[17] The ^{1}H NMR spectrum of both the dichloromethane and toluene solvate derivatives of **5** in C_6D_6 are anomalous since neither show bands assignable to a η-cycloheptatrienyl ligand although bands due to the dppe ligand are present.

Reduction of the hexafluorophosphate salt of the 17 electron cation [Mo(η-C_7H_7)(dppe)Cl]$^+$ (*vide infra*) with sodium amalgam in dichloromethane gave **5** in high yield. When the reduction was carried out in tetrahydrofuran solution then brown crystals were obtained whose stoichiometry also corresponded to **5** but whose ^{1}H NMR showed all the bands to be expected, including a triplet at δ 4.9 assignable to a η-cycloheptatrienyl group coupled to two equivalent ^{31}P nuclei. The brown isomer may be a polymorph of **5**.

Houk and Beall have described a compound [Mo(η-C_7H_7)(dppe)I].[8] We have prepared a compound **6** of the same stoichiometry from the reaction between **3** and lithium iodide. Initially a light green precipitate forms which redissolves and then brown crystals of **6** separate. Also, treatment of the acetonitrile derivative **2** with lithium iodide in acetonitrile followed by recrystallisation of the involatile products from acetone gives the compound **6**. The IR and NMR spectra of **6** do not correspond to that reported and, as found for the green isomer of **5**, the compound **6** did not show a band in the ^{1}H NMR spectrum assignable to the η-cycloheptatrienyl hydrogens. These anomalous absences of η-C_7H_7 resonances may be due to traces of paramagnetic impurities.

The compounds **5** and **6** are readily oxidised by iodine and, after addition of ammonium hexafluorophosphate, the paramagnetic compounds {[Mo(η-C_7H_7)(dppe)Cl]PF_6}, **7**, and {[Mo(η-C_7H_7)(dppe)I]PF_6}, **8**, are formed.

Addition of lithium iodide to the yellow compound **7** at room temperature resulted in an immediate reaction giving metathesis of the hexafluorophosphate anion and the blue iodide salt {[Mo(η-C_7H_7)(dppe)Cl]I, **9**, was isolated. Similarly, treatment of **7** with lithium bromide forms the compound {[Mo(η-C_7H_7)(dppe)Cl]Br}, **10**. Prolonged reaction between **7** and lithium iodide gave **8**, after addition of ammonium hexafluorophosphate.

In an unexpected reaction, it was found that treatment of **3** with dichloromethane or allyl chloride causes oxidation forming **7**. Similarly **3** undergoes oxidation in the presence of 1,2-dibromoethane giving {[Mo(η-C_7H_7)(dppe)Br]PF_6}, **11**.

The ESR data for the compounds **7**, **11** and **8** are given in Table 1. The spectra of the compound **7** and **11** both show hyperfine structure assignable to coupling of the unpaired electron with two equivalent ^{31}P nuclei, with the ^{95}Mo and ^{97}Mo nuclei and, possibly, also with the hydrogens of the η-cycloheptatrienyl ring and with either the Cl or Br nuclei. The spectra have not been fully assigned due to their complexity. The magnetic susceptibility data for the compounds **7**, **9**, **10** is consistent with the presence of one unpaired electron in the cations.

When **1** was treated with an excess of dppe salmon-pink crystals were obtained which had a stoichiometry corresponding to {[Mo(η-C_7H_7)$(dppe)_2$] PF_6}, **12**. The ^{1}H NMR of **12** in deuterioacetone or CD_3CN showed a *triplet* centered at δ 4.9 (J(P–H) 2.1 Hz) assignable to the η-cycloheptatrienyl hydrogens coupled to only two ^{31}P nuclei. The ^{31}P NMR in $(CD_3)_2CO$ showed two bands assignable to phosphorus in dppe systems. The band at -61.4 ppm has a chemical shift value close to that of the coordinated phosphorus in **2** whilst the second band had a chemical shift value at 13.5 ppm which is close to that of uncoordinated dppe. Thus it seems that the compound **12** dissociates a dppe ligand in acetonitrile or acetone solutions. In support of this observation it was found that treatment of **12** in acetone with carbon monoxide gives the compound **4**.

Reduction of **6** with sodium borohydride in tetrahydrofuran gives highly air sensitive red crystals of the hydrido compound [Mo(η-C_7H_7)(dppe)H], **13**. The compound reacts rapidly with $CDCl_3$ giving **5**. Treatment of **6** with methyllithium in warm tetrahydrofuran gives the expected methyl compound [Mo(η-C_7H_7)(dppe)Me], **14**.

DISCUSSION

The reactions and proposed structures for the new compounds are shown in Scheme 1. The characterising data are given in Table 1.

The question of the formal oxidation state of of the molybdenum centre in these compounds arises. Recently we have reported an extensive chemistry of the η-C_7H_7Ti system[18,19] in which we conclude that the η-C_7H_7 ligand is best described as having a formal trinegative charge so that, for example, the titanium centre in the compound Ti(η-C_7H_7)(dmpe)Cl classifies as d^0 (i.e. Ti(IV)).

By analogy, the molybdenum centre in the com-

[o] The stoichiometry was determined by the mass spectrum, *m/e* = 588 (^{96}Mo), corresponding to the parent ion.

pounds of the type Mo(η-C_7H_7)L_2X, and [Mo(η-C_7H_7)L_3]$^+$, where L = a two electron donor, and X = a one electron donor (e.g. Cl, Me), are described as d^2, i.e. Mo(IV). Correspondingly, the paramagnetic compounds [Mo(η-C_7H_7)L_2Cl]$^+$ are d^1 with Mo(V). This accounts for the observation of ESR spectra which are most characteristic of the presence of only one unpaired electron.

The observed reactivity of the Mo(η-C_7H_7) moiety is consistent with this description. For example, the extreme lability of the η-arene ring in [Mo(η-C_7H_7)(η-arene)]$^+$ and its facile displacement by relatively

(ii) Dppe (1 equiv.) in acetone at 65°C for 11 h, *ca* 50%.
(iii) Dissolve in acetonitrile at 20°C, 10 min, > 90%.
(iv) Excess of lithium iodide in acetonitrile at 20°C, 10 min, > 90%.
(v) Dppe (2 equivalent) in ethanol at 60°C for 24 h, > 90%.
(vi) Carbon monoxide at 1 atm in acetone at 20°C for 3 h, 42%.
(vii) Halides = Cl, Br or I. Lithium halides in acetone at 20°C for 30 min, > 70%.
(viii) X = Cl, dissolve in CH_2Cl_2 or allylchloride at room temperature for 10 min, > 90%.
X = Br, dissolve in 1,2-dibromoethane at room temperature for 15 min, > 90%.
(ix) X = Cl or I, add iodine at room temperature for 10 min, > 90%.
(x) X = Cl, stir with Na/Hg in CH_2Cl_2 at room temperature for 1 h, > 90%.
(xi) X = I, $Na[AlH_2(OCH_2CH_2OMe)_2]$ in toluene at 80°C for 1 h, 72%.
(xii) Methyllithium in toluene at 80°C for 1 h, 42%.

"hard" ligands such as halide, methoxide, acetone and MeCN is more consistent with a d^2 than a d^4, or, if the η-C_7H_7 ligands was thought to classify as $C_7H_7^+$, as a d^6 centre. The compound $[Mo(\eta\text{-}C_7H_7(CO)_2I]$ undergoes displacement of both CO ligands by the more strongly donor tertiary phosphine ligands.[8] In contrast, the CO ligands in the d^4 compounds $[Mo(\eta\text{-}C_5H_5)(CO)_3X]$ are much less labile.

The dimers $[(\eta\text{-}C_7H_7)Mo(\mu\text{-}X)_3Mo(\eta\text{-}C_7H_7)]$, X = OMe, Cl, Br, I, may be regarded as having formal d^0 centres, if a Mo–Mo bond is assumed, and reduction to the neutral paramagnetic compounds $[(\eta\text{-}C_7H_7)Mo(\mu\text{-}X)_3Mo(\eta\text{-}C_7H_7)]$ would provide a formal d^1 molybdenum centre, which is consistent with the observed ESR data.[12,13]

The chemistry of the system $[Mo(\eta\text{-}C_7H_7)(dppe)]$ compares generally with that of the well-known $Fe(\eta\text{-}C_5H_5)L_2$-moiety, for example, in the formation of the hydrido and alkyl derivatives.

EXPERIMENTAL

All preparations and reactions were carried out under an atmosphere of purified dinitrogen. Solvents were dried and purified by reflux over a suitable drying agent under dinitrogen, followed by distillation under dinitrogen. Microanalyses were performed by the analytical department of this laboratory or by Alfred Bernhardt Ltd.

IR spectra were recorded on a Pye–Unicam SP2000 double beam, grating spectrophotometer or a Perkin–Elmer 457 double beam, grating spectrophotometer.

NMR spectra were recorded on a JEOL PMX60 (^{1}H, 60 MHz), a Bruker WH90 (^{1}H, 90 MHz; ^{31}P, 36.43 MHz). Solvent bands were used as internal standards. Mass spectra were recorded on an A.E.I. MS 902 spectrometer. ESR spectra were determined on a JEOL JES-PE instrument at 9.5 GHz and calibrated against MnO as external standard.

Bis - 1,2 - (diphenylphosphino)ethane(η - cyclo - heptatrienyl)acetonitrilemolybdenum hexafluoro - phosphate, **2**

The compound $\{[Mo(\eta\text{-}C_7H_7)(\eta\text{-}C_6H_5Me)]PF_6\}$ (1.0 g, 2.36 mmol), prepared as described,[12] and dppe (0.91 g, 2.34 mmol) in acetonitrile (40 cm^3) were heated at 65°C for 12 h. The solution was concentrated under reduced pressure at 70°C and allowed to cool. Red crystals separated and were collected washed with toluene and dried under reduced pressure. Yield 74%.

Synthesis of **3** *from* $\{[Mo(\eta\text{-}C_7H_7)(\eta\text{-}C_6H_5Me)]PF_6\}$

The compound

$$\{[Mo(\eta\text{-}C_7H_7)(\eta\text{-}C_6H_5Me)]PF_6\}$$

(0.76 g, 1.8 mmol) in acetone (20 cm^3) was treated with 1,2-bis(diphenylphosphino)ethane (0.71 g, 1.8 mmol) at 65°C for 11 h. The solvent was removed under reduced pressure and the brown frothy residue of the material **3** was used without further purification in the reactions described below, yield 1.55 g. [Found: C, 54.6 (54.9); H, 6.0 (4.7)%.] Crystals obtained from concentrated acetone solutions analysed as C, 52.6 (54.9); H, 5.1 (4.7)%.

Bis - 1,2 - (diphenylphosphino)ethane(η - cyclo - heptatrienyl)carbonylmolybdenum hexafluorophosphate, **4**

Method A. The compound **3** (0.3 g, 0.38 mmol) in acetone (5 cm^3) was treated with carbon monoxide at 1 atm for 3 h. The initially brown solution became red. Ethanol (20 cm^3) was added and the solution was concentrated under reduced pressure giving red crystals. These were recrystallised twice from dichloromethane: petroleum ether (40–60°C) mixture. The resulting red crystals were washed with petroleum ether (40–60°C) (2 × 10 cm^3) and dried *in vacuo*, 0.12 g, 42%. The compound was identified by analysis. [Found (calc.): C, 53.6(53.9); H, 3.9(4.1)%.] Specific conductance in CH_2Cl_2 was 0.435 mho cm^{-2}. The IR spectrum was identical to that described (the CO stretch was at 1952vs cm^{-1}).

Method B. The compound

$$\{[Mo(\eta\text{-}C_7H_7)(dppe)_2]PF_6\}$$

(0.07 g, 0.06 mmol) in dicholoromethane (5 cm^{-3}) was treated with carbon monoxide at 1 atm and at room temperature for 5 h. The solvent was removed under reduced pressure and the residue was recrystallised from acetone: ethanol mixture. The resulting crystals were washed with petroleum ether (40–60°C) (2 × 10 cm^3) and dried *in vacuo*, 0.023 g, *ca* 50%.

Bis - 1,2 - (diphenylphosphino)ethane(η - cyclo - heptatrienyl)chloromolybdenum, **5**

Method A. The compound **3** (0.2 g, 0.25 mmol) in acetone (10 cm^3) was treated with lithium chloride (0.2 g, 4.8 mmol) in acetone (20 cm^3). The initially brown solution turned green. After 2 h the solvent was removed under reduced pressure and the residue was extracted with toluene (10 cm^3). The extract was filtered and petroleum ether (100–120°C) was added to the filtrate. Concentration of the mixture under reduced pressure gave green needle crystals which were collected and dried *in vacuo* 0.13 g, 72%.

Method B. The compound $\{[Mo(\eta\text{-}C_7H_7)(dppe)Cl]PF_6\}$ (0.5 g, 0.65 mmol) in dichloromethane (40 cm^3) was treated with sodium amalgam (10 g of 2% sodium in mercury) and stirred for 1.5 h. The mixture was allowed to stand for 2 h and the green supernatant solution was separated by filtration and the filtrate was treated with petroleum ether (60–80°C: 60 cm^3). After concentration under reduced pressure green crystals separated over a period of several days, 0.2 g, 44%. [Analytical data for $[Mo(\eta\text{-}C_7H_7)(dppe)Cl]\cdot\frac{1}{2}CH_2Cl_2$: Found (calc.): C, 57.9(57.9); H, 4.6(4.6); Cl, 14.9(15.1)%.]

Bis - 1,2 - (diphenylphosphino)ethane(η - cyclo - heptatrienyl)iodomolybdenum, **6**

A solution of the compound **3**, prepared from **1** (0.50 g, 1.18 mmol) in acetone (5 cm^3) and dppe (1 equivalent) in acetone (5 cm^3) was treated with

anhydrous lithium iodide (0.5 g, 3.75 mmol) in acetone (10 cm^3). Fibrous green crystals separated immediately but after 15 min these redissolved and a new precipitate of brown lustrous cubic crystals separated. These were collected, washed with acetone (2 × 5 cm^3) and dried *in vacuo*, 0.73 g, *ca* 87%. The specific conductance in CH_2Cl_2 was 0.0094 mho cm^{-2}. The mass spectrum showed a parent ion peak at $m/e = 714$.

The compound could be recrystallised from toluene: petroleum ether (100–120°C) mixture as yellow–green fibrous crystals whose IR spectrum differed slightly from that of the brown–green cubic crystals.

Bis - 1,2 - (*diphenylphosphino*)*ethane*(*η* - *cyclohepta* - *trienyl*)*chloromolybdenum hexafluorophosphate*, **7**

Method A. The compound **3** (0.5 g) was dissolved in dichloromethane (20 cm^3). After 15 min at room temperature the solution was yellow–orange. The solvent was removed under reduced pressure and the residue was recrystallised from acetone: ethanol mixture, *ca* 90%.

Method B. The compound

$$[Mo(\eta\text{-}C_7H_7)(dppe)Cl]$$

(0.1 g, 0.16 mmol) in dichloromethane was treated with iodine (0.2 g, 0.7 mmol). Addition of petroleum ether (60–80°C) followed by concentration under reduced pressure precipitated black crystals. These were separated and dissolved in aqueous acetone. Aqueous ammonium hexafluorophosphate was added and the mixture was concentrated giving yellow crystals which were collected and dried *in vacuo*, *ca* 90%.

Bis - 1,2 - (*diphenylphosphino*)*ethane*(*η* - *cyclo* - *heptatrienyl*)*iodomolybdenum hexafluorophos* - *phate*, **8**

The compound $[Mo(\eta\text{-}C_7H_7)(dppe)I]$ (0.18 g, 0.25 mmol) in toluene (80 cm^3) was treated with one equivalent of iodine in toluene (10 cm^3) giving a black precipitate. This was collected and extracted with aqueous acetone. The extract was filtered and aqueous ammonium hexafluorophosphate was added. The filtrate was concentrated under reduced pressure giving scarlet red crystals. These were recrystallised from dichloromethane: petroleum ether (40–60°C), yield 90%.

Bis - 1,2 - (*diphenylphosphino*)*ethane*(*η* - *cyclo* - *heptatrienyl*)*chloromolybdenum iodide*, **9**

The compound $\{[Mo(\eta\text{-}C_7H_7)(dppe)Cl]PF_6\}$, **7** (0.2 g, 0.26 mmol), was treated with anhydrous lithium iodide (0.5 g, 3.7 mmol) in acetone (10 cm^3). Blue crystals separated and after 4 h these were collected, washed with ethanol and dried *in vacuo*, *ca* 72%.

Bis - 1,2 - (*diphenylphosphino*)*ethane*(*η* - *cyclo* - *heptatrienyl*)*chloromolybdenum bromide*, **10**

The compound $\{[Mo(\eta\text{-}C_7H_7)(dppe)Cl]PF_6\}$, **7** (0.2 g, 0.26 mmol) was treated with anhydrous lithium iodide (0.5 g, 3.7 mmol) in acetone (10 cm^3). Orange–yellow crystals separated and after 4 h these were collected, washed with ethanol and dried *in vacuo*, *ca* 75%.

Bis - 1,2 - (*diphenylphosphino*)*ethane*(*η* - *cyclohepta* - *trienyl*)*bromomolybdenum hexafluorophosphate*, **11**

The compound was prepared from **3** and 1,2-dibromoethane as described for the chloro analogue **7**, *ca* 90%.

Bis(1,2 - *bis*(*diphenylphosphino*)*ethane*)(*η* - *cyclo* - *heptatrienyl*)*molybdenum hexafluorophosphate*, **12**

The compound

$$\{[Mo(\eta\text{-}C_7H_7)(\eta\text{-}C_6H_5Me)]PF_6\}$$

(0.4 g, 0.94 mmol) and dppe (1.0 g, 2.54 mmol) in ethanol (150 cm^3) were heated at 60°C for 24 h. The mixture was cooled to room temperature and pink crystals separated together with white crystals of dppe. The solid was separated and washed with diethyl ether (2 × 20 cm^3) and the residue was recrystallised from acetone: ethanol mixture. The red crystals were collected, washed with diethyl ether and dried *in vacuo*, 0.6 g, 50%.

Bis - 1,2 - (*diphenylphosphino*)*ethane*(*η* - *cyclo* - *heptatrienyl*)*hydridomolybdenum*, **13**

The compound $Na[AlH_2(OCH_2CH_2OMe)_2]$ (0.6 cm^3 of a 70% solution in benzene, 2.08 mmol) was added to $[Mo(\eta\text{-}C_7H_7)(dppe)I]$ (1.0 g, 1.41 mmol) in toluene (30 cm^3) and the mixture was heated to 90°C for 1.5 h. The initially brown solution became red and, after cooling to room temperature, water (0.5 cm^3) was added. The toluene layer was separated and concentrated under reduced pressure. Addition of petroleum ether (100–120°C) gave red rhombic crystals which were collected and washed with cold petroleum ether (30–40°C) and dried *in vacuo*, *ca* 73%. The compound is pyrophoric in air.

Bis - 1,2 - (*diphenylphosphino*)*ethane*(*η* - *cyclo* - *heptatrienyl*)*methylmolybdenum*, **14**

Methyl-lithium (1.6 cm^3 of a 1.9 M solution in diethyl ether, 3.05 mmol) was added to [Mo(*η*-

C_7H_7)(dppe)I] (0.2 g, 0.28 mmol) in tetrahydrofuran (40 cm^3). The mixture rapidly became red. It was warmed to 65°C for 15 min and then the solvent was removed under reduced pressure. The red residue was extracted with toluene (2 × 20 cm^3) and wet diethyl ether (5 cm^3) was added. Concentration of the mixture and addition of petroleum ether (100–120°C) (20 cm^3) gave deep red prism crystals. These were collected, washed with petroleum ether (30–40°C) and dried *in vacuo*, 0.07 g, *ca* 42%. The mass spectrum show a parent ion peak at $m/e = 602$.

(*Received* 2 *July* 1984; *accepted* 7 *November* 1984)

Abstract—The anilinium β-octamolybdate dihydrate has been prepared in acidic aqueous solution. TG, DTG, IR and ^{1}H NMR techniques have been used to identify the compound. It belongs to a series of molybdates of alkyl-N- and -N,N-substituted anilinium cations. Single crystals have been analyzed by X-ray diffraction. Crystal data are: $(C_6H_8N)_4[Mo_8O_{26}]\cdot 2H_2O$, space group $P\bar{1}$, $Z = 1$, $a = 10.007(1)$, $b = 8.014(2)$, $c = 14.645(8)$Å, $\alpha = 109.81(3)$, $\beta = 108.59(2)$, $\gamma = 85.44(2)°$, $V = 1052.9(6)$ Å^3, $D_o = 2.49(1)$, $D_x = 2.52$ mg m^{-3}, $R = 0.026$ and $R_w = 0.031$ for 5297 observed reflexions. The crystal structure consists of discrete $[\beta\text{-}Mo_8O_{26}]^{4-}$ polyanions, two crystallographically independent $(C_6H_8N)^+$ cations and one independent water molecule. Polyanions are linked to the cations and to the water molecules by hydrogen bonds of types N–H···O and O–H···O.

In a previous paper[1] we reported on the different types of octamolybdate anions. It seems that in the solid state the most frequent type is the β-isomer. In order to investigate the other types, we have tried with a family of protonated organic bases such as anilinium, N-methylanilinium, N-ethylanilinium, N,N-dimethylanilinium and N,N-diethylanilinium. The first analyzed member, the title compound, corresponds to the β-octamolybdate family. The alkylanilinium polymolybdates have been prepared and they will be reported soon.

EXPERIMENTAL

Aniline (5 cm^3) was added to a stirred suspension of MoO_3 (5 g) in hot water (850 cm^3, 80°C). The slightly turbid solution (pH = 2.5) was filtered. Crystals of anilinium octamolybdate dihydrate (**I**) appeared in the solution after two days. The brownish prismatic crystals were washed with water, ethanol and ether and finally dried in air. They were found to be stable to air, light and X-ray exposure.

Compound **I** appeared to be a dihydrate; Found: Mo, 48.39; C, 18.26; H, 2.19; N, 3.68; weight loss at 570°C, 72.60%; Calc. for $(C_6H_8N)_4[Mo_8O_{26}]\cdot 2H_2O$: Mo, 48.09; C, 18.06; H, 2.27; N, 3.51; weight loss at 570°C, 72.15%.

IR spectra were recorded in KBr pellets or as Nujol mulls on a Beckman IR-4240 (4000–250 cm^{-1}) spectrophotometer. ^{1}H NMR spectra were recorded on a Perkin–Elmer R-12B (60 MHz) instrument in deuterated DMSO solution using TMS as internal standard. TG and DTG analyses were performed with a Perkin–Elmer TGS-2 thermobalance in nitrogen stream under atmospheric pressure.

The cell parameters, as given in the abstract, were determined by least-squares fit from the 2θ values of 35 reflexions measured for both positive and negative Bragg angles. The crystal dimensions were $0.20 \times 0.15 \times 0.20$ mm. An automatic four-circle diffractometer with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) was used. Intensity data for 6034 independent reflexions were collected up to $\theta = 30°$ with an $\omega/2\theta$ scan technique. No absorption corrections were applied ($\mu = 23.97$

* Author to whom correspondence should be addressed.

cm^{-1}). After correction for Lorentz and polarization effects, 5297 reflexions with $I > 3\sigma(I)$ were considered as observed and used in the remaining calculations. Scattering factors for neutral atoms and anomalous dispersion corrections for Mo were taken from the literature.[2] The Mo atoms were located on a Patterson synthesis and the structure was expanded by Fourier syntheses. Several cycles of anisotropic least-squares refinement (unit weights and H-atoms as isotropic fixed contributors) gave the disagreement indices $R = 0.026$ and $R_w = 0.031$ for the observed reflexions.

Lists of atomic parameters, observed and calculated structure factors and anisotropic thermal coefficients for non-H atoms have been deposited with the Editor as supplementary material.*

* Supplementary material has also been deposited with the Cambridge Crystallographic Data Centre.

Most calculations were performed using the XRAY76 System[3] running on a VAX 11/750 computer.

DISCUSSION

Compound I exhibits in the IR spectrum the well known bands for the $[\beta\text{-}Mo_8O_{26}]^{4-}$ polyanion.[4,5] The octamolybdate anion is assumed to have C_{2h} symmetry. This assumption agrees roughly with the X-ray model. The lines at 950 and 910 cm^{-1} have been assigned to the Mo–O_t stretching vibrations, the strong band at 925 cm^{-1} corresponding to the Mo–O stretching. The Mo–O bending and stretching vibrations are represented by the peaks at 845 and 740 cm^{-1}, while the Mo–O–Mo bendings are associated with the lines at 655, 545, 520, 460, 380 and 360 cm^{-1}.

Anilinium cations and water molecules have been detected in the IR spectrum between 3600 and 1000 cm^{-1}. ^1H NMR spectra present a broad singlet (δ = 5.4 ppm, 3H), showing a protonated aniline.

The thermal decomposition of I shows its hydrated state. The two water molecules are lost in two stages corresponding to the ranges 95–130 and 130–176°C. There are nine stages in the total thermal decomposition, the final product being MoO_3 as characterized by IR and powder diffraction. The formation of MoO_3 corresponds to the weight loss given in the chemical analysis.

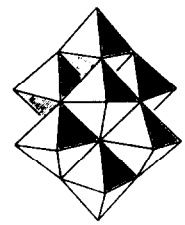

Fig. 1. The $[\beta\text{-}Mo_8O_{26}]^{4-}$ polyanion.

The anionic unit is built up of eight MoO_6 distorted octahedra sharing edges and corners. These centrosymmetric units are the well known $[\beta\text{-}Mo_8O_{26}]^{4-}$ polyanions.[6–9] The Mo–O distances within these units are listed in Table 1, where three families of Mo–O bond lengths are found, short, medium and long. A drawing of this atomic group can be seen in Fig. 1. The O–Mo–O bond angles are shown in Table 2. The distortion of the MoO_6 octahedra has been evaluated in terms of $\Delta = \Sigma |d_i - \bar{d}|/12$, where d_i represents the individual O–O

INTERACTIONS BETWEEN EUROPIUM(III) ION AND METHYL GLYCOFURANOSIDES IN AQUEOUS SOLUTION

ANTTI VESALA* and RAINER KÄPPI
Department of Chemistry and Biochemistry, University of Turku, SF-20500 Turku, Finland

(*Received* 24 *September* 1984; *accepted* 9 *November* 1984)

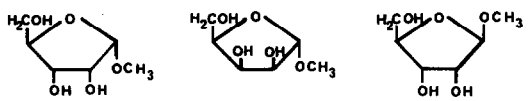
Abstract—The interactions between Eu(III) ion and some methyl glycofuranosides have been studied luminometrically in aqueous solution. The measurements were based on the delayed fluorescence of the Eu(III) ion known to be environmentally sensitive. The reciprocal lifetimes, i.e., the decay constants of this fluorescence, depend on the number of OH bonds in the primary hydration sphere of the ion. These were determined in aqueous glycofuranoside solutions of various concentrations. These data enable us to discuss the effect of ligand configuration on the binding sites in the formed complexes. The formation constants for these complexes have been evaluated with the aid of decay rate equations.

Luminescence excitation spectroscopy of the $^7F_0 \rightarrow {}^5D_0$ transition in the Eu(III) ion has been successfully applied to the study of the environment of the metal ion in solutions of various ligands and biomolecular systems.[1] The luminescence decay constants derived from the excited-state lifetimes have been observed to correlate with the number of OH bonds in the primary solvation sphere of the europium ion.[2,3] The technique has been applied in cases, where ligands are charge bearing and the interactions strong.[4] On the other hand, weak interactions that common anions like Cl^-, NO_3^- and ClO_4^- in aqueous solutions exert on the europium ion have been studied in this way so that even formation constants could be determined.[5,6] The utility of the technique is increased by the fact that in solution the Eu(III) ion functions as a satisfactory model for an ion with noble gas structure even in biological systems.[1]

We have previously studied the interactions that some s-block cations, especially alkaline earth metal cations, exert on monomeric carbohydrates with low molecular weight, methyl aldofuranosides. Employing calorimetric and potentiometric techniques stoichiometries and strengths of the interactions could have been elucidated.[7–12] The results seem to be in agreement with the concept that the interactions are strongest if the ligand has a *cis–cis* triol configuration or its structure is close to that.[13]

The aim of the present study is to apply luminometric measurements in furthering our knowledge about the neighbourhood of a spherical cation in the solutions of neutral ligands with oxygen donors. Since the determined decay constants are dependent on the number of OH oscillators in the solvation sphere of the cation, detectable effects are expected to occur when water molecules with their two OH bonds are replaced by the hydroxyl groups or ether oxygens of the glycoside. Owing to the special character of the OH bonds in the method it is possible to differentiate between bindings *via* hydroxyl and ether oxygens. Also the distinction between inner sphere and outer sphere complexes can be discussed on the basis of the data.

EXPERIMENTAL



The reagents were commercial ($EuCl_3 \cdot 6H_2O$, Aldrich) or were prepared as described elsewhere (the glycosides).[14–16] Distilled and degassed water was used through all experiments. The concentration of the Eu(III) ion was 0.010 mol dm^{-3} in each solution. The sample solutions were prepared by weighing appropriate amounts of glycoside and determining the density and concentration of the resulting solution by a Parr 45 densitometer. The solid 1:2 europium–glycoside adducts were prepared by dissolving the reagents in minimum amount of water. The mixture was then evaporated in a vacuum desiccator to a constant weight. Because of their hygroscopic nature the adducts were kept in a desiccator until measured.

* To whom correspondence should be addressed.

The intensity of emission of europium fluorescence at 592 nm was followed by a Perkin–Elmer Luminescence Spectrometer LS-5, which was controlled by an Apple II Microcomputer. The excitation was taken place at the wavelength of 395 nm. The intensity of emission falls exponentially. Therefore the exact lifetimes of the excited state can be extracted from semilogarithmic plots of intensity vs. time of delay. The luminescence decay constant is defined as the reciprocal lifetime of the excited state. With the aid of the Apple II Computer it was possible to select measuring conditions and the number of consecutive determinations. Six intensity values were recorded at each time increment. The observed decay constants are collected in Table 1. The values measured in H_2O and D_2O solutions satisfactorily agree with those reported earlier.[2,3,5,6] The experiments with solid samples were carried out by measuring the luminescence emission of a thin sample layer on a cell holder. Because of the great deliquescence of the samples the results proved to be tentative. Temperature was maintained constant in the experiments by a Haake Thermostat. The control was carried out by a thermistor and a Fluke 8860 A Digital Multimeter.

RESULTS AND DISCUSSION

Previous results indicate detectable complex forming abilities of methyl α-D-ribo- (1) and methyl β-D-lyxofuranosides (2) with alkaline earth metal and lanthanum ions, whereas methyl β-D-ribofuranoside (3) shows only a weak ability.[7–12] The present

(1) (2) (3)

luminometric data (Table 1) agree well with this concept. The decay constants remain almost unchanged for β-riboside, while those for the other glycosides decrease clearly even at low ligand concentrations. The magnitudes of this decrease differ with α-riboside and α-lyxoside owing to the stabilities and/or the binding sites of the formed complexes.

In this study the ligand concentrations vary from 2 to 400 times the metal ion concentration. While 1 : 1 stoichiometry was established on the calorimetric basis, where these concentrations had equal magnitudes,[9,10] 1 : 2 stoichiometry has also to be accounted for. This can be seen in Fig. 1, where the curvature of the plots with decreasing $[L]^{-1}$ can be assigned to this phenomenon. The observed k values for the solid 1 : 2 adducts were 4.8–5.1 ms^{-1} for α-

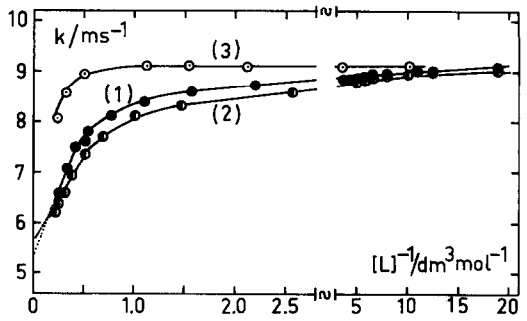


Fig. 1. The observed decay constants for the delayed fluorescence of Eu(III) ion vs reciprocal ligand concentration in solutions of the ligands (1), (2) and (3).

lyxoside and 4.1–4.3 ms^{-1} for α-riboside as ligands. These agree quite well with the intercepts of the curves in Fig. 1, because it has to be noticed that the solid adducts most probably contain one chloride in the inner solvation sphere of the ion, i.e., have the form of $[EuClL_2(H_2O)]^{2+}$.[5] In solution samples the concentration of this form is negligible because of low metal and chloride concentrations.

The hypotheses on the binding sites of the ligands are based on the previous information[7,8] and the recent communication by Angyal.[17] The binding is assumed to take place via MeO-1, HO-2 and HO-3 for methyl α-D-ribofuranoside and via HO-2, HO-3 and HO-5 for methyl α-D-lyxofuranoside. Methyl β-D-ribofuranoside may interact via two oxygens.[7] Accordingly, when the hydrated metal ion and the glycoside ligand are interacting, the loss of three water molecules occurs for both (1) and (2), but the gains of 2 OH and 3 OH, respectively, make the net loss of 2 H_2O for (1) and 1.5 H_2O for (2). If the number of water molecules in the primary hydration sphere of the Eu(III) ion is assumed to be nine,[1] the decay constants for the various forms of complexes can be calculated with the aid of the Horrocks–Sudnick correlation.[2] Here a value of $k(H_2O) - k(D_2O) = 9.12 - 0.41 = 8.71$ ms^{-1} corresponds to 9 H_2O, i.e. we get 0.484 ms^{-1} for each OH bond. By using this value the decay constants of 4.28 ms^{-1} and 5.25 ms^{-1} can be calculated for the solid α-riboside and α-lyxoside adducts mentioned above. In the solution the metal and chloride concentrations are low compared with the ligand concentration. That is why, three emitting forms have to be assumed to exist, viz. $[Eu(H_2O)_n]^{3+}$ (form A),

$$[EuL(H_2O)_{n-x}]^{3+},$$

(form B) and

$$[EuL_2(H_2O)_{n-2x}]^{3+},$$

(form C). The decay constants for the above forms,

[a] The standard errors of the k values varied from 0.02 ms^{-1} to 0.04 ms^{-1}.

k_A, k_B and k_C, based on the assumptions presented have been calculated for the three ligands in Table 2. In conclusion, the data and the binding hypotheses appear to be in agreement.

The complex equilibria (1) and (2) prevail in the solution and are determined by the conventional constants β_1 and β_2.

$$[Eu(H_2O)_n]^{3+} + L = [EuL(H_2O)_{n-x}]^{3+} + xH_2O \quad (1)$$

$$[Eu(H_2O)_n]^{3+} + 2L = [EuL_2(H_2O)_{n-2x}]^{3+} + 2xH_2O. \quad (2)$$

Provided that the equilibria are established in times shorter than the lifetimes of the excited states we can define the observed decay constant with the aid of constants k_A, k_B, k_C, β_1 and β_2.[18,19] If the total concentration of the emitting species is S ($=A+B+C$), the decay rate is defined by eqn (3).

$$-\frac{dS}{dt} = k_A A + k_B B + k_C C. \quad (3)$$

When the concentrations of the emitting species are calculated via the equations for β_1 and β_2, we get

$$-\frac{dS}{dt} = \frac{k_A + k_B\beta_1[L] + k_C\beta_2[L]^2}{1+\beta_1[L]+\beta_2[L]^2} S. \quad (4)$$

The observed decay constant is then

$$k = \frac{k_A + k_B\beta_1[L] + k_C\beta_2[L]^2}{1+\beta_1[L]+\beta_2[L]^2}. \quad (5)$$

Because of the insensitivity of eqn (5) it is not possible to evaluate the whole set of parameters with a reasonable accuracy from the available data. If the 1:1 complex is assumed to be a major form at [L] < 0.2 mol dm^{-3}, eqn (5) is reduced to

$$k = \frac{k_A + k_B\beta_1[L]}{1+\beta_1[L]}. \quad (6)$$

The above equation can be rearranged to give β_1. When this is done, the constants of (0.77 ± 0.12) dm^3 mol^{-1} for (1) and (1.22 ± 0.08) dm^3 mol^{-1} for (2) are derived. These results agree with the previous observation about the order of stability of lanthanum ion–glycofuranoside complexes in methanolic solution.[11] A noticeable matter is that this order is the reverse of the respective Ca^{2+} system. One reliable explanation may be the influence of the greater charge in the central ion. This is able to change the ligand into a favourable configuration. This means especially α-lyxoside, where the binding occurs via the hydroxymethyl group. On the other hand, the calorimetrically determined enthalpies of

[a] Based on the interaction via two oxygens.

interaction have shown to be more negative for the Ca^{2+} system. As the observed stability constants are roughly of equal magnitude (for Ca^{2+} system $\beta_1 =$ 1.4 and 0.9 $dm^3\,mol^{-1}$, respectively for the ligands (1) and (2)) the complex formation is favoured by entropy in the La^{3+} and Eu^{3+} systems.

The constants β_2 can be roughly evaluated by eqn (5). Values of 0.5 $dm^6\,mol^{-2}$ for α-lyxoside and 0.05 $dm^6\,mol^{-2}$ for α-riboside as ligands can be obtained from the data in ligand concentrations that exceed 0.2 mol dm^{-3}. These constants, although tentative, show that 1 : 2 interactions are meaningful.

It is evident on the basis of the present data that the interactions between the spherical ion and the given ligands occur in the inner solvation sphere of the ion. These are present even at moderately low concentrations depending on the configuration of the ligand. Packing of H_2O molecules towards the inner sphere of the cation that seems to take place, for instance, with ClO_4^- anion[5,6] have not been detected.

To quantify the thermodynamics of the system, measurements are in progress at various temperatures. Despite the insensitivity of the equations derived, the method, however, belongs to the few by which reliable information can be obtained from weak interactions between compounds which are difficult to analyze.

PREPARATION OF NOVEL POLYMER LIGANDS CONTAINING TETRAAZA MACROCYCLIC SCHIFF BASE AS A HIGHLY SELECTIVE EXTRACTANT FOR COPPER(II)

NOBORU KUBOTA, MANABU FUJIWARA, TAKAYUKI MATSUSHITA* and TOSHIYUKI SHONO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565, Japan

(*Received* 24 *September* 1984; *accepted* 9 *November* 1984)

Abstract—Three types of the novel polymer ligands in which 6,8,15,17-tetramethyl-dibenzo-5,9,14,18-tetraaza-cyclotetradecene (L) is present as an integral part of the polymer backbone have been prepared. These polymer ligands are oligomers whose polymerization degree may be about five. Their complexing abilities and extractabilities for copper(II) and nickel(II) have been investigated. Among the polymer ligands, Poly-L3, which contains triethyleneglycol bis(*p*-phenylene) group as a linkage group, was found to be an excellent extractant for copper(II).

Selective separation of heavy metal ions is an important subject in the fields of industrial and analytical chemistry. For this purpose, many extractants and chelating resins have so far been synthesized and some of them have been applied in practice. Zolotov *et al.* have reported that the macrocyclic Schiff base ligand (L, Fig. 1) exhibits a high selectivity for copper(II) in solvent extraction.[1,2] However, its extraction rate was found to be slow compared with those observed for the alkylated derivatives of saturated tetraaza macrocycles.[3] This may be caused by the rigid structure of L itself, which results in a slow rate of the complex formation as found in the case of porphyrins.[4]

We have preliminarily reported that the polymer ligand (Poly-L1, Fig. 1), in which L is present as an integral part of the polymer backbone, exhibits a high selectivity for copper(II) as well as L in the solvent extraction and that the extraction rate by Poly-L1 is much faster than that by L.[5] In the present paper, we describe the preparation of the novel polymer ligands shown in Fig. 1 and their extractabilities for copper(II) and nickel(II).

EXPERIMENTAL

Preparation of dianhydride derivative of L

The monomeric ligand, 6,8,15,17 - tetramethyl - dibenzo - 5,9,14,18-tetraaza-cyclotetradecene (L), was prepared by the method described in the literature.[6] Dianhydride derivative of L was obtained by reacting 4-chloroformylphthalic anhydride with L, by a slight modification of the method described in the literature[7] as follows. A solution of 4-chloroformylphthalic anhydride[8,9] (3.79 g, 18.0 mmol) in 30 cm^3 of acetonitrile was added dropwise to a hot (65°C) solution of acetonitrile (700 cm^3) containing L (3.10 g, 9.0 mmol). After the mixture was stirred for 20 min, it was cooled in an ice-water bath for 2 h to give a brownish orange precipitate. It was collected on a glass filter and dried *in vacuo*. The precipitate was dissolved in 100 cm^3 of chloroform with stirring and filtered off. The reddish orange filtrate was concentrated to about 40 cm^3 and poured into 1000 cm^3 of petroleum ether to give a brownish orange precipitate. It was filtered, washed with petroleum ether, and recrystallized from benzene to give the dianhydride of L as reddish orange crystals in an 18% yield (1.13 g). Found: C, 68.84; H, 4.27; N, 8.04%. Calc. for $C_{40}H_{28}O_8N_4$: C, 69.36; H, 4.07; N, 8.09%.

Preparation of polymer ligands

Three types of polymer ligands were prepared by polycondensation of the above dianhydride of L with diamines such as 1,3-propanediamine, 4,4'-diaminodiphenyl ether, and triethyleneglycol bis(4-aminophenyl) ether.

Preparation of Poly-L1

To a solution of 1,3-propanediamine (0.16 g, 2.15 mmol) in 50 cm^3 of *N*-methyl-2-pyrrolidone (NMP)

* Author to whom correspondence should be addressed.

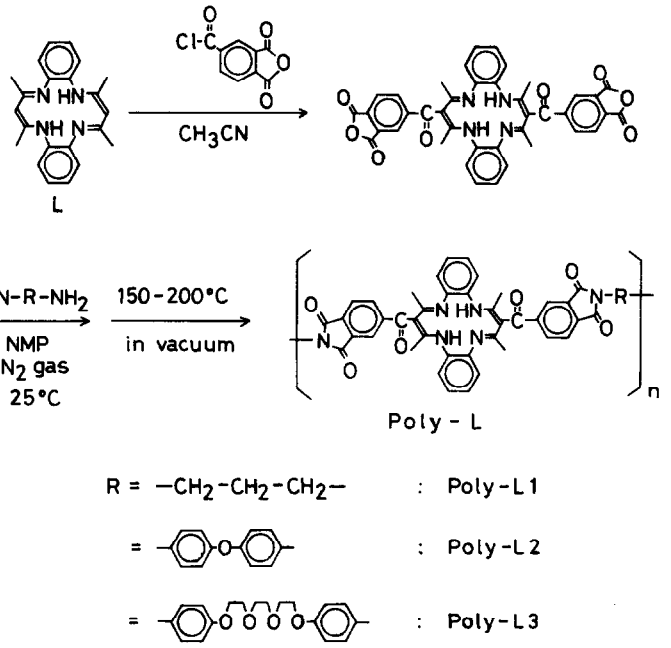

Fig. 1. Synthesis of polymer ligands.

was added a powdered dianhydride of L (1.49 g, 2.15 mmol) at 25°C under nitrogen atmosphere, and the yellowish orange solution was stirred vigorously for 3 h. It was poured into 1200 cm^3 of ether to give a yellow precipitate, which was collected on a glass filter, washed with ether, and dried *in vacuo*. The yield of the product, which was Poly(amic acid)-1, was 1.61 g. Found: C, 65.19; H, 5.27; N, 10.86%. Calc. for $(C_{43}H_{38}N_5O_9)$-$(C_{43}H_{38}N_6O_8)_4$-NH_2: C, 67.04; H, 5.02; N, 10.91%. This Poly(amic acid)-1 was converted to Poly(imide)-1 upon heating near 185°C for 1 h under vacuum. This was confirmed by the IR spectrum of the resulting brownish orange powder: absorption bands due to imide ring appeared at 1770 and 1710 cm^{-1} and those due to amide around 1630 cm^{-1} disappeared. This product, which is abbreviated as Poly-L1 hereafter, is soluble in chloroform and *N*,*N*-dimethylformamide (DMF) but insoluble in methanol (MeOH) and water.

Preparation of Poly-L2

A powdered dianhydride of L (0.48 g, 0.7 mmol) was added to a solution of 4,4′-diaminodiphenyl ether (0.14 g, 0.7 mmol) in 4 cm^3 of NMP under nitrogen atmosphere, and the solution was stirred vigorously at 25°C for 4 h. The highly viscous, yellowish orange solution was poured into 150 cm^3 of MeOH to give a yellow precipitate. It was filtered, washed with MeOH and then ether, and dried *in vacuo*. The yield of the product, which was Poly(amic acid)-2, was 0.60 g. This was converted to Poly(imide)-2 upon heating near 190°C for 1 h under vacuum. The conversion was confirmed by the IR spectrum of the resulting brownish yellow powder as described above. However, this product was partially insoluble in chloroform, so that a soluble part in chloroform was separated from it for use as a solvent extractant. The above Poly(imide)-2 (0.4 g) was added to 80 cm^3 of chloroform and the mixture was stirred at room temperature for 1 h, and the insoluble part was removed by filtration. The reddish orange filtrate was concentrated to about 15 cm^3 and poured into 200 cm^3 of petroleum ether to give a brownish orange precipitate. It was collected on a glass filter, washed with MeOH and then ether, and dried *in vacuo*. The yield was 0.24 g. This Poly(imide)-2 is abbreviated as Poly-L2 hereafter.

Preparation of Poly-L3

Triethyleneglycol bis(4-aminophenyl) ether [m.p.: 94.0–95.0°C, MS (*m/e*): 332 (M^+)] was obtained by hydrogenation of triethyleneglycol bis(4-nitrophenyl) ether [m.p.: 99.5–100°C, MS (*m/e*): 392 (M^+)] which was prepared by the reaction between *p*-nitrophenol and triethyleneglycol dibromide in the presence of K_2CO_3 in acetone.

To a solution of triethyleneglycol bis(4-aminophenyl) ether (0.17 g, 0.5 mmol) in 3 cm^3 of NMP was added a powdered dianhydride of L (0.35

g, 0.5 mmol) at 25°C under nitrogen atmosphere, and the solution was stirred vigorously for 5 h. The highly viscous yellowish orange solution was poured into 125 cm^3 of MeOH to give a yellow precipitate. It was filtered, washed with MeOH and then ether, and dried *in vacuo*. The yield of the product, which was Poly(amic acid)-3, was 0.4 g. This was converted to Poly(imide)-3 upon heating at 150°C for 30 min under vacuum. Its conversion was confirmed by the IR spectrum of the resulting brownish orange powder as described in the above polymer ligands. This Poly(imide)-3 is soluble in chloroform and DMF but insoluble in MeOH and water, which is abbreviated as Poly-L3 hereafter.

The analytical data and ^1H NMR spectral data in $CDCl_3$ for these polymer ligands are summarized in Table 1 along with their intrinsic viscosities in NMP.

Complexation in DMF

The complexation reactions of L and the polymer ligands with copper(II) and nickel(II) were studied in a homogeneous DMF solution. An absorption cell (cell length: 10 mm) with a stopper containing a DMF solution (5 cm^3) of L (5.0×10^{-5} M, 1 M = 1 mol dm^{-3}) or a polymer ligand (5.0×10^{-5} unit M) was thermostated at 25 ± 0.1°C. After the measurement of the absorption spectrum of the DMF solution over the range from 280 to 700 nm, a DMF solution of a metal acetate (0.1 cm^3, 2.5×10^{-3} M) was added to it. The absorption cell was shaken several times and thermostated again. And then the absorption spectra of the mixed DMF solution were measured at regular time intervals. The extent of the complexation was calculated from the absorption spectral changes.

Procedure for solvent extractions

Solvent extractions were carried out by shaking a 10 cm^3 test-tube (inner diameter: 14 mm) with a stopper at room temperature, which contains a chloroform solution (5 cm^3) of the ligand as an organic phase and an equivolume of acetate buffer solution (0.2 M) of the metal acetate as an aqueous phase. After a definite time of shaking, the content of the residual metal ions in aqueous phase was determined by atomic absorption spectrometry.

Measurements

UV and visible absorption spectra were recorded on a Hitachi 340 recording spectrophotometer. IR spectra were recorded on a Hitachi 215 grating spectrophotometer. Atomic absorption spectra were attained by use of a Nippon Jarrel Ash AA-1. ^1H NMR spectra were taken with a JEOL-PS 100 spectrometer, using $CDCl_3$ as the solvent and TMS as the internal standard. A pH value of a sample solution was measured with a Shibata 671 pH meter. Viscosities of the polymer ligands were measured in NMP with an Ostwald viscometer at 25°C, and the solutions of the polymer ligands were prepared in concentration from 0.05 to 0.80 g/100 cm^3 of NMP.

Table 1. Elemental analyses, ^1H NMR spectral data, and intrinsic viscosities of the polymer ligands

Polymer ligand	Found (calc.)[b]			δ (ppm)[c]			
	C	H	N	Methyl	Methylene	Phenyl ring	$[\eta]$[d]
Poly-L1	69.90 (69.98)	5.11 (4.75)	11.51 (11.39)	2.0 (2.14)	2.1, 3.8 (1.00)	7.0–8.5 (2.39)	0.12

[a] Ash was left in the elemental analyses of these polymer ligands.

[b] For Poly-L1 and Poly-L2, calculated on the assumptions that one of the end groups of a polymer chain is an amine moiety and the other a carboxyl moiety and that the polymerization degree (n) is five. For Poly-L3, calculated on the assumptions that both end groups are amine moieties and n is four.

[c] Measured in $CDCl_3$. The values in parentheses are relative ratios calculated from the integrated signal intensities.

[d] Measured in NMP at 25°C. Under the same conditions, the η_{sp}/C values (C = 0.80 g/100 cm^3) for polystyrene oligomers were 0.06 (MW = 1400) and 0.09 (MW = 2500).

Materials

All reagents were of reagent grade. Chloroform and acetonitrile were refluxed over P_2O_5 and distilled. *N,N*-dimethylformamide was distilled over CaH_2 under reduced pressure prior to use. Other solvents were purified by a usual manner. Water was deionized. Acetate buffer solutions (0.2 M) were used for adjusting pH from pH 3.5 to 5.8. The pH values below pH 3.5 or above pH 5.8 were adjusted by addition of an adequate amount of 1 M hydrochloric acid or sodium hydroxide.

RESULTS AND DISCUSSION

Polymerization degree of polymer ligands

Polymerization degree of the polymer ligands was estimated from viscosities, ^1H NMR spectra, and elemental analyses (Table 1). The intrinsic viscosities of the polymer ligands were determined by the extrapolation of the linear η_{sp}/C vs C plots to infinite dilution, where η_{sp} and C denote a specific viscosity and a concentration of the polymer solution, respectively. Specific viscosities of two polystyrene oligomers, whose molecular weights are determined to be *ca.* 1400 and 2500, are included in Table 1 for comparison. The relatively low viscosities of the polymer ligands indicate that these are oligomers whose polymerization degrees may be about five. Of course, they may consist of a mixture of polymer chains having different polymerization degrees.

The ^1H NMR spectrum of the Poly-L1 in $CDCl_3$ exhibited the following resonances: methyl protons at 2.0 ppm, methylene protons at 2.1 and 3.8 ppm, and phenyl ring protons in the 7.0–8.5 ppm region. The integrated intensity ratio $CH_3:CH_2:C_6H_4$ and C_6H_3 is 2.14:1.00:2.39. These values agree reasonably with the calculated values 2.00:1.00:2.33 from the assumption that one of the end groups of a polymer chain is an amine moiety and the other a carboxyl moiety. In addition, the analytical data for Poly-L1 are in best agreement with the calculated values on the basis of the above assumption and the polymerization degree (n) of five (Table 1). On the other hand, the integrated intensity ratio of the signals for Poly-L3 is 1.00 (CH_3): 1.25 (CH_2): 1.93 (C_6H_4 and C_6H_3), which is in agreement with the calculated value 1.00:1.25:2.00 based on the assumptions that both of the end groups of the polymer chain are amine moieties and that the polymerization degree is four. However, the analytical data for Poly-L3 deviate slightly from the calculated value on the basis of the above assumptions. This is believed to be due to the formation of ash in the elemental analysis.

As for Poly-L2, ^1H NMR spectrum could not be measured owing to poor solubility in $CDCl_3$, and also the ash was left in this case. However, this polymer ligand is considered to be an oligomer from the relatively low viscosity as well as Poly-L1 and Poly-L3.

Complexations of L and polymer ligands with copper(II) and nickel(II) in DMF

The complexing abilities of L and the polymer ligands for copper(II) and nickel(II) were studied in a homogeneous DMF solution. These were obtained from the absorption spectral changes of the DMF solution containing each of the ligands and the equimolar amount of the metal ion. Figure 2 shows the absorption spectral changes caused by the complex formation between (A) L and copper (II) and (B) Poly-L1 and copper(II). In the former case, the absorption maximum of L was shifted from 344 to 382 nm with decreasing its intensity and increasing the intensity of the new absorption band. With Poly-L1 the absorption maximum was shifted from 322 to 382 nm. For other systems, similar spectral changes were observed; the absorption maximum of the free ligands around 330 nm was shifted to around 380 and 390 nm by the complex formation with copper(II) and nickel(II), respectively. These results are summarized in Table 2. It should be noted that the pattern in the absorption spectral changes for the polymer ligands is quite similar to that for the monomer ligand, L. This indicates that the metal ions are coordinated with N_4-macrocyclic hole of the polymer ligands to form a square planar complex as well as the case of L.

From these absorption spectral changes the rates of complex formation for all systems were determined. As shown in Fig. 2, however, the rates of complex formation slowed down rapidly after 2 h even in the cases of copper(II). Thus, the final state that means a 100% complexation of the ligand was not obtained under the above conditions. Therefore, the final states for the complexation of L with the metal ions were estimated from the molar extinction coefficients of the isolated complexes; Cu(L) and Ni(L). On the other hand, those for the polymer ligands were obtained from the absorption spectra when excess amounts of the metal ions were further added to the DMF solutions after spectral changes were no longer observed. Figure 3 shows the plots of the extent of complexation of L and the polymer ligands with copper(II) and nickel(II). In each ligand, the complexation rate with copper(II) was found to be much faster than that with nickel(II). Moreover, the complexation rates of the ligands with both metal ions were found to be faster in the order of L $\ll$ Poly-

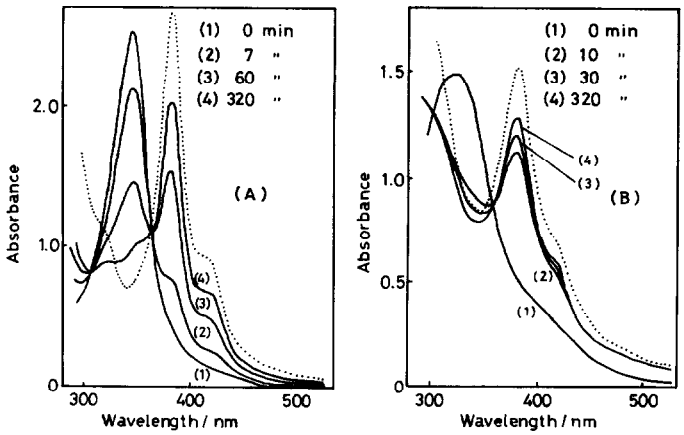

Fig. 2. Absorption spectral changes by complexation of (A) L (5×10^{-5} M) and (B) Poly-L1 (5×10^{-5} unit M) with copper(II) (5×10^{-5} M) in DMF solutions at 25°C. Absorption spectra shown by dotted lines were obtained by the addition of excess copper(II) (5×10^{-4} M). Cell length: 10 mm.

L1 ≃ Poly-L2 < Poly-L3. These results indicate that the polymer ligands possess a high selectivity for copper(II) as well as L and a faster complexation rate than that of L. These findings led us to apply the polymer ligands as selective extractants for copper(II).

Solvent extraction

The extractabilities of the polymer ligands obtained in the present work for copper(II) and nickel(II) have been investigated in comparison with L.

Effect of shaking time on extraction

Figure 4 shows the effect of shaking time on extraction of copper(II) by L and the polymer ligands under the conditions: the pH values of aqueous phase were adjusted to 5.6 with acetate buffer (0.2 M) and the concentration of the ligands in organic phase was ten times as much as that of copper(II) in aqueous phase (1×10^{-4} M). With the polymer ligands a 100% extraction of copper(II) was achieved after shaking within 30 min, whereas with L the extraction attained the equilibrium at *ca* 95% after shaking for 2 h. Noticeably, all of copper(II) in aqueous phase was extracted by Poly-L3 within 10 min. That is to say, the extraction rates of copper(II) by the polymer ligands are much faster than that by L. On the other hand, no nickel(II) was extracted by these ligands after shaking for 8 h (L), for 4 h (Poly-L1 and Poly-L2), and for 2 h (Poly-L3). These results are

Table 2. Absorption maxima of the ligands and their complexes with copper(II) and nickel(II)

Ligand	$\frac{\lambda \text{ max}}{\text{nm}}$ (log ε)		
	Free ligand	Copper(II) complex	Nickel(II) complex
L	344 (4.70)	382 (4.73)	392 (4.53)
Poly-L1	322 (4.48)	382 (4.51)	388 (4.41)
Poly-L2	314 (4.46)	380 (4.46)	386 (4.36)
Poly-L3	320 (4.47)	382 (4.49)	386 (4.41)

The molar extinction coefficients for the polymer ligands and their complexes are determined as per unit mol.

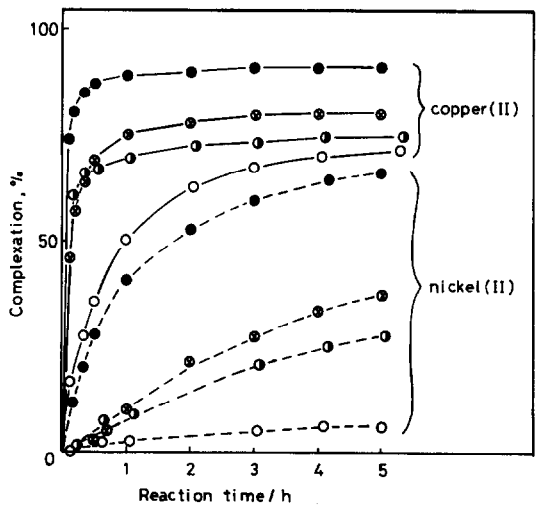

Fig. 3. Time-courses of complexation of L (5×10^{-5} M) and polymer ligands (5×10^{-5} unit M) with copper(II) and nickel(II) (5×10^{-5} M) in DMF solutions at 25°C. (○): L, ◑: Poly-L1, ⊗: Poly-L2, ●: Poly-L3.

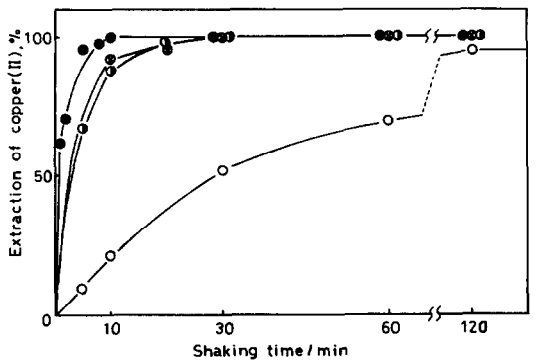

Fig. 4. Effect of shaking time on extraction of copper(II) (1×10^{-4} M) by L (1×10^{-3} M) and polymer ligands (1×10^{-3} unit M) at pH 5.6. ○: L, ◑: Poly-L1, ⊗: Poly-L2, ●: Poly-L3.

consistent with those observed in the complexation reactions described above.

Effect of pH on extraction

Figure 5 shows the pH dependence of extraction of copper(II) by the ligands. The concentrations of the ligands in organic phase and of copper(II) in aqueous phase were the same as those described in the above. The following shaking time was adopted for each system; 2 h for L, 30 min for Poly-L1 and Poly-L2, and 10 min for Poly-L3. These are the adequate time which is needed for attainment of the extraction equilibrium as mentioned above. The efficiency of extraction by these ligands decreases with a decrease in pH of the aqueous phase. In the case of the polymer ligands, the maximal extraction (100%) was observed in the pH range 5–7. Whereas, in the case of L, it was observed in the narrow pH range around 6.75.

Effect of molar ratio of copper(II) to ligand

Figure 6 shows the effect of the molar ratio of copper(II) to the polymer ligands. The concentration of the ligands in the organic phase was kept constant (1×10^{-3} unit M) and that of copper(II) in aqueous phase was varied from 1×10^{-4} to 1×10^{-3} M at pH 5.6. The shaking time was 60 and 30 min for Poly-L1 and Poly-L3, respectively. The efficiency of extraction increases with decrease in the molar ratio of copper(II) to the ligand. It is noticeable that Poly-L3 can extract copper(II) completely at the molar ratio of 1:5 (copper(II): unit M of the ligand), whereas with Poly-L1 and Poly-L2 the molar ratio of 1:10 was needed for its attainment (100%) in the same shaking time, 30 min (see Fig. 4). This indicates that Poly-L3 possesses the highest extractability for copper(II) among the polymer ligands investigated here.

Recovery of copper(II)

The recovery of copper(II) which was transferred into the organic phase by the complex formation with the polymer ligands was carried out by shaking with acidic solution. First, the copper(II) in aqueous phase (1×10^{-4} M) was transferred into the organic phase containing the polymer ligand (1×10^{-3} unit M) at pH 5.6 by shaking for 60 min for Poly-L1 and Poly-L2 and for 30 min for Poly-L3. After the complete extraction of copper(II), conc. hydrochloric acid (0.25 cm^3) was added to the aqueous phase and then shaken for an adequate time. The back-extracted copper(II) into the acidic aqueous solution was determined by atomic absorption spectrometry. The results are shown in Fig. 7. The recovered copper(II) was increased with an increase

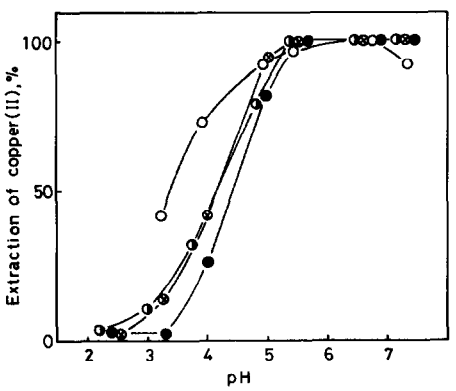

Fig. 5. The pH dependence of extraction of copper(II) (1×10^{-4} M) by L (1×10^{-3} M) and polymer ligands (1×10^{-3} unit M). ○: L (shaking for 2 h), ◑: Poly-L1 (for 30 min), ⊗: Poly-L2 (for 30 min), ●: Poly-L3 (for 10 min).

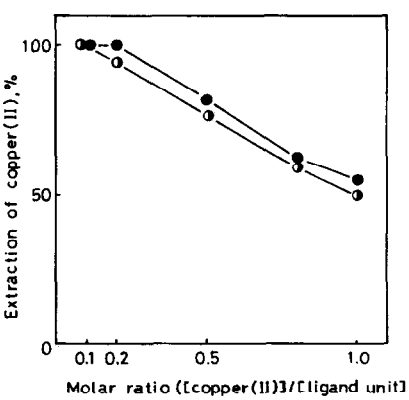

Fig. 6. Effect of the molar ratio of copper(II) to polymer ligands (1×10^{-3} unit M) on extraction at pH 5.6. ◑: Poly-L1 (shaking for 60 min), ●: Poly-L3 (for 30 min).

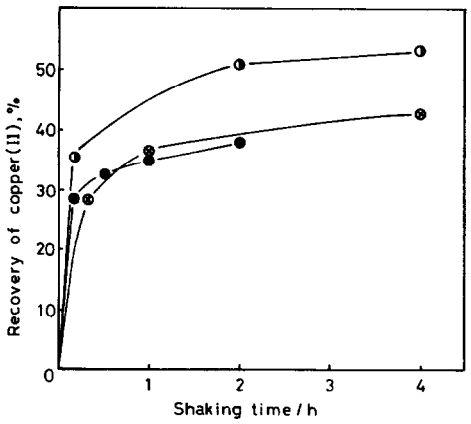

Fig. 7. Back-extraction (recovery) of copper(II) (1×10^{-4} M) with acidic solutions after complete extraction by polymer ligands (1×10^{-3} unit M). ◑: Poly-L1, ⊗: Poly-L2, ●: Poly-L3.

in shaking time. After shaking for 2 h, it was *ca* 50% for Poly-L1 and *ca* 40% for Poly-L2 and Poly-L3. Such a relatively low recovery of copper(II) may be caused by the high stability of the macrocyclic Schiff base complexes formed. It should be noted that some decomposition of these polymer ligands is unavoidable when in contact with acidic solution. Thus, the extent of decomposition of the polymer ligand was determined by measuring absorbances of their chloroform solutions after shaking for definite periods with acidic solutions. These were roughly estimated to be 12 and 8% for Poly-L1 and Poly-L2, respectively, after shaking for 4 h and 5% for Poly-L3 after shaking for 2 h. On the contrary, the monomeric ligand, L was found to be hydrolyzed almost completely within 30 min under the same conditions. These results indicate that the polymer ligands are superior to L for use as extractants.

General discussion

As we have described above, the polymer ligands, Poly-L1, -L2, and -L3 have marked advantages over the monomer ligand, L, in the extraction rate, with high selectivity for copper(II) as well as L. This can be ascribed to the fact that the complexation rate of the polymer ligands is much faster than that of the monomer ligand (L), which is clearly shown in the complexation reaction in a homogeneous DMF solution. These results are mainly caused by "polymer effects", that is, a local increase in concentration of the chelating group (L) is established in the polymer ligands. Morever, with the polymer ligands the recovery of the copper(II) transferred into the organic phase could be achieved by shaking with an acidic aqueous solution, without bringing about extensive decomposition.

As for three polymer ligands investigated here, Poly-L3 was found to display the fastest rate in the extraction and complexation than any others. This may arise from a difference in the nature of the linkage groups in the polymers, namely, which are trimethylene, diphenyl ether, and triethyleneglycol bis(*p*-phenylene) for Poly-L1, -L2, and -L3, respectively. The last group is considered to be much less hydrophobic than the former two groups. Such a less hydrophobic group may provide a thermodynamically preferable environment for the complex formation between a chelating group and a hydrated metal ion. This is a main reason why the extraction rate of Poly-L3 is accelerated, because the extraction rate should be determined by the rate of complex formation in such rigid tetraaza macrocyclic ligands as investigated here. A similar effect may operate for the complex formation of Poly-L3 with copper(II) and nickel(II) in a homogeneous DMF solution. A triethyleneglycol group of Poly-L3 may coordinate weakly to the metal ion by removing some molecules of solvated DMF, which would result in acceleration in the rate of complex formation between the macrocyclic chelating group and the metal ion.

In conclusion, Poly-L3 is the best extractant for copper(II) compared with the other ligands investigated in this work.

(*Received* 3 *October* 1984; *accepted* 9 *November* 1984)

Abstract—Intermolecular thermal-substitution reaction between aquaammineruthenium(III) complex and amino acid or imidazole derivative has been investigated in the solid state by the TG–DTA method. Pentaammineruthenium(III) complexes containing amino acid or imidazole derivative have been obtained directly by the thermal reactions. Glycine, β-alanine, and γ-aminobutyric acid coordinate to Ru(III) through their carbonyl oxygen, and imidazole does through its N(3) atom. Distinct coordination site is provided in the complex with histidine and/or adenine: the bonding site depends on the outer-sphere anion of aquaammine complex. The N(3) atom of the histidine and N(7) atom of the adenine coordinate to Ru(III) taking the paratoluenesulphonate salt of aquaammineruthenium(III) into the reaction. When the methanesulphonate salt is used, the nitrogen atom in the side-chain amino-group participates in complexation. Direct chelation of the glycine, histidine, and adenine to the deaquated *cis*-diaquatetraammineruthenium(III) complex has been confirmed.

The thermal matrix method, proposed by Wendlandt *et al.*,[1,2] was used for the preparation of some cobalt complexes. The method is based on a liberation of the volatile ligand, and followed by the migration of coordinatable solid compound to the position where the ligand had existed. One of the authors has tried this method for the synthesis of the uranyl-citrate complexes,[3] and Oki has also applied it to that of the Cr(III)–amino acid complexes.[4,5] We took up the reaction between the aquaammineruthenium(III) complex and amino acid, and/or imidazole derivative, because it needs many steps as reduction-oxidation of ruthenium to prepare the complex containing the latter ligand by solution reaction.[6] The present work was carried out with the following intentions: (i) investigating the possibility for direct bond-formation of amino acid or imidazole derivative to Ru(III) by intermolecular reaction in the solid phase. Direct chelation of them to the diaqua-Ru(III) complex is particularly interesting; (ii) elucidating the coordination site of the complexed solid ligand.

EXPERIMENTAL

Materials

The complexes $[Ru(OH_2)_n(NH_3)_{6-n}]X_3$ ($n = 1$ and X = PTS, MS; $n = 2$ and X = PTS, MS, TFMS) were prepared according to the literature.[7,8] The abbreviations used are as follows: PTS, paratoluenesulphonate ion; MS, methanesulphonate ion; TFMS, trifluoromethanesulphonate ion. Their purity was confirmed by the usual elemental analyses and by electronic spectral measurements. Three kinds of amino acids (glycine, β-alanine, γ-aminobutyric acid) and imidazole derivatives (imidazole, histidine, adenine), purchased from the Wako Pure Chemicals Co. Ltd, were used after the confirmation of their chemical purity.

Procedures and apparatus

A mixture of the aquaammine complex and the amino acid, and that of the aquaammine complex and imidazole derivative with 1:1 mole ratio was ground in a mortar and pestle. Then it was heated

with a rate of 5°C min^{-1} in Ar atmosphere using a Shimadzu DTG-20 type micro differential thermobalance. The abbreviations for the eleven mixture systems taken for thermal analyses are as follows: Gly(1), the complex [n = 1, X = PTS] and glycine; Ala(2), the complex [n = 1, X = PTS] and β-alanine; Aba(3), the complex [n = 1, X = PTS] and γ-aminobutyric acid; Imi(4), the complex [n = 1, X = PTS] and imidazole; His(5), the complex [n = 1, X = PTS] and histidine; Ade(6), the complex [n = 1, X = PTS] and adenine; His(7), the complex [n = 1, X = MS] and histidine; Ade(8), the complex [n = 1, X = MS] and adenine; Gly(9), the complex [n = 2, X = TFMS] and glycine; His(10), the complex [n = 2, X = PTS] and histidine; Ade(11), the complex [n = 2, X = MS] and adenine. The product after the thermal reaction was washed with cold solution of 0.1 mol dm^{-3} $HClO_4$, then with ether. Electronic spectra were measured on a Hitachi Recording Spectrophotometer 323. IR and far-IR spectra were recorded in KBr disks or in Nujol mulls with a JASCO A702 Spectrophotometer. X-ray diffraction patterns were obtained with a Shimadzu XD-3A diffractometer using nickel filtered copper K_α.

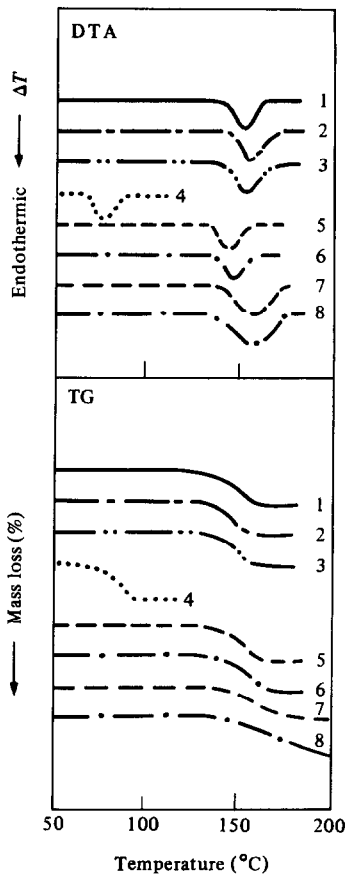

Fig. 1. DTA and TG curves of the mixture systems: 1, Gly(1); 2, Ala(2); 3, Aba(3); 4, Imi(4); 5, His(5); 6, Ade(6); 7, His(7); 8, Ade(8).

RESULTS AND DISCUSSION

Thermal analyses

Figures 1 and 2 show the derivatograms for the eleven mixture systems of aquaammineruthenium(III) complex and solid ligand. The first mass-loss stage in Fig. 1 is the release of one mol water, whose percentage is consistent within ±0.15%. Initiation temperature of deaquation from the aqua complex with PTS ion is observed in the range from 126 to 129°C, except for the Imi(4)-system. On the deaquation step, an endothermic peak is detected at 145, 150, 150, 139, and 140°C for Gly(1), Ala(2), Aba(3), His(5), and Ade(6), respectively. In Imi(4) system, the water liberation was accelerated because the co-melting of imidazole (m.p. = 90°C) and aqua complex occurred at lower temperature (75°C on DTA). On the other hand, the mass loss was initiated at 134 or 136°C with endothermic peak-maximum at 164 or 165°C in the systems of His(7) and Ade(8). The above fact suggests the difference of bond strength between H_2O and Ru(III) in the aqua complex with distinct counter ions and or the occurrence of another type of reaction. In the systems involving the *cis*-diaqua complex, the mass loss was initiated at 110, 113, and 117°C for Gly(9), His(10), and Ade(11), respectively. Continuous liberation of water molecules was found on the first stage but it has occurred by steps since two endothermic changes were separated on the DTA curve at 121, 137°C for Gly(9), at 126, 133°C for His(10), and at 128, 139°C for Ade(11).

In the present thermal reaction, the intermolecular interaction between the aqua complex and the solid compound is suggested strongly for the following reasons: the derivatogram for the mixture is distinguishable from that for the starting mono- or di-aqua complex; a steady line after the first mass-loss stage indicates the existence of a stable compound, and the analytical data of which confirms the completion of the deaquation reaction (see Table 1).

X-ray diffraction

Two typical X-ray diffraction patterns are shown in Fig. 3. The deaquation product A of the unmixed complex $[Ru(OH_2)(NH_3)_5](MS)_3$ reveals many diffractions in the 2θ (Cu, K_α) range of 20–50°, the pattern of which differs from that of the original aqua

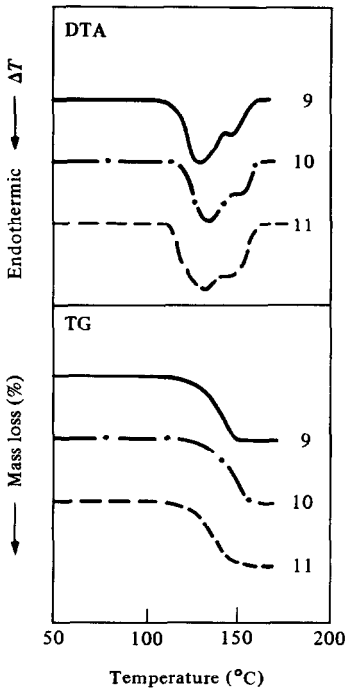

Fig. 2. DTA and TG curves of the mixture systems: 9, Gly(9); 10, His(10); 11, Ade(11).

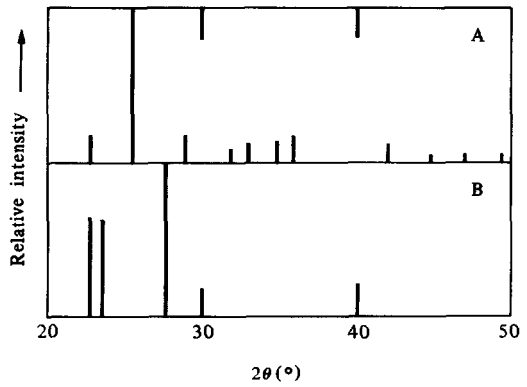

Fig. 3. X-ray diffraction powder patterns of the thermal-deaquation products obtained: A, from the unmixed $[Ru(OH_2)(NH_3)_5](MS)_3$; B, from the mixture between $[Ru(OH_2)(NH_3)_5](MS)_3$ and histidine.

complex. Most of diffractions, however, observed in A and/or original complex has been diminished on the reaction product B of the mixture between the aqua complex and histidine. A simple diffraction pattern, detected in the range of 20–30°, suggests the existence of a single species produced by the intermolecular thermal-reaction between aqua complex and histidine.

Electronic spectra

Electronic spectra of deaquation products observed with 0.1 mol dm^{-3} $HClO_4$ are shown in Table 2. Amino acid systems and imidazole derivative systems show two or three absorption bands λ_1 and λ_3. In amino acid systems, Gly(1), Ala(2), Aba(3), the band λ_1 (287–290 nm, ε = 700–1500 cm^{-1} mol^{-1} dm^3) is assigned to LMCT band contributed from carboxyl oxygen to metal ion.[9,10] The band λ_2 (344–352 nm, ε = 1100–2100) results from the nitrogen atom in amino group.[11,12] The VS-region band λ_3, with a low extinction coefficient 150–410, proved difficult to assign but it may be caused by some electronic interactions between new ligand and Ru metal. Since

[a] Measured in 0.1 mol dm^{-3} $HClO_4$ at RT.

the intramolecular substitution of aqua ligand for outer-sphere PTS ion hardly proceeds due to steric hindrance, the electronic spectral data indicate the coordination of the amino acid through the carboxylic oxygen atom.

In the imidazole derivative systems, Imi(4), His(5), Ade(6), the band λ_1 (302–306 nm, ε = 1100–1700) has the same absorption as observed in the pentaammineimidazoleruthenium(III) complex,[6,13] or in the pentaamminehistidineruthenium(III) complex.[14] The band λ_1, then, is assigned to LMCT band of the imidazole N-atom to Ru(III). The band λ_2 detected in His(5) and Ade(6) due to the side-chain amino group. The band λ_3 around 440 and 540 nm, in imidazole derivative systems, could be assigned to a CT transition from π-orbital of the ligand to a t_{2g} level of Ru(III).[15,16] It is noteworthy that the spectra of His(7) and Ade(8) with MS ion differ from those of His(5) and Ade(6) with PTS ion. The CT band λ_1 has revealed a blue shift from 303 to 263 nm with enhanced intensity. The λ_2 has diminished and the His(5)'s λ_3 has exhibited a red shift from 538 to 566 nm.

The thermal deaquation–anation reaction has been known in the aquapentaammineruthenium(III) complex with TFMS anions.[17] However, the coordination of the O-atom in TFMS ion and that of the imidazole N-atom have been ruled out by the above spectral changes and by the fact that no characteristic IR-band of ν_{as}(S=O) has been detected in the region 1300–1420 cm^{-1} due to the coordination of TFMS ion.[17] The coordination of the amido N-atom, therefore, is indicated in His(7), and Ade(8).

The CT band λ_1 of the tetraammine complex Gly(9) has revealed a red shift from 287 nm in Gly(1) to 295 nm, while that of His(10) has exhibited a blue shift from 303 nm in His(5) to 295 nm. Spectral feature has been reported[18] for the chelated complexes, the absorption maximum is at 288 nm (ε = 1900) for $[Ru(III)(\underline{N}H_2–CH_2–CO\underline{O})(NH_3)_4]^{2+}$ and 296 nm (ε = 1500) for $[Ru(III)(\underline{N}H_2–CH_2–C(NH_2)–\underline{O})(NH_3)_4]^{3+}$. Two bands are observed as λ_1 on Ade(11)'s spectrum; they are very similar to that found in Ade(6) and Ade(8). The extinction coefficients of λ_2 and λ_3 are deduced in Gly(9), His(10), Ade(11), and the absorption maximum exhibits a red shift of 10–15 nm. The formation of the chelated complex should be suggested by the additional bonding of the amido N-atom in Gly(9) and His(10) and by that of the imidazole N(9)- or N(7)-atom[12] in Ade(11): the electronic charge on the complex ion may be +3.[18]

IR spectra of amino acid system

The characteristic IR bands are shown in Table 3. On the spectra for the deaquated products of Gly(1), Gly(9), Ala(2), and Aba(3), no band assignable to the carboxyl group has been seen around 1750 cm^{-1}. In Gly(1), Ala(2), and Aba(3), the symmetrical and asymmetrical vibrations $\nu(COO^-)$ of the ionized carboxylic group have shifted 10–30 cm^{-1} to lower position. It is clear that the carboxylic group engages in complexation.

When a carboxylate ion coordinate to metal ion as a unidentate ligand, a shifting of $\nu_s(COO^-)$ to lower wavenumber and that of $\nu_{as}(COO^-)$ to higher

Table 3. IR spectral data for the amino acid compound

System	Compound	Band (cm^{-1}) assignments $\nu_{as}(COO^-)$	$\nu_s(COO^-)$	$\nu_s(CCN)$	$\Delta(COO^-)$
Free	Glycine	1603(s)	1405(s)	893(s)	201
Gly(1)	$[Ru(Gly)A_5]X_3$	1575(m)	1395(m)	893(m)	180
Gly(9)	$[Ru(Gly)A_4]Z_3$	1572(m)	1398(s)	889(w)	174
Free	β-Alanine	1628(s)	1403(s)	885(m)	225
Ala(2)	$[Ru(Ala)A_5]X_3$	1572(m)	1395(m)	*	177

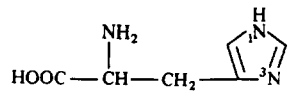
Aba(3)	$[Ru(Aba)A_5]X_3$	1595(w)	1392(m)	*	203

* Not recorded clearly.

wavenumber has been known.[19] The separation between two $\nu(COO^-)$ will be much larger in the unidentate ligand than in the free ion. The opposite trend should be observed if carboxylate ion plays as a bidentate ligand. Although the separation in Gly(1), Ala(2), and Aba(3) was not so large their mass-loss and analytical data are indicative of unidentate coordination. The reverse shifts to lower wave number of $\nu_{as}(COO^-)$ could be considered that the remaining –C=O bond in COO^- might be released owing to attractive interaction between the O-atom and the H-atom in amino group or in ammine ligand. Such interaction has been noted in the guanine cobalt(III) complex between the amido H-atom and the carbonyl O-atom.[20]



Electronic spectral indication for Gly(9) is the (O, N) chelate. Bidentate coordination, however, remained for carboxylic group, but the band due to ν_s(C–C–N) has shifted with weak intensity from 893 to 889 cm^{-1}, so that direct chelation of glycine (O, N) has been assured in Gly(9).

IR spectra of imidazole derivative system

The result for the Imi(4)-system is shown in Table 4. The strong band of ν(N(3)–H) at 2800 cm^{-1} for imidazole has clearly disappeared. The ring vibration band of ν_{as}(C=N–C=C) for free imidazole exhibits a higher shift of 12 cm^{-1}, while the band of ν_s(C=N–C=C) gives a lower shift of 25 cm^{-1}. The shifts indicate the coordination of imidazole by the N(3)-atom.[21] A weak shoulder also appears at 435 cm^{-1}. According to the Irving–Williams relation,[22] the ratio of $\nu(M-N_{imidazole})/\nu(M-N_{ammine})$ is in the range of 0.7–0.8. The observed one is 0.83, so that the band at 435 cm^{-1} in Imi(4) could be assigned to the stretching vibration mode of Ru–N(3). Additional evidence for N(3) coordination is as follows: the strong band of ν(N(1)–H) remained at 1055 cm^{-1}; the band of δ(N(1)–H) at 935 cm^{-1} has remarkably decreased in intensity and the ring vibration at 662 cm^{-1} also gave reduced intensity, which implies the existence of charge on the imidazole N(1)-atom.[23]

Band assignments[24,25] for His(5), His(7), His(10) are given in Table 5. Characteristic IR-band of ν_{as}(S=O) on the coordination of sulphonate ion[17] was not clear because the band overlaps with other vibrations. The bands ν_s and ν_{as} modes of COO^- do not exhibit any shift, from which the coordination by carboxyl O-atom is excluded in those complexes. The imidazole ring vibrations of ν(C=C), ν(C=N) and the bands ν, δ(N(1)–H) have been detected without any changes, though the former's intensity has markedly decreased. In the spectra of His(5)-system, the bands δ_s, δ_{as} mode of NH_3^+ and ν_s(C–C–N) contributed from amino group appear to be identical with the analogous bands for free histidine. In the spectra of His(7)-system, the vibration modes of $\delta_s(NH_3^+)$, ν_s(C–C–N) have exhibited a shift of band to lower position and a decrease of intensity. The new band at 423 cm^{-1} is assignable to ν(Ru–N_{amido}). In the spectra of His(10)-system, the spectral change of imidazole ring is observed and the same vibrational profile of NH_2 group with the His(7)-system is also found. As a consequence, the coordination of the imidazole N(3)-atom for His(5), the amido N-atom for His(7), and the chelation by the N(3) and N_{amido} atoms for His(10) has been assumed. The results are in agreement with the UV–VS spectral data.

Band assignments for Ade(6) and Ade(8) are shown in Table 6. The in-plane deformation band of

Table 6. IR spectral data for the adenine compounds 

System Compound	Free Adenine	Ade(6) $[Ru(Ade)A_5]X_3$	Ade(8) $[Ru(Ade)A_5]Y_3$	Assignments
	2680(s)	2690(m)	2680(m)	ν(N(9)–H)
	915(m)	918(w)	913(w)	δ(N(9)–H)
	872(m)	875(w)	—	[out plane]

	725(s)	723(m)	718(m)	[in plane]
	940(s)	940(m)	938(m)	$\delta(NH_2)$ [out plane]
	1255(m)	1245(m)	—	$\delta(NH_2)$ [wag.]
	1024(m)	—	1020(m)	ν(N(7)–H)
	1310(s)	1312(s)	1315(w)	ν(C–NH_2)
	—	—	435(w, sh)	ν(Ru–N_{amido})

NH_2 group at 1670 cm^{-1} does not reveal any change, which could be seen when the N(1)-atom is protonated.[26] The band due to ν(N(9)–H) is detected in both Ade(6) and Ade(8),[27,28] whereas the band ν(N(7)–H) is observed not in Ade(6) but in Ade(8). The above information implies that the proton does exist not on the N(1)-atom but on the N(9)-atom in both Ade(6) and Ade(8). In the spectra of Ade(8)-system, the disappearance of $\delta_{wag}(NH_2)$,[29] the lower shifts of δ_s and δ_{as} of NH_2, and the higher shift of ν(C–CH_2) with reduced intensity are observed. This type of IR-spectral change suggests the binding of the amido N-atom,[30] which is in accordance with the UV–VS spectral information, though the coordination of adenine by amido nitrogen is noted in a few cases.[31] The weak shoulder at 435 cm^{-1} is assignable to the Ru–N_{amido} stretching mode. In the spectra of the Ade(6)-system, the unchanged vibrations assigned to NH_2 group indicate that the N_{amido} atom does not coordinate. The N(7)-atom, then, is a most likely coordination site in Ade(6).

With respect to the Ade(11)-system, two possibilities of chelation by N_{amido}–N(7) or N_{amido}–N(9) pairs are provided from the electronic spectra. If the latter pair N_{amido}–N(9) participated in coordination, the complex should be presumably a linear single-bridged structure as reported on the Co(II)–adenine complex.[32] Unfortunately, the mass-loss and analytical data do not support the coordination of such bridging type. Disappearance of the bands ν(N(9)–H), ν(N(7)–H), ν(C=N), and some of $\delta(NH_2)$ may support the chelation by the N_{amido} and N(7) atoms in Ade(11).

Conclusion

The solid-phase thermal reaction for the mixture, taken in this work, was the intermolecular substitution reaction between aqua ligand and solid compound (Y, amino acid; Z, imidazole derivative): $[Ru(OH_2)(NH_3)_5]X_3 + Y$ or $Z \rightarrow [Ru(Y \text{ or } Z)(NH_3)_5]X_3 + H_2O$ (1); *cis*-$[Ru(OH_2)_2(NH_3)_4]X_3 + Y$ or $Z \rightarrow [Ru(Y \text{ or } Z)(NH_3)_4]X_3 + 2H_2O$ (2). The unidentate coordination of amino acid, by eqn (1), has been confirmed, whose site is carboxylic oxygen atom. The chelation of glycine has been completed by eqn 2 with (O, N) coordination. Imidazole coordinates to the complex with its N(3)-atom. Distinct binding site has been found in the histidine and adenine systems: the amido N-atom in the MS-salt, and the imidazole N-atom in the PTS-salt are concerned with the coordination. It was found that the deaquation temperature is higher *ca.* 10°C in the MS-salt than in the PTS-salt, which reflected the bond breaking of H_2O: the hydrogen bonding of outer-sphere ion with the H-atom in aqua- and ammine-ligand is enhanced in the MS-salt than the PTS-salt because the sterical hindrance in crystal lattice and the electrostatic interaction to metal ion of the former ion should be smaller. Nucleophilic attack of the carboxyl group may be predominant in the histidine because its pK value is the smallest. The carboxyl group, however, should have undergone much stronger electronic-repulsion from the PTS-ion than the MS-ion in the mixture; the coordination of the imidazole N-atom may then preponderate in the PTS-salt. The favourable coordination site of the amido N-atom in the MS-salt could be correlated with the fact that a high energy was employed in the thermal reaction. For the adenine systems, similar explanations of the effect of outer-sphere ion could be appropriate, in which the pK value of N(1)-atom is the smallest.

NEW SYNTHESIS OF $K_2[TcF_6]$

R. ALBERTO and G. ANDEREGG
Laboratorium für Anorganische Chemie, ETH Zürich, CH-8092 Zürich, Switzerland

(*Received* 19 *October* 1984; *accepted* 9 *November* 1984)

Abstract—A new high yield synthesis of $K_2[^{99}TcF_6]$ is given. It is based on eqn (1) and uses 40% aqueous HF as solvent.

$$[^{99}TcBr_6]^{2-} + 6F^- + 6Ag^+ \rightarrow [^{99}TcF_6]^{2-} + 6AgBr \quad (1)$$

The hexahalogenotechnetate(IV) anions have been known for a long time.[1] Those with X = Cl, Br, I can be obtained by the reduction of pertechnetate in the corresponding aqueous hydrogen halide solutions. On the other hand, up to now $K_2[TcF_6]$ was prepared by analogy with the synthesis of $K_2[ReF_6]$,[2] i.e., from $K_2[TcBr_6]$ in a melt of KHF_2 ($T = 220°C$), followed by an aqueous work up.[3] This method is lengthy and rather complicated, if radioactive substances are used, and the yields are unsatisfactory.

During the course of our work we became interested in a Tc(IV) starting material which is stable towards hydrolysis over the largest possible pH range. The hexahalogenotechnetate ions with X = Cl, Br, and I, however, are hydrolysed very rapidly in aqueous solution to TcO_2. Since TcF_6^{2-} fulfils these expectations, we developed a simpler and better synthesis. We find that TcF_6^{2-} is formed in a good yield by reacting $TcBr_6^{2-}$ with a 40% HF solution. No hydrolysis takes place at this hydrogen ion concentration and the substitution of Br^- by F^- in the Tc(IV) complex is fully accomplished. After bromide ions are removed from the solution by precipitation with a silver(I) solution, a red intermediate with an absorption band at 552 nm is produced very rapidly. The decrease of the absorbancy of the solution of the red species is accompanied by a parallel increase of the amount of the $[TcF_6]^{2-}$ produced. At room temperature the half-life of this reaction is about 110 h, at 80°C 100 min. After 24 h we obtain a solution containing $[TcF_6]^{2-}$ in 98% yield, the rest, the Tc, being in the form of TcO_4^-.

EXPERIMENTAL

0.4 g (6.09×10^{-4} mol) of $K_2[TcBr_6]$ were suspended in 15 cm^3 of a 40% HF solution. 3.69 mmol Ag^+ in the form of a 1.95 M AgF solution in 40% HF were dropped to the mixture. The black precipitate, which formed initially, changed to white AgBr and the solution became intensely red in colour. After 10 hr the AgBr precipitate was filtered off, dried and weighed. It corresponded to 99% of the calculated value. 14 h later the reaction was complete. The solution was cooled to room temperature, 45 cm^3 of EtOH were carefully added to the reaction mixture and on stirring $K_2[TcF_6]$ precipitated as a white powder (0.158 g, yield 89%).

Characterization

UV/VIS: $\lambda = 352$ nm, $\varepsilon = 15.9$; $\lambda = 291$ nm, $\varepsilon = 20.4$. IR: Tc-Fst 574 cm^{-1}; $R_f = 0.42$ (CH_3CN: H_2O = 2.5:1 v/v).

Elemental analysis

Found: K: 25.2 F: 38.3 Tc: 31.7%. Calc. for $K_2TcF_6 \cdot H_2O$: K: 25.3 F: 36.9 Tc: 32.0%.

^{99}Tc was determined by liquid scintillation; K^+ by complex formation with Kryptat 2.2.2 (Merck, Darmstadt), F^- potentiometrically by titration with $La(NO_3)_3$ solutions and a LaF_3 electrode.

THE STRUCTURE AND DYNAMICS OF THE COPPER(II)–L-PROLINE 1:2 COMPLEX IN SOLUTION

BERNARD HENRY, JEAN-CLAUDE BOUBEL and JEAN-JACQUES DELPUECH*

Laboratoire d'Etude des Solutions Organiques et Colloïdales, UA CNRS 406, Université de NANCY I, B.P. 239, 54506 Vandoeuvre-Les-Nancy Cedex, France

(*Received* 24 *July* 1984; *accepted* 29 *November* 1984)

Abstract—The ^{13}C relaxation times (T_1 and T_2) and isotropic contact shifts ($\Delta\omega$) of a one molar aqueous solution of L-proline at pH = 11 (or pD = 11.4) containing *ca* 10^{-4} M copper(II) perchlorate are measured at 62.86 MHz over a temperature range of 26–70°C. The purely dipolar longitudinal relaxation of carbon-13 nuclei contrasting with purely scalar transverse relaxation allowed us to extract carbon-to-metal distances (through T_1 measurements) and hyperfine coupling constants and dynamic parameters (from T_2 and $\Delta\omega$ measurements). The structure of the complex in solution is found closely similar to that in the solid state. Curve-fitting procedures allowed us to derive the hyperfine electron–carbon coupling constants $A_C = -1.95, +0.42, +1.90$ and -1.70 MHz for carbons $\alpha, \beta, \gamma, \delta$, of the pyrrolidinic ring, the reorientation correlation time of the complex, τ_R (25°C) $= 1.15 \times 10^{-10}$ sec, the L-proline exchange rate, k_M (25°C) $= 4.0 \times 10^5$ sec^{-1} (and the corresponding activation parameters $\Delta H^{\neq} = 9.0$ kcal mol^{-1} and $\Delta S^{\neq} = -0.7$ e.u.), and the electronic relaxation time, $T_{1e} = 1.13 \times 10^{-8}$ sec (at 25°C). The latter value was found in agreement with the one computed from ESR data and the above τ_R value, showing the predominant contributions of spin–rotation interaction and, to a lesser extent, of the effect of g-tensor anisotropy to the electronic relaxation rate.

The structure of aminoacid–paramagnetic ion complexes in aqueous solutions from ^{13}C relaxation studies has been the subject of only a small number of investigations in spite of their possible biological relevance.[1–7] Paramagnetic probes used for such studies are mainly the cobalt(II), manganese(II) and copper(II) ions.[8,9] The latter ion is effectively present in biological tissues, and its transport in the human body seems to involve copper(II)–oligopeptide complexes.[10–13] However NMR investigations on copper(II) complexes seem to be much more difficult than those involving cobalt(II) or manganese(II) ions. This is due to (i) decreased dipolar relaxation rates (which carry all the structural information) as a result of a smaller magnetic moment, (ii) line-broadenings of great amplitude due to long electronic relaxation times[14,15] $T_{1e} \simeq 10^{-9}$ sec, (iii) the difficulty in interpreting electronic relaxation rates in the absence of a mechanism involving the modulation of zero-field splitting tensor, (iv) the plasticity given to the metallic centre by virtue of the Jahn–Teller effect which may result in unexpected distortions of the geometry of Cu^{2+} complexes.[16,17] This explains why detailed NMR relaxation data are available in the literature for a few systems only, such as the hexahydrate ion[14,15,18–21] or complexes with pyridines[22] or acetylacetonate.[23]

As a first step in the NMR studies of copper(II)–peptide systems, we selected the example of the copper(II)–L-proline system for two reasons. This system has been thoroughly investigated in the literature by a variety of methods: potentiometry,[24] X-ray crystallography[25–27] of the solid complex and ESR of solid and aqueous samples. The second reason is that we have studied previously the complex of L-proline with manganese(II) ions and that we have in hand a convenient methodology in this case.[6,7]

Structural parameters were obtained from T_1 and T_2 relaxation times and paramagnetic shifts $\Delta\omega$ of the $\alpha, \beta, \gamma, \delta$ carbon-13 nuclei of the pyrrolidine ring. Experiments were carried out in D_2O solutions at pD = 11.4 using concentrations in the range [Cu^{2+}]

$\simeq 10^{-4}$ M and [L-proline] = 1.02 M. Under these conditions, the Cu(II) cation is bound to the aminoacid under the form of a single bis-proline complex Cu(L-Pro$^-$)$_2$.[24] Two species only are existing in solution, the free L-proline molecules and the ligand molecules in the bis-L-proline complex. Carbon nuclei may therefore exist either in a diamagnetic or a paramagnetic site respectively (these two sites are denoted D and M in the following). Ligand exchange is fast at high temperature (60°C) and intermediate at lower temperatures. The measured nuclear parameters T_1, T_2, $\Delta\omega$ therefore depend on their values in the paramagnetic site (T_{1M}, T_{2M}, $\Delta\omega_M$) and in the diamagnetic site (T_{1D}, T_{2D}, $\Delta\omega_D$ respectively), and on the exchange rate $1/\tau_M$ of the bound proline molecule. Extracting T_{1M}, T_{2M}m $\Delta\omega_M$ and $1/\tau_M$ from the experimentally observed quantities T_1, T_2, $\Delta\omega$ is the first point of these investigations. The longitudinal relaxation rates $1/T_{1M}$ in the paramagnetic site are almost exclusively dipolar, thus allowing us in turn to deduce the ion-to-ligand distances r_C and the rotational correlation time τ_R of the complex. The transverse relaxation rate $1/T_{2M}$ are on the contrary predominantly scalar in character, thus allowing us to derive the hyperfine coupling constants A_C between carbon nuclei and the unpaired electron, and the electronic relaxation time T_{1e}.

The purpose of these experiments was to answer some important questions about the structure and dynamics of copper(II) complexes; (i) is the geometry of the solid complex a convenient model for structures in aqueous solutions, (iii) what are the kinetic parameters of ligand exchange about the copper(II) centre, (iii) are NMR data compatible with ESR data (this concerns mainly the experimental electronic relaxation time T_{1e})?

EXPERIMENTAL

L-Proline and hydrated copper(II) perchlorate $Cu(ClO_4)_2 \cdot 4H_2O$ were obtained from Bachem Feinchemikalien and Fluka, respectively, and were used without further purification. Concentrations $C_S = 0, 3.0, 5.0, 10.0, 20.0, 30.0 \times 10^{-5}$ M of the Cu(II) cation and a fixed concentration $C_L = 1.02$ M of L-proline were used in this study. Solutions were added with deuterated soda NaOD to obtain pD = 11.4. Potentiometric measurements were carried out with a Methrom EA436 potentiometer and a combined glass–calomel Ingold microelectrode. All samples were prepared in a nitrogen atmosphere using water which has been purged with nitrogen and NMR tubes equipped with tight-fitting caps. The magnetic susceptibility of the complex $\mu_M = 2.03$ Bohr magnetons in water solution was measured according to the method first described by Evans[29], and then by Crawford and Swanson[30]. Longitudinal relaxation times of ^{13}C nuclei at 62.86 MHz are obtained from partially relaxed Fourier Transform spectra using a CAMECA 250 spectrometer, D_2O as an internal heteronuclear lock, and 180°–τ–90° pulse sequence with the fast inversion-recovery variant.[31] Transverse relaxation times are obtained from linebroadenings $\Delta\nu$ (measured at half width on spectra). Specific relaxation rates: $1/T_{ir} = (1/T_i - 1/T_{iD})/P_M$ (i = 1, or 2) are obtained from the slope of the least squares lines representing the relaxation rates $1/T_1$ and $1/T_2$ measured as a function of the fraction of bound ligand $p_M = 2C_S/C_L$. T_1 and T_2 values were determined at two (33° and 60°C) and at seven (26°, 33°, 38°, 46°, 51°, 60° and 70°C) temperatures, respectively. All calculations were performed on a Texas Instruments 980A minicomputer equipped with a digital plotter, Hewlett–Packard 7210A.

DETERMINATION OF STRUCTURAL AND KINETIC PARAMETERS

Theoretical expressions relating $\Delta\omega$, $1/T_1$, $1/T_2$ to C_S, C_L (or $p_M = 2C_S/C_L$), and T are well-known at the present time[32]. However, the computing path used for this purpose is far from being straight forward and its exact formulation should be reassessed in each particular case. The logical filiation in using the set of theoretical equations (1)–(9) starts from the ligand exchange effect (Swift and Connick equations:[14]

$$1/T_{1r} = (1/T_1 - 1/T_{1D})/p_M = 1/(T_{1M} + \tau_M) \quad (1)$$

$$1/T_{2r} = (1/T_2 - 1/T_{2D})/p_M = \frac{1}{\tau_M} \frac{1/T_{2M}^2 + 1/T_{2M}\tau_M + \Delta\omega_M^2}{(1/T_{2M} + 1/\tau_M)^2 + \Delta\omega_M^2} \quad (2)$$

$$\Delta\omega_r = \Delta\omega/p_M = \frac{\Delta\omega_M}{(1 + \tau_M/T_{2M})^2 + \tau_M^2\Delta\omega_M^2}. \quad (3)$$

Variable concentrations of copper(II) ion are seen to intervene in the obtaining of the normalized relaxation rates and paramagnetic shift, $1/T_{1r}$, $1/T_{2r}$ and $\Delta\omega_r$ (from least squares plots where correlation coefficients are always larger than 0.995). In a second step, the intermediary parameters τ_M, T_{1M}, T_{2M}, $\Delta\omega_M$ are expressed as a function of the temperature T and the resonant frequencies of carbon nuclei ω_C and of the unpaired electron $\omega_e \cdot \tau_M$ is simply assumed to

obey an Arrhenius law

$$\tau_M = \tau_M^{\circ} \exp(E_M/RT). \quad (4)$$

$\Delta\omega_M$ is related to the hyperfine coupling constant A_C through the equation

$$\Delta\omega_M/\omega_C = 2\pi A_C \mu_M \sqrt{S(S+1)}/3kT\gamma_c. \quad (5)$$

Relaxation rates in the paramagnetic site are expressed by classical equations relating $1/T_{1M}$ and $1/T_{2M}$ to ω_e, ω_C, τ_R and T_{1e}.[33] These expressions may be greatly simplified in the present case where

$$\tau_M (\sim 10^{-6} \text{ sec}) \gg T_{1e} (\sim 10^{-8} \text{ sec}) \gg \tau_R (\sim 10^{-10} \text{ sec}),$$

and

$$\omega_e^2 T_{1e}^2 \text{ and } \omega_e^2 \tau_R^2 \gg 1:$$

$$1/T_{1M} = \frac{2\times 10^{-14}}{5} \frac{\mu_M^2 \gamma_c^2}{r_c^6} \tau_R \quad (6)$$

and

$$1/T_{2M} = (7/6)(1/T_{1M}) + 4\pi^2 A^2 S(S+1) T_{1e}/3 \quad (7)$$

(provided that the contribution of the pseudocontact interaction to the overall hyperfine coupling constant is negligible compared to contact shift interactions, see the discussion below).

τ_R is again assumed to obey an Arrhenius law:

$$\tau_R = \tau_R^0 \exp(E_R/RT). \quad (8)$$

The electron relaxation rate may be shown to be inversely proportional to the reorientation correlation time:

$$1/T_{1e} = K/\tau_R \quad (9)$$

where the constant K is independent from T and ω (see Discussion).

We have then to adjust a set of unknown parameters, some of which refer to the whole complex (τ_M^0, E_M^0, τ_R^0, E_R^0, K) or to each ^{13}C nucleus characterized by its own electron-to-nucleus distance r_c ($r_{c\alpha}$, $r_{c\beta}$, $r_{c\gamma}$, $r_{c\delta}$ for carbons α, β, γ, δ, respectively) and hyperfine coupling constants (A_α, A_β, A_γ, A_δ). These parameters are adjusted so as to obtain the best fit between the theoretical and experimental $1/T_{1r}$, $1/T_{2r}$ and $\Delta\omega_r$ values measured at several temperatures according to a generalized least squares procedure. As the great number of unknown parameters makes a one-step adjustment rather hazardous, a stepwise procedure has been devised in a previous investigation.[7] Its adaptation to the present example is schematically described in the following. In a first step, all the adjustable parameters are given an approximate value (denoted by superscript (1) thereafter), which in turn allows us to initiate an iterative procedure of optimization. Thus the hyperfine coupling constants $A_C^{(1)}$ (in fact $A_\alpha^{(1)}$, $A_\beta^{(1)}$, $A_\gamma^{(1)}$, $A_\delta^{(1)}$) are obtained by taking $\Delta\omega_M = \Delta\omega_r$ as a limiting expression for eqn (3) at temperature higher than 50°C. $\tau_M^{(1)}$ and $T_{2M}^{(1)}$ (at any temperature) are then deduced from eqns (2) and (3) which are recast under the form

$$1/T_{2M} = \frac{\Delta\omega_M(1/\tau_M - 1/T_{2r}) - \Delta\omega_r/\tau_M}{\Delta\omega_r} \quad (2\text{bis})$$

$$\Delta\omega_M = \frac{\Delta\omega_r}{(1-\tau_M/T_{2r})^2 + \tau_M^2 \Delta\omega_r^2}. \quad (3\text{bis})$$

Four τ_M values can be computed in this way, and the value finally adopted results from their arithmetic mean. Longitudinal relaxation rates in the paramagnetic site are computed from eqn (1):

$$(T_{1M}^{(1)})^{-1} = (T_{1r} - \tau_M^{(1)})^{-1}.$$

The chemical exchange is in fact fast enough to make $\tau_M^{(1)}$ negligible with respect to T_{1r}. $T_{1M}^{(1)}$ values obtained for carbons α, β, γ, δ of the pyrrolidine ring in the L-proline molecule allows us in turn to position the copper(II) with respect to ligand molecules. The procedure has been fully explained in a previous paper[6,7] and is based on the consideration of the three ratios

$$\lambda_{ij}^6 = \frac{T_{1M}^{(1)}(C_j)}{T_M^{(1)}(C_i)} = \left(\frac{r_{cj}}{r_{ci}}\right)^6, \quad \text{with } i, j = \alpha, \beta, \gamma, \delta.$$

The Cu^{2+} ion is therefore located on three spheres S_{ij} whose diameter M_iM_j is determined by the two points M_i and M_j which share the internuclear vector C_iC_j in a known ratio λ_{ij}. The position of the copper(II) nucleus results from the intersection of three spheres $S_{\alpha\beta}$, $S_{\beta\gamma}$, $S_{\gamma\delta}$. Two positions are actually obtained in this way, one of which can be rejected on account of a too close proximity of the Cu^{2+} ion to the pyrrolidine ring (one distance is less than 1 Å). This allows in turn to compute $\tau_R^{(1)}$ from eqn (6). Similar computations are also performed at 33°C. They yield similar distances r_c (Table 1) and a second value $\tau_R^{(1)}$ (33°C) which, combined with $\tau_R^{(1)}$ (60°C), allows us to deduce the Arrhenius parameters $\tau_R^{0(1)}$ and $E_R^{(1)}$. The longitudinal contribution to the transverse relaxation time is estimated as 7/6 $(T_{1M}^{(1)})^{-1}$ and is subtracted from the overall transverse relaxation rate T_{2M}^{-1} to isolate the scalar contribution

$$(T_{2M}^{(1)})_{RS}^{-1} = 4\pi^2 A^2 S(S+1) T_{1e}/3 \quad (7\text{bis})$$

(in fact the longitudinal contribution was always found to represent less than 1% of the total relaxation rate). The electronic relaxation time $T_{1e}^{(1)}$ is then extracted from eqn (7bis) and then the constant $K^{(1)}$ from eqn (9).

Table 1. The relaxation times T_{1M} (sec) of ^{13}C in bound L-proline molecules at 33 and 60°C; the distances (Å) between the Cu(II) cation and the atoms of L-proline in the complex Cu(L-Pro$^-$)$_2$(H$_2$O)$_2$ (see Fig. 3), and the corresponding values deduced from X-ray crystallography of the solid complex[27]

Atom	Aqueous solution 33°C		60°C		Solid state (room temperature)
	T_{1M}^{-1}	r	T_{1M}^{-1}	r	
C_α	2206±105	2.82±0.20	1304±95	2.91±0.19	2.85
C_β	323±33	3.88±0.29	190±18	4.01±0.28	3.98
C_γ	253±26	4.04±0.26	152±18	4.04±0.26	4.12
C_δ	1862±83	2.88±0.21	1088±73	2.88±0.21	2.96
C_0		2.77		2.93	2.82
N		1.98		2.06	1.96
O_1		1.99		2.03	2.03
O_2		3.97		4.07	4.04

A least squares optimization procedure is then started so as to obtain the best fit between the experimental and theoretical values of the function $1/T_{2r}(T)$ (Fig. 1). In this computational step, the parameters $A_C^{(1)}$ and $r_c^{(1)}$ are kept constant, and the five remaining parameters τ_M^0, E_M, K, τ_R^0, E_R are adjusted in the course of successive iterations, taking as initial values for the first iteration the above approximate set of parameters $\tau_M^{0(1)}$, $E_M^{(1)}$, $K^{(1)}$, $\tau_R^{0(1)}$, $E_R^{(1)}$. Let $\tau_M^{0(2)}$, $E_M^{(2)}$, $\tau_R^{0(2)}$, $E_R^{(2)}$ be the set of adjusted parameters at the end of this first optimization.

The whole cycle of computations is then started again using a slightly modified value of the hyperfine coupling constant A_C until a best value is found by trial and error for A_C (ensuring an absolute minimum of the squares of the residuals of the function $1/T_{2r}(T)$). This approach can be made easier if one decides to perform an auxiliary fit of the function $\Delta\omega_r(T)$ (Fig. 2) where all the parameters except A_C are given constant values equal to the above set $\tau_M^{0(2)}$, $E_M^{0(2)}$, etc.

Four sets of parameters are actually obtained in this way, since we may choose to optimize individual hyperfine coupling constants A_α, or A_β, or A_γ, or A_δ. The differences however are reasonably small (Table 2) and the final values of these parameters are then obtained as their arithmetic mean over the four carbon nuclei.

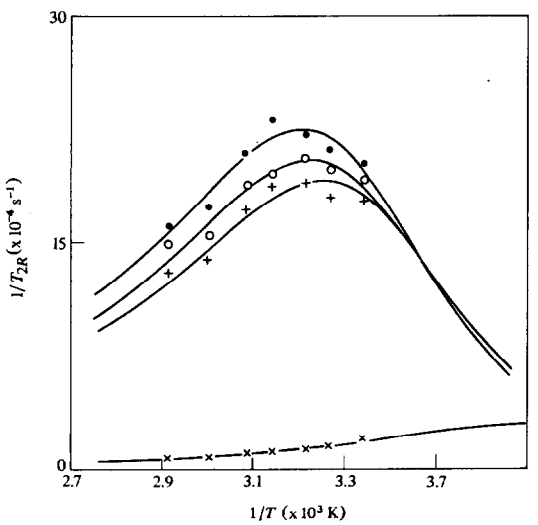

Fig. 1. Temperature variation of the specific relaxation rate $1/T_{2r} = (1/T_2^{obs} - 1/T_{2D})/P_M$ for the L-proline carbons at 62.86 MHz, obtained from 1.02 M solutions of L-proline in D_2O at pD = 11.4 and with $[Cu^{2+}] = 3.0$–30.0×10^{-5} M: (●) C_α, (×) C_β, (○) C_γ, (+) C_δ. The curves were computed using the parameters in Tables 1–3, and correspond to the best fit.

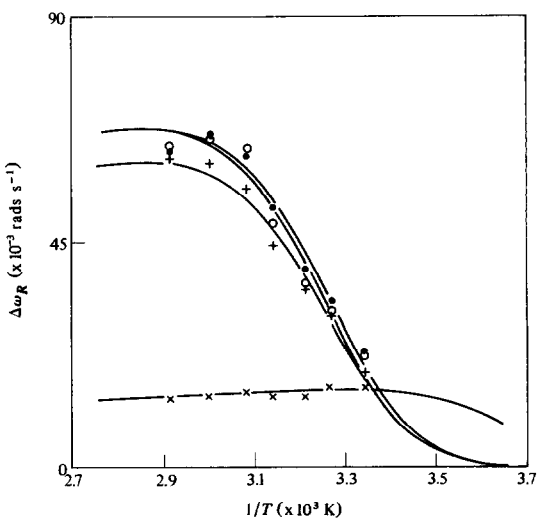

Fig. 2. Temperature variation of the specific paramagnetic shift $\Delta\omega_R = (\omega_{obs} - \omega_D)/P_M$ of the L-proline carbons at 62.86 MHz, using the same conditions and notations as in Fig. 1.

Table 2. Fitted values of the parameters $1/\tau_M^0$ (10^{13} sec^{-1}); τ_R^0 (10^{-14} sec), E_M and E_R (kcal mol^{-1}), and K (10^{22}) for carbons α to δ, and the corresponding mean values

	C_α	C_β	C_γ	C_δ	Mean
$1/\tau_M^0$	1.19±0.24	1.73±0.42	0.78±0.28	1.17±0.32	1.21±0.25
E_M	10.36±0.10	10.30±0.15	10.04±0.06	10.24±0.08	10.23±0.10
τ_R^0	2.77±0.52	3.13±0.27	4.22±0.48	3.91±0.52	3.51±0.56
E_R	4.95±0.09	4.70±0.04	4.80±0.03	4.72±0.06	4.79±0.08
K	1.34±0.25	1.00±0.18	1.02±0.27	0.96±0.32	1.08±0.13

RESULTS

Values of the longitudinal relaxation times T_{1M} are displayed in Table 1, together with the Cu^{2+}–^{13}C distances in the complex. The proline atomic coordinates which serve as a basis for the computation of these distances are taken from crystallographic data relative to the Cu^{2+}–proline complex.[27] Longitudinal relaxation times are determined with an error of *ca* 5%. Ratios such as λ_{ij} are then obtained with an error $\Delta\lambda_{ij}/\lambda_{ij}$ of 1.5%. Values $\lambda_{ij}\pm\Delta\lambda_{ij}$ are then introduced into the computer program to estimate all the possible sets of distance $r_{c\alpha}, r_{c\beta}, r_{c\gamma}, r_{c\delta}$. Each of these distances is given in Table 1 as the mean over the eight sets resulting from the combinations of the $\lambda_{\alpha\beta}$, $\lambda_{\beta\gamma}$, $\lambda_{\gamma\delta}$ ratios, and the corresponding errors are estimated as the difference between the maximum and the minimum values obtained for each parameter. Four sets of adjusted parameters τ_M^0, E_M, τ_R^0, E_R and K are computed for each carbon atom, each one with its own uncertainty (Table 2). Final values of these parameters are given in Tables 2 and 3 as arithmetic means over the four sets of data. These values allow us in turn to extrapolate correlation times and exchange rates for a conventional temperature of 25°C (Table 3).

DISCUSSION

Structure of the complex

X-ray diffraction of solid Cu^{2+}–L-proline[25–27] shows that copper is surrounded by two diagonal oxygens and two diagonal nitrogens at distances of 2.03 and 1.99 Å, respectively, in a square planar arrangement. The tetragonal arrangement is completed by two axial water oxygens at a distance of 2.52 Å. There is a good agreement between the distance found in the solid complex and those deduced from our NMR measurements (Table 1). This is a strong evidence for similar ligand arrangements in the solid and liquid states. The presence of two water molecules in the coordination sphere rapidly exchanging with the bulk solvent is demonstrated by the contact shift and line-broadening for the water protons (see below). The internuclear distances N–Cu^{2+} and O1–Cu^{2+} (1.98 and 1.99 A at 25°C) were computed by

Table 3. Parameters calculated from ^{13}C relaxation and contact shift data

Hyperfine coupling constants (MHz)
$A_{C\alpha} = -1.95\pm0.27$; $A_{C\beta} = 0.42\pm0.08$; $A_{C\gamma} = 1.90\pm0.30$; $A_{C\delta} = 1.70\pm0.30$ MHz

Reorientation correlation times
τ_R (25°C) $= (1.15\pm0.31)\times10^{-10}$ sec
$\tau_R^0 = (3.15\pm0.56)\times10^{-14}$ sec; $E_R = 4.79\pm0.08$ kcal mol^{-1}

Electronic relaxation parameters
T_{1e} (25°C) $= (1.13\pm0.41)\times10^{-8}$ sec; $K = (1.08\pm0.13)\times10^{22}$

Kinetic parameters
τ_M (25°C) $= 2.50\times10^{-6}$ sec or $k_M = 4.00\times10^5$ sec^{-1}
$1/\tau_M^0 = (1.21\pm0.25)\times10^{13}$ sec^{-1}
$E_M = 10.23\pm0.10$ kcal mol^{-1}
$\Delta H^{\neq} = 9.60\pm0.10$ kcal mol^{-1}
$\Delta S^{\neq} = -0.7\pm0.3$ e.u.

positioning first the Cu^{2+} cation with respect to carbons C_α, C_β, C_γ, C_δ of each proline ligand by the method explained above, and then by positioning the other atoms of the proline molecule with respect to the Cu^{2+} cation (using the known geometry of the proline molecule in the solid state). The structure of the whole complex is represented in Fig. 3, obtained from a computer using program ORTEP.[34]

It can be observed that hyperfine coupling constants of the carbon nuclei do not reflect the proximity of the metallic centre. Not only the most remote carbon C_γ is endowed with an abnormally large hyperfine coupling constant, but also there is an alternation in the signs of observed paramagnetic shifts. This could arise from a variable dipolar contribution (pseudo-contact shift) to the overall isotropic shift which we have reduced implicity to its Fermi contact term. This question is also of importance for computing the dynamic parameters of Tables 2 and 3 since eqn (7) is valid only in the absence of pseudo-contact effects. Pseudo-contact shifts (δ_{pc}) can be estimated from the principal components $g_\parallel$ and $g_\perp$ of the g-tensor according to the formula[35]

$$\delta_{pc} = \frac{\bar{g}\beta^2 S(S+1)(g_\parallel - g_\perp)}{9kT}\left(\frac{3\cos^2\theta - 1}{r_c^3}\right), \quad (10)$$

where $\bar{g} = (g_\parallel + 2g_\perp)/3$, β is the Bohr magneton, and θ the angle between the tetragonal axis and the internuclear Cu^{2+}–C vector. Taking $r_c = 2.82$ Å for carbon α (Table 1), $g_\parallel = 2.1853$ and $g_\perp = 2.0669$ from ESR data,[28] the pseudo-contact term at 25°C amount to *ca* 2 ppm compared to an overall paramagnetic shift $\Delta\omega_M = 240$ ppm. This contribution is clearly negligible with respect to the Fermi contact shift, this validates all the rest of calculations.

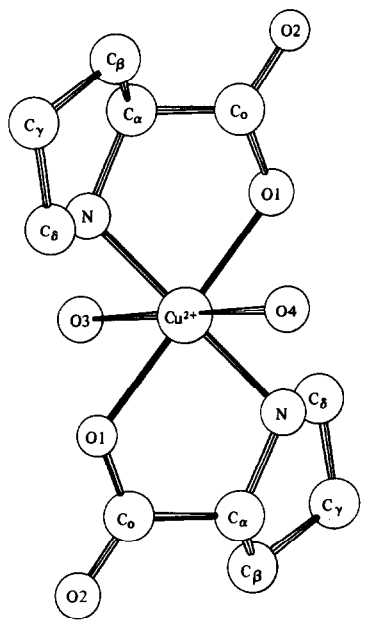

Fig. 3. The structure of the Cu(II)–L-proline complex in D_2O solution at pD = 11.4 and T = 33°C.

The hyperfine coupling constants A_C represent the electron spin density ρ on the observed nucleus according to Fermi formula,[17]

$$A = \frac{8\pi}{3h} g_e\beta_e g_N\beta_N\rho(0)$$

with

$$\rho(0) = (P^\alpha - P^\beta)\,|\varphi_S(0)|^2, \quad (11)$$

where P^α and P^β are the populations of the so called α or β spins (parallel on antiparallel to the magnetic field) and $|\varphi_s(0)|^2$ is the squared amplitude of the electronic wave function at the nucleus. Spin densities may be positive or negative depending on the sign of spin polarization. The value of ρ depends on spin delocalization and spin polarization through σ or π bonding. In copper(II)–proline complex, ESR studies show a fairly covalent bonding between the metal ion and the ligand, involving mainly the $d_{x^2-y^2}$ orbitals of the metal.[28] Theoretical studies show that spin delocalization *via* metal–ligand σ bonding involving filled ligand σ molecular orbitals should be characterized by positive coupling constants which attenuate rapidly as the number of bonds between the lone pair and the observed nucleus increases.[36] However, these predictions were not verified in the σ-electron system of piperidine,[37] in which case the observed chemical shifts alternate in sign, the coupling constant A_C being negative (upfield shifts) or positive (downfield shifts) for α- or β-carbons, respectively. The apparent discrepancy was traced to the neglect of correlation effects. This situation is clearly very similar to the one encountered in the present case for the σ-electron system of the five-membered pyrrolidinic ring of L-proline, where upfield or downfield contact shifts are observed for carbons in an α- or β-position with respect to the nitrogen atom.

The value of the magnetic moment $\mu_M = 2.03 \pm 0.10$ Bohr magnetons is in agreement with the value of 1.82 BM computed for an electron spin number $S = 1/2$ and the $g_\parallel$ and $g_\perp$ values mentioned above according to the formula

$$\mu_M^2 = (g_\parallel^2 + 2g_\perp^2)\beta^2 S(S+1)/3. \quad (12)$$

The NMR value is somewhat larger than the one deduced from ESR measurements[28] and eqn (12); this may be due to slightly modified $g_\parallel$ and $g_\perp$ values by going from the solid state to aqueous solutions of the complex.

Dynamics of the complex

The tumbling correlation time τ_R (25°C) = 1.15×10^{-10} sec is clearly larger than that of the aquo-complex $Cu(H_2O)_6^{2+}$, τ_R (25°C) = 2.0×10^{-11} sec as expected from the different sizes of the two complexes and, on the contrary, is closely similar to the one found for the Mn^{2+}–L-proline complex,[7] $\tau_R = 1.28 \times 10^{-10}$ sec.

Interesting conclusions result from the measured electronic relaxation times, $T_{1e} = 1.13 \times 10^{-8}$ sec at 25°C. For paramagnetic ions with $S = 1/2$, ESR relaxation times depend on anisotropic hyperfine constants and g-tensor, and from spin-rotational effects. The first contribution to the longitudinal relaxation rate $(1/T_{1e})_{g,A}$ has been studied by McConnell[38] and Kivelson[39] as resulting from the interaction of the unpaired electron of copper(II) ion with the copper nuclei with $I = 3/2$ (the two stable isotopes ^{63}Cu and ^{65}Cu each have spin $I = 3/2$ and nearly the same magnetic moment). The magnitude of this contribution can be expressed according to the approximate equation[38]

$$(1/T_{1e})_{g,A} = \frac{8\pi^2}{15}\left(\frac{\Delta g \beta B_0 + bI_z}{h}\right)^2\left(\frac{\tau_c}{1+\omega_e^2\tau_c^2}\right), \quad (13)$$

where $\Delta g = g_{\parallel} - g_{\perp} = 0.1184$, $B_0 = 5.87T$, $b = A_{\parallel} - A_{\perp}$, with $A_{\parallel}$ and $A_{\perp} = 3.134$ and 0.312×10^9 sec^{-1}, respectively.[28] τ_c is the correlation time for the reorientation of the tetragonal axis bearing $g_{\parallel}$. This reorientation may be due either to the random reorientation of the complex in the liquid (in which case $\tau_c = \tau_R$) or to dynamical Jahn–Teller effects as discussed by Lewis and Morgan.[40] However, Jahn–Teller effects are likely to occur only in the case of homogeneous hexacoordinated copper(II) complexes[41] such as $Cu(H_2O)_6^{2+}$. We are then left with the first possibility and $\tau_c = \tau_R$. Using the above values of τ_R and $\omega_e = 1.033 \times 10^{12}$ rad sec^{-1} results into $\omega_e^2\tau_R^2 \gg 1$, so that eqn (13) can be reduced to

$$(1/T_{1e})_{g,A} = \left(\frac{8\pi^2}{15}\right)\frac{1}{\omega_e^2\tau_R}\left(\frac{\Delta g \beta B_0 + bI_z}{h}\right)^2. \quad (14)$$

I_z is the magnetic number of the copper nuclei, $I_z = -3/2$, or $-1/2$, or $+1/2$, or $+3/2$. As pointed by McLachlan[42] and then by Poupko and Luz,[21] there is no single T_{1e} for Cu^{2+}, but rather a multi-exponential law for electronic relaxation whose rate constants are obtained by solving the $(2S+1)(2I+1)$ dimensional (8×8) relaxation matrix. However, according to McLachlan, we can calculate an average longitudinal relaxation rate $(1/T_{1e})^{-1}$ as the arithmetic mean of the four $1/T_{1e}$ values obtained from eqn (14) for each of the four I_z values.

The spin-rotational contribution $(1/T_{1e})_{SR}$ to $1/T_{1e}$ has been studied theoretically by Atkins and Kivelson[43] in the frame of the Hubbard's equations.[44] It can be expressed in terms of the deviations of the principal g-tensor components from the free electron value $g_e = 2.00233$:

$$(1/T_{1e})_{SR} = \delta g^2/9\tau_R, \quad (15)$$

where $\delta g^2 = (g_{\parallel} - g_e)^2 + 2(g_{\perp} - g_e)^2$.

Adding eqns (14) and (15) together results into the expression of the electronic relaxation time

$$1/T_{1e} = (1/T_{1e})_{g,A} + (1/T_{1e})_{SR} = K/\tau_R, \quad (16)$$

where

$$K = \delta g^2/9 + (8\pi^2/15h^2\omega_e^2)(\Delta g^2\beta^2 B_0^2 + b^2 I(I+1)/3). \quad (17)$$

This explains the origin of eqn (9) used to represent the electronic relation rate as mentioned above. With the values of $g_{\parallel}$ and $g_{\perp}$ quoted above, the spin-rotational contribution is in fact predominant, $(1/T_{1e})_{SR} = 4.04 \times 10^7$ sec^{-1} compared to $(1/T_{1e})_{g,A} = 4.49 \times 10^6$ sec^{-1} and $1/T_{1e} = 4.49 \times 10^7$ sec^{-1} at 25°C. More refined treatments following Kivelson *et al.*[39] do not change appreciably the above values of $1/T_{1e}$. The electronic relaxation time $T_{1e} = 1.31 \times 10^{-8}$ sec thus computed from ESR data is relatively close to the one obtained from our NMR data, $T_{1e} = 1.18 \times 10^{-8}$ sec. This consistency strongly supports the validity of the models used. The electronic relaxation time in the Cu^{2+}–L-proline complex is smaller by one order of magnitude than the one measured for the aquo-complex $Cu(H_2O)_6^{2+}$ from dynamic nuclear polarization experiments,[15] $T_{1e} = 1.67 \times 10^9$ sec at 30°C. This difference is probably due to both smaller correlation times τ_c and larger Δg^2 and δg^2 values in eqns (13), (16) and (17).

Kinetic parameters show intermediate ligand exchange rates, e.g. $k_M = 4.0 \times 10^5$ sec^{-1} at 25°C, between those of the Cu^{2+}–DMSO complex[45] ($k_M = 7.9 \times 10^3$ sec^{-1}) on the one hand, and those of $Cu(H_2O)_6^{2+}$ or $Cu(MeOH)_6^{2+}$ on the other hand ($k_M = 2 \times 10^8$ and 7.4×10^7 sec^{-1}, respectively).[14,21] In the first case, the difference arises from a much higher activation enthalpy for the Cu^{2+}–L-proline than for the Cu^{2+}–DMSO complex ($\Delta S^{\neq} = -0.7$ against -13.6 e.u.), more than counterbalancing an unfavorable activation enthalpy increase ($\Delta H^{\neq} =$ 9.60 against 7.25 kcal mol^{-1}). In the second case, the decreased exchange rate for the Cu^{2+}–L-proline complex arises from a higher activation enthalpy ($\Delta H^{\neq} = 9.60$ against 5 or 6.6 kcal mol^{-1}, respectively) and not too different activation entropies ($\Delta S^{\neq} = -0.7$ against -4 and -2.6 e.u.). Another interesting comparison is with the Mn^{2+}–L-proline complex previously studied[7] where ligand

exchange is slower than for the Cu^{2+}/L-proline complex ($k_M = 7.41 \times 10^4$ against 4.0×10^5 sec^{-1}), while the corresponding complexes with DMSO[45] show a reverse sequence of magnitude ($k_M = 2.7 \times 10^6$ and 7.9×10^3 sec^{-1}). These results cannot be rationalized in the present state of these investigations.

The water molecules. Only one line is observed for the protons of water, as the result from either a fast molecule exchange or a fast proton transfer between bond and free water molecules. An upfield shift of 0.0192 ppm and a line-broadening of 16 Hz are observed in a solution containing 0.01 M of the Cu^{2+}–L-proline complex. Pseudo-contact contribution to this shift can still be shown to be negligible using formula (10) with a distance $r_{Cu^{2+}-H}$ of 4.2 Å and cos $\theta = 0.9134$ (computed from the crystallographic data mentioned above). Under these conditions, eqns (1) to (5) are still valid and allow us to compute the electron–proton hyperfine coupling constant, $A_H = -1.7113$ MHz and an exchange rate $1/\tau_M$ (H_2O) $= 1.2 \times 10^8$ sec^{-1} at 25°C, not very far from the one found for the exchange of the axial water molecules in the aquo-complex, $1/\tau_M(H_2O) = 2 \times 10^8$ sec^{-1}. The sign of the paramagnetic shift is in agreement with predictions of Luz and Shulman[19] involving spin density transfer from the metal ion to the oxygen atomic orbital p_x perpendicular to the plane of the water molecule. In the case of the aquo-complex $Cu(H_2O)_6^{2+}$, the hyperfine constant is measured with poor accuracy and seems to be positive, $A \sim 0.1$ MHz;[19] this could result from positive shifts for water molecules in the equatorial plane averaging out the negative shift for the water molecules in axial position (assumed to have a contact shift of the same sign as in the Cu^{2+}–L-proline complex). It should however be emphasized that results pertaining to the aquo-complex are still controversial due to unresolved ESR spectra and to the possibility of dynamic Jahn–Teller effects.

CONCLUSION

These investigations show the importance of the Cu(II) cation as a paramagnetic probe, and the wealth of information resulting from combined NMR, ESR and X-ray crystallographic data. The electron relaxation rate is dominated by spin-rotational interaction and, to a lesser extent, by the effect of g-tensor anisotropy, thus making the electronic relaxation time directly proportional to the reorientation correlation time and almost independent from the magnetic field strength. This points to the possibility of using high magnetic field strengths to increase paramagnetic shifts in copper(II) complexes without extra line-broadening. Ligand exchange about the copper(II) ion is still slow on the NMR timescale, and transverse relaxation is purely scalar, so that selective line-broadening experiments are not sufficient by themselves to determine the binding sites of the ligand. However, the purely dipolar longitudinal relaxation contrasting with purely scalar transverse relaxation makes copper(II) a suitable paramagnetic probe to extract carbon-to-metal distances (through T_1 measurements of ^{13}C nuclei) and hyperfine coupling constants and dynamic parameters (from T_2 and shift measurements).

(*Received* 16 *October* 1984; *accepted* 29 *November* 1984)

Abstract—The dioxo-uranium(VI)–8-hydroxyquinoline–succinate system has been studied polarographically at constant ionic strength (μ = 0.6 M KCl) in aqueous alcohol (7:3) at different temperatures. The reduction of the simple and mixed complexes is reversible and diffusion controlled. The DeFord–Hume and Schaap–McMaster methods have been applied in the determination of composition and stability constants of the simple and mixed complexes respectively. The thermodynamic parameters ΔG, ΔH and ΔS have also been calculated.

The polarographic behaviours of uranium has been studied in various electrolytes and complexing agents under different conditions.[1–5] Mixed ligand complexes of uranium has only been studied potentiometrically.[6] Recently, dioxo-uranium(VI) complexes of amino acids[7] and hexamethylenetetramine[8] have been studied polarographically. The literature reveals that the mixed complexes with 8-hydroxyquinoline and succinate have not been studied polarographically. In the present communication, the polarographic behaviour of the UO_2^{2+}–8-hydroxyquinoline–succinate system has been studied systematically at different temperatures. The thermodynamic parameters ΔG, ΔH and ΔS have also been calculated.

EXPERIMENTAL

Materials. All the chemicals used were of analytical reagent grade and their solutions were prepared in conductivity water. 8-Hydroxyquinoline (8-HQ) and potassium succinate were used as ligands. Triton X-100 (0.002%) was used as the maximum suppressor. The ionic strength was maintained constant at μ = 0.6 M (KCl).

Apparatus and procedure. Polarograms in all instances were recorded with a manual polarograph (Toshniwal CLO2) in conjuction with a polyflex galvanometer (Toshniwal PL 50). A saturated calomel electrode was used as the reference electrode and was connected to the polarograph cell through a potassium chloride agar–agar-bridge. Oxygen was expelled by passing a slow stream of purified nitrogen into the test solution. The dropping mercury electrode (DME) had the following characteristics:

$h_{corr} = 30$ and

$m^{2/3}t^{1/6} = 2.236\ mg^{2/3}\ sec^{-1/2}$ in 0.1 M KCl

with open circuit.

RESULTS AND DISCUSSION

The reduction of UO_2^{2+} in 8-HQ and succinate, separately, was found to be reversible and diffusion controlled. The slopes of linear plots of log $i/i_d - i$ vs $E_{d.e.}$ were of the order of 59 ± 1 mV indicating one-electron changes. The same value of n was obtained by the millicoulometric studies.[9] Stability constants of simple complexes of UO_2^{2+} with 8-HQ and succinate were determined separately prior to the study of the mixed ligand system. Identical

* Author to whom correspondence should be addressed.

conditions were maintained in both the simple and mixed systems.

UO_2^{2+}–8-*hydroxyquinoline system*

A series of polarograms were obtained with increasing concentration of 8-HQ (0.02–0.10 M) at constant ionic strength, μ = 0.6 M KCl, at 20, 30 and 40°C. In each case, a well-defined reversible one-electron change diffusion controlled wave was obtained. A plot of $E_{1/2}$ vs log [8-HQ] was a smooth curve, indicating the formation of successive complexes. The DeFord and Hume's[10] method was applied to determine the stability constants of successive complexes. At 20°C, UO_2^{2+} forms three complexes with 8-HQ where as at 30 and 40°C it forms only two complexes (Table 1).

UO_2^{2+}–*succinate system*

Similar studies were carried out with increasing concentration of succinate (0.1–0.5 M) at constant ionic strength, μ = 0.6 M (KCl), at 20, 30 and 40°C. In each case, a well defined, reversible one-electron change and diffusion controlled wave appeared. A plot of $E_{1/2}$ vs log [succinate] was a smooth curve indicating the formation of successive complexes. DeFord and Hume's method was applied for the calculation of stability constants. An analysis of the $F(Y)$ functions reveals the formation of three successive complexes at 20°C and two at 30°C and 40°C similar to the UO_2^{2+}–8-HQ system. The results are summarized in Table 2.

UO_2^{2+}–8-*HQ–succinate system*

The concentration of 8-HQ was varied from 0.02–0.10 M keeping [succinate] constant at 0.1 M, at 20, 30 and 40°C. The $E_{1/2}$ values were more negative than those obtained in the absence of succinate showing the formation of mixed complexes. The system was also repeated at another concentration of succinate (0.2 M). These constant concentrations were termed as series 1 and 2. In all the cases, a well-defined diffusion controlled, reversible one-electron change wave appeared. Therefore, the method of Schaap and McMaster[11] was applied to determine the stability constants of the mixed complexes. The $F(X, Y)$ functions (X = 8-HQ, and Y = succinate) of these systems were determined. From the plots of $F(X, Y)$ data vs [8-HQ], the constants A, B, C, D were obtained. The stability constants have been calculated from these constants and are summarized in Table 3. At 20°C only two species $[UO_2(8\text{-HQ})(\text{succinate})]^-$ and $[UO_2(8\text{-HQ})_2(\text{succinate})]^{2-}$ exist in the aqueous solution while the negative values of log β_{12} ruled out the possibility of $[UO_2(8\text{-HQ})(\text{succinate})_2]^{3-}$ in the aqueous solution. At 30

At 20°C, log $A = 1.653$, log $B = 2.840$, log $C = 4.079$, log $D = 5.2$, log $\beta_{11} = 3.720$, log $\beta_{12} = -$, log $\beta_{21} = 4.835$.
At 30°C, log $A = 1.477$, log $B = 3.176$, log $C = 4.409$, log $\beta_{11} = 4.164$.
At 40°C, log $A = 1.301$, log $B = 2.00$, log $C = 4.219$, log $\beta_{11} = 2.83$.

and 40°C only the $[UO_2(8\text{-HQ})(\text{succinate})]^-$ exists in the aqueous solution. While the negative value of log β_{12} ruled out the possibility of β_{12} complex in the aqueous solution.

The formation constant of the mixed ligand complex log β_{11} at 30°C is equal to 4.23 (average of the values at 0.1 and 0.2 M succinate, Tables 3 and 4). The results of this study at 30°C are summarized below and the numerical values shown are the log of equilibrium constants of the reactions indicated.

The tendency of the succinate anion to add as the second ligand to $[UO_2(\text{succinate})]$ and $[UO_2(8\text{-HQ})]^+$ can be compared. The log K values are 0.918 and 2.63 respectively. Because the statistical factor is only 2 in favour of mixed complexes, the largest part of the difference in log K values must be attributed to the neutralization of charge. The tendency to add the charged 8-HQ anion as the second ligand to $[UO_2(8\text{-HQ})]^+$ and to $[UO_2(\text{succinate})]$ can also be compared. In this case also charge neutralization effect is expected and, indeed is observed. Log K values are 1.29 and 2.452 respectively.

$$2[UO_2(8\text{-HQ})(\text{succinate})]^- \rightleftharpoons [UO_2(8\text{-HQ})_2] + [UO_2(\text{succinate})_2]^{2-}.$$

The constant for this disproportionation reaction is 0.0013, i.e. log $K = -2.8$; naturally the mixed complex is favoured. Similar conclusion can be drawn from K_M values, i.e. log $K_M = \log \beta_{11} - 1/2$ [log β_{02} + log β_{20}]. The positive value of

At 20°C, log A = 1.778, log B = 3.04, log C = 4.17, log D = 5.431, log β_{11} = 3.83, log β_{12} = –, log β_{21} = 4.96.

At 30°C, log A = 1.602, log B = 3.602, log C = 4.894, log β_{11} = 4.296.

At 40°C, log A = 1.477, log B = 2.477, log C = 4.377, log β_{11} = 3.12.

Table 5. Stepwise free energy change ΔG, enthalpy change ΔH and entropy change ΔS in kcal/mole at 30°C

Thermodynamic parameters	UO_2–(8-HQ) system	UO_2(II)–(succinate) system
$-\Delta G_1$	2.208	2.453
$-\Delta G_2$	3.988	3.720
ΔH_1	−15.05	−7.31
ΔH_2	+11.70	+4.80
ΔS_1	−42.409	−16.039
ΔS_2	51.840	+28.11

log K_M (1.44) indicated that the mixed complex $[UO_2(8\text{-HQ})(\text{succinate})]^-$ is more stable than the binary complexes $[UO_2(8\text{-HQ})_2]$ and $[UO_2(\text{succinate})_2]^{2-}$. The value of log β_{11} given in the literature is 3.57.[13] The difference might be due to the experimental conditions, i.e. temperature, medium and the ionic strength.

The thermodynamic constants of the UO_2–(8-HQ) and UO_2–(succinate) have been calculated using the known equations[14] and are summarized in Table 5. The values of free energy change, i.e. ΔG of the above complexes (Table 5) gives an idea of their relative stability. Stepwise enthalpies (ΔH_1, ΔH_2) for the formation of mono and bis 8-HQ complexes of UO_2^{2+} are −15.05 and +11.70 kcal/mole whereas in the case of the UO_2^{2+}–(succinate) system stepwise enthalpies are $\Delta H_1 = -7.31$ kcal/mole and $\Delta H_2 = +4.8$ kcal/mole. The entropy changeΔH which is negative for mono complexes may be due to the loss of transitional degree of freedom by the ligand attached. But this may be off-set by loss of hydration of the metal ion, which may in fact be sufficient to swing the entropy change over to the positive side. The residual positive charge on the central ion may still be sufficient to maintain some degree of ordering of the solvent outside the sphere of the ligand.

(*Received* 9 *April* 1984; *accepted after revision* 29 *November* 1984)

Abstract—Some five- and six-coordinated di- and tri-*n*-butyl tin(IV) complexes of the type Bu_2SnL, Bu_2SnL_2 and Bu_3SnL (where L is the anion of a monofunctional bidentate or bifunctional tridentate Schiff base) have been synthesized and characterised on the basis of microanalyses, molecular weight determinations, IR, NMR (^1H, ^{13}C, ^{119}Sn) and ^{119}Sn Mössbauer spectroscopy. These complexes are highly active towards bacteria.

Schiff bases continue to occupy an important position as ligands in metal coordination chemistry even after almost a century since their discovery. Sulphur and fluorine have long been used to increase the biological activity of an organic moiety[1] and organotin compounds have also found applications in medicinal chemistry.[2,3] However, no systematic study has been performed on such complexes. It was therefore considered of interest to prepare organotin complexes of the ligands of the structure given below:

and study their spectral properties and activity on pathogenic bacteria.

EXPERIMENTAL

Chemicals and solvents used were dried and purified by standard methods, and moisture was excluded from the glass apparatus using $CaCl_2$ drying tubes. The ligands were prepared by literature methods,[4,5] The complexes were prepared by methods similar to reported in earlier publications.[6] The details are given in Table 1.

The complexes were analyzed by the literature methods and the molecular weights were determined by the Gallenkamp ebulliometer or cryoscopically in freezing benzene. ^{119}Sn Mössbauer spectra were recorded with $Ba^{119}SnO_3$ source at 77 K and the values relative to SnO_2. The details of spectroscopic measurements are similar to those reported earlier.[7] All the complexes and starting materials were tested for bacterial activity by the method reported earlier.[8]

RESULTS AND DISCUSSION

Reactions of di-*n*-butyl and tri-*n*-butyl tin oxides with these ligands have been carried out in 1:1 and 1:2 molar ratios in refluxing benzene. These reactions proceed with the liberation of water, which is removed azeotropically with benzene.

$$Bu_2SnO + N\begin{matrix}OH\\SH\end{matrix} \rightarrow Bu_2Sn(O\hat{N}\hat{S}) + H_2O$$

$$Bu_2SnO + 2N\hat{X}H \rightarrow 2Bu_2Sn(\hat{XN})_2 + H_2O$$

$$(Bu_3Sn)_2O + 2N\hat{X}H \rightarrow 2Bu_3Sn(N\hat{X}) + H_2O.$$

The above reactions are quite facile and can be completed in 8–10 hr of refluxing. The resulting

	Brown red semi-solid		474.09	25.04	55.58	6.10	6.75

complexes are yellow to dark brown in colour. The complexes vary in state from solid to viscous liquids. Solids were recrystallized from a mixture of petroleum ether (30–40°C) and benzene (30:70). These monomeric complexes are soluble in common organic solvents.

A broad and strong band is observed in the region, 3300–2850 cm^{-1}. This band is attributed to ν(OH) and/or ν(NH) which does not appear in the complexes showing the deprotonation of these groups. A sharp and strong band at $\sim$ 1635 cm^{-1} in the complexes, of Schiff bases derived from *p*-fluoroaniline, compared to one at $\sim$ 1620 cm^{-1} in these ligands may be assigned to ν(C=N). However, in ligands derived from *o*-aminothiphenol, a strong band at 1670–1705 cm^{-1} is assigned to the N–H diformation vibrations, and the absence of ν(SH) at 2500–2600 cm^{-1} and ν(C=N) at 1600–1650 cm^{-1} are indicative of the benzothiazoline structure of the ligands and not the Schiff base structure.[9] In the metal complexes a new band appears at $\sim$ 1605 cm^{-1} which is assigned to ν(C=N) vibration.

In all ligands but benzaldehyde benzothiazoline, a band due to phenolic C–O stretching vibrations appears at $\sim$ 1275 cm^{-1} which shifts to the higher frequency indicating the bonding of ligand to the metal atom through phenolic oxygen.

In $Bu_3Sn(\widehat{OX}N)$ and $Bu_2(\widehat{O}N\widehat{S})$ type of complexes

The spectrum was recorded only in –Bu region.

two bands at ~ 595 and 575 cm^{-1} may be assigned to asymmetric and symmetric modes of (Sn–C) vibrations ($Bu_2Sn(\widehat{ON})_2$ show two (Sn–C) bands at ~ 595 and 520 cm^{-1} whereas $Bu_2Sn(\widehat{SN})_2$ show only one band at ~ 595 cm^{-1} due to asym (Sn–C). New bands at ~ 540, 420 and 370 may be assigned to ν(Sn–O), ν(Sn–N) and ν(Sn–S) respectively.[10]

The ^1H NMR data of these complexes have been listed in Table 2. The OH and NH proton signals are present in ligands and which are not observed in the metal complexes indicating the coordination of oxygen or sulphur with tin atom. The phenyl protons are observed in the region, δ 6.35–7.20 ppm and protons due to –CH or $-CH_3$ show marked downfield shift on complex formation. Protons due to butyl groups are also observed in the region δ 0.3–2.10 ppm in all complexes.

^{119}Sn Mössbauer spectra for two complexes of the type $Bu_2Sn(\widehat{NO})_2$ have been obtained and the values are given in Table 2. The observed isomer shift values are indicative of the presence of tin(IV) consistent with six coordinated Sn environments with *cis*-Bu groups.[1] The increase in observed ΔE values may be accounted for by distortion in the field.[12]

The mass spectrum of the compound $Bu_3Sn(OC_6H_4CHNC_6H_4F)$ has been analyzed and the fragmentation scheme is shown in Fig. 1. The molecular ion peak is observed at *m/e* 504 as well as the M^{2+} ion peak.

^{13}C NMR data for a few representative samples have been recorded and given in Table 3. The shifts in the positions of carbons attached with O or S and N are indicative of their coordination with the metal atom. The carbon of Bu groups are observed at

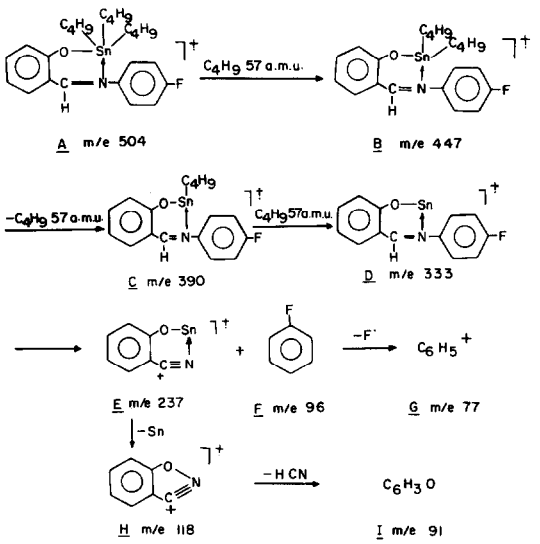

Fig. 1. Mass spectrum of $[C_{25}H_{36}OFNSn]$.

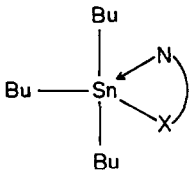

Table 4. Antibacterial activity of organotin Schiff base complexes

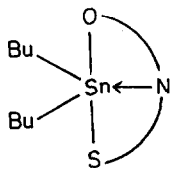
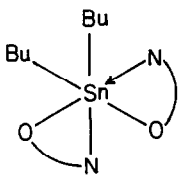
Bacteria	Compound	Diameter of inhibition zone (mm)							
		Bu_3Sn $(OC_{17}H_{11}NF)$	Bu_2Sn $(OC_{17}H_{11}NF)_2$	Bu_3Sn $(OC_{13}H_9NF)$	Bu_2Sn $(OC_{13}H_9NF)_2$	$OHC_{17}H_{11}NF$	$OHC_{13}H_9NF$	$(Bu_3Sn)_2O$	Bu_2SnO
Bacillus subtilis		35	22	38	15	10	5	20	12
Staphylococcus aureus		22	17	25	15	6	0	11	8
Escherichia cocii		0	0	0	0	0	0	0	0

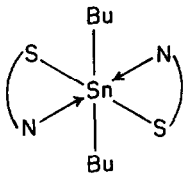


positions comparable to other similar compounds. The compound $Bu_3Sn(C_6H_5CHNC_6H_4S)$ gives a $^1J(^{119}Sn–^{13}C)$ value of 465 Hz, which indicates a five coordination.[13]

The compound $Bu_3Sn(OC_{10}H_6CHNC_6H_4F)$ gives a signal at +125.5 ppm whereas $Bu_3Sn(C_6H_5CHNC_6H_4S)$ gives a signal at +91.3 ppm in ^{119}Sn NMR, indicative of five coordination around tin atom and in agreement with previously reported values.[14,15]



On the basis of the foregoing discussions, the following tentative structures may be proposed.



(I)

(II)

(III)

(IV)

A preliminary screening of some of these complexes and ligands has been done and the results are given in Table 4. None of the complexes or ligands is active against Gram (−)ve bacteria whereas all the complexes show marked activity against Gram (+ve) bacteria as compared to their ligands which suggests that the complex formation increases the activity.

Acknowledgements—The authors are thankful to Professor T. N. Mitchell (W. Germany) for kindly recording the spectra. A. Saxena is thankful to CSIR, New Delhi for the award of SRF. The International Tin Research Council is thanked for permission to publish the paper.

(*Received* 11 *July* 1984; *accepted after revision* 29 *November* 1984)

Abstract—$(n+1):n$ sodium : dibenzo-30-crown-10 complexes are formed in nitromethane solutions. A model based on the coexistence in solution of 1 : 1, 2 : 1 and 3 : 2 complexes can account for the observed Na-23 chemical shifts, transverse and longitudinal relaxation rates. Logarithms of the equilibrium constants of formation at (25 ± 1)°C are (2.1 ± 0.3) and (2.5 ± 0.3) for the 2 : 1 and 3 : 2 complexes respectively. The characteristic Na-23 relaxation rates and chemical shifts of the aggregated complexes are compatible with a structure of ion pairs linked by the crown ether.

Large crown ethers form three-dimensional complexes with alkali metal cations in solution: for example, dibenzo-24-crown-8 (DB24C8) wraps around sodium cation and insulates it from solvent molecules or from the counter-anion.[1] A "wrap-around" structure has also been shown for Cs^+–DB30C10 using ^{133}Cs[2] or ^1H and ^{13}C NMR.[3] X-ray structures for the complex K^+–DB30C10 have been published in the case of the iodide[4] and of the thiocyanate.[5] Wrapping of the polyether chain around potassium is mainly accomplished by a change in four C–O bonds conformations, from *trans* to *gauche*.[5] Conformations in solution are consistent with the crystal in the case of K^+, not Na^+.[3]

A flexible thirty membered ring, comprising ten donor atoms, could accommodate two cations if the electrostatic repulsion is not redhibitory. Such 2 : 1 alkali metal cations: crown ethers have been only rarely reported in the literature. Sodium *o*-nitrophenolate,[6] potassium isothiocyanate[7] and DB24C8 form 2 : 1 complexes whose X-ray structures have been determined.[6,7] DB30C10 forms a 2 : 1 complex with sodium isothiocyanate in the solid state.[8] Indications have been given for the formation in solution of 2 : 1 and 3 : 2 sodium tetraphenylborate : DB30C10 complex.[2]

We confirm in this note the formation of 2 : 1 and 3 : 2 Na^+: DB30C10 complexes with tetraphenylborate counter anion, in nitromethane solutions.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

Dibenzo-30-crown-10 was synthesized in two steps from the tetrahydropyranyl monoprotected catechol. Details of the synthesis will appear elsewhere. After recrystallization from ethylacetate, DB30C10 was vacuum-dried at 60°C for several hours. Sodium tetraphenylborate (Aldrich, 99 + %) and sodium hexafluorophosphate (Alfa products) were dried over phosphorus pentoxide under vacuum for three hours prior to use. Nitromethane (Baker) was dried under reflux with calcium hydride under nitrogen and stored after distillation over 4 Å molecular sieves, under nitrogen.

Measurements of Na-23 chemical shifts and bandwidths at half-height were made on a Varian FT-80 NMR spectrometer operating at 21.04 MHz and on a Varian XL-300 NMR spectrometer operating at 79.35 MHz. Chemical shifts are expressed in ppm from $NaBPh_4$ 0.1 M in D_2O solution. An external D_2O lock was used at 21.04 MHz. No lock was used at 79.35 MHz. Longitudinal relaxation times were measured at 79.35 MHz using a 180°–τ–90° pulse sequence (90° pulse width = 22.5 μsec).

Non-linear regression analysis has been performed with a parametric least-squares fitting,[9] incorporating Newton–Raphson iteration.[9] The errors on the calculated values of $\log K_2$, ν_2, $\log K_3$ and ν_3 reported in Table 1 have been determined after several regressions (> 25) with different input parameters. The reported value corresponds to the

Table 1.

$\log K_1$	$\log K_2$	$\log K_3$	ν_1 (Hz)	ν_2 (Hz)	ν_3 (Hz)	δ_1 (ppm)	δ_2 (ppm)	δ_3 (ppm)
>5	2.1 ± 0.3	2.5 ± 0.3	250 ± 30	800 ± 100	500 ± 100	-10.2 ± 0.1	-8	-13

Values of $\log K_1$, $\log K_2$ and $\log K_3$ [eqns (1–3)] at (298 ± 1) K, of ν_2, the bandwidth at half-height and of δ_2, the limiting chemical shift, characterizing the 2:1 Na^+ : DB30C10 complex and the "external" sodium belonging to the 3:2 complex. ν_3 and δ_3 are the corresponding parameters for "internal" sodium of the 3:2 complex and ν_1 and δ_1 for the 1:1 complex. $[NaBPh_4] = 0.050$ M, solvent: nitromethane (see Experimental for discussion of the errors).

best standard deviation obtained (33 Hz). These standard deviations are in the range of the mean of all the experimental errors of the measured linewidths. δ_2 and δ_3 have been calculated by a two parameters regression, using the K values obtained from linewidths. A full five parameters regression on the chemical shifts gave compatible results in the error limits. We found that there is some degree of correlation between the independent variables K_i and ν_i:[10] a standard deviation flat minimum is obtained for a range of K_i and ν_i values, specially in the case of the chemical shifts. This is reflected in the large error limits given in Table 1. Chemical shifts should be considered as only indicative of their order of magnitude.

RESULTS AND DISCUSSION

In Figs 1 and 2, chemical shifts (δ) and bandwidths at half-height ($\nu_{1/2}$) of the lorentzian Na-23 signals are given as a function of the ratio (ρ) DB30C10 : sodium tetraphenylborate in nitromethane.

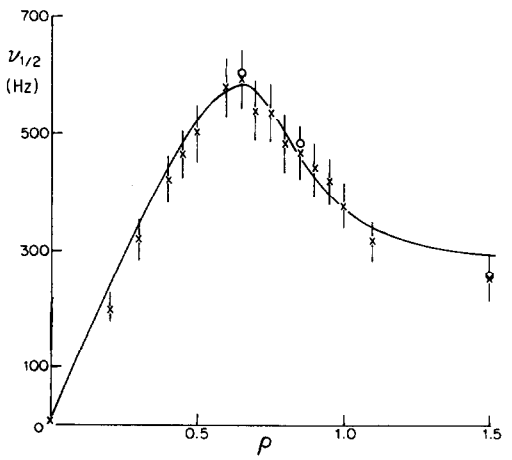

Fig. 1. Na-23 NMR signal bandwidth at half-height ($\nu_{1/2}$) as a function of the ratio $\rho = [DB30C10]/[NaBPh_4]$. $[NaBPh_4] = 0.050$ M. Solvent: nitromethane. (×): $(\pi T_2)^{-1}$ at 21.04 MHz; (○): $(\pi T_1)^{-1}$ at 79.35 MHz. The points are experimental and the curve is calculated following eqns (4)–(6) and values from Table 1.

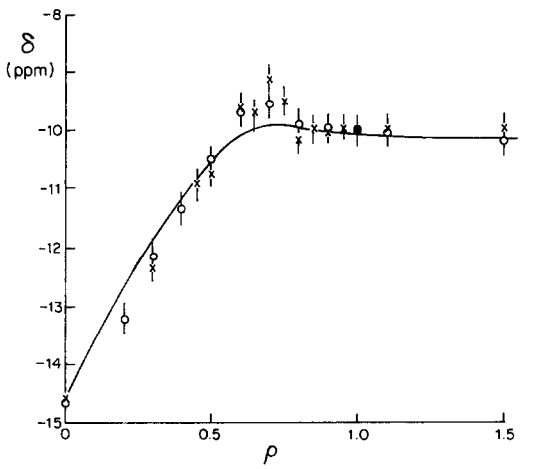

Fig. 2. Na-23 NMR chemical shifts observed in the same conditions as Fig. 1. (×: 21.04 MHz; ○: 79.35 MHz.) The points are experimental and the curve is calculated following eqns (4)–(6) and values from Table 1.

Concentration of $NaBPh_4$ was kept constant at 0.050 M. $\nu_{1/2}$ increases from 9 Hz in nitromethane to a maximum of 590 Hz for $\rho = 0.65$. Chemical shifts vary from -14.5 ppm in nitromethane to a maximum of -9.1 ppm for $\rho = 0.70$. A plateau is reached for $\rho > 0.85$ at a value of -10.0 ppm.

In order to check for the possibility of an exchange contribution to the observed linewidths we made a T_1 study at 79.35 MHz. In the limits of the experimental errors, $(1/\pi T_1)_{79.35} = (1/\pi T_2)_{21.04}$ showing that there is no detectable exchange contribution to the line broadening at 21.04 MHz. The dynamic constants of 1:1 complex formation reaction of DB30C10 with sodium in methanol ($k_c > 1.6\times10^7$ M^{-1} sec^{-1}, $k_{dec} > 1.3\times10^5$ sec^{-1}), as reported by Chock,[11] are consistent with fast exchange conditions. The presence of a maximum associated with an inflexion point suggests the coexistence of 2:1 and 1:1 complexes. The 1:1 complex is characterized by a large equilibrium constant. The 2:1 complex must be characterized by a short relaxation time, due to a dissymetric electronic charge distribution. A model based only

on the presence in solution of those two complexes can not fit the experimental data : in particular, it can not account for the sharp decrease of the chemical shifts observed for $\rho > 0.75$.

Following the proposal by Popov[2] we incorporate the 3:2 complex in our treatment [eqns (1)–(3)] (C = DB30C10)

$$C + Na^+ \rightleftharpoons C, Na^+ \quad (1)$$

$$C, Na^+ + Na^+ \rightleftharpoons Na^+, C, Na^+ \quad (2)$$

$$Na^+, C, Na^+ + Na^+, C \rightleftharpoons Na^+, C, Na^+, C, Na^+. \quad (3)$$

Equations (1), (2) and (3) are characterized by equilibrium constants K_1, K_2 and K_3 respectively. They lead to eqns (4)–(6), where "a" is the concentration of solvated Na^+, C_0 and M_0 are the total concentrations of crown and sodium, X_{obs} is the observed linewidth or chemical shift, X_0, X_1, X_2, are the characteristic linewidths or chemical shifts for the species $(Na^+)_{solv.}$, (C, Na^+), (Na^+, C, Na^+) respectively. For the 3:2 complex, we consider two types of sodium : "external" and "internal" which are characterized respectively by X_2 and X_3. X_0 and X_1 are experimentally determined (at $\rho = 0$, and $\rho = 1.5$ respectively).

$$\begin{aligned} &a^5(4\beta_3 - \beta_2^2) + a^4[\beta_2^2(M_0 - 2C_0) \\ &\quad - 4\beta_3(2M_0 - 3C_0)] + a^3[\beta_1^2 + 2\beta_2 \\ &\quad + \beta_1\beta_2 C_0 + \beta_3(2M_0 - 3C_0)^2] \\ &\quad + a^2[\beta_1^2(C_0 - M_0) + 2\beta_2(3C_0 - M_0) \\ &\quad + 4\beta_1] + a[3 + \beta_1(3C_0 - 4M_0)] - 3M_0 = 0 \end{aligned} \quad (4)$$

where $\beta_i = K_1, \ldots, K_i$. After resolution of eqn (4) for "a", calculation of the free crown concentration "b", is straightforward [eqn (5)]

$$b = \frac{2M_0 - 3C_0 - 2a}{\beta_2 a^2 - \beta_1 a - 3}. \quad (5)$$

X_{obs} is given by :

$$\begin{aligned} M_0 X_{obs} = {} & aX_0 + \beta_1 abX_1 + 2\beta_2 a^2 bX_2 \\ & + \beta_3 a^3 b^2(2X_2 + X_3). \end{aligned} \quad (6)$$

A non-linear regression on eqns (4)–(6) provides the results of Table 1 (see Experimental). We can obtain only a lower estimate for $\log K_1$: the regression is not sensitive to variation of $\log K_1 > 5$. Lower values of $\log K_1$ do not permit to fit the experimental data. The relaxation rate of the 2:1 complex ("external" sodium) reflects a high value of the sodium quadrupolar coupling constant and/or of the reorientational correlation time.[12] It is gratifying to note that the relaxation rate of the "internal" sodium in the 3:2 complex is smaller than the one calculated for "external" sodium. This reflects the expected higher symmetry of the charge distribution around a sodium cation surrounded by two crown molecules, and coordinated by oxygen atoms only. The large quadrupolar coupling constant found in the case of exposed sodium reflects the approach of anion or solvent molecules in the coordination sphere of sodium to form two loose or tight ion pairs linked by the crown ether. This structure which reduces the electrostatic repulsion between the two cations is reminiscent of the dicationic complexes formed with spiro-bis-crown ethers,[13] which are also less disfavored than could have been expected on the basis of electrostatic repulsion.[13] Even if one has to be cautious with the values of δ_2 and δ_3 furnished in Table 1, their trend is significant : δ_2 ("external", exposed, sodium) = −8 ppm has to be compared with −5 ppm and −4 ppm, lower estimates for the Na-23 chemical shifts of the complexes 15C5 : Na^+ and B15C5 : Na^+ [14] and δ_3 ("internal", sandwiched, sodium) = −13 ppm has to be compared with −11 ppm for the sandwiched 15C5 : Na^+ : 15C5 complex.[14] Finally, one should also note a large difference in the values of the linewidths for the 1 : 1 complexes in the cases of different counter anions : tetraphenylborate (250 Hz) and hexafluorophosphate (120 Hz). This result suggests a participation of the anion in the coordination sphere of sodium, a result in contrast with the behaviour of DB24C8.[1]

PULSED RADIOLYSIS OF PERRHENATE IN NEUTRAL AQUEOUS SOLUTION: COMPARISON WITH PERTECHNETATE

GEOFFREY A. LAWRANCE* and DAVID F. SANGSTER†
* Department of Chemistry, The University of Newcastle, NSW 2308, Australia; and
† Division of Chemical Physics, CSIRO, Lucas Heights Research Laboratories, Sutherland 2232, Australia

(*Received* 25 *October* 1984; *accepted* 18 *December* 1984)

Abstract—Reaction of perrhenate with the aquated electron in neutral aqueous solution yields ReO_4^{2-} (k_f 1.3×10^{10} M^{-1} s^{-1}), with an absorption maximum at 290 nm (ε 1700). This decays by a second-order path (k_d 1.5×10^9 M^{-1} s^{-1}) at a rate ~ 100-fold faster than the decay of TcO_4^{2-} under similar conditions.

The chemistry of the oxyanions of the heavier members of the manganese triad in oxidation states below VII has not been extensively investigated. Reaction of pertechnetate with the hydrated electron (e_{aq}) in neutral aqueous solution has been reported recently,[1] allowing measurement of the formation and decay rates and of the spectrum of TcO_4^{2-} in that medium. Despite the ready availability of perrhenate, and the similarity in the chemistries of rhenium and technecium, there is no report of the pulsed radiolysis of ReO_4^- solutions extant, apart from an uninformative conference abstract.[2] Since we are currently investigating the chemistry, including the pulsed radiolysis, of rhenium complexes, it was of interest to investigate the reaction of ReO_4^- with e_{aq} and to compare this with the data for TcO_4^-.

The 1 MeV pulse radiolysis facility, optical system and process of kinetic analysis have been described previously.[3] Solutions of potassium perrhenate in triply-distilled water ([Re] $\leqslant 10^{-3}$ M) were reacted with e_{aq} using an N_2-purged solution containing 0.1 M *t*-butylalcohol as a radical scavenger of OH. Thiocyanate dosimetry was used for calibration of the system. The formation rate was determined by monitoring decay of e_{aq} at 680 nm in the presence of various concentrations of ReO_4^-. Initial and final optical density changes were measured at 5–25-nm intervals from signal averaged data in the range 250–600 nm, permitting construction of electronic spectra (Fig. 1). Intermediate decay kinetics were followed at several wavelengths.

For the manganese triad, the MO_4^- species may be reduced electrochemically in multielectron steps in aqueous solution. In aprotic solvents, one-electron reductions of all of these anions have been reported, and are increasingly negative down the triad (MnO_4^-, −0.60 V; TcO_4^-, −1.74 V; ReO_4^-, −2.30 V, vs SCE).[4] With the fast kinetic technique of pulsed radiolysis, one-electron reduction with the powerful reductant e_{aq} (E° −2.8 V) allows examination of the fate of the reduction product. Apparently stability of the M(VI) oxyanion decreases down the triad, since MnO_4^{2-} is stable in dilute base, while TcO_4^{2-} generated radiolytically in aqueous base is stable on a timescale greater than 10 ms but less than 50 ms.[5]

When solutions of ReO_4^- were irradiated, the optical density due to e_{aq} disappeared according to a rate law first order in both e_{aq} and ReO_4^-, with $k = 1.3 \times 10^{10}$ M^{-1} s^{-1}. This is consistent with the disappearance of e_{aq} and appearance of the putative species ReO_4^{2-}, which can form via

$$ReO_4^- + e_{aq} \rightarrow ReO_4^{2-} \quad (1)$$

and

$$ReO_4^- + H \rightarrow ReO_4^{2-} + H^+ \quad (2)$$

Since the formation rates in neutral and basic (0.01 M NaOH) solution are essentially the same, presumably eqn (2) does not contribute much above pH 6. The species formed has a maximum at 290 nm, and decays by second-order kinetics. Decay can arise, in the absence of OH, from the following reactions:

$$2Re(VI) \rightarrow Re(VII) + Re(V), \quad (3)$$

$$2Re(V) \rightarrow Re(VI) + Re(IV), \quad (4)$$

Table 1. Comparative data for pulsed radiolysis of TcO_4^- and ReO_4^- in neutral aqueous solution

λ_{max} (nm)	325	290
ε_{max} (M^{-1} cm^{-1})	2600	1700

* Reference 1.
† k_f and k_d in M^{-1} s^{-1}.
‡ This work.

$$Re(VI) + H_2O_2 \rightarrow Re(VII) + OH + OH^- \quad (5)$$

Comparison of ReO_4^- and TcO_4^- reacting with e_{aq} in neutral solution appears in Table 1. Formation rates are the same, consistent with reaction of ions of the same symmetry, charge and almost the same size. The absorbance maximum of ReO_4^{2-} is at slightly higher energy than that of TcO_4^{2-}, following the like trend for MO_4^-. Since ReO_4^- does not absorb much above 260 nm, uncorrected observed optical density changes have been used to calculate the spectrum of ReO_4^{2-}. The major difference in the two species is the 100-fold higher rate of decay of ReO_4^{2-} vs TcO_4^{2-}. Disproportionation of MnO_4^{2-} in dilute acid has been studied recently,[6] and a decay rate at pH 6 of $\sim 10^2$ M^{-1} s^{-1} can be estimated from that data. Thus there is clearly an increase in the reactivity of the MO_4^{2-} ion down the triad, which correlates with the increasing negative one-electron reduction potential down the triad.

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A & M University, College Station, TX 77843, U.S.A.

(*Received* 15 *October* 1984; *accepted* 18 *December* 1984)

Abstract—The compound $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4$ was prepared by reaction of $Ru_2Cl(O_2CCH_3)_4$ with $4\text{-}Cl\text{-}C_6H_4CONH_2$ at 180°C. Crystals of the composition $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4CH_3OH$ were obtained by slow diffusion of CH_3OH containing Et_4NCl into a Me_2SO solution of the compound. The structure of the crystalline product, which loses solvent of crystallization on removal from the mother liquor, was solved by X-ray crystallography by mounting a single crystal in a capillary containing the mother liquor. The crystals belong to the space group $P\bar{1}$ (triclinic crystal system) with $a = 12.731(3)$ Å, $b = 14.389(3)$ Å, $c = 12.604(3)$ Å, $\alpha = 103.41(2)°$, $\beta = 106.43(2)°$, $\gamma = 64.90(2)°$, $V = 1988.6(8)$ Å^3 and $Z = 2$. There are two half ruthenium dimers linked by a Cl atom and an uncoordinated solvent CH_3OH molecule per asymmetric unit. The ruthenium dimers lie on two centers of inversion at 0, 0, 0 and 1/2, 0, 0. The chloride ions bridge dinuclear cations in the crystal, forming infinite zigzag chains. The average Ru–Ru distance is 2.296[1] Å and each ruthenium atom has a $RuClN_2O_2$ coordination sphere where the average Ru′–Ru–Cl angle is virtually linear (175.68[6]°). The metal oxidation states in the complex are +2 and +3, giving an average value of +2.5. The arrangement of four bridging 4-Cl–benzamidato ligands is of the 2:2 type. The average Ru–N, Ru–O, Ru–Cl distances and Ru(1)–Cl(1)–Ru(2) angle are 2.036[6] Å, 2.044[5] Å, 2.583[2] Å and 117.26(8)°, respectively. The IR spectrum of the compound shows two N–H stretches at 3380 and 3340 cm^{-1}. The electronic spectrum of the compound in Me_2SO exhibits bands at 558 nm ($\varepsilon = 340$ M^{-1} cm^{-1}), 425 nm (1000) and 320 nm (22,700).

Since the report[1] of the first X-ray structural studies on $Ru_2Cl(O_2CC_3H_7)_4$[2] in 1969 from this laboratory, several other diruthenium tetracarboxylato compounds have been prepared[2–8] and subjected to structural studies[3–5] which show that such complexes have short Ru–Ru distances ranging from 2.25 to 2.29 Å. Theoretical calculations[9,10] have also been performed to explain their three electron magnetic moment and the formal oxidation states of +2.5 of ruthenium in such complexes.[11] An SCF–Xα–SW calculation done on $Ru_2(O_2CH)_4Cl$ showed[10] that the ground state configuration should be $\sigma^2\pi^4\delta^2\pi^{*2}\delta^{*1}$.

Recent work from this[12] and other laboratories[13,14] has shown that three-atom bridging ligands with the –NHCO– functionality can be used to prepare a new class of diruthenium(II,III) complexes of the type $Ru_2Cl(RCONH)_4$ which closely resemble the carboxylato species in their physical and chemical properties. While we have reported[12] the synthesis and reactivity of $Ru_2Cl(PhCONH)_4$ having R = aryl group, the work of Bear and coworkers shows[13,14] that other amides, viz. with R = alkyl groups (e.g. CH_3 or CF_3) are also useful in preparing tetraamidato species. These developments in diruthenium chemistry are of considerable interest because previously a systematic study[11] had been done only on the $Ru_2Cl(O_2CR)_4$ complexes. Like carboxylato anions, the anions of the amides, RCONHR′, can be used to study the electronic and steric effects of the R and R′ groups on the physical and chemical properties of the dimeric species. The interesting structural feature[1,3–5] in $Ru_2Cl(O_2CR)_4$ complexes is the presence of infinite zigzag chains in which the diruthenium units are linked by bridging chloride atoms. From the results published to date on the

* Author to whom correspondence should be addressed.

diruthenium amidato species it is apparent that this sort of bonding is also present in these complexes. All other reported[15–20] diruthenium species are known to be discrete dimeric species.

Our report[12] on $Ru_2Cl(PhCONH)_4$ shows that this complex when reacted with PPh_3 forms a novel compound which has been structurally characterized as $Ru_2(Ph)_2(PhCONH)_2[Ph_2POC(Ph)N]_2$. In order to better understand the effect of the bridging benzamidato ligand on the reactivity of the diruthenium unit attempts have been made to crystallize the $Ru_2Cl(PhCONH)_4$ compound. We were unsuccessful with the $PhCONH^-$ ligand, but by using a substituted benzamide, viz. 4-Cl-$C_6H_4CONH_2$, we have been able to isolate single crystals of $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot MeOH$. In this paper we report the synthesis and X-ray structure of this complex. Its reactivity and that of other $Ru_2Cl(RCONH)_4$ compounds will be reported in a future paper.

EXPERIMENTAL

Synthesis of $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$

A 1 g quantity of 4-Cl-$C_6H_4CONH_2$ was added to 0.1 g of $Ru_2Cl(O_2CCH_3)_4$.[2] The mixture was heated to 180°C and stirred for 48 h under a dinitrogen atmosphere. Excess ligand was then removed by sublimation under reduced pressure. The residue was dissolved in 10 cm^3 of Me_2SO and filtered. The color of the solution was dark brown. A 5 cm^3 volume of Me_2SO solution was placed in a test tube (diameter 15 mm). A 10 cm^3 volume of methanol containing 0.05 g of Et_4NCl was carefully added on the top of the Me_2SO solution, maintaining a distinct interface between the two solvents. Slow diffusion of the solvents as well as electrolytes gave dark brown crystals in *ca* 50% yield. The compound is but sparingly soluble in common organic solvents other than Me_2SO. On removal from the mother liquor the crystals lose crystallinity due to loss of solvent of crystallization. Found: C, 38.98; H, 2.50; N, 6.53%. Calc. for $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4$: C, 39.27; H, 2.34; N, 6.54%. IR (KBr phase): 3380, 3340, 1590, 1572, 1510, 1475, 1440, 1425, 1275, 1255, 1210, 1175, 1115, 1090, 1010, 945, 842, 820, 800, 742, 725, 655, 625, 585, 488, 435, 335, 300 cm^{-1}. λ_{max} (nm) (ε, M^{-1} cm^{-1}): 558 (340), 425 (1000), 320 (22,700) (in Me_2SO).

Measurements

The elemental analysis was obtained from Galbraith Lab. Inc. The IR spectrum was recorded using a Perkin–Elmer 785 spectrophotometer. The electronic spectrum was obtained from a Me_2SO solution of the compound using a Cary 17D spectrophotometer.

X-ray crystallographic procedures

The structure of the single crystal of $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$ was determined by using procedures described in a general way elsewhere.*[21] A dark-brown single crystal was wedged inside a capillary containing a Me_2SO–CH_3OH mixture in 1:4 proportion. The ends of the capillary were sealed to prevent any loss of solvent. It was observed that the crystals lost crystallinity rapidly when mounted in epoxy on a glass fiber. All geometric and intensity data were taken from this crystal at 5°C by using an automated four-circle Syntex $P\bar{1}$ diffractometer, equipped with graphite-monochromated Mo-$K\alpha$ radiation.

The standards showed a 12.5% decay in intensity during 126 h exposure time. An empirical absorption correction was made based on azimuthal scans of nine reflections with Eulerian angle χ near 90°. Corrections were also made for Lorentz, polarization and decay effects.

The positions of the two Ru atoms in the crystallographic asymmetric unit were found by the direct methods program MULTAN, and refined by least-squares. Successive iterations of difference Fourier maps and least-squares cycles led to the development and convergent refinement of the remainder of the structure.

Towards the end of the refinement, a disordered CH_3OH molecule was identified. There were three pairs of peaks with each pair having a peak-to-peak distance that was reasonable for C–O in CH_3OH. One pair of peaks was refined with a site occupancy factor (SOF) of 0.5. The other two pairs were refined with SOF = 0.25. As a whole there is one CH_3OH molecule per asymmetric unit. The molecule is present as a solvent of crystallization and does not interact with the complex molecule. The C and O atoms of the solvent molecule were refined isotropically. The final difference Fourier map was featureless except for peaks with $e/Å^3$ ranging from 1.4 to 1.7 at positions less than 1.0 Å from the Ru centers.

Crystallographic data and other basic information pertaining to the data collection are summarized in Table 1. Complete tables of bond

* Calculations were done on the VAX-11/780 computer at the Department of Chemistry, Texas A & M University, College Station, Texas with a VAX-SDP software package.

distances and angles as well as atomic positional and anisotropic thermal parameters and structure factors have been deposited as supplementary material with the Editor at Queen Mary College.*

RESULTS AND DISCUSSION

The compound $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4$ was prepared in quantitative yield by reacting $Ru_2Cl(O_2CCH_3)_4$ with molten 4-chlorobenzamide ligand at 180°C under a dinitrogen atmosphere. The resulting product which is dark brown in color is indefinitely stable in air. It is only sparingly soluble in common organic solvents other than Me_2SO. Single crystals of this compound with composition $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$ were obtained by slow diffusion of CH_3OH containing Et_4NCl into a solution of $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4$ in dimethyl sulfoxide. Our interest in structural studies of the diruthenium amidato complexes arises from the recent developments in this chemistry,[12–14] the most noteable feature of which is their reactivity[12] towards PPh_3. Such complexes also display reversible redox behavior which has been extensively studied[13,14] by Bear and coworkers.

Selected bond distances and angles for $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$ are presented in Table 2. The structure of the compound along with the atom labelling scheme is illustrated in Fig. 1 which shows two crystallographically independent dimeric units, at 0, 0, 0 and 1/2, 0, 0 which are bridged by a chloride ion. Each diruthenium unit resides on a

* Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

* Numbers in parentheses are estimated standard deviations in the least significant digits.

center of inversion and the asymmetric unit consists of two half dimers linked by Cl, as well as a CH_3OH molecule of crystallization, which is disordered on three sites with 0.5, 0.25 and 0.25 occupancy, and does not interact with the complex.

Each ruthenium dimer is bonded to four bridging amidato ligands which adopt a 2:2 type arrangement (required by inversion symmetry) and to axial chlorine atoms which link the dimetal units. There are four small and slightly different torsional angles for the four bridging ligands, viz.: N(1)–Ru(1)–Ru(1)′–O(1)′ = 0.7°; N(2)–Ru(1)–Ru(1)′–O(2)′ = 1.4°; N(3)–Ru(2)–Ru(2)′–O(3)′ = 0.8°; and O(4)–Ru(2)–Ru(2)′–N(4)′ = 2.0°. Among $Ru_2Cl(O_2CR)_4$ complexes the asymmetric unit consists of only one half of the dimeric unit.[1,3–5] The observed difference between amidato and carboxylato species could be due to the difference in the spatial arrangements of the dimeric units. Since there has been no other structural report on an amidato species, a definitive comparison between the two types of systems is not possible. The two systems resemble each other in the

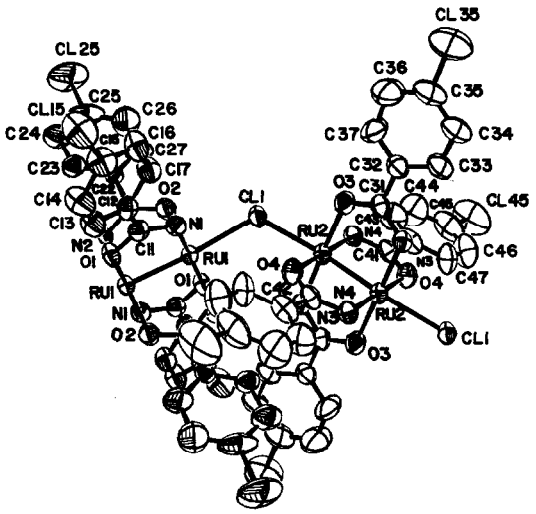

Fig. 1. An ORTEP drawing of the $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$ complex. Atoms are represented by thermal vibration ellipsoids at the 50% level and the atom numbering scheme is defined.

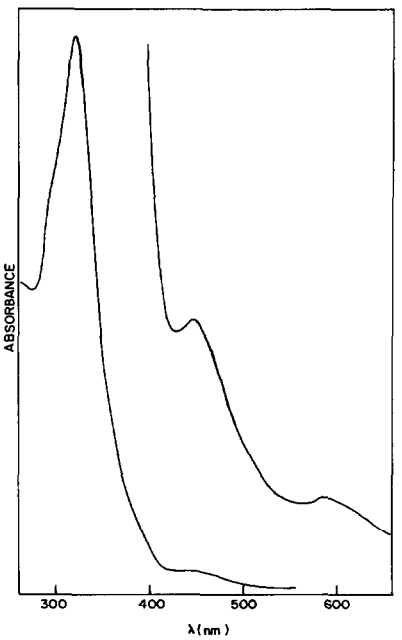

Fig. 3. Electronic spectrum of $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$ in Me_2SO.

formation of infinite zigzag chains[1,3–5] in which dimeric units are linked by bridging chloride atoms. The crystal packing for $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$ is displayed in Fig. 2 which shows the propagation of the chain along the *a*-axis.

The geometry at each ruthenium atom is pseudooctahedral with a $RuClN_2O_2$ coordination sphere. The Ru–Ru distances in the two crystallographically independent dimeric units are 2.299(1) and 2.292(1) Å. The average Ru–Cl, Ru–O and Ru–N distances are 2.583[2], 2.044[5] and 2.036[6] Å, respectively. Each of the Cl–Ru–Ru–Cl chains is essentially linear. The average Ru'–Ru–Cl angle is 175.68[6]°. The angle between two dimeric units, i.e. the Ru(1)–Cl(1)–Ru(2) angle is 117.26(8)°, which is responsible for the zigzag nature of the chain. The Ru–Ru–O angles are all slightly obtuse while the Ru–Ru–N angles are all slightly acute. There is no indication of disordering of O and NH in this case. The angles Cl(1)–Ru(1)–O(1), N(2) and Cl(1)–Ru(2)–O(3), N(4) are considerably greater than 90°. The remaining Cl–Ru–O and Cl–Ru–N angles are acute, ranging from 88.5(2) to 88.7(2)°.

The average Ru–Ru distance, which is 2.296[1] Å, is slightly longer than the distances of 2.250–2.290 Å found in $Ru_2Cl(O_2CR)_4$ complexes but shorter than those in $Ru_2(CH_2Bu^t)_6$ ($Ru^{III}Ru^{III}$ = 2.311(3) Å)[16] and $(Ru(OEP))_2$ ($Ru^{II}Ru^{II}$ = 2.408(1) Å).[15] The Ru–Ru distances in totally polar complexes, viz., in $Ru_2Cl(hp)_4(Hhp)$,[18] $Ru_2Cl(chp)_4$[19] and Ru_2Cl

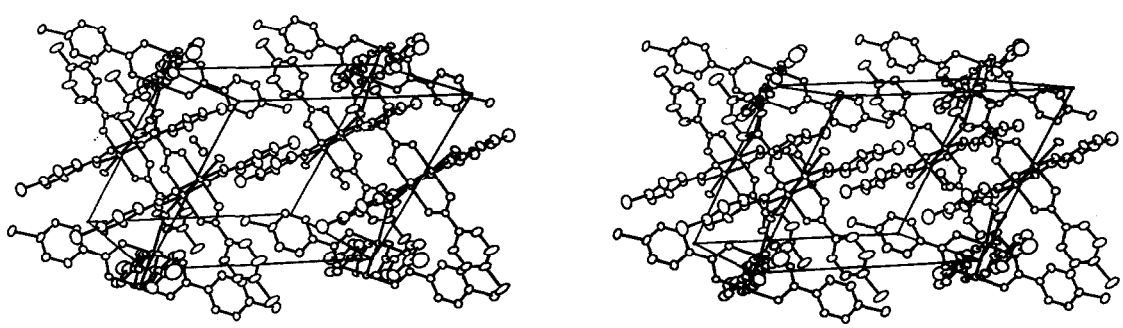

Fig. 2. Stereoscopic view of the crystal packing in $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$ as seen down the *c*-axis with the *a*-axis vertical and the *b*-axis horizontal. The thermal ellipsoids are at the 20% probability level. Only the major orientation of the disordered CH_3OH molecule is shown.

$(PhNpy)_4$,[18] range from 2.275(3) to 2.286(1) Å. The shortest Ru–Ru distance known[17] occurs in $Ru_2(mhp)_4 \cdot CH_2Cl_2$, where it has a value of 2.238(1) Å. The Ru–Cl distance in $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4 \cdot CH_3OH$ is quite long but similar distances are also observed[1,3–5] in $Ru_2Cl(O_2CR)_4$ complexes. In $Ru_2Cl(hp)_4(Hhp)$, the Ru–Cl distance is 2.558(2) Å but in $Ru_2Cl(PhNpy)_4$ and $Ru_2Cl(chp)_4$ the Ru–Cl distances are 2.437(7) and 2.443(2) Å, respectively.[18,19] Elongation of the Ru–Cl bond occurs only when both axial sites of the diruthenium unit are coordinated by ligands. As in the carboxylato species, the Ru–Cl bonds in amidato complexes are weak. From our earlier work[12] and from the work of Bear and co-workers[13,14] it is evident that in polar solvents the amidato species no longer exists in the polymeric form but forms discrete molecular species, with perhaps some loss of Cl^- ligands.

The electronic spectrum of the compound in Me_2SO, shown in Fig. 3, displays three bands. The band at 320 nm is very strong compared to the other two at 558 nm ($\varepsilon = 340\ M^{-1}\ cm^{-1}$) and 425 nm ($\varepsilon = 1000\ M^{-1}\ cm^{-1}$). The visible absorption spectrum of $Ru_2Cl(PhCONH)_4$ in Me_2SO is known[12] to exhibit an intense band at 445 nm. The band observed[13] for $Ru_2Cl(HNOCCF_3)_4$ in Me_2SO is at 459 nm. The diffuse reflectance spectrum of solid $Ru_2Cl(O_2CCH_3)_4$ shows[22] bands at 463 and 559 nm. A polarized absorption spectrum reported[5] for $Ru_2Cl(O_2CCH_3)_4$ shows bands at 558 and 444 nm with a shoulder at 526 nm. Wilson and Taube observed[23] that $Ru_2Cl(O_2CCH_3)_4$ in D_2O displays a sharp band at 425 nm, a broad band at 1000 nm and a shoulder at 310 nm. SCF–Xα–SW calculations on $Ru_2(O_2CH)_4^+$ assigned[10] the band at 425 nm to an allowed $O(\pi) \rightarrow RuRu(\pi^*)$ transition, where the $O(\pi)$ orbital is primarily an Ru–O bonding orbital with appreciable Ru–Ru π-bonding contributions. The lower energy band at 558 nm is assigned[10] to a $Cl \rightarrow \pi^*$ or $Cl \rightarrow \delta^*$ transition. The bands at 558 and 425 nm in $Ru_2Cl(4\text{-}Cl\text{-}C_6H_4CONH)_4$ may have similar origins.

(*Received* 15 *October* 1984; *accepted* 18 *December* 1984)

Abstract—The reaction of $NbCl_4(THF)_2$ with an excess of PMe_3 in toluene solution afforded a 70% isolated yield of green $NbCl_4(PMe_3)_3$. When a slurry of $TaCl_5$ in toluene containing a slight excess of PMe_3 was reduced with sodium amalgam overnight, a 60% yield of orange to red (depending on crystal size) $Ta_2Cl_8(PMe_3)_4$ was obtained. Both compounds have been fully characterized by X-ray crystallography. $NbCl_4(PMe_3)_3$ forms monoclinic crystals ($P2_1/c$) with unit cell dimensions $a = 15.061(3)$ Å, $b = 11.677(4)$ Å, $c = 11.583(4)$ Å, $\beta = 91.71(3)°$, $V = 2036(2)$ Å^3, and $Z = 4$. It is isomorphous with its $TaCl_4(PMe_3)_3$ homolog, and the bond lengths and angles are very similar. $Ta_2Cl_8(PMe_3)_4$ forms cubic crystals ($Im3$) with $a = 16.377(2)$, $V = 4392(2)$ Å^3 and $Z = 6$. It is thus isomorphous with its niobium homolog, and the internal dimensions are quite comparable. The Ta–Ta distance is 2.830(1) Å, consistent with the existence of a single bond.

Studies of the stereochemistry and properties of tertiary phosphine adducts of niobium(IV) and tantalum(IV) chlorides have shown an unexpected variety of structures as well as complex and not fully understood behavior in solution.[1–5] The more sterically demanding phosphines, i.e. PEt_3 and larger ones, seem consistently to give *trans*-octahedral $MCl_4(PR_3)_2$ type complexes, both in solution and in the solid state. For PMe_3 and PMe_2Ph adducts, structural diversity has been observed. Tantalum[3] has given the seven-coordinate $TaCl_4(PMe_3)_3$, as well as *cis*-$TaCl_4(PMe_2Ph)_2$, while in the case of niobium, dinuclear complexes with eight-coordinate metal atoms and four chloride bridges have been reported.[1,2] Two aspects of the chemistry involving these smaller phosphines have been of special interest. First, the structures of the dinuclear complexes, $Nb_2Cl_8L_4$, are unprecedented, for these or any other elements. Second, there was an apparent lack of similarity between the niobium and tantalum chemistry, contrary to what might have been expected for these two metals. We were especially puzzled by the apparent failure of tantalum to form the dinuclear species. To clarify these points, further studies on the PMe_3 adducts have been undertaken. We have now found that both the dinuclear tantalum species, $Ta_2Cl_8(PMe_3)_4$, and the seven-coordinate niobium complex, $NbCl_4(PMe_3)_3$, can, in fact, be prepared in high yield, provided the reaction conditions are chosen correctly.† We present here a summary of our findings on the chemistry of the Nb(IV) and Ta(IV) trimethylphosphine adducts and their relations to similar complexes in lower oxidation states.

EXPERIMENTAL

All manipulations were carried out under an atmosphere of argon. Standard vacuum line techniques were used. The pentachlorides of niobium and tantalum and trimethylphosphine were purchased from Aldrich and Strem Chemicals Inc., respectively, and used as received. $NbCl_4(THF)_2$ was prepared according to the literature method.[4] EPR spectra were recorded on an X-band Varian E-6S EPR spectrometer.

* Author to whom correspondence should be addressed.

† As this manuscript was in preparation a preliminary communication reported that $Ta_2Cl_8(PMe_3)_4$ had been obtained in small quantities as a byproduct when $TaCl_5$ was treated with PMe_3; a preliminary structure report was also given.[6]

Preparation of $Ta_2Cl_8(PMe_3)_4$

Trimethylphosphine (1 cm^3, 11.1 mmol) was added to a slurry of $TaCl_5$ (1.8 g; 5.0 mmol) in 40 cm^3 toluene. Sodium amalgam (0.4%, 0.14 g Na; 5.0 mmol) was added and the solution was stirred overnight. The toluene was decanted off and the reaction mixture was extracted with 3×50 cm^3 of CH_2Cl_2. The combined pale-green extracts were filtered and reduced in volume to *ca* 10 cm^3. An orange precipitate formed slowly and was collected on a frit and dried in vacuum. A yield of 1.3 g (1.5 mmol, 59%) of the red solid was obtained. X-ray quality crystals were grown by carefully layering 25 cm^3 hexane over the concentrated extract. Slow diffusion of the two solvents resulted in the formation of small, red, block-like crystals.

Preparation of $NbCl_4(PMe_3)_3$

$NbCl_4(THF)_2$ (0.76 g, 2.0 mmol) was slowly added with stirring to a solution of PMe_3 (1 cm^3, 11.1 mmol) in 30 cm^3 of toluene. The solution turned green and a solid of the same color precipitated (0.45 g, 50% yield based on $NbCl_4(PMe_3)_3$). Additional product was obtained by cooling the supernatant liquid after filtration. The combined yield of $NbCl_4(PMe_3)_3$ was 0.65 g, *ca* 70%. Crystals suitable for X-ray diffraction were obtained by slow cooling of the post-reaction solution.

X-ray crystallography

Single crystal X-ray analyses were carried out by application of general procedures that have been

described elsewhere.[7] Numerical data pertaining to the structure determinations are summarized in Table 1. Polarization, Lorentz and absorption corrections were applied to the intensity data for both compounds. A correction for decomposition was also applied to the Nb data. Refinements of the $NbCl_4(PMe_3)_3$ and $Ta_2Cl_8(PMe_3)_4$ structures were initiated by using the positional parameters of the heavy atoms found in the isomorphous compounds of the other metal. The remaining atoms, including hydrogen atoms in the tantalum compound were located in a difference Fourier map. All non-hydrogen atoms were assigned anisotropic thermal parameters and the structures were refined to convergence. A final difference Fourier map for $NbCl_4(PMe_3)_3$ contained two peaks with electron density about 1.0 $e/Å^3$. However they were located *ca* 1.1 Å away from the metal atom and were of no chemical significance.

Tables of observed and calculated structure factors, atomic positional and anisotropic thermal parameters and full lists of bond lengths and angles have been deposited as supplementary material with the Editor at Queen Mary College.†

† Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Solid state structures

Positional and isotropic equivalent thermal parameters and important interatomic dimensions for $NbCl_4(PMe_3)_3$ and $Ta_2Cl_8(PMe_3)_4$ are presented in Tables 2–4. Complete listings of bond distances and bond angles are included in the supplementary material. ORTEP drawings of the molecules are shown in Figs. 1 and 2.

Each of the new complexes reported here is isomorphous with its niobium or tantalum counterpart, whose structure has been reported previously.[2,3] As seen in Table 3 geometrical parameters of the analogous Nb and Ta molecules are identical in the sense that no difference, Δ, exceeds $3\sigma(\Delta)$. The metal–ligand bond lengths in the dimers are longer than in the seven coordinate monomers, which can be attributed to the higher coordination number of the metal atoms in the former.

Among the complexes of general formula $[MCl_n(PMe_3)_m]_k$, where M = Nb or Ta, structural data are now available for Ta in oxidation states from II to IV. A comparison of bond distances in these compounds is presented in Table 5. For Ta(II) only one complex is known while both monomeric and dimeric species have been isolated for the III and

IV oxidation states. No crystallographic data are available for $TaCl_3(PMe_3)_3$.[11] According to the data in Table 5 oxidation state is only one of several factors determining the lengths of the tantalum to ligand bonds. The presence of metal to metal bonding, steric crowding and disposition of ligands appear to be of comparable importance.

The dinuclear square-antiprismatic geometry of $Ta_2Cl_8(PMe_3)_4$ is also found in another formally Ta(IV) species $[TaCl_2(PMe_3)_2(\mu\text{-H})(\mu\text{-Cl})]_2$. They have comparable M–X distances (see Table 5) but also exhibit some significantly different features. In the former the terminal P_2Cl_2 squares are eclipsed while in the latter P atoms are positioned opposite to Cl atoms at the other end and vice versa. The hydride bridges cause shortening of the metal–metal bond by *ca* 0.2 Å, from 2.830(1) to 2.621(4) Å for the tetra-μ-chloro and di-μ-chloro-di-μ-hydrido complexes, respectively.

Synthesis and properties in solution

Reactions between $NbCl_4(THF)_2$ and PMe_3 can afford any of several adducts of general formula $NbCl_4(PMe_3)_n$, where $n = 2$, 3 and 4, depending on conditions. With $n = 2$ the product is red and dinuclear, $Nb_2Cl_8(PMe_3)_4$, while the one with $n = 3$ is green, seven-coordinate $NbCl_4(PMe_3)_3$. Both of these can be isolated in a pure state. The dimer is best obtained upon addition of the ligand to a suspension of $NbCl_4(THF)_2$ in THF or CH_2Cl_2. Synthesis of the pure tris complex is accomplished by mixing the same reactants in the reverse order. The addition of $NbCl_4(THF)_2$ to a mixture of excess PMe_3 and toluene produces a green solution from which spontaneous crystallization of $NbCl_4(PMe_3)_3$ occurs in about 50% yield. The supernatant solution, from which more of the seven-coordinate complex may be obtained by cooling, was shown, by EPR, to contain the complex $NbCl_4(PMe_3)_4$. The presence of

quintets with $A = 25$ G in the spectrum indicates coupling of Nb to four phosphorus atoms. Since pure $NbCl_4(PMe_3)_3$ in solution gives a broad and poorly resolved EPR resonance, it cannot be detected in the supernatant by this method.

The chemical behavior of the $NbCl_4$–PMe_3 system can be qualitatively understood in the following way. The addition of $NbCl_4(THF)_2$ to a solution containing a greater than four-fold molar ratio of PMe_3 to $NbCl_4(THF)_2$ gives rise to the eight-coordinate complex $NbCl_4(PMe_3)_4$, which can be detected in solution by EPR but which we have not yet been able to isolate as a solid. Eight-coordination is not uncommon for Nb(IV) but the well-defined examples containing phosphines are those with bidentate ligands, e.g. $NbCl_4(diphos)_2$.[12] Clearly, with the four separate PMe_3 ligands there will be more ligand–ligand repulsion and a greater tendency to dissociation. An equilibrium between $NbCl_4(PMe_3)_4$ and $NbCl_4(PMe_3)_3$ is thus likely to be established and precipitation of the latter, which is relatively insoluble, occurs.

The compound $Nb_2Cl_8(PMe_3)_4$ is quite stable and rather insoluble and it is therefore the favored solid product at lower PMe_3/Nb ratios, as, for example, when PMe_3 is added to a suspension of $NbCl_4(THF)_2$. Although there is transient formation of a green solution, the red dinuclear complex precipitates promptly and in good yield. Similarly, when the volume of a green solution containing $NbCl_4(PMe_3)_3$ is reduced under vacuum, the red solid crystallizes. Although the dinuclear complex is only slightly soluble, it does afford very dilute solutions in CH_2Cl_2 from which it can be recovered.

Whether a six-coordinate intermediate, $NbCl_4(PMe_3)_2$, ever exists to any appreciable extent or for any length of time is unknown. There is as yet no evidence for it, but it is possible that it might be isolable from some appropriate solvent.

When $Nb_2Cl_8(PMe_3)_4$ is prepared by using stoichiometric amounts of $NbCl_4(THF)_2$ and PMe_3, a pale green solution remains after the product has precipitated. This color is apparently not due to the seven- or eight-coordinate complexes but rather to some species that contain THF. This conclusion is based on the EPR spectra which indicate that a mixture of at least two EPR-active Nb(IV) species is present, neither of which is $NbCl_4(PMe_3)_4$. These spectra display at least eleven (not ten) lines, each a close doublet (presumably due to superhyperfine structure caused by one PMe_3 bound to the Nb atom). When frozen to −196°C these solutions show a long series of signals separated by *ca* 25 G with relative intensities that change from one sample to another.

There are also other color changes that are observed from time to time in the dilute solutions of $Nb_2Cl_8(PMe_3)_4$ which are probably caused by decomposition. The compound is extremely reactive towards traces of oxygen, moisture and other protic materials.

Turning now to tantalum, the fact that both $TaCl_4(PMe_3)_3$ and $Ta_2Cl_8(PMe_3)_4$ can be prepared in good yield and high purity indicates that the chemistry is rather similar to that of niobium, as would be expected. However, a practical difference is that the versatile starting material with labile THF ligands, $NbCl_4(THF)_2$, does not as yet have a known tantalum analog. Consequently, the tantalum chemistry cannot be investigated so thoroughly as that of niobium. Furthermore, all of our attempts to measure EPR spectra for tantalum(IV) phosphine adducts gave only very broad, featureless spectra that were of little use in identifying products.

Synthesis of $Ta_2Cl_8(PMe_3)_4$ in high yield is straightforward, by the method described here, because of its stability and low solubility. Although a stoichiometric ratio of reactants would normally be used, the presence of a moderate excess of phosphine does not appear to affect either yield or purity.

No doubt the $Ta_2Cl_8(PMe_3)_4$ molecule may be assumed to have a Ta–Ta single bond, as we have already suggested for $Nb_2Cl_8(PMe_2Ph)_4$ and $Nb_2Cl_8(PMe_3)_4$; the recent work of Boyd *et al.*[6] provides detailed support for this suggestion.

To obtain the seven-coordinate tantalum complex, $TaCl_4(PMe_3)_3$, loss of PMe_3 from the reaction mixture must be minimized. This can best be done by employing a volatile solvent such as CH_2Cl_2, which can be efficiently removed under vacuum without major loss of PMe_3.

TRANS-BIS(DIMETHYLGLYOXIMATO) COBALT(III) COMPLEXES CONTAINING IMIDAZOLE AND THIOCYANATE AS AXIAL LIGANDS

JAYANTA K. DAS and KAILASH C. DASH*
Department of Chemistry, Utkal University, Vani Vihar, Bhubaneswar, 751004, India

(*Received* 23 *July* 1984; *accepted after revision* 18 *December* 1984)

Abstract—Imidazole(Im), benzimidazole(BzIm), morpholine (Morph) and their derivatives react with $Co(CNS)_2$ and dimethylglyoxime(DH_2) in ethanolic medium in presence of air to form a number of new cobalt(III) complexes of the type *trans*-$[Co(DH)_2(L)(SCN)]$, which are characterised on the basis of electronic and IR spectra, NMR (^1H and ^{13}C) and mass spectra as well as thermogravimetric (TG–DTA) and conductance measurements. The thiocyanate groups are S-bonded. The NMR observations suggest that in solution these compounds exist as mixtures of the neutral species $[Co(DH)_2(L)(SCN)]$ and the salt $[Co(DH)_2(SCN)_2]^-$ $[Co(DH)_2(L)_2]^+$. The mass spectra does not show the molecular ion peak of the complex. The TG–DTA measurements show that the thermolysis of these complexes proceeds through polymeric intermediates giving Co_3O_4 as the end product.

Bis-(dimethylglyoximato) cobalt(III) complexes (cobaloximes) containing the $Co(DH)_2^+$ moiety (DH is the monoanion of dimethylglyoxime, DH_2) are shown to reproduce the fundamental reactions of cobalamins and are of importance in the study of the mechanism of Vitamin-B_{12} catalysed biochemical processes.[1,2] They closely simulate the reactions of Vitamin B_{12} and are important in Vitamin B_{12} model chemistry.[3–5] The biochemical and other applications of cobaloximes are also known. Simple cyanocobalamins activate and increase the cell membrane permeability.[6] Cobaloximes are useful reagents in synthetic organic chemistry, and are employed as protecting groups in the synthesis of certain amino acids.[7]

Imidazole behaves both as a good σ-donor and as a π-acceptor and is a fundamental component of nucleic acids (*via* the purines) and enzymes or proteins (*via* the amino acid histidine) and provides a potential binding site for metal ions.[8,9] It is one of the choicest ligands in nature. The biological significance of cobaloximes and imidazole prompted us to synthesise imidazole complexes of cobaloximes of the type *trans*-$[Co(DH)_2(Im)(SCN)]$ and study their stereochemical and biochemical characteristics. Earlier work from this laboratory[10–13] and by others[14,15] were centred mostly around homoleptic complexes of imidazoles with divalent first-row transition metals. Attempts to synthesise such homoleptic complexes of cobalt(III) with imidazole met with no success, even though it was possible to synthesise mixed-ligand systems[16,17] using imidazole along with ethylenediamine and acetylacetonate. Synthesis of $[Co(acac)_2(NO_2)(Im)]$[18] and the synthesis and hydrolysis of $[Co(en)_2(Cl)(Im)]Cl_2$[19–21] have also been reported. Reports on mixed-ligand complexes of cobaloximes with imidazole[22–24] and other ligands[25–29] have been made. A series of imidazole derivatives of cobaloximes,

$[Co(DH)_2(X)(Im)]$

(X = Cl, Br, CN, NO_2, OCN, SeCN, SCN),

were reported[23] where the formation of compounds

$$[Co(DH)_2(SCN)(Im)]_2(Im)H_2O$$

and

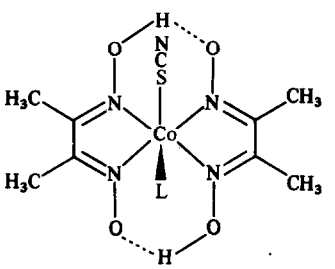
$$[Co(DH)_2(SeCN)(Im)]_2Im$$

were suggested, primarily on the basis of analytical data. We have prepared not only these two compounds, but a large number of other imidazole derivatives of the thiocyanato cobaloximes and studied their stoichiometry and thermal behaviour very carefully and in no case we obtained evidences in

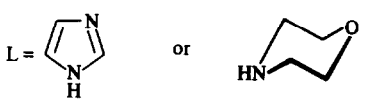
* Author to whom correspondence should be addressed.

favour of such formulation[23] where the imidazole ligand bridges the two

$$[Co(DH)_2(SCN)(Im)]$$



or



$$[Co(DH)_2(SeCN)(Im)]$$

moieties. The present paper reports systematic studies on mixed-ligand complexes of cobalt(III) with dimethylglyoxime (DH_2) and imidazole (Im), morpholine (Morph) and their various substituted derivatives, where the stereochemistries of the complexes have been deduced on the basis of electronic, IR, NMR (^1H and ^{13}C) and mass spectra as well as their electrical conductivity and thermal analysis measurements.

EXPERIMENTAL

Materials. Imidazole, morpholine and their derivatives were used as supplied by BASF, 2-methyl benzimidazole was prepared by a method analogous to the literature method.[30] Cobalt(II) thiocyanate was obtained by metathetic reaction of hydrated $Co(NO_3)_2$ (BDH) and KCNS (BDH) in ethanolic medium. The precipitated KNO_3 was filtered off and the solution, somewhat reduced in volume, was used as the source of $Co(NCS)_2$.

Synthesis of complexes. Complexes of the type $[Co(DH)_2(SCN)(L)]$ where L = imidazole or morpholine and their derivatives were prepared in 30–70% yield, by bubbling air for a period varying from 1 to 6 h through a solution of $Co(NCS)_2$, dimethylglyoxime (DH_2) and the ligand in 1:2:2 proportions. This was allowed to stand for 1 h and the microcrystalline solid was collected on a frit, washed with small aliquots of EtOH, then with Et_2O and finally dried in a vacuum desiccator. The reaction presumably proceeds in the following manner:

$$2Co(SCN)_2 + 4DH_2 + 4L + \tfrac{1}{2}O_2 \rightarrow 2[Co(DH)_2(SCN)(L)] + 2L \cdot HSCN + H_2O. \quad (1)$$

The time period for bubbling air for oxidation was different for the substituted imidazoles. Generally, the C-2 substituted derivatives of imidazole required more time than others. A typical method of preparation is given below.

$Co(DH)_2(SCN)(Im)$. To a hot ethanolic solution of cobalt(II) thiocyanate (0.002 mole), in a 250 cm^3 Erlenmeyer's flask was added 0.490 g (0.0042 mole) of dimethylglyoxime and 0.286 g (0.0042 mole) of imidazole and boiled for 2–3 min. The solution was then cooled to room temperature and air was bubbled through the solution for 1 h during which period micro-crystalline yellow–brown solid gradually deposited at the bottom. The solid was collected by filtration, washed successively with small portions of EtOH and Et_2O and dried *in vacuo* (yield 0.498 g (60%)).

Analyses. Cobalt was determined by the method of Laitenen and Burdett.[31] Sulphur was estimated gravimetrically as $BaSO_4$, after fusion of the sample with NaOH and Na_2O_2 and extraction of the melt with H_2O. Microanalytical data for nitrogen and (in some cases) carbon and hydrogen were from CDRI, Lucknow.

Electrolytic conductivity measurements, electronic and IR spectra. Electrolytic conductivity measurements were performed at room temperature in $MeNO_2$, Me_2CO and MeOH solution ($\sim 10^{-3}$ M) with an ELICO conductivity bridge type CM82 and a dip type cell with a cell constant of 0.5.

Electronic spectra in dil. MeOH solutions were recorded in a Varian 634 spectrophotometer. IR spectra in the 4000–400 cm^{-1} region were recorded as Nujol mull or KBr pellets in a Perkin–Elmer 337 or 377 grating spectrometer. In some cases, for comparison IR was recorded in $MeNO_2$ medium.

^1H and ^{13}C NMR spectra. The NMR spectra were measured in CD_3NO_2 with respect to internal TMS (4%). The PMR spectrum was recorded in a Varian FT-80A spectrometer operating on Fourier mode using 5 mm insert tubes at a spin rate of 20 rpm. PMR spectrum was recorded at room temperature and at −40°C and the spectra were virtually identical.

Full spectral width (6000 Hz) random-noise ^1H decoupled ^{13}C NMR spectra were measured on the JEOL FX-100 spectrometer operating on Fourier mode at an observed frequency of 25 MHz using 10 mm insert tubes. The field : frequency ratio was stabilized by a time-shared deuterium lock on the solvent. The total number of pulses required for a

reasonably good spectra varied from 14,000 pulses for [Co(DH)$_2$(1-AlIm)(SCN)] to 95,000 pulses for [Co(DH)$_2$(2-MeIm)(SCN)]. For ^{13}C NMR spectra the chemical shifts are reported in δ (ppm) relative to TMS, but they were observed with CD_3NO_2 (δ = 62.8 ppm) as the internal standard.

RESULTS AND DISCUSSION

All the compounds reported in this work are presented in Table 1, along with their analytical data, m.p. and conductance values. The conductance measurements were made in dilute solutions of Me_2CO, $MeNO_2$ and MeOH. The molar conductivity values obtained favour the neutral, non-ionic formulations, although in certain cases higher values are obtained.

The ligand-field spectra of the complexes in MeOH medium show a peak of weak to moderate intensity[32] at around 18,000 cm^{-1}. The two other main bands centred at about 40,000 cm^{-1} and 28,000–30,000 cm^{-1} are due to the intra-ligand $\pi \rightarrow \pi^*$ transition in the coordinated dimethylglyoximato anion and to the imidazole $\rightarrow$ cobalt transitions respectively. The strong band at 47,000 cm^{-1} may be the $d_\pi(Co) \rightarrow \pi^*(DH^-)$ transitions (Fig. 1).[33,34]

The IR absorption frequencies show the main bands due to the coordinated dimethylglyoxime, the ligands (imidazole or morpholine) and the vibrations of the ambidentate 16-electron thiocyanate ligand. The more prominent IR bands were located almost in the same position in all the complexes and not much effective variation was detected. The important IR bands of some typical thiocyanatocobaloximes are shown in Table 2. A comparison of the IR spectra of these complexes was made with those of the free dimethylglyoxime (DH_2) and the bis(dimethylglyoximato) nickel(II) complex [Ni(DH)$_2$] and it was found that while the free DH_2 has no bands at 1240 cm^{-1}, a strong band appears in the Ni(DH)$_2$ complex at 1240 cm^{-1}, due to the ν(N–O) of the ionised N–OH grouping of dimethylglyoxime.[35] For the cobaloxime complexes under discussion this band is seen almost in the same region at 1240–1250 cm^{-1}. The ν(C=N) stretching vibration of free, non-coordinated DH_2 at 1620–1630 cm^{-1} region is shifted to 1560–1570 cm^{-1} region in the complexes. The weak band around 1750 cm^{-1} belongs to the deformation mode of the intramolecular hydrogen bridge and suggests a *trans*-configuration for the complexes.[36,37] This observation was also further substantiated by the chemical behaviour of these cobaloximes in readily forming an O–BF_2–O bonding by the interaction of two O–H . . . O bridges in cobaloximes with $BF_3 \cdot Et_2O$.[38] The characteristic ν(Co–N) frequencies are situated at 515 and 430 cm^{-1} close to the position in well known NH_3 and en containing cobalt(III) complexes.[39]

The IR bands due to the ambidentate thiocyanate groups determine its mode of attachment,[40,41] either through the S-end or the N-end or as a bridging ligand. Class "a" or hard metals are expected to bond through the N-end of the thiocyanate group and class "b" or soft metals through the S-end. Cobalt(III) is an example of a hard acid,[42] but the dimethylglyoximato ligand system, $(DH)_2$, modifies the typical class "a" or "hard" Co(III) centre to such an extent that class "b" or "soft" behaviour is often observed in $Co(DH)_2^+$ moiety.[43–45] This change in behaviour from class "a" to class "b" for the hard cobalt(III) is facilitated by ligands like DH_2 that are soft or have a π-acceptor capacity and imidazole which is also a good π-acceptor inspite of its being a good σ-donor. The thiocyanate group is usually bonded to Co(III) centre in cobaloximes through the S-end,[27,46] although in [Ph_4As][Co(DH)$_2$(SCN)$_2$], Epps and Marzilli[47] were able to isolate all the three isomers, namely S–S, S–N and N–N. The ν(CN) in our complexes was usually obtained as a very intense and sharp peak at 2120 cm^{-1} indicating the coordination of the thiocyanate group. The intensity and sharpness of the ν(CN) band is indicative of Co–SCN bonding.[48]

The NMR spectra

The ^{1}H NMR spectra of some cobaloximes has been discussed in terms of their *trans*-structure.[26,27,47,49] The ^{1}H NMR shifts of the complexes (Table 3) show that on coordination the CH_3 groups of DH_2 at 1.98 ppm undergo a clear downfield shift by about 0.4 to 2.36–2.40 ppm. The imidazole protons also undergo a considerable

downfield shift and further the H-4 and H-5 protons of imidazole give rise to separate signals on complexation. The *trans*-structure of the cobaloximes should render the four methyl groups of $(DH)_2$ groups equivalent resulting in only one signal whereas the *cis*-compound, because of lower symmetry should give rise to more number of signals. This is in practice observed for the *trans*-, chloro- and azido-cobaloxime complexes with imidazoles[50] and other N-donor ligands.[36] But, in the present cases, instead of the single peak for the four CH_3 protons as expected for the *trans*-configuration, either two or three signals are observed, indicating the presence of more than one distinct chemical species in solution. Even though the available evidences in solid state favour the formulation as $[Co(DH)_2(Im)(SCN)]$, the complexes are apparently, on the basis of NMR evidences, mixtures of the neutral species

$$[Co(DH)_2(Im)(SCN)]$$

and the salt

$$[Co(DH)_2(Im)_2]^+[Co(DH)_2(SCN)_2]^-$$

in solution. This behaviour is very similar to the observation of Hill and Morallee[49] for $[Co(DH)_2(Ph_3P)(CN)]$ complexes and of Trogler *et al.*[26] for

$$[(t\text{-BuPy})Co(DH)_2X]$$

and $[(Bu_3P)Co(DH)_2X]$

complexes and their corresponding ion-pairs. However, we were unable to observe this tendency of salt formation in the corresponding chloro- and

azido-cobaloxime complexes with imidazoles,[50] $[Co(DH)_2(Im)(Cl)]$ and $[Co(DH)_2(Im)(N_3)]$, respectively, where clear sharp signals assignable to the neutral species alone were obtained. The PMR signals observed are shown in Table 3. In some cases, the CH_3 protons of $(DH)_2$ are superimposed giving less number of peaks than expected. The imidazole protons are assigned following earlier work[16] and signals of imidazole protons in the neutral and cationic species are also noted. It has been reported[26] that the ion-pair is formed by the cobalt(II) catalysed reactions (Co(II) present as an impurity in trace amounts before oxidation is complete) of $[Co(DH)_2(L)(SCN)]$ giving the following equilibrium:

$$2[Co(DH)_2(L)(SCN)] \overset{Co(II)}{\rightleftharpoons} [Co(DH)_2(L)_2][Co(DH)_2(SCN)_2]$$

which depends markedly on the nature of solvent and the ligand.

The ^{13}C NMR spectra of the thiocyanato-cobaloxime complexes with imidazoles (Table 4) indicate a downfield shift of ^{13}C signals of ligands on complexation and the ^{13}C NMR measurements support the conclusions drawn on the basis of ^1H NMR measurements. The ^{13}C NMR spectra of some

cobaloximes was reported by Trogler *et al.*[26] who suggested the the changes of ^{13}C shifts as a function of the axially coordinated anions in cobaloximes are caused by the electronically induced (e.g. through-bond) changes in the electronic environment about the carbon centre. On going from X = Cl to N_3 to NCS in $[Co(DH)_2(Im)(X)]$ complexes (Im = imidazole derivative) the ^{13}C chemical shifts of the CH_3 groups of $(DH)_2$ change progressively from 12.4 to 13.0 to 13.2 ppm and the imine carbon chemical shifts vary from 152.0 to 154.2 to 155.1 ppm.[50] The ^{13}C chemical shifts are tabulated in Table 4. Although a single peak was expected for the ^{13}C of the CH_3 groups of $Co(DH)_2^+$, in practice invariably 2 (or more) signals were obtained indicating the presence of more than one distinct chemical species, i.e. the neutral compound and the ion-pair in variable proportions in solution. In the IR spectra either in the solid state or in solution, we did not get any evidence of this type of behaviour as always only a sharp peak at 2110 cm^{-1} was obtained for the ν(CN). This obviously indicates the Co–SCN bonding in all the species that may be present in solution. As observed in the ^1H NMR, coordination to the cobalt(III) centre also creates some striking changes in the ^{13}C behaviour of imidazole carbons. Even though the ^{13}C of the imidazole carbons are obtained as single peaks in most cases, at least in some cases more than one peak is obtained for each of the carbons again favouring the formulation of the compounds as a mixture of the neutral species and the ion-pair, in solution, as discussed (Fig. 2).

Mass spectra and thermal analysis

The mass spectra of free dimethylglyoxime, the bis(dimethylglyoximato)nickel(II) complex, $Ni(DH)_2$ and the cobaloximes $[Co(DH)_2(SCN)(L)]$ have been studied. While the molecular ion peak of the DH_2 and $Ni(DH)_2$ are obtained, no such peak for the cobaloxime complexes was obtained. The thermal stability of the complexes is also very high and with increase in temperature mass losses are seen corresponding to polymeric intermediates and the ultimate formation of Co_3O_4 as the end product.

Acknowledgements—The authors are thankful to Dr Y. Inoguchi, Gakushuin University, Japan for getting the ^1H and ^{13}C NMR done. One of the authors (JKD) thanks the UGC, Delhi for a teacher-fellowship and the Govt. of Orissa for the leave of absence.

Abstract—The hydrides $[MH(O_2CCF_3)(CO)(PPh_3)_2]$ (M = Ru or Os) react with disubstituted acetylenes PhC≡CPh and PhC≡CMe to afford vinylic products $[M\{C(Ph)=CHPh\}(O_2CCF_3)(CO)(PPh_3)_2]$ and $[M\{C(Ph)=CHMe\}(O_2CCF_3)(CO)(PPh_3)_2]/[M\{C(Me)=CHPh\}(O_2CCF_3)(CO)(PPh_3)_2]$ respectively. Acidolysis of these products with trifluoroacetic acid in cold ethanol liberates *cis*-stilbene and *cis*-PhHC=CHMe respectively thus establishing the *cis*-stereochemistry of the vinylic ligands. The complexes $[M(O_2CCF_3)_2(CO)(PPh_3)_2]$ formed during the acidolysis step undergo facile alcoholysis followed by β-elimination of aldehyde to regenerate the parent hydrides $[MH(O_2CCF_3)(CO)(PPh_3)_2]$ and thereby complete a catalytic cycle for the transfer hydrogenation of acetylenes. The molecular structure of the methanol-adduct intermediate, $[Ru(O_2CCF_3)_2(MeOH)(CO)(PPh_3)_2]$ has been determined by X-ray methods and shows that the coordinated methanol is involved in H-bonding with the monodentate trifluoroacetate ligand [MeO–H---OC(O)CF_3; O···O = 2.54 Å]. The hydrides $[MH(O_2CCF_3)(CO)(PPh_3)_2]$ react with 1,4-diphenylbutadiyne to afford the complexes $[M\{C(C{\equiv}CPh){=}CHPh\}(O_2CCF_3)(CO)(PPh_3)_2]$. The ruthenium product, which has also been obtained by treatment of $[RuH(O_2CCF_3)(CO)(PPh_3)_2]$ with phenylacetylene, has been shown by X-ray diffraction methods to contain a 1,4-diphenylbut-1-en-3-yn-2-yl ligand. The osmium complexes $[Os(O_2CCF_3)_2(CO)(PPh_3)_2]$, $[OsH(O_2CCF_3)(CO)(PPh_3)_2]$ and $[Os\{C(C{\equiv}CPh){=}CHPh\}(O_2CCF_3)(CO)(PPh_3)_2]$ all serve as catalysts for the oligomerisation of phenylacetylene. Acetylene reacts with $[Ru(O_2CCF_3)_2(CO)(PPh_3)_2]$ in ethanol to afford the vinyl complex $[Ru(CH{=}CH_2)(O_2CCF_3)(CO)(PPh_3)_2]$.

Current interest in the chemistry of platinum group metal–acetylene complexes,[2] stimulated by the commercial importance of many transition metal catalysed acetylene reactions,[3] prompted an investigation of the activity of our catalyst system

$[M(O_2CCF_3)_2(CO)(PPh_3)_2]/$
$[MH(O_2CCF_3)(CO)(PPh_3)_2]$ (M = Ru or Os)[4]

towards terminal and non-terminal acetylenes. Reactions examined include the oligomerisation of aryl acetylenes (ArC≡CH), transfer hydrogenation of diarylacetylenes (ArC≡CAr) and the synthesis of a variety of vinylic complexes of ruthenium(II) and

osmium(II). We have also determined the crystal and molecular structure of the methanol solvated complex

$$[Ru(O_2CCF_3)_2(CO)(MeOH)(PPh_3)_2]$$

and the 1,4-diphenylbut-1-en-3-yn-2-yl derivative

$$[Ru\{C(C{\equiv}CPh){=}CHPh\}(O_2CCF_3)(CO)(PPh_3)_2]$$

isolated in the course of this investigation. Some of this work has been described in a preliminary report.[5]

EXPERIMENTAL

The ruthenium and osmium precursors were prepared as previously described.[6] Solvents, light petroleum (40–60°C) and acetylenes were used as purchased. Melting points were taken in sealed tubes under nitrogen using a Buchi melting point apparatus. Analyses were performed by the microanalytical laboratories at University College, London. IR spectra were taken on a Perkin–Elmer 457 grating spectrometer using mulls in Nujol. NMR spectra were obtained on a Bruker HFX-90 spectrometer operating in the F.T. mode. The ^{31}P chemical shifts were recorded relative to an external standard of 85% H_3PO_4 and are reported in ppm with positive values indicating a resonance at low field relative to H_3PO_4. The ^{19}F chemical shifts were recorded relative to an internal hexafluorobenzene standard and are reported in ppm with positive values indicating resonances at high field relative to C_6F_6. Samples were examined using deuteriochloroform as solvent.

Physical data for the new complexes presented in this paper are given in Table 1.

Preparation of carbonyl(η^1-1,4-diphenylbut-1-en-3-yn-2-yl) trifluoroacetatobis (triphenylphosphine) ruthenium(II) from phenylacetylene

A mixture of phenylacetylene (0.5 cm^3) and carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium (0.2 g) in ethanol (5 cm^3) was heated under reflux. From the deep yellow solution, a yellow precipitate rapidly deposited. After 30 min the mixture was cooled and the precipitate filtered off, washed successively with methanol, *n*-hexane and methanol, then recrystallised from dichloromethane/methanol as *bright yellow crystals.* These were filtered off and dried *in vacuo.* Yield: 0.15 g, 72.5%.

Carbonyl(η^1-1,4-di-p-tolylbut-1-en-3-yn-2-yl) trifluoroacetatobis (triphenylphosphine) ruthenium(II) was similarly prepared from *p*-tolylacetylene. Yield: 60%.

In the preceding reactions, products identical to the ones described above were also obtained when the complex $[RuH(O_2CCF_3)(CO)(PPh_3)_2]$ was substituted for $[Ru(O_2CCF_3)_2CO(PPh_3)_2]$, and when the ethanol solvent was replaced by benzene. When benzene was employed as solvent, addition of ethanol was necessary to precipitate the product.

Oligomerisation of phenylacetylene in the presence of carbonylbis (trifluoroacetato) bis (triphenylphosphine) osmium(II)

Phenylacetylene (2.0 cm^3) and carbonylbis (trifluoroacetato) bis (triphenylphosphine) osmium (0.05 g) were heated under reflux in benzene (10.0 cm^3) for 2 h, during which time the mixture rapidly darkened. The solution was then evaporated *in vacuo* to leave a dark brown oil which was treated with light petroleum (100 cm^3) to produce a dark brown solution. The solution was filtered then evaporated *in vacuo* and the residue dissolved in benzene (*ca* 5.0 cm^3) and passed down an alumina column. A single band was eluted from the column, and the eluate was evaporated to leave a dark brown powder. This was washed with cold methanol and dried *in vacuo.* Yield: 0.42 g. (Found: C, 91.88; H, 5.67%; M.wt.: 800. Calc. for $C_{64}H_{48}$: C, 94.12; H, 5.88%; M.wt.: 816.)

Oligomerisation of p-*tolylacetylene in the presence of carbonylbis (trifluoroacetato) bis (triphenylphosphine) osmium(II)* was similarly achieved and afforded 0.27 g of product as a dark brown solid. (Found: C, 90.45; H, 6.74%; M.wt.: 1200. Calc. for $C_{90}H_{80}$: C, 93.11; H, 6.89%; M.wt.: 1160.)

Similar oligomers were obtained when the complex $[OsH(O_2CCF_3)CO(PPh_3)_2]$ was substituted for $[Os(O_2CCF_3)_2CO(PPh_3)_2]$ in the above reactions and when the benzene solvent was replaced by ethanol.

Preparation of carbonyl(η^1-1,4-diphenylbut-1-en-3-yn-2-yl) trifluoroacetato (triphenylphosphine) ruthenium(II) from 1,4-*diphenylbutadiyne*

1,4-Diphenylbutadiyne (0.1 g) and carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium (0.2 g) were heated under reflux in ethanol (5 cm^3). A yellow solution rapidly formed from which yellow crystals precipitated. After 30 min the mixture was cooled and the precipitate filtered off, washed with methanol and then recrystallised from dichloromethane/methanol as *bright yellow crystals.* These were filtered off and dried *in vacuo.* Yield: 0.18 g, 79%.

Carbonyl(η^1-1,4-diphenylbut-1-en-3-yn-2-yl) trifluoroacetatobis (triphenylphosphine) osmium(II)

was similarly prepared from carbonylbis (trifluoroacetato) bis (triphenylphosphine) osmium and obtained as *bright yellow* crystals. Yield: 0.15 g, 70%

Similar procedures employing

$$[MH(O_2CCF_3)CO(PPh_3)_2]$$

in a benzene reaction medium instead of

$$[M(O_2CCF_3)_2CO(PPh_3)_2] \ (M = Ru, Os)$$

in the preceding pair of reactions produced identical results.

Reaction of carbonyl{η^1 - 1,4 - diphenylbut - 1 - en - 3 - yn - 2 - yl} trifluoroacetatobis (triphenylphosphine) ruthenium(II) with trifluoroacetic acid

Trifluoroacetic acid (0.25 cm^3) and carbonyl {η^1 - 1,4 - diphenylbut - 1 - en - 3 - yn - 2 - yl} trifluoroacetatobis (triphenylphosphine) ruthenium(II) (0.2 g) were heated under reflux in benzene (10 cm^3) for 30 min. The mixture was cooled and the solvent removed *in vacuo* to leave an orange oil. This was crystallised and recrystallised from dichloromethane/methanol as *deep yellow crystals.* The product was identified as carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium by its IR spectrum and melting point. Yield: 0.13 g, 71%.

Carbonyl(1 - phenylprop - 1 - en - 1 - yl) trifluoroacetatobis (triphenylphosphine) ruthenium(II) and carbonyl (3 - phenylprop - 2 - en - 2 - yl) - trifluoroacetatobis (triphenylphosphine) ruthenium(II) (ca 1/1 *isomer mixture*)

Methylphenylacetylene (0.5 cm^3) and carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium (0.5 g) were heated under reflux in ethanol (10 cm^3). A yellow solution rapidly formed and yellow crystals precipitated from solution. After 1 h the mixture was cooled and the precipitate filtered off, then washed with methanol, and recyrstallised from dichloromethane/methanol as *bright yellow crystals.* These were filtered off, washed with methanol and dried *in vacuo.* Yield: 0.33 g, 66%.

Carbonyl(1 - phenylprop - 1 - en - 1 - yl) trifluoroacetatobis (triphenylphosphine) osmium(II) and carbonyl (3 - phenylprop - 2 - en - 2 - yl) trifluoroacetatobis (triphenylphosphine) osmium(II) (ca 1/1 *isomer mixture*) was similarly prepared from carbonylbis (trifluoroacetato) bis (triphenylphosphine) osmium and obtained as *bright yellow crystals.* Yield: 0.29 g, 60%.

Carbonyl (cis - 1,2 - diphenylethenyl) trifluoroacetatobis (triphenylphosphine) ruthenium(II)

Diphenylacetylene (0.1 g) and carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium (0.2 g) were heated under reflux in ethanol (5 cm^3). The yellow solution rapidly precipitated yellow crystals; heating was continued for a total of 30 min and then the mixture was allowed to cool. The crystals were filtered off, washed with methanol, and recrystallised from dichloromethane/methanol as *bright yellow crystals.* These were filtered off and dried *in vacuo.* Yield: 0.2 g, 94%.

Carbonyl (cis - 1,2 - diphenylethenyl) trifluoroacetatobis (triphenylphosphine) osmium (II) was similarly prepared from carbonylbis (trifluoroacetato) bis (triphenylphosphine) osmium and obtained as *bright yellow crystals.* Yield: 0.17 g, 80%.

Similar procedures employing

$$[MH(O_2CCF_3)CO(PPh_3)_2] \ (M = Ru, Os)$$

in benzene in place of

$$[M(O_2CCF_3)_2(CO)(PPh_3)_2]$$

produced identical results.

Cleavage of stilbene from carbonyl (cis - 1,2 - diphenylethenyl) trifluoroacetatobis (triphenylphosphine) ruthenium(II)

Carbonyl (*cis* - 1,2 - diphenylethenyl) trifluoroacetatobis (triphenylphosphine) ruthenium (3.6 g) and trifluoroacetic acid (3.0 cm^3) were stirred together in benzene (50 cm^3) at 20°C for 2 h. The initial bright yellow solution rapidly became deep red, and over the period of the reaction slowly became bright yellow again. The benzene was removed by evaporation *in vacuo* and the resultant dark oil was dissolved in dichloromethane (5 cm^3) then diluted with light petroleum (100 cm^3). The solution was allowed to stand for 24 h during which time yellow crystals (A) were precipitated. These were filtered off, and the filtrate reduced *in vacuo* to *ca* 15 cm^3, and again allowed to stand for 24 h. During this time a second crop of yellow crystals (B) precipitated, and were filtered off. The filtrate was further reduced in volume to *ca* 5 cm^3 and then eluted down a short alumina column with dichloromethane. Collection of solution from the column was continued until the eluate became yellow. Evaporation of the initial colourless fraction produced white crystals, these were identified by their IR and NMR spectra as *cis*-stilbene (0.40 g, 53%). The second yellow eluate fraction was found to contain a mixture of *cis*-stilbene and carbonyl-bis (trifluoroacetato) bis (triphenylphosphine) ruth-

enium (by IR and NMR spectroscopy). The crystals (A) and (B) were identified by their IR spectra as carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium (total yield: 3.03 g, 85%).

Catalytic hydrogenation of diphenylacetylene in propan-1-ol

Diphenylacetylene (1.0 g), trifluoroacetic acid (0.33 g) and carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium (0.2 g) were heated together in boiling propan-1-ol (30 cm^3). After 5 min a 1.0 cm^3 sample was withdrawn from the yellow reaction mixture by means of a calibrated syringe. This sample was evaporated *in vacuo* to produce an oily solid and an IR spectrum of this solid was taken. The sampling procedure was repeated at 30 min intervals for a total of 4 h. The spectra obtained in this way all contained, in addition to broad weak bands arising from the presence of carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium, strong sharp vibrations attributable to diphenylacetylene and *trans*-stilbene. The conversion was monitored by comparing the relative intensities of the vibration at 965 cm^{-1} (attributable to *trans*-stilbene) and the vibration at 920 cm^{-1} (attributable to diphenylacetylene) over a period of several hours. Ratios of diphenylacetylene to *trans*-stilbene were estimated by comparison of spectra with those of a standard mixture of diphenylacetylene/*trans*-stilbene. After 4 h the conversion of diphenylacetylene to *trans*-stilbene was approximately half complete.

In an attempt to increase the rate of conversion of diphenylacetylene to *trans*-stilbene, a higher boiling alcohol, butan-1-ol, was employed in place of propan-1-ol. Using a similar procedure to that described above, the conversion of 1.0 g of diphenylacetylene by 0.2 g of carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium in 30 cm^3 of solvent, was found to be complete in *ca* 2 h. From the reaction *trans*-stilbene (0.85 g, 84%) was recovered. Gas-chromatographic analysis of a small sample of the volatiles distilled from the reaction showed the presence of *n*-butyraldehyde.

Carbonyl (ethenyl) (trifluoroacetato) bis (triphenylphosphine) ruthenium(II)

Carbonylbis (trifluoroacetato) bis (triphenylphosphine) ruthenium (0.2 g) was added to cold ethanol (5.0 cm^3), and acetylene bubbled through this solution for 5 min. The mixture was then heated under reflux while passage of acetylene was continued. After *ca* 5 min the initial yellow complex had dissolved and a second pale yellow complex was precipitating from the pale yellow solution. Heating was containued for a further 15 min and the mixture was then cooled. The precipitated solid was filtered off, washed with methanol, then recrystallised from dichloromethane/methanol as fine *pale yellow needles* which were again filtered off and dried *in vacuo*. Yield: 0.12 g, 67%. The reactions of acetylene with $Ru(O_2CCF_3)_2(CO)(PPh_3)_2$ in benzene solution and with $Os(O_2CCF_3)_2(CO)(PPh_3)_2$ in ethanol or benzene solution led to intractable mixtures of products which were not amenable to separation.

X-Ray crystal structure determinations of the complexes $Ru(O_2CCF_3)_2(MeOH)(CO)(PPh_3)_2$ *and* $Ru\{C(C{\equiv}CPh){=}CHPh\}(O_2CCF_3)(CO)(PPh_3)_2$

The preparation and crystallisation

$$(CH_2Cl_2/MeOH)$$

of

$$Ru(O_2CCF_3)_2(MeOH)(CO)(PPh_3)_2$$

have been reported in a previous paper.[6] The preparation and crystallisation (CH_2Cl_2/MeOH) of $Ru\{C{\equiv}CPh){=}CHPh\}(O_2CCF_3)(CO)(PPh_3)_2$ is described above.

The crystals were mounted on glass fibres for X-ray examination, cell dimensions were determined by least squares refinement based on automatically determined diffractometer setting angles.[7]

Crystal data. (I) $Ru(O_2CCF_3)_2(MeOH)(CO)(PPh_3)_2$—compound (I). $C_{42}H_{34}O_6F_6P_2Ru$, M = 911.75, monoclinic, a = 10.519(2), b = 22.108(3), c = 17.393(2) Å, β = 95.33(2)°, V = 4027 $Å^3$, space group $P2_1/n$, D_m = 1.50 g cm^{-3}, Z = 4, D_c = 1.503 g cm^{-3}, $F(000)$ = 1848, μ(Cu-K_α) = 48.13 cm^{-1}, λ(Cu-K_α) = 1.54178 Å.

(II) $Ru(O_2CCF_3)\{C(C{\equiv}CPh):CHPh\}(CO)(PPh_3)_2$—compound (II). $C_{55}H_{41}O_3F_3P_2Ru$, M = 969.54, triclinic, a = 11.526(2), b = 12.469(1), c = 18.025(3) Å, α = 88.44(2), β = 102.41(2), γ = 110.21(2)°, V = 2371 $Å^3$, space group $P\bar{1}$, D_m = 1.34 g cm^{-3}, Z = 2, D_c = 1.358 g cm^{-3}, $F(000)$ = 992, μ(Cu-K_α) = 22.36 cm^{-1}, λ(Cu-K_α) = 1.54178 Å.

Data collection and processing. Intensity data were recorded on a Nonius CAD4 diffractometer using an $\omega/2\theta$ scan mode in a manner previously described in detail.[7] For compound (I) 4088 unique data were recorded, of which 2961 were observed [$I > 2.5\sigma(I)$]. For compound (II) 6964 unique data were measured, of which 5475 had $I > 2.5\sigma(I)$.

Structure analysis and refinement. The structures were solved and refined by standard methods. For both compounds phenyl rings were refined as regular hexagons and hydrogen atoms were included in idealised positions. All non-hydrogen atoms were

assigned anisotropic temperature factors for structure (II), but due to the paucity of data for structure (I), phenyl ring carbons were refined isotropically. Final R values are 0.062(R) and 0.066(R_ω) for compound (I) ($\omega = 1/\sigma^2 F + 0.0002F_o^2$) and 0.054 for compound (II) (unit weights).

Tables of the final atomic coordinates, thermal parameters, observed and calculated structure factors and the full list of bond lengths and angles have been deposited as supplementary material with the Editor from whom copies are available on request. Copies of the atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

In two previous papers we have reported on the fluxional behaviour of the complexes $[M(O_2CCF_3)_2(CO)(PPh_3)_2]$ (M = Ru or Os)[8] and on their ability to catalyse the dehydrogenation of primary and secondary alcohols to aldehydes and ketones respectively.[4] We now describe further work on the interaction of these systems with acetylenic hydrocarbons. The complexes

$$[M(O_2CCF_3)_2(CO)(PPh_3)_2]$$

undergo facile alcoholysis to afford the corresponding hydrides

$$[MH(O_2CCF_3)(CO)(PPh_3)_2],$$

these products in turn react with diphenylacetylene by addition of the M–H group across the acetylenic triple bond to yield the vinylic species

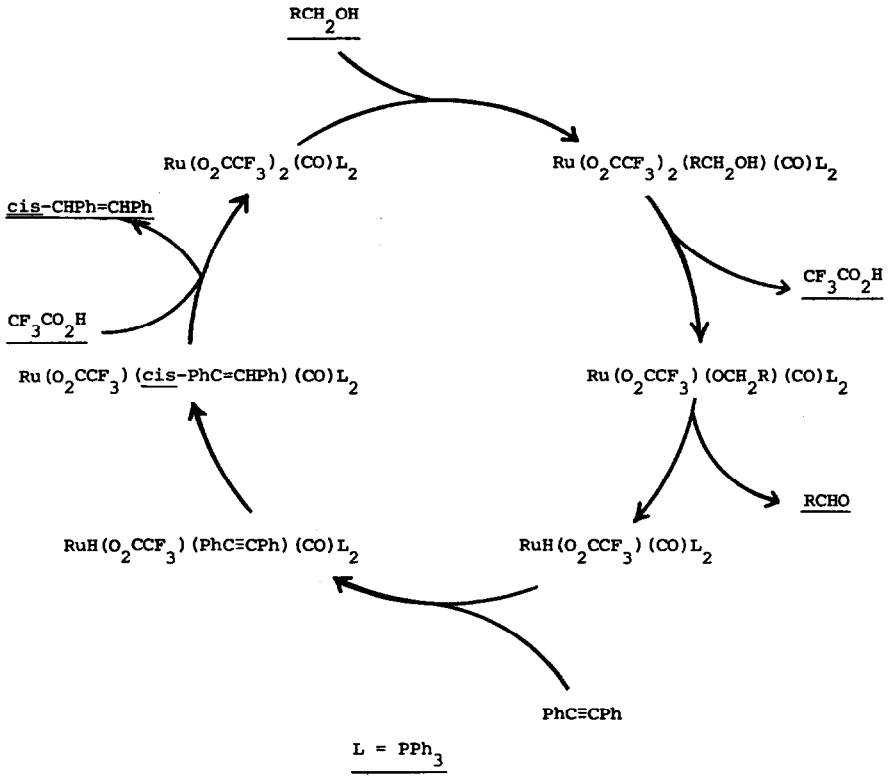
$$[M(PhC{=}CHPh)(O_2CCF_3)(CO)(PPh_3)_2].$$

In similar reactions involving phenylmethylacetylene a finely balanced combination of steric and electronic factors leads to formation of *ca* 1/1 mixture of the isomeric products

$$[M(MeC{=}CHPh)(O_2CCF_3)(CO)(PPh_3)_2]$$

and

$$[M(PhC{=}CHMe)(O_2CCF_3)(CO)(PPh_3)_2]$$



which was analysed on the basis of NMR data given in Table 1. Cleavage of the metal–carbon bonds in their vinylic complexes with cold trifluoroacetic acid affords the vinylic products *cis*-PhCH=CHPh and *cis*-PhCH=CHMe respectively, thereby implying that in each case the original acetylene "insertion" reaction has *cis*-stereochemistry. The stereochemistry of acetylene "insertion" reactions is known to show a critical dependence on the identity of the metal oxidation state, auxiliary ligands and nature of the substituents on the acetylene.[9] Although the complexity of the factors involved has prevented a general interpretation of the mechanism; the occurrence of stereoselective *cis*-insertion is best accounted for in terms of a concerted mechanism involving a four-centre transition state.[2] Such a mechanism is postulated in the present instance. Cleavage of the metal–vinyl linkage under more vigorous conditions is accompanied by isomerisation of the olefinic products to the more thermodynamically stable *trans* form.

The complexes $[M(O_2CCF_3)_2(CO)(PPh_3)_2]$, formed during the cleavage process, undergo alcoholysis, as previously described, to afford the hydrides $[MH(O_2CCF_3)(CO)(PPh_3)_2]$. These hydrides in turn react with more acetylene to regenerate the vinyl complex and thus complete a catalytic cycle (scheme 1) for the transfer hydrogenation of disubstituted acetylenes.

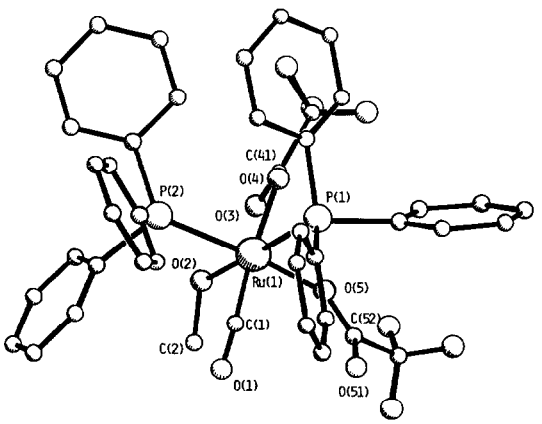
The feasibility of this process has been demonstrated experimentally by the catalytic transfer hydrogenation of diphenylacetylene to *trans*-stilbene using *n*-butanol as the source of hydrogen and $[Ru(O_2CCF_3)_2(CO)(PPh_3)_2]$ as the catalyst. Examination of the volatile products from this reaction by GLC confirmed the formation of *n*-butyraldehyde. If the butyraldehyde is allowed to accumulate within the system the catalyst is converted to the catalytically inactive dicarbonyl species $[Ru(O_2CCF_3)_2(CO)_2(PPh_3)_2]$.

The mechanism proposed for the transfer hydrogenation process (Scheme 1) involves coordination and dehydrogenation of an alcohol substrate and is, therefore, closely akin to that previously advanced for the catalytic dehydrogenation of primary and secondary alcohols.[4] In each mechanism an alcohol is first coordinated to the metal centre, then loses a proton to form an alkoxide ligand which subsequently undergoes β-elimination to generate a molecule of aldehyde (or ketone). Evidence supporting this mechanism has been provided by the results of an X-ray diffraction study performed on a crystal of the catalyst $[Ru(O_2CCF_3)_2(CO)(PPh_3)_2]$ obtained from dichloromethane/methanol solution. The crystal was found to consist of solvated molecules $[Ru(O_2CCF_3)_2(CO)(PPh_3)_2(MeOH)]$ which have the structure shown in Fig. 1. Selected geometric parameters are given in Table 2.

The solvate retains the *cis* arrangement of triphenylphosphine ligands [$\angle$ P–Ru–P = 99.5(1)°, Ru–P 2.341(3) Å (*trans* to MeOH) and 2.361(3) Å (*trans* to $OC(O)CF_3$)] found in the parent complex $[Ru(O_2CCF_3)_2(CO)(PPh_3)_2]$ but has incorporated a molecule of methanol into the coordination sphere [Ru–O 2.174(7) Å] at the expense of the trifluoroacetate ligands, both of which are now monodentate [Ru–O 2.139(6) Å (*trans* to carbonyl) and 2.101(7) Å (*trans* to PPh_3)]. The sixth

Scheme 1.

coordination site is occupied by the carbonyl ligand [Ru–CO 1.81 Å]. The metal–ligand distances are typical for octahedral ruthenium(II). However, the most interesting feature of the structure, and the one most relevant to the present discussion, is the steric relationship between the coordinated methanol and one of the trifluoroacetate ligands. The orientation of this trifluoroacetate relative to the methanol is convenient for the establishment of a hydrogen bond [Me–O–H · · · O–C(O)CF_3] between these two ligands. Moreover the $O_2 \cdots O_3$ distance (2.54 Å) is within the range expected for such an interaction.[10]



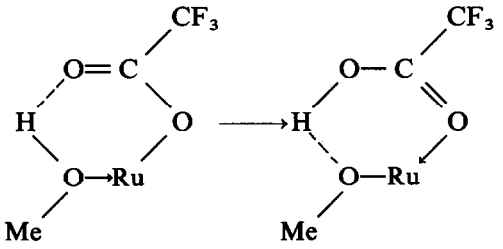


Fig. 1.

The presence of H-bonding, which is confirmed by IR data [hexachlorobutadiene mull, broad band centred at 3000 cm^{-1}], points to a simple and attractive mechanism for the alcoholysis step involving transfer of the H-bonded proton from the alcohol to the carboxylate anion.

Subsequent steps in the catalytic cycle (Scheme 1) are loss of acid CF_3CO_2H, β-elimination of aldehyde (or ketone) coordination of PhC≡CPh, migration of hydride ligand onto coordinated PhC≡CPh, and finally acidolysis of Ru-vinyl linkage to liberate stilbene and regenerate

$$[Ru(O_2CCF_3)_2(CO)(PPh_3)_2].$$

With terminal acetylenes, RC≡CH, a rather different reaction sequence is observed. Arylacetylenes ArC≡CH (Ar = Ph or *p*-tolyl) react with the complexes $[RuH(O_2CCF_3)(CO)(PPh_3)_2]$ and $[Ru(O_2CCF_3)_2(CO)(PPh_3)_2]$ to afford air-stable yellow crystalline products of stoichiometry

$[Ru(C_4HAr_2)(O_2CCF_3)(CO)(PPh_3)_2]$. In contrast the corresponding osmium complexes catalyse oligomerisation of these aryl acetylenes to yield amorphous light-brown hydrocarbon solids with molecular weights in the range 800–1200 a.m.u. However, the osmium complex

$$[Os(C_4HPh_2)(O_2CCF_3)(CO)(PPh_3)_2]$$

and its ruthenium analogue

$$[Ru(C_4HPh_2)(O_2CCF_3)(CO)(PPh_3)_2]$$

are readily obtained by addition of 1,4-diphenylbutadiyne to the corresponding hydrides

$$[MH(O_2CCF_3)(CO)(PPh_3)_2].$$

An X-ray diffraction study on the ruthenium derivative

$$[Ru(C_4HPh_2)(O_2CCF_3)(CO)(PPh_3)_2],$$

using crystals prepared from phenylacetylene and

$$[Ru(O_2CCF_3)_2(CO)(PPh_3)_2],$$

was undertaken to determine the structure and stereochemistry of the hydrocarbon ligand and thus elucidate the mechanism of its formation. The structure of the complex is shown in Fig. 2. Selected geometric parameters are given in Table 3. The octahedral ruthenium(II) centre is coordinated to a *trans* pair of triphenylphosphine ligands [Ru–P 2.369(2) and 2.372(2)Å], a carbonyl group [Ru–CO 1.79(1) Å], a chelate trifluoroacetate [Ru–O 2.235(6) Å (*trans* to carbonyl) and 2.352(7) Å (*trans* to C_4HPh_2 ligand)] and a 1,4-diphenylbut-1-en-3-yn-2-yl ligand. The geometry of the hydrocarbon ligand is more clearly shown in Fig. 3. The structure of the

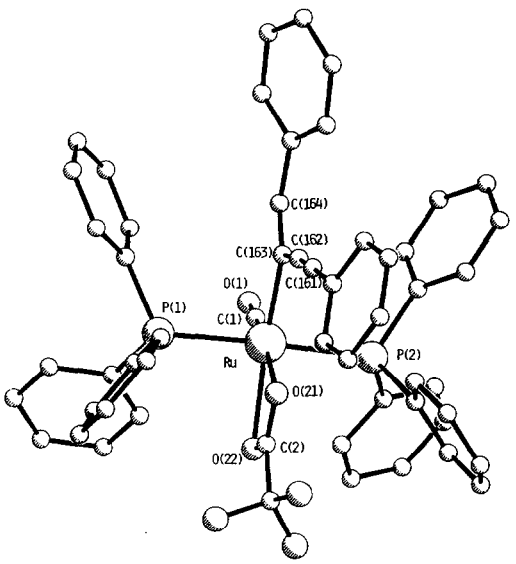

Fig. 2.

hydrocarbon ligand is of particular interest because of relevance to the problems of metal/terminal acetylene interactions and metal catalysed acetylene oligomerisation reactions. Terminal acetylenes are known to undergo oxidative addition reactions at unsaturated metal centres to afford metal acetylide complexes[11] and the subsequent "insertion" of further molecules of acetylene into the M-acetylide linkage has been advanced as a plausible mechanism for acetylene oligomerisation reactions.[2,3] However, it has recently been shown that in their reactions with metal centres terminal acetylenes may also afford vinylidene ligands (M=C=CHR)[12–15] which in

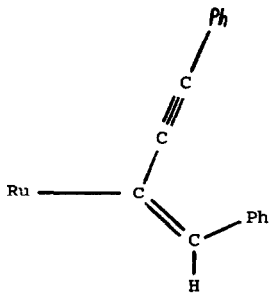

Fig. 3.

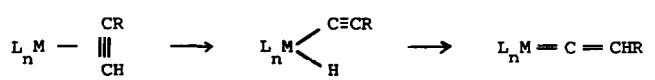
turn can react with further molecules of acetylene to build up more complex hydrocarbon structures.[16] Formation of the vinylidene ligand in these systems is thought to involve η^2-coordination of the acetylene followed by conversion to an acetylide intermediate (Scheme 2). This mechanism has recently been confirmed for a rhodium/acetylene system.[17]

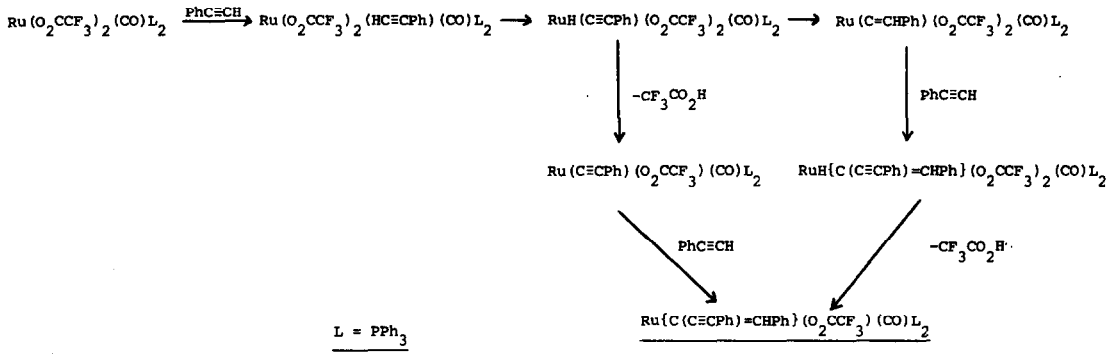
The 1,4-diphenylbut-1-en-3-yn-2-yl ligand generated in the

$$[Ru(O_2CCF_3)_2(CO)(PPh_3)_2]/PhC{\equiv}CH$$



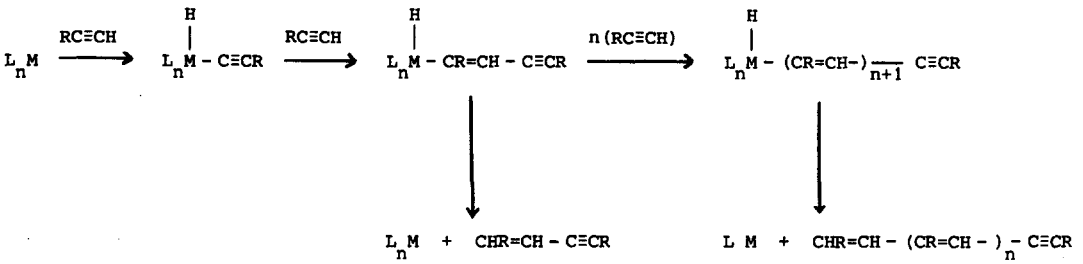
reaction is clearly *not* formed by insertion of a second molecule of acetylene into a metal–acetylide linkage. Therefore the alternative routes given in Scheme 3 were considered. According to the first of these the coordinative unsaturation required to accommodate the incoming acetylene is provided by the chelate trifluoroacetate ligand which relinquishes a coordination site. Subsequent oxidative addition of the coordinated acetylene across the ruthenium centre would afford a seven-coordinate, eighteen electron ruthenium(IV) species which could react further by elimination of acid, CF_3CO_2H, and formation of a ruthenium(II) acetylide complex

$$[Ru(C{\equiv}CAr)(O_2CCF_3)(CO)(PPh_3)_2].$$

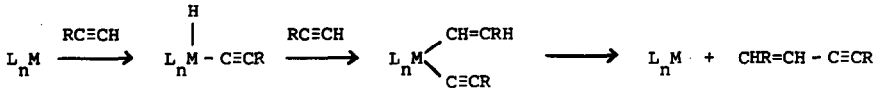


This, in turn, could afford the observed product

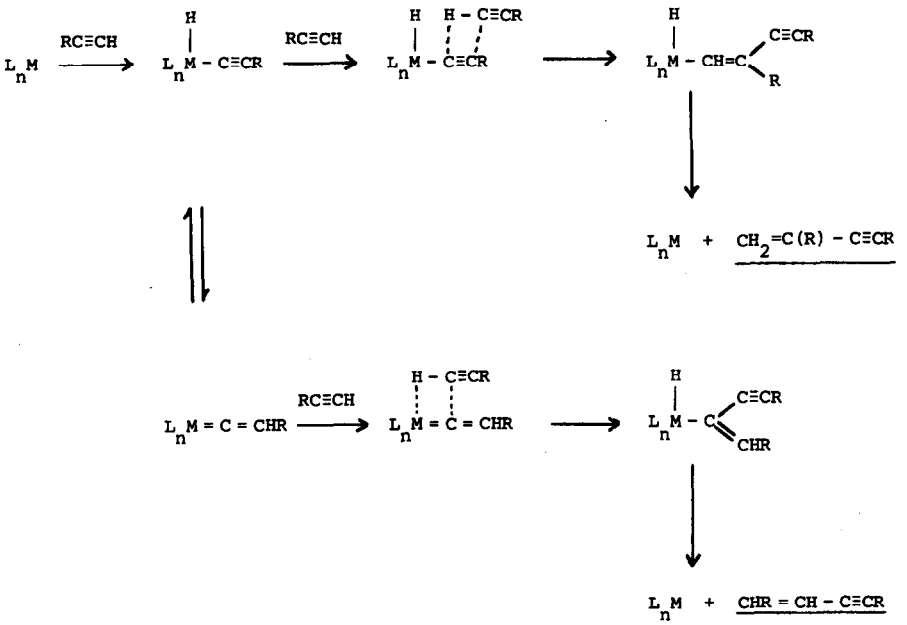
$$[Ru\{C(C{\equiv}CAr){=}CHAr\}(O_2CCF_3)(CO)(PPh_3)_2]$$



by *trans* addition of a second molecule of acetylene across the triple bond of the acetylide ligand. In a preliminary communication[5] this reaction sequence was advanced as the most probable mechanism for formation of the 1,4-diphenylbut-1-en-3-yn-2-yl ligand. However, the recent work on the formation of vinylidene complexes from terminal acetylenes[14–17]



Scheme 2.



Scheme 3.

Scheme 4.

Scheme 5.

Scheme 6.

points to an alternative mechanism which must now be considered. Rearrangement of the proposed seven-coordinate ruthenium(IV) acetylide intermediate $[RuH(C{\equiv}CAr)(O_2CCF_3)_2(CO)(PPh_3)_2]$ to a more stable six-coordinate ruthenium(II) vinylidene intermediate

$$[Ru(=C{=}CHAr)(O_2CCF_3)_2(CO)(PPh_3)_2]$$

could be followed by *cis*-1,2-addition of a second molecule of acetylene across the ruthenium–vinylidene bond and subsequent elimination of acid, CF_3CO_2H, to afford the observed product. Attack by terminal acetylene on a vinylidene ligand formed by a 1,3-hydrogen shift in a hydrido(ethynyl) ruthenium complex has previously been postulated to account for the ruthenium metallocyclic product obtained from the $RuH_2(CO)(PPh_3)_3/HC{\equiv}C{-}CO_2CH_3$ system.[18]

In an attempt to differentiate between these two possible reaction mechanisms the reactions of $[Ru(O_2CCF_3)_2(CO)(PPh_3)_2]$ with one molecule of $PhC{\equiv}CH$ in dilute benzene or ethanol solution were examined by IR and NMR (^1H, ^{13}C and $^{31}P\{^1H\}$] spectroscopy. The pale yellow product isolated from the evaporated solution displayed strong sharp IR bands attributable to carbonyl [ν(CO) 1986 and 1944 cm^{-1}] acetylide [$\nu(C{\equiv}CPh)$ 2052 cm^{-1}] and vinylidene ligands [$\nu(C{=}CHPh)$ 1680 cm^{-1}]. On the basis of these data we tentatively identify the residue as a mixture of

$$[Ru(O_2CCF_3)_2(C{=}CHPh)(CO)(PPh_3)_2]$$

and

$$[Ru(O_2CCF_3)(C{\equiv}CPh)(CO)(PPh_3)_2].$$

The $^{31}P(^1H)$ NMR spectrum consists of two singlets (δ 29.9 and 33.5 ppm) and is therefore compatible with the proposed formulation. However, the ^{13}C NMR spectrum does not show the resonance at *ca* 360 ppm characteristic of vinylidene ligands[13] and therefore casts some doubt on our interpretation. Either way the result does not enable us to determine which of the two proposed mechanisms is operative.

The transition metal catalysed dimerisation and polymerisation of terminal acetylenes, $RC{\equiv}CH$, has generally been attributed to single and multiple "insertion" of $RC{\equiv}CH$ moieties into the metal–carbon bond of the developing hydrocarbon ligand (Scheme 4).[19–23] The fact that certain group VIII metal catalysts specifically (or predominantly) catalyse dimer production may simply mean that in their systems the "insertion" of acetylenes into the metal-vinylic linkage is kinetically and/or thermodynamically less favourable than "insertion" into a metal acetylide bond, and that for this reason reductive elimination of dimer takes precedent over the second "insertion" step. An alternative mechanism for dimerisation of terminal acetylenes, proposed by Hagihara *et al.*,[24] involves alkenyl-alkynyl intermediates (Scheme 5). However, the present work points to a further possible mechanism based in part on the participation of vinylidene intermediates which may be particularly relevant in systems where steric hindrance inhibits coordination of the second molecule of acetylene at the metal centre. According to this proposal (Scheme 6) addition of the terminal acetylene to the catalyst leads to a mixture of acetylide and vinylidene species. Stereochemically controlled addition of a second molecule of acetylene across the acetylide triple bond and across the metal–vinylidene double bond would afford the head-to-tail ($CH_2{=}CR{-}C{\equiv}CR$) and head-to-head ($CHR{=}CH{-}C{\equiv}CR$) dimers respectively. In each case the reverse mode of addition would be prevented or seriously hindered by stereochemically interactions between the incoming acetylene and the ancillary ligands on the metal.

(*Received* 13 *December* 1984; *accepted* 4 *January* 1985)

Abstract—The reaction of $Rh_2(O_2CMe)_4$ with the sodium salt of 3,5-dimethylpyrazole (3,5-Me_2pzH) in acetonitrile gives $Rh_2(3,5\text{-}Me_2pz)_4 \cdot 2MeCN$. This yellow diamagnetic compound on heating gives $Rh(3,5\text{-}Me_2pz)_4$, which in turn forms adducts with different unidentate ligands, L, to give $Rh_2(3,5\text{-}Me_2pz)_4 \cdot 2L$. The binuclear tetra bridged structure has been established for the acetonitrile complex by X-ray diffraction. The Rh–Rh distance is 2.353(3) Å and the Rh–N (acetonitrile) distance is 2.202(5) Å. Some unsubstituted pyrazolates have been made.

Of the relatively few rhodium(II) compounds known most are binuclear,[1–3] commonly having four carboxylato bridges. Unlike other dimeric complexes,[2] such as the quadruply bonded Cr_2^{4+} and Mo_2^{4+} compounds, there has been little variation in the nature of the bridging ligands, although compounds have been prepared with wide variety of axial ligands.[1]

The chelating ability of pyrazole is well-known, examples being heteronuclear systems such as the polypyrazolylborates.[4] Recently, numerous di-rhodium(I) and di-rhodium(III) compounds with pyrazolato bridges have been reported.[5,6]

We now report the synthesis and characterisation of the first quadruply bridged pyrazolates of di-rhodium, the first for any metal.

RESULTS AND DISCUSSION

3,5-Dimethylpyrazolato compounds. The complex $Rh_2(3,5\text{-}Me_2pz)_4 \cdot 2MeCN$ was first obtained in low yield from the reaction of $[HB(3,5\text{-}Me_2pz)_3RhCl_2]_2$[7] with $NaBH_4$ in THF. The product when recrystallized from MeCN gave bright yellow crystals of $Rh_2(3,5\text{-}Me_2pz)_4 \cdot 2MeCN$. However, an improved procedure is the direct reaction of $Rh_2(O_2CMe)_4$ with $Na(3,5\text{-}Me_2pz)$ in MeCN.

In contrast to exchange reactions of $Rh_2(O_2CMe)_4$ with carboxylic or other similar acids only small yields are obtained using $3,5\text{-}Me_2pzH$ as a melt or in MeCN solution. Use of MeOH or THF as a solvent leads to decomposition, while in water the adduct $Rh_2(O_2CMe)_4 \cdot (3,5\text{-}Me_2pzH)_2$ is formed. The compound $Rh_2(3,5\text{-}Me_2pz)_4 \cdot 2MeCN$ has been fully characterised by elemental analysis and spectral data. The mass spectrum shows $M^+ - 2MeCN$ ($m/e = 586$) but no parent ion (M^+). The IR spectrum shows strong bands at 1560, 1262 and 752 cm^{-1} for a pyrazolate complex with weak ν(CN) bands at 2293 and 2263 cm^{-1} for coordinated MeCN.

The ^1H NMR spectrum in CD_2Cl_2 shows two singlets for the pyrazolyl group indicating that the pyrazoles are in a symmetric environment. This is supported by the X-ray crystal structure (see below).

The acetonitrile complex was sufficiently soluble in CH_2Cl_2 to study its electrochemistry. Cyclic voltametry (CV) measurements show an irreversible oxidation at + 1.1 V *vs* SCE. This is in contrast to the

*Authors to whom correspondence should be addressed.

carboxylates which undergo reversible one-electron oxidation.

The axial MeCN ligands can be removed by heating the solvate under vacuum to yield a deep purple solid which is insoluble in all common solvents. The mass spectrum shows the parent ion ($m/e = 586$). The IR is similar to that of the acetonitrile complex but without the solvent bands.

Other adducts can be obtained by substitution of MeCN in the acetonitrile complex with pyridine or methanol but the latter is unstable and dissociates under vacuum.

Pyrazolate complexes. Similar complexes can be obtained from pyrazole. The reaction of $Rh_2(O_2CMe)_4$, with Napz in MeCN gives the solvated complex which is more soluble in organic solvents than the 3,5-Me_2pz complex. The terminal MeCN molecules also can be removed by heating under vacuum to give $Rh_2(pz)_4$.

X-ray studies. The structure of Rh_2(3,5-$Me_2pz)_4 \cdot 2MeCN$ is shown in Fig. 1; selected bond lengths and angles are given in Table 1. The molecule has a crystallographic centre of symmetry, but neglecting the acetonitriles, the Rh_2(3,5-$Me_2pz)_4$ unit has approximately D_{4h} symmetry. The Rh–Rh distance of 2.353(3) Å is slightly smaller than is common for Rh_2(carboxylate)$_4$ systems (2.386–2.403 Å),[1,2] even though the pyrazolate ligands can bridge metals much further apart than this.[6] There seems, therefore, to be very little weakening of the Rh–Rh system by the CH_3CN molecules, even

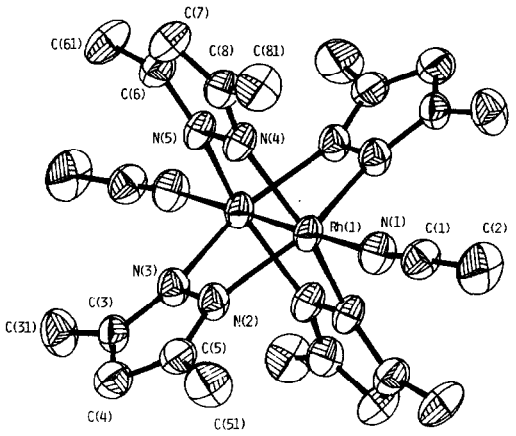

Fig. 1.

though the Rh–N distance of 2.202(5) Å is shorter than that in most axial N-bonded ligands.[8] The Rh–N(pyrazole) bond length of 2.055 and 2.064(5) Å are also slightly smaller than those found in the complex $[Rh(CO)(pz)PPh_3]_2$.[6]

Attempts to make tetra bridged species of other metals have so far been unsuccessful. Interaction of $Mo(CO)_6$, $Mo_2(O_2CMe)_4$, or the blue reduced ruthenium chloride solutions in methanol or tetrahydrofuran with 3,5-dimethylpyrazole or its sodium salt gave intractable products. From $Cu_2(O_2CMe_2)_4$ a deep red highly insoluble product was obtained but this could not be recrystallised.

EXPERIMENTAL

Microanalyses were by Imperial College and Pascher Laboratories. Melting points were determined in sealed capillaries and are uncorrected. IR spectra were recorded in the region 4000–200 cm^{-1} on a Perkin–Elmer 683 grating spectrometer in Nujol mulls, or on a Perkin–Elmer 983 spectrometer as a KBr disc. ^1H NMR spectra were recorded on a JEOL FX90Q spectrometer (δ values in ppm). Electrochemical studies employed a E.G. and G PAR 174A polarographic analyser and $^nBu_4NBF_4$ solution (0.20 mol dm^{-3}) in CH_2Cl_2 at room temperature and −78°C with Pt working and auxilliary electrodes, and a SCE reference electrode (against which ferrocene is oxidised at $E_{1/2}$ = +0.65 V). Electronic spectra were obtained on a Perkin–Elmer 551 spectrometer. Mass spectra, VG 7070. All manipulations were carried out under argon. Solvents were distilled and degassed before use.

Analytical data are given in Table 2.

1. *Tetra - μ - (3,5 - dimethylpyrazolato)dirhodium(II) bis(acetonitrile)*

To $Rh_2(O_2CMe)_4$ (0.98 g, 2.22 mmol) suspended in MeCN (100 cm^3) was added $Na(3,5\text{-}Me_2pz)$ (1.3 g, 11.02 mmol), either as a solid or in acetonitrile.

After refluxing for 3 h the solution became dark yellow with a white precipitate. The solution was filtered, and residual yellow solid being removed by washing with MeCN and filtered. The solvent was reduced in volume and cooled to give yellow crystals. Yield: 1.25 g, 85%.

Mass spectrum. *m/e*: 586 (M − 2MeCN); 96 ($3,5\text{-}Me_2pz$); 41 (MeCN).

^1H NMR (CD_2Cl_2). 5.207s [4-H(pz)]; 2.475s (CH_3CN); 2.144s [CH_3(pz)].

IR (KBr disc). 3103w, 2295w, 2263w, 1560w, 1522s, 1440s, 1261s, 1150m, 1085s, 1023s, 930m, 866w, 801s, 744s, 648w.

Electronic spectrum. 410 nm, $\varepsilon = 224$ dm^3 cm mol^{-1}.

2. *Tetra-μ-(3,5-dimethylpyrazolato)dirhodium(II)*

$Rh_2(3,5\text{-}Me_2pz)_4 \cdot 2MeCN$ (0.50 g) was heated under vacuum at 150 °C for several h whereupon the yellow solid gradually turned deep purple.

Mass spectrum. *m/e*: 586 (M^+); 96 ($3,5\text{-}Me_2pz$).

IR. 3098w, 1526s, 1440s, 1428m, 1262m, 1150w, 1089m, 1053m, 810m, 760m, 752s, 648w.

3. *Tetra - μ - (3,5 - dimethylpyrazolato)dirhodium(II) bis(pyridine)*

To a suspension of $Rh_2(3,5\text{-}Me_2pz)_4 \cdot 2MeCN$ (0.52 g, 0.88 mmol) in Et_2O (30 cm^3) was added excess pyridine. After 2 h the solution was filtered and the yellow solid dried. Yield: 0.14 g, 62%.

IR. 3082w, 1590s, 1518s, 1435s, 1410m, 1339m, 1228m, 1200s, 1080w, 1058s, 1040w, 1032w, 1000w, 753s, 740s, 710s, 650m, 621w.

4. *Tetra - μ - acetatodirhodium(II)bis(3,5 - dimethylpyrazole)*

To $Rh_2(O_2CMe)_4$ (0.99 g, 2.24 mmol) suspended in H_2O (100 cm^3) was added $Na(3,5\text{-}Me_2pz)$ (1.09 g, 11.4 mmol). The colour rapidly changed from blue/green to purple; on refluxing no further change occurred. The solid was filtered and dried. Yield: 1.20 g, 85%.

Mass spectrum. *m/e*: 442 (M-2 × 3,5-Me_2pz); 96 (3,5-Me_2pz); 60 (O_2CMe).

^{1}H NMR ($CDCl_3$). 6.181s [4-H(pz)]; 2.545s, (CH_3CO_2) 1.879s [CH_3(pz)].

IR. 3220br, 1600s, 1582s, 1560s, 1403m, 1336m, 1278msh, 1140w, 1162m, 1014m, 779m, 717m, 695m, 621w.

5. *Tetra-μ-pyrazolatodirhodium(II)bis acetonitrile*

$Rh_2(O_2CMe)_4$ (0.72 g, 1.63 mmol) was refluxed in MeCN (60 cm^3) with excess Na(pz) (0.63 g). The filtered solution was reduced to yield a fine yellow powder. Yield: 0.61 g, 68%.

^{1}H NMR ($CDCl_3$). 7.27br [3,5-H(pz)]; 6.063 br [4-H(pz)]; 2.081s (MeCN).

IR. 3100w, 2200m, 1560s, 1280m, 1195s, 1172m, 1065s, 972w, 945w, 920w, 845w, 749s, 631m, 440w.

Mass spectrum. *m/e*: 68 (pz); 41 (MeCN).

6. *Tetra-μ-pyrazolatodirhodium(II)*

$Rh_2(pz)_4 \cdot 2MeCN$ (0.40 g, 0.72 mmol) was heated under vacuum at 150°C for several h leaving a dark purple solid.

IR. 2100w, 1283m, 1195s, 1172m, 1060s, 970w, 947w, 920w, 865w, 750s, 631m, 437w.

X-ray crystallography

The crystal used was sealed under argon in a glass capillary. Unit cell and intensity data were obtained at 295 K using a Nonius CAD4 diffractometer, operating in the ω–2θ scan mode and using graphite monochromatized Mo-K_α radiation (λ = 0.71069 Å) in a manner previously described in detail.[10]

The structure was solved and refined via routine heavy atom procedures. Non-hydrogen atoms were refined anisotropically. Methyl hydrogen atoms were placed in idealised positions and the CH_3 groups refined as rigid bodies. The two pyrazolyl hydrogens on C(4) and C(7) were refined freely with isotropic thermal parameters.

Crystallographic data. $C_{24}H_{34}N_{10}Rh_2$, M = 668.41, tetragonal, $a = b = 16.730(1)$, c = 10.488(1) Å, space group $P4_2/n$, $Z = 4$, $D = 1.51$ g cm^{-1}, μ(Mo-K_α) = 10.4 cm^{-1}. Data recorded over $1.5 \leqslant \theta \leqslant 25.0$, giving 2580 unique and 1877 observed [$I > 1.5\sigma(I)$] data. $R = 0.0286$, $R_\omega = 0.0270$ for 191 parameters, with weights of $\omega = 1/[\sigma^2(F_o) + 0.0001(F_o)^2]$.

Final atomic parameters, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

SYNTHESIS AND CRYSTAL STRUCTURE OF THE COMPLEX $[MoW\{\mu\text{-}C_2(C_6H_4Me\text{-}4)_2\}(CO)_4(\eta\text{-}C_5H_5)\{\eta^5\text{-}C_9H_6(COMe)\text{-}1\}]$: AN UNUSUAL PRODUCT OF THE REACTION BETWEEN $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ AND $[MoMe(CO)_3(\eta^5\text{-}C_9H_7)]$

(*Received* 30 *November* 1984; *accepted* 18 *December* 1984)

Abstract—The compounds $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ and $[MoMe(CO)_3(\eta^5\text{-}C_9H_7)]$ (C_9H_7 = indenyl) react readily in toluene at 60°C to give the unusual dimetal complex $[MoW\{\mu\text{-}C_2(C_6H_4Me\text{-}4)_2\}(CO)_4(\eta\text{-}C_5H_5)\{\eta^5\text{-}C_9H_6(COMe)\text{-}1\}]$, which has been structurally characterised by an X-ray diffraction study. The metal–metal bond [2.976(1) Å] is transversely spanned by the alkyne ligand $C_2(C_6H_4Me\text{-}4)_2$, formed by coupling of two carbyne fragments. The tungsten atom carries a cyclopentadienyl ring and two carbonyl groups. The molybdenum atom also has two carbonyl ligands, one of which semi-bridges the Mo—W bond [Mo—C—O, 168.7(5)°]. Unexpectedly the indenyl group attached to the molybdenum centre carries a COMe substituent.

The alkylidyne–tungsten compounds $[W(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$ (R = C_6H_4Me-4 or Me) are proving to be versatile reagents for the preparation of complexes containing bonds between tungsten and other transition elements.[1,2] As part of our studies in this area, two trimetal species with Mo—W bonds have been prepared. Thus treatment of $[Mo_2(CO)_4(\eta\text{-}C_5H_5)_2]$ with $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ affords the trimetallatetrahedrane cluster $[Mo_2W(\mu_3\text{-}CC_6H_4Me\text{-}4)(CO)_6(\eta\text{-}C_5H_5)_3]$,[3] while the reaction between the tolylmethylidynetungsten species and $[Mo(CO)_3(NCMe)_3]$ gives $[MoW_2(\mu\text{-}CC_6H_4Me\text{-}4)_2(\mu\text{-}CO)_2(CO)_4(\eta\text{-}C_5H_5)_2]$; a complex with a bent W—Mo—W spine.[4] No dimetal compounds with a Mo—W bond have as yet been obtained *via* reactions between the reagents $[W(\equiv CR)(CO)_2(\eta\text{-}C_5H_5)]$ and suitable organo-molybenum complexes. In an attempt to prepare such a complex, we investigated the reaction between $[MoMe(CO)_3(\eta^5\text{-}C_9H_7)]$ (C_9H_7 = indenyl) and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ in the hope of obtaining a bridged-carbene species $[MoW\{\mu\text{-}C(C_6H_4Me\text{-}4)Me\}(\mu\text{-}CO)(CO)_4(\eta\text{-}C_5H_5)(\eta^5\text{-}C_9H_7)]$. In actuality the reaction followed an unexpected and unusual course, as described below. It may be mentioned that the sought for addition of a Mo—Me group across a W≡C bond was prompted by the observation that the complexes $[N(PPh_3)_2][WH(CO)_5]$ and $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ react to give the salt $[N(PPh_3)_2][W_2\{\mu\text{-}C(C_6H_4Me\text{-}4)H\}(CO)_7(\eta\text{-}C_5H_5)]$,[5] a process formally involving W—H addition to W≡C. The compound $[MoMe(CO)_3(\eta^5\text{-}C_9H_7)]$ was the reagent of choice in the present work, rather than $[MoMe(CO)_3(\eta\text{-}C_5H_5)]$, because indenyl-molybdenum compounds can react *via* an associative mechanism which is assisted by the transformation $Mo(\eta^5\text{-}C_9H_7) \rightarrow Mo(\eta^3\text{-}C_9H_7)$; this slippage creating a vacant site on the metal for attack by a substrate molecule.[6]

RESULTS AND DISCUSSION

The two compounds $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ and $[MoMe(CO)_3(\eta^5\text{-}C_9H_7)]$ did not react in toluene solution at ambient temperatures, but readily did so when heated to 60°C. Chromatography of the reaction mixture afforded some unreacted starting material, together with a red crystalline compound in *ca* 25% yield. The nature and structure of this product could not be deduced from the microanalytical and spectroscopic data, and hence a single-crystal X-ray diffraction study was undertaken. The results are summarised in Table 1, and the molecular structure is shown in Fig. 1.

C(21)—C(5)—O(5)	120.6(5)	C(21)—C(5)—C(6)	118.8(5)
O(5)—C(5)—C(6)	120.6(6)		

The compound has a Mo—W bond which is transversely bridged by an alkyne ligand $C_2(C_6H_4Me\text{-}4)_2$. Thus the molecule has a dimetallatetrahedrane core [Mo—W 2.976(1), C(38)—C(48) 1.371(7) Å] of similar dimensions to those found in the species [$Mo_2(\mu\text{-}C_2Ph_2)(CO)_4(\eta\text{-}C_5H_5)_2$] [Mo—Mo 2.956(1), C—C 1.329(6) Å],[7] [$W_2(\mu\text{-}C_2H_2)(CO)_4(\eta\text{-}C_5H_5)_2$] [W—W 2.987(1), C—C 1.33(3) Å],[8] and [$W_2(\mu\text{-}C_2Et_2)(CO)_4$\{$\eta$-$C_5Et_4(C_6H_4Me\text{-}4)$\}$(\eta\text{-}C_5H_5)$] [W—W 3.003(1), C—C 1.361(14) Å].[9] Each metal centre is ligated by two CO groups, one of which [C(3)O(3)] semi-bridges the metal–metal bond [Mo—C(3)—O(3) 168.7(5)°]. This arrangement of the carbonyl ligands, with three terminally bound and one semi-bridging, is a common structural feature of alkyne-bridged di-molybdenum or -tungsten compounds, with the notable exception of [Mo_2\{μ-$C_2(SiMe_3)_2$\}$(CO)_4(\eta\text{-}C_5H_5)_2$].[10]

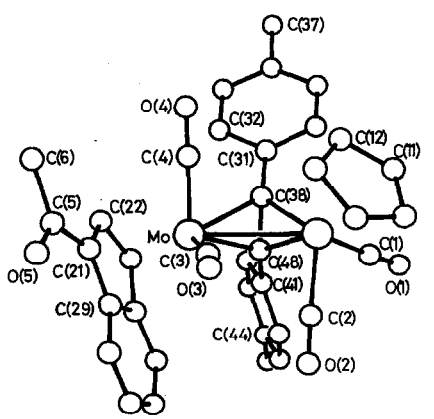

Fig. 1. Molecular structure of the complex [MoW{μ-$C_2(C_6H_4Me\text{-}4)_2$}$(CO)_4(\eta\text{-}C_5H_5)$\{$\eta^5$-$C_9H_6(COMe)$-1}] showing the atom numbering scheme.

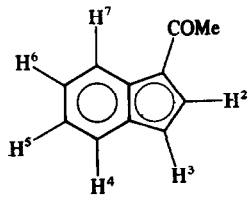
The tungsten atom carries a C_5H_5 ligand, and the molybdenum an indenyl group. Surprisingly, however, the latter has an acyl substituent on C(21). Evidently the compound is formed from [$W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)$] and [$MoMe(CO)_3(\eta\text{-}C_9H_7)$] *via* a complicated pathway. At some stage, the latter results in a coupling of two alkylidyne–tungsten fragments, to produce a μ-$C_2(C_6H_4Me\text{-}4)_2$ ligand. Many reactions of [$W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)$] are now known involving coupling of tolylmethylidyne groups to give either the di-tungsten complex [W_2\{μ-$C_2(C_6H_4Me\text{-}4)$\}$(CO)_4(\eta\text{-}C_5H_5)_2$],[3,11] or cluster compounds containing a μ-$C_2(C_6H_4Me\text{-}4)_2$ ligand.[12] The stoicheiometry of formation of [MoW{μ-$C_2(C_6H_4Me\text{-}4)_2$}$(CO)_4(\eta\text{-}C_5H_5)$\{$\eta^5$-$C_9H_6(COMe)$-1}], however, also implies an unusual cleavage of a carbon–tungsten triple bond. Such a process is not without precedent, having



been observed previously in reactions between [W(≡CC_6H_4Me-4)$(CO)_2(\eta\text{-}C_5H_5)$] and the species [W(CO)(alkyne)$_3$],[9] and between [W(≡CC_6H_4Me-4)$(CO)_2(\eta\text{-}C_5H_5)$] and [$Et_3NH$][$Fe_3(\mu$-H)$(CO)_{11}$].[13]

The presence of the acyl-substituted indenyl ligand in [MoW{μ-$C_2(C_6H_4Me\text{-}4)_2$}$(CO)_4(\eta\text{-}C_5H_5)$\{$\eta^5$-$C_9H_6(COMe)$-1}] is surprising, and may imply a process in which [MoMe$(CO)_3(\eta^5\text{-}C_9H_7)$] is attacked by [W(≡$CC_6H_4$Me-4)$(CO)_2(\eta\text{-}C_5H_5)$] to generate an intermediate containing an Mo(COMe)$(\eta^5\text{-}C_9H_7)$ moiety, with the acyl ligand subsequently migrating to the C_9 ring, from which a hydrogen atom is lost. However, the observation[14] that the compound [Mo(COPh)$(CO)_3(\eta\text{-}C_5H_5)$] decarbonylates to give [$Mo_2(CO)_6(\eta\text{-}C_5H_5)(\eta\text{-}C_5H_4Ph)$], and not a product containing a η-C_5H_4(COPh) ligand, suggests that a Mo(COMe)$(\eta^5\text{-}C_9H_7)$ group if formed would release CO and afford a Mo$(\eta^5\text{-}C_9H_6Me)$ system, rather than Mo$\{\eta^5\text{-}C_9H_6(COMe)\}$. Transfer of a σ-bonded alkyl group from molybdenum to a ligated ring system is well established in the pyrolysis of [MoEt$(CO)_3(\eta\text{-}C_5H_5)$], a process which affords [$Mo_2(CO)_6(\eta\text{-}C_5H_4Et)_2$].[15]

Having established the molecular structure of [MoW{μ-$C_2(C_6H_4Me\text{-}4)_2$}$(CO)_4(\eta\text{-}C_5H_5)$\{$\eta^5$-$C_9H_6(COMe)$-1}] it was possible to interpret the spectroscopic data. Bands at 1981, 1921, and 1866 cm^{-1} are observed in the CO stretching region of the IR spectrum; that at 1866 cm^{-1} may be ascribed to the semi-bridging carbonyl ligand.[10] In the ^{1}H NMR spectrum, resonances are observed for the C_5H_5 (δ 5.24), COMe (δ 2.52) and Me-4 (δ 2.37 and 2.35) groups. The presence of the two inequivalent C_6H_4Me-4 substituents is revealed, not only by the two Me-4 signals, but by the presence of several resonances in the aromatic region of the spectrum. Thus an $(AB)_2$ quartet at δ 6.86 and 7.12 [J(AB) 8 Hz] integrates for one C_6H_4 fragment. A broad signal at δ 6.60 and a doublet at 7.04 [J(HH) 8 Hz] may be assigned to two protons of the other C_6H_4 unit; the remaining two protons of this group having their resonances hidden under others in the region. The $(AB)_2$ quartet is typical of a freely rotating μ-C—C_6H_4Me-4 group, but the pattern observed for the other C_6H_4 fragment suggests restricted rotation about a C—C_6H_4 axis, discussed further below, and as observed previously in [CoW{μ-σ:η^3-C(C_6H_4Me-4)C(Me)C(Me)H}$(\mu\text{-}CO)$(CO)$(\eta\text{-}C_5H_5)(\eta\text{-}C_5Me_5)$][$BF_4$].[16]

The signals for the η^5-C_9H_6 protons were assigned (Table 2) by selective homonuclear decoupling experiments. The chemical shift for H^7 is similar to that of the analogous proton in 1-acetyl and 1-formyl naphthalene.[17] Selective irradiation of the resonance at δ 8.37 decoupled the signal at δ 7.20 (H^6) to a doublet and simultaneously sharpened that at δ 6.96 (H^5). Similarly, selective irradiation of the peak at δ 5.89 reduced the triplet at δ 6.96 to a doublet, and also sharpened the signal at 7.20. As the resonances for H^4 and H^5 would be coupled to each other and H^5 would also be coupled to H^6, the peaks at δ 5.89 and 6.96 can be assigned to H^4 and H^5, respectively. This leaves the remaining resonances at δ 6.60 and 4.96 to be assigned to H^3 and H^2, respectively. The broadness of the signals for H^3 and H^4, as well as the resonances of one of the C_6H_4 groups, mentioned above, suggests that these two groups may be sterically interacting. This could lead to restricted rotation about C(48)—C(41); the C(41)—C(47) group being in proximity with the η^5-C_9H_6(COMe) ligand.

Table 2. ^{1}H NMR data for the η^5-C_9H_6(COMe)-1 ligand

Proton	δ* (ppm)
2	4.96 [d, J(H^2H^3) 4]
3	6.60 (br)
4	5.89 (br)
5	6.96 [t, J(H^4H^5) 8, J(H^6H^5) 8]
6	7.20 [t, J(H^5H^6) 8, J(H^7H^6) 8]
7	8.37 [d, J(H^6H^7) 8]

* Measured in CD_2Cl_2, coupling constants in Hz.

The molecule undergoes dynamic behaviour in solution, as revealed by the ^{13}C-{^{1}H} NMR spectrum which, when recorded at −50°C, shows four CO resonances (δ 233.5, 231.0, 215.9 and 209.8 ppm) but when measured at ambient temperatures shows two peaks for these groups. The mechanism of site-exchange of the CO ligands in di-molybdenum and -tungsten alkyne-bridged complexes has been discussed in detail elsewhere.[9,10]

EXPERIMENTAL

The complexes [W(≡CC_6H_4Me-4)$(CO)_2(\eta\text{-}C_5H_5)$][18] and [MoMe$(CO)_3(\eta^5\text{-}C_9H_7)$][19] were prepared by published methods. Solvents were rigorously dried before use, and all reactions were carried out in Schlenk tubes under oxygen-free nitrogen.

Alumina used in chromatography was BDH aluminium oxide (Brockman activity II). Light petroleum refers to that fraction, b.p. 40–60°C.

Reaction between the complexes $[MoMe(CO)_3(\eta^5\text{-}C_9H_7)]$ *and* $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$

A toluene (30 cm^3) solution of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ (0.41 g, 1 mmol) and $[MoMe(CO)_3(\eta^5\text{-}C_9H_7)]$ (0.31 g, 1 mmol) was heated at 60°C for 48 h in an evacuated Schlenk tube, fitted with a high pressure stopcock. Removal of solvent *in vacuo* gave a brown residue, which was dissolved in dichloromethane–light petroleum (1 : 1, *ca* 2 cm^3) and chromatographed on an alumina column (2 × 10 cm). Elution with the same solvent mixture afforded an orange band which contained an inseparable mixture of the two starting reagents. Further elution with dichloromethane gave a red eluate. Removal of solvent yielded a red powder which was crystallised from dichloromethane–light petroleum (1 : 3) to give red *crystals* of the complex $[MoW\{\mu\text{-}C_2(C_6H_4Me\text{-}4)_2\}(CO)_4(\eta\text{-}C_5H_5)\{\eta^5\text{-}C_9H_6(COMe)\text{-}1\}]\cdot CH_2Cl_2$ (0.18 g, 23%) (Found: C, 47.8; H, 3.3%. $C_{36}H_{28}MoO_5W\cdot CH_2Cl_2$ requires C, 49.0; H, 3.4%), m.p. 143–144°C, ν_{max}(CO) at 1981s, 1921s, 1914(sh) and 1866s cm^{-1} (in Nujol). NMR: ^1H (CD_2Cl_2), δ 2.35 (s, 3H, Me-4), 2.37 (s, 3H, Me-4), 2.52 (s, 3H, COMe), 5.24 (s, 5H, C_5H_5), for resonances due to η^5-C_9H_6 group see Table 2; $^{13}C\text{–}\{^1H\}$ (CD_2Cl_2—CH_2Cl_2, measured at −50°C), δ 233.5, 231.3, 215.9, 209.8 (CO), 195.8 (*C*OMe), 141.5, 139.5 [$C^1(C_6H_4)$], 136.7, 135.2 [$C^4(C_6H_4)$], 131.0, 129.2, 128.9, 128.5 [C^2 and $C^3(C_6H_4)$], 126.9, 126.3, 125.7, 122.4, 116.6, 113.5, 98.6, 92.0 (η-C_9H_6), 90.8 (η-C_5H_5), 88.3 (η-C_9H_6), 28.0 (CO*Me*), 21.4 and 21.3 ppm (Me-4).

Crystal structure determination for $[MoW\{\mu\text{-}C_2(C_6H_4Me\text{-}4)_2\}(CO)_4(\eta\text{-}C_5H_5)\{\eta^5\text{-}C_9H_6(COMe)\text{-}1\}]$

Crystals grow as red needles from dichloromethane–light petroleum. Diffracted intensities were collected at 200 K on a Nicolet *P3m* four-circle diffractometer using a crystal of dimensions *ca* 0.33 × 0.22 × 0.1 mm. Of the total 5622 reflections, measured to $2\theta \leqslant 50°$ (θ–2θ scans), 4527 had $I \geqslant 2.5\sigma(I)$, and only these were used in the refinement of the structure, after the data had been corrected for Lorentz, polarisation and X-ray absorption effects, the latter by an analytical absorption procedure.[20]

Crystal data. $C_{36}H_{28}MoO_5W\cdot CH_2Cl_2$, M = 905.3, monoclinic, a = 18.531(7), b = 10.368(4), c = 18.668(6) Å, β = 109.73(3)°, U = 3376(2) Å^3, space group $P2_1/c$, Z = 4, D_x = 1.78 g cm^{-3}, $F(000)$ = 1768, Mo-K_α X-radiation (graphite monochromator), $\bar{\lambda}$ = 0.71069 Å, μ(Mo-K_α) = 40.4 cm^{-1}.

The structure was solved by conventional heavy-atom and electron-density difference methods and was refined by blocked-cascade least squares. The asymmetric unit was also found to contain a well ordered dichloromethane molecule of crystallisation. All non-hydrogen atoms were given anisotropic thermal parameters and the cyclopentadienyl and aryl hydrogen atoms were included in calculated positions with isotropic thermal parameters *ca* 1.2 times U_{iso}(equiv.) of their parent carbon atoms. The methyl hydrogen atoms were also included in calculated positions and were given common refined thermal parameters. Refinement converged at R 0.029 (R_w 0.030) with a weighting scheme of the form $w = [\sigma^2(F_o) + 0.001|F_o|^2]^{-1}$ giving a satisfactory weight analysis. A final electron density difference synthesis showed no peaks > 1.2 e Å^{-3}. All computations were carried out on an Eclipse S230 (Data General) computer with the SHELXTL system of programs.[20] Atomic scattering factors, anomalous dispersion corrections and mass absorption coefficients were taken from Ref. 21. The atomic co-ordinates for this work are available on request from the Editor and have been deposited with the Cambridge Crystallographic Data Centre. SLOW DIMERIZATION OF ISOPROPOXYBERYLLIUM TETRAISOPROPOXYALUMINATE

R. C. MEHROTRA* and M. AGGRAWAL
Chemical Laboratories, University of Rajasthan, Jaipur 302004, India

(*Received* 2 *July* 1984; *accepted after revision* 18 *December* 1984)

Abstract—An interesting dimerization behaviour has been observed in the freshly distilled monomeric isopropoxy beryllium tetra-isopropoxyaluminate on standing.

The association of metal alkoxides (although subject to steric factors, i.e. size of the metal atom and the nature of the alkyl group) is generally quite facile,[1] but in border-line cases it could be rather slow. For example, freshly distilled trimeric aluminium isopropoxide has been shown[2] to change to the tetrameric form on being allowed to stand (age) for a few days; further association does occur but is comparatively far slower[3] (~ by an order of 2).

Another instance of a similar ageing effect has been observed recently in the case of isopropoxyberyllium tetraisopropoxyaluminate,[4]

$$[(Pr^iO)Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2],$$

which can be distilled (b.p. 156°C/0.3 mm) unchanged and the freshly distilled product shows a molecular weight (347) corresponding to the above formula (332) in chloroform (by ebullioscopic measurements). The above product on being allowed to age in the neat form for a few days at ambient temperatures (~ 20°C) dimerizes to

$$[(Pr^iO)_2Al(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2],$$

which is sufficiently stable to show a dimeric molecular weight (~ 678) in refluxing chloroform. The proton magnetic resonance spectra (Fig. 1) of the two forms lend support to the suggested structures of the two derivatives.

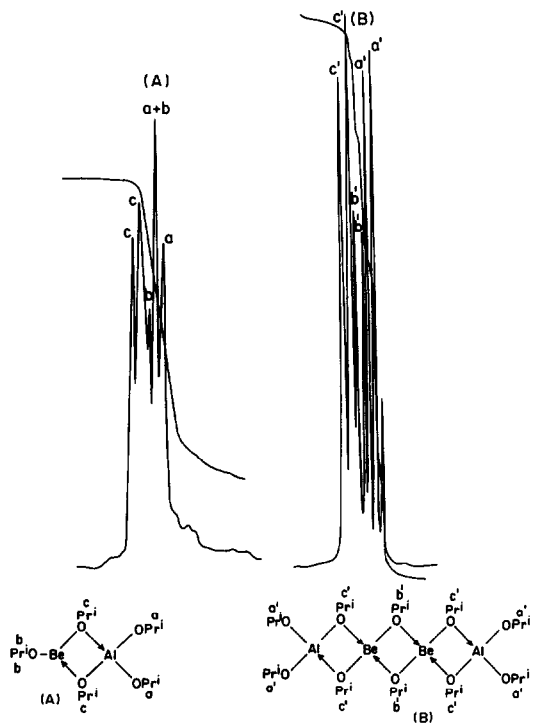

Fig. 1. PMR spectra of methyl protons of $[Pr^iOBe\{Al(OPr^i)_4\}]$ at 90 MHz. (A) Freshly distilled. (B) Aged samples.

Although a 3-coordinated environment around beryllium in some tertiary butoxide derivatives has been previously proposed,[5,6] the stability (cf., the corresponding analogues of Mg, Zn, Cd, and Hg could not be isolated) and rather slow dimerization of $[(Pr^iO)Be\{Al(OPr^i)_4\}]$ may be assigned to steric factors and the strong tendency of beryllium to attain a 4-coordinated state; the same has been exploited in the synthesis of a number of stable volatile termetallic alkoxides, e.g. $[(Pr^iO)_4Nb(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$, for the first time.[7]

KINETICS OF THE AQUATION OF *CIS*-CHLOROCYANOBIS(2,2′-BIPYRIDINE)COBALT(III) AND *CIS*-CHLOROCYANOBIS(1,10-PHENANTHROLINE)COBALT(III) CATIONS

GAETANO SCHIAVON* and FULVIA MARCHETTI
Istituto Chimico "G. Ciamician", Università di Bologna, Italy

(*Received* 27 *July* 1984; *accepted* 5 *January* 1985)

Abstract—We have studied the kinetics of aquation of *cis*-chlorocyanobis(2,2′-bipyridine)Co(III), and *cis*-chlorocyanobis(1,10-phenanthroline)Co(III) cations, and determined activation parameters, in order to compare the labilities of these cations with the lability of the analogous compounds containing ethylenediamine and other non-participating ligands such as Cl^- and NO_2^-.

We have studied the kinetics of the equation of complexes *cis*-$[Co(bpy)_2(CN)Cl]^+$ and *cis*-$[Co(phen)_2(CN)Cl]^+$, and we have determined the activation parameters to compare the labilities of the chlorocyano complexes containing the two aromatic α-diimines with the lability of the analogous ethylenediamine containing complex.

We have therefore completed the kinetic data collected by Palade *et al.*[1] about the series of compounds of the type *cis*-$[Co(N–N)_2(A)Cl]^+$ where N–N = ethylenediamine (en), 2,2′-bipyridine (bpy), and 1,10-phenanthroline (phen), in order to find out or to exclude a *trans*-labilizing effect of the chelate on the labile ligand Cl^-.

Aquation kinetic studies were carried out by determination of the values of specific conductivity on 5×10^{-3} M solution of the complex, at variable ionic strength. To calculate the values of the first-order rate constants we used the differential method of Guggenheim.

The preparation of *cis*-$[Co(bpy)_2(CN)Cl]^+$ has been described elsewhere,[2] while the preparation of *cis*-$[Co(phen)_2(CN)Cl]^+$ together with preparations of corresponding aquocyano complexes are till now unpublished results. The aquocyano complexes retain the *cis* configuration, since the impossibility of the *trans* form[3] has been shown for all Co(III) complexes containing bpy or phen, due to steric hindrance.

In Table 1 are reported the values of the first-order rate constants and activation parameters of the aquation reactions of two chlorocyano complexes containing bpy or phen, determined in the temperature range 60–90°C. The dependence of the rate constant on the absolute temperature satisfies the Eyring equation. From these data we have calculated the first-order rate constants of aquation at 25°C, which are: $(1.6 \pm 0.9) \times 10^{-7}$ s^{-1}, and $(2.7 \pm 0.5) \times 10^{-7}$ s^{-1} for *cis*-$[Co(bpy)_2(CN)Cl]^+$ and for *cis*-$[Co(phen)_2(CN)Cl]^+$ respectively.

In Table 2 are reported the values of the first-order rate constants and of activation parameters of three chlorocyano complexes containing en, phen, and bpy respectively. While the rate constants are of the same magnitude, activation parameters are different. In particular the value of ΔH^* for the ethylenediamine containing complex is higher than the ΔH^* values of the two analogous complexes containing the aromatic α-diimines. On the other hand the ΔS^* values of the last two complexes are more negative than the value of the first one. This indicates a more associative character in the aquation mechanism for the complexes containing phen or bpy, π-electron acceptor ligands like the cyano-group, respectively in *trans* and in *cis* position to the leaving group.

The same conclusion may be drawn from the data reported in Table 3 for the corresponding aquation of chloronitro complexes. Here we find *k* values of the same magnitude again, but greater difference between ΔH^* and ΔS^* corresponding to aromatic α-diimines containing complexes on the one hand and ethylenediamine containing complex on the other.

Values of K, ΔH^*, and ΔS^* reported in Table 4 for dichloro complexes containing respectively en, phen, and bpy, point out, instead, the dissociative character of the aquation's mechanism, due to the presence *cis* to the leaving group of one chloride ion σ and π-donor ligand.

Finally the examination of the values of the first-order rate constants reported in Tables 2, 3, and 4 shows that also with the two chlorocyano complexes containing phen or bpy is verified the rate reducing effect of the cyano-group in respect of the *cis* leaving ligand, made evident by Tobe[4] in the aquation reaction of *cis*-$[Co(en)_2(CN)Cl]^+$. From this examination we can however exclude a *trans*-labilizing effect of the aromatic α-diimines.

TITANIUM NMR SPECTROSCOPY: A COMMENT ON SOME RECENT ASSIGNMENTS

MICHAEL J. McGLINCHEY*
Department of Chemistry, McMaster University, Hamilton, Ontario, L8S 4M1, Canada

and

DOUGLAS G. BICKLEY*

(*Received* 26 *November* 1984; *accepted* 6 *February* 1985)

Abstract—The recently reported ^{47}Ti and ^{49}Ti NMR chemical shift data for Cp_2TiX_2 are reassigned. Arguments based on absolute frequencies and relaxation time data show that the ^{49}Ti peak is always 266 ppm higher frequency than its corresponding ^{47}Ti resonance.

The recent claim[1] to have made the "first NMR observations of the ^{47}Ti and ^{49}Ti nuclei in cyclopentadienyl complexes" prompts us to offer some relevant comments. The statement is made that "the ^{49}Ti resonance exhibits a shielding effect of *ca* 266 ppm relative to the ^{47}Ti signal which, furthermore, always gives the most narrow bandwidth". There then follows a listing of chemical shifts in which the broader peak at higher field (lower frequency) is consistently assigned to the ^{49}Ti nucleus. This assignment is somewhat surprising since the absolute frequencies for $TiCl_4$ (quoted[2] such that the protons in tetramethylsilane resonate at exactly 100 MHz) are $\Xi(^{49}Ti) = 5{,}644{,}259 \pm 10$ and $\Xi(^{47}Ti) = 5{,}642{,}757 \pm 10$ Hz, with the ratio $\Xi(^{49}Ti/\Xi(^{47}Ti) = 1.000266$, a value in excellent accord with previous determinations.[3,4] In short, the ^{49}Ti resonance will always be 266 ppm higher frequency (lower field) than the corresponding ^{47}Ti for the same chemical environment.

The mis-assignment is perhaps understandable since the peak heights are always such that the less shielded (higher frequency) ^{49}Ti peak is the sharper and taller despite the relative abundances (^{49}Ti; 5.51%: ^{47}Ti; 7.28%). However the crucial factor is the relative broadness of the peaks. The peak width at half-height, $W_{1/2}$, is given by:

$$W_{1/2} = \frac{3\pi}{10} \cdot \left(\frac{2I+3}{I^2(2I-1)}\right)\left(1+\frac{\eta^2}{3}\right)\left(\frac{e^2qQ}{h}\right)^2 \tau_c,$$

where I is the nuclear spin, eQ is the nuclear electric quadrupole moment, eq is the electric field gradient and η is the asymmetry parameter which describes the deviation from cylindrical symmetry; τ_c is the correlation time characterising the fluctuation of the electric field. Thus, for molecular systems differing only in the identity of the metal isotope, $W_{1/2}$ varies only with Q and I. Now, for ^{47}Ti, $Q = 0.29 \times 10^{-28}$ m^2 and $I = 5/2$: for ^{49}Ti, $Q = 0.24 \times 10^{-28}$ m^2 and $I = 7/2$.[5] The $f(I)$ terms are 8/25 for the former and 20/147 for the latter. Hence, the nucleus with the *larger* spin gives rise to the narrower lines by a factor of 3.43. It is clear, therefore, that in titanium NMR spectroscopy the less shielded and sharper peak is attributable to the ^{49}Ti resonance.

With this correction, the chemical shift values reported for the series of cyclopentadienyl titanium halide complexes match closely the data already reported on these same complexes by two other groups of workers.[2,6]

COMMUNICATION

REINVESTIGATION OF A TRANSMETALLATION SYNTHESIS OF BIS(CYCLOPENTADIENYL)SAMARIUM(II) AND FORMATION OF A NEW SOLUBLE CYCLOPENTADIENYLSAMARIUM(II) COMPOUND

G. B. DEACON,* G. N. PAIN and T. D. TUONG
Chemistry Department, Monash University, Clayton, Victoria 3168, Australia

(*Received* 28 *January* 1985; *accepted* 12 *February* 1985)

Abstract—The transmetallation reaction between $(C_5H_5)_2Hg$ and activated samarium metal in tetrahydrofuran (thf)/ether did not give $(C_5H_5)_2Sm(thf)_2$ but $(C_5H_5)_3Sm(thf)$, whilst reduction of the last compound with potassium in thf gave $KSm(C_5H_5)_3$, a soluble organosamarium(II) complex.

There is currently great interest in the synthesis of soluble divalent organolanthanide complexes, which have potential in catalyst systems utilising the M(III)/M(II) couple,[1] and are useful as reductants in the synthesis of lanthanide(III) organometallics[2] and in organic synthesis.[3] Soluble isolable organosamarium(II) compounds are of special value since samarium(II) is a more powerful reductant than europium(II) or ytterbium(II).[4] Pseudo-Grignard reagents RSmI have been shown to contain large amounts of samarium(III)[5] and the oxidation state in recently prepared thiophen-2-ylsamarium iodide and C_6F_5SmBr[6] has not been established nor have the compounds been isolated. Both $(\eta\text{-}C_5Me_5)_2Sm(thf)_2$[7] and $(\eta\text{-}C_5Me_5)_2Sm$[8] have been isolated and are soluble. However, $(C_5H_5)_2Sm(thf)$[9] and $(C_5H_5)_2Sm(thf)_2$[10] have low solubilities, the latter being reported to leave a colourless solution on deposition from tetrahydrofuran (thf). However, in a recent synthesis from $(C_5H_5)_2Hg$ and activated (by transmetallation with mercuric chloride[11]) samarium metal,[12,13] it was claimed that $(C_5H_5)_2Sm(thf)_2$ was isolated from solution.[13] The oxidation state of the final product is also surprising, since we have shown that the transmetallation between thallous cyclopentadienide and samarium gives $(\eta\text{-}C_5H_5)_3Sm(thf)$ even when an excess of activated samarium metal is used.[14] We now report a reinvestigation of the transmetallation with $(C_5H_5)_2Hg$ and the synthesis of a new soluble and isolable organosamarium(II) compound by reduction of $(\eta\text{-}C_5H_5)_3Sm(thf)$ with potassium.

On reaction of $(C_5H_5)_2Hg$ with activated samarium in thf/ether under the reported conditions [only 0.033 g $(C_5H_5)_2Hg$; 0.075 g Sm used], a yellow solution indicative[14] of $(\eta\text{-}C_5H_5)_3Sm$ [cf. purple and insoluble for $(C_5H_5)_2Sm(thf)_{1\text{ or }2}$[9,10]] was obtained. Filtration to remove excess samarium and mercury and evaporation gave $(\eta\text{-}C_5H_5)_3Sm(thf)$ in approximately quantitative yield. When the reaction was repeated on a more realistic scale [0.50 g $(C_5H_5)_2Hg$; 1.13 g Sm], the trivalent complex was isolated in 88% yield. The compound was identified by its highly characteristic[14] visible/near-IR spectrum. Single crystals grown from thf had an identical microscopic appearance to those (from C_5H_5Tl and Sm) characterized crystallographically.[14] Thus only reaction (1) occurs:

$$3(C_5H_5)_2Hg + 2Sm \rightarrow 2(C_5H_5)_3Sm + 3Hg\downarrow \quad (1)$$

Reduction of $(\eta\text{-}C_5H_5)_3Sm(thf)$ with potassium metal in thf containing a trace of benzophenone gave a purple insoluble solid. This is similar to precipitation of $(C_5H_5)_2Sm(thf)$ when potassium naphthalenide is used as the reductant.[9] After washing with hot thf to remove unreacted $(\eta\text{-}C_5H_5)_3Sm(thf)$ and benzophenone, extraction of the residue with 1,2-dimethoxyethane (dme), filtration and evaporation gave $KSm(C_5H_5)_3$ as a pyrophoric purple solid in 85–90% yield. Qualitative tests and electron microprobe analysis indicated the presence of potassium, and the composition was established by analysis (C, H, K, Sm). The visible/near-IR spectrum in dme, $\lambda_{max}(\varepsilon)$ 370(354), 400(300)

* Author to whom correspondence should be addressed.

and 498(216) nm, was featureless from 500 to 1500 nm, conclusively eliminating samarium(III) species.[5,15,16] On exposure of the purple solution to air, it rapidly turned yellow and the spectrum (λ_{max} 410, 598, 952, 973, 1080, 1098, 1232, 1255, 1268, 1471 and 1538 nm) indicated oxidation to samarium(III). The IR spectrum showed only absorptions attributable to cyclopentadiene, confirming the absence of thf or dme molecules. Although the complex crystallized in what appeared to be clusters of single crystals which were homogeneous on microscopic examination, no X-ray diffraction pattern could be obtained. Further attempts are being made to obtain crystals suitable for a structure determination. The reducing power of the compound can be seen in reduction of mercury and thallium salts and tetraethyllead to the corresponding metals and the synthetic potential of these reactions is being examined.

Acknowledgements—We are grateful to the Australian Research Grants Scheme for support, to Monash University for a Post-Doctoral Fellowship (G.N.P.), to Dallas Wilkinson for X-ray measurements, and to Adrian van den Bergen and Robyn Elliott for electron microprobe measurements.

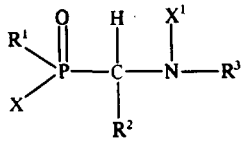
REACTIONS OF PHOSPHORUS TRICHLORIDE WITH SCHIFF BASES



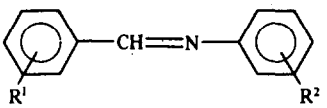
R. P. NARAIN* and MAHTAB Z. SIDDIQUI
Department of Chemistry, University of Gorakhpur, Gorakhpur—273001, India

(*Received* 6 *December* 1983; *accepted after revision* 9 *May* 1984)

Abstract—The reactions of Schiff bases with phosphorus trichloride in the medium of acetone containing pyridine are facile and compounds of the types $RC(PCl_2)=NR'$ and $[RC(PCl_2)=N]_2C_6H_4$ have been prepared.

Much work has been done on the reaction of Schiff bases with silicon tetraacetate,[1] triethylsilane[2] and phosphorus(III) acid chlorides.[3] Singh and Tandon[1] have reported the formation of complexes by the reaction of $Si(OAc)_4$ and bifunctional polydentate ligands.

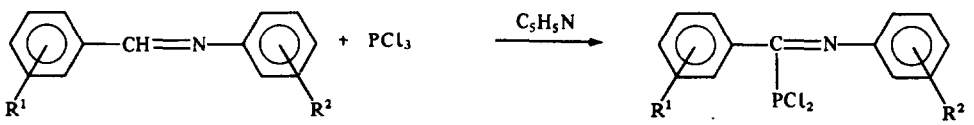
The reaction of triethylsilane with aromatic azomethines was reported by Andrianov *et al.*[2] Nurtdinov *et al.*[3] have carried out the reaction between phosphinous chlorides and Schiff bases and have reported the formation of phosphinic ester, acids or even tertiary phosphine oxides of the type:



where R^1 = ethyl, phenyl; R^2 = propyl, phenyl; R^3 = butyl, methyl, phenyl; X = ethyl, ethoxy, hydroxy, propoxy; X^1 = acetyl, hydrogen, ethyl, propyl.

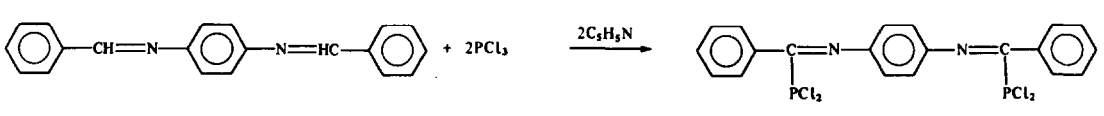
The reactions of isocyanates with azomethines in the presence of SO_2 were reported by Arbuzov *et al.*[4]

Deodhar *et al.*[5] have reported the synthesis of 3-substituted 2-styryl-4-3(H) quinazolinones by Schiff bases. The reactions of primary chlorophosphines with azomethines and acetylacetone have been reported by Nurtdinov *et al.*[6]



In the present communication we report the substitution of azomethine hydrogen by the Cl_2P-group in various Schiff bases.

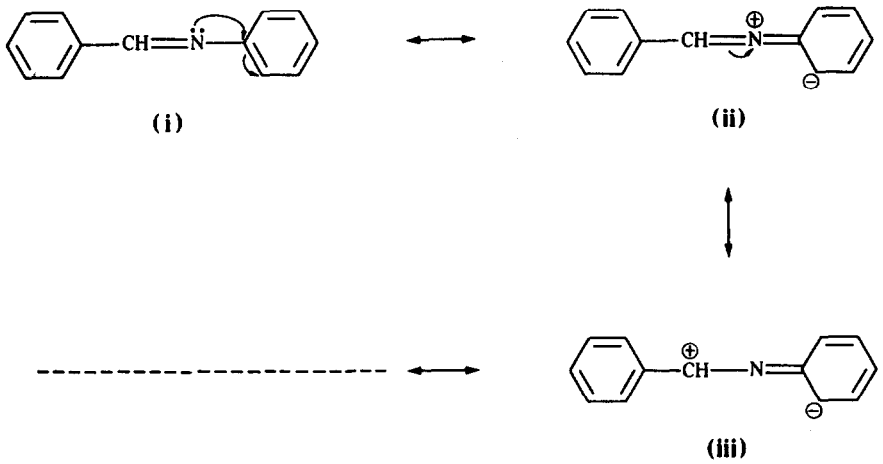
Schiff bases of general formula:



were reacted with phosphorus trichloride in molar ratios 1:1 and 1:2 in the medium of acetone containing pyridine and the reactions may be represented by the following equations:

Molar ratio 1:1

Molar ratio 1:2



* Author to whom correspondence should be addressed.

where R^1 = H; R^2 = Cl, NO_2, H, PhCH=N—.

It was found that the compounds obtained from benzylidene-*o*-phenylenediamine and PCl_3 in both the molar ratios were white solids, whereas the remaining compounds were of intense yellow/orange coloured crystalline solids. All of them were soluble in alcohol, carbon tetrachloride, chloroform, acetone and acetophenone. They appeared to decompose in their melting point determination.

The formation of these compounds could be explained on the basis that the electrons present on the nitrogen of the azomethine group, may be delocalized with the adjacent phenyl group resulting in a number of canonical forms:

Due to the above resonance effect, the azomethine carbon (iii) becomes a carbonium centre and the hydrogen attached to this electron-deficient carbon becomes acidic and may be replaced under special conditions. The PCl_3 moiety can attack this azomethine carbonium centre or the ring attached to it.

The absence of a peak in NMR spectra in the region (τ value 4.0–5.0) which is characteristic of the presence of an olefinic proton shows the replacement of the azomethine hydrogen by the PCl_3 moiety.

The base-catalyzed nature of the reaction rules out the possibility of the homolytic mechanism and indicates that the rate-determining step involves elimination of a proton.

The longer time for the completion of the reaction between phosphorus trichloride and Schiff bases prepared by the reaction of *o*- and *p*-phenylenediamine and benzaldehyde is due to the presence of PhCH=N— group at the end of the molecule. The reactivity of nitro and chloro derivatives was due to the R and I effect which would facilitate the removal of the proton from azomethine carbon.

EXPERIMENTAL

All-glass apparatus with interchangeable joints was used throughout and special precautions were taken to exclude moisture.

Acetone, pyridine, benzene, ether and acetophenone were purified by standard procedures. Phosphorus trichloride was distilled before use.

Silica gel G (BDH) was used for TLC and spots were detected by UV lamp, iodine chamber and treating the plates in an oven after spraying with 10% H_2SO_4.

Preparation of Schiff bases

Schiff bases were prepared by mixing the corresponding amines with benzaldehyde. The reactions were exothermic. The contents were refluxed over a fractionating column followed by continuous removal of water–benzene azeotrope until the distillate attained a constant temperature of 80°C. Excess solvent was removed and the solid products were purified by crystallization from acetone or acetone–benzene mixture. The melting points of Schiff bases were within 1°C of literature values.

Analysis

Phosphorus was estimated as ammonium phosphomolybdate and chlorine as silver chloride, both gravimetrically by standard methods.[7]

Nitrogen was estimated by the Kjeldhal method.[7] Analytical results are given in Table 1.

Ir spectra [ν_{max} (cm^{-1})] (Table 2) of compounds were recorded on a Perkin–Elmer Spectrophotometer Model 577 in KBr discs and NMR [chemical shifts (τ) (ppm)] (Table 3) were recorded on a EM-360 (60 MHz) NMR Spectrometer in CCl_4 with TMS as internal standard, both working at the Chemical Laboratories of Central Drug Research Institute (Lucknow, India). The values obtained were interpreted by comparing the absorption bands and τ values with those reported in the literature.[8,9]

Molecular weights were determined cryoscopically using acetophenone as a solvent.

Methods of preparation being the same for all the

reactions, only one method has been described in detail while a summary of all is given in Table 1.

Reaction of phosphorus trichloride with benzylideneaniline (molar ratio 1 : 1)

To a solution of phosphorus trichloride (0.56 g) taken in acetone (15.00 g) was added a solution of benzylideneaniline (0.75 g) in pyridine. The contents of the flask were cooled and stirred during the addition of the reactants. After addition the contents were subjected to refluxing for 4 h. Acetone was distilled off and the residue was washed several times with dry pyridine to remove the pyridine hydrochloride. Final traces of pyridine hydrochloride were removed by sublimation under reduced pressure. The solid obtained was washed with ether, dried in vacuum and recrystallized from acetone–benzene mixture. The purity of the compound was checked by thin layer chromatography.

THIN LAYER CHROMATOGRAPHY

The chromatoplate was prepared by applying a uniform layer of silica gel in water, drying first at room temperature for 8 h and then at 100°C for 30 min. A 10% solution of the compound in dry acetone was applied over the plate which was then dried at room temperature for 2 h and at 100°C for 10 min.

The plate was then put in the eluant containing ethyl acetate–benzene mixture 1 : 3 by volume.

Finally the spots were located in UV light under a UV lamp, as well as in iodine chamber. A single spot was obtained.

The compound was characterized by elemental analysis, IR and NMR spectra. Found : P, 10.96 ; Cl, 24.94 ; N, 4.91%. $C_{13}H_{10}NPCl_2$ requires : P, 10.99 ; Cl, 25.17 ; N, 4.96%.

Acknowledgements—We express our gratitude to Professor R. P. Rastogi, Head, Department of Chemistry, University of Gorakhpur, Gorakhpur for providing necessary laboratory facilities. One of us (M.Z.S.) is thankful to the State Council of Science and Technology, Lucknow for providing a Junior Research Fellowship.

(*Received* 30 *April* 1984; *accepted* 26 *September* 1984)

Abstract—The ^{1}H NMR spectrum of $Fe_2(SMe)_2(NO)_4$ has been measured in a total of 22 solvents, and the activation barrier ΔG^+ for the $C_{2h} \rightleftharpoons C_{2v}$ isomerisation in nine of these solvents. In aromatic solvents, the solvent-induced shifts are consistent with the formation of charge-transfer complexes, either 1 : 1 or 1 : n; in non-aromatic, non-halogenated solvents of high dipolarity/polarizability the solvent-induced shifts follow the variation of the solvatochromic parameter, π^*. The behaviour of $Fe_2(SeMe)_2(NO)_4$ in a limited range of solvents is similar. The activation barrier ΔG^+ in $Fe_2(SMe)_2(NO)_4$ is *ca* 78 kJ mol^{-1} in the majority of solvents, but that for $Fe_2(SeMe)_2(NO)_4$ is significantly higher.

In the course of an NMR study of the $C_{2h} \rightleftharpoons C_{2v}$, **I** $\rightleftharpoons$ **II**, interconversion of the isomers of esters of Roussin's red salt, of general type $Fe_2(SR)_2(NO)_4$ (R = Me, Et, *n*-Pr, *i*-Pr, *t*-Bu, $PhCH_2$), it was observed[1] that upon changing the solvent from $CDCl_3$ to

I **II**

$C_6D_5CD_3$ at ambient temperature, the ^{1}H chemical shifts all experienced a significant shift to higher field, although the corresponding change in the ^{13}C chemical shift was rather small. For example, in $Fe_2(SMe)_2(NO)_4$ the ^{1}H shift from $CDCl_3$ to toluene-d_8 is *ca* 0.6 ppm, while in $Fe_2(SEt)_2(NO)_4$ the ^{1}H shifts are *ca* 0.4 ppm for the methyl and *ca* 0.5 ppm for the methylene protons: the corresponding ^{13}C shifts are *ca* 0.3, 0.15 and 0.05 ppm, respectively. These observations, and similar findings for other members of the $Fe_2(SR)_2(NO)_4$ series, imply a considerable specificity in the operation of the solvent effect, in discriminating between ^{1}H and ^{13}C shifts in a common methyl or methylene group.

In an attempt to shed further light upon this behaviour we have now carried out a study of the ^{1}H NMR spectrum, as a function of temperature, of the representative ester $Fe_2(SMe)_2(NO)_4$, in a range of solvents. We have also made an outline survey of the behaviour of the selenium analogue $Fe_2(SeMe)_2(NO)_4$ in a limited range of solvents.

EXPERIMENTAL

The ester $Fe_2(SMe)_2(NO)_4$ was prepared as previously described:[1] the selenium ester $Fe_2(SeMe)_2(NO)_4$ was prepared similarly. Purity was established by TLC, IR, and ^{1}H and ^{13}C NMR spectroscopy. All solvents were of the highest available commercial grade and were dried by conventional methods: deuterated solvents were of at least 98.5% isotropic purity.

NMR spectra were recorded for 1% solutions, sealed under vacuum, using a Bruker WP-80 spectrometer. The results for $Fe_2(SMe)_2(NO)_4$ are recorded in Table 1. In addition to the solvents listed in Table 1, an attempt was also made to record similarly the ^{1}H spectrum in CD_3OD: on each of a number of occasions, the sample exploded. It was found for most solvents that the solubility of $Fe_2(SMe)_2(NO)_4$ was too low for the recording of satisfactory ^{13}C NMR spectra. The ^{1}H spectral results for $Fe_2(SeMe)_2(NO)_4$ are recorded in Table 2.

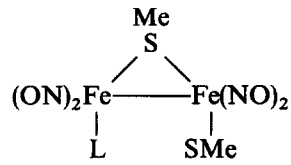
RESULTS AND DISCUSSION

With the exception of solutions in CD_3NO_2, DMSO-d_6, DMF-d_7 and pyridine, the ^1H NMR spectra (Table 1) show that $Fe_2(SMe)_2(NO)_4$ always exists, at ambient spectrometer temperature (308 K), as an equimolar mixture of two isomers, assigned previously[1,2] as having C_{2h} and C_{2v} structures respectively, **I** and **II**. No resolution of the spectrum was achieved at any temperature for solutions in CD_3NO_2, while for solutions in DMSO, DMF and pyridine it was apparent both from the ^1H NMR spectra and subsequently from EPR spectra that paramagnetic species were present. In pyridine, the complex $[Fe(NO)_2(pyridine)_2]^+$ is formed,[3] while in DMSO no definitive identification was achieved, although the paramagnetic complex appears to be $[Fe(NO)_2(SMe)(DMSO)]$: in DMF the two complexes $[Fe(NO)_2(SMe)(DMF)]$ and $[Fe(NO)_2(DMF)_2]^+$ are formed at elevated temperatures.[3] Solutions in benzonitrile and benzaldehyde also underwent major decomposition, as the predominant absorption in the ^1H spectra in these solvents was that of CH_3S^-. Solutions in methanol-d_4 consistently exploded, and so no attempts were made to record spectra in other alcohols.



Subject to these limitations, satisfactory ^1H spectra were obtained for all the other solvents listed in Table 1. The ^1H chemical shifts can be divided rather readily into three principal groups. The first group, having $\delta(^1H)$ in the range 2.75–2.83, comprises chlorinated hydrocarbons and cyclohexane: these are all solvents of low polarity, low polarisability and low acid–base potential, and hence the chemical shifts observed in these solvents may be regarded as typical of those in uncoordinated $Fe_2(SMe)_2(NO)_4$ molecules, otherwise unperturbed by any influence of the solvent.

The second group, having $\delta(^1H)$ in the range 2.2–2.7 (together with C_6F_6 having $\delta = 2.92$) comprises aromatic solvents. Aromatic solvent-induced shifts (ASIS) represent a puzzling phenomenon, for which a variety of interpretations have been put forward.[4–7] It has been suggested[7] that the observation of ASIS is restricted to those molecules possessing a permanent electric dipole moment. We note however that if the *anti* isomer (**I**) of $Fe_2(SMe)_2(NO)_4$, and by inference of other $Fe_2(XR)_2(NO)_4$ species also, possesses genuine C_{2h} symmetry in solution, as hitherto supposed,[1] then it cannot exhibit a permanent dipole moment. On the

other hand it is clear from the data of Table 1 that both isomers of $Fe_2(SMe)_2(NO)_4$ exhibit ASIS of similar magnitudes; likewise a range of other $Fe_2(SR)_2(NO)_4$ (R = Et, *n*-Pr, *i*-Pr, *t*-Bu, $PhCH_2$) complexes exhibit comparable ASIS between $CDCl_3$ and toluene-d_8 as solvents.[1] In the solid state[8] the *anti* isomer of $Fe_2(SEt)_2(NO)_4$ exhibits crystallographic $\bar{1}$ (C_i) and molecular symmetry. However if the terminal methyl carbons are discounted (as appropriate for $Fe_2(SMe)_2(NO)_4$), the molecular symmetry then becomes essentially C_{2h}. Consequently it would be of considerable interest, and importance in terms of the ASIS phenomenon, to determine the molecular structure of isolated $Fe_2(SMe)_2(NO)_4$, e.g. by gas-phase electron diffraction. The variation of the ASIS for substituted benzenes as solvents is entirely consistent[9–12] with their acting as electron donors or acceptors towards the solute $Fe_2(SMe)_2(NO)_4$, according as the substituents on the benzene nucleus are themselves $+I$ or $-I$ substituents. The ASIS data are therefore qualitatively consistent with models based upon either specific 1:1 charge-transfer complexes[5] or dynamic 1:*n* complexes,[6] but appear at this stage to be incompatible with any model based upon the permanent dipole moment of the solute.[7]

The third group of solvents, having $\delta(^1H)$ in the range 2.8–3.0, consists (with the exception of C_6F_6) of strongly polar and strongly electron-donating solvents. Each of these aliphatic solvents, being non-protonic and non-polychlorinated, and having a single, predominant bond dipole fulfils Taft's criteria for "select solvents".[13–15] Many quantitative scales of solvent properties for such solvents have been devised,[16–19] which are all linearly related to the solvatochromic parameter, π^*;[13–15] they all describe in fact that the dipolarity/polarizability of a solvent rather than its acid-base properties. Accordingly there is a reasonable correlation between $\delta(^1H)$ and π^* for this group of solvents: in general the chemical shifts induced by the solvents are simply a reflection of the intrinsic properties of the solvents themselves and do not necessarily imply or require any donor–acceptor interactions between solvent and solute.

For a limited number of solvents (toluene, benzene, nitrobenzene, CD_2Cl_2, cyclohexane, CD_3CN, acetone, dioxan and THF) we were able to measure the coalescence temperature, T_c, for the $C_{2h} \rightleftharpoons C_{2v}$ equilibrium, and the coalescence data, together with the derived values of $\Delta G^{\ddagger}$ are given in Table 1: the $\Delta G^{\ddagger}$ values are accurate within ± 0.5 kJ mol^{-1}. No coalescence was observed even at the solvent boiling point for solutions in C_2Cl_4, $(CCl_2{=}CCl)_2$, CCl_4 and $CDCl_3$, while no resolution of the spectra of the two isomers was observed at any temperature down to the solvent freezing point in either CD_3NO_2 or C_6F_6. No attempt was made to carry out a variable-temperature study in C_6H_5X (X = Cl, Br, I) or in dichlorobenzene as deuterated samples were not available and the use of the normal isotopic forms as solvents gave rise to a considerable number of side-bands. In all solvents studied, except CD_3CN and acetone, the value of $\Delta G^{\ddagger}$ found is the same within 2 kJ mol^{-1}, and hence may be taken as constant, so that the same process is being observed in each of these solvents. In both acetonitrile and acetone the $\Delta G^{\ddagger}$ is significantly lower: however, neither of these solutions shows any evidence for the existence of paramagnetic species when freshly prepared although extremely weak EPR signals can be detected in solutions which have been aged for > 2 months. It is therefore unlikely that the lower $\Delta G^{\ddagger}$ reflects any fission of the Fe_2S_2 ring sufficient to yield paramagnetic complexes: nor is it easy to see that formation of a donor–acceptor complex such as **III** (L = solvent) would have an NMR spectrum

III

virtually unchanged from those of **I** and **II**.

In Table 2, we record results for the spectra of the selenium analogue $Fe_2(SeMe)_2(NO)_4$ in a very limited range of solvents. The chemical shifts are very little different from those of $Fe_2(SMe)_2(NO)_4$, but the $\Delta\nu$ values are consistently larger. In all solvents other than DMSO, no coalescence was observed at temperatures up to, or indeed somewhat above, the boiling points of the solvents. For $Fe_2(SMe)_2(NO)_4$ the value of $\Delta G^{\ddagger}$ was essentially constant at 78 kJ mol^{-1} whether the solvent was benzene, toluene or methylene chloride: assuming that this constancy is true also for $Fe_2(SeMe)_2(NO)_4$ (and we have no means at present of proving this), then we estimate as a lower limit for $\Delta G^{\ddagger}$ for the $C_{2h} \rightleftharpoons C_{2v}$ equilibrium in $Fe_2(SeMe)_2(NO)_4$, a value of at least 86 kJ mol^{-1}. This is significantly higher than the value for the sulphur analogue: we do not know why this should be so.

A FOUR-MEMBERED CHELATE COMPLEX OF Cu(II) WITH CREATININE

M. MITEWA and P. R. BONTCHEV*
Department of Chemistry, University of Sofia, 1126 Sofia, Bulgaria

and

K. KABASSANOV
Institute of Solid State Physics, Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria

(*Received* 13 *August* 1984; *accepted* 26 *September* 1984)

Abstract—The complex formation between Cu(II) and creatinine was studied by means of electronic, IR and EPR spectroscopy. The spectral data show the formation of a Cu(II) four-membered chelate with distorted rhombic structure.

The investigations on the complexation ability of creatinine towards different metal ions might be of interest in connection with the creatinine metabolism studies.[1–3] On the other hand only a few papers are available up to now dealing with complex formation of creatinine with some metal ions, namely Hg(II), Cd(II), Co(II) and Zn(II).[2–4] It has been proved that creatinine coordinates as a monodentate ligand through the cyclic N-atom.[2,3]

The aim of the present work was to synthesize and study the structure of the Cu(II) complex of creatinine.

EXPERIMENTAL

Synthesis of the Cu(II) *complex*

The Cu(II) complex was obtained in neutral medium (pH ~ 6) and isolated as a precipitate. Aqueous 0.1 M solutions of $CuCl_2$(Riedel de Haën AG, p.a.) and creatinine (Loba Chemie, p.a.) in molar ratio 1 : 5 were mixed and then a solution of sodium tetraphenylborate (NaTPB) (Merck, p.a.) was added. The blue precipitate formed was filtered off and washed with water and ethanol.

Analytical data

Elemental analysis of N was provided according to Dumas. Copper was determined by means of atomic absorption analysis after treatment of the complex with conc. HNO_3. The data obtained together with the calculated values for different metal to ligand ratios are represented in Table 1.

Apparatus

The electronic and IR spectra were obtained on recording spectrometers "Specord UV-Vis" (VEB Carl Zeiss, Jena) and on "Perkin–Elmer 580" (KBr disks) respectively. The EPR measurements were provided on an X-band spectrometer ESR 220 (GDR), Mn(II) being used as *g*-marker, the atomic absorption analysis on "Pye–Unicam SP 1950".

RESULTS AND DISCUSSION

The data represented in Table 1 show that a Cu(II) complex with creatinine (creat) is formed with a metal : ligand ratio of 1 : 2, resulting in a blue shift of the *d–d* band from 12,500 to 14,200 cm^{-1}, together with an increase in ε value.

The structure of the complex formed was studied by means of IR and EPR spectroscopy. For our purpose the IR spectra of the free ligand and the $Cu(creat)_2TPB$ were recorded in the 4000–200 cm^{-1} range. The data about the principal bands assigned according to the literature[2–4] are shown in Table 2. It should be noted that new bands are not observed in the range 500–200 cm^{-1}, where the valency vibrations ν_{M-N} or ν_{M-O} are expected to appear.

It is evident that both $\rangle C{=}O$ and cyclic $\rangle NH$

groups are involved in the complexation as the corresponding bands are shifted in the $Cu(creat)_2$ complex, while the bands due to =NH and >C=N groups remain unaffected ($\nu_{=NH}$) or slightly affected ($\nu_{C=N}$). On the basis of these data it might be concluded that in $Cu(creat)_2$ complex 4-membered chelate rings are formed (str. I), differing significantly from the corresponding Co(II), Cd(II), Zn(II) and Hg(II) complexes.[2,3] In the latter only the cyclic >NH group coordinates to the metal ions:

In order to obtain additional information about the $Cu(creat)_2$ structure its EPR spectra were recorded—both a polycrystalline sample and frozen glass solutions in several donor solvents: H_2O, pyridine (py), hexamethylphosphortriamide (HMPA) and dimethylsulphoxide (DMSO). The data obtained are summarized in Table 3.

All the spectra are anisotropic with solvent dependent EPR parameters. The four-component $^{63,65}Cu$ ($I = \frac{3}{2}$) hyperfine splitting is readily observed in the $g_{\|}$ component allowing evaluation of $A_{\|}$. The $A_{\perp}$ values were approximated by dividing the maximum and minimum difference by 3.

According to Hathaway and Billing[5] anisotropic EPR spectra with $g_{\|} > g_{\perp}$ are typical for rhombic symmetry with slight misalignment of the tetragonal axes, e.g. a structure close to square-planar. The visible spectral data are consistent with such supposition as the spectrum obtained is similar to those assigned to distorted rhombic or square-planar Cu(II) complexes.[6]

On the basis of numerous experimental data[7–10] it was proved that such complexes tend to form 1:1 adducts with neutral donor molecules connected

with an increase in g-values together with a decrease in A values. As can be seen from Table 3 this dependence is valid for the complex studied, thus allowing the α^2 to be determined according to the equation of Kivelson and Neiman.[11] This term is connected with the degree of in-plane σ bonding, being 0.86 for the Cu(creat)$_2$TPB complex. For numerous Cu(II) complexes this value is approximately 0.8,[10,12] showing a square-planar geometry and high degree of ionic bonding. The latter result is in agreement with the lack of $\nu_{(M-O)}$ and $\nu_{(M-N)}$ bands in the IR spectrum. In this case they should be expected at very low frequencies.

In the DMSO spectrum a second EPR signal is observed as well with an approximate g-value of $\sim$ 2.12–2.14. Most probably the latter is due to a Cu(II)–solvato complex, as the system $CuCl_2$–DMSO shows an anisotropic singlet line with g-value 2.14. Recently we have obtained similar results studying the adduct formation of a rhombic Cu(iminopyrophthalone)$_2$ complex.[13,14]

(*Received* 10 *September* 1984; *accepted* 6 *October* 1984)

Abstract—The preparation and characterization of the ligand potassium hydrotris(imidazolyl)borate and some of its complexes with transition metals is reported. These complexes have apparently an octahedral structure except the Cu(II) complex which seems to have a square planar geometry. The values of the ligand field parameters $10Dq$, B and β have been evaluated for most of these complexes.

Recently we have reported[1,2] the synthesis and characterization of the ligands potassium dihydrobis(imidazolyl)borate and dihydrobis(2-methylimidazolyl)borate and their complexes. In continuation of this work, we now report the synthesis and characterization of potassium hydrotris(imidazolyl)borate, which is comparatively more sterically hindered than its dihydrobis-counterpart and a few of its complexes with transition metal ions with a view to studying its coordinating ability.

EXPERIMENTAL

All the metal chlorides and potassium borohydride used in this study were of BDH quality. The imidazole (sisco) was used after recrystallization from ethanol.

Preparation of the ligand

Imidazole (14.70 mmol) and potassium borohydride (4.90 mmol) in DMF were mixed together and the reaction was completed by refluxing for about twenty four hours. The colourless potassium hydrotris(imidazolyl)borate which crystallizes out on cooling was filtered, washed and finally dried for five hours under reduced pressure at room temperature.

Preparation of the complexes

The complexes were prepared by mixing the stoichiometric amounts of metal chloride solutions (1.39 mmol of $MnCl_2$, $CoCl_2$, $NiCl_2$ and $CuCl_2$ and 0.93 mmol of $FeCl_3$) and the ligand solution (2.78 mmol) and refluxing the mixture for 1–2 h. The solids thus obtained were filtered, washed with ethanol and dried in an electric oven at 70°C.

IR spectra (4000–200 cm^{-1}) were run on a Perkin–Elmer 621 spectrophotometer. Micro-analyses were done in the micro-analytical laboratory. Metal analyses were carried out by chelometric titration with standard EDTA.[3] Prior to titration the metal was liberated from the complex by the addition of a few drops of a mixture of nitric acid, sulphuric acid and perchloric acid to an accurately weighed 0.1 g sample. Diffuse reflectance spectra were taken on Carl–Zeiss VSU-2P spectrophotometer. Magnetic susceptibility measurements were carried on a vibrating sample magnetometer model 155 at room temperature.

RESULTS AND DISCUSSION

In the formation of the ligand potassium hydrotris(imidazolyl)borate the hydrogen atom at

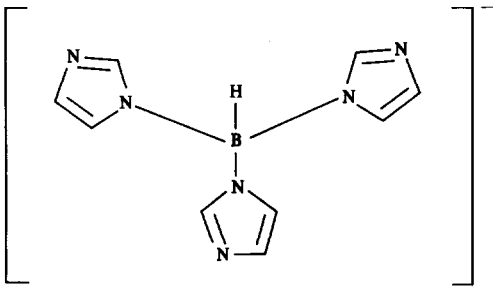
position 1 of the imidazole molecules are removed together with the three hydrogen atoms from the potassium borohydride according to the reaction.



$$KBH_4 + 3C_3H_4N_2 \rightarrow K^+(C_9H_{10}N_6B)^- + 3H_2.$$

This has been ascertained by measuring the volume of the hydrogen gas evolved during the synthesis. The analytical data (Table 1) agrees well with the proposed composition. The IR spectrum (Table 2) does not show any absorption band in the region 3300–3450 cm^{-1}, indicating the absence of the N–H linkage in the molecule, confirming that the imino-hydrogen atoms of the imidazole has been replaced. This has further been characterized by the appearance of the ν(B–N) peak at 1400 cm^{-1}.[4] A strong band at 2440 cm^{-1} may reasonably be assigned to the B–H stretching frequency.[5] Frequencies characteristic of the imidazole ring system[1] also appear in the spectrum. The following structure in which the boron is bonded to three imidazolyl groups through the imino-nitrogen and

to one hydrogen atom may, therefore, be visualized for this ligand.

The complexes prepared are given in Table 1, together with their colour, elemental analyses and % yield. As can be seen, the metal–ligand molar ratios are 1 : 2 and 1 : 3 for divalent and trivalent metal ions, respectively. The ligand studied here would have two possible interaction sites in a molecule to the metal ions. The B–H stretching frequencies of the ligand in the IR spectra shift to lower frequencies by about ~ 30 cm^{-1} upon coordination to the metal chlorides, as shown in Table 2, which indicates that the ligand interacts with the metal ion through the pyrrolic nitrogen atom. The other ring frequencies are affected only slightly from those in the free ligand and the observed shifts, if any, are found to be nearly independent of the metal ion. It is not unusual that there is only a small change in these frequencies after complexation.[6] Metal–ligand stretching frequencies occur in the usual range (250–450 cm^{-1}) for nitrogen donor ligands.[7,8] However, because of the fact that the ligand also has an absorption band in this region the assignments of the M–L stretches are rather uncertain. Considerable mixing between M–L stretching vibrations and ligand modes will certainly be present.

For evidence about the coordination around the metal ions, and the ligand field strength of the ligand, the reflectance spectra and magnetic moment of the solid compound were taken. Band maxima, assignments and calculated values for $10Dq$, B and β are given in Table 3.

The assignment of the electronic spectrum for the Mn(II) compound corresponds with an octahedral ion. The bands at 25,625, 24,775 and 18,822 cm^{-1} are assigned as $^6A_{1g} \rightarrow {}^4A_{1g}(G)$, $^6A_{1g} \rightarrow {}^4E_g(G)$ and $^6A_{1g} \rightarrow {}^4T_{1g}(G)$ respectively. The observed magnetic moment of the Mn(II) complex 5.83 B.M. indicates the formation of a high spin complex.

The electronic spectrum of the Fe(III) complex exhibits well resolved bands at 23,148 and 18,018 cm^{-1} characteristic of the octahedral array of ligands around the metal ion. The magnetic moment of 5.89 B.M. also indicates a high spin complex.

For an octahedral Co(II) complex, three bands are expected corresponding to the three spin-allowed transitions $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ (ν_1), $^4T_{1g}(F) \rightarrow {}^4A_{2g}$ (ν_2) and $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ (ν_3). However, it has been pointed out[9] that the transition $^4T_{1g}(F) \rightarrow {}^4A_{2g}$ corresponds to a two electron jump and as such will have a much lower oscillator strength than the other two bands and will be much weaker. The band at about 10,526 cm^{-1} can, therefore, be assigned to the ν_1 transition and the band at 23,255 cm^{-1} to the ν_3 transition. Using the following equations, which have been derived[10] from the energy matrix of the two

Table 3. Magnetic susceptibility, electronic spectra and ligand field parameters

Complex	μ_{eff} (B.M.)	Electronic bands (cm^{-1})	Possible assignments	$10Dq$	B	β
$[Mn(C_9H_{10}N_6B)_2]$	5.83	25,625	$^4A_{1g}(G) \leftarrow {}^6A_{1g}$	10,400	800	0.83
		24,775	$^4E_g(G) \leftarrow {}^6A_{1g}$			
		18,822	$^4T_{1g}(G) \leftarrow {}^6A_{1g}$			
$[Fe(C_9H_{10}N_6B)_3]$	5.89	23,148	$^4T_{2g}(G) \leftarrow {}^6A_{1g}$	14,337	924	–
		18,018	$^4T_{1g}(G) \leftarrow {}^6A_{1g}$			
$[Co(C_9H_{10}N_6B)_2]$	4.80	23,255	$^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$	10,625	855	0.76
		21,286	$^4A_{2g} \leftarrow {}^4T_{1g}(F)$			
		10,526	$^4T_{2g}(F) \leftarrow {}^4T_{1g}(F)$			
$[Ni(C_9H_{10}N_6B)_2]$	3.14	26,397	$^3T_{1g}(P) \leftarrow {}^3A_{2g}$	9477	977	0.90
		15,339	$^3T_{1g}(F) \leftarrow {}^3A_{2g}$			
		10,204	$^3T_{2g} \leftarrow {}^3A_{2g}$			
$[Cu(C_9H_{10}N_6B)_2]$	1.82	22,371	$^2A_{1g} \leftarrow {}^2B_{1g}$	15,267	–	–
		15,267	$^2E_g \leftarrow {}^2B_{1g}$			

$^4T_{1g}$ levels, it is possible to obtain the values of Dq and B from the position of the ν_1 and ν_3 bands.

$$Dq = [(2\nu_1+\nu_3)+(\nu_3^2+\nu_1\nu_3-\nu_1^2)^{1/2}]/20,$$

$$B = (\nu_3-2\nu_1+10Dq)/15.$$

Using the relationship $\nu_2 = \nu_1+10Dq$, the ν_2 band would be expected to occur at about 21,150 cm^{-1}, i.e. close to the ν_3 band. A very weak shoulder does occur on the ν_3 band in this region but this may arise from spin–orbit splitting.[9] The reflectance spectrum clearly shows the complex to be octahedral, and this is supported by the magnetic moment which lie in the range normally observed for the Co(II) octahedral complexes. When a solution of the cobalt(II) chloride and the ligand are treated with hydrogen peroxide a dark coloured solution results, indicating the feasibility of making the Co(III) complex.

The solid reflectance spectrum of the Ni(II) complex exhibit three main crystal field transitions at around 10,204 cm^{-1} (σ_1), 15,339 cm^{-1} (σ_2) and 26,397 cm^{-1} (σ_3). An octahedral structure may be inferred for this complex on the basis of the position and intensity of these bands. Moreover, the ratio σ_2/σ_1 for the present complex is 1.60 as predicted for octahedral Ni(II) complexes. The observed μ_{eff} value of 3.14 B.M. also suggests an octahedral environment for the nickel ion.

The electronic spectrum of the Cu(II) complex display two d–d transitions at 15,267 and 22,371 cm^{-1}. These spectral bands may be assigned to the transitions $^2B_{1g} \rightarrow {}^2A_{1g}$ and $^1B_{1g} \rightarrow {}^2E_g$ respectively indicating square planar stereochemistry. The magnetic moment value is 1.82 B.M., corresponding to one unpaired electron.

(*Received* 11 *May* 1984; *accepted* 9 *October* 1984)

Abstract—The molecular orbitals, normalization constants and energies of the $M_8(O_h)$, $M_4(T_d)$ and $M_6(O_h)$ clusters are derived and tabulated through the *d*-atomic orbitals. A vector method, adapted to computer application, is devised to compute *s*, *p* and *d* overlap between variously oriented orbitals at atoms that do not have co-directional local axes. Mixing of σ, π and δ orbitals to give the same irreducible representation is also included. As illustrations, the orbitals of Sr_8, La_8, TiO_6 and AlO_6 clusters are computed by the Mulliken–Wolfsberg and Helmholz approximations. During solid phase transitions in the perovskite structures of $SrTiO_3$ and $LaAlO_3$, the TiO_6 octahedron rotates about the C_4 axis whereas the AlO_6 octahedron rotates about the C_3 axis. This difference is explained qualitatively in terms of the relative symmetries of the cluster HOMOs and LUMOs using the second-order Jahn–Teller effect. Allusions are made to the application of this cluster symmetry approach to other systems.

Metal cluster compounds have become of increasing interest to chemists of all disciplines. This interest resulted in two almost consecutive feature articles in *Chemical and Engineering News*, one by Cotton and Chisholm[1] and one by Muetterties.[2] Related books[3,4] and review articles[5–8] are also available. While there are qualitative theories of the bonding of clusters[9,10] and molecular fragments,[4,11] there has been much less work on quantitative, analytical expression for molecular orbitals (MOs) in these clusters.

In 1964, Cotton and Haas[12] treated M_6 *d*-orbital clusters quantitatively. This work was refined[13] later by Cotton's group in 1980. In 1966, Watanabe[14] derived cluster symmetry orbitals using atomic *p*-orbitals (no *d*-orbitals) for $M_4(T_d)$, $M_6(O_h)$ and $M_8(O_h)$ without normalization (in terms of overlap integrals) and without energy expression (in terms of resonance integrals). In 1977, Purcell and Kotz[15] included atomic *d*-orbitals, qualitatively for $M_6(O_h)$ clusters, but again did not include details of overlap or energy expressions. The existing angular overlap model[15] (AOM) of Schaffer[4,16] and Jorgensen[4,17] is concerned mainly with charge overlap between the center metal atom and ligands instead of among ligands clusters *per se*. The tabulated overlaps[4] are for a center atom at the origin and the ligand atom having *codirectional* local axes instead of general relative orientations. As interest increases in larger and larger clusters, there is increasing need for the MOs of basic clusters and for an expedient method to deal with orbitals with arbitrary orientations. The latter is especially true of the bridged complexes[18,22] and unsymmetrical clusters.

In this work we derived quantitative and analytical MOs including *d*-orbitals and energies of the basic clusters, $M_8(O_h)$, $M_6(O_h)$ and $M_4(T_d)$. We also devised a computer-adaptable vector method to

* Contribution No. 0003, ITI Basic Research Laboratory.

† Author to whom correspondence should be addressed.

derive the overlap between *s*, *p* and *d* orbitals with any arbitrary relative orientation. This method supersedes the conventional Euler angle method.[23] Examples of $M_8(O_h)$ clusters[24–27] are $[Cu_8\{S_2C_2(CN)_2\}_6]^{4-}$ and $[Ni_8(CO)_8(\mu\text{-pph})_6]$. An example of an $M_6(O_h)$ cluster[28] is $Ru_6(CO)_{18}H_2$, and $[Fe_4(CO)_{13}]^{2-}$ is an example of an $M_4(T_d)$.[29] Naked clusters are of interest both *per se* and as building blocks. For example, $M_8(O_h)$ and $M_6(O_h)$ can be used to build a face-centered cubic cell. In such a building-up and the subsequent mixing of MOs the complete structure must have the *same* transformation matrix for the degenerate representations of the same symmetry but belonging to *two different clusters* (e.g. M_6 within M_8, both of O_h) under the same operation. We took pains to ascertain this point quantitatively. Within a cluster, e.g. $M_6(O_h)$, irreducible representations with same symmetry (e.g. t_{1u}) but containing different orbitals (σ *vs* π) do not mix in the case of *p*-orbitals (e.g. the overlap between $t_{1u}(P_\sigma)$ and $t_{1u}(P_\pi)$ equals zero). However, this is not generally true. For example, the overlap $s[t_{1u}(d_{z^2})t_{iu}(d_{xz})] \neq 0$. Such mixing between irreducible representations containing $d\sigma$, $d\pi$, and $d\delta$ orbitals is treated in this work for $M_8(O_h)$, $M_4(T_d)$ and $M_6(O_h)$.

Aside from the above mentioned interest in cluster complexes, there is a developing direction in solid state chemistry[4,30,31] toward making use of clusters as building fragments.[32] Band structure calculations[33,34] when extended to three dimensions and cluster calculations[35,36] on minerals, may also require the *d*-overlap methods we have developed here. As another application of the cluster concept in solid state, we note that the phase transition in ferroelectric perovskites ABO_3 which are face-centered cubics involves rotation[37–41] of the inside BO_6 octahedron cluster with respect to the surrounding A_8 cubic cluster. In the case of $SrTiO_3$ the rotation is around the C_4 axis and the transition is from cubic to tetragonal. On the other hand, in the case of $LaAlO_3$ the rotation is around the C_3 axis and the transition is from cubic to rhombohedral (Fig. 1).

Taking inspiration from both Woodward and Hoffmann's[42] success in applying the symmetry of orbitals in a dynamic situation and Pearson's[43] use of symmetry rules to predict molecular structure, we attempt in this work to explore the effect of relative (M_6 vs M_8 cluster) orbital symmetry in determining the axis of rotation during transition. Application of the symmetry of fragments to the determination of the relative barriers of rotation is known from the work of Hoffmann's group on polyene–ML_2 complexes, etc.[44] Our application of a single face-centered cubic unit cell to an infinite system is a drastic theoretical extension. It must be a semi-empirical approach calibrated by known experimental results. The extent of success or failure of the attempt will at least let us know what kind of electronic factors must be included to understand the phase transition. Hopefully, by comparing two parallel systems with the same initial cubic crystal symmetry, $SrTiO_3$ and $LaAlO_3$, the errors of the approximation will balance out and some qualitative trend will emerge.

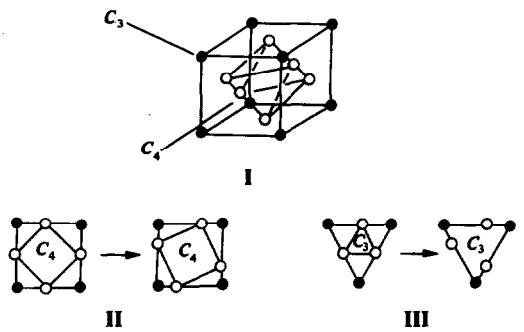

Fig. 1. Phase transition in face-centered cubic ABO_3 perovskite crystals (I). Solid dot for atom "A". Open dots for oxygen atoms. Atom B in the center is not shown. Rotation with respect to C_4 axis corresponds to the cubic to tetragonal transition case of $SrTiO_3$ (II) and rotation with respect to C_3 axis corresponds to the cubic to rhombohedral transition case of $LaAlO_3$ (III).

OVERLAP OF CLUSTER *s*, *p* AND *d* ORBITALS WITH ARBITRARY LOCAL AXIS ORIENTATIONS

Within an M_8 cluster there are $28(={}_8C_2)$ combinations of atomic pairs, each having up to 25 *d*-orbital overlap possibilities. While in $M_6(O_h)$ case, application of symmetry simplifies the calculations, in the general case the prospect of deriving scores of Euler angles[23] and hundreds of overlaps is dizzily discouraging. To expedite and systematize the task, we abandon the Euler angle technique and devise a vector method. First we establish a common origin at the center of $M_8(O_h)$, $M_6(O_h)$ or $M_4(T_d)$ with coordinates system axes along unit vectors $\mathbf{i} = (1, 0, 0)$, $\mathbf{j} = (0, 1, 0)$ and $\mathbf{k} = (0, 0, 1)$. Then we define all local atomic axes in terms of local parallels to **i**, **j** and **k**. Figures 2 and 3 show this choice of atomic labelling and coordinates. Tables 1 and 2 give orientation of local axes. For any given atomic pair *AB*, the relative vector **R** is also defined in terms of the unit vectors **i**, **j** and **k**. **R** is defined as the σ_z overlap direction, with one unique direction instead of the usual two opposite, σ (or *z*) directions for the two overlapping atoms. The overlap π_X and π_Y directions are chosen to be right-handed and mutually

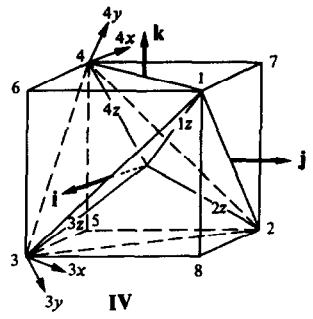

Fig. 2. Local coordinates and atomic labels for $M_4(T_d)$ and $M_8(O_h)$ clusters. The set of numbers 1, 2, 3, and 4 and the set of numbers 5, 6, 7, 8 each compose a tetrahedron. The set of numbers 1, 2, 3, 4, 5, 6, 7, 8 represents a cubic cluster. Unit vectors **i**, **j**, and **k** centered at the origin are common to both clusters.

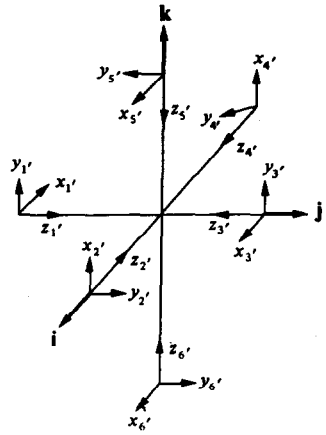

Fig. 3. Local coordinates and atomic labels for $M_6(O_h)$ cluster. The unit vectors **i**, **j** and **k** are common to the $M_8(O_h)$ and $M_4(T_d)$ clusters. These clusters may be superimposed; orbitals of the same symmetry and transformation may be mixed.

perpendicular to **R**, and also expressed in terms of **i**, **j**, **k**. To compute the *p*-overlap, we first project the *p*-orbitals of *A*, $\mathbf{A}_1(=\mathbf{P}_{A_x})$, $\mathbf{A}_2(=\mathbf{P}_{A_y})$ and $\mathbf{A}_3(\mathbf{P}_{A_z})$, onto the $\sigma_z(\equiv \mathbf{R}_3)$, $\pi_x(\equiv \mathbf{R}_1)$, $\pi_y(\equiv \mathbf{R}_2)$ directions, viz. take $\mathbf{A}_1$ (similar projections for $\mathbf{A}_2$, $\mathbf{A}_3$),

$$\mathbf{A}_1 = P_{11}\mathbf{R}_1 + P_{12}\mathbf{R}_2 + P_{13}\mathbf{R}_3. \qquad (1)$$

In as much as $\mathbf{A}_1$, $\mathbf{R}_1$, $\mathbf{R}_2$ and $\mathbf{R}_3$ each has three components (along the common unit vectors), there are three simultaneous linear equations which can be solved by computer for the three projection coefficients, P_{11}, P_{12} and P_{13}. The latter are respectively the π_x, π_y and σ_z components of the orbitals $\mathbf{A}_1(\equiv \mathbf{P}_{A_x})$. Similar projection of **B** (e.g. the $\mathbf{B}_3 = \mathbf{P}_{B_z}$ orbital) gives,

$$\mathbf{B}_3 = Q_{31}\mathbf{R}_1 + Q_{32}\mathbf{R}_2 + Q_{33}\mathbf{R}_3. \qquad (2)$$

In terms of the tabulated π and σ overlaps, the

$X_6 = (-1/\sqrt{2}, -1/\sqrt{2}, 0)$	$X_8 = (-1/\sqrt{2}, 1/\sqrt{2}, 0)$
$Y_6 = (-1/\sqrt{6}, 1/\sqrt{6}, 2/\sqrt{6})$	$Y_8 = (-1/\sqrt{6}, -1/\sqrt{6}, -2/\sqrt{6})$
$Z_6 = (-1/\sqrt{3}, 1/\sqrt{3}, -1/\sqrt{3})$	$Z_8 = (-1/\sqrt{3}, -1/\sqrt{3}, 1/\sqrt{3})$

* Only coordinates for atoms 5, 6, 7 and 8 are given. The remainder may be obtained by inversion of the physical system as follows:

$$\mathbf{i}X_{5678} = -X_{1234},$$
$$\mathbf{i}Y_{5678} = Y_{1234},$$
$$\mathbf{i}Z_{5678} = Z_{1234},$$

but the vector component changes are just the opposite. For example:

$$\mathbf{i}X_5 = -X_1 \quad \text{means} \quad X_1 = (1/\sqrt{2}, -1/\sqrt{2}, 0) = X_5;$$
$$\mathbf{i}Y_5 = Y_1 \quad \text{means} \quad Y_1 = (-1/\sqrt{6}, -1/\sqrt{6}, 2/\sqrt{6}) = -Y_5;$$
$$\mathbf{i}Z_5 = Z_1 \quad \text{means} \quad Z_1 = (-1/\sqrt{3}, -1/\sqrt{3}, -1/\sqrt{3}) = -Z_5.$$

The choice of coordinate system is the same as that of Watanabe.[14] Note, however, the possible confusion in his footnote on p. 183.

Table 2. Local coordinates and atomic labels for $M_6(O_h)$ cluster*

$X_{1'} = (-1\ 0\ 0)$	$X_{3'} = (1\ 0\ 0)$	$X_{5'} = (1\ 0\ 0)$
$Y_{1'} = (0\ 0\ 0)$	$Y_{3'} = (0\ 0\ 1)$	$Y_{5'} = (0\ -1\ 0)$
$Z_{1'} = (0\ 1\ 0)$	$Z_{3'} = (0\ -1\ 0)$	$Z_{5'} = (0\ 0\ -1)$
$X_{2'} = (0\ 0\ 1)$	$X_{4'} = (0\ 0\ 1)$	$X_{6'} = (1\ 0\ 0)$
$Y_{2'} = (0\ 1\ 0)$	$Y_{4'} = (0\ -1\ 0)$	$Y_{6'} = (0\ 1\ 0)$
$Z_{2'} = (-1\ 0\ 0)$	$Z_{4'} = (1\ 0\ 0)$	$Z_{6'} = (0\ 0\ 1)$

* Choice of coordinate system is the same as Purcell and Kotz.[15]

overlap between P_{A_x} and P_{B_z} is

$$S_{xz}^{A,B} = (P_{11}Q_{31} + P_{12}Q_{32})S^{A,B}(P_\pi P_\pi) - P_{13}Q_{33}S^{A,B}(P_\sigma P_\sigma). \quad (3)$$

The minus sign for σ overlap is due to the unique z (not opposite z) direction for A and B. For a d–d overlap, first project the arbitrarily oriented d-orbital D on A in terms of the five d-orbitals in the coordinate system of the common relative vector $\mathbf{R}_3$, viz. ($\Gamma = \theta = d_{z^2}$, $\Gamma = \varepsilon = d_{x^2-y^2}$, $\Gamma = \xi = d_{yz}$, etc.)

$$D_\Gamma^A = A_\theta \tfrac{1}{2}(2\mathbf{R}_3 - \mathbf{R}_1^2 - \mathbf{R}_2^2) + A_\varepsilon(\sqrt{3}/2)(\mathbf{R}_1^2 - \mathbf{R}_2^2) + A_\xi\sqrt{3}\mathbf{R}_2\mathbf{R}_3 + A_\eta\sqrt{3}\mathbf{R}_1\mathbf{R}_3 + A_\zeta\sqrt{3}\mathbf{R}_1\mathbf{R}_2. \quad (4)$$

The projection coefficients A_Γ are obtained by writing the given $D_\Gamma^A = \sum_{ij} C_{ij}\mathbf{A}_i\mathbf{A}_j$ and expanding $\mathbf{A}_i$ and $\mathbf{A}_j$s in terms of $\mathbf{R}_1$, $\mathbf{R}_2$ and $\mathbf{R}_3$ as in equation (1). Thus,

$$A_\theta = \sum_{ij} C_{ij}P_{i3}P_{j3};$$

$$A_\varepsilon = (2/\sqrt{3})\left[\sum_{ij} C_{ij}P_{i1}P_{j1} + \tfrac{1}{2}A_\theta\right]$$

$$A_\xi = (1/\sqrt{3})\left[\sum_{ij} C_{ij}(P_{i2}P_{j3} + P_{i3}P_{j2})\right]$$

$$A_\eta = (1/\sqrt{3})\left[\sum_{ij} C_{ij}(P_{i1}P_{j3} + P_{i3}P_{j1})\right]$$

$$A_\zeta = (1/\sqrt{3})\left[\sum_{ij} C_{ij}(P_{i2}P_{j3} + P_{i3}P_{j2})\right]. \quad (5)$$

A similar projection for d-orbital at B yields B_θ, B_ε, B_ξ, B_η and B_ζ. The overlap between the D_Γ^A and $D_{\Gamma'}^B$ orbitals in terms of tabulated σ, π and δ overlaps is:

$$S_{\Gamma\Gamma'}^{A,B} = A_\theta B_\theta S^{AB}(d\sigma d\sigma) - (A_\xi B_\xi + A_\eta B_\eta)S^{A,B} \times (d\pi d\pi) + (A_\varepsilon B_\varepsilon + A_\zeta B_\zeta) \times S^{A,B}(d\delta d\delta). \quad (6)$$

After the projections of the p and d orbitals have been calculated it is easy to obtain s–p overlap where the s orbitals combine only with the $\mathbf{R}_3$ projection of p, (namely the P_z orbitals). Similarly the s orbital combines only with the A_θ projection coefficient (the d_{z^2} orbital). To obtain the P_π–d_π overlap combine the P_π projection of P (namely on $\mathbf{R}_1$ and $\mathbf{R}_2$) and the d_π projection on d (namely through A_η and A_ξ) respectively and multiply by -1. For the P_σ–d_σ overlap combine the P_σ projection of P (namely on $\mathbf{R}_3$) and the d_σ projection of d (namely through A_θ). The atomic overlaps are given in Table 5b (s–d, M_8); Table 6 (d–d, M_8); Table 9 (d–d, M_4); Table 12 (d–d, M_6); Table 14 (P–P, M_6). The projection coefficients in equation (5), etc. are basic geometrical properties of the clusters and are independent of the cluster size. The σ, π and δ overlap integrals of equation (6) differ with cluster size and can be fed into the computer program. So can the orientation vector **Rs** which are different for clusters of other than the geometry considered here. General and sample computer programs for the projection coefficients and total overlaps are available on request.

CLUSTER MO ENERGIES AND MIXING OF σ, π AND δ ORBITALS

The d-atomic cluster molecular orbitals $M_8(O_h)$ and $M_4(T_d)$ and their energies appear to have never been obtained. The M_6 orbitals and energies were clarified in 1980 by Bursten, Cotton and Stanley.[13] To insure that the cluster can be superimposed as building blocks, we have used the same coordinates and origin. To insure that the degenerate orbitals of the same symmetry can mix, not only between different clusters but also among s, p and d cluster orbitals, we have maintained consistent phase and transformation properties for *all* of the MOs. To expedite the process of finding MOs for d-orbitals we look for transformation properties of d-orbitals which are similar to those of the p-orbitals which have been given.[14] The following correspondences among atomic orbital transformations were found, after some tedious algebra and anxious anticipation, to be true for operators of the O_h and T_d and point

groups:

$$s \sim z \sim d_{z^2}$$

$$x \sim dxz \sim dxy$$

$$y \sim d_{yz} \sim d_{x^2-y^2}.$$

From there on the construction of MOs was straightforward except for the necessary checking of phases to make sure that the correct and *identical* transformation matrix holds for the three components, e.g. $t_{1u}(s)$, $t_{1u}(P_x, P_y)$, $t_{1u}(P_z)$, $t_{1u}(d_{z^2})$, $t_{1u}(d_{xz}, d_{yz})$ and $t_{1u}(d_{x^2-y^2}, d_{xy})$ in $M_8(O_h)$. Irreducible representations of s, p and d cluster orbitals are summarized in Table 3. Detailed MOs and energy normalizations are given in the Tables 4 (M_8), 7 (M_4) and 10 (M_6). From the atomic overlaps derived in the last section, the normalization factors for these MOs can be obtained. As long as the degenerate orbitals are mutually orthogonal, their energies can be obtained from any one of the degenerate sets in a straightforward manner. We used the Mulliken–Wolfsberg–Helmholz[23,45] method of approximating the Coulomb integral H_{AA} by the valence orbital ionization energy of the corresponding s, p and d orbitals represented symbolically by ε. The resonance integral is assumed to be proportional to the overlap between the two atomic orbitals A and B;

$$\beta_{AB} = KS\tfrac{1}{2}(H_{AA}+H_{BB}). \qquad (7)$$

For mixing between MOs of the same irreducible representation, one needs to take only one of the degenerate components from each set since we have made sure these components share an *identical* transformation matrix. For example, referring to Table 4, we may mix $t_{1uz}(\theta)$ with $t_{1uz}(\varepsilon)$ and $t_{1uz}(\pi)$. The resulting mixing coefficients are equally applicable to $t_{1ux}(\theta)$, $t_{1ux}(\varepsilon)$ and $t_{1ux}(\xi)$. The resonance integral for mixing again may be taken to be proportional to the group overlaps—these are derived and tabulated in Table 5a (d–d, M_8), Table 5b (s–d, M_8), Table 7 (d–d, M_4) and Table 11 (d–d, M_6).

In summary, symmetry orbitals are first generated by group theory as a linear combination of atomic

* p-orbital clusters ($P\sigma P\pi$) without normalization and energy have been given by Watanabe.[14] We use the same coordinate system and atomic numbering of Watanabe (note some confusion in their # 5 and # 8 on the footnote of p. 183 which we clarify). This is so that *orbital mixing of* p *and* d *if desired may be easily made.* It is noted that θ transforms as P_z, dxy and dxz both transform as Px, and $d_{x^2-y^2}$ and dyz both transform as Py. The normalization and energy of the $M_8(O_h)$ p-orbital cluster may be obtained in parallel to the d-cluster.

† Components for degenerate representation are specified exactly and consistently so that mixing with corresponding components of $M_4(T_d)$ and/or $M_8(O_h)$ of the same symmetry may be correctly effected.

‡ Normalized up to nearest neighbor overlap, e.g. between adjacent atoms but not opposite atoms. Only those required for energy computation are given in detail including overlap.

§ Energy expression may be obtained from one of the degenerate levels provided the latter are orthogonal to one another. Only energies for the orbital of a given type (for example, $d\sigma$ or $d\pi$ orbitals) and a given symmetry (for example A_{1g} or t_{1u} symmetry) *per se* are given. Mixing of different types of orbitals of the same symmetry [e.g. $t_{1u}(d\sigma)$ with $t_{1u}(d\pi)$] not included here. For group overlap responsible for such mixing see Table 2.

Table 5a. Group d-orbital overlap for mixing of $M_8(O_h)$ cluster MOs of the same irreducible representation*

* If one constructs an 8×8 square matrix of atomic labels, the 64 matrix elements representing combinations of atomic orbitals run from 1st row to 8th row as (11, 12, 13, 14) (15, 16, 17, 18) (21 ... 24) (25 ... 28) (31 ... 34) (35 ... 38) (41 ... 44) (45 ... 48) ... (81 ... 84) (85 ... 88). The corresponding overlap integrals have quality patterns as follows: $(0\,s\,s\,s')(\sim 0\,s''\,s''\,s''')(s\,0\,s'\,s)(s''\sim 0\,s'''\,s'')(s\,s'\,0\,s)(s''\,s'''\sim 0\,s'')(s'\,s\,s\,0)$ $(s'''\,s''\,s''\sim 0)(0\,s''\,s''\,s''')(0\,s\,s\,s')(s''\sim 0\,s'''\,s'')(s\,0\,s'\,s)(s''\,s'''\sim 0\,s'')(s\,s'\,0\,s)$ $(s'''\,s''\,s''\sim 0)(s'\,s\,s\,0)$. In the special case of S–d_{z^2} overlap $s = s'$, $s'' = s'''$ $= 0$.

† N_1 and N_2 represent symbolically the first and second normalization constants of the two molecular orbitals.

‡ Numerical values for S–d atomic overlap are for La_8 in $LaAlO_3$ cubic crystal. $a = 3.80$ Å.

orbitals (Tables 4, 7, 10 and 13). The "energies" of these preliminary molecular orbitals are computed from coulomb and atomic resonance integrals. The former is approximated by the valence orbital ionization energies (VOIE) of the atomic orbitals—the latter by the Mulliken–Wolfsberg–Helmholz method, using the atomic overlaps in Tables 6, 9 and 12. When it happens that n of these preliminary molecular orbitals has the same symmetry, these n-symmetry orbitals are again linearly combined. The mixing coefficients and energies of such combinations as final molecular orbitals are obtained by solving the $n \times n$ secular determinant. The group coulomb integral in this secular determinant is approximated by the preliminary molecular orbital energies and the group resonance integral by the group overlaps (Tables 5, 8 and 11), again via the Mulliken–Wolfsberg–Helmholtz method.

RELATIVE ORBITAL SYMMETRY OF CLUSTERS AND THE PEROVSKITE PHASE TRANSITION

Phase transitions in solids have been treated with sophisticated techniques,[39–41] many of which invoke the cooperative Jahn–Teller effect.[38,46] Here

*Superscripts stand for the numbering of the two atomic d-orbitals in the cluster. Subscripts stand for the orbital type ($\theta = d_{z^2}$, $\varepsilon = d_{x^2-y^2}$, $\xi = d_{yz}$, $\eta = d_{xz}$, $\zeta = d_{xy}$). Accuracy is ± 0.0004.

† $S^{1,2}$ and $S^{1,4}$ are given in the $M_4(T_d)$ case of the same numbering and coordinate system (Table 9). Many overlap integrals between different atomic numbering (labelling) are found to be equal under the coordinate and labelling system used. viz. $S^{1,6}_{ij} = S^{1,7}_{ij} = S^{2,5}_{ij} = S^{2,8}_{ij} = S^{3,5}_{ij} = S^{3,8}_{ij} = S^{4,6}_{ij} = S^{4,7}_{ij} = S^{5,2}_{ij} = S^{5,3}_{ij} = S^{6,1}_{ij} = S^{6,4}_{ij} = S^{7,1}_{ij} = S^{7,4}_{ij} = S^{8,2}_{ij} = S^{8,3}_{ij}$. Similarly, $S^{1,8}_{ij} = S^{2,7}_{ij} = S^{3,6}_{ij} = S^{4,5}_{ij} = S^{5,4}_{ij} = S^{6,3}_{ij} = S^{7,2}_{ij} = S^{8,1}_{ij}$. Also, when four atoms are added to build up to $M_8(O_h)$, the many overlaps in $M_4(T_d)$ case are equal to the new overlaps. viz. $S^{1,2}_{ij} = S^{5,6}_{ij} = S^{5,7}_{ij} = S^{6,5}_{ij} = S^{6,8}_{ij} = S^{7,5}_{ij} = S^{7,8}_{ij} = S^{8,6}_{ij} = S^{8,7}_{ij}$. Similarly, $S^{1,4}_{ij} = S^{5,8}_{ij} = S^{6,7}_{ij} = S^{7,6}_{ij} = S^{8,5}_{ij}$. The overlaps between opposite atoms are assumed negligible, viz. $S^{1,5} = S^{2,6} = S^{3,7} = S^{4,8} = S^{5,1} = S^{6,2} = S^{7,3} = S^{8,4} \cong 0$. The 'overlaps' between the same atom are either zero ($S^{kk}_{ij} = 0$) or one ($S^{kk}_{ii} = 1$).

Table 7. $M_4(T_d)$ d-orbital cluster:* MO† normalization‡ constants and energies§

$t_{2\xi} = [\sqrt{3}(-\zeta_1+\zeta_2-\zeta_3+\zeta_4)+\varepsilon_1-\varepsilon_2+\varepsilon_3-\varepsilon_4]$	
$t_{2\eta} = [\sqrt{3}(\zeta_1+\zeta_2-\zeta_3-\zeta_4)+\varepsilon_1+\varepsilon_2-\varepsilon_3-\varepsilon_4]$	$E(t_2) = (\varepsilon-2\beta_{\varepsilon\varepsilon}^{1,2}+\beta_{\varepsilon\varepsilon}^{1,4})/(1-2S_{\varepsilon\varepsilon}^{1,2}+S_{\varepsilon\varepsilon}^{1,4})$
$t_{2\zeta} = (-\varepsilon_1+\varepsilon_2+\varepsilon_3-\varepsilon_4)/(4-8S_{\varepsilon\varepsilon}^{1,2}+4S_{\varepsilon\varepsilon}^{1,4})^{1/2}$	

*†‡§ See the footnotes for Table 4.

we attempt to find a qualitative chemist's way of viewing the transition from orbital symmetry. Our ultimate purpose is to find a qualitative day-to-day guide for the preparation of shape-memory alloys[47] that exhibit martensitic transitions.[47–49] For an illustration of the theory we take the perovskite[37] crystal ABO_3 which consists of one octahedral BO_6 cluster inside a cubic A_8 cluster. We wish to explore the electronic difference between $SrTiO_3$ and $LaAlO_3$ that accounts for their different phase transition characteristics (see Figs. 1, 2 and 3). The cubic crystal dimensions are $a = 3.90$ Å for $SrTiO_3$[50] and $a = 3.790$ Å for $LaAlO_3$.[51] Since for comparison absolute errors are not important, we make the following Mulliken–Wolfsberg–Helmholz approximations.[23] We take for the resonance integral the VOIE of neutral atoms and consider only the atomic orbitals that apply to the neutral atom. The resonance integral is taken to be proportional to the overlap [equation (7)] with a proportionality constant[52] of $K = 1.75$ for all. The VOIEs are obtained or estimated using data from McGlynn's book.[23] For La, they are obtained from the spectroscopic tables of Moore.[53] Single zeta Slater atomic orbitals are used with the zeta value calculated according to Burn's prescription.[54] The overlap integrals are taken from the tables of Boudreaux, Cusachs and Dureau.[55] Energies and orbitals of the clusters are first obtained for $O_6(2p)$, $La_8(6s)$, $La_8(5d)$ and $Sr_8(5s)$. Then the Ti($3d4s4p$) and Al($3s$, $3p$) orbitals are mixed in O_6 for the TiO_6 and AlO_6 octahedrons. Mixing among the orbitals with the same symmetry in La_8 is also effected by using the initial cluster energy as the Coulomb integral. The effect of $6s$ on the $5d$ levels of La_8 is seen to be small. The numerical values of overlaps for specific systems

Table 8. d-Orbital overlap* for mixing of $M_4(T_d)$ cluster MOs of the same irreducible representation

Mixing of	
π, δ	$S[t_{1z}(\eta)t_{1z}(\zeta)] = N_1N_2(-8S_{\eta\zeta}^{1,2}+4S_{\eta\zeta}^{1,4})$
π, δ	$S[eV(\eta)eV(\zeta)] = N_1N_2(8S_{\eta\zeta}^{1,2}+4S_{\eta\zeta}^{1,4})$
σ, π, δ	$S[t_{2\zeta}(\theta)t_{2\zeta}(\xi)] = N_1N_2(8S_{\theta\xi}^{1,2}-4S_{\theta\xi}^{1,4})$
	$S[t_{2\zeta}(\theta)t_{2\zeta}(\varepsilon)] = N_1N_2(8S_{\theta\varepsilon}^{1,2}-4S_{\theta\varepsilon}^{1,4})$
	$S[t_{2\zeta}(\xi)t_{2\zeta}(\varepsilon)] = N_1N_2(-8S_{\xi\varepsilon}^{1,2}+4S_{\xi\varepsilon}^{1,4})$

* N_1 and N_2 symbolically stand for the normalization constants of the two molecular orbitals for which the overlap is derived.

$t_{2g\eta} = N_{t2g}(\zeta_1-\zeta_3)$	$E(t_{2g}) = (\varepsilon-\beta^{1'3'}_{\zeta\zeta})/(1-S^{1'3'}_{\zeta\zeta})$
$t_{2g\zeta} = N_{t2g}(\zeta_5-\zeta_6)$	

* Qualitative symmetry orbitals for $M_6(O_h)$ have been given in Appendix to Chap. 18 of Purcell and Kotz.[15] Their results did not include normalization constants, energy expression, orthogonalization of one $e_g(\sigma)$ component with A_{1g} nor consistent phases and transformation matrices for the degenerate components. All of these we have now included. We used the same coordinate system and atomic labelling as theirs but add a 'prime' to distinguish the atoms from the $M_8(O_h)$ set.

Table 11. Group d-orbital overlap* for mixing of $M_6(O_h)$ cluster MOs of the same irreducible representation

Mixing of	
σ, π	$S[t_{1ux}(\eta)t_{1ux}(\theta)] = N_1N_2 8S_{\eta\theta}^{1'2'} = -N_1N_2 8S_{\eta\theta}^{3'2'}$
σ, δ	$S[e_gU(\varepsilon)e_gU(\theta)] = N_1N_2 24S_{\varepsilon\theta}^{1'2'} = +N_1N_2 24S_{\varepsilon\theta}^{3'2'}$
π, δ	$S[t_{2g\xi}(\xi)t_{2g\xi}(\zeta)] = N_1N_2 8S_{\zeta\xi}^{2'1'} = -8N_1N_2S_{\zeta\xi}^{2'3'}$
π, δ	$S[t_{2u\eta}(\varepsilon)t_{2u\eta}(\xi)] = N_1N_2 8S_{\varepsilon\xi}^{1'2'} = -8N_1N_2S_{\varepsilon\xi}^{3'2'}$

* N_1 and N_2 symbolically stand for the normalization constants of the two molecular orbitals for which the overlap is derived.

are recorded in Tables 6, 9, 12 and 14 where the general projections due to orientation are shown. Energies are given in Tables 15 and 16. The energy of TiO_6 is given next to that of Sr_8, similarly AlO_6 next to La_8.

If the crystal were completely ionic, the $Sr_8^{+16}(5s)$ orbitals would be completely empty as would be the $La_8^{+24}(6s5d)$ orbitals. By contrast, all oxygens now have a charge of -2, each having six $2p$ electrons. The TiO_6^{-8}, AlO_6^{-9} orbitals will both be filled with 36 electrons or up to the slightly antibonding $t_{1g}\pi$ molecular orbital which is essentially the oxygen orbital. The covalent bonding of oxygen to Ti and to Al have been accounted for by the mixing of Ti/Al orbitals in the MO_6 cluster orbital. The orbital ordering is essentially the same in the AlO_6 and TiO_6 clusters. The difference lies in the Sr_8 *vs* La_8 cluster orbitals. For the oxygen cluster to give some electrons to Sr for covalent bonding, the lowest empty orbital must be the $A_{1g}Sr_8(5s)$ orbital [Fig. 4(a)], which features bonding along the edges and favors C_4 rotation of the O_6 octahedron towards the edge. For the oxygen cluster to give some electrons to La for covalent bonding, there is in addition to $A_{1g}La_8(6s)$, another closely lying $A_{1g}La_8(5d\sigma)$ bonding orbital which is now empty. This orbital features bonding through the center [Fig. 4(b)] and favors C_3 rotation bringing all 6 of the octahedral atoms (instead of the 4 atoms in C_4 rotation) inside the cube to seek out the empty $5d_{z^2}$ orbitals lobes [Fig. 4(c)]. This we feel is one reason for the cubic to rhombohedral transition in $LaAlO_3$. The above,

vastly simplified view, explains the experimental facts but suffers from some drawbacks. We do not know exactly how many electrons are transferred back to the M_8 cluster, hence while the LUMO we considered may play a part, higher empty orbitals of M_8 may also be involved. When excitation to higher orbitals is considered, it is tempting to consider the second-order Jahn–Teller effect[4] which was used by Pearson[43] to predict the molecular geometry. The vibration that determines the geometry will have

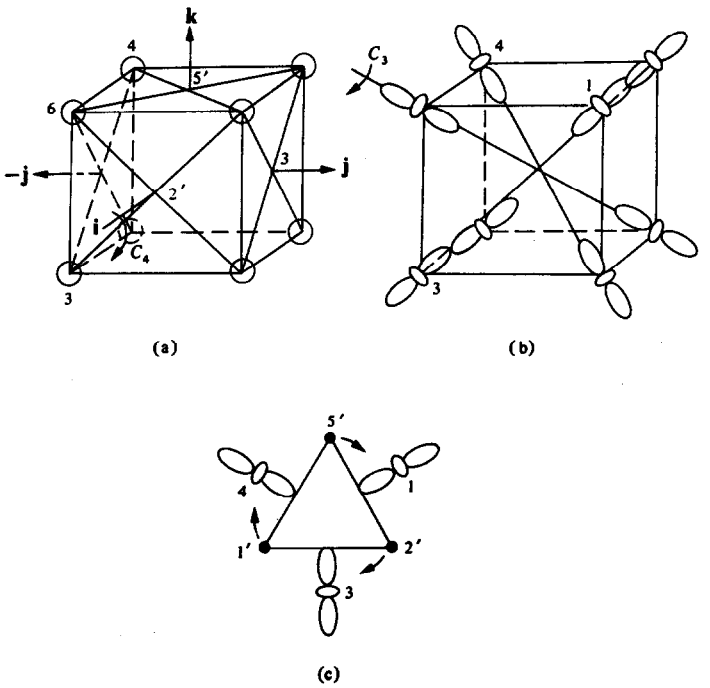

Fig. 4. The 'LUMO' $A_{1g}(6s)$ orbital of Sr_8^{+16} (a) and the 'LUMO' $A_{1g}(dz^2)$ orbital of La_8^{+24} (b). Three-fold rotation allows electrons in the occupied orbitals of the O_6 octahedron (1', 2', 3', 4', 5' and 6') to seek the empty and bonding orbital of La_8 (c).

the same symmetry as the transition density, and the effect will be inversely proportional to the energy separation between the ground and excited state. The normal vibrations of both the M_8 cube and the M_6 octahedron will have irreducible representations spanned by the $P_{\pi x}$, $P_{\pi y}$, P_z cluster orbitals given in Table 3. Among these, the e_g vibrations of O_h decomposes[56] to the $A_{1g}(+B_{1g})$ irreducible representation of D_{4h} and thus can cause cubic to tetragonal distortion (without determining which is

Table 16. Cluster MO energy levels of $SrTiO_6$ (eV)

the axis of rotation or which atom moves etc.). Similarly the T_{2g} vibration contains the $A_{1g}(+E_g)$ irreducible representation of D_{3d} and can cause cubic to rhombohedral distortion. The question is, then, will electronic factors in $SrTiO_3$ yield a transition density of e_g (distorts to tetragonal) symmetry, and in $LaAlO_3$ will they produce a transition density of T_{2g} (distorts to rhombohedral) symmetry? From Tables 15 and 16, it is seen that the energy levels of Sr_8 are higher than those of La_8; therefore, excitation is not favoured. If the charge on Sr is $+1.5$ Sr_8^{+12} has 4 electrons (8×0.5) transferred from TiO_6. The last two give a t_{1u} hole in Sr_8^{+12}. The remaining two electrons in TiO_6 give a t_{1g} hole, then,[5] $t_{1g} \times t_{1u} = A_{1u} + E_u + T_{1u} + T_{2u}$. Neither e_g nor T_{2g} occurs here and no information results. If the charge on La is 2.375, La_8^{+19} has 5 electrons (8×0.625) transferred from AlO_6, all coming from t_{1g}. The acceptor orbitals will become $(A_{1g}6S)^2$, $(A_{1g}3d)^2$, (e_g).[1] The 1 electron going to e_g will result in a transition density of $t_{1g} \times e_g = T_{1g} + T_{2g}$. A T_{2g} vibration is precisely what causes the cubic rhombohedral distortion in a second-order Jahn–Teller effect. The energetic factors are more favorable here, because e_g of La_8 is lower than all of the orbitals of Sr_8. Small variation of charges will not alter the qualitative result. To account for the variation, other charge-transfer states may be mixed in with various coefficients (Fig. 5). Lest we be carried too far by the apparent success of such qualitative arguments, we should add that there are still interesting systems that are not so obviously explained which will be the subject of our next investigation. For example, in the perovskite structure of $PbTiO_3$, the rotation is C_4, but in the perovskite structure $BiFeO_3$ (another trivalent ion, Bi) the rotation is C_3. Yet both Pb_8 and Bi_8 presumably have similar 6p-cluster orbitals. In the closely related perovskite $BaTiO_3$, the rotation is either C_3 or C_4. These will be challenging systems for the application of the cluster orbitals and symmetry views developed in this paper. The methods we used are admittedly crude and qualitative. We would like to mention that similar Mulliken–Wolfsberg–Helmholz MO approximation was also applied to the study[58,59] of superconductivity in A_3B alloys with multiply-bonded A-metal atom chains, and with reasonable success.

Strictly speaking, the second-order Jahn-Teller effect should be discussed in terms of the MOs of the whole cluster A_8MO_6. But note that the energies of the set of empty A_8 orbitals and those of the set of filled MO_6 orbitals are far apart—of the order of 8 eV

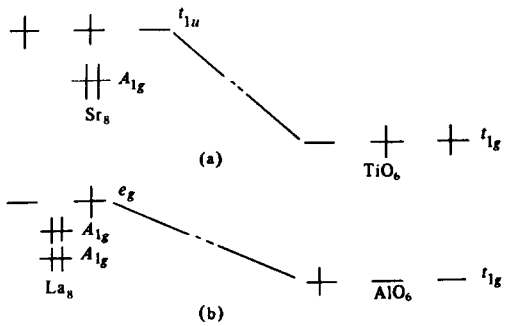

Fig. 5. Idealization of the charge transfer interaction between the donor (MO_6) and acceptor (A_8) clusters. (a) $TiO_6(t_{1g}^6) \rightarrow TiO_6(t_{1g}^2)Sr_8(A_{1g}^2 t_{1u}^2)$. The symmetry of the charge-transfer state and the transition charge density is t_{1g}(hole) $\otimes$ t_{1u}(hole). (b) $AlO_6(t_{1g}^6) \rightarrow AlO_6(t_{1g}^1)$ $La_8(A_{1g}^2 A_{1g}^2 e_g^1)$. The symmetry of the charge-transfer state is $t_{1g} \otimes e_g$. Only the optimum charge-transfer state is given that agrees with experimental observation. Actual transfer of charges may differ by small fractions—this difference can be accounted for by linear combination of other possible charge-transfer states with various coefficients. Note that although the empty states of TiO_6 are close to Sr_8, those states are essentially Ti atomic orbitals further away from Sr, shielded by O_6, and the closer ones don't have the right symmetry (t_{1u}). Same may be said of the AlO_6 and La_8 situation.

and the mixing between them is expected to be small. We have purposely omitted the mixing to see how expedient a qualitative model can be. Instead of mixing, we use the charge-transfer model between the filled HOMO (highest occupied MO) and the empty LUMO (lowest unoccupied MO) to account for deviation from ionicity and to discuss the relative motion between A_8 and MO_6. This is in the spirit of interaction between HOMO and LUMO of the *two reactants* commonly used in the study of inorganic reactions[60] (we have, in parallel, the 'reaction' of *two clusters*). It is also in the spirit of Woodward and Hoffmann's approach based on orbital symmetry.[42] The main purpose of the work is to give analytical expressions of the MOs and the overlaps of M_4, M_6 and M_8 clusters. The qualitative model for phase transition is exploratory. The results of this exploration will serve as encouragment and a guide to future endeavors.

Acknowledgements—Thanks are due Ms. Debora Anderson for her expert and patient typing. The assistance of Kong-seh Chiu with calculations on an IBM home computer is greatly appreciated. YNC wishes to thank the staff, especially Mr. Juan Gallegos, of the Computer Center of the Catholic University of America, for the advice on FORTRAN programming. Also, a word of thanks to Mrs. Vicky Himes of the National Bureau of Standards who very kindly helped with a literature search for crystallographic data.

(*Received* 14 *June* 1984; *accepted* 10 *October* 1984)

Abstract—XP spectra of seven five-coordinated Pt(II) complexes of general formula [Pt(olefin)(N–N)Cl_2] reveal significant differences from analogous four-coordinated Pt(II) complexes. Pt4*f* and N1*s* signals give evidence for π-back-donation from Pt onto both the olefin and the nitrogen chelating ligands, provided the latter belong to conjugated moieties. As a result, π-back-donation is more intense and Pt atoms more positive in 5- than in 4-coordinated complexes with similar ligands; this is in keeping with the previously reported decrease of nucleophilic reactivity of coordinated olefins in 5-coordinated Pt(II) complexes. The above electronic shifts are strongly reinforced by conjugation within the coordinated olefin such as with 2-butenedinitrile.

The chemistry of platinum(II)–olefin complexes is well understood in its usual square-planar coordination. However, in recent years several new olefin complexes have been isolated[1,2] with the general formula [$PtXL_3$(olefin)] and [PtX_2L_2(olefin)] (X = halide or methyl, L_3 = tridentate anionic ligand, L_2 = neutral chelating ligand) where platinum is five-coordinated, and despite the relatively low number of observations on five-coordinated complexes, some significant differences in chemical behaviour between four and five-coordinated Pt(II)–olefin complexes have been pointed out. Coordinated olefins undergo easily nucleophilic addition in square-planar Pt(II) complexes,[3] whereas no such reactivity has been found for trigonal bipyramidal Pt(II)–olefin compounds.[4] Theoretical calculations concerning the reactivity of coordinated olefins toward nucleophiles[5] suggest that olefins are considerably deactivated with regard to a nucleophilic attack on going from a square-planar to a trigonal–bipyramidal coordination in d^8 complexes, and that the unsaturated ligand is not effectively re-activated by the slipping from the η^2 to η^1 coordination mode in the transition state. Such behaviour appears to be strictly connected, on the one hand with coordination geometry, and on the other with electron density on the olefin: theoretical calculations[5] predict a strong increase of the latter quantity owing to back-donation. We undertook the present work with aim at a possible experimental confirmation of such an effect, and to that purpose we resorted to the technique of X-ray photoelectron spectroscopy (XPS or ESCA), which has already proved capable of supplying direct information on charge density shifts in coordination compounds.[6,7] Thus, XPS has been used previously to characterize the oxidation state and charge density in platinum complexes;[8,9] it gives good evidence for π-acceptor properties of olefin ligands,[10,11] (the additive value + 1.0 eV assigned to η^2-olefins in metal complexes by Feltham and Brant[12] points to a highly pronounced characterization of π-back-donation), and has not yet been applied systematically to the study of coordination geometry in metal–olefin complexes. The present

* Author to whom correspondence should be addressed.

work deals with XPS characterization and the corresponding structural implications of a series of five-coordinated Pt(II)–olefin complexes of general formula $[PtCl_2(\eta^2\text{-olefin})(N\text{–}N)]$, where (N–N) is a bidentate nitrogen donor ligand, together with a parallel study, for comparison purposes, of some related four-coordinated Pt(II)–olefin species.

EXPERIMENTAL

Synthesis. The investigated complexes are listed in Table 1, and were prepared by known literature methods;[13–18] further details will appear in a forthcoming paper by Albano *et al.*,[2(c)] and their purity checked by physical constants. Of the three compounds in Table 1 not previously mentioned in the literature, [ethylene)$PtCl_2$(ACIM)] was prepared by addition of the ligand to an acetone solution of $[PtCl_2(C_2H_4)]_2$ in equimolar ratio, and subsequent crystallization from acetone–petrol ether; ^{1}H NMR ($CDCl_3$): $C(CH_3)_3$ 1.80*s*, $=CHCH_3$ 2.94*d*, $=CHCH_3$ 8.2*q*, $CH_2=CH_2$ 4.95*s* (J_{Pt-H} = 60 Hz). $PtCl_2$(DHB) and $PtCl_2$(teten) were obtained from the corresponding five-coordinated olefins complexes by loss of ethylene in benzene solution (for ligand abbreviations, see Table 1).

Spectra measurements. XP spectra were taken on a VG-ESCA 3 spectrometer using the Al-K_α (1486.6 eV) source. No radiation damage was observed even after long irradiation times, so cooling of the samples was not found necessary, and all spectra were run at ambient temperature. The X-ray power level for all present experiments was 120 W (12 kV at 10 mA). Typical ultimate vacuum in the spectrometer chamber, during measurements, was $1\text{–}2 \times 10^{-9}$ torr. Sample charging and spectral calibration were achieved by referring to the C1*s* contamination signal taken as 285.0 eV. The average value of C1*s* contamination level was around 20% in apparent number of atoms, in the upper sampling layer, with respect to the sample. No attempts were made to clean the sample, by ion bombardment, in order to avoid decomposition. The calibration procedure was not straightforward owing to presence of several kinds of C atoms in the ligand moieties; a first rough alignment of the spectra was achieved by assuming either constant Cl2*p* b.e. (which however to a more accurate evaluation turns to vary slightly across the investigated series; see below), or constant C1*s* maximum b.e. of the composite band; in both cases, deviation turned to be quite small (it has to be recalled that overall FWHM of C1*s* is around 2.6–2.7 eV, indicating that individual b.e. differences between various kinds of C atoms are rather small). Subsequently a refinement through gaussian analysis of the C1*s* bands was attempted, aided by quantitative evaluation of atomic ratios from XPS band intensities by means of Scofield's σ values,[19] which allowed more precise identification of the contamination C1*s* signal, never differing however by more than 0.2 eV from the composite band maximum. Reproducibility was good, the standard deviation on aligned spectra not exceeding 0.1 eV for measurements repeated at least six times; however,

Table 1.[a]

Compound[b]	Formula	b.e. Pt4$f_{7/2,5/2}$	b.e. Cl2*p*	b.e. N1*s*
1	DHB	—	—	399.4
2	$PtCl_2$(DHB)	72.5–75.9	198.2	400.1
3	(ethylene)$PtCl_2$(ACIM)	72.8–76.1	198.9	400.3
4	$PtCl_2$(teten)	72.2–75.6	198.3	400.3
5	(ethylene)$PtCl_2$(DEA)	72.4–75.6	198.0	400.3
6	(ethylene)$PtCl_2$(py)	73.5–76.9	198.8	399.2
7	(ethylene)$PtCl_2$(DHBIE)	73.0–76.3	198.6	399.9 broad
8	(ethylene)$PtCl_2$(DHB)	72.9–76.2	198.4	339.9
9	(E-2-butene)$PtCl_2$(DHB)	73.0–76.3	198.6	400.0
10	(E-2-butenedinitrile) $PtCl_2$(DHB)	73.7–76.9	198.5	399.3 {398.8, 399.8}
11	(ethylene)$PtCl_2$(BIE)	73.3–76.6	198.7	399.6
12	(ethylene)$PtCl_2$(BIP)	73.3–76.7	198.7	399.4 {399.2, 399.6}
13	(ethylene)$PtCl_2$(teten)	72.4–75.7	198.4	400.3

[a] Binding energy in eV.
[b] Formulas are given in Fig. 1.

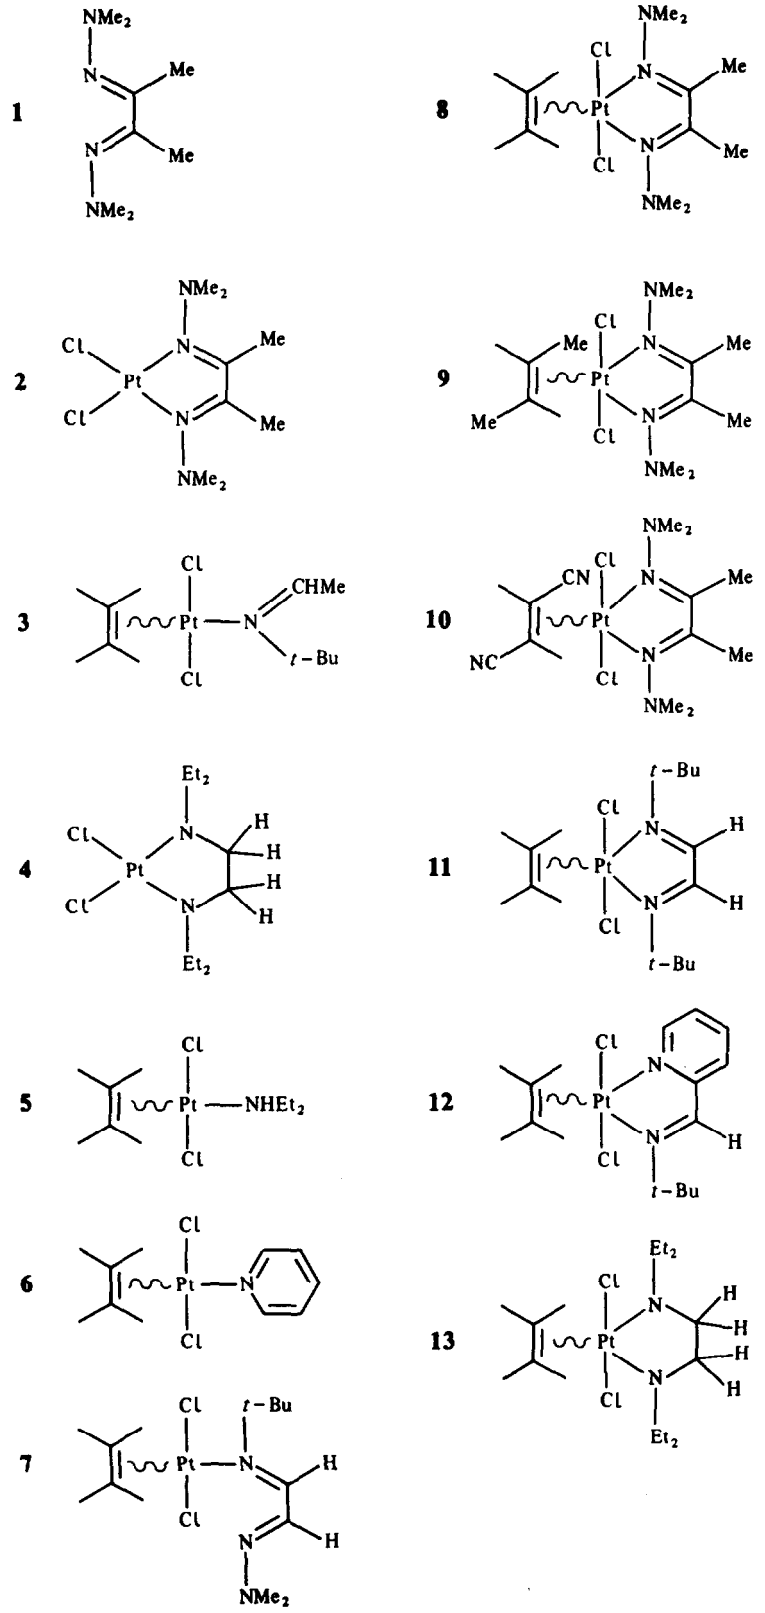

Fig. 1. Formulas (see Table 1).

owing to the composite nature of the C1*s* band and the indirect calibration procedure, the final accuracy of the b.e. values quoted in Table 1 is to be estimated roughly as 0.2 eV.

RESULTS

The relevant XPS data are listed in Table 1 for a series of seven five-coordinated [$PtCl_2$(olefin)(N–N)] complexes where the nature of the olefin ligand is varied (olefin=ethylene, E-2-butene, E-2-butenedinitrile) for (N–N)=glyoxal-bis-dimethylhydrazone (DHB), and the (N–N) ligand is varied at fixed choice of the olefin ligand (C_2H_4) from the wholly saturated teten (=N,N,N′,N′-tetraethylethylenediamine) to conjugated ligands derived from substituted imines (or hydrazones) of diacetyl or glyoxal, and in one case from pyridine-2-aldehyde. For the sake of comparision, the free ligand DHB and five square-planar Pt(II) complexes of related composition were also measured and included in Table 1.

For the five-coordinated complexes we assumed, in agreement with previous X-ray[20–22] and other structural determinations,[15,21,23] a trigonal bipyramidal geometry with both Cl atoms in axial position, the η^2 olefin and both donor atoms of the (N–N) ligand in the equatorial plane. The four-coordinated counterparts belong obviously to the *cis*-[$PtCl_2$(N–N)], respectively to the *trans*-[$PtCl_2N(\eta^2$-olefin)] chromophore type.

The most evident feature emerging from a survey of the XPS data in Table 1 is a trend to higher Pt4*f* b.e. values in the 5- than in the 4-coordinated complexes. This effect is not large, but well defined both from statistical average, and from direct comparisons (such as in the complexes

[$PtCl_2$(DHB)]/[(ethylene)$PtCl_2$(DHB)],

and

[(ethylene)$PtCl_2$(ACIM)]/[(ethylene)$PtCl_2$(BIE)]);

in other cases, such as the couples

[$PtCl_2$(teten)]/[(ethylene)$PtCl_2$(teten)]

and

[(ethylene)$PtCl_2$(DEA)]/[(ethylene)$PtCl_2$(teten)],

the effect is smaller or vanishing. We conclude that Pt(II) is more positive or less electron rich in 5- than in 4-coordinated complexes; in other words, the dominant electronic effect accompanying c.n. expansion from 4 to 5 is enhanced π-back-donation rather than increased σ-donation by the fifth ligand; this conclusion is to be compared with similar theoretical predictions,[5] and with experimental findings on the reduced nucleophilic reactivity of 5-coordinated Pt(II) species.[4]

The acceptors of the increased π-back-donation are both the olefin ligands (e.g. the couples [$PtCl_2$(DHB)]/[(ethylene)$PtCl_2$(DHB)] and [$PtCl_2$(teten)]/[(ethylene)$PtCl_2$(teten)], and the conjugated nitrogen ligands. The latter effect is indeed absent from complexes with saturated nitrogen ligands in [$PtCl_2$(teten)], [(ethylene)$PtCl_2$(DEA)] and [(ethylene)$PtCl_2$(teten)], platinum is more negative with b.e. *ca.* 72.3 eV, and nitrogen more positive with N1*s* b.e. as high as 400.3 eV, but is larger in complexes with imines, hydrazones or pyridine ligands (Pt4*f* b.e. in the 73 eV range; N1*s* around 399 eV), and it is more pronounced with increasing conjugation within the organic ligand: in fact, π-back-donation appears to be larger in [(ethylene)$PtCl_2$(BIE)] than in [(ethylene)$PtCl_2$(ACIM)], and to tend to a limit in the highly conjugated systems [(ethylene)$PtCl_2$(py)] and [(ethylene)$PtCl_2$(BIP)].

It can be debated whether the Pt → olefin or the Pt → N back-donation is larger: the comparison between

[$PtCl_2$(DHB)] and [(ethylene)$PtCl_2$(ACIM)],

and between

[($PtCl_2$(DHB)] and [(ethylene)$PtCl_2$(DHBIE)]

(and indirectly between

[(ethylene)$PtCl_2$)(ACIM)]

and

[(ethylene)$PtCl_2$(DMB)])

suggest the former, although

[$PtCl_2$(teten)]/[(ethylene)$PtCl_2$(DEA)]

indicates that the effect is anyway not large. Probably the π-acceptor effects due to olefins and to $\leftarrow N\!\!\diagup\!\!=$ ligands are of comparable magnitude, the latter varying strongly according to the nature of the conjugated system comprising the nitrogen ligands (e.g. N1*s* varies from 399.2 eV in [(ethylene)$PtCl_2$(py)] to 400.3 eV in [$PtCl_2$(DHB)]). The electronic effect of substituents in the ligated olefin appears to be small between [(ethylene)$PtCl_2$(DHB)] and [(E-2-butene)$PtCl_2$(DHB)], and larger in [(E-2-butenedinitrile)$PtCl_2$(DHB)], where the high Pt4*f* b.e. (73.7 eV) and the low N1*s* b.e. (399.3 eV average, which points to *ca.* 398.8 for —C≡N) are consistent with a push–pull reinforcement of charge shift from Pt until the conjugated nitrogen atoms of the nitrile groups.

As for the electronic structure of nitrogen, XP

spectral data suggest that it is determined almost exclusively by its first neighbours (mainly Pt), and not by remote substituents or by minor variations in the electronics structure of the first neighbours. The donor effect on metal complexation is evident from the N1*s* b.e. shift from 399.4 eV in the free ligand DHB, to 399.8–400.1 eV in [$PtCl_2$(DHB)] and in the three [(olefin)$PtCl_2$(DHB)] complexes in Table 1. Actually, the N1*s* signal in [(ethylene)$PtCl_2$(DHB)] is composite, even if not resolved, owing to presence of two kinds of nitrogen atoms in ratio 1:1; assuming that the signal from $-NR_2$ is not significantly changed, and that the chemical shift on complexation affects only the $\leftarrow N\!\!=$ signals, a possible reconstruction of the N1*s* band components consistent with the experimental data would place $N\text{–}\underline{N}R_2$ at 399.7 eV, free $\underline{N}\text{–}NR_2$ at *ca* 399.2 eV, and complexed $\underline{N}\text{–}NR_2$ at 400.2 eV; replacing $-NR_2$ by a large alkyl groups as in [(ethylene)$PtCl_2$(BIP)] lowers only slightly the b.e. of N1*s* in coordinated $\leftarrow N\!\!=$ (399.6–399.9 eV). Coordinated nitrogen in aliphatic amines as in

[$PtCl_2$(teten)], [(ethylene)$PtCl_2$(teten)]

and

[(ethylene)$PtCl_2$(DEA)]

has relatively high N1*s* b.e. (around 400.3 eV), as noted before, because of lack of Pt → N back-donation effects, as confirmed by the relatively low 4*f* b.e. of platinum in the same complexes. Further N1*s* b.e. regions for nitrogen functions include coordinated pyridine ring nitrogen around 399.2 eV, and nitrile (in coordinated butenedinitrile) at 398.8 eV.

Less evident and less significant structural implications are contained in the Cl2*p* signals, whose b.e. spread is small (between 198.2 and 198.9 eV, with one exception); there seems to be a trend to lower b.e. with increasing proximity of negative ligands, mainly the second coordinated chloride: so the highest b.e.s (198.8–198.9 eV) occur with the quadratic *trans*-dichlorocomplexes

[(ethylene)$PtCl_2$(py)]

and

[(ethylene)$PtCl_2$(ACIM)],

and the lowest ones (198.2–198.3 eV) with the square-planar *cis*-species [$PtCl_2$(DHB)] and [$PtCl_2$(teten)], the 5-coordinated species falling in the intermediate range (*ca* 198.3–198.7 eV) in accordance with the *trans*-position of the two axial Cl ligands, slightly more labilized by the negative charge of three equatorial ligands. [(ethylene)$PtCl_2$(DEA)] has a lower Cl2*p* b.e. value (198.0 eV), which does not fit in the above scheme; we may perhaps suspect hydrogen bond interactions in this case, since [(ethylene)$PtCl_2$(DEA)] is the only complex in the investigated series containing a secondary instead of a tertiary nitrogen ligand.

Institute of Chemistry, University of Gdańsk, ul. Sobieskiego 18, 80-952 Gdańsk, Poland

and

ANNA JANKOWSKA
Institute of Physics, University of Gdańsk, ul. Sobieskiego 18, 80-952 Gdańsk, Poland

(*Received* 13 *August* 1984; *accepted* 9 *November* 1984)

Abstract—A new pentadentate Schiff base 2,6,10-triaza-1,11-bis(2′-aminophenyl)-undeca-1,10-diene, *abaDPT*, and its complexes of general formula M(*abaDPT*)X_2 where M = Cu(II), Ni(II), X = Cl, Br, I, NO_3, and ClO_4, have been prepared. The complexes have been characterized by electronic and IR spectra, EPR, magnetic moments, molar conductances, and elemental analysis. IR data show an interaction between halide anion of the outer coordination sphere and the complexed amino group. EPR and spectrophotometric data of most of the copper compounds are consistent with a distorted square pyramidal geometry. Single crystal EPR studies of Cu(*abaDPT*)$(NO_3)_2$ and Cu(*abaDPT*)Br_2 revealed that copper atoms in the former compound occupy two magnetically inequivalent places in the lattice while copper atoms in the latter compound take identical sites. Principal g tensor axes of the two compounds have been determined.

Transition metal complexes of Schiff base ligands are of interest since they exhibit a tendency to form various structural types and display a wide variety of magnetic properties. Although numerous linear pentadentate Schiff bases were prepared and investigated in recent years, only a limited number contained a set of five identical donor atoms. Prince and Stotter,[1] Coleman and Taylor,[2] and Simmons *et al.*[3] prepared linear Schiff bases with solely nitrogen donors derived from 2-formylpyridine and polyamines. Copper complexes of some of them functionally resemble hemocyanin in its capacity of reversible binding of oxygen.

Interesting properties of the aforementioned compounds prompted us to study metal complexes with other linear Schiff bases comprising identical sets of donor atoms. Preparative studies in our laboratory have shown that 2-aminobenzaldehyde condenses with bis(3-aminopropyl)amine to give 2,6,10 - triaza - 1,11 - bis(2′ - aminophenyl) - undeca - 1,10-diene, *abaDPT*, a doubly condensed Schiff base with potentially five donor nitrogen atoms. This paper reports the synthesis and properties of *abaDPT* and its complexes with copper(II) and nickel(II).

EXPERIMENTAL

Bis(3-aminopropyl)amine and 2-nitrobenzaldehyde were obtained from Fluka and were used without further purification. All chemicals and solvents were of reagent grade or equivalent. 2-Aminobenzaldehyde was prepared from 2-nitrobenzaldehyde by the literature method.[4]

2,6,10 - *Triaza* - 1,11 - *bis*(2′ - *aminophenyl*) - *undeca* - 1,10 - *diene*, abaDPT

A solution of freshly prepared 2-aminobenzaldehyde (0.05 mol) and bis(3-aminopropyl)amine (0.025 mol) in benzene (1.5 dm^3) was heated in a flask equipped with a Dean–Stark trap and a reflux condenser. After the stoichiometric quantity of water forming in the reaction was collected in trap, the mixture was concentrated under reduced pressure and the oily residue was extracted several times with hot *n*-hexane. Collected extracts deposited upon cooling the Schiff base which was recrystallized from

* Author to whom correspondence should be addressed.

n-hexane to give a white powder of *abaDPT* (30–40% yield).

General preparation of Cu(abaDPT)X_2 (X = Cl, Br, NO_3, ClO_4) *and* Ni(abaDPT)X_2 (X = Cl, Br, I, NO_3, ClO_4) *complexes*

To a hot solution of 5 mmol of the appropriate metal salt in 20 cm^3 of the methanol–water 1:1 mixture (in the case of $CuCl_2$ 10 cm^3 of pure methanol was used) a solution of 5 mmol of *abaDPT* in 20 cm^3 of methanol was added slowly. After 30 min of stirring in room temperature the precipitated complex was filtered off, washed with cold methanol and recrystallized twice from a methanol–water mixture. Crystals of copper complexes were olive-green and those of nickel complexes ranged in colour from green to grey–brown.

Preparation of Cu(abaDPT)I_2

Hot solutions of copper(II) sulphate (0.01 mol in 30 cm^3 of the methanol–water 1:1 mixture) and *abaDPT* (0.01 mol in 20 cm^3 of methanol) were mixed together. To the resulting mixture a solution of barium iodide (0.01 mol in 100 cm^3 of water) was added. After cooling the precipitate was filtered off, washed with cold methanol and extracted with a hot methanol-water mixture. Collected extracts deposited Cu(*abaDPT*)I_2 which was recrystallized twice from methanol–water mixture to give dark-green crystals.

Physical measurements

IR spectra in the 400–4000 cm^{-1} region were obtained using a Perkin–Elmer Model 621 spectrometer. Spectra of solid samples were recorded as Nujol or hexachlorobutadiene mulls. UV visible, and near IR spectra were obtained with a Beckman DK2 spectrometer using 1 cm stoppered silica cells. EPR spectra were recorded on an X-band spectrometer produced by Polish Academy of Science at room temperature; magnetic field was calibrated with DPPH. PMR spectra were obtained using a Tesla BS 487 80 MHz spectrometer in $CDCl_3$ solution with HMDS as internal reference. Electron impact mass spectra were recorded on a Varian MAT 711 spectrometer at 70 eV.

The magnetic measurements were performed by the Gouy method; Diamagnetic corrections were made employing Pascal's constants.[5] Potentiometric titrations were performed using a Radelkis Model OP-205 precision pH-meter. Conductance measurements were made with a K-58 conducting bridge constructed in the Technical University of Warsaw.

RESULTS AND DISCUSSION

Synthesis of the pentadentate ligand *abaDPT* involves refluxing of 1 equivalent of bis(3-aminopropyl)amine with 2 equivalents of 2-aminobenzaldehyde in benzene solution. The results of elemental analysis (Table 1), PMR spectrum, and

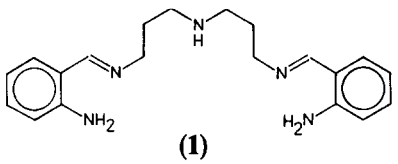

Table 1. Analytical results[a] and molar conductances

[c] Molar conductances of 10^{-3} M aqueous solutions at 298 K.

(1)

mass spectrum are consistent with formula (1). A sharp singlet at 8.15 ppm and a broad one at 6.21 ppm in the PMR spectrum are assigned to the azomethine and the NH_2 protons respectively. The bridging methylene protons give rise to three multiplets with baricentres at 3.43, 2.55, and 1.77 ppm respectively. Multiplets of aromatic protons appear in the region of 6.4–7.1 ppm. In the mass spectrum of *abaDPT* a prominent molecular peak is observed at 337 *m/e*, the most abundant fragmentation ions arise from the fissions of C–C bonds within the polyamine chain.

Complexes of empirical formula

$$M(abaDPT)X_2$$

where M = Cu(II), Ni(II), X = Cl, Br, I, NO_3, and ClO_4 are formed when the ligand dissolved in methanol reacts with metal salts MX_2 dissolved in methanol–water mixture. Elemental analysis (Table 1) and conductance measurements (all complexes are electrolytes in water with molar conductances above 200 Ω^{-1} cm^2 mol^{-1} at concentration of 10^{-3} M, Table 1) suggest that the pentadentate Schiff base coordinates copper and nickel ions as a neutral molecule. All the complexes have reasonably good solubility in water, formamide, and N,N-dimethylformamide, but are insoluble in non-coordinating organic solvents. The solubility characteristics are also consistent with salt formulation.

Infrared spectra have been obtained for ligand and complexes (Table 2). Bands in the 3100–3500 cm^{-1} region, which may be assigned to N–H stretching vibrations of both NH_2 and NH groups, are presented in Fig. 1. It is evident from Fig. 1 and Table

2 data that vibrations of the complexed amino group are influenced by the anions of the outer coordination sphere. A lower frequency of the N–H stretching vibrations in metal halide complexes as compared to metal perchlorate complexes may be due to intramolecular hydrogen bonding between the halide and the NH_2 group, a feature not present in the latter complexes. A similar interaction between the halide and the complexed NH_3 ligand was reported for hexaaminecobalt(III) halides.[6] IR spectra of both copper and nickel perchlorate complexes show a strong band around 1100 cm^{-1} and a medium one at 615 cm^{-1} which indicate a T_d symmetry of ClO_4 and an ionic nature of the complexed metal–ClO_4 bond.[7] Reliable conclusions concerning the bonding of the anion in metal nitrate complexes could not be made from their IR spectra as the main nitrate bands were hidden by the organic ligand bands. However the copper nitrate complex shows a single $\nu_1+\nu_4$ combination band at 1742 cm^{-1} consistent[8] with ionic nitrate group. The spectrum of the nickel nitrate complex exhibits however two weak bands in the 1750 cm^{-1} region separated by 14 cm^{-1}. These bands may accrue from the splitting of $\nu_1+\nu_4$ band, thus indicating the interaction existing between the nitrate and nickel ions[8] in the solid state.

Magnetic moments of solid complexes range from 1.79 to 1.81 B.M. for Cu(*abaDPT*)X_2 and from 2.96 to 2.98 B.M. for Ni(*abaDPT*)X_2 complexes, and show no change with temperature in the 77–298 K range. Magnetic moment data reveal only a small orbital contribution to the predicted spin only value. The evident lack of anomalous moments suggests the absence of appreciable metal–metal interaction in the solid phase.

EPR data of finely powdered Cu(*abaDPT*)X_2 samples are given in Table 3. All the copper complexes show good resolved three g-value spectra (Fig. 2) except of Cu(*abaDPT*)I_2. It had been pointed

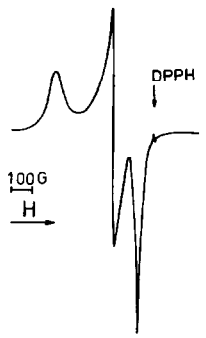

Fig. 2. EPR spectrum of powdered Cu(*abaDPT*)$(ClO_4)_2$.

out earlier[9] that in a three value spectrum with $g_1 < g_2 < g_3$ the value of $R = (g_2-g_1)/(g_3-g_2)$ may indicate the predominant ground state of a mononuclear copper complex containing co-ordinated nitrogen atoms. Calculated R values (see Table 3) suggest that in Cu(*abaDPT*)Cl_2, Cu(*abaDPT*)$(NO_3)_2$, and Cu(*abaDPT*)$(ClO_4)_2$ a predominant $d_{x^2-y^2}$ ground state is present which may be associated with a structure approximate to square pyramidal geometry. A relatively large value of R for Cu(*abaDPT*)Br_2, much exceeding 1, suggests a predominant d_{z^2} ground state and a structure approximate to trigonal bipyramidal.

In order to verify the reliability of the powder g and R values we studied additionally EPR spectra of single crystals of both Cu(*abaDPT*)$(NO_3)_2$ and Cu(*abaDPT*)Br_2.

The former compound crystallizes in the form of rhombic plates while the latter forms small needles. Observation in a polarisation microscope shows that they are not twinned crystals. The angular dependence of the electron spin resonance of Cu(II) measured in single crystal of Cu(*abaDPT*)$(NO_3)_2$ is shown in Fig. 3. It is evident from Fig. 3(b) that the EPR spectrum of a single crystal in a magnetic field oriented perpendicularly to the Z axis [see Fig. 3(a)] consists of two lines which change their separation

Table 3. g-Values for copper complexes[a]

Compound	g_1	g_2	g_3	R[b]	[c]
Cu(*abaDPT*)Cl_2	2.031	2.074	2.202	0.34	$d_{x^2-y^2}$

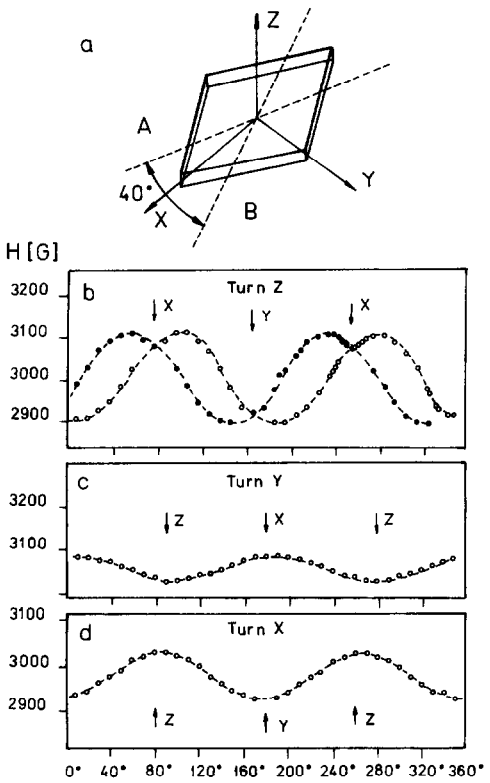

Fig. 3. Angular variation of the EPR of Cu(II) in single crystal of Cu(*abaDPT*)$(NO_3)_2$ on rotation around (b) *Z*, (c) *Y*, (d) *X* axis. (a) Schematic representation of the crystal, *X*, *Y*, *Z*: rotation axes, *A*, *B*: principal *g* tensor axes. The magnetic field was always perpendicular to the axis of rotation. Arrows indicate angles at which one of the axes (*X*, *Y*, or *Z*) is parallel to the magnetic field.

during rotation around the *Z* axis. The two lines of equal intensity indicate that copper atoms in crystalline Cu(*abaDPT*)$(NO_3)_2$ are incorporated in two magnetically inequivalent places. Based on the described earlier method [10] we constructed the $\langle g^2 \rangle$ matrix from the experimental data, which after diagonalization allowed us to calculate the principal *g* tensor values. They are: $g_{11} = 2.037$, $g_{22} = 2.097$, and $g_{33} = 2.188$. It is interesting to note that the principal *g* tensor axes do not coincide with the *X*, *Y*, and *Z* axes [see Fig. 3(a)]. Two of the principal *g* tensor axes of magnetically inequivalent copper atoms in single crystal of Cu(*abaDPT*)$(NO_3)_2$ lie in the *XY* plane [lines *A* and *B* in Fig. 3(a)] forming an angle of approximately 40°. An angular variation study of Cu(*abaDPT*)Br_2 reveals the presence of only one copper centre indicating that Cu(II) occupies identical sites in the lattice. Using the aforementioned method we obtained after processing of the data the following principal *g* tensor values for Cu(*abaDPT*)Br_2: $g_{11} = 2.032$, $g_{22} = 2.121$, and $g_{33} = 2.168$. Comparing EPR spectra of copper complexes with various Schiff bases comprising a set of five nitrogen donors we see that complexes obtained in this work are of much lower symmetry than those reported by Simmons *et al.*[3] for which axial EPR spectra were observed.

Copper complexes dissolved in water display a broad absorption at 16,130 cm^{-1} ($\varepsilon = 220$) with less defined band around 12,120 cm^{-1}. Hathaway[9] summarized the energy ranges covered by the *d–d* transitions of CuN_{4-6} chromophores of different stereochemistry. The *d–d* bands of Cu(*abaDPT*)X_2 complexes fit in well with the range reported for structure of approximate square pyramidal geometry.

Electronic spectra of nickel complexes dissolved in water give bands at 10,530 and 18,350 cm^{-1} which may be interpreted as the spin-allowed transitions $^3T_2 - ^3A_2$ and $^3T_1(F) - ^3A_2$ respectively in approximately octahedral environment. The weak band which appears as a shoulder at *ca* 12,200 cm^{-1} may result from the distortion of octahedral geometry. We consider the octahedral stereochemistry to arise from the coordination of water molecules to give [Ni(*abaDPT*)H_2O]X_2 rather than from the coordination of a counter ion leading to [Ni(*abaDPT*)X]X. This observation is in perfect agreement with the results of our electrochemical studies: molar conductances indicate on 2:1 electrolytes and curves obtained as a result of potentiometric titration of nickel halide complexes with silver nitrate were symmetrical with one inflection point at molar ratio of the complex to Ag(I) as 1:2.

Both copper and nickel complexes are very sensitive towards acids. Solutions of Cu(*abaDPT*)X_2 even slightly acidified by diluted strong acids change the green colour into a yellow which transforms immediately into a very faint blue. The absorption spectrum of the resultant solution shows a weak *d–d* band at 12,600 cm^{-1} ($\varepsilon = 11$) with a shoulder at 9400 cm^{-1} and resembles closely the spectrum of a hydrated copper(II) ion.[11] In the case of Cu(*abaDPT*)I_2 acidification results in the formation of free I_2 and CuI. Absorption spectra of nickel complexes in acidic aqueous solution are very similar to the spectrum of the hydrated nickel(II) ion comprising bands at 15,150 ($\varepsilon = 2$), 13,900 ($\varepsilon = 2$), and 8400 cm^{-1} ($\varepsilon = 3$).[12]

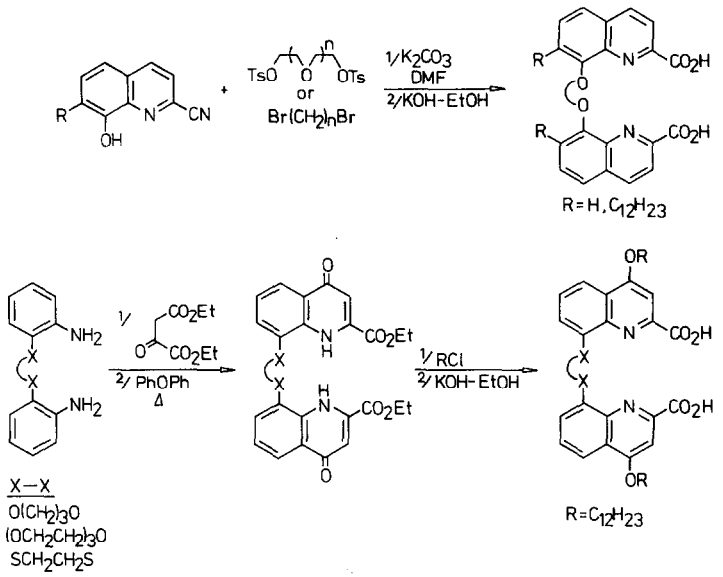
(*Received* 10 *September* 1984; *accepted* 9 *November* 1984)

Abstract—Bis-quinoline-2-carboxylic acids in which the quinoline rings were joined *via* ether linkages to the 8-position have been synthesized and tested for metal extraction. The reagents extracted Cu^{2+} and Zn^{2+} selectively in the presence of Fe^{2+} and Fe^{3+} from aqueous sulphate solution.

We have previously reported the syntheses and metal extractant properties of substituted quinoline-2-carboxylic acids.[1] This paper presents a study of bis-quinoline-2-carboxylic acids (bis-quinaldic acids) as metal extractants. These tetradentate reagents were prepared with the aim of improved metal ion selectivity and enhanced extractant ability compared with the known bidentate analogues.[1–3]

RESULTS

The bis-quinoline-2-carboxylic acids **1–8** were prepared from 8-hydroxyquinoline-2-carbonitrile by alkylation with ditosylates or dibromoalkanes (Scheme 1, Table 1). The reagents **1–6** were found to be sparingly soluble in chloroform. Hence the more lipophilic reagents **9–11** which possess a dodecenyloxy substituent in the 4-position and the reagents **12** and **13** which have a C_{12}-alkyl group in the 7-position were prepared, as was also the bis-quinaldic acid **7** which has a *n*-decyl group in the triethylene glycol chain.



The reagents were tested for the ability to extract Cu^{2+}, Zn^{2+}, Fe^{2+}, Fe^{3+}, Ni^{2+}, Co^{2+}, Cd^{2+} and K^+ from aqueous sulphate solutions at pH 2 or 4 into a chloroform phase. The metal concentrations in the aqueous phase were measured by atomic absorption spectrophotometry. During the extraction tests with reagents **1–4** and **6** a third phase was formed. These reagents formed stable Cu^{2+} and Zn^{2+} complexes but no complex formation with Fe^{2+} was observed at pH 2. The results from mixed metal extraction tests with the more soluble reagents are presented as $pH_{1/2}$ values in Table 2. The reagents **3**, **7**, and **9–11** extracted Cu^{2+} completely at pH 1.8–1.9 but only small amounts of Fe^{3+} were extracted: 11% using reagent **9** at pH 1.9 and less than 5% with the other reagents.

The ^1H NMR spectra of the zinc complexes of **6** and **10** showed significant differences compared to the corresponding spectra of the free ligands. The peaks due to the triethylene glycol part of **6** appeared as an AA'BB' system at 4.41 and 4.10 ppm and a broad singlet at 3.94 ppm from the central glycol unit (Fig. 1). In the Zn^{2+} complex of **6** the signals from the four OCH_2CH_2OAr protons were separated and the OCH_2CH_2O singlet was split into an apparent doublet (J = 10 Hz) at 2.79 and 3.19 ppm. The coupling constants and chemical shifts of the OCH_2CH_2OAr part are indicated in Fig. 2. The Zn^{2+} complex of the reagent **10**, the 4-alkoxy analogue of **6**, had a similar ^1H NMR spectrum in this region.

DISCUSSION

Open-chain oligoethylene glycol ether compounds with 8-quinolinyloxy end groups are known complexing agents for, e.g. alkali metal ions.[4,5] In these ligands the ether oxygen and the quinoline

* Author to whom correspondence should be addressed. Present address: Boliden Kemi AB, Box 902, S-251 09 Helsingborg, Sweden.

Scheme 1.

nitrogen atoms are the donor atoms. Bis-quinaldic acid derivatives have previously been described, but they were not used for metal extraction.[6] Bis-quinaldic acids may form 1 : 1 complexes with two-valent metal ions if the quinoline rings are joined by a chain that permits both carboxylate oxygens and quinoline nitrogen atoms to coordinate to the same metal ion (**A**). The ^{1}H NMR spectrum of the Zn^{2+} complex of **6** is in agreement with a tetrahedral coordination where the triethylene glycol chain is in a synclinal conformation. The bis-thio reagent **11** was found to form a stable Cd^{2+} complex. In this reagent the sulphur atoms may coordinate to the Cd^{2+} in an octahedral structure (**B**).

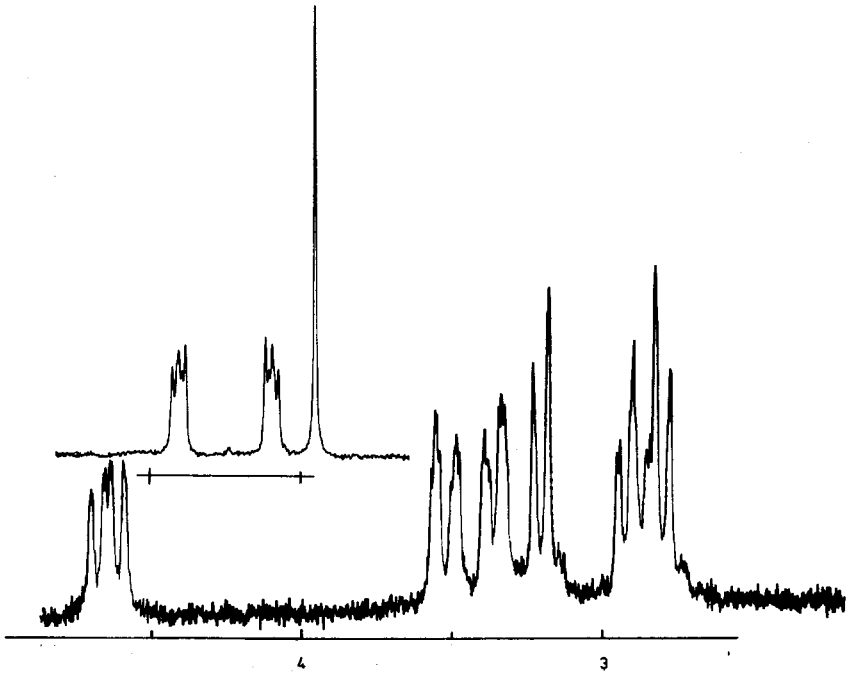

Fig. 1. ^{1}H NMR spectra of 1,8 - bis(2 - carboxy - 8 - quinolinyloxy) - 3,6 - dioxaoctane (**6**) (upper) and its zinc(II) complex (lower).

The metal ion extraction selectivity of the reagents was not greatly influenced by the length of the hydrocarbon chain joining the quinoline rings. The low efficiency of extraction of Fe^{2+} and Fe^{3+} compared with that of Cu^{2+} and Zn^{2+} is a common feature of the bis-quinaldic acid reagents. This selectivity was also observed for bidentate 8-alkoxyquinaldic acids.[1] The reagents **12** and **13** which have a branched C_{12}-alkyl group in the 7-position were poor extractants; this may be due to a steric interference of the 7- and 8-substituents in the complexes.

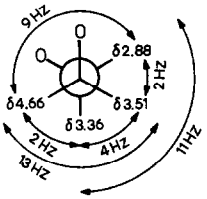

Fig. 2. Proton coupling constants of the $ArOCH_2CH_2O$ part of the zinc(II) complex with reagent **6**.

EXPERIMENTAL

The methods of testing metal extraction are described in an earlier paper.[1]

Preparation of bis-quinaldic acids **1–8**, **12** *and* **13**

8-Hydroxyquinoline-2-carbonitrile[7] (3.40 g, 20 mmol), K_2CO_3 (3.04 g, 22 mmol) and DMF (35 cm^3) were stirred and heated to 75°C. The appropriate

ditosylate (11 mmol) for the preparation of reagents **1** and **4–8** or dibromoalkane, for the preparation of reagents **2** and **3**, was then added over 25 min. The reaction mixture was then heated at 75°C for an additional 20 h, cooled and poured into ice-water (300 cm^3). The precipitated product was recrystallized or purified by column chromatography on silica gel (Table 3).

Reagents **12** and **13** were prepared similarly from 7 - (1 - ethenyl - 3,3,5,5 - tetramethylhexyl) - 8 - hydroxyquinoline - 2 - carbonitrile.[1] The dinitrile precursors to reagents **7**, **12** and **13** were isolated by ether or toluene extraction. The ditosylate used in the preparation of reagent **7** was synthesized by a known method.[8]

The dinitriles were hydrolyzed to dicarboxylic acids by KOH in EtOH–H_2O, Claisen's alkali or glycol at 70–140°C until the evolution of ammonia had ceased. The reaction mixture was poured into water, acidified with 2 M HCl, and the product recrystallized.

1,3 - *Bis*(2 - *carbethoxy* - 1,4 - *dihydro* - 4 - *oxo* - 8 - *quinolinyloxy*)*propane* (**9b**)

This compound was prepared by the Conrad–Limpach–Knorr reaction.[9] K_2CO_3 (5.52 g, 40 mmol) was added to 2-nitrophenol (5.56 g, 40 mmol) in DMF (20 cm^3), followed by 1,3-dibromopropane (4.04 g, 20 mmol) and the reaction mixture was kept at 70°C overnight. The reaction mixture was cooled, poured into water and recrystallized from ethanol to give 1,3-di(*o*-nitrophenoxy)propane (4.80 g, 75% yield). This product was reduced with hydrazine (3 cm^3) and Pd(C) (0.2 g) in ethanol (150 cm^3) at reflux for 1.5 h and the resulting diamino compound was converted into its hydrochloride. 1,3-Di(*o*-aminophenoxy)propane hydrochloride (4.38 g, 13 mmol) was stirred at room temperature for two days with diethyl oxalacetate sodium salt (5.56 g, 26.5 mmol), anhydrous Na_2SO_4 (5.8 g) and absolute ethanol (26 cm^3). Water was then added and the product extracted with ether, yielding 6.60 g (85%) of the condensation product. This was dissolved in diphenyl ether (15 cm^3) and the solution added dropwise to 60 cm^3 refluxing diphenyl ether over 7 min. Reflux was continued for an additional 8 min and then most of the solvent was distilled off under reduced pressure. Chromatography on silica gel (90 g) with 5% EtOH in CH_2Cl_2 followed by recrystallization yielded 1.44 g (14% yield based on 2-nitrophenol), m.p. 191–192°C (MeOH). IR (KBr): 3390 (NH), 1720 (C=O), 1630 (C=C—C=O), 1595 cm^{-1} (aromat.). ^1H NMR ($CDCl_3$): δ 1.42 (6H, t, J = 7 Hz, CH_3), 2.58 (2H, m, J = 6 Hz, CCH_2C), 4.45 (4H, q, J = 7 Hz, CH_2OCO), 4.47 (4H, t, J = 6 Hz, CH_2OAr), 6.94 (2H, d, J = 2 Hz, H-3), 7.15 (2H, dd, J = 1 and 8 Hz, H-7), 7.27 (2H, dd, J = 8 Hz, H-6), 7.88 (2H, d, J = 8 Hz, H-5) and 9.34 (2H, bs, NH).

1,3 - *Bis*[2 - *carboxy* - 4 - (5,5,7,7 - *tetramethyl* - 2 - *octenyloxy*) - 8 - *quinolinyloxy*]*propane* (**9**)

This reagent was obtained by alkylation (K_2CO_3/DMF) of **9b** (1.37 g, 2.7 mmol) with 1 - chloro - 5,5,7,7, - tetramethyl - 2 - octene (1.30 g, 6.4 mmol) at 85°C overnight. The crude product was hydrolyzed with KOH–EtOH–H_2O at reflux (5 h). Addition of water and then dilute H_2SO_4 to pH 3 gave the dicarboxylic acid (1.98 g, 94% yield). IR (KBr): 1770, 1720 (C=O), 970 cm^{-1} (CH=CH-*trans*). ^1H NMR ($CDCl_3$): δ 0.98 (18H, s, *t*-Bu), 0.99 (12H, s, CH_3), 1.26 (4H, s, CH_2), 2.10 (4H, d, J = 7 Hz, CH_2–CH=), 2.65 (2H, m, CCH_2C), 4.58 (4H,

CH_2O), 4.87 (4H, d, $OC\underline{H}_2$–CH=), 5.8 (2H, m, CH=CH), 6.0 (2H, m, CH=CH), 7.30 (2H, d, H-7), 7.58 (2H, dd, H-6), 7.71 (2H, s, H-3) and 7.82 (2H, d, H-5).

1,8 - *Bis*(2 - *carbethoxy* - 1,4 - *dihydro* - 4 - *oxo* - 8 - *quinolinyloxy*) - 3,6 - *dioxaoctane* (**10b**)

This compound was prepared in a similar way as **9b** from 2-nitrophenol and triethylene glycol ditosylate. The bis-quinolone **10b** was obtained as a precipitate on addition of petroleum ether to the diphenyl ether solution, m.p. 141–2°C (MeOH), yield 23% based on 2-nitrophenol. IR (KBr): 3400 (NH), 1725 (C=O), 1640 cm^{-1} (C=C—C=O). ^1H NMR ($CDCl_3$): δ 1.41 (6H, t, J = 7 Hz, CH_3), 3.83 (4H, s, CH_2O), 3.97 (4H, m, CH_2O), 4.33 (4H, m, $C\underline{H}_2OAr$), 4.42 (4H, q, J = 7 Hz, $C\underline{H}_2Me$), 6.96 (2H, d, J = 1.9 Hz, H-3), 7.10, (2H, dd, J = 8 and and 1 Hz, H-7), 7.25 (2H, dd, J = 8 Hz, H-6), 7.90 (2H, d, J = 8 Hz, H-5) and 9.49 (2H, bs, NH).

1,8 - *Bis*[2 - *carboxy* - 4 - (5,5,7,7 - *tetramethyl* - 2 - *octenyloxy*) - 8 - *quinolinyloxy*)] - 3,6 - *dioxaoctane* (**10**)

The bis-quinolone compound, **10b**, (2.70 g, 4.66 mmol) was stirred at 60°C (20 min) with K_2CO_3 (1.40 g, 10.2 mmol) in DMF (20 cm^3). 1 - Chloro - 5,5,7,7 - tetramethyl - 2 - octene (2.13 g, 10.5 mmol) was added and the reaction mixture heated at 60°C (40 h). Workup by ether extraction and recrystallization from petroleum ether–ether (3 : 1) gave the 4-alkoxy ester (3.20 g, 75% yield), m.p. 78–80°C. IR (KBr): 1720 cm^{-1} (C=O). Partial ^1H NMR ($CDCl_3$): δ 1.46 (t, CH_3), 4.47 (q, OCH_2) (ethyl ester).

This diethyl ester (3.10 g, 3.4 mmol) was hydrolyzed with KOH in EtOH–H_2O at reflux for 1 h. Yield: 2.29 g (79%). IR ($CHCl_3$): 3500 (O–H), 1760, 1730 cm^{-1} (C=O). ^1H NMR ($CDCl_3$): δ 1.00 (30H, s, CH_3), 1.28 (4H, s, CCH_2C), 2.11 (4H, d, J = 7.3 Hz, $C\underline{H}_2$–CH=), 3.94 (4H, s, CH_2O), 4.08 (4H, m, CH_2O), 4.39 (4H, m, $C\underline{H}_2OAr$), 4.72 (4H, d, J = 5.8 Hz, $C\underline{H}_2$–CH=), 5.76 (2H, dt, J = 5.9 and 15.5 Hz, CH=CH), 6.00 (2H, dt, J = 7.3 and 15 Hz, CH=CH), 7.08 (2H, d, J = 7 Hz, H-7), 7.33 (2H, s, H-3), 7.47 (2H, dd, J = 8 Hz, H-6), 7.60 (2H, d, J = 8 Hz, H-5).

1,2 - *Bis*(2 - *carbethoxy* - 1,4 - *dihydro* - 4 - *oxo* - 8 - *quinolinylthio*)*ethane* (**11b**)

This product was prepared by analogy with **9b** from 1,2-di(*o*-aminophenylthio)ethane dihydrochloride.[10] The bis-quinoline (**11b**) was precipitated on addition of petroleum ether (160 cm^3) to the diphenyl ether solution (80 cm^3). Yield: 26%, m.p. 226–228°C ($CHCl_3$–toluene). IR (KBr): 3330 (NH), 1720 (C=O). 1630 (C=C—C=O), 1590 cm^{-1} (aromat.). ^1H NMR ($CDCl_3$): δ 1.45 (3H, t, J = 7 Hz, CH_3), 2.95 (2H, s, CH_2S), 4.49 (2H, q, J = 7 Hz, CH_2O), 7.00 (1H, d, J = 2 Hz, H-3), 7.31 (1H, dd, J = 8 and 8 Hz, H-6), 7.81 (1H, dd, J = 7 and 1.4 Hz, H-7), 8.34 (1H, ddd, J = 8.1, 1.4 and 0.6 Hz, H-5) and 9.95 (1H, bs, NH).

1,2 - *Bis* - [2 - *carboxy* - 4 - (5,5,7,7 - *tetramethyl* - 2 - *octenyloxy*) - 8 - *quinolinylthio*]*ethene* (**11**)

This reagent was obtained by alkylation with dodecenyl chloride in analogy with **10b**. The 4-alkoxy ester was obtained in 83% yield, m.p. 127–145°C (petroleum ether b.p. 100–125°C). IR (KBr): 2960 (C–H), 1715 (C=O), 1590, 1500 cm^{-1} (aromat.). Partial ^1H NMR ($CDCl_3$): δ 1.45 (t, CH_3), 4.46 (q, CH_2) (ethyl ester).

The diethyl ester (1.51 g, 1.76 mmol) was hydrolyzed with KOH (1 g), EtOH (20 cm^3) and H_2O (4 cm^3) at reflux overnight. Addition of water and acidification gave 1.09 g (77% yield). IR (KBr): 3240 (OH), 2960 (C–H), 1760 (C=O), 1590, 1505 cm^{-1} (aromat.). ^1H NMR ($CDCl_3$): δ 0.99 (30H, s, CH_3), 1.26 (4H, s, CH_2), 2.10 (4H, d, J = 7 Hz, $C\underline{H}_2CH$=), 3.42 (4H, s, CH_2S), 4.85 (4H, d, J = 5 Hz, $OC\underline{H}_2CH$=), 5.79 (2H, m, CH=CH), 6.01 (2H, m, CH=CH), 7.45–7.65 (4H, m, H-6, H-7), 7.66 (2H, s, H-3) and 8.08 (2H, d, J = 8 Hz, H-5).

THE MOLYBDENUM–MOLYBDENUM TRIPLE BOND—XVII.* SYNTHESES, SPECTROSCOPIC AND STRUCTURAL CHARACTERIZATIONS OF $Mo_4F_4(O\text{-}t\text{-}Bu)_8$ AND $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ (Mo≡Mo)

(*Received* 8 *October* 1984; *accepted* 9 *November* 1984)

Abstract—Hydrocarbon solutions of $Mo_2(O\text{-}t\text{-}Bu)_6$ and PF_3 (2 equiv) yield $Mo_4F_4(O\text{-}t\text{-}Bu)_8$, **I**, and $PF_2(O\text{-}t\text{-}Bu)$. Compound **I** contains a bisphenoid of molybdenum atoms with two short Mo–Mo distances, 2.26 Å, and four long Mo–Mo distances, 3.75 Å, corresponding to localized Mo–Mo triple bonding and non-bonding distances, respectively. The tetranuclear compound may be viewed as a dimer, $[Mo_2(\mu_2\text{-}F)_2(O\text{-}t\text{-}Bu)_4]_2$, and addition of PMe_3 to hydrocarbon solutions of **I** yields $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$, **II**, which contains an unbridged Mo–Mo triple bond of distance 2.27 Å. Each molybdenum atom is coordinated to two oxygen atoms, one fluorine atom and the phosphorus atom of the PMe_3 ligand in a roughly square planar manner. The overall central $Mo_2O_4F_2P_2$ skeleton has C_2 symmetry and NMR studies (^1H, ^{19}F and ^{31}P) are consistent with the maintenance of this type of structure in solution. Infrared and electronic absorption spectral data are reported. These are the first compounds containing fluorine ligands attached to the $(Mo{\equiv}Mo)^{6+}$ unit.

As part of our continuing studies of the chemistry associated with compounds containing a central $(Mo{\equiv}Mo)^{6+}$ unit, we reported the fortuitous discovery of two molecules,

$$Mo_4(\mu\text{-}F)_3(\mu\text{-}NMe_2)(O\text{-}t\text{-}Bu)_8$$

and $Mo_4(\mu\text{-}F)_4(O\text{-}t\text{-}Bu)_8$, that cocrystallized in the same unit cell.[2] We describe here the synthesis and characterization of the pure compound $Mo_4(\mu\text{-}F)_4(O\text{-}t\text{-}Bu)_8$ (Mo≡Mo) and its cleavage by trimethylphosphine to yield the dinuclear product $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ (Mo≡Mo).

RESULTS AND DISCUSSION

Synthesis. In hydrocarbon solvents at room temperature $Mo_2(O\text{-}t\text{-}Bu)_6$ reacts with two equivalents of phosphorus trifluoride to give the tetranuclear product $Mo_4(\mu\text{-}F)_4(O\text{-}t\text{-}Bu)_8$ (**I**) as outlined in eqn (1).

$$2Mo_2(O\text{-}t\text{-}Bu)_6 + 4PF_3 \xrightarrow[20°C]{\text{hexane}} Mo_4F_4(O\text{-}t\text{-}Bu)_8 + 4\,PF_2(O\text{-}t\text{-}Bu). \quad (1)$$

The reaction proceeds smoothly at room temperature and appears to be complete within several hours. The ^1H NMR spectra of the products obtained by stripping the reaction mixture *in vacuo* show that formation of **I** is essentially quantitative. If less than two equivalents of phosphorus trifluoride are added, only compound **I** and unreacted starting material are recovered. Recrystallization from hot toluene solution gives the black, crystalline product in 40% yield based on eqn (1). We attribute the orginal isolation[2] of crystals containing a mixture of $Mo_4F_4(O\text{-}t\text{-}Bu)_8$ and $Mo_4F_3(NMe_2)(O\text{-}t\text{-}Bu)_8$ to the presence of $Mo_2(NMe_2)(O\text{-}t\text{-}Bu)_5$ as an impurity in the $Mo_2(O\text{-}t\text{-}Bu)_6$ sample. Presumably the impurity arose from incomplete alcoholysis in the preparation of $Mo_2(O\text{-}t\text{-}Bu)_6$ from $Mo_2(NMe_2)_6$.

Compound **I** is readily cleaved by trimethylphosphine to give the dinuclear compound $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ (**II**) as outlined in eqn (2)

$$Mo_4F_4(O\text{-}t\text{-}Bu)_8 + 4PMe_3 \xrightarrow[20°C]{\text{toluene}} 2Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2. \quad (2)$$

Reduction of the volume of solvent and slow cooling gives compound **II** as a red-brown crystalline product in 60% yield based on eqn (2).

Both **I** and **II** are air and moisture sensitive and

* See Ref. 1 for Part XVI.

† Author to whom correspondence should be addressed.

must be handled in dry and oxygen-free atmospheres and solvents. These compounds are more soluble in aromatic hydrocarbon solvents than in aliphatic ones. A cryoscopic molecular weight determination in benzene indicates that **I** retains its nuclearity in solution.

Solid state and molecular structures of $Mo_4(\mu\text{-}F)_4(O\text{-}t\text{-}Bu)_8$. Structural data for the $Mo_4(\mu\text{-}F)_4(O\text{-}t\text{-}Bu)_8$ molecule has been reported[2] based on the crystallographic characterization of a crystal that contained 2 molecules $Mo_4F_3(NMe_2)(O\text{-}t\text{-}Bu)_8$ and 1 molecule $Mo_4F_4(O\text{-}t\text{-}Bu)_8$ in the unit cell. We have not determined the molecular structure $Mo_4F_4(O\text{-}t\text{-}Bu)_8$ in its pure crystalline state since we believe this will be essentially equivalent to that seen previously.

An ORTEP view of the $Mo_4F_4(O\text{-}t\text{-}Bu)_8$ molecule is shown in Fig. 1. The $Mo_4(\mu\text{-}F)_4(O\text{-}t\text{-}Bu)_8$ molecule contains a bisphenoid of molybdenum atoms. There are two short Mo-to-Mo distances, 2.26 Å (averaged), corresponding to localized Mo-to-Mo triple bonds and four long, nonbonding Mo-to-Mo distances, 3.75 Å (averaged). The local geometry of each $Mo_2F_4O_4$ unit (Mo≡Mo) compares very closely with that observed for the $Mo_2O_4O_4'$ unit in $Mo_2(O\text{-}t\text{-}Bu)_4(O_2CO\text{-}t\text{-}Bu)_2$ (Mo≡Mo).[3] One striking structural feature in this molecule is that the Mo-to-Mo triple bonds are maintained. Indeed, it appears as though the Mo-to-Mo triple bonds are purposefully held apart by the bridging fluoride ligands. Another interesting observation is that these bridging fluoride ligands have Mo–F–Mo angles of 125° (averaged). Fluoride ligands show a strong tendency to form linear bridges[4] as in $[MoF_4(\mu\text{-}F)]_4$, and it has been proposed[5] that this is a result of ligand to metal π-bonding in the bridge. However, one other example of a structurally related dinuclear compound with bent fluoride bridges was recently reported by Crabtree *et al.*:[6] $[(Ph_2MeP)_6H_4Mo_2(\mu_2\text{-}F)_3]^+BF_4^-$.

$Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$. Selected bond distances and angles are given in Tables 1 and 2, respectively. ORTEP views looking down, and perpendicular to a twofold rotation axis which bisects the Mo≡Mo bond are shown in Figs. 2 and 3 respectively.

It may be seen in Fig. 3 that the rotational conformation is far from eclipsed as in quadruply bonded species (e.g., $Mo_2Cl_8^{4-}$ or $Mo_2Me_8^{4-}$) but at the same time not fully staggered. This partially staggered conformation is seen in other d^3–d^3 dimers of formula $Mo_2X_6L_2$[7] and results from a minimization of steric repulsive interactions.

The following points are worthy of note. (1) The Mo–Mo distance of 2.27 Å is typical of a Mo–Mo triple bond.[8] (2) Two distinct Mo–O distances are observed. Short Mo–O distances of 1.87 Å (averaged) exist for oxygen atoms *trans* to fluoride ligands, and longer Mo–O distances of 1.93 Å for oxygen atoms *trans* to Mo–P bonds.

There are many factors which may influence an

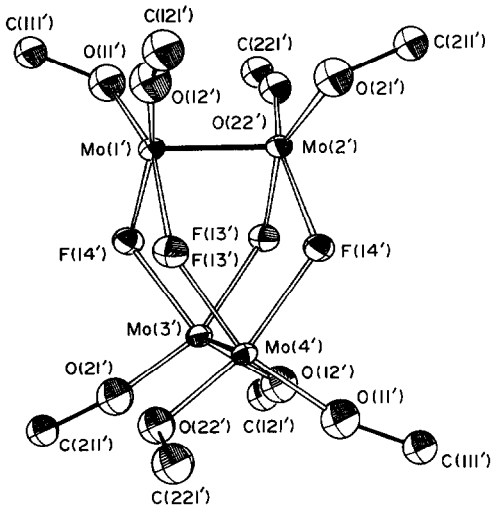

Fig. 1. An ORTEP view of the central skeleton of the $Mo_4(\mu\text{-}F)_4(O\text{-}t\text{-}Bu)_8$ molecule. Pertinent distances (Å) and angles (°) are: Mo(1')–Mo(2') = 2.262(2), Mo(3')–Mo(4') = 2.263(2), Mo(1')–Mo(3') = 3.743(2), Mo(1')–Mo(4') = 3.730(2), Mo(2')–Mo(3') = 3.713(2), Mo(2')–Mo(4') = 3.700(2), Mo–μ-F = 2.10(2) (averaged) and Mo–O = 1.94(2) (averaged), Mo–F–Mo = 125° (averaged).

individual M–O distance, particularly the oxidation state of the metal, the *trans*-ligand and steric and electronic properties of adjacent ligands.[9] The single bond covalent radii for Mo(III) and oxygen have been determined to be 1.40 Å and 0.77 Å respectively.[8] This then sets $d(\text{Mo–O}) = r_{\text{Mo}} + r_{\text{O}} = 2.06$ Å and this value is typical of Mo–μ-OR distances, but considerably longer than any seen for terminal Mo–OR groups which fall in the range 1.80–1.96 Å. In $Mo_2(OCH_2\text{-}t\text{-}Bu)_6$, the average Mo–O distance is 1.88(2) Å.[10] Upon association of other ligands, as in $Mo_2(OR)_6L_2$[7] compounds, the Mo–O distances are in the range 1.90–1.96 Å, consistent with a net decrease in Mo–O π-bonding. In the title compound $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ the alkoxy ligands *trans* to fluorine show a Mo–O bond length of 1.87 Å (averaged) and for alkoxy ligands *trans* to phosphorus a Mo–O bond length of 1.93 Å (averaged).[11] These distances are well within the range where some oxygen-to-molybdenum π-bonding is involved. The alkoxy ligands with short Mo–O bond lengths have Mo–O–C angles of 163.4° (averaged) while those with long Mo–O distances have Mo–O–C angles of 125.1° (averaged). In general the larger M–O–C angle correlates with increased π-donation.[12] We conclude that the Mo–O bonds reflect the *trans*-influence order of the *trans*-ligands: $PMe_3 > F^-$.

The C_{sp^3}–F distances in CH_3F and C_2H_5F average 1.38 Å.[13] Given that this is a single bond distance and that the radius of C_{sp^3} is 0.77 Å, then the covalent radius of fluorine (single bond) is placed at 0.61 Å (cf. 0.64 Å from reference 13). Given that the single bond covalent radius for molybdenum is 1.40 Å, then this sets $d_{(\text{Mo–F})} = r_{\text{Mo}} + r_{\text{F}} = 2.01$ Å. This value is in fact very close to the observed terminal Mo–F distance of 1.98 Å found in $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$. We conclude that there is negligible F-to-Mo π-bonding.

Spectroscopic studies

NMR studies on $Mo_4F_4(O\text{-}t\text{-}Bu)_8$. When the reaction of $Mo_2(O\text{-}t\text{-}Bu)_6$ with PF_3 is carried out at −80°C and monitored by $^{31}P\{^1H\}$ NMR, one initially observes the ^{31}P resonance of free PF_3: there is no evidence for the simple adduct $Mo_2(O\text{-}t\text{-}Bu)_6(PF_3)_2$. Upon warming the NMR tube the PF_3 resonance disappears and the resonance assignable to $PF_2(O\text{-}t\text{-}Bu)$ grows in. By $^{31}P\{^1H\}$, ^{19}F and ^1H NMR spectroscopy the reaction is quantitative based on eqn (1).

The tetranuclear compound $Mo_4F_4(O\text{-}t\text{-}Bu)_8$, as shown in Fig. 1, has idealized D_{2d} symmetry. In the D_{2d} point group, the eight $OC(CH_3)_3$ ligands are all equivalent, and as expected, the room temperature ^1H NMR spectrum shows only one singlet, $\delta = 1.60$ ppm. Similarly, the four bridging fluoride ligands are equivalent and the ^{19}F NMR spectrum shows one singlet at −148.2 ppm, consistent with the solid state molecular structure.

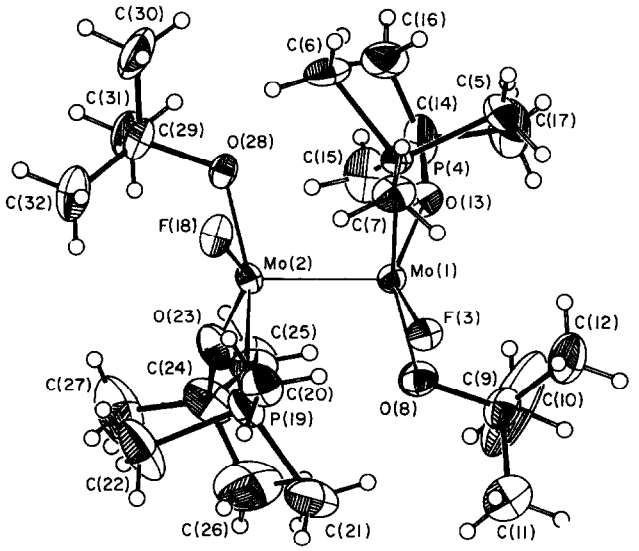

Fig. 2. An ORTEP view looking down the two-fold rotation axis of the $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ molecule giving the numbering scheme used in the tables.

$Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$. As seen in Figs. 2 and 3, $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ has a twofold rotation axis which makes the fluorine atoms (and phosphines) chemically but not magnetically equivalent, and thus part of an AA'XX' spin system. Both $^{31}P\{^1H\}$ and ^{19}F NMR show half of the expected AA'XX' spectrum shown in Figs. 4 and 5 respectively, but only six of expected ten lines are observed. AA'XX' spin systems have been well studied and their spectra may be regarded as superposition of a_2 and ab subspectra.[14] If there are weak or closely spaced lines, one often observes spectra whose appearance resemble that of a simpler type of spectrum because of the apparent deficiency of lines.[15] Successful spectral simulation at both 40.5 and 340 MHz was based on the assumption of degenerate ab subspectra. The coupling constants

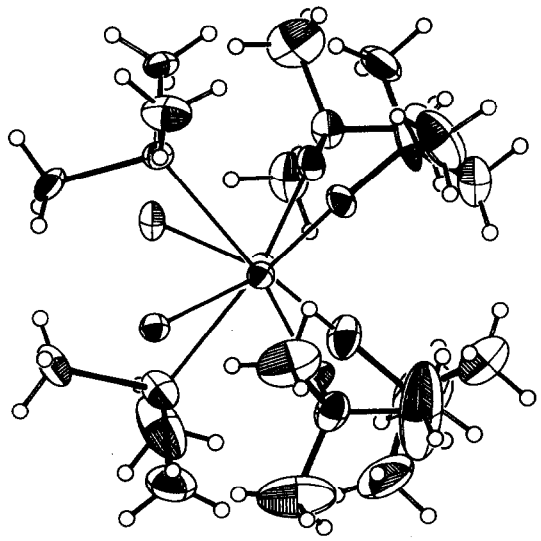

Fig. 3. An ORTEP view looking down the M–M bond and perpendicular to the two-fold rotation axis of the $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ molecule.

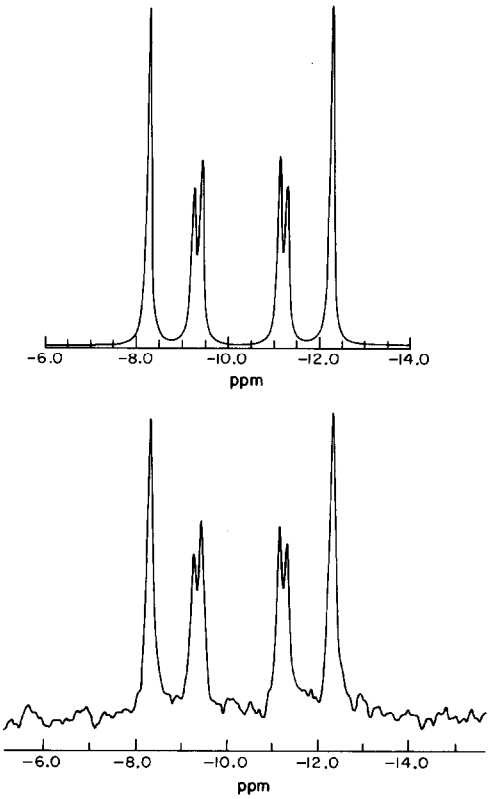

Fig. 4. Observed (bottom) and simulated (top) 40.5 MHz $^{31}P\{^1H\}$ NMR spectra of the $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ molecule.

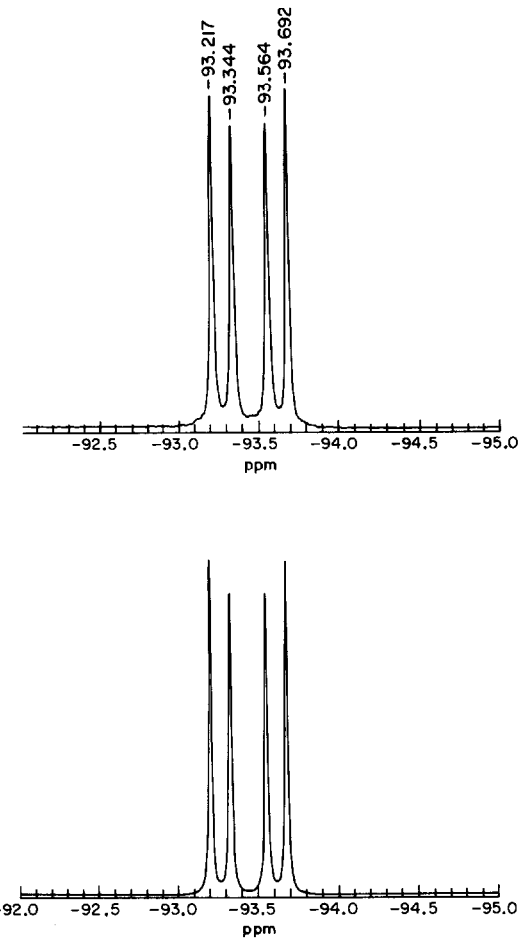

Fig. 5. Observed (top) and simulated (bottom) 340 MHz ^{19}F NMR spectra of the $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ molecule.

were then calculated using the method of Gunther[14] and computer simulation gave the spectra shown in Figs. 4 and 5 for ^{31}P and ^{19}F, respectively. The ^{19}F and ^{31}P spectra should be identical. When 6 Hz of line broadening is applied to the ^{19}F spectrum recorded at 340 MHz (the measured natural line width is 6.1 Hz for ^{19}F) the central lines become too close to be resolved. This simulation gives $^2J_{P-F}$ = 118.6 Hz, $^3J_{P-P}$ = 43.2 Hz, $^3J_{F-F}$ = 6.7 Hz and $^3J_{P-P}$ = 1.0 Hz. $^2J_{P-F}$ and $^3J_{P-F}$ are necessarily of the same sign but the relative signs of J_{F-F} and J_{P-P} cannot be ascertained.

The room temperature ^1H NMR spectra are also consistent with the solid state structure. Two singlets for the $OC(CH_3)_3$ ligands are observed at 1.80 and 1.33 ppm, as well as one doublet for $P(CH_3)_3$ at 1.44 ppm. It is interesting to note that under routine conditions (~60 FT acquisitions) only one rotational isomer is observed by ^1H NMR. Only during ^{19}F data collection (when an extraordinary 700 FT acquisitions were collected) was there any evidence for other rotamers in solution. The major rotamer is consistent with the solid state conformation.

Infrared spectra. Barraclough *et al.*[16] studied the infrared spectra of a number of metal alkoxides and the ν(C–O) and ν(M–O) bands were tentatively assigned. It has been observed that ν(C–O)M and ν(M–O) bands generally appear in the region 900–1150 cm^{-1} and 600–500 cm^{-1}, respectively. The position of the bands is determined by the metal and the nature of the alkoxy groups. The IR spectra of the dimeric $Mo_2(OR)_6$ alkoxides exhibit ν(Mo–O) bands which are higher in energy than those reported by Barraclough presumably because of the strong RO-to-M π-bonding in the former. For example, under D_{3d} symmetry, $Mo_2(O\text{-}i\text{-}Pr)_6$ exhibits two strong bands as expected which can tentatively be assigned as A_{2u} (651 cm^{-1}) and E_u (625 cm^{-1}). The A mode, being totally symmetric, should lie at higher energy. For $Mo_2(O\text{-}t\text{-}Bu)_6$ these two bands are observed at 600 and 560 cm^{-1}. The bands for ν(C–O) come as expected between 900 and 1000 cm^{-1} for all $Mo_2(OR)_6$ compounds. It should be noted, however, that C–O, C–C and M–O coupling will complicate the assignments especially under lower symmetry. For $Mo_4F_4(O\text{-}t\text{-}Bu)_8$, ν(Mo–O) are observed as medium intensity bands at 625 and 555 cm^{-1}, and for $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ ν(Mo–O) are observed at 599 and 540 cm^{-1}.

Terminal M–F stretching bands generally appear in the region of 750–500 cm^{-1}.[17] By comparisons of the IR spectra for I and II we tentatively assign ν(Mo–F) to medium intensity bands at 730 and 740 cm^{-1} for the terminal Mo–F bonds in $Mo_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$. For the bridging fluorides ν(Mo–F) is observed at 510 cm^{-1} in $Mo_4F_4(O\text{-}t\text{-}Bu)_8$.

Electronic absorption spectra. The electronic

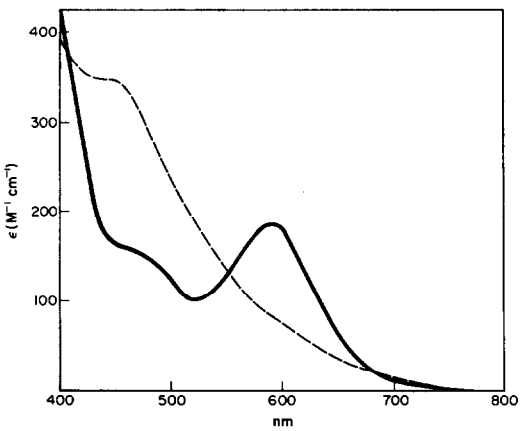

Fig. 6. Comparison of the visible electronic absorption spectra of $Mo_4(\mu\text{-}F)_4(O\text{-}t\text{-}Bu)_8$ (solid line) and $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ (dashed line) in hexane solution.

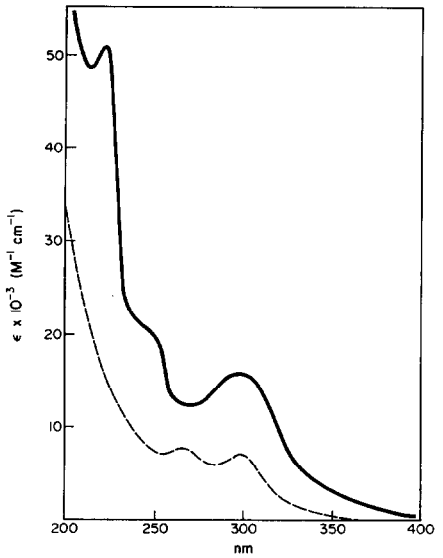

Fig. 7. Comparison of the ultraviolet electronic absorption spectra of $Mo_4(\mu\text{-}F)_4(O\text{-}t\text{-}Bu)_8$ (solid line) and $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ (dashed line) in hexane solution.

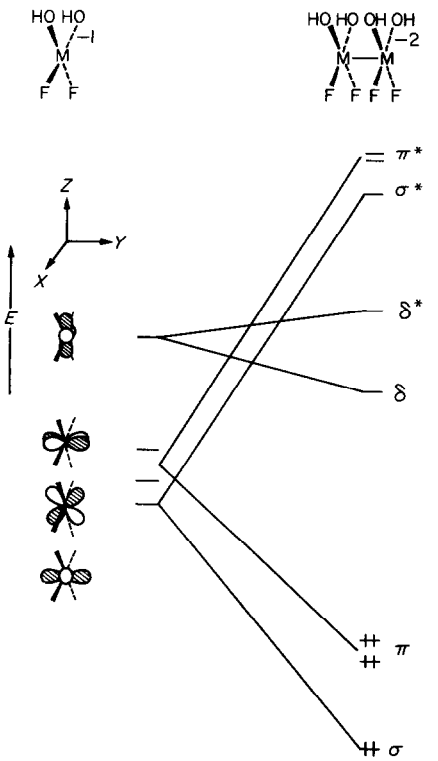

Fig. 8. Schematic drawing showing the derivation of the molecular orbitals of the d^3–d^3 dimer, $Mo_2F_4(OH)_4^{2-}$ (right), from the valence atomic orbitals of a $MoF_2(OH)_2^-$ fragment (left).

spectra of both compounds show weak absorptions ($\varepsilon < 400\ M^{-1}\ cm^{-1}$) in the visible spectra and strong absorptions ($\varepsilon = 10{,}000$–$50{,}000\ M^{-1}\ cm^{-1}$) in the ultraviolet. Visible and ultraviolet absorption spectra are shown in Figs. 6 and 7, respectively. $Mo_4F_4(O\text{-}t\text{-}Bu)_8$ and $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$ are green and red–orange because of low energy absorptions at 590 and 480 nm, respectively.

An extended Hückel calculation[18] on the model compound $Mo_2F_4(OH)_4^{2-}$ which can be taken as one half of $Mo_4F_4(O\text{-}t\text{-}Bu)_8$ gives the expected electronic configuration of $\sigma^2\pi^4$ for the M–M bond. A schematic drawing of these molecular orbitals is shown in Fig. 8. In the symmetry groups C_2 and D_{2d} virtually all transitions are allowed. The molecular orbital diagram suggests that the lowest energy transition should be of the type M–M $\pi \rightarrow \delta/\delta^*$. The stronger absorptions in the ultraviolet region are then tentatively assigned M–M $\pi \rightarrow \pi^*$ and LMCT transitions, in increasing order of energy. For comparison we note that for $Mo_2(OR)_6$ compounds[19] there are no absorption maxima in the visible region and that SCF–Xα–SW calculations[20] on $Mo_2(OH)_6$ predict the lowest energy absorption, M–M $\pi \rightarrow \pi^*$, to lie well into the ultraviolet.

CONCLUSIONS

This work demonstrates that replacement of an O-*t*-Bu group by the smaller and more electronegative fluoride ligand promotes a Lewis base association reaction. Probably $Mo_2F_2(O\text{-}t\text{-}Bu)_4$, once formed, associates with itself through the agency of metal–ligand–metal bridges. The choice of bridging ligand is established to be $F > O\text{-}t\text{-}Bu$ which is not what might have been anticipated in view of the well known ability of alkoxides to bridge two or three metal atoms with flexible M–O–M angles.[16]

This work suggests that the choice of bridging ligand $F > O\text{-}t\text{-}Bu$ may be a result of the π-donor properties of the ligands which appear to lie in the inverse order. Through the agency of fluoride bridges, the alkoxide ligands can remain terminal and *cis* in order to maximize π-donation to the metal.

When a strong Lewis base such as trimethylphosphine is added to the fluoride bridged tetramer, the fluoride bridges are readily cleaved to give $Mo_2F_2(O\text{-}t\text{-}Bu)_4(PMe_3)_2$. This supports the view that the tetranuclear compound $Mo_4F_4(O\text{-}t\text{-}Bu)_8$ is best considered $[Mo_2(\mu\text{-}F)_2(O\text{-}t\text{-}Bu)_4]_2$ (M≡M).

At this point it is interesting to speculate about what factors will favor dinuclear compounds containing M–M bonds of multiple order compared with cluster compounds of the same empirical formula in which metal–metal bonding is delocalized.

We note, for example, that molybdenum in oxidation state +3 with halide and alkoxide ligands exists as the tetranuclear compound $Mo_4F_4(O\text{-}t\text{-}Bu)_8$ which contains localized Mo-to-Mo triple bonds, and as square (X = Cl) and butterfly (X = Br, I) clusters $Mo_4X_4(O\text{-}i\text{-}Pr)_8$ with delocalized metal–metal bonding.[21] We also note that molybdenum in oxidation state +3 with halide and dialkylamide ligands exists in dinuclear compounds $Mo_2X_2(NR_2)_4$ with localized Mo-to-Mo triple bonds.[22] There appears to be a subtle balance between the ability of the ligands to π-donate, the ability to bridge, and steric bulk.[23]

Further studies on compounds of these types should provide additional insight to the delicate balance between localized and delocalized bonding in these fascinating molecules.

EXPERIMENTAL

Physical techniques. ^1H NMR spectra were recorded on a Nicolet NT-360 spectrometer at 360 MHz in dry and oxygen-free toluene-d_8 or benzene-d_6. ^{19}F NMR spectra were recorded on the same instrument at 340 MHz in toluene-d_8 or benzene-d_6. ^{31}P NMR spectra were run on a Varian XL-100/Nicolet 1080 FT spectrometer at 40.5 MHz in the same solvents. All ^1H NMR chemical shifts are reported in ppm relative to the CHD_2 quintet of toluene-d_8 set at $\delta = 2.09$ or the ^1H impurity in benzene-d_6 set at $\delta = 7.15$. All ^{19}F NMR chemical shifts are reported in ppm relative to the CF_3 singlet of CF_3COOH used as an external lock and set at $\delta = -78.90$ ppm relative to $CFCl_3$. ^{31}P NMR chemical shifts are reported relative to 85% H_3PO_4.

Infrared spectra were recorded on a Perkin–Elmer 283 spectrophotometer as Nujol mulls between CsI plates. Electronic absorption spectra were obtained with a Perkin–Elmer 330 spectrophotometer. Samples were run versus a solvent blank using matched 1.00 cm or 1.0 mm quartz cells.

Synthesis. All reactions were carried out under an atmosphere of dry and oxygen-free nitrogen using standard Schlenk and glove-box techniques. Hexane and toluene were degassed and eluted from activated copper catalyst and molecular sieve columns and then stored under nitrogen. Phosphorus triflouride was purchased from Pennwalt and used without purification. Trimethylphosphine was purchased from Strem and was stored under a vacuum. Elemental analyses were performed by Alfred Bernhardt Microanalytishes Laboratorium, West Germany.

$Mo_4F_4(OBu^t)_8$. In a Schlenk reaction vessel $Mo_2(O\text{-}t\text{-}Bu)_6$[3] (1.00 g, 1.59 mmol) was completely dissolved in toluene (50 cm^3). The solution was frozen at −196°C and PF_3 (3.18 mmol) was condensed into the flask using a calibrated vacuum manifold. The reaction mixture was allowed to warm to room temperature and left to stir for 12 h. During this time the color of the solution changed from orange to red and finally to red–brown. The volume of toluene was reduced to 1/4 the original volume at which time a green precipitate formed. This solution was heated to 90°C on a hot H_2O bath to force all the precipitate back into solution. The flask was then allowed to slowly cool to room temperature overnight which produced many large black crystals. The flask was then cooled to −15°C for another 2 days. The crystals were collected by filtration and dried *in vacuo*. A second crop of crystals was obtained by reducing the volume of the filtrate and cooling [total yield 0.35 g, 42% based on eqn (1)]. Calc. for $Mo_4F_4O_8C_{32}H_{72}$: C, 36.76; H, 6.95; F, 7.27. Found: C, 36.51; H, 6.82; F, 7.12%.

^1H NMR (22°C): singlet, $\delta = 1.60$.

^{19}F NMR (22°C): singlet, $\delta = -148.24$.

IR (cm^{-1}): 1230 m, 1175s, 1025w, 990s, 915m, 895s, 790m, 775s, 625m, 555m, 510m, 485m, 390w, 370w, 350w, 285w.

UV–visible absorption spectra in hexane solution: λ_{max}, nm (ε, M^{-1} cm^{-1}) 590 (180), 480 (150) sh, 295 (15,000), 245 (21,000) sh, 220 (51,000).

$Mo_2F_2(OBu^t)_4(PMe_3)_2$. In a Schlenk reaction vessel $Mo_4F_4(OBu^t)_8$ (0.25 g, 0.24 mmol) was dissolved in toluene (20 cm^3). The solution was frozen at −196°C and trimethylphosphine (0.98 mmol, 4 equiv) was condensed into the flask using a calibrated vacuum manifold. The reaction mixture was allowed to warm to room temperature. The color of the solution changed from green to red–brown. The volume of solution was reduced by 1/2 and cooled to −15°C. Red–brown crystals were isolated after 6 days. A second crop of crystals was obtained by reducing the volume of the filtrate and cooling [total yield 0.20 g, 61% based on eqn (2)]. Calc. for $Mo_2F_2O_4P_2C_{22}H_{54}$: C, 39.20; H, 8.08; F, 5.64. Found: C, 39.10; H, 7.96; F, 5.48%.

^1H NMR (22°C): δ (O-*t*-Bu) = 1.80 and 1.33, equal intensity singlets; δ (PMe_3) = 1.44, doublet, $^2J_{P-H} = 9.0$ Hz.

$^{31}P\{^1H\}$ NMR (21°C): δ (PMe_3) = −10.26, half of the expected AA'XX' spectrum (Fig. 4). Successful simulation gives $^2J_{P-F} = 118.6$ Hz, $^3J_{P-F} = 43.2$ Hz, $^3J_{F-F} = 6.7$ Hz and $^3J_{P-P} = 1.0$ Hz. See discussion section about signs of coupling constants.

^{19}F NMR (22°C): δ (F) = −93.45; half of the expected AA'XX' spectrum; see Fig. 5. As mentioned in the discussion section, 700 FT acquisitions were collected to observe minor rotational components. To accomplish this a 220 ppm spectral window was

used with 16 K data points, 8 K of which are real. As a consequence, not enough data points were collected to resolve small coupling. For successful ^{19}F spectral simulation $^3J_{P-P} = 0$ Hz and $^3J_{P-F} = 3.0$ Hz was used.

IR (cm^{-1}): 1295m, 1280m, 1230m, 1165s, 1020w, 1000s, 980s, 960s, 920s, 895m, 845w, 785m, 762m, 762s, 740m, 730m, 670w, 599m, 540m, 490s, 385m, 370m, 350m, 290m.

UV–visible absorption spectra in hexane solution: λ_{max}, nm (ε, M^{-1} cm^{-1}) 450 (350) sh, 300 (6500), 265 (6700).

PF_2(O–*t*-Bu). $^{31}P\{^1H\}$ NMR: triplet, $^1J_{P-F} = 1290$ Hz, $\delta = -120$ ppm. ^{19}F NMR: doublet, $^1J_{P-F} = 1290$ Hz, $\delta = -42.2$ ppm. ^1H NMR: singlet, $\delta = 1.13$ ppm.

Crystallographic studies

General operating procedures and listings of programs have been given previously.[24] Crystal data for $Mo_2F_2(O\text{–}t\text{-}Bu)_4(PMe_3)_2$ are given in Table 3. A suitable crystal was transferred to the goniostat using standard inert atmosphere handling techniques employed by the IUMSC and cooled using a gas flow cooling system.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima of orthorhombic symmetry, with systematic extinctions corresponding to the unique space group Pbca.

The structure was solved by a combination of Patterson and Fourier techniques, and refined by full-matrix least squares refinement. A difference Fourier phased on the non-hydrogen parameters located peaks which could be assigned to 46 of the 54 hydrogen atoms. An attempt was made to refine hydrogen atoms (using calculated positions for the missing eight hydrogens), but those on several methyl groups failed to refine properly, especially those involving C(10), C(11), C(25), C(26) and C(27). For this reason all hydrogen atoms were placed in idealized, fixed positions with dC–H = 0.95 Å for the remainder of the refinement.

A final difference Fourier was featureless, the largest peak being 0.32 e/Å.^{3} No absorption correction was attempted.

(*Received* 12 *October* 1984; *accepted* 9 *November* 1984)

Abstract—From the reactions between 1,4-dilithiobutane and 1,2-$M_2Cl_2(NMe_2)_4$ compounds in hydrocarbon solvents, the 1,2-dimetallacyclo-1,2-hexyne compounds $M_2(CH_2)_4(NMe_2)_4$(M≡M), where M = Mo and W, have been obtained as yellow–orange, volatile microcrystalline compounds. Spectroscopic data are consistent with expectations based on previous studies of gauche 1,2-$M_2R_2(NMe_2)_4$ compounds in solution and a structural model based on the observed molecular structure of 1,2-$Mo_2Et_2(NMe_2)_4$ is presented and compared with the observed molecular structure of $Mo_2(CH_2)_4(NMe_2)_4$ found in the solid state. Pertinent bond distances (Å) and angles (°) are: Mo–Mo = 2.200(1), Mo–N = 1.96(1) (averaged), Mo–C = 2.165(8) (averaged), Mo–Mo–N = 105(1), Mo–Mo–C = 97(1).

There are a large number of compounds which contain triple bonds between molybdenum and tungsten atoms having a central unit $X_nM{\equiv}MX_n$ where X = a ligand atom directly bonded to the metal and $n = 3, 4, 5$ and 6, e.g., $M_2(NMe_2)_6$ where X = N and $n = 3$ and $W_2(O_2CNMe_2)_6$ where X = O and $n = 6$.[1] Within this group the so-called ethane-like dimers, $X_3M{\equiv}MX_3$, where X = C, N, O, S, have attracted the most study. A subset of the latter group are compounds of formula 1,2-$M_2R_2(NMe_2)_4$, where R = an alkyl[2] or aryl ligands.[3] These exist in solution as a mixture of anti and gauche rotamers and provide an excellent starting point for the study of the chemistry of alkyl/aryl ligands at dinuclear metal centers. One of the reactions we have been particularly interested in studying involves reductive-elimination from the dinuclear center to give M–M quadruple bonded compounds by either C–C or C–H bond formation. This was first observed for molybdenum as shown in eqn. (1)[4] and subsequently extended to tungsten, eqn. (2).[5]

$$1,2\text{-}Mo_2R_2(NMe_2)_4 + CO_2 \rightarrow Mo_2(O_2CNMe_2)_4 + \text{alkene} + \text{alkane} \quad (1)$$

[R = a β-hydrogen containing alkyl]

$$1,2\text{-}W_2R_2(NMe_2)_4 + 4R'COOCOR' \rightarrow W_2(O_2CR')_4 + \text{alkene and alkane} + 4R'CONMe_2. \quad (2)$$

Studies involving the use of labelled alkyls, e.g., CH_2CD_3, showed[4] that the β-H or D atom of one ligand was transferred to the α-carbon of the other alkyl ligand, e.g., CD_3CH_2–Mo≡Mo–CH_2CD_3 → [Mo≡Mo] + $CH_2{=}CD_2$ + CH_2DCD_3. This is consistent with an overall reaction scheme which incorporates an irreversible β-hydrogen abstraction step followed by reductive elimination by C–H bond formation. Just how these steps are achieved at the dimetal center poses several fascinating possibilities and reactions (1) and (2) are rare examples of dinuclear reductive-elimination.[6] In mononuclear chemistry the study of metallacycles of general formula $L_nM(CH_2)_x$, where $x = 3, 4$ and 5, has been helpful in elucidating the nature of the β-hydrogen abstraction step as well as other processes.[7,8] A similar situation could hold for the dinuclear reductive eliminations of the type described in eqns (1) and (2). We describe here the preparation and characterization of 1,2-dimetallacyclo-1,2-hexyne derivatives of molybdenum and tungsten.

RESULTS AND DISCUSSIONS

Synthesis

The new compounds were prepared according to the reaction shown in eqn. (3) and were isolated as microcrystalline yellow or orange solids by sublimation *in vacuo* (80–100°C, 10^{-4} torr) in 40–

* Author to whom correspondence should be addressed.

45% theoretical yield.

$$1,2\text{-}M_2Cl_2(NMe_2)_4 + LiCH_2CH_2CH_2CH_2Li \xrightarrow{\text{hexane}} M_2(CH_2)_4(NMe_2)_4 + 2LiCl. \quad (3)$$

Early problems associated with these reactions centered around the preparation of the 1,4-dilithiobutane and the choice of solvent. We found that the best procedure for the preparation of 1,4-dilithiobutane involved the reaction between lithium sand and 1,4-dichlorobutane. The use of the dichlorobutane is preferable to the dibromobutane and lithium sand is more reactive than the Li wire containing 0.8% Na recommended in the Whitesides' procedure.[8] The use of a non-oxygen containing hydrocarbon solvent in reaction (3), e.g., hexane or toluene, is required since the $M_2Cl_2(NMe_2)_4$ [9] compounds react with THF, ether and other O-donor solvents, etc. This, of course, leads to a rather slow reaction since the dilithiobutane is virtually insoluble in hexane and toluene. Nevertheless the pure compounds can be isolated in reasonable yields in this manner.

Physicochemical and spectroscopic properties

The new compounds of formula $M_2(CH_2)_4(NMe_2)_4$, where M = Mo and W, are yellow–orange, sublimable (80–100°C, 10^{-4} torr), microcrystalline compounds. They are extremely air-sensitive and were handled in dry and oxygen free atmospheres (N_2) and solvents. The compounds showed molecular ions M^+ in the mass spectrometer with characteristic isotope envelopes for the M_2-grouping. The compounds are appreciably soluble in hydrocarbon solvents such as hexane, benzene and toluene. Crystals suitable for detailed X-ray studies were obtained from pentane solutions. Only finely divided micro-crystalline samples were obtained by sublimation.

^{1}H NMR spectra, recorded at 360 MHz and at ambient temperatures, of toluene-d_8 solutions of $M_2(CH_2)_4(NMe_2)_4$ compounds are not very informative because of the complex spin-system (AA'BB'XX'YY') for the methylene protons of the $M_2(CH_2)_4$ ring and the temperature dependent rate of proximal and distal N-methyl exchange.[10] At lower temperatures rotations about M–N bonds are frozen out leading to two types of proximal N–Me resonances and two distal N–Me resonances. These are in agreement with expectations based on the gauche central $M_2N_4C_2$ unit which is imposed by the μ-C_4H_8 ligand. At higher temperatures rotations about M–N bonds become rapid on the NMR time-scale leading to a pairwise collapse of the proximal–distal N–Me signals. Below 110°C in toluene-d_8 gauche $\rightleftharpoons$ gauche isomerization/enantiomerization is not observed on the NMR time-scale.

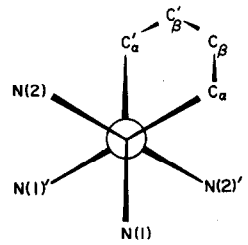

Fig. 1. A Newman projection of the central $M_2C_4N_4$ skeleton of the $M_2(CH_2)_4(NMe_2)_4$ molecules.

The low temperature proton decoupled ^{13}C spectra show four NMe signals assignable to the two proximal and two distal NMe groups. The chemical shift separation of the proximal and distal NMe groups is *ca* 15–20 ppm due to the magnetic anisotropy of the M≡M bond.[1,10] Two other signals of equal intensity are seen and these are assigned to the α,α' and β,β' carbon atoms of C_4-methylene chain. In the case of the ditungsten compound one of these signals shows tungsten satellites, $J_{^{183}W-C} = 113$ Hz, which identifies it as arising from the α,α' carbon atoms. The NMR spectra thus reliably establish the gauche ethane-like geometry depicted by the Newman projection shown in Fig. 1.

A simulated structure

A structure for the $Mo_2(CH_2)_4(NMe_2)_4$ molecule can be simulated from the observed structure of

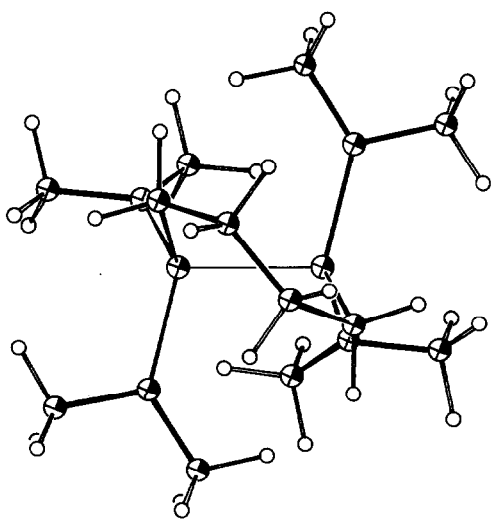

Fig. 2. An ORTEP view showing the anticipated molecular structure of $Mo_2(CH_2)_4(NMe_2)_4$ based on the observed molecular structure for gauche-$Mo_2Et_2(NMe_2)_4$.

gauche $Mo_2Et_2(NMe_2)_4$.[2] The latter molecule has its ethyl groups turned outward from the Mo_2 center. By keeping the Mo–Mo and Mo–C distances and the Mo–C–C angle the same and twisting about the Mo–C bonds one can direct the methyl groups of the ethyl ligands into a proximal position. Then by positioning the β carbon atoms 1.54 Å apart one can replace two C–H bonds by a C–C bond to create the desired four methylene chain spanning the Mo≡Mo bond. A view of the $Mo_2(CH_2)_4$ unit so formed is given in Fig. 2. The hydrogen atoms are positioned on the β,β' carbon atom in idealized tetrahedral sites. The change from Mo-to-W would have little effect since $d_{(W\equiv W)}-d_{(Mo\equiv Mo)} = ca\ 0.08$ Å.

Solid state molecular structure of $Mo_2(CH_2)_4(NMe_2)_4$

An ORTEP view of the molecular structure found for the $Mo_2(CH_2)_4(NMe_2)_4$ in the solid state is given in Fig. 3. Bond distances and bond angles are reported in Tables 1 and 2, respectively.

The observed structure is seen to be very similar to that anticipated from the known structure of gauche-$Mo_2Et_2(NMe_2)_4$. The only significant differences lie in the internal Mo–Mo–C angles which are smaller in the dimetallacycle, 97° vs. 101°. This allows for a greater puckering of the Mo_2C_4 skeleton such that near idealized staggered ethane-like conformations are attained.

Concluding remarks

Metallacycles containing two metal atoms directly bonded to one another are still compara-

tively rare in organometallic chemistry, especially when the organic portion of the ring is saturated and composed of methylene groups, viz. $M_2(CH_2)_n$.[7,11] Certainly the compounds reported here are the first of their kind incorporating a M–M triple bond within the 6-membered ring. Further studies of their reactions are planned. The six membered ring clearly imposes restrictions for M–H–C interactions and this may provide mechanistic insights into dinuclear reductive-elimination reactions of type (1) and (2).

EXPERIMENTAL SECTION

General procedures. Dry and oxygen-free solvents and atmospheres (N_2) were used throughout. Bench-top operations were performed by Schlenk and vacuum-line techniques. The preparation of infrared and NMR samples were performed in a Vacuum Atmospheres Co. Dri-Lab assembly.

Infrared spectra were recorded as Nujol mulls between KBr plates on a Perkin–Elmer 283 speetrophotometer. NMR speetra were recorded using a Nicolet 360 spectrometer equipped with a variable temperature probe. The solvent was toluene-d_8 and chemical shifts, δ in ppm, are relative to Me_4Si, $\delta = 0$. Elemental analyses were obtained from Alfred Bernhardt Microanalytisches Laboratorium, West Germany. Mass spectra were obtained courtesy of Mr. Peter Cook, Queen Mary College, London.

Materials. 1,4-$C_4H_8Cl_2$ was purchased from Aldrich Chemical Co. and distilled before use. The compounds $M_2Cl_2(NMe_2)_4$ were prepared by published procedures.[9] 1,4-dilithiobutane, 1,4-$Li_2C_4H_8$, was prepared by a modification of the procedure described by Whitesides and co-workers,[8] employing Li sand rather than Li wire.

Preparations

$Mo_2(CH_2)_4(NMe_2)_4$. $Li_2C_4H_8$ (2.5 cm^3 of a 0.41 M soln in Et_2O) was added via a syringe into a Schlenk

apparatus and the Et_2O was evaporated by vacuum. The resultant cream–white solid was kept under a dynamic vacuum for *ca* 4 h to be sure all traces of $C_4H_8Cl_2$ were removed. The Schlenk apparatus was then transferred to the Dry Box and $Mo_2Cl_2(NMe_2)_4$ (439 mg, 1 mmol) was added followed by hexane (20 cm^3). The reaction mixture was stirred for 5 h at room temperature by use of a magnetic stirrer/spin bar yielding a dark brown solution with suspended solids. The reaction mixture was filtered through a Celite pad and the filtrate was collected and evaporated to dryness in a dynamic vacuum yielding brown solids. Sublimation of this residue at 100°C, 10^{-4} torr yielded a yellow sublimate $Mo_2(CH_2)_4(NMe_2)_4$ (190 mg, 45% yield based on Mo).

Found: C, 34.03; H, 7.51; N, 13.22. Calc. for $Mo_2N_4C_{12}H_{32}$: C, 33.97; H, 7.60; N, 13.20%.

IR data (cm^{-1}): 2810m, 2766m, 1439m, 1414m, 1390w, 1327vw, 1316vw, 1240s, 1186w, 1147s, 1116w, 1040m, 938vs, 887vw, 793w, 648w, 557w.

^1H NMR data at −40°C: $\delta = 4.30, 3.35, 2.54, 2.40, 2.15$ multiplets: $Mo_2(CH_2)_4$. $\delta = 4.10, 3.88$ singlets: proximal N-methyls; $\delta = 2.51, 2.48$ singlets: distal N-methyls.

^{13}C NMR data (proton decoupled) at −40°C: $\delta = 56.9, 55.0$ proximal N-methyls; $\delta = 41.7$: distal N-methyls (fortuitously degenerate); $\delta = 43.7, 37.6$; $C_\alpha, C_{\alpha'}$, $C_\beta, C_{\beta'}$ carbons of $Mo_2(CH_2)_4$ ring.

A molecular ion at 424 (*m/e*) corresponded to $Mo_2(CH_2)_4(NMe_2)_4^+$.

$W_2(CH_2)_4(NMe_2)_4$ was prepared in a directly analogous manner to that described above employing $W_2Cl_2(NMe_2)_4$.

Found: C, 24.54; H, 5.09; N, 9.61. Calc. for $W_2N_4C_{12}H_{32}$: C, 24.02; H, 5.37; N, 9.34%.

Crystallographic studies

General operating procedures and listings of programs have been published.[12]

Crystal data are summarized in Table 3. The space group was determined by a reciprocal lattice search on the goniostat and found to be $P\bar{1}$.

The structure was solved by direct methods and Fourier techniques and all atoms (including hydrogen atoms) were located and refined. A final difference Fourier was featureless, the largest peak being 0.34 Å. ψ scans were flat and no absorption correction was performed.

Acknowledgements—We thank the donors of the Petroleum Research Fund administered by the American Chemical Society and the Wrubel Computing Center for support of this work.

Supplementary materials available—Tables of fractional coordinates and thermal parameters have been deposited with the Cambridge Crystallographic Data Centre. Complete structural information is available from the Editor at Queen Mary College and, in microfiche form, from the Indiana University Chemistry Library, Bloomington, Indiana 47405 at a cost of $2.50 per structural report. For $Mo_2(CH_2)_4(NMe_2)_4$ request MSC No. 84074.

A STUDY OF MIXED LIGAND COMPLEXES USING DIFFERENTIAL PULSE POLAROGRAPHY

H. M. KILLA,* M. G. ABD EL WAHED and H. A. DESSOUKI
Chemistry Department, Faculty of Science, Zagazig University, Zagazig, Egypt

(*Received* 24 *August* 1984; *accepted* 14 *November* 1984)

Abstract—Differential pulse polarography was used to study the mixed ligand complexes of trimethylenediamine (TMDA) and oxalate (OX) with Cd(II) at constant ionic strength ($\mu = 1$, $NaNO_3$) at 25°C. It has been found that the reduction of complexes is reversible and diffusion-controlled. Three mixed complexes, [Cd(TMDA)(OX)], $[Cd(TMDA)(OX)_2]^{2-}$ and $[Cd(TMDA)_2(OX)]$, are formed. Their overall stability constants are: $\log \beta_{11} = 6.78$, $\log \beta_{12} = 7.53$ and $\log \beta_{21} = 8.20$, respectively.

Electroanalytical methods, and especially polarography have played an important part in investigations of the composition and stability of complexes and of the mechanisms of complex formation. Deford and Hume[1] have derived an expression to study the stepwise formation of complexes while Schaap and McMasters[2] treated the case of mixed ligand complexes.

Heath and Hefter[3] have derived an equation for the determination of stability constants of complex ions by differential pulse (d.p.) polarography. This technique offers a considerable number of advantages[3] compared to DC polarography. On the other hand, the limitations of the original Deford–Hume[1] treatment have been documented.[4–6] Thus, any technique which enables $\Delta E_{1/2}$-values to be measured more accurately than by DC polarography will lead to improved calculations of the stability of complexes and especially the mixed ligand complexes. In the present work, d.p. polarography was extended to study the mixed ligand complexes of Cd(II)–trimethylenediamine–oxalate system which had not been studied before.

EXPERIMENTAL

All current–potential polarograms were obtained using an IBM EC/225 Voltammetric Analyzer with a 7424 M *X–Y* recorder. A conventional three electrode cell with a saturated sodium chloride calomel electrode (SSCE) was employed. A drop time of 1.0 s and sample time of 16.7 ms were used in the case of fast polarography measurements. A potential pulse 50 mV was used throughout the d.p. polarography measurements.

All measurements were made at 25°C and an ionic strength was maintained constant at $\mu = 1$ using $NaNO_3$ as supporting electrolyte. The concentration of Cd^{2+} ions which was used for all the data reported was 1×10^{-4} M.

Reagent grade chemicals, deionized water and triple distilled mercury were employed in all cases. No maximum suppressor was used.

THEORY

Stability constants of polarographically reversible systems may be determined by differential pulse (d.p.) polarography using the Deford–Hume equation[1] as modified by Heath and Hefter.[3] This equation may be expressed as

$$F_0(X) = \Sigma B_j C_X^j = \text{antilog}\left\{\frac{0.4343nF}{RT} \times [(E_p)_s - (E_p)_c] + \log\left[\frac{(I_p)_s}{(I_p)_c}\right]\right\}, \quad (1)$$

where $F_0(X)$ represents the experimentally measured right-hand side of the equation, B_j is the overall stability constant of the jth complex, C_x is the analytical concentration of the ligand, E_p is the peak potential of the d.p. polarography wave, I_p is the peak current of the d.p. wave and the subscripts s and c refer to the free and complexed ions respectively. Other symbols are those used conventionally.

Since Cd^{2+} forms hexacoordinate complexes with

* Author to whom correspondence should be addressed.

(TMDA)[7] and (OX)[2] individually, there can be at most three mixed complex species.

$$F_{00}(XY) = \text{antilog}\left[\frac{0.4343nF}{RT}\Delta E_{1/2} + \log\left(\frac{I_M}{I_C}\right)\right]. \quad (2)$$

Thus, eqn (2) may be changed to the form

$$F_{00}(XY) = \text{antilog}\left\{\frac{0.4343nF}{RT}\Delta E_p + \log\left[\frac{(I_p)_s}{(I_p)_c}\right]\right\}, \quad (3)$$

where $\Delta E_p = (E_p)_s - (E_p)_c$ is the shift in the peak potential due to complexation.

It has been reported,[3] that for a reversible diffusion controlled process, the peak potential (E_p) obtained from d.p. polarography wave is related to the half-wave potential of DC polarography by the expression

$$E_p = E_{1/2} - \frac{\Delta E}{2},$$

where ΔE is the magnitude of the pulse amplitude.

From Leden's approach[8]

$$\begin{aligned} F_{00}(XY) = {} & \{B_{00} + B_{01}[Y] + B_{02}[Y]^2 \\ & + B_{03}[Y]^3\}[X]^0 \\ & + \{B_{10} + B_{11}[Y] + B_{12}[Y]^2\}[X] \\ & + \{B_{20} + B_{21}[Y]\}[X]^2 \\ & + \{B_{30}\}[X]^3 \end{aligned}$$

or

$$F_{00}(XY) = A + B[X] + C[X]^2 + D[X]^3.$$

The original graphical method[1] may be applied to F_{00} if the activity of one of the ligands is held constant while that of the other is varied. The intercept on the F_{00} axis in the plot of F_{00} vs $[X]$ gives A, and

$$F_{10} = \frac{F_{00} - A}{[X]} = B + C[X] + D[X]^2.$$

By a similar plotting of F_{10} vs $[X]$, B is obtained and then C and D by iteration.

From the knowledge of C, the mixed stability constant β_{21} may be calculated. In order to determine β_{11} and β_{21}, B must be evaluated at two concentrations of Y.

RESULTS AND DISCUSSION

Equation (1) by Deford and Hume as modified by Heath and Hefter[3] was applied to determine the stability constants of the simple complexes using d.p. polarography. The stability constants are recorded in Table 1. For Cd(OX) system, the stability constants are in good agreement with previously reported values.[2,9–11] In the case of the Cd(TMDA) system, the results agree well with the values reported by Gupta[7] considering the differences in experimental conditions.

Table 1. Stability constants of simple and mixed complexes

Complex species	Stability constants at 25°C	
$[Cd(OX)]$	$\log \beta_{01}$	2.65
$[Cd(OX)_2]^{2-}$	$\log \beta_{02}$	4.10
$[Cd(OX)_3]^{4-}$	$\log \beta_{03}$	5.07
$[Cd(TMDA)]^{2+}$	$\log \beta_{10}$	5.60
$[Cd(TMDA)_2]^{2+}$	$\log \beta_{20}$	7.54
$[Cd(TMDA)_3]^{2+}$	$\log \beta_{30}$	8.55
$[Cd(TMDA)(OX)]$	$\log \beta_{11}$	6.78
$[Cd(TMDA)(OX)_2]^{2-}$	$\log \beta_{12}$	7.54
$[Cd(TMDA)_2(OX)]$	$\log \beta_{21}$	8.20

It is important to show that for simple and mixed complexes of our work, the ΔE_p values obtained from d.p. polarograms were confirmed using tast polarography ($\Delta E_{1/2}$). It was found that the ΔE_p and $\Delta E_{1/2}$ are not in exact agreement, but in all cases are within the experimental error. The E_p values were generally reproducible to ± 1 mV.

In the mixed ligand system, the concentration of trimethylenediamine was varied while that of the oxalate ions was kept constant at two values, 0.04 M and 0.2 M. The derived functions F_{00}, F_{10}, F_{20} and F_{30} are recorded in Tables 2 and 3.

The half-peak width of a d.p. polarography wave has been reported by a number of workers.[3,12,13] They reported a value of 62 mV for reversible two-electrons reduction with an applied pulse of 50 mV. In the present work, for simple and mixed complexes the d.p. polarograms in nitrate medium had half-peak widths of 62 ± 1 mV, as shown from Tables 2 and 3, indicating the reversibility of the reduction. For further confirmation, tast polarography was used under the same conditions used for d.p. polarography. The plots of $\log [i/(i_d - i)]$ vs $E_{d.e.}$ were linear of 31 ± 1 mV, indicating a high degree of reversibility. Furthermore, the plots of peak current (i_p) of d.p. waves vs $h^{1/2}$ of mercury column were linear, indicating that the reduction of simple and mixed complexes was diffusionally controlled.

The stability constants of the mixed ligand complexes were evaluated using Schaap and McMasters'[2] method using eqn (3) of the d.p. wave. The results of A, B, C and D are presented in Tables 2 and 3.

For the two values of B, the formation constants

0.35	0.828	216	0.0477	62	2287.17	652.90	18.40	4.13

$A = 2 \times 10^4$, $B = 7 \times 10^5$, $C = 4 \times 10^7$, $D = 3.9 \times 10^8$.

β_{11}, β_{12} were calculated for [Cd(TMDA)(OX)] and $[Cd(TMDA)(OX)_2]^{2-}$ as shown from Table 1. The two values of C gave two values for $\log \beta_{21} = 8.12$, 8.28, in good agreement with each other. On the other hand, the average values of D ($\log \beta_{30}$) from both series is 8.71 ± 0.1. This agrees well with values of $\log \beta_{30} = 8.55$ calculated for the $[Cd(TMDA)_3]^{2+}$ complex from the simple system.

It was observed that the addition of trimethylenediamine to a solution of Cd(II) and oxalate shifts the E_p to more negative side, showing that mixed complexes are formed in solution.

The mixing constant,[14,15] $\log K_m = \log \beta_{11} - \frac{1}{2}(\log \beta_{02} + \log \beta_{20})$ and stabilization constant ($\log K_s = \log K_M - \log 2$)[16] are 0.96 and 0.66 respectively. The positive values of mixing constant and stabilization constant show that the ternary complexes more stable than the binary complexes.

Moreover, the disproportionation reaction

$$2[Cd(TMDA)(OX)] \rightleftharpoons [Cd(TMDA)_2]^{2+} + [Cd(OX)_2]^{2-}$$

has a value of $\log K = -1.92$, which shows the stability of the mixed complexes.

Table 3. Derived (F_{i0}) functions for the cadmium (TMDA–oxalate) system. $[Cd]^{2+} = 1 \times 10^{-4}$ M. Ionic strength = 1 M. [Oxalate] = 0.2 M. $(E_p)_s = -0.612$ V

0.30	0.829	217	0.0545	62	251.16	83.22	2.37	6.47
0.35	0.835	223	0.0545	62	400.11	113.89	3.17	6.97

$A = 1.5 \times 10^5$, $B = 3 \times 10^6$, $C = 7.3 \times 10^7$, $D = 6.5 \times 10^8$.

The stability constants of mixed complexes have been estimated theoretically using the method of Watters and DeWitt.[17] The values are

$$\log \beta_{11} = 5.32, \quad \log \beta_{12} = 6.70,$$
$$\text{and} \quad \log \beta_{21} = 7.86.$$

These values are less than the observed values by amounts $10^{1.46}$, $10^{0.83}$ and $10^{0.34}$ respectively. The higher experimental values may be due to cooperative effects of electrostatic forces between different kinds of ligands and steric effects as concluded by other workers.[2,10,18]

The equilibrium constants (log values) have been calculated and written against each equilibrium:

		log K
(1)	$Cd^{2+} + (TMDA) + OX^{2-} \rightleftharpoons [Cd(TMDA)(OX)]$	6.78
(2)	$Cd^{2+} + (TMDA) + 2OX^{2-} \rightleftharpoons [Cd(TMDA)(OX)_2]^{2-}$	7.53
(3)	$Cd^{2+} + 2(TMDA) + OX^{2-} \rightleftharpoons [Cd(TMDA)_2(OX)]$	8.20
(4)	$[Cd(TMDA)]^{2+} + OX^{2-} \rightleftharpoons Cd(TMDA)(OX)]$	1.18
(5)	$[Cd(TMDA)_2]^{2+} + OX^{2-} \rightleftharpoons [Cd(TMDA)_2(OX)]$	0.66
(6)	$[Cd(OX)] + TMDA \rightleftharpoons [Cd(TMDA)(OX)]$	4.13
(7)	$[Cd(OX)_2]^{2-} + TMDA \rightleftharpoons [Cd(TMDA)(OX)_2]^{2-}$	3.43
(8)	$[Cd(OX)_3]^{4-} + TMDA \rightleftharpoons [Cd(TMDA)(OX)_2]^{2-} + OX^{2-}$	2.46
(9)	$[Cd(TMDA)(OX)] + OX^{2-} \rightleftharpoons [Cd(TMDA)(OX)_2]^{2-}$	0.75
(10)	$[Cd(TMDA)(OX)] + TMDA \rightleftharpoons [Cd(TMDA)_2(OX)]$	1.42
(11)	$[Cd(TMDA)(OX)_2]^{2-} + TMDA \rightleftharpoons [Cd(TMDA)_2(OX)] + OX^{2-}$	0.67
(12)	$[Cd(TMDA)_2(OX)] + TMDA \rightleftharpoons [Cd(TMDA)_3] + OX^{2-}.$	0.35

It is seen from the above equilibria that TMDA adds to [Cd(TMDA)(OX)] complex more easily than OX^{2-} [equilibria (9) and (10)]. The saturated mixed complexes can accommodate TMDA in place of OX^{2-} [equilibria (8), (11) and (12)]. Thus, the complexing tendency of TMDA is much more than OX^{2-}. These observations are in line with the weaker nature of the oxalate ligand. Equilibrium (8) favours mixed complexation over the simple. In the same way there are many other reactions which favour mixed complexation over the simple ones [equilibria (4)–(7)].

ORGANOTELLURIUM CATIONS: ORGANOTELLURIUM PERCHLORATES AND THEIR COMPLEXES WITH LEWIS BASES

T. N. SRIVASTAVA, V. K. SRIVASTAVA and R. C. SRIVASTAVA*
Chemistry Department, Lucknow University, Lucknow 226007, India

(*Received* 6 *September* 1984; *accepted* 14 *November* 1984)

Abstract—Solutions of diorganotellurium(IV) diperchlorates $R_2Te(ClO_4)_2$ (where R = Ph, *p*-$CH_3OC_6H_4$, $R_2Te = \overline{C_4H_8Te}$) may be prepared by the reaction of R_2TeCl_2 and $AgClO_4$ or by the reaction of diorganyltelluroxide with excess of 70% $HClO_4$. IR and conductivity data indicate that $Ph_2Te(ClO_4)_2$ possesses covalently bonded perchlorate groups in solution. Interaction of the freshly prepared solutions with Lewis bases affords cationic complexes of the types $[R_2Te(ClO_4)(L)][ClO_4]$ and $[R_2Te(L)_2][ClO_4]_2$ which have been characterised by IR elemental analyses and conductivity measurements.

Triorganotelluronium salts containing the monocation $[R_3Te]^+$ are numerous (but see Ref. 1) but the dications $[R_2Te]^{2+}$ are yet to be prepared. displacement of the halide groups (X) from R_2TeX_2 by poorly coordinating groups may be expected to yield the dication. The only attempt in this direction seems to have been made by Lowry and Gilbert who isolated dimethyltellurium diperchlorate and formulated it as $[Me_2Te(OClO_3)]^+[ClO_4]^-$ on the basis of only conductivity data.[2]

In this paper we report (a) the solution behaviour of $Ph_2Te(ClO_4)_2$ and (b) the preparation of a few cationic complexes of diorganotellurium diperchlorates. A complex of $[Ph_2TeMe][ClO_4]$ has also been included for comparison. Lewis bases used include triphenylarsine oxide (TPAsO), pyridine-N-oxide (PyO), 4-picoline-N-oxide (γ-PicO), lutidine-N-oxide (LutO), dimethyl sulphoxide (DMSO), tetramethyl urea (TMU), tetramethylethylenediamine (TMEN), pyridine (Py), tetramethylpiperidine (TMP) and triphenylphosphine sulfide (TPPS). The analytical data for the complexes are shown in Table 1.

EXPERIMENTAL

Diaryltellurium dichlorides,[3,4] 1-telluracyclopentane diiodide,[5] diphenylmethyltelluronium iodide,[6] diphenyltelluroxide[7] and silver perchlorate[8] were prepared by reported methods. All the Lewis bases were obtained from BDH and were further purified, either by distillation under reduced pressure or by recrystallisation from suitable solvents. Molecular weight was determined cryoscopically using a Beckmann thermometer of ±0.01° accuracy. Molar conductance of 10^{-3} *M* solution was determined at 25°C using a Philips conductivity assembly PR-9500. The IR spectra were recorded on a Perkin–Elmer 577 grating spectrophotometer. Nuclear magnetic resonance spectra in $CDCl_3$ or $(CD_3)_2CO$ were recorded on a Perkin–Elmer R-32 spectrophotometer.

Preparation of complexes

Typical experiments are described below.

All operations were carried out under dry nitrogen.

1. *$Ph_2Te(DMSO)(ClO_4)_2$*. Diphenyltellurium dichloride (0.70 g; 2 mmol) in dichloromethane (~ 30 cm^3) was stirred with $AgClO_4$ (0.83 g; 4 mmol) for ~ 1 h at room temperature. The precipitated silver chloride (0.53 g, 95%) was filtered off and the filtrate containing diphenyltellurium diperchlorate was treated with dimethylsulphoxide (0.15 g; 2 mmol) in dichloromethane (~ 10 cm^3). The mixture was refluxed for ~ 5 h. Excess of the solvent was distilled off and the desired product was obtained as a white crystalline solid by addition of excess pet.-ether (bp 40–60°C). It was recrystallized with a mixture of dichloromethane and pet.-ether (1 : 3) and dried *in vacuo*.

The same complex, $Ph_2Te(DMSO)(ClO_4)_2$, was

also prepared by refluxing a mixture of diphenyltelluroxide (1.15 g; 4 mmol) in ethanol (80 cm^3), slight excess of perchloric acid (70%) and dimethyl sulphoxide (0.31 g; 4 mmol) for ~ 10 h.

2. *$\overline{C_4H_8Te}(Py)_2(ClO_4)_2$*. $\overline{C_4H_8TeI_2}$ (0.87 g; 2 mmol) in dichloromethane (40 cm^3) was stirred with $AgClO_4$ (0.83 g; 4 mmol) for 1 h at room temperature. The precipitated silver iodide (0.93 g; 98%) was filtered off, and the filtrate was treated with a solution of pyridine (0.31 g; 4 mmol) in dichloromethane (10 cm^3). The mixture was refluxed for ~ 5 h. Excess of the solvent was distilled off and the product was precipitated by addition of an excess of pet.–ether. It was washed several times with the same solvent and dried *in vacuo*.

3. *$Ph_2MeTe(PyO)(ClO_4)$*. Ph_2MeTeI (0.84 g; 2 mmol) was stirred with $AgClO_4$ (0.41 g, 2 mmol) at room temperature for 1 h. The precipitated silver iodide (0.46 g; 98%) was filtered off under dry nitrogen. The filtrate, on concentration, yielded diphenylmethyltelluronium perchlorate, m.p. 156°C (see Table 1).

Diphenylmethyltelluronium perchlorate (0.79 g, 2 mmol) in dichloromethane (50 cm^3) was treated with pyridine-N-oxide (0.19 g; 2 mmol) in the same solvent (20 cm^3) and the solution was refluxed for 5 hr. Excess of the solvent was distilled off and the residual solution was kept overnight in a freezer. Colourless crystals were obtained. The complex was recrystallized from $CHCl_3$/pet.–ether (1:3) and dried *in vacuo*.

RESULTS AND DISCUSSION

Diorganotellurium(IV) dihalides react with silver perchlorate metathetically to give solutions of the corresponding diperchlorates. Dichloromethane solution of $Ph_2Te(ClO_4)_2$ is nonconducting (conductance = 0.78 Ω^{-1} mol^{-1} cm^2) whereas its solution in acetonitrile shows 1:1 electrolytic (conductance = 158.5 Ω^{-1} mol^{-1} cm^2) behaviour.[9] The IR spectrum of $Ph_2Te(ClO_4)_2$ in chloroform shows the presence of monodentately bonded perchlorate groups (*vide infra*). These observations suggest that $Ph_2Te(ClO_4)_2$ possesses covalently bonded perchlorate groups and the Te atom is four coodinated. Unfortunately, our attempts to isolate $R_2Te(ClO_4)_2$ invariably resulted either in its reduction to Te metal or isolation of a crystalline compound (structure of which is under investigation) which shows the presence of strong absorptions due to ν(OH) and δ(OH) in its IR spectra.

In order to get more insight into the nature of the perchlorate groups, the solutions of diorganotellurium diperchlorates were reacted with a number of Lewis bases. Whereas $Ar_2Te(ClO_4)_2$ afforded 1:1 complexes even in the presence of an excess of ligand, the $\overline{C_4H_8Te}(ClO_4)_2$ gave 1:2 complexes.

$$R_2Te(ClO_4)_2 + nL \rightarrow R_2Te(L)_n(ClO_4)_2 \quad (1)$$

$$R = Ph,\ p\text{-}CH_3OC_6H_4;\quad n = 1$$

$$R_2Te = \overline{C_4H_8Te};\quad n = 2.$$

The complexes of diaryltellurium diperchlorates were also obtained by refluxing a mixture of R_2TeO, $HClO_4$ (70%) and the Lewis base in ethanol.

Diphenylmethyltellurium perchlorate also interacts with one mole of pyridine-N-oxide forming the complex $Ph_2MeTe(PyO)(ClO_4)$. Attempts to prepare 1:2 adducts resulted in the decomposition of the complex.

All of the complexes (Table 1) are colourless crystalline solids and generally soluble in dichloromethane, acetone and acetonitrile. The complexes are generally stable towards atmospheric moisture and melt sharply, excepting $[\overline{C_4H_8Te}(DMSO)_2][ClO_4]_2$ which explodes at ~ 116°C; other complexes explode only on strong heating.

The molecular weights of the newly synthesised compounds were determined cryoscopically in freezing nitrobenzene and were found to be approximately one third of the calculated value for the complexes $\overline{C_4H_8Te}(L)_2(ClO_4)_2$ and half of the calculated values for $Ar_2Te(L)(ClO_4)_2$ and $Ph_2MeTe(L)(ClO_4)$.

Molar conductance of 10^{-3} *M* solution of the complexes in acetonitrile and acetone was determined at room temperature; the data are collected in Table 1. The values for the complexes $\overline{C_4H_8Te}(L)_2(ClO_4)_2$ in acetonitrile lie in the range (265–271 Ω^{-1} mol^{-1} cm^2 whereas for $Ar_2Te(L)(ClO_4)_2$ and $Ph_2MeTe(L)(ClO_4)$, the range is 120–160 Ω^{-1} mol^{-1} cm^2. In acetone, the corresponding values are 186–188 and 100–140 Ω^{-1} mol^{-1} cm^2 respectively. The conductivity and molecular weight data indicate that the complexes $\overline{C_4H_8Te}(L)_2(ClO_4)_2$ behave as 1:2 electrolytes whereas $Ar_2Te(L)(ClO_4)_2$ and $Ph_2MeTe(L)(ClO_4)$ are 1:1 electrolytes.[9] Molar conductance of $Ph_2Te(ClO_4)_2$ in $CHCl_3$ was found to be 0.7 Ω^{-1} mol^{-1} cm^2 which corresponds to its non-electrolytic nature.

Perchlorate group. The nature of the bonding of perchlorate groups in the complexes can be distinguished by identifying the number of infrared active bands.[10–12] The ionic perchlorate group belongs to point group T_d having nine vibrational degrees of freedom distributed between four normal

modes of vibration. It shows only two IR active absorption due to ν_3 (1100 cm^{-1}) and ν_4 ($\sim$ 620 cm^{-1}) whereas ν_1 and ν_2 are Raman active.[10] If the perchlorate group is involved in partial covalent bonding between one of its oxygen atom and the cation, the symmetry of the perchlorate group is lowered to C_{3v}. The triple degeneracy is removed with the result that ν_3 and ν_4 both split into two peaks and ν_1 ($\sim$ 930 cm^{-1}) and ν_2 (460 cm^{-1}) modes become IR active.[10,13]

The IR spectra of $Ph_2Te(ClO_4)_2$ in $CHCl_3$ shows the splitting of ν_3 and ν_4 bands into two appearing at (1125, 1080 cm^{-1}) and (630, 620 cm^{-1}) respectively indicating the presence of monodentately bonded perchlorate groups.[10] A medium absorption at 920 cm^{-1} due to ν_1 which has become infrared active (due to reduction of the local symmetry of ClO_4 from T_d to C_{3v}) also supports the presence of covalently bonded perchlorate groups.[14] This observation is also supported by the conductivity data of $Ph_2Te(ClO_4)_2$ in chloroform in which it behaves as a non-electrolyte.

Diphenylmethyltelluronium perchlorate was assigned an ionic structure $[Ph_2MeTe][ClO_4]$ on the basis of conductivity data.[15,16] In the present work this structure has been substantiated by recording its IR spectrum. The IR spectra of $Ph_2MeTe(ClO_4)$ and $Ph_2MeTe(PyO)(ClO_4)$, give rise to a broad absorption band at 1100 cm^{-1} due to ν_3 and a sharp band at 620 cm^{-1} due to ν_4 (Table 2) which indicates the nature of the perchlorate group to be ionic.[10–12] Moreover, the absence of a band at 920 cm^{-1} due to ν_1 mode supports the ionic nature of the perchlorate group.[14] These observations are also supported by conductivity data (Table 1) and are in accordance with Figs. 1 and 2.

An examination of the IR spectra of the complexes $Ar_2Te(L)(ClO_4)_2$ (Ar = Ph, *p*-$CH_3OC_6H_4$) reveals that in the 1100 cm^{-1} region the spectrum is fairly complex. However, it is possible to assign the peaks in this region to ionic and coordinated perchlorate groups. In the spectrum of each of these compounds the peak around 1100 cm^{-1} is assigned to ionic perchlorate group and the peaks around 1140 and 1080 cm^{-1} (Table 2) are attributed to monodentately coordinated perchlorate group. The spectra of these complexes also show a weak but sharp absorption around 910 cm^{-1} due to the ν_1 mode, which has become IR active due to the reduction of the symmetry of one of the two perchlorate groups from T_d to C_{3v}. The band at 625 cm^{-1} is also split showing coordination of one of the perchlorate groups.[10] The extent of the splitting in the latter case is however so small that in several cases the peak due to ionic perchlorate overlaps with one of the two peaks due to coordinated perchlorate with the result that only two peaks are observed. The ν_2 band expected around 450 cm^{-1} is generally obscured by the strong ring vibration in this region.[14]

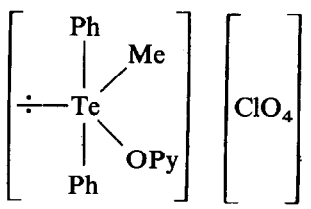

Fig. 2.

The fact that only one perchlorate group is coordinated in the complexes $Ar_2Te(L)(ClO_4)_2$ is also supported by conductivity data (Table 1) of these complexes which behave as 1 : 1 electrolytes even in acetonitrile and acetone in accordance with Fig. 3.

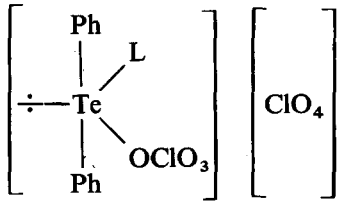

Fig. 3.

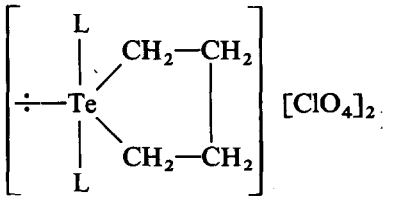

Fig. 4.

In the spectra of the complexes $\overline{C_4H_8Te}(L)_2(ClO_4)_2$, the presence of only one broad band around 1100 cm^{-1} (due to ν_3) and a single sharp band around 625 cm^{-1} (due to ν_4) suggests that both the perchlorate groups are ionic, Fig. 4. The disappearance of the absorption band around 920 cm^{-1} (due to ν_1) rules out the presence of a monodentately coordinated perchlorate group. This

observation is also supported by the conductivity data (Table 1). These complexes behave as 1:2 electrolytes in acetonitrile in accordance with Fig. 4.

Coordinated ligands. A critical comparison of the spectra of free ligands with those of the corresponding complexes has been made and the data (Table 3) interpreted in terms of coordination from the Lewis bases.

Oxygen donors. In the complexes with oxygen donors the coordination site was established by a change of $\nu_{E=O}$ frequency (E = N, S, C or As). A negative shift of $\nu_{E=O}$ is taken as a convincing evidence for coordination through the oxygen atom of the bases (Table 3).[17–21]

TPPS. The ν(P=S) mode of vibration has been identified for the free ligand at 630 cm^{-1} by previous workers.[22] Its negative shift to 535 cm^{-1} is attributed to a decrease in double bond character of the (P=S) double bond due to S → Te bonding.

Py. In the free base the C=C, C=N and ring stretchings occur at 1583, 1578 and 1439 cm^{-1} respectively. On complexation these absorptions undergo positive shifts, appearing at ~ 1625, ~ 1595 and ~ 1480 cm^{-1} respectively (Table 3) and thus support the coordination from the nitrogen atom of the base.[23]

TMP. The coordination through the nitrogen atom of the TMP is confirmed by the negative shifts of ν(N–H), δ(N–H) and ν(C–N) appearing at 3330, 1570 and 1240 cm^{-1} in pure ligand to ~ 3000, ~ 1575 and ~ 1220 cm^{-1} respectively in the complexes (Table 3).[24]

TMEN. A comparison of the spectrum of the free ligand (TMEN) with that of its complexes reveals a positive shift of ν(C–N) mode of vibration on complexation (Table 3) indicating coordination from the "N" atom of the ligand.[25] The presence of coordinated base was further confirmed by ^{1}H NMR spectra.

^{1}H NMR spectra of a few representative complexes are listed in Table 4.

(*Received* 6 *November* 1984; *accepted* 29 *November* 1984)

Abstract—The photolysis of $Fe(\eta^1\text{-dmpm})(dmpm)_2$ [dmpm = bis(dimethylphosphino) methane] with $Cr(CO)_6$ and $Fe(CO)_5$ under UV irradiation produces $FeCr(CO)_6(\mu\text{-dmpm})_2$, $Fe_2(CO)_6(\mu\text{-CO})(\mu\text{-dmpm})$ and $Fe_2(CO)_4(\mu\text{-CO})(\mu\text{-dmpm})_2$ respectively. The interaction of $Mo(CO)_3(MeCN)_3$ and $(C_7H_8)Cr(CO)_3$ with dmpm produces $Mo_2(CO)_6(\mu\text{-dmpm})_3$ and *cis*-$Cr(CO)_2(dmpm)_2$ respectively. The X-ray crystal structure of $FeCr(CO)_6(\mu\text{-dmpm})_2$ shows the molecule to contain a trigonal bipyramidal $Fe(CO)_3P_2$ unit plus a square pyramidal $Cr(CO)_3P_2$ unit held closely together by the methylene bridges of the dmpm ligands with steric compression between the CO groups causing distortions from ideal geometry in each case. The Cr . . . Fe distance is 3.111(6) Å and there seems to be little structural evidence of any form of interaction between the 16*e* Cr(0) centre and the Fe-containing unit. The structure of $Fe_2(CO)_4(\mu\text{-CO})(\mu\text{-dmpm})_2$ contains a symmetrical μ_2-carbonyl and a single bond between the two symmetry related (m) iron atoms. The Fe . . . Fe distance is 2.719(4) Å.

We have recently reported the synthesis of the bis(dimethylphosphino)methane complexes $Fe(\eta^2\text{-dmpm})(dmpm)_2$ and $FeR_2(dmpm)_2$ (R = Me and CH_2Ph).[1] Here we report further studies on the reactivity of $Fe(\eta^1\text{-dmpm})(dmpm)_2$, which has a free phosphorus atom available to act as a ligand, towards $Fe(CO)_5$ and $Cr(CO)_6$ to give mixed Fe–Fe or Fe–Cr dimers; the further coordination of η^1-bis(diphenylphosphino)methane(dppm) complexes is already established.[2] We also describe the synthesis of $Mo_2(CO)_6(\mu\text{-dmpm})_3$ and *cis*-$Cr(CO)_2(dmpm)_2$. After completion of these studies, a recent paper has described some similar chemistry of dmpm, including the compounds $Mo_2(CO)_6(dmpm)_3$, $Fe_2(CO)_5(dmpm)_2$ and $Fe_2(CO)_7(dmpm)$ described herein, but no X-ray crystallographic data was obtained.[3]†

RESULTS AND DISCUSSION

Reactions of $Fe(\eta^1\text{-dmpm})(dmpm)_2$

(a) *With hexacarbonylchromium.* When the iron compound in tetrahydrofuran containing excess $Cr(CO)_6$ was irradiated with ultraviolet light at room temperature a red crystalline compound was obtained. Recrystallisation from toluene gave $FeCr(CO)_6(dmpm)_2 \cdot C_7H_8$, which is moderately stable in air. The structure was determined by X-ray diffraction and a molecule is shown in Fig. 1; selected bond lengths and angles are given in Table 1. At the simplest level, the complex can be considered to comprise two $M(CO)_3P_2$ units linked together by the bridged dmpm ligands, with the heterobimetallic nature of the complex giving rise to potential differences in geometries at the metal centres. Furthermore, the differences in electron counts at the metals, 18 at Fe and 16 at Cr, might be expected to

†The compounds $Fe_2(\mu\text{-CO})(CO)_n(\mu\text{-}R_2pyPR_2)_m$, $n = 6$, $m = 1$, $n = 4$, $m = 2$, including R = Me and Y = CH_2, have also been reported by DeLeew *et al.*, *J. Organomet. Chem.* 1984, **375**, 99.

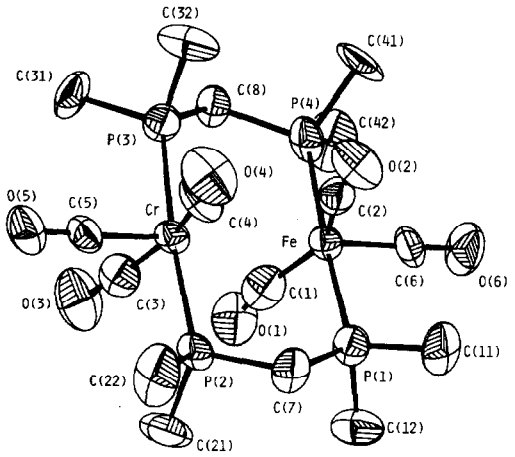

Fig. 1.

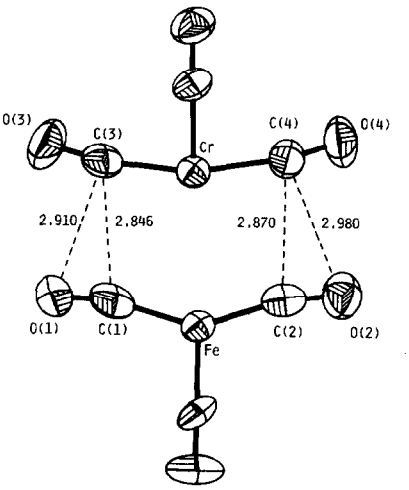

Fig. 2.

lead to some kind of interaction between them. At both centres, the two M–P bonds are mutually *trans* and give P–M–P angles close to 180°; this leaves the arrangement of the "equatorial" carbonyl ligands to reflect any differences in geometry. It is therefore convenient to view the structure in a direction parallel to the P–M–P directions, and this is shown in Fig. 2. The most obvious interpretation of the distribution of the three carbonyls at each metal is that the $Fe(CO)_3P_2$ unit has a distorted trigonal bipyramidal geometry, whilst the $Cr(CO)_3P_2$ unit has a distorted square pyramidal geometry. The main source of the distortion is most likely to be steric compression between those carbonyl groups which are required to point towards each other.

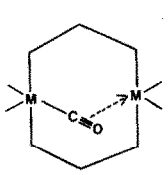

Table 1. Selected bond lengths and angles for $FeCr(CO)_6(dmpm)_2 \cdot C_7H_8$

(a) Bond lengths (Å)			
P(1)–Fe(1)	2.201(4)	P(2)–Fe(1)	2.201(4)
C(1)–Fe(1)	1.931(7)	C(2)–Fe(1)	1.733(8)

Key to symmetry operations relating designated atoms to reference atoms at (x, y, z): (a) $x, 0.5-y, z$.

Thus, the expected 120° angle between the CO groups C(1), C(2), on the iron atom is increased to 146°, whilst the expected obtuse axial/basal angles C(5)–Cr–C(3), C(4) on the chromium atom have been made acute, with values of *ca* 82°. The close approaches between the CO groups which still remain are seen on Fig. 2.

The "square pyramidal" 16*e* Cr(0) system coordinated by five π-acceptor ligands, might be expected to seek further electron density to achieve an 18*e* configuration. This would occur in one of two ways: (a) by one of the CO groups on Fe acting as a

1

2

σ–π bridge, of the type **1** suggested for $Mn_2(CO)_5(dppm)_2$,[4] or (b) via direct Fe → Cr σ-bonding, using a filled orbital on iron. The former seems most unlikely in view of the arrangement of the CO groups on Fe (Fig. 2) where the Fe–C–O unit is bent at the carbon, directing the C=O bond away from the chromium. Accordingly we assume that any interaction involving the chromium atom is most likely to be of the Fe → Cr type, even though the Fe–Cr distance is long, at 3.111(6) Å.

The IR, ^1H and ^{31}P–$\{^1H\}$ NMR spectra of the compounds (see Experimental) are consistent with the structure as determined.

(b) *With pentacarbonyliron.* Similar photolysis in THF containing excess $Fe(CO)_5$ gave two compounds $Fe_2(CO)_5(dmpm)_2$ and $Fe_2(CO)_7(dmpm)$ both of which are moderately stable in air, slightly soluble in saturated hydrocarbons but soluble in toluene.

The molecular structure of $Fe_2(CO)_5(dmpm)_2$, which has mirror symmetry, is shown in Fig. 3; selected bond lengths and angles are given in Table 2. In this case, if the bridging carbonyl is considered to be "ketonic", and acting as a 1*e* σ ligand for each Fe atom, then completion of 18*e* configuration for the metal requires a single Fe–Fe bond. The closer association of the two metal centres in this complex is seen both in Fig. 3 and in the value of the Fe . . . Fe distance 2.719(4) Å. The structure as found was also proposed on the basis of spectroscopic data.[3]

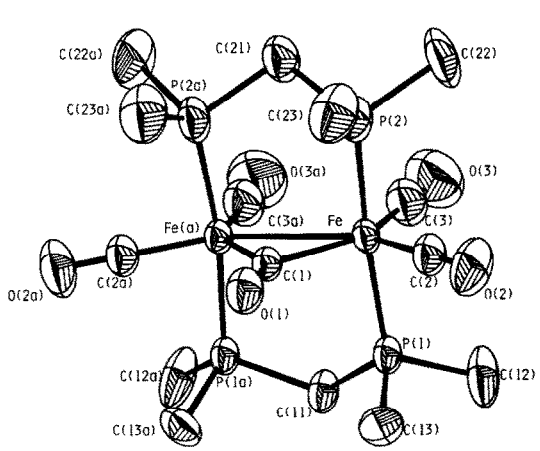

Fig. 3.

The compound $Fe_2(CO)_7(dmpm)$ is readily formulated as $Fe_2(CO)_6(\mu\text{-CO})(\mu\text{-dmpm})$ on the basis of spectra (cf. ref. 3).

$Mo_2(CO)_6(dmpm)_3$ and $Cr(CO)_2(dmpm)_2$

The displacement of cycloheptatriene from $C_7H_8M(CO)_4$, (M = Cr and Mo) gives $M_2(CO)_6(dmpm)_3$.[3] These species were formulated on the basis of NMR spectra as having one bridging and two chelating dmpm ligands; also the reaction of $Mo(CO)_3(MeCN)_3$ with dmpm in *boiling* MeCN is said to give $Mo(CO)_3(dmpm)_3$ that has three unidentate dmpm ligands.[3]

However, we find that interaction of dmpm with $Mo(CO)_3(MeCN)_3$ at *ambient* temperature affords pale yellow prisms (from MeCN) of a compound of the same stoichiometry as King's, namely $Mo_2(CO)_6(dmpm)_3$, but which is evidently an isomer with three bridging dmpm ligands, since the ^1H and ^{31}P NMR spectra differ considerably from King's complex.

Thus the ^1H spectrum in CD_3CN shows two broad singlets at δ1.54 and 2.11 ppm corresponding to the CH_2 and CH_3 protons of dmpm while the ^{31}P spectrum in CD_3CN shows only a singlet at −12.0 ppm. The IR spectrum has two terminal CO stretches at 1930 and 1800 cm^{-1}. Analogous compounds $M_2(CO)_6(P\text{–}P)_3$, M = Cr, Mo, W and P–P = dppe and dmpe, are known[5] but, like King's compound, Connor formulated $Mo_2(CO)_6(dmpe)_3$ as having both chelate and bridging dmpe ligands since two ^{31}P and two ^1H (CH_2) resonances were observed.

The unstable $Cr_2(CO)_6(dmpe)_3$ made in low yield from $C_7H_8Cr(CO)_3$ and dmpe in boiling hexane[3] is said to be converted in solution to $Cr(CO)_3(dmpm)_2$ for which it is proposed that one of the dmpm ligands is unidentate on the basis of NMR spectra.[3]

Again, in the reaction at ambient temperature there appears to be a difference since our product appears to be *cis*-$Cr(CO)_2(dmpm)_2$. The IR spectrum has terminal CO stretches at 1908 and 1800 cm^{-1}. The ^1H NMR spectrum in C_6D_6 shows four doublets at δ1.39 ppm ($^2J_{PH}$ = 6.1 Hz), 1.25 ppm ($^2J_{PH}$ = 7.2 Hz), 1.14 ppm ($^2J_{PH}$ = 6.8 Hz) and 0.83

ppm ($^2J_{PH}$ = 3.5 Hz) for the CH_3 protons; there is a doublet of triplets at 2.6 ppm ($^2J_{PH}$ = 9.2 Hz, 1.3 Hz) and a doublet of doublets at 1.69 ppm ($^2J_{PH}$ = 3.3, 6.13 Hz) for the CH_2 protons. The ^{31}P–$\{^1H\}$ spectrum in C_6D_6 shows two triplets at 20.7 and 0.87 ppm with $^2J_{PP}$ = 35.5 Hz. These spectra suggest that the compound is the *cis* compound **2**. Connor has formulated both the Cr and Mo compounds, $M(CO)_2(dmpe)_2$ as *cis* on the basis of spectroscopic data.[5] The tetracarbonyl *cis*-$Cr(CO)_4(dmpm)$ has also been recently reported[3,6] [cf. *cis*-$M(CO)_4(dmpe)$[5]].

EXPERIMENTAL

Microanalyses were by Pascher (Bonn). IR spectra were obtained on a Perkin–Elmer 683 spectrometer; data in cm^{-1} for Nujol mulls unless otherwise specified. NMR spectra were recorded on a JEOL FX90Q; data in δ ppm referenced to Me_4Si (^1H) and 85% H_3PO_4 (^{31}P). Molecular weights were determined cryoscopically in benzene.

All operations were carried out under argon, nitrogen or *in vacuo*. All chemicals used were of reagent grade. Solvents were dried by standard procedures, distilled, and deaerated prior to use. Melting points were taken in sealed capillaries and are uncorrected. Fe(η^1-dmpm)(dmpm)$_2$,[1] $Mo(CO)_3(CH_3CN)_3$[7] and $Cr(C_7H_8)(CO)_3$[8] were made by published methods. Irradiations were made using an Applied Photo-Physics Ltd. medium pressure mercury lamp (125 W) type PR 311.0 and a water-cooled reactor.

1. *Hexacarbonyl bis[μ - bis(dimethylphosphino) methane)]iron chromium*(0)

A solution of Fe(dmpm)$_2$(η^1-dmpm) (0.46 g, 1 mmol) and $Cr(CO)_6$ (0.44 g, 2 mmol) in THF (150 cm^3) was photolysed for 18 hr at ambient temperature. The progress of the reaction was monitored by IR spectroscopy and the irradiation was continued until no further change in the spectrum of the reaction mixture was discernable. The orange red solution was evaporated under vacuum, the residue washed with hexane (2 × 50 cm^3) and extracted into toluene (2 × 50 cm^3). The filtered solution was concentrated to *ca* 20 cm^3 and cooled to −20°C to give red crystals. Yield: 0.4 g, 62%; m.p. 75°C (decomp.). The compound is slightly soluble in saturated hydrocarbons but readily soluble in toluene $CHCl_3$ and THF. [Found (required); C, 42.8 (43.1); H, 5.7 (5.7); P, 19.0 (19.4); O, 15.2 (15.0)%.]

IR: 2059w, 1963m, 1916vs, 1880vs, 1878vs, 1832vs, 1805s, 1780s, 1489w, 1411m, 1300m, 1286m, 1277m, 930s, 907w, 893m, 848w, 768m, 743m, 726m, 718m, 688m, 652s, 640m, 630m, 585s.

NMR: $^1H(CDCl_3)$: 2.18m (CH_2); overlapping doublets centred 1.55, $^2J_{PH}$ = 6 Hz; 1.50, $^2J_{PH}$ = 4.4 Hz (CH_3). ^{31}P–{^1H}($CDCl_3$): complex A_2B_2 14 line pattern centred at 36.5 ppm.

2. *Tetracarbonyl(μ - carbonyl)bis[μ - bis(dimethylphosphino)methane]diiron*(0); *hexacarbonyl(μ - carbonyl)μ - bis(dimethylphosphino)methane diiron*(0)

A solution of Fe(dmpm)$_2$(η^1-dmpm)(0.46 g, 1 mmol) and $Fe(CO)_5$ (2 cm^3, 15.2 mmol) in THF (1500 cm^3) was photolysed for 18 hr at ambient temperature and monitored by IR as above. The orange red solution was evaporated under *vacum*. The residue was washed with hexane (2 × 50 cm^3), then extracted with toluene (2 × 40 cm^3) to give a red solution. The residue was extracted with CH_2Cl_2 (2 × 30 cm^3). The CH_2Cl_2 solution was then filtered, concentrated to *ca* 5 cm^3 and cooled to −20°C to give orange crystals of $Fe_2(CO)_6$(μ-CO)(μ-dmpm). Yield: 0.13 g, 30%; m.p., 182°C (decomp.). [Found (required): C, 32.2 (32.5); H, 3.3 (3.2); P, 13.7 (13.9); O, 25.6 (25.3)%.]

IR: 2028s, 1986s, 1955s, 1942s, 1930s, 1907s, 1732s, 1423w, 1415w, 1302w, 1293w, 938m, 853w, 776w, 752w, 729w, 654w, 629m, 603m, 580w, 482w, 452w.

NMR: $^1H[(CD_3)_2CO]$: 2.50 t, $^2J_{PH}$ = 12 Hz, (CH_2); 1.70 pseudo t, $^2J_{PH}+{}^4J_{PH}$ = 9.3 Hz (CH_3). ^{31}P–{^1H}[$(CD_3)_2CO$]: 47.4s.

The above red toluene extract was evaporated *in vacuo*, and residue dissolved in CH_2Cl_2 (*ca* 2 cm^3). To the filtered solution was slowly added Et_2O (*ca* 5 cm^3) until the solution showed slight turbidity when it was cooled to −20°C to yield dark red crystals of $Fe_2(CO)_4$(μ-CO)(μ-dmpm)$_2$. Yield: 0.1 g, 20%; m.p. 210°C (decomp.). [Found (required): C, 34.0 (34.4); H, 5.3 (5.4); P, 23.3 (23.6); O, 15.5 (15.3)%.]

IR: 1940m, 1880s, 1862s, 1846m, 1660s (μ-CO), 1410w, 1406w, 1298w, 1286w, 937s, 850m, 754w, 742w, 722m, 650w, 630m, 615w, 480m.

NMR: $^1H[(CD_3)_2CO]$: 2.24m (CH_2); 1.53br.s (CH_3). ^{31}P–{^1H}[$(CD_3)_2CO$]: 52.7s.

3. *Hexacarbonyl tris[μ - bis(dimethylphosphino) methane]dimolybdenum*(0)

Dmpm (1 cm^3, 6.6 mmol) was added to a solution of $Mo(CO)_3(MeCN)_3$ (1.05 g, 3.46 mmol) in MeCN (50 cm^3) at ambient temperature. The mixture was stirred for 16 hr. After evaporation in vacuo the residue was washed with hexane (2 × 30 cm^3) and extracted into MeCN (40 cm^3). The solution was filtered, concentrated to *ca* 25 cm^3 and cooled to −20°C to give pale yellow crystals, insoluble in alkanes and Et_2O but soluble in MeCN. Yield: 1.2 g, 90%; m.p. 140°C (decomp.). Found (required): C, 32.5 (32.8); H, 5.4 (5.5); P, 23.8 (24.2); O, 12.7 (12.5)%.]

IR: 1930vs, 1800vs, 1435m, 1415m, 1300m, 1282m, 1115m, 940s, 930s, 900s, 865w, 840w, 820w, 792m, 730s, 710s, 680w, 630m, 612m, 600m, 523w, 460w.

NMR: $^1H(CD_3CN)$: 1.54br.s (CH_3); 2.11br.s (CH_2). ^{31}P–{^1H}(MeCN): −12.0s.

4. Cis - *bis(carbonyl)bis[bis(dimethylphosphino) methane]chromium*(0)

Dmpm (0.5 cm^3, 3.3 mmol) was added to a solution of $(C_7H_8)Cr(CO)_3$ (0.2 g, 0.88 mmol) in hexane (60

X-ray crystallography

For both compounds, crystals used for X-ray study were sealed under argon in thin-walled glass capillaries. Following preliminary photography, unit cell and intensity data were obtained using an Enraf–Nonius CAD4 diffractometer and graphite monochromatised Mo-K_α radiation ($\lambda = 0.71069$ Å), following standard procedures.[9] The structures were solved and refined *via* use of the heavy atom method and full matrix squares.[10] For the CrFe complex, which gives toluene solvated crystals the crystal quality and accordingly the intensity data were slightly below par. As a result no hydrogen atoms could be located and none were not included in the refinement. For the Fe_2 complex however, all hydrogens were located and freely refined with isotropic thermal parameters. Crystal data and details of the data collections and refinement are given in Table 3. Atomic co-ordinates, thermal parameters, full lists of bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor from whom copies are available on request. Atomic co-ordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Acknowledgement—We thank the SERC for support and for provision of the X-ray diffractometer.

SYNTHESIS AND CHARACTERISATION OF SOME SALTS OF THE IONS $[Rh(OXALATO)_2(Rpy)_2]^-$

A. Y. ALI MOHAMED,* R. D. GILLARD† and F. L. WIMMER‡
Department of Chemistry, University College, P.O. Box 78, Cardiff CF1 1XL, Wales, U.K.

(*Received* 7 *November* 1984; *accepted* 29 *November* 1984)

Abstract—Salts of three bisoxalato bis(pyridine) species, *trans*-$[Rh(ox)_2(py)_2]^-$, *trans*-$[Rh(ox)_2(3\text{-Mepy})_2]^-$ and *trans*-$[Rh(ox)_2(4\text{-Mepy})_2]^-$ have been isolated from the substitution of N-heterocycles into trisoxalatorhodate(III) and characterised on the basis of ^1H NMR and ^{13}C NMR spectra, which are similar to that of the *trans*-$[Co(oxalato)_2(R\text{-py})_2]^-$ complex.

Trisoxalatorhodate(III)§ hydrolyses in strong perchloric acid solution (like the analogous chromium(III) species) to a *cis–trans* equilibrium mixture of $[Rh(H_2O)_2(ox)_2]^-$ ions:[1,2] both the *cis*- and *trans*-isomers were isolated[2] after separation by anion exchange chromatography.

This *cis*-diaquoisomer reacts readily[2] with chloride to give the known *cis*-dichlorobisoxalatorhodate(III), which isomerises to *trans*-dichlorobisoxalatorhodate(III) when its solution is boiled, as noted by Delépine.[3]

There is, in the light of the present stereochemical findings, another related area of oxalatometallate(III) complex chemistry, that of dioxalatodipyridine iridate(III). This complex was prepared by Delépine:[4a,b] by heating either *cis*- or *trans*-$K_3[IrCl_2(ox)_2]$ for 1 hr or $K_3[Ir(ox)_3]$ for 4 hr with pyridine in a sealed tube at 130°C, sulphur-yellow crystals of *trans*-$K[Ir(ox)_2py_2]$ were obtained. The mother liquor gave an amorphous, yellow, readily soluble product, presumably containing the *cis*-isomer. The former product was not resolved by natural strychnine (though it gave a solid salt), and Delépine therefore allotted the *trans*-configuration to the ion in the *crystals*.

Although substitution of oxalate in trisoxalatoruthenate(III) by pyridine has been reported,[5–7] substitution in trisoxalatorhodate(III) has not previously been studied. Our aim was to investigate the reactions of $K_3[Rh(ox)_3]$ with pyridine.

EXPERIMENTAL

IR spectra (either in Nujol mulls or KBr discs) were obtained using Perkin–Elmer 257 and 457 double-beam grating spectrophotometers and a Unicam SP 3200 spectrophotometer. Electronic absorption spectra were measured using a Unicam SP 8000 spectrophotometer, using matched silica cells. ^1H NMR spectra were recorded on a Varian R32 spectrometer at 90 MHz, ^{13}C NMR spectra were recorded on a Varian X1-100-12 NMR spectrometer (25.2 MHz). Thermogravimetric analyses were recorded on a Stanton Redcroft VO 750 balance in N_2 atmosphere, with heating rates 2–10°/min. Carbon, hydrogen, nitrogen and halogen analyses were performed by the microanalytical laboratory at University College, Cardiff.

All chemicals (mainly from B.D.H.) were either of reagent grade or of analytical grade purity, and were used without further purification, except N-heterocyclic solvents which were dried over CaH_2, and distilled. "Rhodium trichloride-n-hydrate" was obtained from Johnson Matthey Chemicals Limited.

Preparation of $K_3[Rh(ox)_3]4.5H_2O$. This compound was prepared according to the method[8] of

§ Throughout this paper, the ethane-di-oic acid is called oxalic acid and the second conjugate base is called oxalate rather than the more familiar ethane-di-oate. This paper is based in part on the doctoral thesis of A. Y. Ali Mohamed (Univ. of Wales, 1982) where detailed spectra and the like are to be found.

Werner and Poupardin. A mixture of $RhCl_3 \cdot nH_2O$ (0.997 g), $K_2C_2O_4 \cdot H_2O$ (2.175 g) and water (27 cm^3), was heated on a steam bath for 3 hr. Ethanol was added to the deep red solution, and an oily material formed. On heating, the red oil changed to a yellow solid, which on further heating dissolved. The solution was concentrated by evaporation until yellow crystals began to form. On the addition of ethanol and cooling, a mass of yellow crystals separated. These were collected, washed with ethanol, air dried, and kept over silica gel (yield 3.0 g).

Reaction of $K_3[Rh(ox)_3]4.5H_2O$ *with pyridine.* A mixture of $K_3[Rh(ox)_3]4.5H_2O$ (0.13 g), water (6 cm^3) and pyridine (4 cm^3), was heated under reflux for 18 hr. The colour of the solution changed from orange to lemon yellow. Potassium oxalate was precipitated by the addition of an excess of ethanol, and the solution was concentrated to give yellow crystals of *trans*-$K[Rh(ox)_2py_2]1.5H_2O$ (0.079 g) which were recrystallised from hot water. Analysis for *trans*-$K[Rh(ox)_2py_2]1.5H_2O$ ($C_{14}H_{13}N_2O_{9.5}KRh$): Found: C, 33.58; H, 2.43; N, 4.95; Calc.: C, 33.41; H, 2.6; N, 5.56%.

Reaction of $K_3[Rh(ox)_3]4.5H_2O$ *with aqueous 4-methyl or 3-methyl pyridine.* A mixture of $K_3[Rh(ox)_3]4.5H_2O$ (165 mg), water (8 cm^3) and of either 4- or 3-methyl pyridine was refluxed for 26 hr. The colour of the refluxed mixture changed from yellow orange to yellow. A charge test on Sephadex resin [C25 and A25 columns] showed the product to be anionic. The final refluxed mixture was evaporated to dryness on a steam bath, then dissolved in a small volume of water: ethanol was added to this solution, when $K_2C_2O_4$ separated. This was removed by filtration and the filtrate taken to dryness. The residue was extracted with hot water: the extract, cooled at room temperature, gave fine pale yellow crystals of *trans*-$K[Rh(ox)_2(4\text{-}Mepy)_2]3H_2O$ (yield 65 mg, 39%), or pale creamy yellow fine crystals of $K[Rh(ox)_2(3\text{-}Mepy)_2]3H_2O$ (yield 70 mg, 42%). Analysis for *trans*-$K[Rh(ox)_2(Mepy)_2]3H_2O$ ($C_{16}H_{20}N_2O_{11}KRh$): Found: C, 35.49; H, 3.15; N, 5.5 (for 4-Mepy complex): C, 34.31; H, 3.02; N, 5.89 (for 3-Mepy complex): Calc.: C, 34.4; H, 3.58; N, 5.1%.

RESULTS AND DISCUSSION

Reaction of $[Rh(ox)_3]^{3-}$ *with pyridine.* When a solution of $K_3[Rh(ox)_3]$ in aqueous pyridine was heated under reflux, the colour of the solution changed from orange to lemon-yellow over a period of approximately 18 hr. Monitoring the reaction via the electronic spectrum showed a change in the wavelength of absorption due to the *d–d* transition from 400 to 348 nm. The product was shown to be anionic using ion exchange columns (Sephadex C25 gave no retention but A25 gave strong retention). The new complex ion was isolated as yellow crystals of its potassium salt from warm water and was characterised as $K[Rh(ox)_2py_2]1.5H_2O$.

A solution of $[Rh(ox)_2py_2]^-$ in aqueous pyridine (even with H_3PO_2 (5%) as catalyst) was unchanged after heating under reflux for 8 days. Possible reaction was monitored via the electronic spectrum. Samples were also periodically removed from the reaction mixtures and passed through short columns of Sephadex C25 and A25 resins: anionic starting material remains anionic (*trans*-$[Rh(ox)_2py_2]^-$).

Successive recrystallisation of $K[Rh(ox)_2py_2]$ from aqueous ethanolic solution gave three crops with constant electronic and infrared spectra suggesting the presence of one isomer only. The stereochemistry is established using the ^{13}C NMR spectrum, which shows only one resonance with chemical shift similar to that for $[Rh(ox)_3]^{3-}$ due to the oxalate groups as expected for *trans*-stereochemistry. If the complex were the *cis*-isomer, two resonances are expected from the oxalate C_2 groups. Two such resonances are indeed seen in the case of *cis*-$K[Co(ox)_2py_2]H_2O$.

The preparation of $[Co(ox)_2py_2]^-$ uses mild conditions: the filtrate after isolation of *trans*-isomer was poured on a column of Dowex 50W-X8 resin in the Li form. Then upon concentrating the eluate at low temperature the *cis*-isomer was obtained.

In the early thirties, it was shown that $K_3[Cr(ox)_3]$ precipitates glycine from solution in dilute alcohol. Then, in 1938, Bergman[9] found that $K[Cr(ox)_2py_2]$ forms sparingly soluble salts with some amino acids; the so-called "dioxypyridates".[9] Formation of the insoluble "dioxypyridate" of alanine was used as a means of estimating alanine in protein hydrolysates. A *cis*- and a *trans*-form of "dioxypyridic acid" may be expected. The *cis*-form should exist in two antipodes and therefore yield two series of diastereoisomeric salts with an optically active amino acid. Bergman[9] did not observe the two series of amino acid "dioxypyridates". Our attempt to use this method, for DL-alanine 0.01 M and 0.01 M $[Rh(ox)_2py_2]^-$, gave no precipitation of the *trans*-$[Rh(ox)_2py_2]^-$ ion as its alanine salt.

Reaction of $[Rh(ox)_3]^{3-}$ *with substituted pyridines.* Here, using 3- or 4-methylpyridine in place of pyridine, the reaction conditions were the same as for the parent *trans*-$K[Rh(ox)_2py_2]$. The solutions were evaporated to dryness and the products recrystallised from lukewarm water to give yellow fine solids, characterised as $K[Rh(ox)_2(4\text{-}Mepy)_2]3H_2O$ and $K[Rh(ox)_2(3\text{-}Me\text{-}py)_2]3H_2O$.

Solutions of $K[Rh(ox)_2(4\text{-}Mepy)_2]3H_2O$ and

$K[Rh(ox)_2(3\text{-}Mepy)_2]3H_2O$ in aqueous 4-methylpyridine and 3-methylpyridine respectively were heated under reflux for 2 days, but showed no change in spectrum indicating that further addition of 3- or 4-methylpyridine is not possible by this route. Isolation confirmed (by IR and chemical analysis) that the starting material was unchanged.

In the case of 2-methylpyridine, as the reaction proceeded there was a shift during two days in the wavelength of the band of the *d–d* transition from 400 to 362 nm. The product was anionic (retained by Sephadex A25): after removing potassium oxalate by precipitation with ethanol, the product was isolated as a yellow powder, and yellow crystals were obtained by recrystallisation from lukewarm water.

Infrared spectra of the solid product show C=O bands in the region 1700–1665 cm^{-1}, and the bands arising from the complexed 2-methylpyridine show slight shifts from neat 2-methylpyridine and some splitting. Elemental analyses suggest that the product is $K[Rh(ox)_2(OH)(2\text{-}Mepy)]$ although the proton resonance shows two methyl signals. This difference in product (2-methylpyridine ≠ 3- or 4-methylpyridine) probably stems from steric hindrance by the methyl group of the 2-methylpyridine molecule. This case is also reported by Shibata *et al.*[10] for the substitution of oxalate by 2-methylpyridine in $K_3[Co(ox)_3]3H_2O$.

Cis- and *trans*-octahedral bisoxalato–metallate complexes have been distinguished[11a,b] by the presence of four (for *cis*) and three (for *trans*) stretching vibrations of the non-bonded C–O groups occurring near 1700 cm^{-1}. This region is free from absorption by coordinated pyridines, and for the *trans*-compounds (point group D_{2h}), only two IR active non-bonded C–O stretching vibrations of B_{2u} and B_{3u} symmetry are predicted. These stretching vibrations of the non-bonded C–O groups of planar bisoxalato complexes are not affected greatly by coupling (unlike those of octahedral trioxalato complexes). For *cis*-compounds having C_{2v} symmetry, four IR active vibrations are predicted, two of *A* symmetry and two of *B* symmetry.

Pratt[12] reported that PMR spectra may be a tool for the stereochemistry of amine complexes.[12,13] This technique was used by Shibata *et al.*[10] to distinguish between the *cis-* and the *trans*-Co(III) bispyridines. In those, the γ-proton resonates at lower field for the *trans*-isomer, and at slightly higher field for *cis*-isomer. Our work has confirmed that result and applied such techniques to the bispyridinerhodium(III) complexes which are shown in Table 1.

In free pyridine, the α, γ and β protons resonate[14] at 8.51, 7.55, and 7.14 ppm (in CCl_4) respectively. The ^1H NMR analyses of the complexes $[Rh(ox)_2(R\text{-}py)_2]^-$ (R-py = py, 3-methylpyridine and 4-methylpyridine) are summarised in Table 1. There is a marked difference in chemical shift for the γ-protons of these complexes compared to the *cis*-isomer of the *cis*-Co(III) bispyridine as a reference. This clearly suggests that the Rh(III)bis-pyridine or bismethylpyridine complexes prepared here have the *trans*-configuration.

This has been confirmed by ^{13}C NMR spectra for bis(3- and 4-methylpyridine)bisoxalates which show only one resonance due to the oxalate group (Table 2). For bis(3-methylpyridine)bisoxalate, the spectral assignment is unambiguous for C-3 since its resonance appears as a single line in off resonance spectra. All other aromatic carbon resonances appear as doublets due to large one bond C^{13}–H spin–spin couplings. Assignments of the doublets to specific carbon atoms are based upon the known assignment in pyridine[15] and substituent effects established for monosubstituted pyridines.[16,17a,b] These doublets will appear as singlets in the ^1H noise decoupled spectra. Thus 5 bands are expected as shown in Table 2. The sixth singlet at 168.666 ppm is assigned to C-1 of the oxalato group.

As for bis(4-methylpyridine)bisoxalate, in the ^1H noise decoupled spectra one would expect 3 singlets, as found, one for C_2 and C_6 at 154.186 ppm, one for C_3 and C_5 at 128.216 ppm, one for C_4 at 150.684 ppm. The fourth singlet at 168.689 ppm is assigned to C_1 of the oxalato group as shown in Table 2.

(*Received* 8 *June* 1984; *accepted after revision* 29 *November* 1984)

Abstract—The complexes of *trans*-[Co(III)(R,CH_3-dioxH)$_2$(py)$_2$]I† (R = CH_3, C_2H_5, *n*-C_3H_7 and *n*-C_4H_9) were investigated in solution by ^1H and ^{13}C NMR spectra and ^{13}C spin–lattice relaxation time measurements. The ^1H- and ^{13}C-resonances of the R = C_2H_5, *n*-C_3H_7 and *n*-C_4H_9 groups were shifted to higher field than those of the free ligands by the complexation; it was attributable to the ring current shielding due to the axial pyridine ligands of the complexes. ^{13}C spin–lattice relaxation times were interpreted as due to movement of the axial pyridine ligands as if they twist around the Co–N (pyridine nitrogen) bond axis and the above R groups were moving segmentally. These segmental movements allowed the R groups to approach closely toward the axial pyridine ring plane to experience the ring current shielding.

In the thermal, pyridine liberation–anation reactions in the crystalline states of the complexes, *trans*-[Co(III)(R,CH_3-dioxH)$_2$(py)$_2$]I† where R is a long chain alkyl group, the reaction rates were found to be described by Taft's equation.[1] This fact suggests that the reaction rates are controlled not only by electronic effects but also by such a steric arrangement of the R groups locating near to the axial pyridine ring plane in the crystals.

In the similar reactions of these complexes in dimethylsulphoxide (DMSO) solution, the alkyl groups were found to play a role in preventing the reactions.[2] It implies that the alkyl groups are still having a tendency to locate near to the axial pyridine ring plane in the complex molecules in solution. If the alkyl groups were located as above, such structural situation might be reflected in the NMR spectra. In the present research, the same complexes were subjected to investigation by ^1H and ^{13}C NMR and ^{13}C relaxation time measurements. For comparison, the complexes of the type [Co(III)(R,CH_3-dioxH)$_2$(py)I] were also investigated.

† The following abbreviations are used. R,CH_3-dioxH$_2$: CH_3–C(=NOH)–C(=NOH)–R (R = CH_3, C_2H_5, *n*-C_3H_7, and *n*-C_4H_9), py: pyridine.

EXPERIMENTAL

Materials

The 2,3-alkanedione dioxime ligands with the general formula, R,CH_3-dioxH$_2$, and their complexes of the two types of the general formulas, [Co(R,CH_3-dioxH)$_2$(py)I] and [Co(R,CH_3-dioxH)$_2$(py)$_2$]I, were prepared as described previously.[1,3]

Measurements

The ^1H NMR, ^{13}C NMR, and $T_1(^{13}C)$ measurements were carried out by use of a JEOL FX-200 spectrometer at 200 MHz for ^1H and at 50 MHz for ^{13}C. The assignments for the ^{13}C resonances were carried out by applying a selective proton decoupling method.[4] Each of the sample solutions was almost saturated with the respective complexes.

RESULTS

^1H NMR spectra

The ^1H NMR spectra of the free ligands and their complexes in DMSO-d_6 solutions are shown in Figs.

1 and 2; the numerical data are tabulated in Table 1. As is seen in Fig. 1, the free CH_3,CH_3-dioxH$_2$ ligand showed two singlet resonances at δ1.97 and 11.37 ppm; these were ascribed to the $C^1H_3(C^4H_3)$ and NOH groups, respectively. The resonances due to the α, β, and γ protons of the free pyridine appeared at *ca* 8.6, 7.4, and 7.8 ppm, respectively. On complex formation, the above $C^1H_3(C^4H_3)$ proton resonance shifted to lower field and appeared at 2.31 ppm for the [Co(CH_3,CH_3-dioxH)$_2$(py)I] and 2.32 ppm for the [Co(CH_3,CH_3-dioxH)$_2$(py)$_2$]I complexes. The proton resonances due to the NOH groups appeared at 18.48 ppm in the former and at 18.18 ppm in the latter, being shifted remarkably to lower field by complexation. In respect of the pyridine, the coordination resulted in lower-field shifts of the β- and γ-proton resonances, but a higher-field shift of the α-proton resonance.

The free C_2H_5,CH_3-dioxH$_2$ ligand showed a singlet resonance at 1.99 ppm, a quartet at 2.61 ppm, and a triplet at 1.03 ppm, as is seen in Fig. 2A; these can be ascribed to the C^1H_3, C^4H_2, and C^5H_3 protons, respectively. By complexing, the C^1H_3 and C^4H_2 proton resonances were shifted to lower field,

whereas the C^5H_3 proton resonance shifted to higher field. It was found that the resonance due to the C^5H_3 protons for either mono- or bis-pyridine type complex consisted of two triplet peaks; this suggested that each of these complexes included two geometrical isomers.

For the complexes included R = n-C_3H_7 and n-C_4H_9, similar shifts of the alkyl proton resonances caused by complexing were observed, as is shown in Figs. 2B and C.

As for the other complexes excluding those with R = C_2H_5, the existence of their isomeric forms was not suggested by the spectra.

The resonance peaks for the NOH groups of the complexes appeared at nearly same positions with each other among the present series of the complexes. It was similarly said with regard to the position of the resonances of the coordinated pyridines.

^{13}C *NMR spectra*

In Fig. 3, the ^{13}C NMR spectra of the free CH_3,CH_3-dioxH$_2$ and pyridine ligands measured in DMSO-d_6 solution are compared with those of the [Co(CH_3,CH_3-dioxH)$_2$(py)I] and [Co(CH_3,CH_3-dioxH)$_2$(py)$_2$]I complexes. With respect to free CH_3,CH_3-dioxH$_2$, the peaks at δ9.2 and 153.1 ppm could be ascribed to the $C^1(C^4)$ and $C^2(C^3)$ atoms, respectively. The free pyridine showed the peaks at 156.1, 130.3, and 142.5 ppm; these were assigned to the C^α, C^β, and C^γ atoms, respectively. Upon complexing, the $C^1(C^4)$ and $C^2(C^3)$ peaks shifted to lower field, while the C^α, C^β, and C^γ resonances shifted to higher field.

The resonance peaks of the free C_2H_5,CH_3-dioxH$_2$ ligand, shown in Fig. 4A, were assigned as follows; 9.2 ppm to C^1, 152.0 ppm to C^2, 157.7 ppm to C^3, 16.5 ppm to C^4, and 10.8 ppm to C^5 atoms. By complexing, the C^1, C^2, C^3, and C^4 resonances were shifted to lower field, while the C^5 peak was shifted to higher field. The splitting of the C^2 and C^3 peaks seen for its bis-pyridine type [Co(C_2H_5,CH_3-dioxH)$_2$(py)$_2$]I complex would be due to the presence of geometric isomers. This observation is in agreement with that on the ^{1}H NMR spectrum, mentioned already. Although, in the case of the mono-pyridine type [Co(C_2H_5,CH_3-dioxH)$_2$(py)I] complex, similar splitting of the peak for the corresponding carbon atoms was not seen; it differed from the ^{1}H NMR results.

The results of the peak assignments for the free n-C_3H_7,CH_3-dioxH$_2$ ligand are given in Fig. 4B. When it formed the complexes, the C^1, C^2, C^3, and C^4 peaks shifted to lower field, whereas the C^5 and C^6 peaks shifted to higher field. For its mono-pyridine type [Co(n-C_3H_7,CH_3-dioxH)$_2$(py)I] complex, the peak due to the C^6 atom appeared at lower field than that due to the C^1 atom; this trend was in line with the observation for the free ligand. On the other hand, the bis-pyridine type [Co(n-C_3H_7,CH_3-dioxH)$_2$(py)$_2$]I complex, the C^6 atom resonated at the higher field than the C^1 atom.

The resonances observed for the free n-C_4H_9,CH_3-dioxH$_2$ ligand and its complexes were

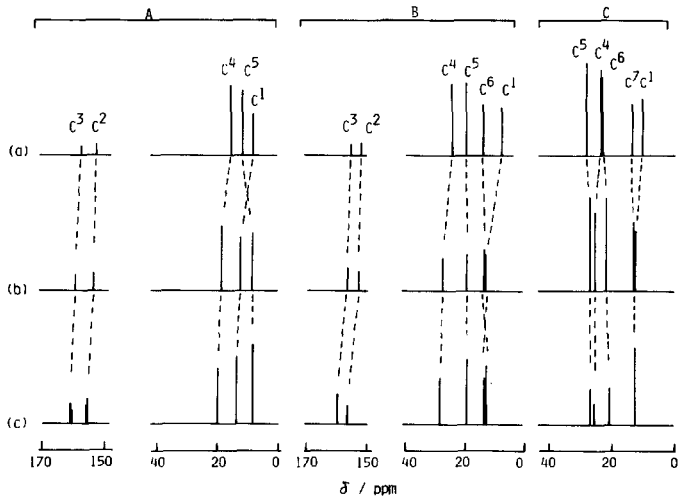

Fig. 4. ^{13}C NMR spectra. A: (a) C_2H_5,CH_3-dioxH$_2$; (b) [Co(C_2H_5,CH_3-dioxH)$_2$(py)I]; (c) [Co(C_2H_5,CH_3-dioxH)$_2$(py)$_2$]I. B: (a) n-C_3H_7,CH_3-dioxH$_2$; (b) [Co(n-C_3H_7,CH_3-dioxH)$_2$(py)I]; (c) [Co(n-C_3H_7,CH_3-dioxH)$_2$(py)$_2$]I. C: (a) n-C_4H_9,CH_3-dioxH$_2$; (b) [Co(n-C_4H_9,CH_3-dioxH)$_2$(py)I]; (c) [Co(n-C_4H_9,CH_3-dioxH)$_2$(py)$_2$]I.

assigned as given in Fig. 4C. The C^1 and C^7 resonances for the bis-pyridine type [Co(n-C_4H_9,CH_3-dioxH)$_2$(py)$_2$]I complex, appeared as one peak, due to overlapping.

T_1 *measurements*

The T_1 measurements were carried out by applying the inversion recovery method[4] for the series of the bis-pyridine type [Co(R,CH_3-dioxH)$_2$(py)$_2$]I complexes, in DMSO-d_6 solution with the concentration of *ca* 5×10^{-2} mol dm^{-3}.* In Fig. 5, the result obtained for [Co(CH_3,CH_3-dioxH)$_2$(py)$_2$]I is given as an example. As is seen in Fig. 5, when the pulse interval, τ, was 0.05 sec, all the peaks were inverted. The time needed for recovery increased in the order of the carbon atoms, $C^\gamma < C^\alpha \simeq C^\beta < C^1(C^4)$. The T_1 value can be obtained as the reciprocal slope of straight line of log $(I_\infty - I_\tau)$ vs τ plot; I_∞ is the equilibrium intensity of a resonance peak, and I_τ, the peak intensities at each τ values. The above plots for all the ^{13}C resonance peaks of the complexes gave good linear relations. As to the [Co(C_2H_5,CH_3-dioxH)$_2$(py)$_2$]I complex which was considered to be composed of two geometric isomers, similar linear relations were observed; this indicated that the isomers have quite similar T_1 values. The T_1 data thus obtained are listed in Table 2. As for free pyridine (*ca* 10% in DMSO-d_6 solution), the T_1 values decreased in the order of its carbon atoms, $C^\beta > C^\alpha > C^\gamma$; as for the coordinated one, these decreased in the order, $C^\beta \simeq C^\alpha > C^\gamma$. Concerning the carbon atoms in the long-chain alkyl groups bound to the dioximato moiety, it was found that the T_1 values increased in the order, $C^4 < C^5 < C^6$. The C^1 atom of the methyl group had rather larger T_1 value than the C^4 atom of the methylene group. The T_1 values of the C^1 and C^7 atoms in the [Co(n-C_4H_9,CH_3-dioxH)$_2$(py)$_2$]I complex were not determined owing to the overlapping of the resonances of these atoms.

In order to investigate temperature dependence of the T_1 values, the [Co(n-C_3H_7,CH_3-dioxH)$_2$(py)$_2$]I complex in CD_2Cl_2 solution was subjected to the measurements at lower temperature. As Fig. 6 shows, with decreasing temperatures, the difference in the T_1 values between C^β ($\simeq C^\alpha$) and C^γ atoms of the pyridine ligand became smaller. However, a small difference was still observed to be present even at -78°C. With regard to the long-chain alkyl groups,

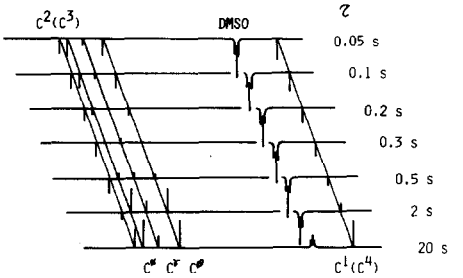

Fig. 5. Relaxation times, T_1, measurements for ^{13}C atoms of [Co(CH_3,CH_3-dioxH)$_2$(py)$_2$]I, in DMSO-d_6 solution.

*For the mono-pyridine type complexes, the T_1 measurements were unsuccessful owing to their scarce solubilities.

Table 2. Relaxation times of ^{13}C atoms for $[Co(R,CH_3\text{-dioxH})_2(py)_2]I$ complexes

Complexes: R	T_1 (s) py C^α	py C^β	py C^γ	R,CH_3-dioxH C^1	C^4	C^5	C^6	C^7
CH_3	0.58	0.64	0.50	1.84	1.84	—	—	—
C_2H_5	0.52	0.52	0.40	1.73	0.36	1.05	—	—
n-C_3H_7	0.39	0.41	0.31	1.33	0.29	0.50	1.49	—
n-C_4H_9	0.34	0.39	0.29	×	0.22	0.48	0.65	×
(free py)	(8.77	9.75	7.60)					

it could be said that the T_1 value of the C^4 atom did not depend so much on temperature, while those of the C^5 and C^6 atoms depended remarkably on it, as shown in Fig. 7. The T_1 value of the C^1 atom also decreased with decreasing temperature.

It may be stated overall that the T_1 values determined in the CD_2Cl_2 solution were appreciably larger than those in the DMSO-d_6 solution.

DISCUSSION

^1H and ^{13}C NMR spectra

Excluding the complexes with $R = C_2H_5$, the complexes examined here showed the ^1H and ^{13}C NMR spectra which were well explained by proposing the structure of the complexes in which the R,CH_3-dioxH ligands are bidentately and planarly coordinated in the manner of *trans* forming two equivalent intramolecular hydrogen bonds;[5] one pyridine molecule and iodide anion of the mono-pyridine type complexes or two pyridine molecules of the bis-pyridine type complexes are coordinated at the axial sites.

As to both types of complex including $R = C_2H_5$, the existence of the two isomeric structures was suggested by the NMR spectra. The ^1H resonance of the C^5H_3 group consisted of two triplet peaks. It can be understood by considering the presence of the two geometric isomers, which may be formed by the *cis*- and *trans*-coordinations of the two C_2H_5,CH_3-dioxH ligands at the equatorial plane. With respect to the C^2 and C^3 atoms, their ^{13}C resonances appeared, respectively, as two peaks for the bis-pyridine type complex, whereas, as one peak for the mono-pyridine type complex due to their incidental overlap.

The lower-field shifts for the ^1H resonances of the C^1H_3 and C^4H_2 groups and for the ^{13}C resonances of the C^1, C^2, C^3, and C^4 atoms caused by the complexation, are considered to be due to the Co(III) atoms which, in general, behave to decrease the electron densities on these proton and carbon atoms.[6] On the other hand, as to the higher field shifts observed for both ^1H and ^{13}C resonances of the C^5, C^6, or C^7 group, it can be attributed to the ring

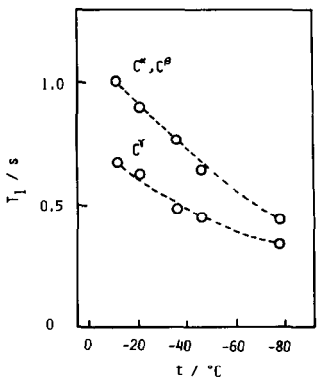

Fig. 6. Temperature dependence of T_1 values for the carbon atoms of the pyridine ligand of $[Co(n\text{-}C_3H_7,CH_3\text{-dioxH})_2(py)_2]I$, in CD_2Cl_2 solution.

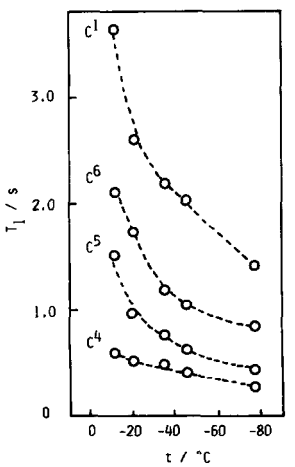

Fig. 7. Temperature dependence of T_1 values of the carbon atoms in the coordinated n-C_3H_7,CH_3-dioxH of $[Co(n\text{-}C_3H_7,CH_3\text{-dioxH})_2(py)_2]I$, in CD_2Cl_2 solution.

current shielding of the axial pyridine ligand.[6] The higher field shifts of the ^1H and ^{13}C resonances were not seen for the C^5 and C^6 groups of the [Co(*n*-C_3H_7,CH_3-dioxH)$_2$(NH_3)$_2$]I complex, in which the shielding due to the axial ammonia ligands could not be expected. Moreover, it is noticed, in Fig. 2, that the amount of the shifts caused by the above ring current effect is larger in the bis-pyridine type complexes than in the corresponding mono-pyridine type ones.

The lower-field shifts for the H^β and H^γ resonances of the pyridine molecules caused by the coordination may be owing to the predominant electron-withdrawing property of the Co(III) atoms, while the higher-field shift for the H^α resonance may be due to the predominant anisotropic effect of the metal chelate rings.[7]

^{13}C *spin–lattice relaxation times,* T_1

It is considered that in such large molecules as those investigated here, the dipole–dipole relaxation is dominant.[8] This assumption was confirmed by measuring the NOE factor (η). The values were found to be within the 2.0 ± 0.1 range for all the carbons of the complexes, indicating the dipole–dipole relaxation mechanism being dominant. Due to probable anisotropical movements, the correlation time could not be calculated. However, molecular movements may be qualitatively discussed on the basis of the T_1 values.

As has been described, the T_1 values for the free pyridine molecule are $C^\beta > C^\alpha > C^\gamma$ (Table 2). This fact is considered to suggest the rotation of the free pyridine molecule taking place a little more preferably around C^γ–N axis than around the other axes. Analogous anisotropic molecular rotation has been known to occur for the several benzene derivatives with the formula C_6H_5X (X = CH_3, NO_2, etc.).[9] Regarding the coordinating pyridine ligands, the T_1 values are also $C^\beta > C^\gamma$, over the four complexes examined. It is of interest that the ratios $T_1(C^\beta)/T_1(C^\gamma)$ are *ca* 1.3 for all of these complexes, being quite similar to the corresponding ratio, 1.3, for the free pyridine molecule. This fact can be explained as follows. If the pyridine ligands were fixed at the axial sites in the complex molecules in such a manner as its ring plane was held at a definite position, the above ratio could be expected to be closer to 1.0. On the other hand, if the puridine ligands were allowed to rotate around the C^γ–N axis, the above ratio could be expected to be much larger than that (1.3) of the free pyridine molecule, since the rotations around the other axes would be inhibited by the coordination. Thus, the fact that the $T_1(C^\beta)/T_1(C^\gamma)$ ratios of the complexes are quite similar to that of the free pyridine molecule is considered to indicate that the pyridine ligand moves as if it twists around the C^γ–N axis.

Regarding the alkyl groups of the complexes, their T_1 values increased in the order of the carbon atoms $C^4 < C^5 < C^6$; this is in line with a prediction that the segmental movement of the R groups would become more brisk along the extended carbon-chains. The similar trend in the movement has been pointed out for the carbon atoms of the *n*-decane or 1-decanol.[10]

As Table 2 indicates, the T_1 value of the C^1 atom in the methyl group is larger than that of the C^4 atom in the methylene group, suggesting more brisk movement in the former than in the latter. In such compound as iso-octane, the CH_3 groups are sterically hindered to rotate within the molecule, and therefore their T_1 values are smaller than that of the CH_2 group.[11]

The T_1 values measured at the lower temperatures for [Co(*n*-C_3H_7,CH_3-dioxH)$_2$(py)$_2$]I in CD_2Cl_2 solution indicate that the coordinated pyridine ligands are still twisting around the C^γ–N axis even at -78°C, though the ratio $T_1(C^\beta)/T_1(C^\gamma)$ decreases from 1.5 at -12°C to 1.3 at -78°C (Fig. 6). The T_1 values of the C^4, C^5, and C^6 atoms become smaller as the temperature decreases (Fig. 7). This is in accordance with an expectation that the segmental movement becomes more stagnant at lower temperature. However, it should be noticed that the changes in the above T_1 values are rather continuous. Hence, the presence of a bonding interaction between the axial pyridine ligand and the prolonged alkyl groups of the complex molecules in the solution has not been substantiated here.[12] With respect to the C^1H_3 group, it is also suggested that the internal rotation becomes more stagnant with the decreasing temperatures.

The larger T_1 values observed in CD_2Cl_2 than in DMSO-d_6 solutions would be ascribed to the smaller viscosity of CH_2Cl_2 than DMSO; the viscosity at 30°C is 0.4 cp for the former and 1.7 cp for the latter.

It is said in conclusion that in the present complexes the axial pyridine ligands are twisting around the Co–N (pyridine nitrogen) bond axis and the long alkyl(R) groups do segmental motions; as the result of these segmental movements, the terminal methyl groups of R may experience the shielding effect of the pyridine ring and the amount of the shifts caused by the above effect is much larger in the bis-pyridine type complexes than in the corresponding mono-pyridine type ones. In the case of the complex including R = *n*-C_3H_7, the chain length is most advantageous for the terminal methyl group to experience the largest shielding effect.

Abstract—Solvolytic reactions between monobromoacetic acid and metal oxides, carbonates, oxalates, formates, sulphites, nitrates, nitrites and chlorides form monobromoacetates. In the case of transition metals, a molecule of solvent is also attached to the solvolysed products. The solvolysed products have been investigated by IR, magnetic susceptibility and molar conductance measurements. Lewis bases form adducts with these products. The solvolytic reactions have been explained on the bases of autoionization of monobromoacetic acid reported earlier[1] as,

$$2CH_2BrCOOH \rightleftharpoons CH_2BrCOOH_2^+ + CH_2BrCOO^-.$$

A few bromoacetates of transition metals are reported in the literature. Melnik and co-workers[2] from EPR studies have shown that copper(II) tribromoacetate is mononuclear while copper(II) monobromoacetate and its adducts with dioxane are binuclear. Physico-chemical properties of vanadyl bromoacetate have been investigated by Walter and co-workers,[3] while studies of bridging monobromocarboxylate complexes of palladium(II) and platinum(II) have also been reported.[4] In the present investigations an effort has been made to explore the solvent potentialities of fused monobromacetic acid with various metal oxides, carbonates, oxalates, formates, sulphites, nitrites, nitrates, chlorides and bromides, at approximately 180°C. In most of the cases insoluble anhydrous monobromoacetates were isolated but in some cases extra molecules of the solvent formed solvates with these acetates.

EXPERIMENTAL

Monobromoacetic acid was purified by the method reported earlier.[5] Metal oxides, oxalates, formates, nitrites, nitrates, sulphites, carbonates were dried over phosphorus pentoxide for 48 h in a vacuum desiccator. Partial solvolysis of some of the compounds could be brought about around 100°C by thoroughly mixing the compounds with monobromoacetic acid. However, in most cases the following procedure was required for complete solvolysis. The anhydrous metal compound (2 g) was added to monobromoacetic acid (10 g) and the reaction mixture was heated under anhydrous conditions for one to seven days, depending upon the reaction. In most cases the solvolysed products have been isolated from solution by the addition of an inert solvent such as petroleum ether or carbon tetrachloride.

Molar conductance values of millimolar solutions have been measured at 25 ± 0.1°C using a precision conductivity bridge (Phillips PR-9500) with a cell having a cell constant = 0.678 ohm^{-1} cm^{-1}. IR spectra were recorded using KBr discs and grating infrared spectrophotometers (Perkin–Elmer, Models 337 and 621). Mulls, Nujol and HCB (hexachlorobutadiene), were prepared in dry box.

Magnetic susceptibility measurements were carried out by using standard Gouy method using a permanent magnet and a sample tube calibrated

with mercury(II) tetrathiocyanato cobalt(II) as standard[6] and the diamagnetic corrections were made by a method as reported earlier.[7]

Analysis of these compounds were done partially by the Guelph Chemical Laboratories Ltd., Guelph, Ontario Canada and partially by the usual methods already reported in literature.[8] Analysis of bromine in the presence of chlorine was done as follows. The bromine was first oxidized to bromate by hypochlorite at a pH range 6–6.5. The excess of hypochlorite was removed by sodium formate and the bromate determined iodometrically.

RESULTS AND DISCUSSION

Zinc and cadmium oxides are insoluble in fused monobromoacetic acid at 50°C. On heating these oxides with fused monobromoacetic acid at nearly 180°C for 20–24 hr compounds of composition $Zn(CH_2BrCOO)_2 \cdot CH_2BrCOOH$ and $Cd(CH_2BrCOO)_2 \cdot CH_2BrCOOH$ are obtained (Table 1). The corresponding acetic acid derivatives are known to have a water molecule attached.[9] This difference may be due to the fact that the present reactions have been carried out at about 180°C and water is lost at this temperature. All attempts to remove the extra solvent molecule from these compounds failed. They are not very sensitive to moisture, and are insoluble in most organic solvents including various aprotic solvents such as nitromethane, acetonitrile, suggesting their possible polymeric nature. Both these compounds are soluble in dimethyl formamide in which the molar conductance values of their millimolar solutions indicate them to be non-ionic in nature (Table 1). The broad absorption band at 3360 cm^{-1} assigned to hydrogen bonded-OH group in pure carboxylic acid[10] becomes quite sharp and shifts to 3380 and 3386 cm^{-1} for the zinc and cadmium complexes respectively, ruling out the possibility of free OH groups in these compounds.[11] This suggests that the OH group of the solvating monobromoacetic acid is not hydrogen bonded but is co-ordinated to the metal atom. No band has been observed around 1720 cm^{-1} showing thus that there is no free carbonyl group present in these complexes. The intense absorption bands at 1520 and 1408 cm^{-1} assigned to asymmetric and symmetric stretching modes of carboxylate group have been shifted to lower frequencies when compared to those found in sodium acetate[12] suggesting that the carboxylate ion

is acting as a bidentate ligand. It is further observed that the asymmetric stretching frequencies of these complexes are split which may be attributed either to a slight difference in the force constants for the chelating and the bridging carboxylate groups or to a solid state lattice interaction. Similar observations have been made by Wilkinson and co-workers[13] in molybdenum (II) carboxylate where the acetate group acts both as bridging and a chelating group. That the central atom is six coordinate and monobromoacetic acid attached to the complex acts as a bridging group is also supported by the degree of separation of symmetric and asymmetric carboxy stretching frequencies. These are not very different from those found in other metal complexes where the acetate group acts as a bridging group. This is unlike those acetate complexes where there is a significant difference between the two frequencies and the acetates are known to act as monodentate ligands.[14] Since both the compounds are insoluble in most of the aprotic solvents it may be reasonable to assume a polymeric structure for these adducts. The spectral bands in the region 440–320 cm^{-1} for the adducts which are absent in pure monobromoacetic acid arise from oxygen–metal vibrations and this assignment has been made on the basis of observations made by Briggis.[15]

The oxides of magnesium, calcium and strontium form bromoacetates of composition $M(CH_2BrCOO)_2 \cdot CH_2BrCOOH$ (Table 1), while in case of barium oxide no compound was isolated. By analogy with the solvated bromoacetates of zinc and cadmium, a similar polymeric structure through solvent bridging may be postulated for these bromoacetates, the central metal atom having octahedral coordination.

The oxides of copper, nickel and cobalt also form bromoacetates, $Cu(CH_2BrCOO)_2$, $Ni(CH_2BrCOO)_2$, and $Co(CH_2BrCOO)_2$ respectively (Table 1), i.e. without the extra monobromoacetic acid. The reaction is accompanied by a change in the colour of the reactants. Like the other complexes reported above, these are non-ionic in nature. No spectral band that could be assigned to –OH group is present in these compounds, indicating that no free monobromoacetic acid is present. The ν(C–O) asymmetric and symmetric vibrations in the region 1400–1600 cm^{-1} are shifted to lower frequencies, suggesting that the metal atom has acquired a tetrahedral environment through the bidentate nature of monobromoacetate group. The bands at 450, 418 and 395 cm^{-1} are due to the metal–oxygen bond.

The nature of these compounds has been further deduced from their magnetic susceptibility measurements. The magnetic moment value of 4.76 B.M. at room temperature, which was observed for the cobalt(II) bromoacetate, is much higher than 3.88 B.M., the spin only value corresponding to three unpaired electrons. The values in the range 4.2–4.8 B.M. are generally observed for the tetrahedral stereochemistry and thus a tetrahedral stereochemistry with $^4A_2$ ground state term may be proposed for Co(II) bromoacetate. The magnetic moment of 4.08 B.M. derived for Ni(II) bromoacetate is in good agreement with the tetrahedral stereochemistry for which the values ranging from 3.5–4.1 B.M. are expected because of the orbital contribution by the $^3T_1$ ground state term.[16] In the case of the Cu(II) bromoacetate a magnetic moment of 1.43 at room temperature is consistent with the dimeric structure for this compound as suggested earlier.[17]

Complexes of pyridine N-oxide and triphenyl phosphine oxide with monobromoacetates of cobalt and nickel have been prepared and characterized. The complexes $Co(CH_2BrCOO)_2 \cdot 2(C_6H_5)_3PO$ and $Ni(CH_2BrCOO)_2 \cdot 2(C_6H_5)_3PO$ are non-ionic and monomeric in nature (Table 1). By combining with two molecules of the ligand the metal atom has acquired an octahedral environment. Among the characteristic non-ligand vibrations in the range 1400–1600 cm^{-1} are the ν asymmetric and symmetric carboxylate vibrations which have been found to shift to higher and lower frequency regions respectively. Since the carboxylate stretching frequency is known to be sensitive to the electronic environment, the observed shifts indicate the electron donation by oxygen of the ligand to the metal atom. This is in agreement with the earlier observations on the infrared spectra of the complexes of some metal carboxylates with some oxygen ligands.[6] The spectral bands observed in the region 375 cm^{-1} (for the nickel complex) and at 395 cm^{-1} (for the cobalt complex) arise from metal–oxygen vibrations. Interest has been focused on the change in the P–O stretching frequency on complex formation. It is interesting to note that there is a decrease in P–O stretching frequency of nearly 39 cm^{-1}. Similar observations have already been reported by Cotton and co-workers.[18] In the case of non-ionic pyridine-N-oxide complexes of composition $Ni(CH_2BrCOO)_2 \cdot 2C_5H_5NO$ and $Co(CH_2BrCOO)_2 \cdot 2C_5H_5NO$, the absorption bands due to N–O stretching vibrations originally present at 1250, 835 and 545 cm^{-1} in the pure ligand[19] are shifted to 1195, 815 and 528 cm^{-1} in these complexes.

The solvolysis of metal oxides (MO) in fused monobromoacetic acid may be explained on the basis of the formation of a solvate which rearranges under the conditions of the reaction to form bromoacetates. The overall reactions thus may be

explained as

$$2CH_2BrCOOH + MO \rightarrow (CH_2BrCOOH)_2MO$$
$$\downarrow$$
$$\leftarrow CH_2BrCOOH_2^+ + CH_2BrCOOMO^-$$
$$M(CH_2BrCOO)_2 + H_2O$$

Formation of metal bromoacetates and the elimination of a water molecule suggests that bromoacetate ion and the protonated monobromoacetic acid ($CH_2BrCOOH_2^+$) are the reactive species in fused monobromoacetic acid and supports the mode of ionization of the solvent as proposed earlier.[1]

Metal chlorides also react in fused monobromoacetic acid to form the corresponding monobromoacetates as

$$MCl_3 + 2CH_2BrCOOH$$
$$\rightleftharpoons MCl_3 \cdot CH_2BrCOO^- + CH_2BrCOOH_2^+$$
$$MCl_3 \cdot CH_2BrCOO^- + CH_2BrCOOH_2^+$$
$$\xrightarrow{180°C} MCl_2 \cdot CH_2BrCOO + CH_2BrCOOH + HCl.$$

Further heating of the intermediate replaces the other chlorine atoms bonded to metal and the final product is the completely solvolysed compound $M(CH_2BrCOO)_3$. Compounds of composition $Al(CH_2BrCOO)_3$, $Fe(CH_2BrCOO)_3$ and $FeCl(CH_2BrCOO)_2$ were isolated using the above methods. These compounds are less hygroscopic than the parent metal chlorides. They are insoluble in conventional non-polar organic solvents but are soluble in polar solvents such as nitromethane, nitrobenzene and acetonitrile. Molar conductance values of their millimolar solutions (Table 1) show them to be fairly ionic in character.

The infrared spectra of this latter group of compounds, especially in the region of asymmetric and symmetric carboxylate group vibrations, are similar to those of transition metal acetates, where the acetate groups are supposed to act as bidentate chelating and bridging group. The intense sharp bands observed in the range 1620–1570 cm^{-1} may be assigned to the bridging groups. Bands at 1520 and 1390 cm^{-1}, though of low intensity, are shifted to lower frequency and the difference in the asymmetric and symmetric stretching modes is also reduced suggesting that there are also bidentate carboxylate groups.

A polymeric structure for these carboxylates cannot be ruled out but the extent of bridging appears small as the compounds are soluble in aprotic solvents. The other important bands in the case of $Al(CH_2BrCOO)_3$ is observed at 490 cm^{-1} which may be attributed to the Al–O stretching mode. No spectral band that could be assigned to aluminium–chlorine stretching mode is present. In the case of the compounds $Fe(CH_2BrCOO)_3$ and $FeCl(CH_2BrCOO)_2$ the asymmetric and the symmetric stretching modes of the carboxylate group (Table 2) indicate that iron must be six coordinate. In the case of $FeCl(CH_2BrCOO)_2$, the iron acquires a coordination number of six through chlorine bridging. The iron–chlorine stretching mode is observed at 435 cm^{-1} which could be assigned to bridging clorine rather than a terminal one, the bridging stretching modes being expected at the lower frequency. Since the monobromoacetate group functions as bidentate chelating group, a possible hexa-coordination structure around iron for both the compounds may be postulated.

Sodium and potassium formates, oxalates, nitrates, sulphites, nitrates and carbonates, etc. undergo rapid solvolysis in fused monobromoacetic acid as one of the products of solvolysis escapes, or decomposes and escapes from the solution. Similarly complete solvolysis of the hydrated nitrates of sodium and potassium has also been carried out.

Table 2. Principal infrared bands of some of the solvolysed products (cm^{-1}) of various metal bromoacetates

Compound	Asymmetric $(COO)^-$	Symmetric $(COO)^-$	M–O	M–Cl	O–H

CuX_2	1580	1395, 1392, 1372	450, 395, 340	—	—

Carbonates of sodium, calcium, zinc and cadmium undergo complete solvolysis within 8 h when heated with excess of monobromoacetic acid at nearly 180°C. The mechanism of all these reactions can be explained through the loss of HX, where X is NO_2^-, NO_3^-, $HCOO^-$, $C_2O_4^{2-}$, SO_3^{2-}, CO_3^{2-}, etc. In most of the reactions, HX escapes from the solutions at higher temperatures.

It may be concluded that all the reactions discussed are consistent with the existence of CH_2BrCOO^- ions in solution, supporting the auto-ionization of $CH_2BrCOOH$ as

$$2CH_2BrCOOH \rightleftharpoons CH_2BrCOOH_2^+ + CH_2BrCOO^-.$$

SOLVENT EXTRACTION OF CALCIUM(II) AND STRONTIUM(II) WITH 1-PHENYL-3-METHYL-4-ACYL-5-PYRAZOLONE

K. SATO, Y. AKAMA* and T. NAKAI
Department of Chemistry, Meisei University, Hodokubo, Hino, Tokyo 191, Japan

(*Received* 17 *October* 1984; *accepted* 29 *November* 1984)

Abstract—The extraction of calcium and strontium from aqueous solution with 1-phenyl-3-methyl-4-acyl-5-pyrazolone (C_n) in MIBK and benzyl alcohol has been studied. In the extraction of Sr with 4-acyl derivatives–MIBK systems, the $pH_{1/2}$ values change with increasing the length of acyl chain in the derivatives. The reagent C_3 is more suitable than the other reagents for the separation of Ca and Sr, using MIBK as solvent.

1 - Phenyl - 3 - methyl - 4 - benzoyl - 5 - pyrazolone (PMBP) is a suitable agent for the extraction of metals due to the great reactively and stability of its complex. Numerous studies[1–3] have been made on metal extraction with PMBP. Recently, we have synthesized systematically the 4-acyl derivatives of 1-phenyl-3-methyl-5-pyrazolone. The extraction of Cu(II)[4] and Mn(II)[5] were studied and the compositions and extraction constants for the complex have been determined. Umetani *et al.*[6] developed a method for the extraction of alkaline earth metals using a mixture of 4-acyl derivatives and trioctylphosphine oxide. However, detailed study of the extraction for the system containing the 4-acyl derivatives of the type $(C_{10}H_9N_2O)(C_nH_{2n+1}CO)$ ($n = 2$–11) has received little attention. In the present paper, the extraction of Ca and Sr with these newly synthesized 4-acyl derivatives into MIBK and benzyl alcohol has been measured at 25°C, and studied the effectiveness of these derivatives in the separation of Ca and Sr.

EXPERIMENTAL

Reagents. The calcium and strontium stock solutions were prepared from calcium carbonate and strontium carbonate respectively. 4-Acyl derivatives were synthesized as previously described and these compounds were purified by several recrystallizing from methanol and the purity (of these reagents) was checked by elemental analysis, and used in MIBK and benzyl alcohol solution. All other reagents were of analytical reagents grade.

Extraction and analytical procedure. All the extraction procedure were carried out in a thermostatted room at 25 ± 1°C. Equal volumes (8 cm^3) of the aqueous (4×10^{-4} M Ca and Sr) and organic (0.05 M 4-acyl derivatives) phases were agitated in a 50 cm^3 centrifuge tube during 30 min. In all cases the time necessary to attain equilibrium was established as 1–2 min. After centrifugation the two phases separated and the pH of the aqueous phase was measured by TOA HM-6A pH meter. A 5 cm^3 portion was pipetted from organic phase and Ca and Sr were back-extracted into 0.1 M hydrochloric acid. The concentration of metals in this solution and in the aqueous phase were determined by an atomic absorption method. The ionic strength of the aqueous phase was maintained constant (0.1 M) by adding sodium perchlorate.

RESULTS AND DISCUSSION

The extraction of Ca and Sr from aqueous solution with 4-acyl derivatives in MIBK and benzyl alcohol were studied. The reagents except for the PMBP are shown as C_n, where the subscript n denote number of carbon involved in acyl chain. These 4-acyl derivatives are β-diketone with pK_a of *ca* 4[4] in 10% (v/v) dioxane–water at 25°C. The solubility in organic solvent such as MIBK is relatively high but that is insoluble in aqueous solution. The extraction of Ca and Sr with 0.01 M PMBP into benzene is negligible.[7] However, when MIBK and benzyl alcohol was used as organic phase the extraction is largely enhanced due to the synergistic effect.

Figure 1 shows the influence of pH on the extraction of Ca and Sr by PMBP in MIBK and benzyl alcohol. High extraction of Ca and Sr was

obtained utilizing the benzyl alcohol, and Ca is extracted more readily than Sr at lower pH. The plots log D vs pH gave straight line of slope near 2, indicating that under these conditions a 1:2 complex, $Ca(PMBP)_2$ and $Sr(PMBP)_2$, are found in the organic phase. Figure 2(a) shows the extraction percentage as a function of pH for the difference derivatives in MIBK. With increasing number of carbon in acyl chain extraction percentage of Sr increased remarkably whereas in Ca extraction little difference between the extraction curves is observed. This phenomenon has an important effect on the separation of Ca and Sr. When benzyl alcohol was used as organic solvent, the substituent effect of 4-acyl derivatives was not recognized for extraction as shown in Fig. 2(b). Figure 3 shows the pH of the half extraction of Ca and Sr with MIBK and benzyl alcohol as solvents. From these results it can be seen that the reagent C_3 is more suitable than the other reagents for the separation of Ca and Sr, using MIBK as solvent. On the other hand PMBP is much more efficient for the extraction of Ca and Sr than the other derivatives, even at low pH. This appears to be a direct consequence of the relatively low pK_a value of PMBP, viz. 3.80, the pK_a values of the other

derivatives (C_3–C_9) all being in the range 4.1–4.2. Figure 4 shows the extraction of Sr and Ca at temperature 5 and 25°C for C_3–MIBK system. The extraction percentage of the Sr and Ca decrease with decreasing temperature. This indicates that the extraction process was found to involve an endothermic reaction. The extraction of Ca at 2×10^{-4} M level with 0.05 M C_3–MIBK solution was studied at 5°C, in the presence of various concentration of Sr (2×10^{-4}–2×10^{-2} M). It was found that the recovery of Ca is about 71% at pH 6.9 while Sr is about 4%.

Further work concerning the use of 4-acyl derivatives for the separation of metals is in progress.

THE DIRECT ELECTROCHEMICAL SYNTHESIS AND CRYSTAL STRUCTURE OF SALTS OF $[M_4(SC_6H_5)_{10}]^{2-}$ ANIONS (M = Zn, Cd)

J. LAWRENCE HENCHER, MASOOD A. KHAN, FAROUQ F. SAID and DENNIS G. TUCK*
Department of Chemistry, University of Windsor, Windsor, Ontario, Canada N9B 3P4

(*Received* 3 *October* 1984; *accepted* 29 *November* 1984)

Abstract—The salts $[(C_2H_5)_3NH]_2[M_4(SC_6H_5)_{10}]$ (M = Zn, Cd) can be prepared by the electrochemical oxidation of the metal in an acetonitrile solution of triethylamine and benzenethiol. An X-ray crystal structure determination shows that the anion consists of a tetrahedron of metal atoms, each carrying a terminal $-SC_6H_5$ ligand, and connected to the three other metal atoms by bridging $>SC_6H_5$ groups. The results are compared with those for similar compounds reported in the literature.

Complexes of both main group and transition metals with sulphur-donor ligands are a subject of current interest, not least because of the biochemical significance of such species. In previous papers, we have shown that the electrochemical oxidation of a metal into a non-aqueous solution of a thiol or disulphide is a convenient and direct route to the neutral thiolato complexes of such elements as zinc, cadmium, mercury,[1] tin,[2] lead,[2] gallium,[3] indium[3] and thallium.[3] As reported briefly in an earlier publication,[4] attempts to synthesise an anionic derivative of $Zn(SC_6H_5)_2$ gave the triethylammonium salt of the unusual $[Zn_4(SC_6H_5)_{10}]^{2-}$ anion. We now report full details of the synthesis of this salt, and its cadmium analogue, and of the X-ray crystallographic study of both compounds. The results are compared with those of other workers on a series of related compounds.

EXPERIMENTAL

General

Acetonitrile was distilled from, and stored over, molecular sieves. All other materials were used as supplied. Proton NMR spectra were run in CD_3CN solution at 60 MHz on a Jelco instrument.

Electrochemical synthesis

The electrochemical methods followed those described in previous publications (e.g. Refs. 1, 2, 5) with a 100 cm^3 tall-form beaker containing 50 cm^3 acetonitrile, 3 cm^3 triethylamine (2.2 g, 21.5 mmol), 3 cm^3 benzenethiol (3.2 g, 29 mmol) and 20 mg tetraethylammonium perchlorate. The anode consisted of a piece of metal, approx. 2 cm^2 in area; the cathode was a similar sized platinum sheet. In the case of zinc, an applied voltage of 10–15 V gave a current of 20 mA, and the metal dissolved smoothly (0.28 g in 20 hr). For cadmium, a voltage of 6–12 V gave a satisfactory rate of dissolution (1.22 g in 24 hr); a spongy deposit of cadmium metal formed on the cathode in the latter stages of the experiment. In both cases, the final solution was filtered to remove any particles of metal; the dropwise addition of diethyl ether, with subsequent overnight cooling, produced well-formed crystals. (Yield approx. 90%, based on metal dissolved.) Typical analytical results for the zinc complex $[(C_2H_5)_3NH]_2[Zn_4(SC_6H_5)_{10}]$ were given previously.[4] Analysis of the analogous cadmium complex for metal by atomic absorption spectrophotometry gave, Cd: 25.3%; calc. 25.75%.

Attempts to replicate these syntheses using a zinc anode and an acetonitrile solution of triethylamine and *n*-butanethiol were unsuccessful. The anode rapidly became coated with a black solid, and as the electrolysis proceeded a white solid was also formed. Both of these products were insoluble in common solvents. The solution phase yielded a yellow oil on removal of solvent *in vacuo*, but no useful products could be isolated from this. Similar differences between arene- and alkane-thiols were noted earlier in studies of the electrochemical oxidation of tin and lead.[2]

Crystallographic analysis

A pale yellow crystal of

$$[(C_2H_5)_3NH]_2[Zn_4(SC_6H_5)_{10}]$$

mounted directly on a glass fibre was used in obtaining cell constants and diffraction intensities. The details of the experimental conditions for these measurements, carried out on a Syntex $P2_1$ diffractometer, are given in Table 1. The procedures used in data collection and processing were essentially those outlined elsewhere.[6] The space group $P\bar{1}$ was identified from the average $(E^2 - 1)$ and E^2, and subsequently confirmed by the agreement between the observed and calculated densities. Diffraction data were corrected for Lorentz and polarisation effects, and analytically for absorption. Scattering factors, anomalous dispersion and correction terms for zinc and sulphur atoms were taken from Ref. 7. Computer programmes were those quoted in Ref. 8.

The positions of the zinc and sulphur atoms of the Zn_4S_{10} skeleton were obtained by direct methods. The remaining non-hydrogen atoms (C and N) were then identified from difference Fourier maps. In the least-squares analysis, all the zinc and sulphur atoms were refined in each cycle, with the blocks C(11)---C(126), N(1), CE(1)---CE(6) and C(131)---C(346), N(2), CE(7)---CE(12) (where CE identifies a carbon atom of an ethyl group of the cation) being refined in alternate cycles until convergence was found at $R = 0.0586$. Thermal parameters were anisotropic for Zn and S, and isotropic for C and N. Hydrogen atoms were not included in the refinement. The resultant structure is shown in Fig. 1. Table 2 gives selected bond lengths

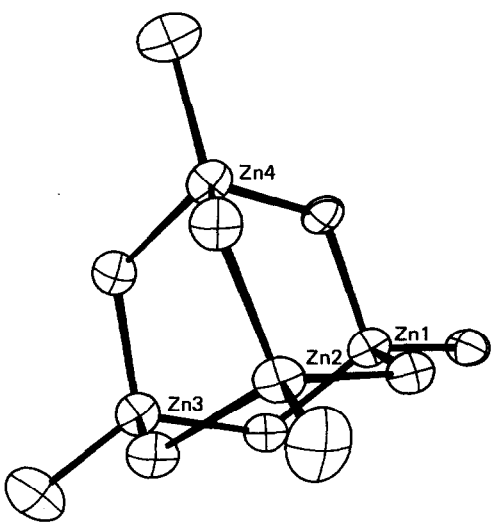

Fig. 1. Zn_4S_{10} core in $[Zn_4(SC_6H_5)_{10}]^{2-}$ anion, showing numbering of zinc atoms. Zinc(1) carries a terminal S(1), and is bonded to S(12) which bridges Zn(1) and Zn(2), etc.

crystal structure of

$$[(C_2H_5)_4N][C_2H_5)_3NH][Cd_4(SC_6H_5)_{10}]$$

had been completed.[9] One interesting point is that the triethylammonium salts of the zinc and cadmium complexes crystallize in different space groups ($P1$ and $P2_1$ respectively).

RESULTS AND DISCUSSION

The structure of $[(C_2H_5)_3NH]_2[Zn_4(SC_6H_5)_{10}]$

As reported previously,[4] this compound consists of triethylammonium cations, whose structure requires no further comment, and the cage or cluster anion based on the Zn_4S_{10} kernel, with both bridging and terminal thiolato groups. A number of analogous species have been reported recently, including $[M_4(SC_6H_5)_{10}]^{2-}$ anions for M = Fe(II),[10,11] Co(II),[12,13] Mn(II)[9] and Co(II),[9] and the related

$[Zn_4(SC_6H_5)_8Cl_2]^{2-}$,[14] $[Fe_4(SC_6H_5)_6Cl_4]^{2-}$,[15]

and $[Zn_4(SC_6H_5)_8CH_3OH]_n$.[16] Holm and his co-workers[10] have emphasised the structural similarities between such molecules and the metallothionen proteins, but an equally valid analogy is with those metal sulphides having a zinc blende structure. This is clearly apposite for $[Zn_4(SC_6H_5)_{10}]^{2-}$, since both in this molecule and in zinc blende one finds four-coordinate zinc surrounded by a tetrahedron of sulphur atoms. The usefulness of this model is confirmed by the work of Dance *et al.*, who have shown that extended structures incorporating both $-SC_6H_5$ and S (e.g. $[S_4M_{10}(SC_6H_5)_{16}]^{4-}$, M = Zn, Cd)[17,18] are readily formed from the parent $[M_4(SC_6H_5)10]^{2-}$, thus emphasising that the ligating properties of S^{2-} and SR^- are such as to make these entities interchangeable in such molecules.

The structure of $[Zn_4(SC_{65})_{10}]^{2-}$ consists of four zinc atoms, each coordinated by one terminal and three bridging $-SC_6H_5$ ligands. The zinc atoms themselves are at the corners of a tetrahedron, while the bridging sulphur atoms are at the corners of a slightly distorted octahedron in which the S_{br}–S_{br} distance is slightly greater than twice the van der Waals radius of sulphur (1.85 Å). One of the interesting aspects of the structural results thus far available is the near constancy of the M–M and S_{br}–S_{br} distances, and of the volumes V_{tot}(M) and V_{oct}(S) calculated from these distances, assuming that the four metal atoms and six sulphur atoms define regular polyhedra. The present results (Zn–Zn = 3.98(6) Å; V(Zn) = 7.43 Å^3; S_{br}–S_{br} = 3.80(14) Å; $V(S_{br})$ = 25.87 Å^3) are in good agreement with those reported in earlier publications[10–13]. This constancy may simply arise because of the restricted range of metals with similar ionic radii, and it would be interesting to see whether this effect extends to derivatives of other metal ions. In this context, it is worth noting that the relevant volumes for the cadmium compound[13] are V(Cd) = 9.46 Å^3 and $V(S_{br})$ = 32.23 Å^3, 39% and 31% respectively greater than those for the zinc compound discussed here (cf. ref. 11, footnote (47)).

The Zn–S_{br} and Zn–S_t bond lengths in the present anion are in good agreement with those published by Dance *et al.*,[12,14] and call for no comment. The angles within the $Zn_4(S_{br})_6$ kernel are on average (108°) close to the 109.5° required for exact tetrahedral ZnS_4 coordination, and a similar average applies to the S_t–Zn–S_{br} angles. The bond lengths and angles in the $-SC_6H_5$ ligand are very close to those reported for analogous complexes with other metal ions.

Spectroscopic results

The identification of two relatively broad resonances in the phenyl region of the ^{1}H NMR spectrum served to confirm the presence of bridging and terminal $-SC_6H_5$ ligands for the zinc complex. A more detailed temperature dependent study[11] at 300 MHz has confirmed this result, showing that the intra-molecular rearrangement implied by these broad absorptions is significantly slowed at 239 K. The room temperature spectrum of the cadmium compound is very similar to that of the zinc analogue, with phenyl resonances centred at 7.13 and 6.77 ppm from Me_4Si (relative intensities 1:1.17).

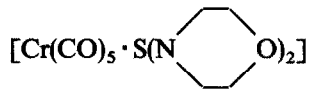
A CHARACTERISTIC REDOX REACTION FOR N,N′-THIOBISAMINES AND SOME OTHER S(II) COMPOUNDS



CARLOS DÍAZ
Universidad de Chile, Facultad de Ciencias Básicas y Farmacéuticas Casilla 653, Santiago, Chile

(*Received* 12 *June* 1984; *accepted after revision* 29 *November* 1984)

Abstract—The reaction of copper(II) perchlorate hexahydrate with a number of sulphur(II) compounds in acetonitrile as solvent were studied. It is found that SCl_2, N,N′-thiobisamines $S(NR_2)_2$, ethoxythiomorpholine

and pentacarbonyl (thiobismorpholine) chromium(0)

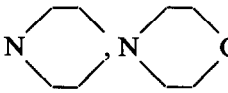
reduce Cu(II) with formation of the complex $Cu[(CH_3CN)_4]ClO_4$ and SO_2.

The hydrolysis of sulphur(II) compounds such as SCl_2, $S(OC_2H_5)_2$ and $S[N(C_2H_5)_2]_2$ has been investigated by Goering.[1] These hydrolytic reactions are very complex and sulphur, sulphur dioxide, thiosulphurous and polythionic acids are obtained as products. The formation of these compounds has been rationalized by assuming the formation of an unstable intermediate the sulphoxilic acid, by hydrolysis of the S(II) compounds, and subsequent redox reaction of this acid. Such reactions have been investigated in an aqueous medium and therefore—because $S(OC_2H_5)_2$ and $S[N(C_2H_5)_2]_2$ are insoluble—in a heterogeneous phase.

In our laboratory we have studied the redox reaction of thiobismorpholine and N,N′-thiobisdimethylamine with copper(II) salts in the presence of water, in a homogeneous medium.[2] In such conditions the reactions are very much more simple, since the products are easy to separate and identify. In this work is reported the reaction of copper(II) perchlorate hexahydrate, with the following S(II) compounds; sulphur dichloride, N,N′-thiobisamines, ethoxythiomorpholine and the complex pentacarbonyl (thiobismorpholine) chromium(0) in acetonitrile as solvent.

EXPERIMENTAL

N,N′-thiobisamines were prepared from SCl_2 by a known method.[3] Ethoxythiomorpholine was synthesized by ethanolysis of thiobismorpholine in the presence of $CuCl_2$.[2] Pentacarbonyl (thiobismorpholine) chromium(0) was obtained by photochemical substitution of the ligand on $Cr(CO)_6$ in THF.[4] Reactions were made as follows: The calculated amount of sulphur compound (2:1, SB_2:Cu(II) stoichiometry) in CH_3CN was added over the $Cu(H_2O)_6 \cdot (ClO_4)_2$ solution with stirring and ambient temperature. The white solid formed was filtered and dried with a stream of dry nitrogen gas. In some cases a green basic Cu(II) salts was obtained as impurity, which was eliminated by dissolution of the solid in hot acetonitrile followed by filtration of the green solid and evaporation of the solvent to afford the white crystalline product. The IR spectra was identical with that synthesized from CuO and perchloric acid.[5]

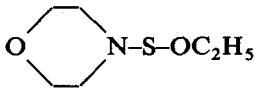


RESULTS AND DISCUSSION

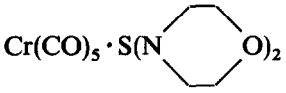
N,N′-thiobisamines react with copper(II) perchlorate hexahydrate in acetonitrile to give the Cu(I)

complex $Cu[(CH_3CN)_4]ClO_4$, sulphur dioxide and the respective ammonium perchlorate salts:

$$2[Cu(H_2O)_6](ClO_4)_2 + S(NR_2)_2 \xrightarrow{CH_3CN} 2[Cu(CH_3CN)_4]ClO_4 + SO_2 + 2[H_2NR_2]ClO_4 + 10H_2O$$



NR_2 = $N(CH_3)_2$, $N(C_2H_5)_2$, $N(CH_2{-}CH{=}CH_2)_2$,

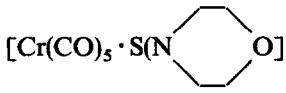


, $N(CH_2{-}C_6H_5)_2$, $N(C_6H_5)_2$.

The Cu(I) complex is a crystalline white solid of easy isolation and identification by IR spectroscopy. The IR spectra show the characteristic bands corresponding to $\nu(C{\equiv}N)$ (2300 and 2260 cm^{-1}), $\nu(ClO_4)$ (ν_{as}, 1000–1120 cm^{-1} and ν_s 922 cm^{-1}) and $\delta(ClO_4)$ (620 cm^{-1}). Further from the filtrate it was possible to identify the $H_2NR_2^+$ species by ^1H NMR. The SO_2 evolved from the reaction was confirmed by the common chemical method.[6]

Similarly from the reaction of SCl_2,

and



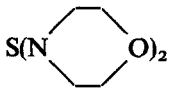
with copper perchlorate in acetonitrile was isolated and identified the sample complex of Cu(I).

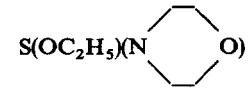
The fact that in all reactions the same product is obtained, the Cu(I) complex, suggests that the reduction of Cu(II) could be made by a common intermediate, namely the sulphoxylic acid which is formed in the hydrolysis of the sulphur compound SB_2,

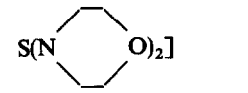
$$SB_2 + 2H_2O \rightarrow S(OH)_2 + 2BH.$$

$S(OH)_2$ could then be oxidized to SO_2 with simultaneous reduction of Cu(II) to Cu(I) and with acetonitrile to yield the complex $[Cu(CH_3CN)_4]ClO_4$. It is interesting to note that the yield of the copper(I) compound is better for the reaction with

than with







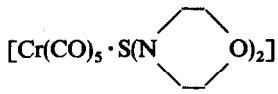


Table 1. Yield of $[Cu(CH_3CN)_4]ClO_4$ with various S(II) compounds

Compound	Yield (%)
SCl_2	50
	60
$S[N(CH_3)_2]_2$	50
$S[N(CH_2{-}CH{=}CH_2)_2]_2$	30
	80
	98

(see Table 1) which could be due to a more facile hydrolysis of thiobismorpholine in the complex than free thiobismorpholine. This is consistent with the greater strength of the S–N bond found in the free thiobismorpholine than in that linked to chromium.[4,7]

In conclusion, the reaction of copper(II) perchlorate hexahydrate with compounds of sulphur in an oxidation state +2 could be considered as characteristic because in all cases the same products namely the complex $[Cu(CH_3CN)_4]ClO_4$ and SO_2 are obtained. On the contrary the reaction of sulphur(II) compounds with other copper(II) salts and solvent affords different products depending of the properties of the substituents on the sulphur.[2]

He I PHOTOELECTRON SPECTRA OF [3]-FERROCENOPHANE AND ITS 7-OXA DERIVATIVE

TOMÁŠ VONDRÁK

ESCA Centre, The J. Heyrovský Institute of Physical Chemistry and Electrochemistry, Czechoslovak Academy of Sciences, Vlašská 9, 118 40 Prague, Czechoslovakia

(*Received* 17 *September* 1984; *accepted* 9 *November* 1984)

Abstract—He I photoelectron spectra of [3]-ferrocenophane and 6,8-dimethyl-7-oxa-[3]-ferrocenophane have been measured. In comparison with ferrocene the energy gap between $^2E'_2(a'^2_1e'^3_2)$ and $^2A'_1(a'^1_1e'^4_2)$ is decreased to 0.28 and 0.22 eV due to the destabilization of the $a'_1(d)$-level originating in its more pronounced mixing with ligand orbitals. The increase of photoionization cross section of the $a'_1(d)$-level in the 6,8-dimethyl-7-oxa-[3]-ferrocenophane spectrum supports this interpretation. The band shapes and ionization potentials of ligand π-levels are strongly influenced by the hydrocarbon bridge.

The electronic structure of bis(η^5-cyclopentadienyl) metal halides, hydrides carbonyls and olefin complexes in which the cyclopentadienyl rings are not coplanar has been extensively studied by ultraviolet photoelectron (PE) spectroscopy[1,2] and by quantum chemical methods.[3,4] The starting point of the bonding schemes of these complexes is the bent bis(η^5-cyclopentadienyl) metal fragment.

In ferrocenophanes the cyclopentadienyls are not coplanar.[5] We have carried out an ultraviolet PE spectroscopic investigation of ferrocenophane species in order to reveal the changes in the electronic structure which come from the bending of the metallocene unit.

Ferrocene is a closed-shell system with fully occupied a'_1 and e'_2 d-levels (D_{5h} symmetry if the eclipsed conformation is assumed for the cyclopentadienyl rings), and the low ionization potential (IP) region of its PE spectrum has been unequivocally assigned.[6] The ring substituents do not introduce any splitting of the doubly degenerate $e'_2(d)$-level.[7,8] Ferrocenophanes seem thus to be excellent model species for the PE spectroscopic investigation of the bent bis(η^5-cyclopentadienyl) metal fragment.

To our knowledge we report the first PE spectra of ferrocenophane species [3]-ferrocenophane (I) (Fig. 1) in which the angle between the planes of cyclopentadienyls is 10°,[5] and that of 6,8-dimethyl-7-oxa-[3]-ferrocenophane (II) (Fig. 2).

In the PE spectrum of ferrocene the bands a and b are assigned to the $e'_2(d)$ and $a'_1(d)$-level, respectively.

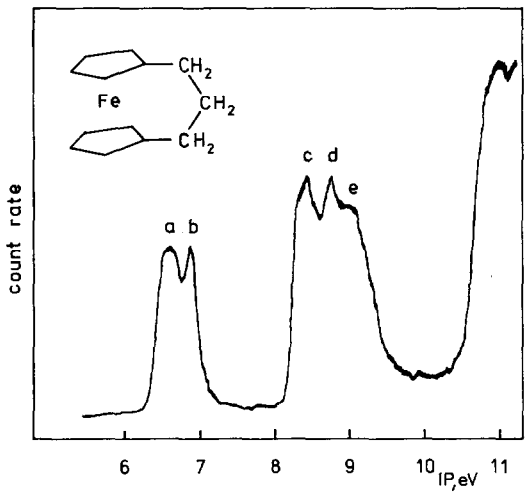

Fig. 1. He I PE spectrum of [3]-ferrocenophane (I).

Since the band shapes of d-ionizations are similar to ferrocene, the same interpretation is adopted here for (I) and (II), though the actual local symmetry is C_{2v}. The IPs of the d-levels of (I) are lowered in comparison with ferrocene due to the weak electrondonor character of the hydrocarbon bridge. The IP of the $e'_2(d)$-level in (I) is exactly between the IP of this level in 1,1′-diethyl and 1,1′-dimethylferrocene whereas the $a'_1(d)$ IP is the same as in 1,1′-diethylferrocene (Table 1). The alkylsubstituents do not affect the energy difference between $^2E'_2(a'^2_1e'^3_2)$ and $^2A'_1(a'^1_1e'^4_2)$ ion states[1,8] (see Table 1). Therefore it may be concluded that tilting of the cyclo-

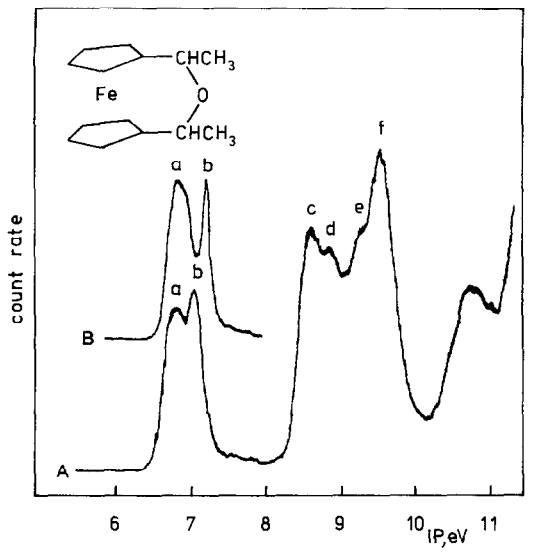

Fig. 2. (A) He I PE spectrum of 6,8-dimethyl-7-oxa-[3]-ferrocenophane (II). (B) He I PE spectrum of ferrocene, *d*-ionizations.

pentadienyl rings is responsible for the decrease of this energy difference to 0.28 eV observed in the spectrum of (I).

The geometry of the 7-oxa derivative (II) is not experimentally determined but the larger tilting of cyclopentadienyls may be anticipated if we take into account the shorter C–O bond length in comparison with that of C–C.[9] The decrease of the energy difference $^2E_2'$–$^2A_1'$ is more pronounced in the PE spectrum of (II) (0.22 eV). The IP of $a_1'(d)$-level is the same as in 1,1′-dimethylferrocene in spite of the electronegative oxygen bridge atom (see Table 1).

The preceding comparison with the IPs of 1,1′-dialkylferrocenes shows that the IP of $a_1'(d)$-level is lowered by bending of the metallocene unit. The increase of the relative photoionization cross-section of $a_1'(d)$-level in comparison with ferrocene indicates its larger mixing with ligand orbitals in (II).

These findings indicate that the $a_1'(d)$-level acquires a slightly antibonding character due to bending of the metallocene unit. The previous calculation of Hoffmann and Lauther[3] support this conclusion.

The band shapes of ligand $e_1'(\pi)$ and $e_1''(\pi)$-ionizations differ significantly from those of parent ferrocene. On the basis of the comparison with the spectra of 1,1′-disubstituted ferrocenes[8] we have tentatively assigned the bands *c* and *d* to the $e_1'(\pi)$-level and the band *e* to the $e_1''(\pi)$-level. In the PE spectrum of (II) the ionization involving oxygen non-bonding orbital n(O) overlaps with the ligand π-ionizations. The intensive band *f* is assigned to the n(O)-orbital. The $e_1'(\pi)$ and $e_1''(\pi)$-orbitals interact directly with the orbitals of the bridge atoms. Hence the influence of bending of the molecule upon the ligand π-levels can be hardly revealed from the PE spectra. Nevertheless, it is worth noting that in the PE spectrum of (I) the band *d* assigned to a component of the doubly degenerate $e_1'(\pi)$-level is shifted to higher IP in comparison with that of ferrocene. It may be assumed that the bending of the molecule is responsible for this increase of the IP since the electron-donating CH_2-groups cannot bring it about.

The first PE investigation of [3]-ferrocenophanes gives evidence on the lowering of the energy gap between the $^2E_2'$ and $^2A_1'$ ion states. A reverse order of ion states could be expected for the ferrocenophane species in which a larger ring tilting occurs.

The He I PE spectra were recorded on the VG Scientific UVG 3 instrument with working resolution of 0.03 eV on the Ar $^2P_{3/2}$ peak. The Ar/Xe mixture was used as the internal calibrant.

EPR ON TETRABUTYLAMMONIUM TETRAIODO-NITROSYLTECHNETATE(II), $(Bu_4N)[Tc(NO)I_4]$

R. KIRMSE and J. STACH
Department of Chemistry, Karl-Marx-University, DDR-7010 Leipzig, Liebigstr. 18, G.D.R.

and

U. ABRAM*
Academy of Sciences of the G.D.R., Central Institute of Nuclear Research Rossendorf, DDR-8051 Dresden, PF 19, G.D.R.

(*Received* 18 *July* 1984; *accepted after revision* 29 *November* 1984)

Abstract—An EPR study on tetrabutylammonium tetraiodo-nitrosyltechnetate(II), $(Bu_4N)[Tc(NO)I_4]$, is reported. The frozen solution EPR spectrum is described by an axially symmetric spin Hamiltonian. The ^{99}Tc hyperfine interaction is used to estimate the spin density distribution in the MO of the unpaired electron which is of "in-plane-π-type".

The widespread use of the metastable isotope of technetium, ^{99m}Tc, in diagnostic nuclear medicine procedures is well documented.[1] This is due to the favourable nuclear properties of ^{99m}Tc (γ-emitter with $E_\gamma = 140$ keV, half-life-time $t_{1/2} = 6$ hr) which allow high resolution γ-camera studies.

The chemistry, however, of this first man-made element is still poorly known. During the recent years the availability of the long lived isotope ^{99}Tc ($t_{1/2} = 2.13 \times 10^5$ years) from fission products in macroscopic amounts has lead to substantial progress in development of the technetium chemistry. Most of the well characterized Tc compounds contain the metal in the oxidation states "+4" and "+5", respectively.[2,3] The coordination chemistry of technetium in which Tc occurs in lower formal oxidation states is much less known.[2]

Tc(II) compounds are favoured for EPR studies because the d^5 low-spin ($S = 1/2$) configuration can be detected by EPR at temperatures $T > 77$ K. Nevertheless, only a few studies have been reported on nitrosyltechnetate(II) complexes containing EPR data:

$(n\text{-}Bu_4N)[Tc(NO)Br_4]$,[2,4,5]

$(n\text{-}Bu_4N)_2[Tc(NO)Cl_5]$,[5,6]

$(n\text{-}Bu_4N)_2[Tc(NO)(NCS)_5]$,[5]

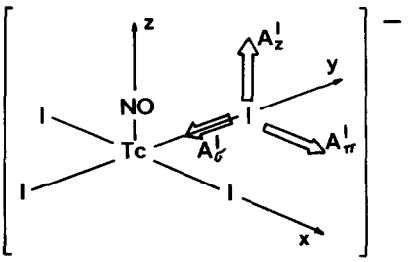
$[Tc(NO)(NH_3)_4(H_2O)]^{3+}$[6]

and

$TcCl_3(NO)(PMe_2Ph)_2$.[7]

EPR studies on frozen solutions of the complexes from which the tensor parameters of $\tilde{g}$ and $\tilde{A}^{Tc}$ can be obtained are available for

$[Tc(NO)(NH_3)_4(H_2O)]^{3+}$,[6]



$[Tc(NO)Cl_5]^{2-}$,[6] $TcCl_3(NO)(PMe_2Ph)_2$[7]

and

$(n\text{-}Bu_4N)[Tc(NO)Br_4]$.[4]

Only for $TcCl_3(NO)(PMe_2Ph)_2$ and $[Tc(NO)Br_4]^-$ have they been used to derive the bonding properties of the Tc–ligand bonds.

In this paper we report EPR studies on the Tc(II) low-spin complex tetrabutylammonium tetraiodo-nitrosyltechnetate(II), (I), which has been made in order to get more insight into the bonding properties of the Tc–ligand bonds. In comparison to the corresponding Tc(II) nitrosyl compounds having

Cl^- or Br^- ligands more covalent bonds are to be expected.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

Due to the radioactivity of ^{99}Tc (weak β^--emitter, $E_{max} = 0.29$ MeV) some health precautions have been taken.[8] All operations have been carried out in a fume cupboard with gloves. EPR measurements have been done in sealed glass tubes to avoid contaminations.

(n-Bu_4N)[Tc(NO)I_4] was prepared according to Ref. 9. EPR spectra were recorded at $T = 295$ and 130 K in the X-band ($\nu \approx 9.3$ GHz) using an E-112 spectrometer (VARIAN, U.S.A.). 5×10^{-4} M solutions of (**I**) were used (solvent: acetone).

RESULTS AND DISCUSSION

The room temperature EPR spectrum of (**I**) is only poorly resolved, obviously due to strongly overlapping lines resulting from the hyperfine interactions with the ^{99}Tc (nuclear spin $I = 9/2$) and the ^{127}I ($I = 5/2$) nuclei. The frozen solution spectrum is shown in Fig. 1. The general feature of the spectrum is characteristic for an axially symmetric, randomly oriented $S = 1/2$ system as described by the spin Hamiltonian

$$\hat{H}_{sp} = \beta_e[g_{\parallel}H_z\hat{S}_z + g_{\perp}(H_x\hat{S}_x + H_y\hat{S}_y)] + A_{\parallel}^{Tc}\hat{I}_z\hat{S}_z + A_{\perp}^{Tc}(\hat{I}_x\hat{S}_x + \hat{I}_y\hat{S}_y), \quad (1)$$

where $g_{\parallel}$, $g_{\perp}$, $A_{\parallel}^{Tc}$ and $A_{\perp}^{Tc}$ are the principal values of the $\tilde{g}$ and the ^{99}Tc hyperfine interaction tensor $\tilde{A}^{Tc}$. These parameters were obtained by use of the usual second-order expressions.[10] ^{99}Tc quadrupolar interactions are expected to be small and have been neglected. The spin Hamiltonian parameters obtained are: $g_{\parallel} = 2.262 \pm 0.003$, $g_{\perp} = 2.144 \pm 0.010$, $A_{\parallel}^{Tc} = (155 \pm 3) \times 10^{-4}$ cm^{-1} and $A_{\perp}^{Tc} = (73 \pm 10) \times 10^{-4}$ cm^{-1}. The corresponding average values—$g_{av} = (g_{\parallel} + 2g_{\perp})/3 = 2.183$ and $a_{av}^{Tc} = (A_{\parallel}^{Tc} + 2A_{\perp}^{Tc})/3 = 100 \times 10^{-4}$ cm^{-1} are in good agreement with the values obtained from the liquid solution spectrum: $g_0 = 2.172 \pm 0.005$ and $a_0^{Tc} = (106 \pm 5) \times 10^{-4}$ cm^{-1}, respectively.

Ligand hyperfine structures due to the interaction of the unpaired electron with the equatorial I-ligands are badly resolved. The linewidth of the parallel part ^{99}Tc hfs lines—$\Delta H_{pp} \approx 5$–6 mT—is noticeably larger than those observed for [Tc(NO)Br_4]$^{-4}$ and [Tc(NO)Cl_5]$^{2-}$.[6] From this linewidth consideration the principal value A_z^I of the ^{127}I hfs tensor $\tilde{A}^I$ can be estimated to be $A_z^I = 2.5$–3.0×10^{-4} cm^{-1}. The other components of $\tilde{A}^I$, A_x^I and A_y^I could not be obtained because the complexity of the perpendicular part of the EPR spectrum of (**I**) in frozen solutions.

In accordance with the results obtained earlier for $TcCl_3(NO)(PMe_2Ph)_2$[7] and [Tc(NO)Br_4]$^{-4}$ the EPR spectra of (**I**) suggest an "in-plane-π-type" for the molecular orbital (MO) of the unpaired electron:

$$\psi_{MO}(B_2) = \beta_2|d_{xy}\rangle - \beta_2'|\phi_L\rangle, \quad (2)$$

where $|\phi_L\rangle$ represents a linear combination of 5p orbitals of the four equatorial I ligands, β^2 is a measure of covalency of the equatorial Tc–I bonds in this MO.

The ^{99}Tc hfs can be used to estimate the degree of covalency of the equatorial Tc–I bonds. Applying the formalism given by McGarvey[11]

$$A_{\parallel}^{Tc} = -K - 4/7\beta^2P + (g_{\parallel} - g_e)P + 3/7(g_{\perp} - g_e)P, \quad (3a)$$

$$A_{\perp}^{Tc} = -K + 2/7\beta^2P + 11/14(g_{\perp} - g_e)P, \quad (3b)$$

and

$$a_{av}^{Tc} = -K + (g_{av} - g_e)P, \quad (3c)$$

where K is a measure of the Fermi contact interaction and $P = (+)200 \times 10^{-4}$ cm^{-1},[11] one arrives at a value of $\beta^2 = 0.72$; $K = (+)136.2 \times 10^{-4}$ cm^{-1}.

A comparison of the β^2 values derived for [Tc(NO)Cl_5]$^{2-}$, $\beta^2 = 0.88$,[9] and [Tc(NO)Br_4]$^-$, $\beta^2 = 0.83$,[4] with that obtained for [Tc(NO)I_4]$^-$ shows a considerable increase of covalency for the Tc–

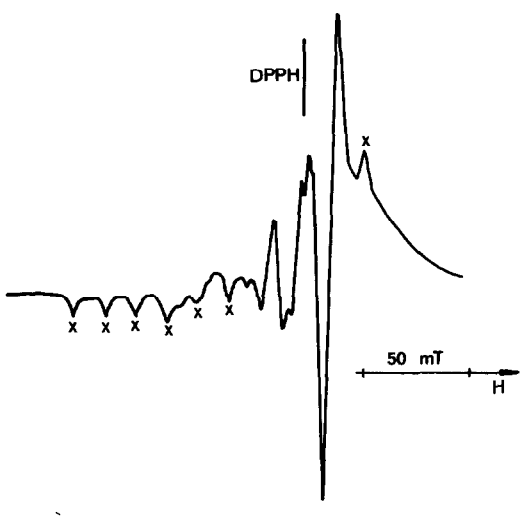


Fig. 1. X-band EPR spectrum of (n-Bu_4N)[Tc(NO)I_4] in acetone, $T = 130$ K (^{99}Tc hfs lines of the parallel part of the spectrum are indicated with (×); remaining parallel lines as well as the perpendicular lines are not detectable unambiguously due to the complexity of the perpendicular part of the spectrum).

(equatorial) ligand bonds if going to the heavier halogenide donors. A similar dependence has been observed for the d^1 type complexes $Mo(V)OX_4Y$ (X = Cl, Br, I; Y = X or solvent).[12]

It should be noted that for pentacyano–nitrosyl complexes of the iron group metals[13] some small hyperfine interactions have been found resulting from the interaction of the unpaired spin density with the ^{14}N nucleus of the NO ligand. For the complexes under study such additional hyperfine splittings have not been resolved, possibly due to the larger linewidths in the EPR spectra of the Tc complexes.

Finally it should be noted that no attempts have been made to interprete the $\tilde{g}$ tensor components in terms of molecular orbital coefficients. Such an interpretation is extremely difficult for the present case because there are more unknown quantities (ordering of energy levels, energy separations between the levels giving important contributions to the $\tilde{g}$ components, the large number of MO coefficients to be considered) than experimentally obtained ones. Results of semiempirical MO calculations which may be very helpful for these purposes[13–15] are not available for Tc compounds of this type up to now.

Acknowledgement—The authors wish to thank Dr. Bernd Lorenz (Leipzig) for his help in preparation of the technetium compounds.

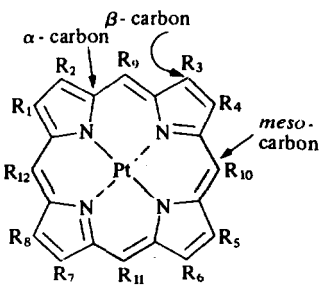
^{1}H AND ^{13}C NMR OF PLATINUM PORPHYRINS—II. PLATINUM COMPLEXES OF *MESO*-TETRAKIS(3,5-DI-*t*-BUTYL-4-HYDROXYPHENYL)PORPHYRIN AND 2,3,7,8,12,13,17,18-OCTAETHYLPORPHYRIN

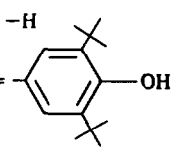
LIONEL R. MILGROM

Imperial College of Science and Technology, Department of Chemistry, Exhibition Rd, London SW7 2AZ, U.K.



(*Received* 13 *August* 1984; *accepted* 18 *December* 1984)

Abstract—The ^{1}H and ^{13}C NMR spectra of the title compounds are reported. In both porphyrins, long-range spin–spin coupling is observed between platinum and the porphyrin protons and carbon atoms. Two-bond Pt–"α-pyrrole" carbon couplings are less than the three-bond Pt–"β-pyrrole" carbon and Pt–"*meso*-carbon" couplings. Also, large upfield shifts of the pyrrole α-carbon resonances are noted. The coupling mechanism appears to proceed via Fermi contact through the porphyrin σ-framework for the carbons, and the π-system for the protons.



The previous paper in this series[1] attempted to rectify a deficiency of NMR data[2] on platinum porphyrins[3,4] by describing, for the first time, long-range coupling between platinum and the porphyrin protons and carbon atoms in platinum *meso*-tetraphenylporphyrin (PtTPP). Also observed were large upfield shifts in the α-carbon resonances of both PdTPP and PtTPP.[1] As thallium(III)[5,6] and phosphorus(V)[6(c)] complexes are the only extensively studied metalloporphyrins which demonstrate ^{1}H–M and ^{13}C–M spin–spin coupling in their NMR spectra, it was decided to extend observation of these couplings into other platinum porphyrin systems. This paper, therefore, reports the ^{1}H and ^{13}C NMR spectra of platinum porphyrins **1** and **2**, and attempts to obtain such spectra for the platinum complex of the naturally-occurring porphyrin protoporphyrin IX dimethyl ester [PtPPIXDME (**3**)] (Fig. 1).

RESULTS AND DISCUSSION

Platinum was inserted into the porphyrins using the method of Büchler and Puppe.[4] Unreacted free-base porphyrins were separated as reported earlier.[1] The synthesis of the free-base porphyrin (**1**) has been described elsewhere.[7]

1 $R_1 - R_8 = -H$

$R_9 - R_{12} =$ 

2 $R_1 - R_8 = -CH_2CH_3$
$R_9 - R_{12} = -H$

3 $R_1 = R_3 = R_5 = R_8 = -CH_3$
$R_2 = R_4 = -CH{=}CH_2$
$R_6 = R_7 = -CH_2CH_2CO_2CH_3$
$R_9 - R_{12} = -H$

Fig. 1.

Table 1.

	Pyrrole β-H[a]	Aryl *ortho*-H	Aryl-OH	Aryl *t*-butyl-H
Free-base porphyrin (1)	8.92[b] (8.75)[c]	8.03 (8.30)	5.52	1.62
Zinc porphyrin (1)	9.04	8.04	5.50	1.62
Platinum porphyrin (1)	8.84[d] (8.74)	7.96 (8.14)	5.50	1.60

[a] Spectra recorded in $CDCl_3$ with TMS as internal reference.
[b] Chemical shifts in δ ppm.
[c] Figures in parentheses are the equivalent chemical shifts for the TPP complex.[1]
[d] Satellites are 5.5 Hz either side of this peak; $^4J_{^1H-^{195}Pt}$ is 10.9 Hz compared to 3–17 Hz.[8]

Pt *complex* **1**

The free-base porphyrin undergoes a facile two-electron oxidation[7] and metal complexes, including the zinc and platinum compounds, are currently under investigation as electrocatalysts for the reduction of oxygen. The ^1H NMR spectrum of the platinum complex **1** was similar to those of the free-base porphyrin and its zinc complex (see Table 1). As with PtTPP,[1] the two satellites flanking the pyrrole β-proton resonance are due to long-range ^1H–^{195}Pt coupling over four bonds. The coupling constant (10.9 Hz) is consistent with this,[8] although slightly smaller than for PtTPP (12.5 Hz[1]). This may reflect small differences in the steric "ruffling" of the macrocycles, induced by the bulky *t*-butyl groups on the *meso*-aryl substituents.

The ^{13}C NMR spectrum of platinum porphyrin **1** is assigned, once again, by comparison with the free-base porphyrin, the zinc complex, and the TPP complexes (see Table 2). The porphyrin macrocyclic carbons are readily assigned. The aryl carbons, being part of a polysubstituted aromatic system, are for the most part predictable on the basis of additivity of chemical shifts of monosubstituted benzenes.[9] On this assumption, the C-3″ carbons appear at higher field than expected. This may be due to aryl-ring distortion brought about by steric interactions of the *t*-butyl and OH substituents.

The large $^{13}C_{meso}$–Tl couplings found in thallium porphyrins[5,6] prompted a reexamination of the ^{13}C NMR spectrum of PtTPP which revealed a ^{13}C–^{195}Pt coupling to the *meso*-carbons (three-bond, 37 Hz) consistent with similar couplings reported elsewhere. In complex **1**, besides the coupling to the β-pyrrole carbons, no other ^{13}C–^{195}Pt couplings are observed due to a poor signal-to-noise ratio.

The large upfield shift of the α-carbons is accounted for[1] by steric "ruffling"[12] of the porphyrin nucleus and/or metal *d*-porphyrin π*-back-bonding.

Pt *complex* **2** (PtOEP)

The ^1H NMR spectrum of this porphyrin is similar to those of the free-base porphyrin and other metallo-OEP complexes[13] (see Table 3). An earlier observation of the ^1H NMR spectrum of **2**[2] failed to note the near-resolution of Pt satellites on the methine-proton resonance. Unlike TlOEP,[5] no coupling was observed between platinum and the methylene protons of the β-pyrrole-substituted ethyl groups.

PtOEP	10.01[d]	4.01(q)	1.90(t)

[a] Spectra recorded in $CDCl_3$ with TMS as internal reference and chemical shifts in δ ppm.

[b] See Ref. 13.

[c] Values reported at 60 MHz.

[d] Values in this work, peak nearly resolved into 1:4:1 triplet with $^4J_{^1H-^{195}Pt} = 4.5$ Hz.

The ^{13}C NMR spectrum of **2** is similar to OEP and other metallo-OEP complexes[6(a)] in that it consists of five main peaks (see Table 4). All the macrocyclic carbons are accompanied by Pt satellites. Unusually for metalloporphyrins,[13] the pyrrole α-carbon resonance is assigned to higher field than the pyrrole β-carbon resonance. This is based on the previously-recorded large high-field shift of the α-carbons in PtTPP[1] and the magnitude of long-range ^{13}C–^{195}Pt coupling, which is greater for β-carbons than for α-carbons. A similar inversion in the resonance position of these carbons is seen in the dication of OEP.[6(a)]

In order to confirm this, a fully proton-coupled ^{13}C NMR spectrum of PtOEP was recorded. It was hoped that long-range ^{13}C–^{1}H coupling (between the pyrrole α-carbons and the *meso*-protons, and the pyrrole β-carbons and the ethyl protons) could be resolved. In the event, only unresolvable multiplets of similar bandwidth were obtained for these carbons. However, the *meso*-carbons were split into a large doublet (155.6 Hz), of which each peak is further split into a 1:4:1 triplet (36.2 Hz). The one-bond ^{13}C-*meso*–^{1}H-methine coupling constant is close to that found for benzene (157.65 Hz).[15] This would indicate little ring strain in the macrocycle even though the Pt cation is too large for central cavity. Further studies are investigating how this coupling constant varies with central metal cation and could act as a probe of porphyrin ring strain.[9]

Although the magnitude of the coupling constants for PtTPP and **2** is smaller than the thallium porphyrins, the data (see Table 5) suggest that the coupling mechanisms are the same. Transmission of long-range coupling is attributed to Fermi contact through the macrocyclic σ-framework while coupling to the *meso*-protons is transmitted through the π-system via a σ–π interaction.[5,6,16] Also ^{13}C–^{195}Pt coupling over three bonds is larger for the pyrrole *meso*-carbons than for the β-carbons. This is because there are two equivalent *cis*-three-bond pathways for the *meso*-carbons, but only one *trans*-three-bond pathway for the β-carbons.

Replacement of haem [Fe(II)PPIX] with PtPPIX could, by virtue of these couplings, act as a sensitive NMR probe for the active sites of haemoproteins. Therefore, **3** was prepared but both the ^{1}H and ^{13}C NMR spectra suffered severe line-broadening. As both solvent and TMS peaks were sharp, this was attributed to extensive aggregation in solution, a conclusion supported by the UV/vis spectrum of **3** (all bands broadened and reduced in intensity).[17,18] If such aggregation is mediated by mutual overlap of d_{z^2} orbitals of Pt then PtPPIXDME would make an ideal one-dimensional conductor.

EXPERIMENTAL

All spectra were obtained, in the FT mode, on a Bruker WM 250 NMR spectrometer. UV/vis spectra

(*Received* 5 *November* 1984; *accepted* 18 *December* 1984)

Abstract—The reactions of K_2PtCl_4 with the aminoacids, S-methyl-L-cysteine, S-ethyl-L-cysteine, S-benzyl-L-cysteine, S-para-nitro-benzyl-L-cysteine, S-diphenyl-methyl-L-cysteine, S-tribenzyl-L-cysteine and S-4′,4′-dimethoxy-diphenylmethyl-L-cysteine were studied in neutral or acidic aqueous solutions. Complexes of the formulae $PtLCl_2$, $[PtL_2]Cl_2$ and $Pt(L–H^+)_2$, where L = aminoacid, were isolated in the solid state and their structures investigated with elemental analysis, conductivity measurements, IR, ^1H NMR and ^{13}C NMR spectra. The results show that the coordination sites of Pt(II) with the amino-acids are the N and S atoms, producing two diastereoisomers around the chiral sulphur atom, which were identified in the ^1H NMR and ^{13}C NMR spectra. The complexes $PtLCl_2$ further react with the nucleosides guanosine and inosine. The complexes $[PtL(nucl)_2]Cl_2$ were isolated from these reactions and studied with the same methods. They showed a $Pt–N_7$ bonding with the nucleosides and retained the N, S bondings with the aminoacids. As a result of the higher *trans* influence of S than N, the nucleoside molecule coordinated to the metal through N_7 and *trans* to S has a weaker bond strength than the other, as it is revealed from the ^1H NMR and ^{13}C NMR spectra of these complexes.

Recently, we reported the syntheses, spectroscopic studies and X-ray crystal structure determination of the complex *cis*-(S-ethyl-L-cysteine) platinum(II) dichloride.[1] This complex, which was among a number of other similar complexes prepared by us with S-alkyl- and -alkylaryl derivatives of cysteine, was shown to occur in two diastereoisomeric forms (R, S), both in solution and in the solid state, due to the chiral sulphur atom. Pd(II) and Pt(II) complexes of S-methyl-L-cysteine also exist in two diastereoisomeric forms in solution[2,3] and in the solid state for Pd(II).[4] The S-methyl-L-cysteine sulphoxide complex of Pd(II) however, was found in only one diastereoisomeric form in the solid state.[3]

Reports on complexes of S-alkyl cysteine derivatives of Pd(II) and Pt(II) are mainly limited to S-methyl cysteine and methionine.[2–8] Recently, Kozlowski *et al.*[9] reported on complexes of Pd with S-benzyl-cysteine and glycyl-S-benzyl-L-cysteine and found also two diastereoisomers on sulphur (R, S). Some S-alkylaryl cysteines on the other hand (e.g. S-trityl cysteine) are antitumor agents in their own right.[10,11] The study therefore of the interactions of Pt(II) with S-alkyl or S-alkylaryl cysteine derivatives presents interests, both from the chemical point of view (e.g. binding sites of the ligands with the metal (S, N, O), stoichiometry of the complexes, possibility for the existence of diastereoisomers around the sulphur atom, etc.) and the possibility of preparing new antitumor agents. (Preliminary screening tests of all the *cis*-Pt(II) complexes with cysteine derivatives prepared in this study, showed them inactive.)

* Author to whom correspondence should be addressed.

Also the study of the reactions of all the new complexes having the *cis* structure, like the *cis*-(S-ethylcysteine) platinum(II) dichloride with nucleosides are comparable to the ones of the antitumor complex *cis*-$Pt(NH_3)_2Cl_2$. Analogous studies of Pt(II) and Pd(II) with cysteine[12] and the reactions of a Pt(II)–cysteine complex with nucleosides[13] were also reported.

This paper describes the reactions of Pt(II) with the above mentioned cysteine derivatives and the interactions of certain of these complexes with a *cis* configuration, with nucleosides.

RESULTS

The L-amino acids used in this study were, S-methyl-L-cysteine (S-MeCys), S-ethyl-L-cysteine (S-EtCys), S-benzyl-L-cysteine (S-BzlCys), S-para-nitro-benzyl-L-cysteine (S-*p*-NO_2-BzlCys), S-diphenyl-methyl-L-cysteine (S-DpmCys), S-tribenzyl-L-cysteine (S-TrtCys) and S-4′,4′-dimethoxydiphenylmethyl-L-cysteine (S-DmbCys).

These amino acids (presented with L) react with K_2PtCl_4 in aqeuous solutions, to produce complexes of various empirical formulae, as follows:

$$K_2PtCl_4 + L \rightarrow PtLCl_2 + 2KCl. \quad (1)$$

The complexes with S-TrtCys and S-DmbCys, were not isolated, due to the hydrolysis of the bulky Trt and Dmb groups, producing complexes of the type PtL'_2Cl_2, with L′ = cysteine[12] (see Experimental).

The 1:2 metal to ligand ratio complexes were prepared either from the 1:1 or directly from the starting materials.

$$PtLCl_2 + L \rightarrow [PtL_2]Cl_2 \quad (2)$$

or

$$K_2PtCl_4 + 2L \rightarrow [PtL_2]Cl_2 + 2KCl. \quad (3)$$

Reaction (3) failed to give pure products, due to the liberated KCl. On the other hand, both reactions (2) and (3) produce soluble and to a lesser extent insoluble materials of the same empirical formulae. A polymeric structure was attributed to the latter (see Discussion).

When the soluble $[PtL_2]Cl_2$ complexes react with freshly prepared Ag_2O, complexes of the empirical formulae $[Pt(L–H^+)_2]$ are prepared:

$$[PtL_2]Cl_2 + Ag_2O \rightarrow [Pt(L–H^+)_2] + 2AgCl + H_2O. \quad (4)$$

The same complexes may also be produced upon neutralization of aqueous solutions of $[PtL_2]Cl_2$ with dilute NaOH solutions, although not in pure condition, due to the inability to separate them from the liberated NaCl, in this case.

$$[PtL_2]Cl_2 + 2NaOH \rightarrow [Pt(L–H^+)_2] + 2NaCl + 2H_2O. \quad (5)$$

Finally, the nucleoside complexes were prepared according to

$$[PtLCl_2] + 2nucl \rightarrow [PtL(nucl)_2]Cl_2. \quad (6)$$

The isolated complexes correspond to the above empirical formulae, as their elemental analysis show (see Table 1).

DISCUSSION

1. $PtLCl_2$ *type complexes*
